β-Chloro-α-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (VI) reacted with a warm benzene solution of excess benzylamine to lose only one equivalent of hydrogen chloride, and form the base (VIII). Warm, aqueous alcohol converted (VIII) to β-hydroxy-α-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (IX). Configuration studies of these dichlorides, including ring closure to the ethylene imine ketones by the α-chloro products, are being undertaken.

**Discussion of Hydrogen Chloride Reaction Mechanisms.**—It seems evident that the first product from the reaction of an ethylene imine ketone with hydrogen chloride is the simple salt (S). A hydrochloride of type (S) was isolated in a previous investigation.[5] The direction of the cleavage of the ethylene imine ring in the salt (S) is determined by the conditions of the experiment and the configuration of the original ethylene imine ketone. The results obtained from the quantitative dry hydrogen chloride experiments suggest several possible mechanisms that serve as a working hypothesis for the kinetic studies that are in progress.

### $S_N1$ and/or $S_N2$ Ring Cleavage Mechanism

If the mechanism is of an $S_N1$ type then the ring would be expected to open, mainly according to scheme [1] if the α-carbon has the greater electron density. For an $S_N2$ type of ring cleavage, scheme [2] would be the major reaction course if the β-carbon is the more electrophilic. It is to be recalled that the *trans* ethylene imine ketones gave, mainly, the α-chloro ketones with minimum amounts of hydrogen chloride. The *cis* form studied reacted much more rapidly to give only slightly more α-chloro ketone than β-chloro ketone, under these conditions. Excess chloride ion concentration should favor the $S_N2$ mechanism and course [2].

### Carbonyl Directed 1–4 Ring Cleavage Mechanism

Under the influence of excess hydrogen chloride the salt (S) might also be expected to undergo ring cleavage by way of a carbonyl directed 1,4-attack, as indicated above. An inspection of scale models indicates that with the *trans* structures transition complex (T) could form readily. In the *cis* form the aryl group on the β-carbon would be expected to repel the chlorine atom of the hydrogen chloride molecule to such an extent that a transition complex (T) would seem unlikely. It is to be recalled that excess dry hydrogen chloride converted the *trans* ethylene imine ketones almost entirely into β-chloro ketones. A similar experiment with the *cis* compound gave only slightly less α-chloro ketone than β-chloro ketone.

**Acknowledgment.**—The senior author appreciates a grant from the Research Council of the University of Nebraska which aided in the completion of this investigation.

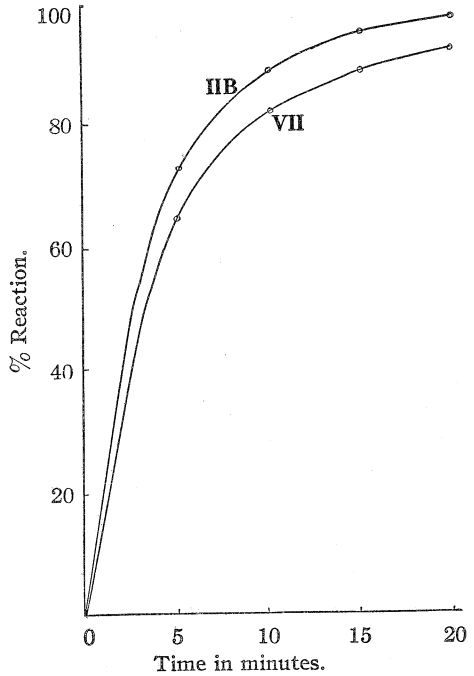

Fig. 1.—Rates of iodine release by α-chloro-β-aminoketones (IIB) and (VII) in a dry acetone–alcohol acidic solution of potassium iodide at 66°.

## Experimental

**Reaction of α,β-Dibromobenzylacetophenone with Benzylamine. Quantitative Studies.**—Following the directions outlined previously[1] for the preparation of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine, a 46% yield of 1-benzyl-2-phenyl-3-benzoylethylenimine, m. p. 108°[6] was obtained from α,β-dibromobenzylacetophenone. It was not possible to isolate a solid, low-melting isomer in this case. The reaction mixture filtrate was treated with an excess of an absolute alcohol solution of dry hydrogen chloride, to give as a first crop, colorless crystals, 24% yield, m. p. 159–164°. Two recrystallizations of this product from methyl alcohol and dry ether gave a 20% yield of (IIA), m. p. 164–166°. Iodine release[6] at 66° in thirty minutes was 6.4% for this product.

*Anal.* Calcd. for $C_{22}H_{21}NOCl_2$: Cl, 18.36. Found: Cl, 18.30.

The filtrate from (IIA) was treated with several times its volume of dry ether and cooled for two days to give a second crop of colorless crystals (20% yield), m. p. 149–150°, of (IIB); recrystallized from methyl alcohol and dry ether, m. p. 151–152°. (IIB) released 95.4% of one equivalent of iodine at 66° in fifteen minutes. See also Figure 1.

*Anal.* Calcd. for $C_{22}H_{21}NOCl_2$: Cl, 18.36. Found: Cl, 18.32. A 50-50 mixture of (IIA) and (IIB) showed a m. p. 150–159° and gave an iodine release value of 51% in either fifteen or thirty minutes.

In this experiment, 90% of the original α,β-dibromobenzylacetophenone was accounted for. Neither (IIA) nor (IIB) underwent any appreciable change on standing at room temperature in dry methyl alcohol solution for four days.

**α-Benzylamino-β-chlorobenzylacetophenone (III).**—A 5.0 g. (0.013 mole) sample of the hydrochloride (IIA) was mixed with 50 ml. of benzene and 1.39 g. (0.013 mole) of benzylamine, heated on the steam-bath for ten minutes, and then allowed to stand at room temperature for three hours. Dry ether was added and the colorless precipitate of benzylamine hydrochloride filtered off, wt. 1.85 g. (99% of one equivalent). The filtrate was evaporated under reduced pressure and petroleum ether added. Colorless crystals formed and were filtered off, wt. 3.0 g. (0.0086 mole, 66% yield), m. p. 92–93°; iodine release at 66° in thirty minutes was 3.0%.

*Anal.* Calcd. for $C_{22}H_{20}NOCl$: C, 75.52; H, 5.76. Found: C, 75.88; H, 5.84.

Compound (III) decomposed after standing at room temperature for twenty-four hours in a vacuum desiccator.

When the hydrochloride (IIB) was placed in benzene and treated with benzylamine, two equivalents of benzylamine hydrochloride were formed immediately. Evaporation of the benzene left an oil which solidified at −15° but which could not be resolved to a solid product at room temperature. This possibily was a low melting form of 1-benzyl-2-phenyl-3-benzoylethylenimine.

**α-Benzylamino-β-hydroxybenzylacetophenone Hydrochloride (IV).**—An attempted recrystallization of this product (III) from hot aqueous alcohol resulted in a hydrolysis, and precipitated a product no longer soluble in ether or acetone, m. p. 210° (IV).

*Anal.* Calcd. for $C_{22}H_{22}NO_2Cl$: C, 71.82; H, 6.03; N, 3.81. Found: C, 71.54; H, 6.20; N, 3.93.

A more extensive decomposition accompanied this hydrolysis as indicated by the presence of benzaldehyde.

**Hydrogenation of (III).**—A 2.0-g. sample of (III) was dissolved in 20 ml. of methanol and 0.5 g. of 10% palladium-on-charcoal catalyst added. This mixture was shaken for two hours with hydrogen at room temperature under a pressure of 38 lb. per sq. inch. The catalyst was filtered off and the methanol evaporated under reduced pressure. Addition of dry ether gave mixed hydrochlorides, wt. 1.0 g., m. p. 205–210°. This product was dissolved in water and the solution treated with dilute sodium hydroxide to give an oily precipitate which was extracted with ether. On passing dry hydrogen chloride into the dried ether solution, a colorless precipitate formed, m. p. 223–225°; recrystallized from alcohol and ether, m. p. 228–229°; wt. 0.7 g. (V).

*Anal.* Calcd. for $C_{22}H_{24}NOCl$: C, 74.66; H, 6.84; N, 3.96. Found: C, 74.36; H, 6.96; N, 3.78.

A sample of 2-benzylamino-1,3-diphenylpropanol-1 hydrochloride was prepared and found to have a m. p. of 228–229° instead of m. p. 220° as previously reported.[7] Several careful mixed m. p. and mixed freezing point experiments indicated this compound to be identical with (V). The picrate of the free base of (V) was prepared, m. p. 149–150°, and found to be identical with the authentic picrate of 2-benzylamino-1,3-diphenylpropanol-1.[7]

**Hydrogenation of (IIB).**—A 0.6 g. (0.00155 mole) sample of the hydrochloride (IIB) was dissolved in 20 ml. of absolute alcohol and 0.1 g. of platinum oxide catalyst added. The mixture was shaken for thirty minutes with hydrogen at room temperature under a pressure of 45 lb. per sq. inch. The catalyst was filtered off and the solvent evaporated under reduced pressure. Addition of dry ether gave 0.15 g. (0.00104 mole) of benzylamine hydrochloride. Evaporation of the ether filtrate gave 0.2 g. (0.00095 mole, 61% yield) of a colorless, crystalline product, m. p. 70°, identical with benzylacetophenone.

**Treatment of 1-Benzyl-2-phenyl-3-benzoylethylenimine with Minimum Amounts of Hydrogen Chloride.**—A 3.0-g. (0.00959 mole) sample of 1-benzyl-2-phenyl-3-benzoylethylenimine (m. p. 108°) was dissolved in 25 ml. of dry acetone and cooled in an ice-bath to 5°. A 25.1-ml. quantity of a 0.383 molar dry, hydrogen chloride-in-ether solution (0.0096 mole of HCl) was added slowly with stirring. A large amount of white precipitate formed immediately and remained for several hours (the ethylene imine ketone hydrochloride).[5] After standing at room temperature for one day, the solution had developed a pale-yellow color, the original precipitate had disappeared and a lesser amount of larger, colorless crystals appeared which were filtered off, m. p. 149°, wt. 1.0 g. (0.00259 mole, 27% yield). This product was identical in all respects with (IIB), giving an iodine release of 93.2% in fifteen minutes at 66°.

*Anal.* Calcd. for $C_{22}H_{21}NOCl_2$: C, 68.39; H, 5.48; N, 3.63. Found: C, 68.17; H, 5.71; N, 3.42.

Evaporation of the filtrate from (IIB) left a semi-solid residue which was recrystallized from a benzene–petroleum ether mixture to give 0.60 g. (0.00192 mole) of the starting ethylene imine ketone, m. p. 103–106°, identified by a mixed m. p. experiment and by its behavior in direct sunlight (turned pink).

Assuming that about 0.0044 mole of the chlorobenzylaminobenzylacetophenones remained in the filtrate from the recovery of the ethylene imine ketone, 11.5 ml. of the 0.383 molar dry, ether–hydrogen chloride solution (0.0044 mole of HCl) were added and the solution cooled in an ice-bath to give an immediate precipitation of a colorless product which was filtered off; wt. 1.5 g. (0.00389 mole); m. p. 141–145°; iodine release, 49.4% in fifteen minutes at 66°.

A separation of this mixed product melting at 141–145° was effected by a method based upon the differences in the basic strengths of α-chloro-β-benzylaminobenzylacetophenone and α-benzylamino-β-chlorobenzylacetophenone. A 0.70 g. (0.00182 mole) sample was mixed with 25 ml. of dry ether and treated with 0.20 g. (0.00187 mole) of benzylamine. After standing for fifteen hours in the ice chest the precipitated benzylamine hydrochloride was filtered off. The ether filtrate was then treated with 0.0009 mole of hydrogen chloride. After cooling at 0° for one day, a colorless product was filtered off, wt. 0.34 g. (0.00088 mole), m. p. 148–150°; iodine release at 66° in fifteen minutes was 77%. This was fairly pure (IIB). To the filtrate was now added a second 0.0009 molar quantity of hydrogen chloride. After standing for twenty-four hours, a second product was obtained, m. p. 161–162°, wt. 0.27 g. (0.0007 mole); iodine release at 66° in thirty minutes was 2.3%. This was fairly pure (IIA).

This entire experiment was repeated with the same results at each step, within 5–10%.

The chloride (IIA) was identical in all respects with the chloride obtained previously from the reaction of excess dry or aqueous hydrogen chloride and 1-benzyl-2-phenyl-3-benzoylethylenimine, and was assigned the structure β-chloro-α-benzylaminobenzylacetophenone hydrochloride.[4,6] Both (IIA) and (IIB) remained unchanged after standing for several days in a mixture of dry benzene and dry ether saturated with dry hydrogen chloride.

**Reaction of *cis* and *trans* 1-Benzyl-2-phenyl-3-*p*-toluylethylenimines with Minimum Amounts of Hydrogen Chloride.**—Following the procedure as outlined above for 1-benzyl-2-phenyl-3-benzoylethylenimine, the following results were obtained with these *cis* and *trans* isomeric ethylene imine ketones.[1]

**From 1.8 g. (0.0055 mole) of this *trans* isomer,** the first hydrochloride product (VII) weighed 0.5 g. (0.00125 mole), m. p. 155–161°; iodine release in fifteen minutes at 66° was 88.7% (see also Fig. 1). When recrystallized from methanol and ether, the melting point increased to 163–167°; but the iodine release value was practically unchanged. This sample (VII) was almost pure α-chloro-β-benzylaminobenzyl-*p*-methylacetophenone hydrochloride. Also obtained in the second step was 0.9 g. (0.00225 mole) of mixed hydrochlorides, m. p. 159–162°, which gave an iodine release of 65.4%. Evaporation of the residual mixture gave 0.35 g. (0.00107 mole) of unreacted ethylene imine ketone.

**From 2.0 g. (0.00612 mole) of the *cis* isomer,** the first hydrochloride product weighed 0.57 g. (0.00142 mole), m. p. 156–159°; iodine release for this product at 66° in fifteen minutes was 53.8%. Evaporation of the filtrate from this product gave 0.2 g. (0.00061 mole) of the *trans* instead of the *cis* ethylene imine ketone, as shown by a mixed m. p. and its light sensitivity. Treatment of the residual solution with more dry hydrogen chloride gave a second hydrochloride product, wt. 1.08 g. (0.0027 mole), m. p. 150–155°. Iodine release for this product in fifteen minutes at 66° was 54.2%.

Continuous fractional recrystallizations from ethanol and dry ether separated both of these products into nearly equal amounts of (VII) and β-chloro-α-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (VI).

**β-Chloro-α-benzylaminobenzyl-*p*-methylacetophenone (VIII).**—Repeating the procedure outlined above for the preparation of (III), 2.0 g. of the hydrochloride (VI) gave 0.714 g. of benzylamine hydrochloride and 1.0 g. of (VIII); recrystallized from an ether–petroleum ether mixture, m. p. 105° (decomposed then resolidified).

*Anal.* Calcd. for $C_{23}H_{22}NOCl$: C, 75.93; H, 6.09; N, 3.85. Found: C, 76.11; H, 6.07; N, 4.10.

**β-Hydroxy-α-benzylaminobenzyl-*p*-methylacetophenone Hydrochloride (IX).**—Following the procedure outlined for the preparation of (IV), 0.4 g. of (VIII) gave 0.23 g. of (IX), recrystallized from methanol and ether, m. p. 208–210°.

*Anal.* Calcd. for $C_{23}H_{24}NO_2Cl$: C, 72.33; H, 6.34; N, 3.67. Found: C, 72.09; H, 6.52; N, 3.71.

## Summary

1. Excess amounts of dry hydrogen chloride react with the *trans* forms of ethylene imine ketones to give mainly the β-chloro-α-aminoketone hydrochlorides. Minimum amounts of this reagent convert these *trans* forms largely into the isomeric α-chloro-β-aminoketone hydrochlorides.

2. The *cis* form of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine reacts very rapidly with excess or minimum amounts of dry hydrogen chloride to give nearly equal amounts of the α-chloro and β-chloro ketones.

3. Structure proofs for the closely related α-chloro-β-aminoketones and β-chloro-α-aminoketones have been devised. Possible mechanisms to account for these different ring cleavages have been discussed.

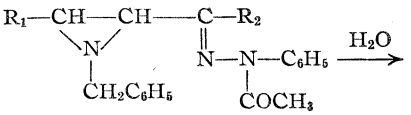
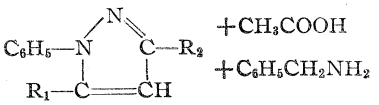
# Ethylene Imine Ketones. VI.[1] Reactions with Phenylhydrazine[2]



BY NORMAN H. CROMWELL AND HERMAN HOEKSEMA[3]

Continuing our comparative studies of the reactions of ethylene imine ketones with known reactions of epoxy ketones it was of interest to investigate the behavior of the former with phenylhydrazine. A similar study of the reaction of hydrazine with an epoxy ketone[4] has shown that the epoxide ring is opened to give an intermediate 4-hydroxypyrazoline which on heating loses water to yield the corresponding pyrazole.



It was of considerable interest to compare the phenylhydrazine reactions of the *cis* and *trans* isomeric 1-benzyl-2-phenyl-3-*p*-toluylethylenimines, reported in a previous communication.[5]

With what may be presumed to be the *trans* forms in each case[1,5] 1-benzyl-2-phenyl-3-benzoylethylenimine,[6] 1-benzyl-2-*p*-tolyl-3-benzoylethylenimine,[7] and 1-benzyl-2-phenyl-3-*p*-toluylethylenimine,[5] each reacted with phenylhydrazine in glacial acetic acid to give the corresponding pyrazoles (I), (II) and (III) and the N-acetylphenylhydrazones of the ethylene imine ketones, (IV), (V) and (VI). The identities of the former were established by comparison with authentic samples synthesized by known methods.

The N-acetylphenylhydrazones (IV), (V) and (VI) have been assigned these structures because on hydrolysis they give the expected pyrazoles, and because they have absorption spectra, see Fig. 1, that are similar only to that of an N-acetylphenylhydrazone.[8]

(IV) $R_1$ and $R_2$ = $C_6H_5$
(V) $R_1$ = *p*-$CH_3C_6H_4$; $R_2$ = $C_6H_5$
(VI) $R_1$ = $C_6H_5$; $R_2$ = *p*-$CH_3C_6H_4$

(I) and (III)

Since it was possible that the general absorption spectra shown by these compounds (V) and (VI) were the result of pyrazole impurities in an acetylated pyrazoline of type (IX), study of the spectrum of a mixture of the pyrazole (III) and of the acetylated product (IX) was undertaken. As is indicated by Fig. 2, such an explanation of the general absorption shown by (VI) is unlikely.

Even with the mildest conditions the pyrazole resulted from the phenylhydrazine reactions with the *trans* form of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine. The mechanism of its formation probably involves the intermediate formation of the phenylhydrazone (A) which then undergoes an intramolecular ring opening and closure to form the 4-benzylaminopyrazoline (B). The configuration of (B) may be such that the benzylamino group on carbon atom-4 and the hydrogen on carbon-5 are on the same side of the pyrazoline ring. Compound (B) might then lose benzylamine readily by an intramolecular reaction as indicated to form the pyrazole.

(I) $R_1$ and $R_2$ = $C_6H_5$
(II) $R_2$ = $C_6H_5$, $R_1$ = $p$-$CH_3C_6H_4$
(III) $R_1$ = $C_6H_5$, $R_2$ = $p$-$CH_3C_6H_4$

The *cis* form (low melting) of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine[5] gave excellent yields of 1,5-diphenyl-3-*p*-tolyl-4-benzylaminopyrazoline (VII). Even in warm glacial acetic acid this *cis* isomer gave only (VII). The structure assigned to (VII) is consistent with the fact that it gives the standard tests for pyrazolines, that it shows the same blue fluorescence as the known parent 1,5-diphenyl-3-*p*-tolylpyrazoline,[9] and that it cannot be hydrogenated to yield aniline as would be expected with a phenylhydrazone. Moreover, in strong acid solution (VII) loses benzylamine to give the corresponding pyrazole (III).

The aminopyrazoline (VII) condensed with benzaldehyde to give a product whose properties indicate it probably has structure (VIII), and with acetic anhydride to give the diacetylated product which has been assigned the structure (IX). These are expected reactions, for the pyrazolines have active hydrogen in the 4-position.[10] Compound (VIII) was converted to pyrazole (III) on heating with dilute sulfuric acid. The properties of compounds of types (VIII) and (IX) are being studied further in an extended investigation. Studies of the absorption spectra of the diacetylated aminopyrazoline (IX) and of the benzaldehyde condensation product (VIII) indicated them to be similar to those of both the parent 1,5-diphenyl-3-*p*-tolylpyrazoline and the 4-benzylamino-1,5-diphenyl-3-*p*-tolylpyrazoline (VII) (see Figs. 1 and 3). It is to be observed that pyrazolines and phenylhydrazones have similar but not identical spectra, see Fig. 3.

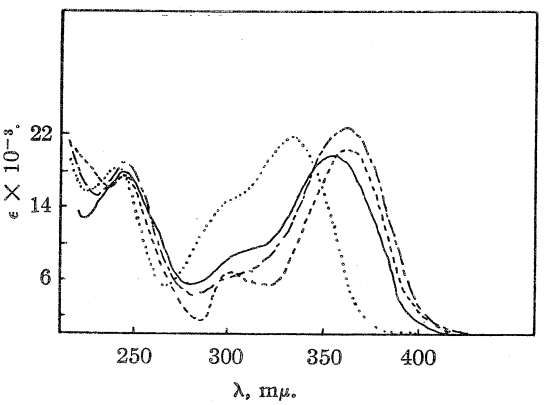

Fig. 3.—1,5-Diphenyl-3-*p*-tolylpyrazoline,—; VII, — –; VIII, – – –; X, ....

The formation of the aminopyrazoline (VII) from the *cis* isomer may be explained by the same mechanism as given above for the formation of (A) and (B) from the *trans* ethylene imine ketone. In the former case, however, the benzylamino group on carbon-4 and the hydrogen on carbon-5 might now be expected to turn up on opposite sides of the pyrazoline ring and intramolecular loss of benzylamine becomes less probable. Thus in neutral or basic media (VIII) is quite stable, but in acid solution, where solvolytic protons are available, (VII) can lose benzylamine to give the pyrazole by the mechanism shown later.

These considerations may suggest why 4-amino derivatives of 1,3,5-triarylpyrazolines have heretofore been unknown.

## Experimental

**Reaction of Ethylene Imine Ketones (*trans* Isomers) with Phenylhydrazine in: (a) Glacial Acetic Acid.**—The ethylene imine ketone (2.1 g., 0.006 mole) was dissolved in 10 ml. of glacial acetic acid. One gram (0.009 mole) of phenylhydrazine was added and the solution warmed to 50° for a few minutes and then cooled to room temperature. After standing at room temperature for twenty-four hours the solution was cooled to 0° and the precipitated product removed by filtration and purified by recrystallization from benzene–alcohol mixtures to give the colorless pyrazole. The acetic acid filtrate was treated with an equal volume of water to give a yellow gummy precipitate which was recrystallized several times from benzene–absolute alcohol and benzene–petroleum ether mixtures to give the yellow N-acetylphenylhydrazones of the ethylene imine ketones.

In this way the pyrazole (I) and N-acetylphenylhydrazone (IV) were obtained from 1-benzyl-2-phenyl-3-benzoylethylenimine[6]; pyrazole (II) and N-acetylphenylhydrazone (V) from 1-benzyl-2-*p*-tolyl-3-benzoylethylenimine[7]; and pyrazole (III) and N-acetylphenylhydrazone (VI) from 1-benzyl-2-phenyl-3-*p*-toluylethylenimine (high m.p.)[5] (see Table I). A mixture of (V) and (VI) melted at 125–135°.

**(b) Pyridine Solution.**—A 35% yield of the pyrazole (III) resulted when the corresponding ethylene imine ketone (high melting) was mixed with one equivalent of glacial acetic acid and 2.5 equivalents of phenylhydrazine in pyridine solution at room temperature. No other products were isolated from this experiment.

**(c) Alcohol Solution.**—To a solution of 3.0 g. (0.009 mole) of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine (high m.p.) in 150 ml. of ethyl alcohol was added 1.0 g. (0.009 mole) of phenylhydrazine and 1.0 g. (0.017 mole) of glacial acetic acid. The solution stood at room temperature for four hours and in the ice chest for three days. The precipitated product was removed by filtration and recrystallized from alcohol, 1.1 g. (38% yield), m.p. 129.5°, mixed with (III), m.p. 129–130°. From the residual reaction mixture was recovered 0.1 g. of the unchanged starting ethylene imine ketone.

**Synthesis of Pyrazoles (I), (II) and (III).**—The pyrazoles (II) and (III) were prepared for the first time from the corresponding benzalacetophenone dibromides by the method outlined by Barnes[11] in 20–35% yields. These products melted the same as (II) and (III), respectively, and mixtures showed no depression of melting point. A mixture of (II) with (III), however, melted at 98–105°.

(11) Barnes and Dodson, THIS JOURNAL, 65, 1585 (1943).

The pyrazole (I), a known compound, was prepared according to the method of Wislicenus[12] in 50% yields and was identical with (I).

**Hydrolysis of the N-Acetylphenylhydrazones (IV) and (VI).**—One-gram samples of compounds (IV) and (VI), respectively, were mixed with 5 ml. of hot alcohol. These suspensions were poured into 25 ml. of boiling 20% sulfuric acid and the resulting mixtures refluxed for ten hours. The solutions were cooled and the colorless products filtered and recrystallized from alcohol. In this way 90–100% yields of the pyrazole (I) resulted from (IV), and the pyrazole (III) from (VI).

**Reaction of 1-Benzyl-2-phenyl-3-*p*-toluylethylenimine (*cis* Form) with Phenylhydrazine: (a) In Alcohol Solution.**—Nine grams (0.027 mole) of the low m.p. ethylene imine ketone was dissolved in 150 ml. of ethyl alcohol. To this solution were added 3.0 g. (0.027 mole) of phenylhydrazine and 3.0 g. (0.05 mole) of glacial acetic acid. As the solution stood at room temperature slow crystal growth was observed. After four hours the mixture was cooled to yield a pale-yellow product which was recrystallized twice from absolute alcohol to give colorless crystals of (VII). All solutions of this product displayed a blue fluorescence. It also gave the Knorr[13] and the Raiford[9] tests for pyrazolines. On refluxing a benzene solution of (VII) for three hours no change took place.

**(b) In Glacial Acetic Acid.**—A 2.1-g. (0.006 mole) sample of the ethylene imine ketone (m.p. 72–74°) was dissolved in 10 ml. of glacial acetic acid and 1.0 g. (0.009 mole) of phenylhydrazine added. The solution was heated to 50° for a few minutes, allowed to stand at room temperature for three hours and finally cooled in the ice chest for several days. No precipitation took place. On adding water to the reaction mixture a gummy product was obtained which, after recrystallization from alcohol, gave a 48% yield of a product identical in all respects with the aminopyrazoline (VII).

**Attempted Hydrogenations of the Aminopyrazoline (VII).**—The aminopyrazoline (VII) resisted hydrogenation and was recovered unchanged from reaction mixtures employing palladium on charcoal and hydrogen at 50 lb./sq. in. at 100°, or platinum oxide under similar conditions. Boiling sodium and alcohol solutions likewise did not change this product.

**Hydrolysis of the Aminopyrazoline (VII).**—A 3.0-g. sample of (VII) was warmed on a steam-bath for three and one-half hours with 50 ml. of 20% sulfuric acid. From the cooled solution was isolated 2.1 g. of a pyrazole identical with (III).

(12) Wislicenus, *et al.*, *Ann.*, **308**, 253 (1899).

(13) Knorr, *Ann.*, **238**, 200 (1887).

**Reaction of Benzaldehyde with the Aminopyrazoline (VII).**—Two grams (0.0048 mole) of (VII) was mixed with 3.1 g. (0.29 mole) of benzaldehyde, 5 ml. of ethyl alcohol and 1 ml. of glacial acetic acid and heated under reflux for eight hours. Cooling the reaction mixture gave a product which, after recrystallization from absolute alcohol and then a benzene–absolute alcohol mixture, was a pale-yellow crystalline material (VIII). Calcd. for $C_{36}H_{38}N_3O$: mol. wt., 523.6. Found: mol. wt., 510. When a sample of (VIII) was heated for five hours with 20% sulfuric acid, pyrazole (III) resulted in a 60% yield.

| | | | 240 | 18.3 | 223 | 15.1 |

[a] A 1.93-mg. sample of (III) and 2.72 mg. of (IX) were dissolved in 200 ml. of 95% alcohol. The molar concn. of this solution was calculated assuming a molecular weight of 501.6 (value for (IX)). [b] Prepared according to the directions of Raiford and Peterson, ref. 9.

**Acetylation of Aminopyrazoline (VII).**—A 1.0-g. sample of (VII) was refluxed for two hours with 15 ml. of acetic anhydride. Most of the acetic anhydride was distilled under vacuum and the residue treated with sodium bicarbonate solution. The solid residue was recrystallized from benzene and petroleum ether and finally from 90% alcohol. The pale-yellow product was dried under vacuum at 80° for three hours to give (IX).

**Benzyl-*p*-methylacetophenone Phenylhydrazone (X).**—This phenylhydrazone (X) was prepared from benzyl-*p*-methylacetophenone in the usual way in 90% yields and recrystallized from ethyl alcohol, m.p. 77–79°. This compound decomposed to a tar after exposure to light and air for a few days.

*Anal.* Calcd. for $C_{22}H_{22}N_2$: N, 8.91. Found: N, 9.10, 8.94.

**Absorption Spectra Measurements.**—These measurements were made using a Beckman Model DU Photoelectric Quartz Spectrophotometer. At the sensitivity used, the maximum band width was one millimicron, with a rated accuracy of 0.1%. Pure 95% alcohol was used as a solvent medium since most of these compounds were not sufficiently soluble in a non-polar solvent such as heptane (see Figs. 1, 2 and 3, and Table II).

## Summary

1. *trans* Ethylene imine ketones react with phenylhydrazine to give the corresponding pyrazoles and N-acetylphenylhydrazones of the ethylene imine ketones.

2. *cis* Ethylene imine ketones give the intermediate 4-aminopyrazolines which are stable in neutral or basic solutions but lose benzylamine to give the pyrazole when a solvolytic proton becomes available in acid solutions.

3. The absorption spectra of these compounds have been compared to aid in the elucidation of their structures. The pyrazolines have similar but not identical spectra with those of related phenylhydrazones.

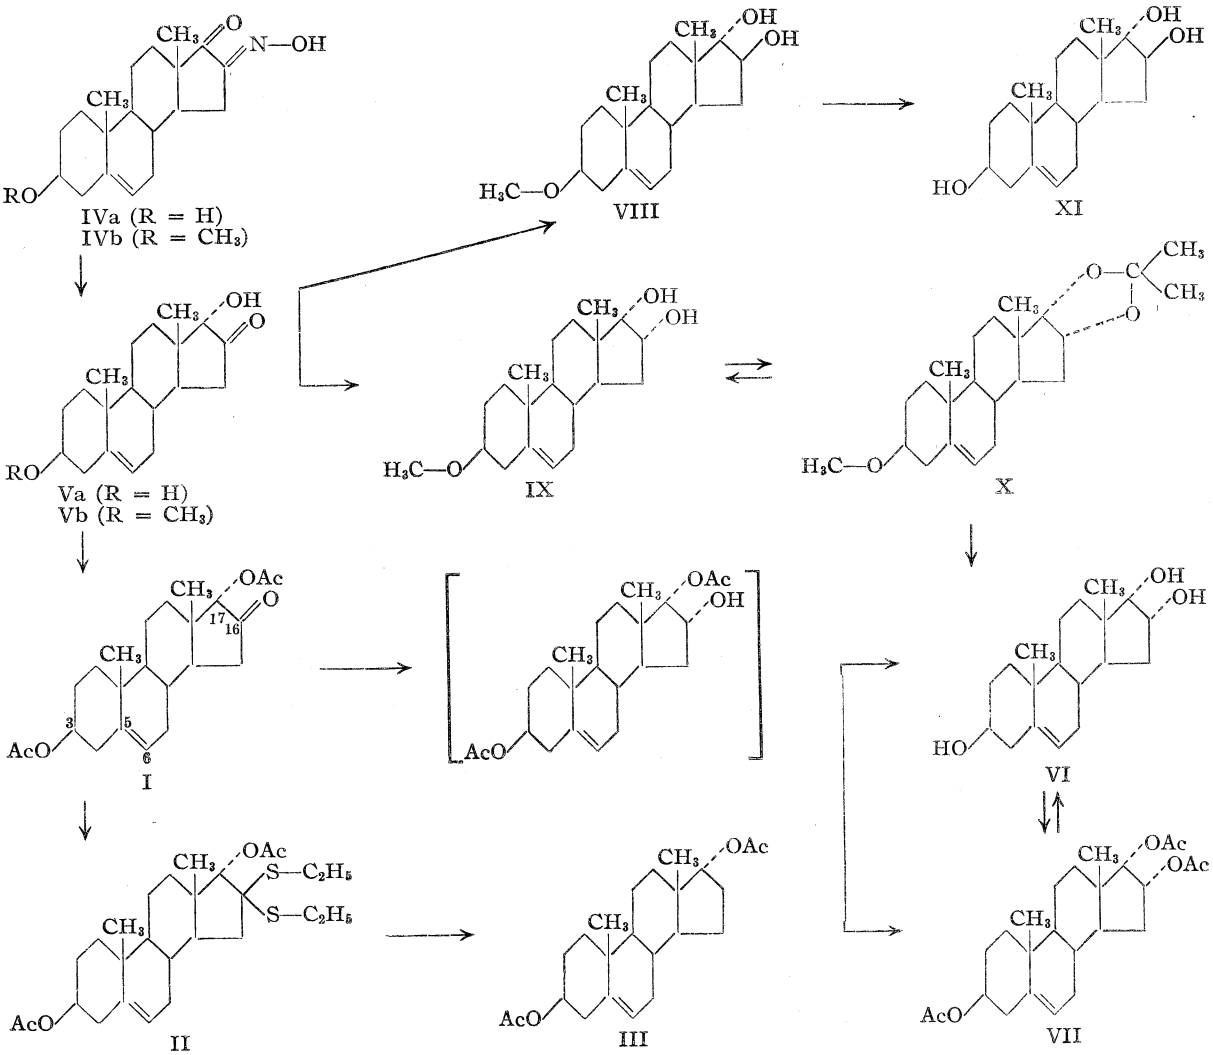
# 16-Substituted Steroids. VI. The Steric Structure of Steroidal 16,17-Ketols and 16,17-Glycols[1]

BY MAX N. HUFFMAN AND MARY HARRIET LOTT



Stodola, Kendall and McKenzie[2,3] have shown that the zinc–acetic acid reduction of 16-oximino-17-ketosteroids followed by acetylation results in the formation of 16-keto-17-acetoxysteroids. The Stodola reduction of 16-oximinodehydroisoandrosterone, for instance, was found to give, after acetylation with acetic anhydride in pyridine, an androstenediolone diacetate in which the ketone group clearly occupied the $C_{16}$ position. We have confirmed this finding of Stodola and co-workers and furthermore shown that the acetoxyl at $C_{17}$ has the $\alpha$ spatial configuration. If the 3($\beta$),17-diacetoxy-16-keto-$\Delta^5$-androstene (I) of Stodola is treated with ethyl mercaptan in the presence of fused zinc chloride and anhydrous sodium sulfate[4] a crystalline diethyl thioacetal (II) is readily obtained in good yield. This thioacetal loses its mercaptyl residues on hydrogenolysis with modified Raney nickel, and there is obtained the known 3($\beta$),17($\alpha$)-diacetoxy-$\Delta^5$-androstene (III). Since in these reactions there can be no question of

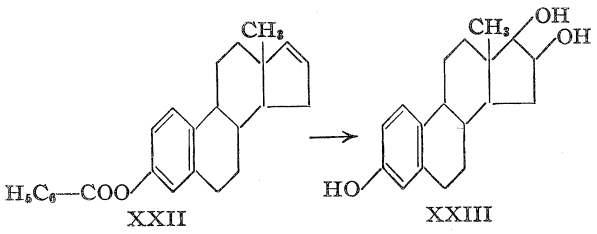
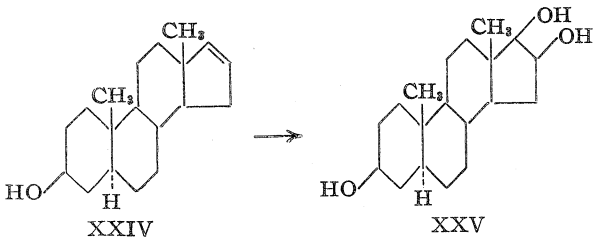
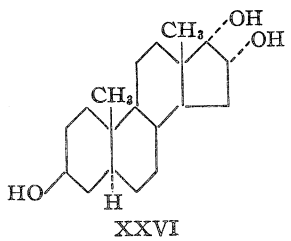
keto–carbinol isomerization, it is certain that the original androstenediolone diacetate had its carbonyl at position 16 and its $C_{17}$ acetoxyl in the $\alpha$ spatial configuration.



It seems clear that the method of carbonyl reduction by thioacetal hydrogenolysis (discovered by Wolfrom and Karabinos[5]) should find wide application in structural studies in the general group of vicinal ketols where the Clemmensen and Wolff-Kishner methods of reduction are decidedly unsuited.



The Stodola reduction of 16-oximino-17-ketosteroids is peculiar in that there is produced, instead of the expected amine, a 16,17-ketol. We feel certain that such ketols are actually 16-keto-17($\alpha$)-hydroxysteroids and that no rearrangement occurs upon acetylation. The zinc–acetic acid reduction of 16-oximinodehydroisoandrosterone (IVa) gives an androstenediolone[6] (Va) which furnishes 3($\beta$),17($\alpha$)-diacetoxy-16-keto-$\Delta^5$-androstene (I) either upon long standing with acetic anhydride and pyridine or upon very rapid acetylation with acetic anhydride and phosphoric acid according to Ciusa and Sollazzo.[7] The yields are virtually identical in both methods of esterification. These facts suggest that no rearrangement of the ketol takes place during esterification. Furthermore, ketols prepared by Stodola reduction of 16-oximino-17-ketosteroids may be acetylated and the resulting acetate then saponified to produce the identical ketol which was originally esterified. For instance, 3-benzyloxy-17($\alpha$)-acetoxy-16-keto-$\Delta^{1,3,5}$-estratriene (XIVb) may be saponified to produce the same estradiolone-3-benzyl ether (XIIIb) from which the 17-acetoxy derivative was formed.



The most decisive evidence in regard to the structure of Stodola-prepared 16,17-ketols comes, in our opinion, from the studies on the oxidation products of these ketols resulting from lead tetraacetate cleavage of steroid Ring D. Baer[8,9] has

shown that vicinal ketols (both acyclic and cyclic) can be oxidized with lead tetra-acetate in aqueous acetic acid with rupture of the carbon to carbon bond between the functional groups to produce an aldehyde and a carboxylic acid. The aldehyde arises from the original carbinol carbon and the carboxylic acid from the original carbonyl carbon of the vicinal ketol so treated. After lead tetra-acetate cleavage of Ring D of Stodola-prepared 16,17-ketols it has been found that the carboxylic acid so produced is not the well-known tertiary one attached to steroid position $C_{13}$. If the 16,17-ketol (XIIIc) prepared by the zinc–acetic acid reduction of 3-methoxy-16-oximino-17-keto-$\Delta^{1,3,5}$-estratriene (XIIc) is treated briefly with lead tetra-acetate in aqueous acetic acid, there is obtained an aldehyde–acid (XV) which furnishes an easily crystallizable semicarbazone-acid (XVI). Treatment of this semicarbazone-acid with diazomethane destroys its acidic properties with formation of the methyl ester (XVII). This semicarbazone-methyl ester is readily saponified to regenerate the original semicarbazone-acid (XVI) under conditions which would not hydrolyze a carbomethoxy group at $C_{13}$. This finding seems interpretable only upon the basis that the original carbonyl on the intact Ring D occupied position 16, for had this carbonyl been at position 17, the carboxylic acid produced by lead tetra-acetate cleavage would have been attached to tertiary position 13 (Contrast Reaction A and Reaction B).

Reaction A

Reaction B

Furthermore, had the original estradiolone-3-methyl ether been a 16-hydroxy-17-ketosteroid, the aldehyde–acid produced on lead tetra-acetate cleavage (as in Reaction B) would have led to the same semicarbazone-methyl ester (XVIII) as that recently prepared by Miescher[10] and which melts at 212–213° (cor.). Our semicarbazone-methyl ester (XVII) decomposes at 166–167.5° (uncor.) with evolution of gas.

From the foregoing evidence, and from evidence shortly to be presented, we feel justified in stating that Stodola-prepared 16,17-ketols possess the structure of 16-keto-17($\alpha$)-hydroxysteroids. It is noteworthy that 16,17-diketosteroids likewise form 16-keto-17($\alpha$)-hydroxysteroids upon reduction with zinc or with titanium trichloride.[11,12]

Stodola, Kendall and McKenzie[2] found that catalytic reduction of 3($\beta$),17($\alpha$)-diacetoxy-16-keto-$\Delta^5$-androstene (I) in ethanol yielded, after further acetylation, the triacetate (VII) of the androstenetriol originally prepared by Butenandt.[6] We have repeated the experiment of Stodola, *et al.*, except that reduction with hydrogen and Raney nickel was effected in a medium of ethyl acetate–ethanol (2.5:1) in order to obviate any danger of saponification of the diacetate (I), the structure of which is now quite securely known. We likewise found that Butenandt's androstenetriol is formed (reduction of I followed by acetylation to give the triacetate VII). Now Butenandt[6] clearly showed that his androstenetriol (VI) possessed the $C_{16}$–OH and $C_{17}$–OH in *cis* relationship from the standpoint of geometric isomerism, and we have confirmed this point as will be seen later; there is, therefore, no doubt that Butenandt's triol is 3($\beta$),16($\alpha$),17($\alpha$)-trihydroxy-$\Delta^5$-androstene (VI).

If a 16-keto-17($\alpha$)-hydroxysteroid be reduced with 2% sodium amalgam in excess dilute ethanolic acetic acid (40°), there is produced a mixture of *cis*-oid and *trans*-oid 16,17-glycols. (At temperatures above 40° there is apparently produced relatively more of the *cis*-oid form.) Thus if 3($\beta$)-

(11) Huffman, *J. Biol. Chem.*, **167**, 273 (1947).
(12) Huffman and Lott, *ibid.*, **172**, 325 (1948).

methoxy-17($\alpha$)-hydroxy-16-keto-$\Delta^5$-androstene (Vb) is reduced with sodium amalgam as described, there is obtained a mixture of geometrically isomeric 16,17-glycols (VIII and IX). In this mixture the *trans*-oid component (VIII) is less soluble and may readily be obtained in pure form by repeated crystallization. The remaining isomer (IX) is obtained by transformation to the cyclic acetonide (X) and by purification in this form. Hydrolysis of this acetonide (X) followed by demethylation furnishes Butenandt's triol[6] (VI) —known with certainty to be 3($\beta$),16($\alpha$),17($\alpha$)-trihydroxy-$\Delta^5$-androstene. Demethylation of the *trans*-oid 3-ether (VIII) yields Hirschmann's triol[13] (XI) which must from the foregoing evidence be 3($\beta$),16($\beta$),17($\alpha$)-trihydroxy-$\Delta^5$-androstene as it is the only *trans*-oid glycol possible from the 16-keto-17($\alpha$)-hydroxy configuration. (At this point it should be carefully noted that proof of the $\alpha$ spatial configuration of the carbinol group in unesterified Stodola-prepared 16,17-ketols is now complete, for such a ketol has been shown to give rise to a known 16($\alpha$),17($\alpha$)-glycol).

Upon sodium amalgam reduction as just described, 3,17($\alpha$)-dihydroxy-16-keto-$\Delta^{1,3,5}$-estratriene (XIIIa) yields a mixture of geometrically isomeric 16,17-glycols (XIX and XX). If this mixture be treated briefly with anhydrous hydrogen chloride in absolute acetone, the *cis*-oid isomer (XX) reacts to furnish a cyclic acetal (XXI) whereas the *trans*-oid (XIX) does not. It was found that the acetal could be readily separated from the *trans*-oid glycol by partitioning between chloroform and 0.1 *N* sodium hydroxide, the free glycol passing to the alkaline phase and the acetal remaining in the chloroform. The *trans*-oid isomer (XIX), recovered from the alkali, proved to be the sex hormone estriol (theelol); and the acetal, after hydrolysis, furnished a substance (XX) identical with the estrogenic triol originally named isoestriol-A.[14] Estriol is, therefore, 3,16($\beta$),17($\alpha$) trihydroxy-$\Delta^{1,3,5}$-estratriene (XIX), and isoestriol-A is 3,16-($\alpha$),17($\alpha$)-trihydroxy-$\Delta^{1,3,5}$-estratriene (XX).

It is to be observed that catalytic hydrogenation[6,2,14] of a 16-keto-17($\alpha$)-hydroxysteroid has, so far, always given the 16($\alpha$),17($\alpha$)-glycol, whereas sodium amalgam reduction yields a mixture of 16($\beta$),17($\alpha$)- and 16($\alpha$),17($\alpha$)-glycols.

In 1945 Prelog, Ruzicka and Wieland[15] submitted 3-benzoxy-$\Delta^{1,3,5,16}$-estratetraene (XXII) to reaction with osmium tetroxide and obtained, after saponification, an isomer (XXIII) of estriol to which was assigned the structure 3,16($\alpha$),17($\alpha$)-trihydroxy-$\Delta^{1,3,5}$-estratriene. It is certain that this estriol possesses its $C_{16}$ and $C_{17}$ hydroxyl groups in *cis* arrangement as the latter groups were introduced by the known osmium tetroxide reaction; however, Prelog, Ruzicka, and Wieland assumed that the $C_{16}$–$C_{17}$ hydroxyl groups would form on the least sterically hindered side of the steroid skeleton (*i. e.*, opposite to the $C_{13}$–methyl group). For the same reasons, Ruzicka, Prelog and Wieland[16] assigned the structure 3($\beta$),16($\alpha$),-17($\alpha$)-trihydroxyandrostane to the triol (XXV) which results from the osmium tetroxide oxidation of 3($\beta$)-hydroxy-$\Delta^{16}$-androstene (XXIV).

Since we have already determined the structure of isoestriol-A as that of 3,16($\alpha$),17($\alpha$)-trihydroxy-$\Delta^{1,3,5}$-estratriene (XX), it follows that the isomeric estriol of Ruzicka, *et al.*, must be a 3,16($\beta$),-17($\beta$)-trihydroxy-$\Delta^{1,3,5}$-estratriene (XXIII) as it is not identical with isoestriol-A, yet must have the $C_{16}$–OH and $C_{17}$–OH in *cis* arrangement. For similar reasons the androstanetriol of Ruzicka, *et al.*,[16] must be 3($\beta$),16($\beta$),17($\beta$)-trihydroxyandrostane (XXV) since this compound is not identical with 3($\beta$),16($\alpha$),17($\alpha$)-trihydroxyandrostane (XXVI) prepared by hydrogenation of Butenandt's triol.

In Table I is presented a résumé of the steric structures of steroidal 16,17-ketols and 16,17-glycols. Only key compounds in these series are included, functional derivatives in general being omitted. While a certain amount of speculation has heretofore been advanced concerning the stereochemistry of these structures, the authors hope now to have placed this subject within the realm of rigorous organic chemistry.

## Experimental[17,18]

### PART I. Proof of Structure of 3($\beta$),17($\alpha$)-Diacetoxy-16-keto-$\Delta^5$-androstene (I)

**Preparation of the Diethyl Thioacetal of 3($\beta$),17($\alpha$)-Diacetoxy-16-keto-$\Delta^5$-androstene.**—3($\beta$),17($\alpha$)-Diacetoxy-16-keto-$\Delta^5$-androstene[2] (I), 0.25 g. (m.p. 124.5–125°), was mixed with 0.50 g. of anhydrous sodium sulfate and 0.25 g. of freshly fused zinc chloride and the whole at once covered with 10 cc. of ethyl mercaptan (Eastman Kodak Co. No. 958). The reaction flask was stoppered, its contents mixed until solution of the diacetate had become complete, and then placed in the ice box for seventy-two hours. The excess mercaptan was removed *in vacuo* at room temperature and the resulting solid residue taken up alternately in 1.0 *N* sodium hydroxide (200 cc.) and ethyl ether (200 cc.) containing a slight amount of pyridine. After the two phases had been shaken together and the alkali separated off, the ether was washed three times with water, dried over sodium sulfate, and evaporated at 50°. The almost colorless oil was crystallized in the ice box from aqueous acetone containing a trace of pyridine. A second crystallization from this medium gave 253 mg. of flakes melting at 136.5–138° (II). An analysis of this material, which contained a touch of yellow color, indicated that it was already substantially pure.

*Anal.* Calcd. for $C_{27}H_{42}O_4S_2$: S, 12.96. Found: S, 12.74, 12.68.

**Hydrogenolysis of 3($\beta$),17($\alpha$)-Diacetoxy-16-keto-$\Delta^5$-androstene Diethyl Thioacetal (II).**—Approximately 3 g. of modified Raney nickel catalyst in absolute ethanol was added to 0.21 g. of thioacetal (m.p. 136.5–138°), and after the addition of 30 cc. of dioxane, the mixture was heated for seven hours on the steam-bath (air condenser). After having been allowed to stand overnight at room tempera-

ture, the mixture was filtered free of catalyst and the filtrate distilled *in vacuo* to a volume of 5–10 cc. Addition of several volumes of water precipitated the hydrogenolysis product, which was filtered after several hours at 5°. The well-washed and dried crystals were dissolved in acetone, filtered from a slight amount of insoluble material, and the acetone evaporated to dryness. Solution was next effected in methanol and crystallization allowed to take place at 5°. The sequence of solution in acetone, filtration from insoluble residue, evaporation of filtrate, and recrystallization from methanol was repeated until no more matter insoluble in acetone was observed. Several further recrystallizations from methanol yielded finally 34 mg. of plates (III) melting at 157–158°. A mixed melting point test with authentic 3(β),17(α)-diacetoxy-$\Delta^5$-androstene[19] (m.p. 158–158.5°) supplied by Dr. Hans Hirschmann showed a melting point value of 157.5–158.5°.

*Anal.* Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.92, 73.84; H, 9.11, 9.16.

From the methanolic mother liquors were recovered an additional 30 mg. of diacetate melting at 153–154.5°.

## PART II. Proof that Stodola-Prepared 16,17-Ketols Are 16-Keto-17(α)-hydroxysteroids.

**3(β),17(α)-Dihydroxy-16-keto-$\Delta^5$-androstene (Va).**—This material, prepared according to Stodola, Kendall and McKenzie,[2] was recrystallized once from aqueous acetic acid to give tiny leaves melting at 197–199°. Butenandt and co-workers,[6] who first prepared this androstenediolone (Va) by another method, reported a melting point of 197°.

**Acetylation of 3(β),17(α)-Dihydroxy-16-Keto-$\Delta^5$-androstene.**—Androstenediolone (400 mg., as above) (Va) was dissolved in 5 cc. of dry pyridine in the cold. Acetic anhydride (3 cc.) was then added, the phases mixed well and left to react for twenty-four hours at room temperature in a stoppered flask. The diacetate was then precipitated by the addition of 200 cc. of ice water, and, after three hours in the ice box, filtered and washed copiously with water. The diacetate, without drying, was dissolved in methanol and recrystallized from boiling aqueous methanol, final crystallization being allowed to take place overnight at 5°. After filtration and drying in the desiccator, the product was treated with charcoal in acetone and the solvent evaporated to leave a colorless oil. This oil was redissolved in 9.0 cc. of 95% ethanol and 3.0 cc. of water. After 24 hours at 5°, 332 mg. of silky needles (I) (desiccator dried) were obtained. These melted at 124.5–125°.

*Anal.* Calcd. for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30. Found: C, 71.22, 71.28; H, 8.30, 8.37.

Another acetylation of androstenediolone (identical batch as above, m.p. 197–199°) was effected according to the method of Ciusa and Sollazzo.[7] Acetic anhydride (10 cc.) was added to 393 mg. of the ketol, and then 1.0 cc. of 90% phosphoric acid (Mallinckrodt) gradually added with continuous swirling. Solution of the steroid took place at once and much heat was evolved. The reaction flask was allowed to cool for thirty minutes with continuous swirling of its contents. Then 200 cc. of ice water was added and the isolation and purification of the diacetate were carried out exactly as in the case of the acetic anhydride–pyridine acetylation. There were obtained 313 mg. of silky needles (I) which melted at 124.5–125° either by themselves or after admixture with the diacetate obtained in the preceding paragraph. The yields by the pyridine method and the phosphoric acid method were thus 65 and 62%, respectively.

**Acetylation of 3-Benzyloxy-17(α)-hydroxy-16-keto-$\Delta^{1,3,5}$-estratriene (XIIIb) and Saponification of the 17-Acetoxy Derivative (XIVb).**—3-Benzyloxy-17(α)-hydroxy-16-keto-$\Delta^{1,3,5}$-estratriene (XIIIb) (m.p. 197–200°, with yellow color),[12] prepared as previously described,[12] (0.37 g.) was treated with pyridine (5 cc.) and acetic anhydride (3 cc.) as usual. The acetate, precipitated with ice water, was recrystallized from hot acetone–ethanol–water, final crystal formation being allowed to take place at 5°. The yield of felt-like needles (XIVb) was 0.38 g., melting at 140–141°. Further recrystallization of this acetate did not improve its melting point.

*Anal.* Calcd. for $C_{27}H_{30}O_4$: C, 77.48; H, 7.23. Found: C, 77.50, 77.57; H, 7.23, 7.16.

3-Benzyloxy-17(α)-acetoxy-16-keto-$\Delta^{1,3,5}$-estratriene (125 mg., m.p. 140–141°) (XIVb) was saponified by re-

(19) Ruzicka and Wettstein, *Helv. Chim. Acta*, **18**, 1264 (1935); Butenandt and Hanisch, *Ber.*, **68**, 1859 (1935).

TABLE I (*Continued*)

| Optical rotation | Steric structure | Formula |
|---|---|---|
| | 3(β),17(α)-Dihydroxy-16-keto-Δ⁵-androstene | Va |

[n] Isoestriol-A in the form of tiny, flat needles melting at 274–276° has been obtained; it is possible that these represent a crystalline modification of the microscopic crystals melting at 267–269°. [o] Prelog, Ruzicka and Wieland, *Helv. Chim. Acta*, **28**, 250 (1945).

fluxing for one hour in 0.25*N* aqueous methanol. After the methanol had been largely removed by distillation on the steam-bath, the cooled mixture was taken up in ethyl ether, and the latter extracted well with alkali and then washed with water. Evaporation of the ether yielded a crystalline residue which was crystallized once from aqueous ethanol and once from absolute methanol to give 63 mg. of tiny needles (XIIIb) melting at 198.5–200.5°. This material showed no mixed melting point depression with authentic 3-benzyloxy-17(α)-hydroxy-16-keto-Δ¹,³,⁵-estratriene.[12]

**Acetylation of 3,17(α)-Dihydroxy-16-keto-Δ¹,³,⁵-estratriene (XIIIa) and Saponification of the 3,17-Diacetoxy Derivative (XIVa).**—This ketol, 302 mg. (m.p. 233–235°) (XIIIa) prepared from 16-oximinoestrone (XIIa) as previously described,[12] was acetylated with acetic anhydride (3 cc.) in pyridine (3 cc.) during forty-eight hours. The excess anhydride was decomposed with ice water and the diacetate taken up in benzene. The benzene phase was washed with dilute sulfuric acid, with bicarbonate, and washed finally with water. Evaporation of the benzene solution yielded a semicrystalline residue which was saponified without further purification. To effect saponification, the crude diacetate (XIVa) was dissolved in 24 cc. of hot methanol and, after cooling, 15 cc. of 1.5*N* potassium hydroxide added; the phases were mixed well and left in a stoppered flask for twenty-four hours at room temperature. The clear solution was diluted with water, acidified with hydrochloric acid and then extracted with ethyl ether. After having been washed with bicarbonate and water, the ethereal phase was evaporated, and the resulting crystalline residue was leached with cyclohexane, treated with charcoal, recrystallized once from aqueous methanol and finally recrystallized from 50% acetic acid to give 187 mg. of ketol (XIIIa) melting at 232–235°. A mixed melting point test performed with this material and authentic 3,17(α)-dihydroxy-16-keto-Δ¹,³,⁵-estratriene gave a value of 234–236°.

A 76-mg. portion of this ketol (187 mg. batch, m.p. 232–235°) gave upon oximation (120 mg. of hydroxylamine hydrochloride, 240 mg. of crystalline sodium acetate, 10 cc. of aqueous ethanol, two hour reflux) 70 mg. of **oxime** decomposing at 224–225°.[12]

**Lead Tetraacetate Cleavage of 3-Methoxy-17(α)-hydroxy-16-keto-Δ¹,³,⁵-estratriene (XIIIc).**—To 352 mg. of 3-methoxy-17(α)-hydroxy-16-keto-Δ¹,³,⁵-estratriene[19a] (m.p. 164–166°) (XIIIc) was added 18 cc. of 0.0705 molar lead tetraacetate in acetic acid. The steroid soon dissolved at room temperature, whereupon 4 cc. of 50% acetic acid was added. After the solution had been swirled continuously for thirty minutes, 200 cc. of 1% ethylene glycol in water was added. The cleaved steroid (XV) was allowed to crystallize at 5° for a day and then filtered, washed well with water, and dried *in vacuo* over sulfuric acid. Semicarbazone formation was effected without further purification.

**7-Methylmarrianolic Acid Hemialdehyde Semicarbazone (XVI).**—The crude aldehyde-acid (of the preceding paragraph) (XV) was dissolved in 40 cc. of methanol and to this solution were added 0.40 g. of semicarbazide hydrochloride and 0.56 g. of crystalline sodium acetate dissolved in 5 cc. of water. This mixture was warmed to dissolve all components and then distilled on the steam-bath during

(19a) Huffman, *J. Biol. Chem.*, **169**, 167 (1947).

thirty minutes until the volume had been reduced to 10 cc. Ice water (50 cc.) was added in one portion to insure precipitation of the semicarbazone-acid in a finely divided state. The mixture of crude semicarbazone-acid was transferred to a separatory funnel using 100 cc. of ethyl acetate, and after the addition of 40 cc. of 0.21*N* hydrochloric acid, partitioned well. After removal of the aqueous phase, the ethyl acetate phase was extracted briefly with 100 cc. of ice-cold 1.0*N* potassium hydroxide. Acidification (ice-bath) of the potassium hydroxide with 85% phosphoric acid (acid to congo red) re-precipitated the semicarbazone-acid which, after a day in the ice box, was filtered and washed copiously with water. The yield of nicely crystalline air-dried 7-methylmarrianolic acid hemialdehyde semicarbazone (XVI) was 316 mg. decomposing at 185–186° with evolution of gas. Recrystallization of a 50-mg. portion of this semicarbazone-acid from aqueous isopropyl alcohol gave 46 mg. decomposing at 188–189°. A second recrystallization from the same medium yielded 41 mg. decomposing at 192–193°; but, oddly, a third recrystallization gave 35 mg. decomposing at the original value of 185–186°. Analysis was performed upon the original 316-mg. batch (XVI).

*Anal.* Calcd. for $C_{20}H_{27}O_4N_3$: C, 64.32; H, 7.29; N, 11.25. Found: C, 64.17, 64.06; H, 7.33, 7.30; N, 11.10, 11.16.

**Esterification of 7-Methylmarrianolic Acid Hemialdehyde Semicarbazone (XVI).**—To a solution of 199 mg. of semicarbazone-acid (dec. 185–186°) (XVI) in 5 cc. absolute ethanol plus 5 cc. of ethyl acetate was added an excess of a concentrated ethereal solution of freshly prepared diazomethane. The yellow solution was then diluted with 100 cc. of ethyl ether and shaken well with 100 cc. of 1.0*N* hydrochloric acid. The ethereal phase was extracted twice with 100-cc. portions of 1.0 *N* potassium hydroxide and washed twice with 50-cc. portions of water. After the addition to the ether of 5 cc. of ethyl acetate and 5 cc. of absolute ethanol, the solution was distilled *in vacuo* at 50°. The nicely crystalline residue of methyl ester (dried *in vacuo* over sulfuric acid and potassium hydroxide) weighed 194 mg. It was recrystallized once from aqueous methanol (containing 1 drop of acetic acid) to give 184 mg. of material decomposing at 166.5–167.5° with evolution of gas. A second crystallization from absolute methanol gave 128 mg. of tiny needles (XVII) in rosettes which decomposed at 166–167.5° with evolution of gas.

*Anal.* Calcd. for $C_{21}H_{29}O_4N_3$: C, 65.09, H, 7.54; N, 10.85. Found: C, 64.99 64.91; H, 7.58, 7.53; N, 10.86, 10.95.

7-Methylmarrianolic acid hemialdehyde (*primary*) semicarbazone methyl ester (XVIII), prepared by Heer and Miescher,[10] melts at 212–213° (cor.), apparently with no decomposition.

**Saponification of 7-Methylmarrianolic Acid Hemialdehyde (tertiary) Semicarbazone Methyl Ester (XVII).**—To a solution of 90 mg. of semicarbazone-methyl ester (dec. 166–167.5°) in 6.0 cc. of methanol was added 2.0 cc. of aqueous potassium hydroxide (from a solution of 4.0 g. of potassium hydroxide in 20 cc. of water) and the mixture swirled continuously for thirty minutes at room temperature. The mixture was then heated for a few seconds on the steam-bath to redissolve a portion of ester which had crystallized from the medium, and the mixture then swirled at room temperature for another thirty minute interval. The mixture was again heated for a few seconds and swirled at room temperature during a third thirty minute interval, after which it was transferred to a separatory funnel using 50 cc. of 1.0 *N* potassium hydroxide, freed of a slight turbidity with 50 cc. of ethyl ether, and the alkaline layer carefully acidified (ice-bath) with 2.6 cc. of 85% phosphoric acid. The semicarbazone soon crystallized; and after a night in the ice box, it was filtered and washed well with water. The yield of white, granular crystals (XVI) was 59 mg. decomposing at 186–187° with evolution of gas. A mixed melting point, performed with this product and the original semicarbazone (dec. 185–186°), showed no depression.

According to Heer and Miescher,[10] the carbomethoxy group at $C_{13}$ is not saponified by refluxing for 2.5 hours in a solution of 4 g. of potassium hydroxide in 60 cc. of methanol and 20 cc. of water. Our semicarbazone-methyl ester actually may be saponified by refluxing in 0.4 molar potassium carbonate in aqueous methanol, although the heat promotes some destruction of the sensitive semicarbazone.

## PART III. Proof of Steric Structure of Steroidal 16,17-Glycols.

**Reduction of 3(β),17(α)-Diacetoxy-16-keto-Δ⁵-androstene (I) to the Glycol Stage.**—To a solution of 147 mg. of 3(β),17(α)-diacetoxy-16-keto-Δ⁵-androstene (m.p. 123–124°) (I) in 25 cc. of ethyl acetate contained in the Cheronis[20] semimicro hydrogenation apparatus was added 1 cc. of Raney nickel catalyst (completely free of alkali) and the latter rinsed down with 10 cc. of absolute ethanol. A stream of hydrogen was blown through the solution for eight hours at a bath temperature of 60–65°. The solution, freed of catalyst by filtration, was evaporated on the steam-bath, and the cooled semi-crystalline residue was acetylated with acetic anhydride (2 cc.) in dry pyridine (3 cc.) at room temperature for two days. The triacetate, obtained in the usual manner, was recrystallized once from aqueous methanol and four times from ethanol to give 30 mg. of plates (VII) melting sharply at 208–209°[21]; these showed no mixed melting point depression with a sample of androstenetriol triacetate (m.p. 206.5–208.5°) furnished by Dr. Stodola. The X-ray patterns of the Stodola triacetate and our triacetate are identical.[22]

*Anal.* Calcd. for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39. Found: C, 69.27, 69.27; H, 8.40, 8.31.

An additional 23 mg. of crude triacetate was obtained from the mother liquors.

Stodola, Kendall, and McKenzie obtained their triacetate by acetylation of the product resulting from the four-hour hydrogenation of 3(β),17-(α)-diacetoxy-16-keto-Δ⁵-androstene (I) in alcohol using Raney nickel catalyst. A consideration of the parallel findings of Stodola, *et al.*,[2] and Butenandt, *et al.*,[6] in this series leaves no doubt that both groups were dealing with the same androstenetriol.

**3(β)-Methoxy-17(α)-hydroxy-16-keto-Δ⁵-androstene (Vb).**—Pure 3(β)-methoxy-16-oximino-17-keto-Δ⁵-androstene[23] (0.99 g.) (IVb) was reduced in the usual way with zinc in aqueous acetic acid (3.0 g. of zinc dust, 75 cc. of 50% acetic acid, one hour reflux) and the 16,17-ketol precipitated by dilution with water. Recrystallization from aqueous ethanol, aqueous methanol, and from aqueous acetone yielded 0.58 g. of ketol melting at 180–183° (with yellow turning).[12] Of this product 50 mg. was treated with charcoal and recrystallized from aqueous ethanol to give 43 mg. melting at 188–191° (Vb).

*Anal.* Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.45; H, 9.44.

**Sodium Amalgam Reduction of 3(β)-Methoxy-17(α)-hydroxy-16-keto-Δ⁵-androstene (Vb).**—3(β)-Methoxy-17(α)-hydroxy-16-keto-Δ⁵-androstene (1.22 g., m.p. 180–183°) (Vb) was dissolved in 150 cc. of 95% ethanol plus 15 cc. of acetic acid and reduced with 300 g. of 2% sodium amalgam, as previously described,[23] the temperature being carefully maintained at 40°, and 10 cc. of 50% acetic acid being added as soon as sodium acetate commenced to precipitate. The reaction mixture was distributed between ether (750 cc.) and water (600 cc.) and the ether further washed, once with 1.0 *N* sodium hydroxide and twice with water. Evaporation of the ether yielded a crystalline residue which was recrystallized twice from acetone–cyclohexane–Skellysolve B and once from aqueous ethanol to give 574 mg. of Hirschmann's triol methyl ether[23] (m.p. 195–196°) (VIII).

(20) Cheronis and Koeck, *J. Chem. Ed.*, **20**, 488 (1943).

(21) With Dr. Stodola's melting point apparatus these crystals melted at 213–214.5° (personal communication, Dr. Stodola).

(22) Personal communication, Dr. Stodola.

(23) Huffman and Lott, *J. Biol. Chem.*, **172**, 789 (1948).

The combined mother liquors were taken up in ether and the solution washed three times with water. The crystalline residue resulting from the evaporation of the ethereal phase was dissolved in 40 cc. of 75% propanol containing 0.40 g. of carboxymethoxylamine hemihydrochloride and 0.60 g. of potassium acetate. This mixture was refluxed for one hour and the ketonic fraction removed from the non-ketonic material in the usual way. There resulted 0.46 g. of crystalline non-ketones. The non-ketonic fraction was dissolved in 42 cc. of absolute acetone at room temperature and 6 cc. of acetone saturated with anhydrous hydrogen chloride added. The acetalizing medium was swirled continuously during fifteen minutes and then added in one portion to 300 cc. of ice-cold 3% potassium carbonate, and thorough mixing effected at once. After a day in the ice box, the precipitated acetonide was filtered, washed with water, and dried *in vacuo* to give 0.42 g. of material. This crude acetonide was recrystallized twice from aqueous methanol containing a trace of pyridine (treatment with charcoal). The yield of glistening plates was 265 mg. melting at 144–145.5°. Of this material 101 mg. was recrystallized from absolute methanol (trace of pyridine) to give 55 mg. of long, flat colorless needles (X) melting at 146.5–148°.

*Anal.*, Calcd. for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07. Found: C, 76.47, 76.56; H, 10.01 10.05.

**The Transformation of 3(β)-Methoxy-16(α),17(α)-dihydroxy-Δ⁵-androstene Acetonide (X) to 3(β),16(α),17(α)-Triacetoxy-Δ⁵-androstene (VII).**—To a solution of 0.34 g. of acetonide (m.p. 144–145.5°), prepared as above, in 50 cc. of ethanol was added 10 cc. of 1.2 molar phosphoric acid and the solution refluxed for thirty minutes and then left overnight at room temperature. The water-clear solution was distributed between ethyl ether and water, and the organic phase then washed with dilute sodium bicarbonate and with water. Evaporation of the ether gave a crystalline residue which was acetylated in pyridine (5 cc.) with acetic anhydride (3 cc.) in the usual manner. The diacetate, procured by precipitation with ice water, was dried thoroughly and then treated with 0.21 g. of *p*-toluenesulfonic acid monohydrate in 21 cc. of acetic anhydride for thirty minutes on the steam-bath by the method previously described.[18] The reaction mixture, after having been cooled in the ice-bath, was diluted with 100 cc. of ice water and then left for three days at 5°. The precipitated triacetate was recrystallized from ethanol to give 199 mg. of waxy plates melting at 204–206°. Another crystallization from 5 cc. of ethanol (ice box) gave 152 mg. melting at 207–208.5°. A third crystallization from 5 cc. of ethanol (ice box) yielded 119 mg. of plates (VII) melting at 208–209.5°. A mixed melting point test performed with androstenetriol triacetate furnished by Dr. Stodola gave no depression.

**The Sodium Amalgam Reduction of 3,17(α)-Dihydroxy-16-keto-Δ¹,³,⁵-estratriene (XIIIa).**—This 16,17-ketol (m.p. 232.5–234°) (XIIIa) was reduced with sodium amalgam in the manner previously described (0.44 g. of ketol in 50 cc. of ethanol plus 5 cc. of acetic acid, 100 g. of 2% sodium amalgam, finally 5 cc. of 50% acetic acid, temperature 40°). The supernatant fluid was decanted from the mercury and the latter rinsed twice with ethanol. To the combined alcoholic solutions was added 50 cc. of water and the diluted liquid distilled (steam-bath) until ebullition had nearly ceased. More water (50 cc.) was then added to the mixture, and after a day in the ice box, the glycols were filtered and dried at 90°. The yield of crystalline material was 0.36 g. Any trace of ketonic material was separated from this residue with carboxymethoxylamine in the fashion previously described (0.25 g. of carboxymethoxylamine hemihydrochloride, 0.50 g. of potassium acetate, 40 cc. of 75% propanol, 1.5 hours reflux).

**Separation of *cis*-oid and *trans*-oid 16,17-Glycols Formed by Sodium Amalgam Reduction of 3,17(α)-Dihydroxy-16-keto-Δ¹,³,⁵-estratriene (XIIIa).**—The crystalline non-ketonic fraction of the preceding section was dissolved in 35 cc. of absolute acetone and 5 cc. of acetone saturated with anhydrous hydrogen chloride added. After the acetalizing medium had been swirled continuously for eighteen minutes, 50 cc. of aqueous potassium carbonate (≈ 1.50 g. of potassium carbonate) was added in one portion, mixed at once, and then diluted to a volume of 400 cc. with water. After a day in the ice box the precipitated material was filtered, washed with water containing 0.5% pyridine, and then dried in the vacuum desiccator. The resulting 0.29 g. of dried material was dissolved in 300 cc. of chloroform and partitioned with 300 cc. of 0.1 *N* sodium hydroxide. The alkaline phase was separated and again washed with 300 cc. of chloroform. The sodium hydroxide fraction was then acidified with 3 cc. of concentrated hydrochloric acid and extracted with 400 cc. of ethyl ether. The ether was washed once with 200 cc. of water, and after the addition of a few drops of pyridine, evaporated to a white crystalline residue. This residue was recrystallized twice from acetone–cyclohexane–Skellysolve B, treated with charcoal, and then finally recrystallized from aqueous acetone. White microscopic crystals of estriol (theelol) (XIX) were obtained (85 mg.). These melted at 268–269.5° and showed no depression of melting point after admixture with authentic theelol supplied by Dr. D. W. MacCorquodale of The Abbott Laboratories. A mixed melting point test performed with authentic isoestriol-A gave a value of 251.5–256°.

Methylation of a portion of this 85-mg. batch of estriol gave **estriol methyl ether** (34 mg. of triol in 25 cc. of 0.5 *N* sodium hydroxide shaken one hour with 0.6 cc. of methyl sulfate). This derivative (13 mg.) melted at 158–161° and showed no mixed melting point depression with authentic theelol methyl ether.

Acetylation of another portion of this estriol (32 mg. in 1 cc. of pyridine and 1 cc. of acetic anhydride) gave a product (42 mg.) melting at 124.5–126°. **Estriol triacetate** melts at 126°.[24]

The 600 cc. of solution comprising the combined chloroform phases in the above separation was washed with water (350 cc.) and evaporated to dryness. There resulted an oily residue which was taken up in 50 cc. of ethanol, and after the addition of 10 cc. of 1.2 molar phosphoric acid, refluxed on the steam-bath for thirty minutes. To the hydrolysis medium was then added 25 cc. of water and boiling allowed to continue without the condenser until most of the ethanol had been removed. The mixture was then left overnight in the ice box and the precipitated material filtered, washed well with water, and dried in the oven (100°); yield, 0.12 g. of white crystals. These were treated with charcoal and recrystallized from aqueous methanol to give 94 mg. of small flat needles (XX) melting at 272–275°. A mixed melting point test performed with known isoestriol-A (m.p. 274–276°)[25] showed no depression.

**Isoestriol-A Acetonide (XXI).**—Isoestriol-A (91 mg., from the preceding experiment) (XX) was covered with 10 cc. of absolute acetone and then 1.5 cc. of acetone saturated with anhydrous hydrogen chloride added. The mixture was swirled for eight minutes, although solution was effected within one minute time. Then, in one portion, 10 cc. of aqueous potassium carbonate (≈ 0.45 g. of potassium carbonate) was added, mixed in at once, and then diluted to a volume of 50 cc. with water. After a day in the ice box, the precipitated acetonide was filtered and washed well with water containing a trace of pyridine. The air-dried product was recrystallized once from water–acetone–pyridine and once from water–methanol–pyridine to give 91 mg. of flakes which nearly melted at 98° but formed a liquid melt only at 182–184°. After several recrystallizations from water–methanol–pyridine it was finally learned that this compound actually possesses a double melting point. The final product (28 mg.) cleared almost completely at 103.5–104.5°, then solidified, and again melted sharply at 183.5–184.5° (XXI). Analysis indicates that it is hydrated with one molecule of water.

(24) Thayer, Levin and Doisy, *J. Biol. Chem.*, **91**, 655 (1931).

(25) Isoestriol-A in the form of tiny, flat needles melting at 274–276° has been obtained; it is possible that these represent a crystalline modification of the microscopic crystals melting at 267–269°.

*Anal.*, Calcd. for $C_{21}H_{28}O_3 \cdot H_2O$: C, 72.80; H, 8.73. Found: C, 72.77, 72.63; H, 8.69, 8.61.

**Attempted Acetonide Formation with Estriol-3-methyl Ether.**—Estriol-3-methyl ether (350 mg., m.p. 157–158°) was covered with 35 cc. of anhydrous acetone and treated with 5 cc. of 8% hydrogen chloride in absolute acetone as usual. After thirty minutes swirling, 50 cc. of aqueous potassium carbonate (≈ 1.5 g. of potassium carbonate) was added in one portion, mixed at once, and placed at 5°. After a day at 5°, the precipitated white plates were filtered, washed well with water (0.5% pyridine), and then dried in the oven. The recovery of estriol-3-methyl ether melting at 158–159.5° was 334 mg.

**3(β),16(α),17(α)-Trihydroxyandrostane (XXVI).**—Adams catalyst (0.10 g.) was suspended in 10 cc. of acetic acid and reduced with hydrogen; then 155 mg. of pure 3(β),16(α),17(α)-triacetoxy-$\Delta^5$-androstene (VII) in 25 cc. of absolute ethanol was added. Hydrogenation was carried out for thirty minutes at atmospheric pressure, the catalyst removed by filtration, and the solution of hydrogenated steroid evaporated *in vacuo*. Saponification of the crystalline residue was accomplished by refluxing for one hour in a solution of 20 cc. of 2 *N* sodium hydroxide and 60 cc. of ethanol. The neutral residue was recrystallized consecutively from aqueous ethanol, aqueous methanol, absolute acetone, aqueous methanol, absolute acetone, and from aqueous ethanol to give 64 mg. of triol melting at 251–253° (XXVI).

*Anal.* Calcd. for $C_{19}H_{32}O_3$: C, 73.98; H, 10.46. Found: C, 73.97, 73.87; H, 10.49, 10.41; $[\alpha]^{26}D$ + 18° ($c$ = 0.53 in 95% ethanol)[26].

**Acknowledgment.**—The authors wish to thank Dr. Frank Stodola for his aid in determining the identity of his and their samples of androstanetriol triacetate. They wish also to extend their appreciation to Dr. Hans Hirschmann for his sample of androstenediol diacetate and for determining the optical rotation of their androstane-3(β),16(α),17(α)-triol. To the United States Standard Products Company, who gave generous financial support to this project, the authors are greatly indebted. Micro-analyses were performed by Dr. E. W. D. Huffman, Denver.

## Summary

The 16,17-ketols resulting from the zinc–acetic acid reduction of 16-oximino-17-ketosteroids and 16,17-diketosteroids have been found to be 16-keto-17(α)-hydroxysteroids.

The steric structures of steroidal 16,17-glycols have been determined.

(26) This optical rotation was determined by Dr. Hans Hirschmann.

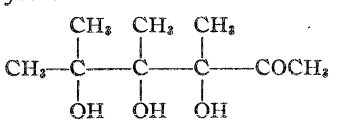
# 2,3-Dimethyl-4-pentyne-2,3-diol as a Source of C-Methyl Sugars

BY CHARLES D. HURD AND JAMES MOFFAT



At the outset of this work it was planned to synthesize a monosaccharide whose alcohol groups were tertiary. 3,4-Dimethyl-3,4-dihydroxy-2-pentanone (I) was selected. Such a structure obviously may be regarded as 1,2,3,3-C-tetramethylglycerose. These steps were visualized in the synthesis: acetone to dimethylethynylcarbinol to 3-methyl-3-hydroxy-2-butanone (II) following known procedures, then to 2,3-dimethyl-4-pentyne-2,3-diol (III) by condensation with acetylene, and finally to I by hydration of III.

Steps through the synthesis of III were completed when the work was interrupted by war. Shortly thereafter, Favorskii and Onishchenko[1] announced their synthesis of both I and III, preparing III by pyrolysis of 2,3,6,7-tetramethyl-4-octyne-2,3,6,7-tetraol (IV), $CH_3(CMeOH)_2C{\equiv}C(CMeOH)_2CH_3$. IV was prepared by gradual addition of II into a mixture of potassium hydroxide and dry ether previously saturated with acetylene. They produced I by hydrating the triple bond of III with mercuric sulfate and dilute sulfuric acid.

We prepared III in about 90% yields directly from II by use of sodium acetylide with liquid ammonia as solvent. The acetic ester of III was prepared readily with ketene as the acetylating agent, whereas it could not be prepared with acetic anhydride and pyridine.

The present synthesis seems general. In other words, just as I is obtainable from II, a similar sequence of steps from I should give rise to a C-pentamethyltetrose:

## Experimental

Dimethylethynylcarbinol and 3-methyl-3-hydroxy-2-butanone (II) were made in accordance with previously established directions.[2] 2,3-Dimethyl-4-pentyne-2,3-diol (III) was synthesized from the latter as follows.

To 300 ml. of dry liquid ammonia at −78° in a protected 3-necked flask was added 10.3 g. of sodium. Dry

(1) A. E. Favorskii and A. S. Onishchenko, *J. Gen. Chem. (U. S. S. R.)*, **11**, 1111 (1941); *C. A.*, **37**, 3735 (1943).

(2) Hurd and McPhee, THIS JOURNAL, **69**, 239 (1947); **71**, 398 (1949).

acetylene gas was passed into the solution until the blue color of the solution was discharged, after which 21.3 g. of 3-methyl-3-hydroxy-2-butanone was added dropwise with stirring. After a reaction period of four hours, the processing steps included distilling off the ammonia, dissolving the residue in water, extracting the solution with ether, drying over potassium carbonate and distilling. The yield of product collected at 75–77° (6 mm.) was 22.9–24.3 g. (86–91%); $n^{25}D$ 1.4600; $d^{25}_4$ 1.001.

*Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.43. Found: C, 65.42; H, 9.11.

**Diacetate.**—A solution was prepared containing 5.5 g. of III, 20–25 g. of benzene, and two drops of sulfuric acid previously dissolved in ether. Ketene was passed into this solution for an hour at room temperature then for thirty minutes at 70–75°. Acidic impurities were removed by rinsing with sodium bicarbonate solution and with water. Then, after drying, the solvent was removed. Most of the product distilled at 120° (15 mm.); yield, 4.2 g. The thick, colorless distillate set to a crystalline mass within a few minutes; m. p. 54–56°. The crystals were very soluble in most organic solvents, including ligroin. The product is very volatile in steam.

Crystallization from solvents was not an easy matter. A 9:1 water–alcohol mixture maintained below 45° (to avoid liquefying the crystals) was the best solvent found. Purification is more readily achieved by sublimation. With conditions chosen at 130° and 40 mm. pure crystals were obtained melting at 55.0–55.5° (uncor.).

*Anal.* Calcd. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60. Found: C, 62.62; H, 7.60.

**Acknowledgments.**—This investigation was supported by a grant during 1942 from the Graduate School of Northwestern University. Micro combustion analyses were performed by Dr. T. S. Ma. Assistance in the purification of the diacetate was given by Dr. Arthur Berger.

## Summary

3,4-Dimethyl-4-pentyne-2,3-diol and its diacetate are described. Attention is called to the fact that the hydration product of the former, namely, 3,4-dimethyl-3,4-dihydroxy-2-pentanone may be regarded as a monosaccharide composed of tertiary alcohol groups.

# Studies of Hemiacetal Formation in Alcohol–Aldehyde Systems. I. Cryoscopic Studies

BY F. E. MCKENNA,[1] H. V. TARTAR AND E. C. LINGAFELTER

The existence of an equimolar addition compound between an alcohol and an aldehyde was probably first mentioned by Jacobson.[1a] He considered the structure to be $CH_3CHOHOC_2H_5$ and called it an aldehyde alcoholate. Perkin[2] noted an initial decrease followed by a rapid increase in temperature when an aldehyde is mixed with an alcohol or water; this change was ascribed to a depolymerization of the alcohol or water followed by compound formation. The term hemiacetal came to be used for this type of supposed addition compound because of the purported relationship to the well-known acetal molecule.

Several more recent workers have investigated binary mixtures of aldehydes and alcohols for evidence on the existence of the hemiacetal. Wolf and Merkel[3] have confirmed Perkin's finding on the temperature changes when aldehydes and alcohols are mixed together. Curves representing density or index of refraction as a function of the composition presented by Adkins and Broderick[4] showed maxima at 50 mole per cent. Herold and Wolf[5] using absorption spectra measurements found maximum absorption with equimolar proportions, the band due to the carbonyl group being replaced by one characteristic of the ether-like linkage ascribed to the hemiacetal. They observed a time lag for this change of absorption which was attributed to the gradual establishment of a hemiacetal–alcohol–aldehyde equilibrium.

De Leeuw[6] determined the freezing point curve for the system acetaldehyde–ethanol. He found two maxima with aldehyde to alcohol ratios of 1:1 and 1:2. He also postulated that the latter compound in the presence of a dehydrating agent or of a catalyst could lose water to form the acetal.

Schimmel and Company[7] reported that mixtures of aliphatic alcohols and aldehydes (*n*-heptyl to *n*-undecyl) gave crystalline compounds of constant composition, 1:1. They were unable to prepare any derivatives of these substances because the reagents caused dissociation to aldehyde and alcohol.

The present results reported herein are from a cryoscopic investigation of the systems: *n*-heptanol–*n*-heptaldehyde, and methanol–propionaldehyde. Previously Schimmel and Company[7] had reported a melting point of 2° for the product obtained from an equimolar mixture of *n*-heptanol and *n*-heptaldehyde. The system methanol–propionaldehyde affords compounds with the smallest alkyl groups adapted to convenient investigation.

## Experimental

**Purification of Materials.**—(a) **Propionaldehyde** was furnished by the Eastman Kodak Co. (White Label); boiling point range 47.8 to 50.5°. It was found that propionaldehyde cannot be kept pure in the presence of air. When distillation was attempted in air a yellow oily substance was produced. Qualitative tests with ammonium thiocyanate to which a crystal of ferrous (free of ferric) ammonium sulfate had been added showed that peroxides were formed and that this was accompanied by an increase in the refractive index from $n^{25}D$ 1.3601 to 1.3630 at room temperature. The rate of change was dependent upon the previous treatment (acidic or alkaline) of the Pyrex flasks even though followed by quite thorough rinsing with distilled water. Brühl[8] has reported the refractive index, $n^{20}D$ 1.3636.

Consequently all samples of propionaldehyde were purified by distillation under nitrogen and collected in glass containers which had been previously boiled out with water for twenty to thirty minutes and dried. The fraction boiling at 48.0 ± 0.05° (760 mm.) was used for all measurements. The refractive index was $n^{25}D$ 1.3601 and the freezing point −80.05°. Walden[9] has reported the freezing point to be −81°.

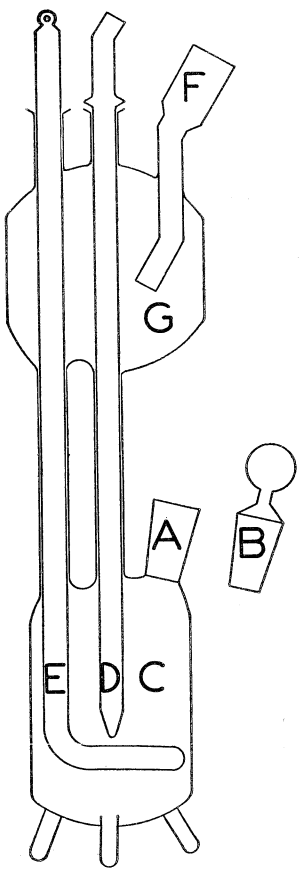

Fig. 1.—Cryostat.

Buckler[10] has stated that his samples of propionaldehyde polymerized spontaneously, even at low temperatures. Such behavior was not observed in this investigation.

(b) **Methanol.**—The material used was the fraction which distilled at 64.6 ± 0.05° (760 mm.). The fractionation was effected under nitrogen to prevent the formation of peroxides. The freezing point was found to be −98.02°. Previous investigators[11] have reported freezing points ranging from −97.0° to −98.54°, the average being −97.6°.

A transition temperature was found by Parks[12] to be −112° and by Kelley[13] −115.7° with supercooling as much as 25° obtainable. A transition temperature of −113.5° was observed with the methanol used in this investigation.

(c) ***n*-Heptanol.**—The *n*-heptanol distilled at 175.4 ± 0.05° (760 mm.) from the Eastman Kodak Co. product (White Label). This was further purified by fractionation under nitrogen; freezing point −34.03°. Deffet[14] reports: f. p., −34.1°; b. p. 176.35°.

(d) ***n*-Heptaldehyde.**—The *n*-heptaldehyde (Eastman White Label) distilled at 152.6 ± 0.05° (760 mm.). To prevent peroxide formation it was fractionated under nitrogen into previously boiled-out flasks. The freezing point was −43.71°. Deffet[14] reported f. p., −43.3°; b. p., 152.8°.

A slight charring of the residual liquid was observed during the fractionation (760 mm.) of both *n*-heptanol and *n*-heptaldehyde.

**Apparatus.**—The original plan was to construct the cryostat of a metal of high thermal conductivity. It was found that solutions of aldehydes and alcohols react with metals, in some cases forming crystalline compounds. Consequently the compounds were distilled in a nitrogen atmosphere directly into the glass cryostat. This apparatus is a modification of that described by Kanolt[15] and is shown in Fig. 1. The ground-glass joint A fits the adapter at the condenser. At other times this opening can be closed with the ground-glass stopper B. The liquids under investigation are contained in bulb C. The thermo-element tube D is removable. E is the stirrer. F is a small funnel for the addition of a small drop of liquid air to induce crystallization in case a solution should supercool. The bulb G permits the circulation of dry nitrogen around the stirrer and the thermo-element tubes to prevent the entry of moist air.

The distillation apparatus consisted of a 500-ml. distilling flask to the neck of which was attached a glass column, 25 cm. long, 1.3 cm. diam., packed with small glass helices. The outlet of the condenser was provided with a ground-glass joint to fit the inlet of the cryostat. A ground-glass cap with a sealed-in tube admitted a slow stream of purified nitrogen into the distilling flask.

The cryostat was placed in an unsilvered, one-liter Dewar flask. The gas pressure between the walls could be varied by means of a vacuum pump, thus allowing control of the rate of cooling or warming of the material in the cryostat. This Dewar, in turn, was contained in a five-liter, silvered, Dewar flask.

The refrigerant in the outer Dewar was liquid air, for the methanol–propionaldehyde system, and solid carbon dioxide in acetone, for the *n*-heptanol–*n*-heptaldehyde system. The cryostat was surrounded by a bath liquid (contained in the unsilvered Dewar) having the following composition by weight: 16.2% chloroform, 28.2% methylene chloride, 37.3% ethyl bromide and 18.3% trichloroethylene. This is similar to the bath liquid suggested by Kanolt[15] as not flammable and freezing around −150°.

**Temperature Measurements.**—The temperatures in the cryostat were measured with a two-junction copper–constantan thermo-element. This was constructed of Leeds and Northrup no. 38 copper and no. 30 constantan wire, which was free of inhomogeneities. The junctions were spot-welded. The thermo-element was given two coats of Bakelite varnish, then wrapped with silk binding tape and given an outer coat of Bakelite varnish. The element was placed in tube D of the cryostat and molten naphthalene poured around it to afford good heat transmission. The e. m. f. was measured with a Leeds and Northrup White Single Potentiometer of 10,000 microvolt range, and a Leeds and Northrup HS galvanometer. The thermo-element was calibrated at the temperatures of melting ice, melting mercury, subliming carbon dioxide and boiling oxygen.

**Procedure.**—The cryostat was steamed out for thirty minutes and dried. The weighed cryostat was attached to the distilling apparatus and a slow stream of nitrogen passed in to flush out the air. Then the components of the solution were distilled into the cryostat.

The unsilvered Dewar flask was evacuated to reduce heat transfer. The cryostat was immersed in the bath liquid and the cooling begun by admitting some gas to the space between the walls.

In determining melting points, a very small amount of refrigerant was kept in the outer Dewar to ensure slow heating not too far removed from equilibrium conditions.

Upon completion of the measurements on a given solution, the cryostat was removed from the bath, brought to room temperature and reweighed. In no case was any loss observed.

## Results

The freezing-point composition data for *n*-heptanol–*n*-heptaldehyde are presented in Table I and Fig. 2. The maximum at 2.25° for the solution with equimolar concentrations shows compound formation (hemiacetal) between one molecule of *n*-heptaldehyde and one molecule of *n*-heptanol.

TABLE I

FREEZING POINT–COMPOSITION DATA FOR THE SYSTEM: *n*-HEPTANOL–*n*-HEPTALDEHYDE

| Alcohol, mole fraction | Freezing point, °C. Primary | Eutectic | Alcohol, mole fraction | Freezing point, °C. Primary | Eutectic |
|---|---|---|---|---|---|
| 0.000 | −43.71 | ..... | 0.456 | + 1.57 | −58.44 |
| .037 | −46.11 | −58.92 | .489 | + 2.25 | ..... |

It was observed that a solid having a composition between that of A and of B could be superheated, the amount depending on the rate of warming. In some cases it was possible to superheat the solid to the melting temperature of the compound C.

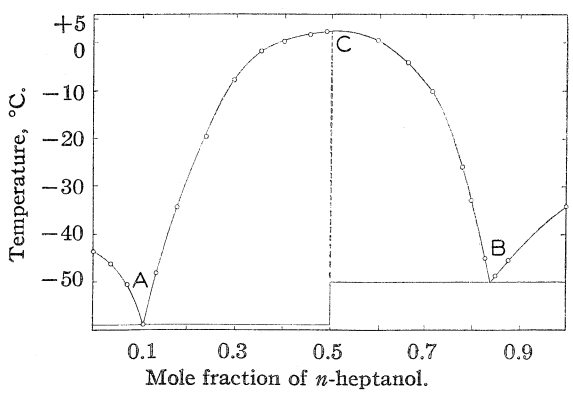

Fig. 2.—Freezing points for the *n*-heptanol–*n*-heptaldehyde system.

Also it was possible to produce a rather high degree of supercooling of some solutions with compositions intermediate between A and B. This was prevented by slow cooling, by seeding the solution with some of the solid or by dropping a small amount of liquid air onto the surface of the solution.

The freezing point–composition data for the methanol–propionaldehyde system are presented in Table II and Fig. 3. Here also a maximum, higher than the melting point of either component of the system, was found at −66.75° for equimolar concentrations of aldehyde and alcohol.

TABLE II

FREEZING POINT–COMPOSITION DATA FOR THE SYSTEM: METHANOL–PROPIONALDEHYDE

| Alcohol, mole fraction | Freezing point, °C. Primary | Eutectic | Transition, °C. |
|---|---|---|---|
| 0.000 | − 80.05 | ..... | |
| .094 | − 96.15 | −114.9 | |
| .151 | −112.2 | −114.9 | |
| .249 | − 91.17 | −114.9 | |
| .353 | − 74.84 | −114.9 | |

| .606 | − 75.49 | −134.0 | −118.5 |
| .706 | −101.1 | −134.0 | −120.5 |
| .793 | −132.9 | −134.0 | ..... |
| .859 | −114.0 | −134.0 | −118.4 |
| .982 | − 99.53 | −134.0 | −114.3 |
| 1.000 | − 98.02 | ..... | −113.5 |

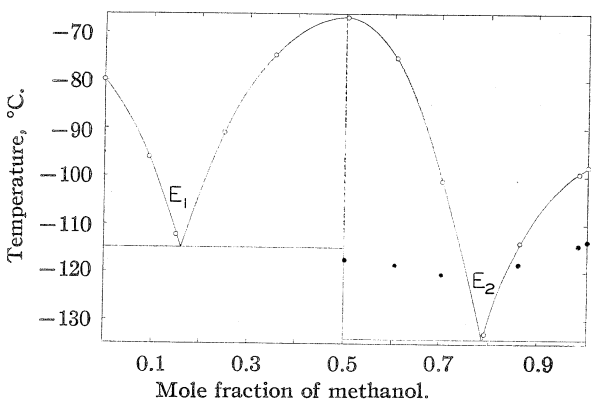

Fig. 3.—Freezing points and transition temperatures for the methanol–propionaldehyde system: O, freezing points; ●, transition temperature.

No superheating was observed in this system; the supercooling was also negligible. In a few instances the solution set to a jelly-like transparent solid but a slight movement of the stirrer caused the jelly-like material to become a crystalline solid.

The transition temperature of methanol was observed in all cases where the solid phase was the alcohol. A transition was also observed in compositions varying from eutectic $E_2$ and 50 mole per cent. methanol; the temperature varied from −113.5 to −120.5°.

The maximum in the curve for the *n*-heptanol–*n*-heptaldehyde system is broader and flatter than that for the methanol–propionaldehyde system. This indicates that the larger hemiacetal molecule is more dissociated than the smaller one. The fact that the system involving the smaller hemiacetal did not supercool or superheat to the extent of that with the larger hemiacetal, may indicate that equilibrium is reached more rapidly between the smaller alcohol and aldehyde molecules.

The solid which separated from a solution which was relatively rich in one of the components was finely divided; the solid formed from a solution of approximately equimolar proportions was in larger crystals.

## Summary

1. The effect of previous treatment of glass surfaces on the properties of propionaldehyde stored in glass vessels has been pointed out.

2. A cryostat has been constructed for use in cryoscopic investigations in solutions of alcohols and aldehydes.

3. The freezing point–composition relationships have been investigated for the systems: (a) *n*-heptanol–*n*-heptaldehyde and (b) methanol–propionaldehyde.

4. The results prove the formation of a compound (hemiacetal) between one molecule of an alcohol and one molecule of an aldehyde.

# 3-(Hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran and Some Derivatives[1,2]

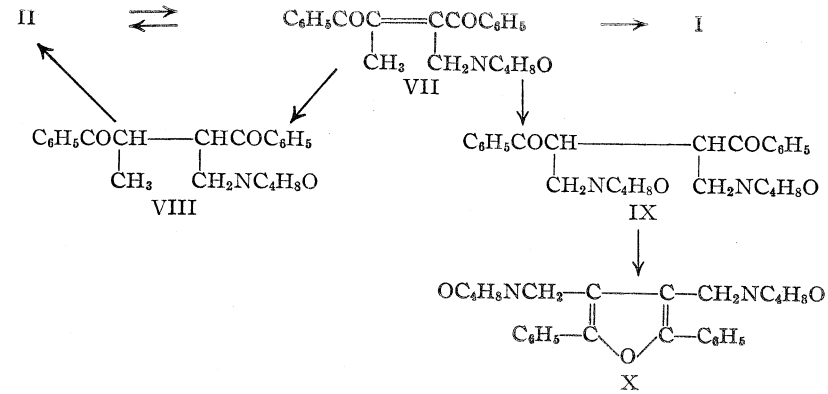
BY PHILIP S. BAILEY AND GENE NOWLIN

In an earlier paper[3] was described the isolation of 3-(hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I) from a Mannich reaction employing 1,2-dibenzoylethane, paraformaldehyde and morpholine hydrochloride in benzene solution. As stated there, the identity of I was not at first apparent. The present paper deals principally with reactions which led to its identification and some interesting reactions of its derivatives. Improvement in the yield of I is reported. The generality of the reaction leading to I has also been demonstrated by the fact that piperidine hydrochloride gives similar results.

Reduction of I by means of hydriodic acid or by stannous chloride gave II, the structure of which was established by synthesis from 3-methyl-2,5-diphenylfuran (VI). This consisted of the bromomethylation of VI to give IV, followed by treatment of IV with morpholine. Any possible doubt as to the course of the bromomethylation reaction was removed by the catalytic hydrogenolysis of IV to give known 3,4-dimethyl-2,5-diphenylfuran (V). Treatment of I with a chloroform solution of hydrogen chloride gave 3-(chloromethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran hydrochloride (III) which in turn was easily converted back to I. The chloromethyl compound (III) also was made by the chloromethylation of 3-(morpholinylmethyl)-2,5-diphenylfuran. These reactions confirm the structure assigned to I because of reactions reported earlier.[3,4]

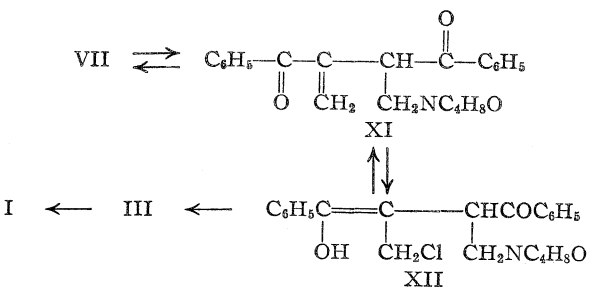
The structures of the two products of the Mannich reaction using piperidine hydrochloride (2,5-diphenyl-3-[piperidylmethyl]-furan and 3-[hydroxymethyl]-2,5-diphenyl-4-[piperidylmethyl]-furan) were proven by characteristic syntheses starting from 3-(bromomethyl)-4-chloro-2,5-diphenylfuran, syntheses earlier carried out for the corresponding morpholine compounds.[4]

1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene (VII) was prepared by the characteristic nitric acid oxidation[5] of II and was found to give some interesting reactions. Reductive furanization of VII back to II, either directly or stepwise through VIII, establishes the structure of VII. When VII is treated with 6 *N* hydrochloric acid it dissolves, and when the resulting solution is neutralized with sodium carbonate, a product shown to be I crystallizes.



(1) Presented before the Southwest Regional Meeting of the American Chemical Society, Shreveport, Louisiana, December 10, 1948. A small portion was included in a paper presented at the Chicago meeting of the American Chemical Society, April, 1948.

(2) This work was partially supported by a University of Texas Research Institute grant, Project 70, and by a Frederick Gardner Cottrell grant from the Research Corporation, New York, N. Y.



(3) Bailey and Lutz, THIS JOURNAL, **70**, 2412 (1948).

(4) Lutz and Bailey, *ibid.*, **68**, 2002 (1946).

(5) Lutz and Wilder, *ibid.*, **56**, 978 (1934).

This is a reaction similar to that between 1,2-dibenzoyl-1-methylethylene and amines, reported earlier.[6] Probably the reaction occurs through the steps shown below. It differs from the amine reaction[6] in that the acidic medium apparently favors cyclization of intermediate XII to a furan (III) rather than ketonization. It has been shown that III is easily hydrolyzed to I, simply upon treatment with sodium carbonate solution.

Treatment of VII with morpholine gave IX, a reaction completely analogous to the reaction of 1,2-dibenzoyl-1-methylethylene with amines.[6] The structure of IX was proven by cyclization to known X. In this connection it is interesting to note that in an earlier paper[4] the structure of the dihydrochloride of X (which analyzed for an extra molecule of water) was left in doubt as to whether it was an extraordinarily stable monohydrate of the furan, or whether it was a diketone, a dihydrochloride having the same structure as the dihydrochloride of the then unknown IX. The dihydrochlorides of X and IX have been shown to be definitely different, although difficulty was experienced in characterizing the salt of IX because of its great hygroscopic properties (the salt of X is not extremely hygroscopic). Upon neutralization, the dihydrochloride of IX gives back IX, not X; whereas the dihydrochloride in question (that of X) gives back X upon neutralization. Of course it is possible that the dihydrochlorides of IX and X are stereoisomers of one another, one a *meso* and the other a *dl*. However, if a ring opening did occur during the formation of a salt of X, the intermediate formed (probably a dienol) should fall into the more stable configuration of IX. Also the mechanism of formation of IX from VII should cause it to have the more stable configuration. Since the salts of IX and X are different, they must have different structures, and the dihydrochloride of X probably is only an unusually stable monohydrate.

## Experimental[7]

**3-(Hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I).**—A mixture of 48 g. of 1,2-dibenzoylethane, 48 g. of morpholine hydrochloride, 28 g. of paraformaldehyde, 2 ml. of concd. hydrochloric acid and 200 ml. of benzene was refluxed with efficient stirring for forty-eight hours, during which time 0.5 g. of paraformaldehyde was added every twelve hours. Two layers were present the entire time. The reaction mixture was worked up by the method described in another paper.[3] Thus was obtained 44.5 g. (65.5% yield) of the hydroxymethyl compound (I) which melted at 169–171°. In a number of different runs of this size the yields varied from 43 to 65%.

Where smaller runs were made, it was necessary to increase the ratio of benzene and hydrochloric acid to dibenzoylethane in order to maintain the above yields. For example, from a reaction mixture consisting of 4.8 g. of dibenzoylethane, 4.8 g. of morpholine hydrochloride, 2.9 g. of paraformaldehyde, 0.2 ml. of hydrochloric acid and 20 ml. of benzene, the yield of I was 7%, while from a similar reaction in which the volumes of benzene and hydrochloric acid were tripled, and everything else remained the same, the yield of I was 43%.

**3-Methyl-4-(morpholinylmethyl)-2,5-diphenylfuran (II) from 3-(Hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I). A. By Hydriodic Acid Reduction.**—A mixture of 15 g. of I and 150 ml. of hydriodic acid (sp. gr., 1.7) was heated at 128° for twenty hours. The precipitate was filtered off and triturated with ethyl acetate; yield, 17.5 g. of brown crystals. A hot methanolic solution of the material was made slightly basic by the dropwise addition of 10% sodium hydroxide solution. After standing overnight the resulting mixture crystallized; 12.2 g. (86% yield), colorless crystals, m. p. 94–96°. Several recrystallizations from methanol raised the melting point to 95–96°.

*Anal.* Calcd. for $C_{22}H_{23}NO$: C, 79.25; H, 6.95. Found: C, 78.97; H, 6.81.

**B. Reduction with Stannous Chloride.**—A solution of 1 g. of I in 5 ml. of glacial acetic acid was added to a hot solution of 5 g. of stannous chloride in 7 ml. of glacial acetic acid and 5 ml. of hydrochloric acid. The resulting solution was refluxed for ten minutes, after which it was cooled and poured into 200 ml. of water, where crystallization occurred. Treatment of the resulting crystals (1.1 g.) with methanol and sodium hydroxide, as described in the preceding experiment, yielded 0.7 g. of colorless crystals (m. p. 94–96°); no depression was observed in a mixture melting point with the material obtained from the hydriodic acid reduction.

**3-Methyl-4-(morpholinylmethyl)-2,5-diphenylfuran (II) from 3-Methyl-2,5-diphenylfuran (VI). A. Bromethylation of VI to IV.** To a solution of 0.3 g. of paraformaldehyde in 3.2 g. of 30% hydrogen bromide–acetic acid reagent, was added a solution of 1.4 g. of VI in 5 ml. of glacial acetic acid. The resulting mixture was stirred at 15° for two hours. The precipitate, which started to form after ten minutes, was filtered off and washed with

(7) All melting points reported here are corrected. Some of the micro-analyses were performed by the Micro-Tech Laboratories of Skokie, Illinois.

cold acetic acid; 1.4 g., m. p. 81–83°. After several recrystallizations from ligroin (b. p. 90–105°) the melting point was 83–84°. The compound gave a positive Beilstein test.

*Anal.* Calcd. for $C_{18}H_{15}BrO$: C, 66.07; H, 4.62. Found: C, 66.05; H, 4.67.

Catalytic hydrogenolysis (Raney nickel) of a small sample of IV in the presence of an equivalent amount of potassium hydroxide in methanol solution yielded 3,4-dimethyl-2,5-diphenylfuran (V), which was identified by a mixture melting point with a known sample.[8]

**B. Treatment of IV with Morpholine.**—A solution of 1 g. of IV and 1 g. of morpholine in 30 ml. of dry ether was allowed to stand overnight, after which the morpholine hydrobromide was filtered off and the filtrate was washed, dried and evaporated. Crystallization of the residual oil from ethanol gave 1.0 g. of II (m. p. 95–96°) which showed no depression in a mixture melting point with the material from the reduction of I.

**3-(Chloromethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran Hydrochloride (III). A. From 3-(Hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I).**—A solution of 1 g. of I in 25 ml. of chloroform, saturated with hydrogen chloride, was set aside for two months, after which time it was evaporated. Several recrystallizations of the residue (1.3 g., m. p., 185–189°) from acetone raised the melting point to 232–233°[9].

*Anal.* Calcd. for $C_{22}H_{23}Cl_2NO_2$: C, 65.35; H, 5.73. Found: C, 65.52; H, 5.97.

**B. From 3-(Morpholinylmethyl)-2,5-diphenylfuran.**—Into a solution of 2 g. of 3-(morpholinylmethyl)-2,5-diphenylfuran hydrochloride and 0.2 g. of paraformaldehyde in 14 ml. of glacial acetic acid, was passed hydrogen chloride for twenty-four hours. The solution was evaporated under reduced pressure and the residue was recrystallized several times from acetone; yield 1.6 g., m. p. 231–233°, no depression in a mixture melting point with the material obtained in part (A).

In another run the reaction mixture was worked up by dilution with water and neutralization with sodium carbonate. The product was I. Also, when crystalline III was shaken with sodium carbonate solution and ether it was converted to I.

**The Mannich Reaction in Benzene Solution Using Piperidine Hydrochloride. A. 3-(Hydroxymethyl)-2,5-diphenyl-4-(piperidylmethyl)-furan.**—A reaction mixture consisting of 4.8 g. of 1,2-dibenzoylethane, 4.3 g. of piperidine hydrochloride, 3.0 g. of paraformaldehyde, 60 ml. of benzene and 0.6 ml. of concd. hydrochloric acid was refluxed with stirring for forty-eight hours, during which time 0.1 g. of paraformaldehyde was added every twelve hours. The mixture was treated with 50 ml. of 6 *N* hydrochloric acid and extracted with ether. When the hydrochloric acid layer was worked up as described in the morpholine experiment[3] there was obtained 3.0 g. (46% yield) of crystals which melted at 161–165°. Several recrystallizations from ethanol raised the melting point to 169–170°.

*Anal.* Calcd. for $C_{23}H_{25}NO_2$: C, 79.50; H, 7.25. Found: C, 79.28; H, 7.36.

**B. 2,5-Diphenyl-3-(piperidylmethyl)-furan.**—When the above reaction was repeated and worked up in precisely the same way with the exception that only 30 ml. of benzene and 0.3 ml. of hydrochloric acid was used, there was obtained 4.7 g. of material (m. p., 201–205°) which did not dissolve in either the hydrochloric acid or the ether layer. From the hydrochloric acid layer was obtained 0.5 g. of 3-(hydroxymethyl)-2,5-diphenyl-4-(piperidylmethyl)-furan. The 4.7-g. batch of crystals was dissolved in hot water, the solution was neutralized with sodium carbonate, and the resulting mixture was extracted with ether. From the ether extract was obtained 2.5 g. of colorless crystals which after recrystallization from ethanol melted at 83–84°.

*Anal.* Calcd. for $C_{22}H_{23}NO$: C, 83.25; H, 7.30. Found: C, 83.13; H, 7.26.

**2,5-Diphenyl-3-(piperidylmethyl)-furan from 3-(Bromomethyl)-4-chloro-2,5-diphenylfuran. A. 3-Chloro-2,5-diphenyl-4-(piperidylmethyl)-furan.**—To a solution of 1 g. of 3-(bromomethyl)-4-chloro-2,5-diphenylfuran[4] in 20 ml. of ether was added 0.7 g. of piperidine. After twelve hours the reaction mixture was filtered and the filtrate was washed, dried and evaporated. Thus was obtained 0.9 g. of colorless crystals which melted at 76–77°, after purification by recrystallization from ethanol.

*Anal.* Calcd. for $C_{22}H_{22}ClNO$: C, 75.09; H, 6.30. Found: C, 75.00; H, 6.48.

**B. Catalytic Hydrogenolysis of 3-Chloro-2,5-diphenyl-4-(piperidylmethyl)-furan** (0.8 g.) was carried out in a solution also containing 0.13 g. of potassium hydroxide and 40 ml. of methanol. The catalyst was Raney nickel (0.2 g.); 59 ml. of hydrogen was absorbed, after which the mixture was filtered, the filtrate was evaporated, and the residue was crystallized from isopropyl alcohol. The product was 0.6 g. of 2,5-diphenyl-3-(piperidylmethyl)-furan (m. p. 83–85°; no depression in a mixture melting point with a sample obtained from the Mannich reaction).

**3-(Hydroxymethyl)-2,5-diphenyl-4-(piperidylmethyl)-furan from 2,5-Diphenyl-3-(piperidylmethyl)-furan.**—A solution of 0.6 g. of paraformaldehyde in 12 g. of 30% hydrogen bromide–acetic acid reagent was added to a solution of 2.5 g. of 2,5-diphenyl-3-(piperidylmethyl)-furan in 8 ml. of glacial acetic acid. After twelve hours the mixture was poured into 200 ml. of water. Neutralization with sodium carbonate gave an oil which crystallized when treated with ether. Recrystallization yielded 0.86 g. of colorless crystals which melted at 167–170° and showed no depression in a mixture melting point with the product obtained from the Mannich reaction.

**1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene (VII).**—To a solution of 6 g. of 3-methyl-4-(morpholinylmethyl)-2,5-diphenylfuran (II) in 40 ml. of propionic acid, cooled to 0°, was added a cold solution of 12 ml. of nitric acid in 24 ml. of propionic acid. After twenty minutes the solution was poured into water and neutralized with sodium carbonate. The resulting mixture was extracted with ether and the ether extract was washed, dried and evaporated. Thus was obtained 6 g. of crude yellow crystals, which after several recrystallizations from ethanol melted at 104–105°.

*Anal.* Calcd. for $C_{22}H_{23}NO_3$: C, 75.62; H, 6.64. Found: C, 75.86, 75.76; H, 6.50, 6.59.

Conversion to the picrate, by treating an ethanolic solution of VII with an ethanolic picric acid solution, gave a yellow solid which melted at 163–165° after several recrystallizations from an isopropyl alcohol–acetone mixture.

*Anal.* Calcd. for $C_{28}H_{26}N_4O_{10}$: C, 58.13; H, 4.53. Found: C, 58.10, 58 15; H, 4.42, 4.35.

**Reduction of 1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene (VII). A. To 3-Methyl-4-(morpholinylmethyl)-2,5-diphenylfuran (II).**—To a solution of 5 g. of stannous chloride, 5 ml. of hydrochloric acid and 7 ml. of acetic acid was added a solution of 0.6 g. of VII in 5 ml. of acetic acid. The mixture was heated over a steam-bath, with stirring, for five minutes, after which it was diluted with water and neutralized with sodium carbonate. Extraction with ether and evaporation of the ether extract gave an oil which was crystallized from ethanol (0.4 g., m.p. 99–100°) and identified as II by a mixture melting point with an authentic sample.

**B. To 1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethane (VIII).**—A porcelain spatulaful of zinc dust was added to a solution of 2 g. of VII in 40 ml of glacial acetic acid. The reaction mixture was stirred and warmed over a steam-bath for nine minutes, after which it was filtered. The filtrate was neutralized with sodium carbonate and extracted with ether. Evaporation of the ether solution and crystallization of the residue from

(8) Lutz and Taylor, THIS JOURNAL, **55**, 1593 (1933).

(9) If the melting point tube is placed in a bath preheated to 200°, the compound immediately melts, then resolidifies and melts again at 232–233°.

ethanol gave 1.2 g. of colorless crystals which melted at 112–113°. The melting point did not change upon recrystallization.

*Anal.* Calcd. for $C_{22}H_{25}NO_3$: C, 75.18; H, 7.17. Found: C, 75.20; H, 7.39.

Furanization of VIII to II was accomplished by treating a solution of 1 g. of VIII in 5 ml. of acetic anhydride with 0.17 ml. of sulfuric acid (to bring about salt formation) followed by five drops excess. After twenty minutes the mixture was poured into water, where it was neutralized with sodium carbonate and extracted with ether. Evaporation of the ether extract and crystallization of the residue from ethanol gave colorless crystals (melting at 98–100°) which were shown to be II by a mixture melting point with an authentic sample.

**Conversion of 1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene (VII) to 3-(Hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I).**—Five-tenths gram of VII was dissolved in 100 ml. of 6 *N* hydrochloric acid and the solution was extracted with ether. Neutralization of the acid layer with sodium carbonate gave 0.48 g. of material which melted at 168–172° after recrystallization from ethanol; it showed no depression in a mixture melting point with known 3-(hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran (I).

**1,2-Dibenzoyl-1,2-di-(morpholinylmethyl)-ethane (IX).**—A solution of 1 g. of 1,2-dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene (VII) in 10 ml. of morpholine was warmed at 75–80° for twenty-four hours. The solution was then poured into water and extracted with ether. Evaporation yielded 0.98 g. of crystals which melted at 135–140°. Several recrystallizations from ethanol raised the melting point to 141–142°. A mixture melting point with 3,4-di-(morpholinylmethyl)-2,5-diphenylfuran (X)[4] (m. p. 143–144°) was depressed to 125–131°.

*Anal.* Calcd. for $C_{26}H_{32}N_2O_4$: C, 71.53; H, 7.39. Found: C, 71.56; H, 7.55.

Treatment of this material with 6 *N* hydrochloric acid, followed by neutralization with sodium carbonate, produced no change.

**Conversion of 1,2-Dibenzoyl-1,2-di-(morpholinylmethyl)-ethane (IX) to 3,4-Di-(morpholinylmethyl)-2,5-diphenylfuran (X).**—To a solution of 0.5 g. of IX in 5 ml. of acetyl chloride was added, dropwise, 0.53 ml. of concd. sulfuric acid. After twenty minutes the dark green solution was poured into water and the resulting solution was neutralized with sodium carbonate. Extraction with ether and evaporation of the ether extract gave 0.41 g. of crystals which melted at 115–122°. Several recrystallizations from ethanol raised the melting point to 143–144°. The material showed no depression in a mixture melting point with known 3,4-di-(morpholinylmethyl)-2,5-diphenylfuran (X),[4] but showed a twenty degree depression in a mixture melting point with starting material (IX).

**The Dihydrochloride of IX** was made by treating an ether solution of IX with excess ethereal hydrogen chloride. It proved to be difficult to purify because of its great hygroscopic properties; for this same reason, a carbon and hydrogen analysis was not made. Several recrystallizations from acetone by the addition of dry ether gave colorless crystals melting at 120–123°.

*Anal.* Calcd. for $C_{26}H_{34}Cl_2N_2O_4$: $Cl^-$, 13.92. Found: $Cl^-$, 13.75.

The dihydrochloride was converted back to IX by neutralizing an aqueous solution of it with sodium carbonate. The yield was 70% and the melting point after one recrystallization from ethanol was 139–141°. There was no depression in a mixture melting point with known 1,2-dibenzoyl-1,2-di-(morpholinylmethyl)-ethane (IX), but a twenty degree depression was observed with known X.

## Summary

A rigorous proof of structure for 3-(hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran is presented. 1,2-Dibenzoyl-1-methyl-2-(morpholinylmethyl)-ethylene has been made and found to undergo some interesting reactions. Treatment of the latter with hydrochloric acid, followed by neutralization with sodium carbonate, gives 3-(hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran, while treatment with morpholine gives 1,2-dibenzoyl-1,2-di-(morpholinylmethyl)-ethane. Mechanisms are discussed.

# Hydrogenation Products from Furfuralacetofuran

BY KLIEM ALEXANDER AND GEORGE H. SMITH, JR.

The chalcone-like compound, furfuralacetofuran,[2] represents a little known type of furfural condensation product. It is readily obtainable by condensing furfural with 2-acetylfuran. The latter intermediate is conveniently available by the preparative procedure of Hartough and Kosak.[3] Total hydrogenation of furfural and difurfural ketone and aldehyde condensation products, in which all of the ethylenic, carbonyl and furyl groups were saturated, has been reported by several authors.[4,5] Intermediates prepared by selective hydrogenation of the alkene and carbonyl groups have, however, received much less attention. Adkins and associates[4,6] have shown that by suitable choice of catalyst and other reaction conditions, the alkene, carbonyl, and furan ring groups of β-furylacrolein can be selectively hydrogenated in that order. In this instance they also observed a complicating side reaction involving ring closure of an intermediate, probably β-furylpropionaldehyde, and leading to the bicyclic structure 1,9-dioxa-5-spirononane. More drastic conditions of hydrogenation gave various ring cleavage and other hydrogenolysis products.

In this study procedures were developed for the conversion of furfuralacetofuran (I) to 1,3-di-

furylpropanone-1 (II), 1,3-difurylpropanol-1 (III), and 1,3-ditetrahydrofurylpropanol-1 (IV). With the exception of II → III, which was not attempted, these are stepwise changes as indicated below. A number of trial reactions performed under varying conditions of temperature and catalyst choice served to show that I → IV occurs rapidly and nearly quantitatively with Raney nickel catalyst at temperatures up to 130°. Likewise I → III occurs very rapidly and almost quantitatively at 110–120° with copper–chromium oxide catalyst, the reaction stopping abruptly with the absorption of two moles of hydrogen. Attempts to go from I to III by use of a nickel on kieselguhr catalyst gave confusing results. Of the two moles of hydrogen that would be required for such a change (saturation of the alkene and carbonyl groups), a rapid absorption of about 1.3 moles, apparently, occurred at temperatures in the range 45–65°. At this point absorption became very slow but increased again to a moderate rate in the range 75–100° and continued at a smoothly decreasing rate to nearly complete saturation of the compound. The product, isolated on stopping the reaction when two moles of hydrogen had been absorbed, was a mixture still showing considerable reactivity toward carbonyl reagents.

Conversion of I to II, using nickel on kieselguhr catalyst, was not entirely satisfactory, since, as indicated above, processes other than the simple saturation of an ethylenic bond are evidently taking place during the first rapid absorption of hydrogen.

Consideration has been given to the possibility that cyclization products analogous to those reported by Adkins[6] and others,[5] may have been formed. Careful fractionation of the total reaction mixture resulting from the preparation of IV, however, failed to show any significant amounts of lower boiling components.

## Experimental[7]

**Catalysts and Apparatus.**—The copper–chromium oxide, Raney nickel, and nickel on kieselguhr catalysts employed were prepared according to the procedures of Adkins.[4] All hydrogenations were conducted in a rocker-type, high-pressure hydrogenation bomb assembly.

**2-Acetylfuran.**—The method of Hartough and Kosak[3] was employed. In agreement with their findings, orthophosphoric acid was the most generally satisfactory catalyst for the acetylation of furan. Yields as high as 77% were obtained from mixtures containing 68 g. (1 mole) of furan and 204 g. (2 moles) of acetic anhydride, to which was added 10 g. of sirupy phosphoric acid (85%). The reaction mixtures were stirred and maintained at 45–60° for one and one-half to two hours.

**Furfuralacetofuran (I).**—A mixture of water (300 cc.), 95% alcohol (225 cc.), 2-acetylfuran (110 g., 1 mole), and freshly distilled furfural (96 g., 1 mole) was placed in a flask provided with a stirrer and cooled to 5–10° by an ice-bath. To this, with stirring, was added a solution of 50 g. of sodium hydroxide in 150 cc. of water. The temperature rapidly increased to about 25° then gradually fell. When, after six to eight minutes, the temperature had fallen to 10–15°, the ice-bath was removed and stirring continued for three to four hours. The product separated as a crystalline yellow solid. The reaction mixture was cooled in an ice–salt mixture, filtered, and the product washed with water until free of alkali. Crystallization from an alcohol–water mixture, after treatment with activated carbon, gave 168 g. (89% yield) of furfuralacetofuran as pale yellow crystals. The m. p., 89–90°, agrees with that reported by Weygand and Strobelt.[2] *Anal.* Calcd. for $C_{11}H_8O_3$: C, 70.2; H, 4.28. Found: C, 70.3; H, 4.47. The compound is stable, showing no color or other changes on standing for several months.

**1,3-Difurylpropanone-1 (II).**—Furfuralacetofuran (94 g., 0.5 mole), dissolved in ethanol and the solution made up to a volume of 370 cc., was hydrogenated in the presence of 3 g. of nickel on kieselguhr catalyst at 45–65° (initial hydrogen pressure 1500 p. s. i.) until the pressure drop corresponded to approximately 0.5 mole of hydrogen absorption. This required twenty to thirty minutes. By stopping the reaction at this point 84 g. of a yellow-orange liquid, b. p. 104–110° (0.5 mm.); $n^{27}D$ 1.5400; $d^{27}_4$ 1.1642 was obtained. *Anal.* Calcd. for $C_{11}H_{10}O_3$: C, 69.4; H, 5.29. Found: C, 69.1; H, 5.45. Further distillation indicated a mixture of products but failed to give appreciable separation of them. That the main product is 1,3-difurylpropanone-1 is indicated by the preparation of an oxime and a 2,4-dinitrophenylhydrazone in good yield.

Oxime: colorless needles, m. p. 83–84°. *Anal.* Calcd. for $C_{11}H_{11}O_3N$: N, 6.83. Found: N, 6.82, 6.88.

2,4-Dinitrophenylhydrazone: fine, red needles from ethanol–ethyl acetate mixture, m. p. 157.5–159.5°; yield, 80–85%. *Anal.* Calcd. for $C_{17}H_{14}O_6N_4$: C, 55.2; H, 3.81; N, 15.13. Found: C, 55.15; H, 3.60; N, 15.18.

**1,3-Difurylpropanol-1 (III).**—Furfuralacetofuran (94 g., 0.5 mole), dissolved in absolute ethanol and the solution, made up to a volume of 370 cc., was hydrogenated in the presence of 4 g. of copper–chromium oxide catalyst. Absorption of hydrogen occurred very rapidly in the temperature range of 90–115° and at pressures of 300–1000 p. s. i. The reaction stopped abruptly when two moles of hydrogen per mole of furfuralacetofuran had been absorbed. Distillation of the product, after removal of catalyst and solvent, gave 87 g. (91% yield) of a nearly colorless liquid, b. p. 99–100° (0.25 mm.); $n^{25}D$ 1.5133; $d^{25}_4$ 1.1388. A sample of this product on further hydrogenation over Raney nickel gave IV in excellent yield. *Anal.* Calcd. for $C_{11}H_{12}O_3$: C, 68.7; H, 6.29. Found: C, 67.4; H, 6.58. This compound formed a 3,5-dinitrobenzoate (colorless, needle crystals from ethanol), m. p. 93.5–94.5°. *Anal.* Calcd. for $C_{18}H_{14}O_8N_2$: C, 56.0; H, 3.65; N, 7.26. Found: C, 55.9; H, 3.48; N, 7.33.

**1,3-Ditetrahydrofurylpropanol-1 (IV).**—Furfuralacetofuran (62.7 g., 0.333 mole) in 220 cc. of ethanol was hydrogenated in the presence of 5 g. of Raney nickel catalyst at temperatures up to 130°. The initial hydrogen pressure was 1700 p. s. i. Absorption began just above room temperature and was essentially complete (6 moles of hydrogen per mole) in fifty minutes at 130°. Filtration from catalyst, followed by removal of solvent and distillation of the product at reduced pressure, gave 63.2 g. (95% yield)

(7) All analyses are micro determinations by C. H. Van Etten and Mary B. Wiele of this Laboratory.

of a colorless, somewhat viscous liquid, b. p. 108–112° (0.5 mm.); $n^{25}D$ 1.4727; $d^{25}_4$ 1.0617; $M_D$ calcd. 52.88; $M_D$ found, 53.41. It is miscible in all proportions with water and with all the common organic solvents. *Anal.* Calcd. for $C_{11}H_{20}O_3$: C, 66.0; H, 10.05. Found: C, 65.8; H, 10.03.

A 100-g. sample of this product on vacuum fractionation through a Podbielniak semi-micro column was found, except for a 3.3 cc. fore-run, to be homogeneous as regards distillation constants and refractive index.

A liquid benzoate ester was obtained in approximately 70% yield when a 0.25-mole sample was refluxed with excess benzoic acid in dry toluene, with *p*-toluene-sulfonic acid as the catalyst, and the water removed by azeotropic distillation. Its constants were: b. p. 182–183° (0.5 mm.); $n^{25}D$ 1.5158; $d^{25}_4$ 1.1038. A sample of this ester, on alkaline hydrolysis, gave an approximately quantitative recovery of benzoic acid and an oil identical with the above 1,3-ditetrahydrofurylpropanol-1 as shown by density, refractive index, boiling point and solubility behavior. *Anal.* Calcd. for $C_{18}H_{24}O_4$: C, 71.0; H, 7.94; S. E. 304.4. Found: C, 71.0; H, 8.04; S. E., 288, 304, 292. With 3,5-dinitrobenzoyl chloride in pyridine solution, the alcohol formed a solid derivative, m. p. 93–94° from ethanol. *Anal.* Calcd. for $C_{18}H_{22}O_8N_2$: C, 54.9; H, 5.62; N, 7.10. Found: C, 54.7; H, 5.41; N, 7.18.

This 3,5-dinitrobenzoate ester was different from that of III above, and both of these were different from that of ethanol, as shown by mixed melting point determinations.

## Summary

1. Furfuralacetofuran has been obtained in about 90% yield by the alkali-catalyzed condensation of furfural with 2-acetylfuran.

2. Procedures are given for the catalytic hydrogenation of furfuralacetofuran to 1,3-difurylpropanone-1, 1,3-difurylpropanol-1, and 1,3-ditetrahydrofurylpropanol-1. Good yields of these were obtained. These hydrogenation products have been characterized by preparation of several derivatives.

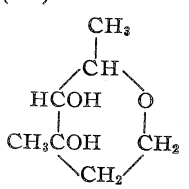
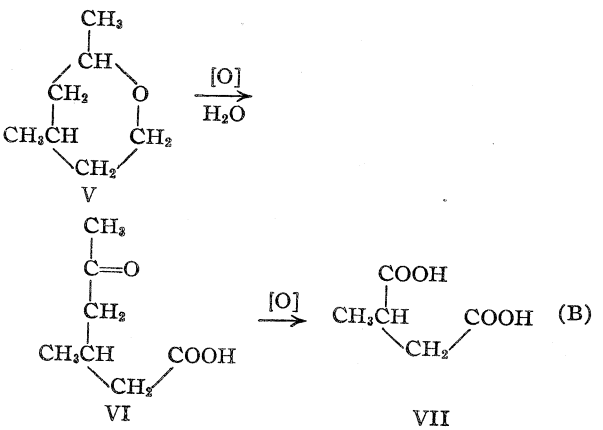
# A Diels–Alder Type Reaction with Formaldehyde



BY THOMAS L. GRESHAM AND THOMAS R. STEADMAN

We wish to report an unusual example of the Diels–Alder reaction,[1] in which formaldehyde (I) participates as a dienophile, reacting (A) with methylpentadiene[2] to yield 2,4-dimethyl-5,6-dihydro-1,2-pyran (III).



II I III (A)

A solid derivative for III was obtained by hydroxylation of the double bond with either potassium permanganate or *t*-butyl hydroperoxide,[3] yielding *cis*-3,4-dihydroxy-2,4-dimethyl-5,6-dihydro-1,2-pyran (IV).

IV

Hydrogenation of III proceeded readily with either Raney nickel or Adams catalyst, yielding 2,4-dimethyltetrahydropyran (V). Oxidation (B) of V with aqueous chromic acid gave 3-methyl-5-oxohexanoic acid (VI) and methylsuccinic acid (VII) confirming the structure (III) anticipated for the pyran from reaction A on the basis of the respective polarizations of the diene and I. The presence of the isomeric 3,5-dimethyltetrahydropyran should have led to the formation of $\alpha,\alpha'$-dimethylglutaric acid as well.

V VI VII (B)

In a recently issued patent[4] regarding the preparation of II from 2-methyl-2,4-pentanediol, the occurrence of 2,4,6-trimethyl-5,6-dihydro-1,2-pyran among the products was reported. This by-product was considered to have arisen by the reaction of acetaldehyde (formed from the glycol by dehydration and concomitant cleavage) with either an intermediate methylpentenol or II. It seems, therefore, quite probable that in general aldehydes will add to II to yield pyrans. Since we were unable to show that either butadiene or

(1) Norton, *Chem. Rev.*, **31**, 319 (1942).

(2) The methylpentadiene was a commercially available material obtained from the Shell Development Company, Emeryville, Calif., reported by them to consist of 85% 2-methylpentadiene-1,3 and 15% 4-methylpentadiene-1,3.

(3) Milas and Sussman, THIS JOURNAL, **59**, 2345 (1937); Milas and Harris, *ibid.*, **60**, 2434 (1938).

(4) Schelling and Anderson, U. S. Patent 2,422,802 (1947).

piperylene would react with I under conditions leading to pyran formation from I and II, we conclude that II is a very active diene in the Diels–Alder synthesis by reason of the favorable polarizing influence of the methyl groups.

## Experimental

**Formaldehyde and Methylpentadiene**—A mixture of 125 g. (1.5 moles) of methylpentadiene and 22.5 g. (0.75 mole) of α-polyoxymethylene was heated in a sealed, stainless steel pressure vessel at 185° for 6.5 hours with agitation. The cooled reaction mixture was dried over anhydrous magnesium sulfate and distilled from a Claisen flask. There was recovered 28 g. (22.5%) of methylpentadiene. A 51.6 g. yield (61.2% yield based on I) of the pyran was obtained: b. p. 125–130° (734 mm.). The properties of a purified sample were: b. p. 126–127° (740 mm.); $n^{30}D$ 1.4401, $d^{30}_4$ 0.877; $MR_D$, calcd. for III, 33.5, obs., 32.9. An examination of the infrared absorption spectrum[5] led to the conclusion that no impurity containing an hydroxyl group was present. From the reaction mixture there was also obtained 27 g. of methylpentadiene dimer, b. p. 110–114° (30 mm.), which accounted for a further 22% of the starting material.

*Anal.* Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 74.47, 74.60; H, 10.75, 10.65. Equivalent weight: calcd. for III, 56. Found[6]: 56.0, 57.5 (bromination with pyridine sulfate bromide); 58.3 (hydrogenation over Adams catalyst).

**Hydroxylation of III.**—To a well-stirred, cooled (15–20°) mixture of 600 ml. of water and 82.5 g. of III was added a solution of 233 g. of potassium permanganate in 3 l. of warm water over a period of three hours. After standing two days at room temperature the reaction mixture was filtered free of the precipitated manganese dioxide and the filtrate evaporated on a steam-bath to a volume of 250 ml. This concentrate was extracted continuously with ether overnight. The ether was distilled from the extract and the residual ether and water removed by distillation with carbon tetrachloride. On cooling, the carbon tetrachloride solution yielded 27.5 g. of crude glycol (IV) (25.6% yield). Recrystallization of crude IV from carbon tetrachloride yielded white crystals, m. p. 74.0–74.5°. On standing for a few days in a vial, the material was found to have changed in melting point: m. p. 90.0–90.5°. By heating this higher melting form for a few minutes above its melting point and allowing crystallization to take place spontaneously, it proved possible to secure the lower melting form.

*Anal.* Calcd. for $C_7H_{14}O_3$: C, 57.55; H, 9.58; mol. wt., 146.2. Found: C, 57.55, 57.40; H, 9.59, 9.62; mol. wt., 144, 141; equivalent weight (neutral sodium periodate), 148, 148.[7]

The same glycol (IV) was obtained by mixing 56 g. (0.5 mole) of III and 90 g. of *t*-butyl hydroperoxide dissolved in 270 g. of anhydrous *t*-butyl alcohol, with 5 ml. of 0.5% osmium tetroxide solution (in *t*-butyl alcohol) as catalyst. After standing six days at room temperature, the reaction mixture was distilled at atmospheric pressure to remove most of the *t*-butyl alcohol. At a pressure of 21 mm., IV distilled as a yellow oil, b. p. 120–130°, which partially solidified on seeding. A recrystallization from carbon tetrachloride gave 5.2 g. of slightly yellow crystals, which after two more recrystallizations melted at 89–91°. The melting point of a mixture with IV obtained by permanganate oxidation showed no depression.

**2,4-Dimethyltetrahydropyran (IV).**—In the reaction vessel of a Burgess–Parr hydrogenation apparatus was placed 56 g. of III and 13 g. of Raney nickel (moist with ethanol). The theoretically expected amount of hydrogen was absorbed during a period of three hours. Distillation of the filtered reaction mixture gave 47 g. of V, b. p. 116–121° (740 mm.). The infrared absorption curve[5] of the material showed the presence of a small amount of an hydroxyl containing material, arising presumably by hydrogenolysis. This impurity was removed by refluxing the product for two hours with 2 g. of sodium. A sample, distilled from sodium, b. p. 118–119°, had the following physical properties: $d^{25}_4$ 0.8422; $n^{25}D$ 1.4188; $MR_D$, calcd. for IV, 34.0, obs., 34.2.

*Anal.* Calcd. for $C_7H_{14}O$: C, 73.63; H, 12.36. Found: C, 73.78, 73.80; H, 12.20, 12.25.

**Oxidation of 2,4-Dimethyltetrahydropyran.**—To a mixture of 149 g. of anhydrous sodium dichromate, 750 ml. of water and 224 g. of concentrated sulfuric acid was added 65 g. of V dropwise with good stirring, keeping the temperature of the reaction mixture between 30 and 40° with the aid of a cold-water-bath. When all the V had been added, the reaction mixture was warmed to 50° for one hour and then heated to the reflux temperature for thirty minutes. The unoxidized V was steam-distilled from the reaction mixture (23 g. recovered) and the residue continuously extracted with ether for sixteen hours. The dried extract was boiled down on a steam-bath, yielding a mixture of VI and VII. A portion of this mixture when treated with semicarbazide yielded a semicarbazone, m. p. 169.5–170.5°. This derivative of VI has been previously reported[8] as melting sharply at a temperature between 170° and 174°, depending on the rate of heating.

*Anal.* Calcd. for $C_8H_{15}N_3O_3$: C, 47.75; H, 7.51; N, 20.88; neutral equivalent, 201.2. Found: C, 47.74, 47.80; H, 7.53, 7.45; N, 20.93, 20.85; neutral equivalent, 196, 198.

Distillation of the crude mixture of acids gave 9.5 g. of an oil, b. p. 137–142° (9 mm.), neutral equivalent 114.6, 114.1. Calcd. for VII, neutral equivalent 66; calcd. for VI, neutral equivalent 144. Therefore the mixture was 62% VI and 38% VII. On standing for two weeks a crystalline deposit of VII was observed in the distilled mixture of acids, m. p. 109–110° after one recrystallization from chloroform. A mixed melting point with a specimen of methylsuccinic acid obtained by hydrogenation of itaconic acid showed no depression.

*Anal.* Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10; neutral equivalent, 66.0; mol. wt., 132.1. Found: C, 45.54, 45.40; H, 6.22, 6.16; neutral equivalent, 67, mol. wt. (ebullioscopic, acetic acid), 130, 134.

## Summary

Formaldehyde reacts with 2-methylpentadiene-1,3 to yield 2,4-dimethyl-5,6-dihydro-1,2-pyran.

# NOTES

## A Method of Estimating and Minimizing the Error of Measurement of the Rate of a Radioactive Exchange Reaction

By Norman Davidson and John H. Sullivan

It has been explicitly pointed out by several authors that for a radio-active exchange reaction between two components in chemical equilibrium, the activity of either component varies in a simple exponential manner with time.[1,2] We present here, as a consequence of this analysis, a method for: (a) the estimation of the error, due to the error of radioassay, in the rate constant for the exchange reaction, as a function of the extent of exchange; (b) the selection of the optimum degree of exchange to minimize this error.[3]

For the case where the rate is measured by the decrease in the activity of the component that initially contained all the activity, the integrated rate expression is

$$\ln\left[\left(\frac{a}{b}+1\right)\frac{x}{c}-\frac{a}{b}\right]=-R(a,b)\,\frac{a+b}{ab}\,t \qquad (1)$$

In this relation: $a$ is concentration of component A that initially contained all the activity; $b$ is concentration of initially inactive component B; $c$ is initial activity of A; $x$ is activity of A at time $t$ and $R(a, b)$ is the rate of exchange.

For very short times of reaction $x$ will be almost the same as $c$ and the error in the rate large. For long times of reaction, the components will be almost in equilibrium with respect to the distribution of activity which will then change but little with time. It is often the case that the errors in $a$, $b$, $t$ are small compared to the errors of radioassay in $x$ and $c$. Set $z = x/c$ and $s = R((a + b)/ab)t$. The variable $s$ is dimensionless and proportional to two factors: (1) $Rt$, the total number of concentration units (*i. e.*, atoms/cc. or moles/liter) that have undergone mutual exchange, and (2) the term $(a + b)/ab$. (Displayed in the form $s = Rt/b + Rt/a$, it is evident that $s$ is the sum of the number of exchanges per atom of $a$, and the number of exchanges per atom of $b$). Then

$$-\frac{\mathrm{d}\ln s}{\mathrm{d}\ln z}=\frac{1+(a/b)\exp(s)}{s}=E(a/b,s) \qquad (2)$$

The relation $\sigma_s = |\mathrm{d}s/\mathrm{d}z|\sigma_z$ holds for the standard deviations, $\sigma_s$ and $\sigma_z$, of $s$ and $z$, because of the assumption that the error in $s$ is due entirely to the error in $z$.[4] Then

$$\frac{\sigma_s}{s}\times\frac{z}{\sigma_z}=-\frac{\mathrm{d}\ln s}{\mathrm{d}\ln z}=E(a/b,s) \qquad (3)$$

For $\sigma_z,(\sigma_z/z)^2 = (\sigma_x/x)^2 + (\sigma_c/c)^2$; the standard deviations of the activities may be due to statistical counting errors or may be manipulative errors determined by reproducibility tests. It is often the case that the fractional error in $x,(\sigma_x/x)$, is a constant; this is roughly true, for example, if the error is principally a counting error and one counts all samples to the same number of counts, or if the error is a manipulative error in preparing chemically identical samples for radioassay. For such cases, the minimum of $E$ locates the point for minimum error in $s$ (and hence in the rate function $R$). Knowing the value of $s$ corresponding to the minimum value of $E$ and using a preliminary value of $R$, the optimum $t$ may be chosen.

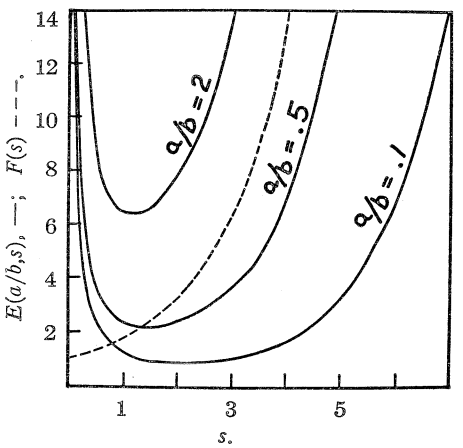

Fig. 1.—Error functions for exchange reactions.

The minimum of the error function, $E$, may be found by solution of the equation: $s - 1 = (b/a)\exp(-s)$. It will generally be more useful to construct a family of curves like those in the figure so that the error in $s$ will be known for any $s$ (or $z$). Estimates of the standard deviation in $s$ obtained in this way are useful, for example as weighting factors in averaging data or in least squares treatments of data on the variation of rate of exchange with temperature or ionic strength. For such applications, the function $E$ is useful even when the fractional error of radioassay is not constant. For these cases, knowing $\sigma_x$ as a function of $x$ and hence (for given $a$ and $b$) as a function of $s$, one could construct the function, $E(s)\sigma_x(s)/x(s)$, and thus select the point of minimum error. For the usual case where $\sigma_x/x$ does not change too rapidly with $x$, it may be sufficient to select by inspection a point in the region of the minimum of the $E(s)$ curve without making the more elaborate calculations required to select the optimum point.

(1) McKay, *Nature*, **142**, 997 (1938).

(2) Duffield and Calvin, This Journal, **68**, 557 (1946).

(3) Roseveare, *ibid.*, **53**, 1651 (1931), has applied similar arguments to the problem of estimating and minimizing the error in the rate constants for chemical reactions.

(4) See, for example, Margenau and Murphy, "The Mathematics of Physics and Chemistry," D. Van Nostrand Co., New York, N. Y., 1943. p. 498.

For the case where the rate of exchange is measured by the growth of activity, $y$, in B

$$y(t) = y(\infty)\ [1 - \exp(-s)] \quad (4)$$

$$\mathrm{d}\ln s/\mathrm{d}\ln(y/y(\infty)) = (\exp(s) - 1)/s = F(s) \quad (5)$$

The figure contains a plot of this function, too. In this case, of course, the fractional error in $y$ cannot possibly be constant as $y$ approaches zero; an estimate of $\sigma_y$ as a function of $y$ is needed for selecting an optimum reaction time or calculating the error of a particular determination.

## A Convenient Synthesis of N,N-Dimethyl-*p*-nitroaniline and N,N-Dimethyl-*o*-nitroaniline

BY TOD W. CAMPBELL

There are a number of methods in the literature for the preparation of N,N-dimethylnitroaniline[1]; but most of them are troublesome and result in low yields of a product which is usually of not too high purity. The methods in the literature[1g,i] which give acceptable or good yields involve a reaction in which a nitrohalobenzene is allowed to react with dimethylamine.

The author has found that this reaction is most conveniently brought about by refluxing a pyridine solution of nitrohalobenzene with a mixture of dimethylamine hydrochloride and sodium bicarbonate. The desired product is obtained in virtually quantitative yield; in the case of the para isomer, the product can be crystallized directly from the reaction solvent in a high state of purity. This procedure is therefore recommended for the preparation of these two substances.

### Experimental Part

***p*-Nitrodimethylaniline.**—A mixture of 42 g. of *p*-bromonitrobenzene, 300 cc. of pyridine, and 50 g. of sodium bicarbonate was placed in a 500-cc. round-bottom flask. To this mixture was added 30 g. of dimethylamine hydrochloride dissolved in about 10 cc. of warm water. The mixture was refluxed for ten hours. Mechanical stirring was not employed, since serious bumping did not occur. At the end of the reflux period, the hot solution was filtered free of inorganic salts, and the latter was extracted with 200 cc. of acetone, which was added to the pyridine solution. The mixed extracts were boiled, and water added to near the cloud point. On cooling, bright yellow needles of *p*-nitrodimethylaniline, 1–3 cm. in length, crystallized out. The melting point was observed to be 163.7–164.1° (lit. 163–166°) on a calibrated Anschütz thermometer in a Hershberg apparatus. The mother liquor on concentration to one third of its original volume gave an additional small yield of fine yellow needles, which had a melting point anywhere from 1–10 degrees low, for various experiments. One recrystallization from methanol raised the melting point to 163.5–164°. The over-all yield of pure product was 32.4–33.6 g. (94–97%).

***o*-Nitrodimethylaniline.**—The above procedure was employed to prepare the ortho substituted derivative. Ten grams of *o*-nitrochlorobenzene gave 8.9 g. (85%) of product; b. p. 149 at 20 mm.; $n^{25}D$ 1.6080.

*Anal.* Calcd. for $C_8H_{10}N_2O_2$; C, 57.81; H, 6.06. Found: C, 57.53; H, 6.21.

## Vapor Density of Diborane[1]

BY E. M. CARR, J. T. CLARKE AND H. L. JOHNSTON

In connection with the process of adding diborane to a calorimeter it was necessary to determine its density at 275.16°K. The diborane was obtained from the Naval Research Laboratory, subjected to a two-plate distillation and shown by the cryoscopic method to have a purity of 99.95 mole per cent. The diborane was introduced into an evacuated, weighed and calibrated 1-liter Pyrex bulb immersed in a constant temperature water-bath at 275.16°K. and constant to 0.01° C. during the measurement. The pressure was read on a 15 mm. i. d. manometer using a Gaertner cathetometer and a standard meter bar in an insulated case; the readings were converted to standard conditions and meniscus corrections made according to Cawood and Patterson.[2] The bulb was then reweighed (using a similar bulb as tare) on a Troemner 4-kg. balance. One bulb had 1/8 inch Pyrex helices with a surface area 16.0 times that of the interior part of the bulb added to it. Since all density measurements were made at approximately atmospheric pressure the amount of adsorption was assumed to be constant.

The results were used to calculate the density and the second virial coefficient $B$ in the equation

$$n - A = \frac{PV}{RT + PV}$$

where $A$ equals moles of diborane adsorbed on the surface of a 1-liter bulb and was found to have a value of $2.4 \times 10^{-5}$ mole. A summary of the data is

| Pressure, atm., $P$ | Temperature, °K., $T$ | Moles in gas phase, $n - A$ | Volume of bulb, ml., $V$ | Second virial coef. $B$ (ml.) 275.16° K. | Density g./l. 1 atm. 275.16°K. |

## The Preparation of Xanthopterin

BY GERTRUDE B. ELION, AMOS E. LIGHT AND GEORGE H. HITCHINGS

The method of Totter[1] for the preparation of xanthopterin (2-amino-4,6-dihydroxypteridine) has several advantages with respect to the time involved, convenience and availability of starting materials, over those of Purrmann[2,3] and Koschara.[4] As will be shown, however, the product of this procedure is impure, as determined spectrographically. Moreover, such impure xanthopterin is shown to have a microbiological activity quite different from that of pure xanthopterin. The possibility exists that some of the reported biological activities of xanthopterin may be attributable to such impurities. This note describes modifications of the Totter procedure which result in their elimination.

### Experimental: Preparation of Xanthopterin

**Leucopterin.**—The leucopterin was prepared by the method of Purrmann.[5] On standing, after neutralization, the acid filtrate from the crystallization of leucopterin deposited a red precipitate which had microbiological activity (Precipitate A, Expt. 9, Table I).

**Dihydroxanthopterin.**—Leucopterin (6 g., 0.03 mole) was suspended in 40 ml. of water and 4% sodium amalgam (88 g., 0.153 mole) was added in small portions with stirring, the temperature being maintained below about 50°. On completion of the reduction the mixture was decanted from the mercury and chilled in an ice-bath. The sodium salt of dihydroxanthopterin precipitated in shiny crystals which were filtered off, washed with 5 ml. of ice water and dried *in vacuo* (3.73 g., 60%). A small additional quantity of dihydroxanthopterin (0.46 g.) was obtained by acidification of the mother liquors. The filtrate from this fraction, on standing several days, deposited a red precipitate which had purine-like activity (Precipitate B, Expt. 10, Table I).

The sodium dihydroxanthopterin (3.73 g.) was dissolved in 300 ml. of hot water, with the aid of a small quantity of sodium hydroxide solution, filtered and acidified with acetic acid. Dihydroxanthopterin monohydrate precipitated as pale yellow microcrystals (3.4 g.); *cf.* Hitchings and Elion.[6]

**Xanthopterin.**—Dihydroxanthopterin monohydrate (2.5 g., 0.0125 mole) was dissolved at room temperature in 200 ml. of water containing 1.4 g. of potassium hydroxide. Potassium permanganate solution (84 ml. of 0.01 $M$) was added dropwise over the course of ten minutes. After coagulation of the manganese dioxide, the solution was separated by centrifugation. The manganese dioxide was extracted with 100 ml. of water; the combined supernatant fluids were filtered and acidified with acetic acid. The yellow-orange xanthopterin precipitate was collected by centrifugation, washed seven times with water, then with alcohol, finally with ether and dried *in vacuo*. The yield was 1.95 g. of xanthopterin monohydrate (79%). At *p*H 11.0 the monohydrate has an $E^{1\%}_{1\text{ cm.}}$ of 0.92 at 255 mμ and 0.355 at 390 mμ.

### Microbiological

Each compound was tested for its ability to serve as a substitute for adenine in the growth of *Lactobacillus casei* with thymine as nutrilite at a concentration of 10 γ per ml.[7] It will be seen (Table I) that whereas pure xanthopterin (Expt. 1) and dihydroxanthopterin (Expt. 5) have only inhibitory effects, the product of the complete Totter procedure (Expt. 2) the product of further purification[8] of this material (Expt. 3) and that obtained by the oxidation of pure dihydroxanthopterin by silver oxide (Expt. 4) all possess purine-like activity. This activity is not due to the starting material (Expt. 6), the intermediate oxalyl derivative (Expt. 7) or leucopterin (Expt. 8). The activities appear to be properties of by-products which are formed in the various steps and in some instances deposit slowly on standing of the solutions (Expt. 9, Expt. 10). This finding demonstrates the necessity for the isolation and purification of the intermediates as a requisite for the preparation of pure xanthopterin.

TABLE I

PURINE-LIKE ACTIVITY OF XANTHOPTERIN AND INTERMEDIATES

| Expt. | Compound | Titer: With compound 1 mg. per 10 ml. | Titer: Control |
|---|---|---|---|
| 1 | Xanthopterin I[a] | 0.4 | 1.1 |

(7) Hitchings, Falco and Sherwood, *Science*, **102**, 251 (1945).
(8) Crude xanthopterin prepared by Totter's method was dissolved in $N$ sulfuric acid, treated with norite and filtered. The product was precipitated with ammonium hydroxide, washed, dried, rewashed and redried. This treatment increased the $E^{1\%}_{1\text{ cm.}}$ at 390 mμ in glycine buffer of *p*H 11.0 from a value of 0.31 to 0.35, the latter indicating approximate purity. The greater part of the microbiological activity remained, however.

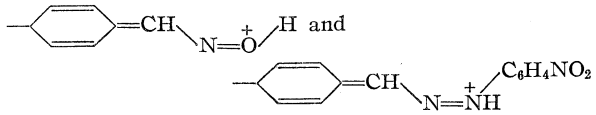
## Absorption Spectra of Some Benzal and Mesitylal Schiff Bases

By Lloyd N. Ferguson and John K. Robinson

When considering the relative light absorptions of two compounds such as

where X is any simple group, it is difficult to predict whether the steric effect of the *ortho* methyl groups in the mesityl compound will decrease absorption from that of the simple phenyl compound or whether there will be an increase in absorption due to hyperconjugation of the methyl groups. For this reason, the spectra of several Schiff bases of benzaldehyde and mesitylaldehyde were measured. The spectral characteristics are listed in Table I.

Table I



Spectral Characteristics of Some Benzal and Mesitylal Schiff Bases

| Compound | Oxime $\lambda_m$ (mμ) | Oxime $\epsilon_m$ | *p*-Nitrophenylhydrazone $\lambda_m$ (mμ) | *p*-Nitrophenylhydrazone $\epsilon_m$ | Ethylenediamine $\lambda_m$ (mμ) | Ethylenediamine $\epsilon_m$ |
|---|---|---|---|---|---|---|
| Benzal | 252 | 14,300 | 407 | 34,200 | 247[1] | 29,000[1] |
| Mesitylal | 252 | 9,400 | 411 | 31,700 | 264 | 8,100 |
| Difference | 0 | 4,900 | 4 | 2,500 | 17 | 20,900 |

From these results, it is observed that there are no significant differences between the wave lengths of maximum absorption of the two oximes or of the two *p*-nitrophenylhydrazones. In going from dibenzalethylenediamine to dimesitylalethylenediamine there is a bathochromic effect. This, perhaps, is due to the hyperconjugation of the methyl groups becoming more prominent since the chromophoric system is double. Actually upon constructing the Fisher–Hirschfelder models of these three classes of compounds there appears to be only a small steric hindrance between the mesityl methyl groups and the group X.[2]

It has been observed before[3] that small steric hindrances have little effect upon $\lambda_{max.}$ but do decrease $\epsilon_{max.}$. This is illustrated in the present case by the oximes and the ethylenediamines. It is noted that this effect is very small in the case of the nitrophenylhydrazones; however, this is understandable. The nitrophenylhydrazones have absorption bands near 400 mu[4] without the aid of the phenyl or mesityl groups at the other end of the molecule, and consequently steric hindrance does not affect appreciably the molecular extinction.

The only explanation offered at this time for the trend in the differences of $\lambda_{max.}$ is to say that forms such as

contribute to the resonances of benzaldoxime and benzal-*p*-nitrophenylhydrazone. Such forms would be opposed by the hyperconjugation of the methyl groups in the mesityl nucleus. It may be that the two effects just cancel one another in the mesitylaldoxime, that the hyperconjugation is slightly more effective than the opposing resonance in the mesitylal-*p*-nitrophenylhydrazone and that in the ethylenediamine compounds, where the corresponding resonant forms cannot exist and the chromophoric system is double, the hyperconjugation causes a much larger bathochromic effect.

## Comparison of Age with the Relative Abundance of Argon and Potassium in Rocks

By R. L. Farrar, Jr., and George H. Cady

The study reported in this communication was done as a test of the proposal of Thompson and Rowlands[1] that the accumulation of argon resulting from decay by K electron capture of $K^{40}$ should serve as a measure of the age of rocks containing potassium. For this study solid rocks of known geologic age were kindly furnished by G. E. Goodspeed of our Department of Geology.

The analytical procedure involved the following steps: (1) A 60-g. sample of sodium carbonate was freed of argon by pumping away gas for three hours from the molten salt held in a stainless steel vessel at about 950°. (2) Argon and other gases were removed from the surface of a 10-g. sample of rock composed of pea-sized pieces by allowing the material to stand for about an hour at room temperature in a vacuum. (3) The rock was then dissolved in the sodium carbonate at 950 to 1000°. This process was allowed to continue for a twenty-four-hour period to secure complete liberation of rare gases. (4) He + Ne and A + Kr + Xe were determined in the gas, using methods previously described by Cady and Cady.[2] Since spectroscopic tests showed that not more than traces of Ne, Kr or Xe could have been present in each case, the results of the analyses are reported in the table as helium and argon, respectively. (5) Potassium was determined in the mass resulting from the sodium carbonate fusion.

Conclusions: (1) These analyses indicate no regular increase of the A/K ratio with age. (2) The range in argon content is much less than that of helium. (3) Most of the argon in at least the first two samples probably originated from a source, perhaps the atmosphere, other than the

TABLE I

COMPARISON OF AGE WITH THE RATIO A/K IN ROCKS

| Description of sample | Location from which obtained | He, cc./g. at S. T. P. | A, cc./g. at S. T. P. | K, % | G. ats. A / G. ats. K | Approximate age in millions of years |
|---|---|---|---|---|---|---|
| Quartz, Cornucopia formation | Cornucopia, N. E. Oregon | $0.022 \times 10^{-4}$ | $1.3 \times 10^{-4}$ | 0.027 | $8.4 \times 10^{-4}$ | 100 (Late Mesozoic) |
| Soda feldspar | Ohanepecosh Hot Springs, Washington | $0.062 \times 10^{-4}$ | $1.9 \times 10^{-4}$ | 0.43 | $7.7 \times 10^{-5}$ | 30 (Tertiary) |
| Potash feldspar, Cornucopia formation | Cornucopia, N. E. Oregon | $0.19 \times 10^{-4}$ | $3.25 \times 10^{-4}$ | 12.8 | $4.4 \times 10^{-6}$ | 100 (Late Mesozoic) |
| Bostonite | Marblehead, Massachusetts | $<0.005 \times 10^{-4}$ | $0.81 \times 10^{-4}$ | 2.08 | $6.8 \times 10^{-6}$ | 300 (Carboniferous) |
| Granite, Silver Plume Formation | Silver Plume, Colorado | $2.4 \times 10^{-4}$ | $1.4 \times 10^{-4}$ | 1.91 | $1.3 \times 10^{-5}$ | 940[3] |
| Granite | Sudbury, Ont. | $0.65 \times 10^{-4}$ | $4.5 \times 10^{-4}$ | 3.33 | $2.4 \times 10^{-5}$ | 700 (Keweenawan) |
| Granite gneiss | Sudbury, Ont. | $0.51 \times 10^{-4}$ | $5.2 \times 10^{-4}$ | 1.05 | $8.6 \times 10^{-5}$ | 1050 (Laurentian) |

decay of potassium-40 in the existing minerals. (4) A careful isotopic analysis would be required to establish the relative proportions of "atmospheric" argon and that formed by the decay of $K^{40}$ in the rock. (5) Without such an analysis, the ratio, A/K, appears not to be a good measure of the age of a rock.[4]

(3) Age by U, Th, Pb method: E. N. Goddard and J. J. Glass, *Am. Mineralogist*, **21**, 199 (1936).

(4) Aldrich and Nier (*Phys. Rev.*, **74**, 876 (1948)) have reported since the date of submission of this note, that the ratio $A^{40}/A^{36}$ is higher in potassium minerals than in air. Their analyses of four samples indicate an increase in the ratio Radio A/K with age.

## Some New Polyhalogenated Phenyl Isocyanates

BY LOUIS W. GEORGES[2] AND CARL HAMALAINEN

Previously reported work on the reaction of organic isocyanates with cellulose has been concerned with (1) the preparation of new cellulose derivatives of possible utility in the plastics field, and (2) the production of a more or less superficial esterification of cotton textiles to impart new properties. Thus, cellulose carbamate and cellulose acetate carbamate,[3] soluble in common organic solvents, and chlorophenyl carbamate of methyl cellulose with as much as 12% chlorine have been obtained.[4] By the preparation of carbamates, cotton textiles have been rendered water repellent,[5] their dyeing characteristics have been modified,[6] and the softening point and solubility properties of cellulose acetate rayon have been altered.[7]

The object of the present study was to investigate the possibility of providing a fire-resistant cotton textile by chemical combination of a fire-retarding agent with the cellulose molecule yet preserving the fibrous character of the cotton. Halogen-containing organic compounds are either not combustible or, in general, burn with difficulty. It seemed likely that partial carbamylation of cellulose with a polyhalogenated phenyl isocyanate would introduce sufficient halogen (27–31%) in cellulose to achieve fire-proofness and still retain the fiber structure. Such partial carbamylations could be successfully effected in a manner similar to that described by Hearon, Hiatt and Fordyce[3c] in which phenyl isocyanate was used. A patent covering the fireproofing of lint cotton has been issued.[8]

It is believed that the polyhalogenated phenyl isocyanates used in the reaction with cotton in the manner described in the patent are new compounds. The preparation of these compounds is given in the experimental section below.

course of the reaction the temperature was raised gradually until there was a gentle refluxing of the solvent. After concentrating the clear chlorobenzene solution under reduced pressure the product was distilled and 26.3 g. (62%) of colorless 2,5-dichlorophenyl isocyanate was obtained; b. p. 83–84° at 3–4 mm. The isocyanate was identified by means of the crystalline di-(2,5-dichlorophenyl)-urea; m. p. 289° (cor.).

*Anal.* Calcd. for $(C_6H_3Cl_2)_2(NH)_2CO$: N, 8.0; Cl, 40.1. Found: N, 7.9; Cl, 40.0.

**2,4,6-Trichlorophenyl Isocyanate.**—Phosgene was passed through a suspension of 50 g. of 2,4,6-trichloraniline hydrochloride in 500 ml. of chlorobenzene. The temperature was raised gradually to the reflux point. The bulk of the suspended material dissolved. The small amount of crystalline compound that was separated by filtration proved to be the disubstituted urea derivative. The clear filtrate was concentrated under reduced pressure until free of chlorobenzene. The hot residue was transferred to a crystallizing dish and stored in a vacuum desiccator in which upon cooling the product crystallized. The yield of crude 2,4,6-trichlorophenyl isocyanate was 29.2 g. (61%). Pure material was obtained on recrystallization from petroleum ether; m. p. 64–65°.

*Anal.* Calcd. for $C_6H_2Cl_3NCO$: N, 6.3; Cl, 47.9. Found: N, 5.9; Cl, 47.3.

The crystalline di-(2,4,6-trichlorophenyl)-urea was prepared; m. p. 295° (cor.).

**2,4,6-Tribromophenyl Isocyanate.**—Dry hydrogen chloride was passed into a solution of 107 g. of 2,4,6-tribromoaniline in 500 ml. of chlorobenzene until a voluminous precipitate of the hydrochloride was formed. Phosgene was then passed into the reaction mixture in a steady stream with continuous stirring until solution of the 2,4,6-tribromoaniline hydrochloride was effected. The reaction mixture was heated gradually during the course of the reaction to the reflux temperature of the solvent. An appreciable amount of the crystalline disubstituted urea was formed and this product was separated by filtration. The clear filtrate was concentrated under reduced pressure until free of solvent and the hot liquid residue transferred to a crystallizing dish. After cooling in a vacuum desiccator a crystalline mass was obtained. The yield of crude 2,4,6-tribromophenyl isocyanate was 44.6 g. (39%). Pure material was obtained on recrystallization from petroleum ether; m. p. 92–94°.

*Anal.* Calcd. for $C_6H_2Br_3NCO$: N, 3.9; Br, 67.5. Found: N, 3.9; Br, 66.8.

The addition of water to a pyridine solution of the isocyanate yielded the di-(2,4,6-tribromophenyl)-urea; m. p. 323° (cor.).

**Acknowledgment.**—We are indebted to Miss Alva Faust and Mr. Richard H. Robinson for the chemical analyses, and to Mr. Frank C. Magne for the melting point determinations.

SOUTHERN REGIONAL RESEARCH LABORATORY
NEW ORLEANS, LOUISIANA RECEIVED AUGUST 30, 1948

## The Chloromethylation of Veratrole[1]

BY OSCAR GAWRON

In connection with a synthesis of a compound of pharmaceutical interest, a large supply of 4-chloromethyl-veratrole was needed. Recourse to the literature showed several unsuccessful attempts[2,3] at chloromethylation of veratrole by the usual procedures and a successful attempt[4] by a two phase chloromethylation. The unsuccessful attempts yielded 2,3,6,7-tetramethoxy-9,10-dihydroanthracene as a condensation product.[3,4]

The successful Bide and Wilkinson[4] procedure was tried and found to give somewhat erratic results, probably due to the critical conditions involved, −2 to +2°, rate of stirring, and rate of passage of the hydrogen chloride. In addition, temperature control of large scale laboratory preparations was difficult, although this was partially solved by the direct addition of dry ice to the reaction mixture from time to time.

Since the above procedure did not prove entirely satisfactory, several chloromethylation experiments were run with chloromethyl ether in glacial acetic acid. These were found to be satisfactory. The conditions used were essentially those employed by Vavon, Bolle and Calin[5] in their study of the influence of substituents on rates of chloromethylation of aromatic compounds.

The procedure finally adopted was as follows: In a one-liter, three-necked, round-bottom flask, equipped with a thermometer, a mercury seal stirrer, and a calcium chloride tube, were placed 282 g. of glacial acetic acid, 247 g. of veratrole (1.8 moles) and 288 g. of chloromethyl ether (3.6 moles). The stirrer was started and the initial temperature was noted. If below 20°, the reaction mixture was gently warmed to 20 to 21°. The reaction was then allowed to proceed for seven hours. In four to six hours the temperature rose to 30° and subsequently the reaction mixture was kept below 30° by means of a cold water-bath. The reaction, which had proceeded to almost 50% completion (analytical method of Vavon, Bolle and Calin[5]) at the end of seven hours was then stopped by pouring with stirring, onto 800 g. of cracked ice and 400 ml. of chloroform. Stirring was continued until most of the ice had melted. The chloroform layer was then separated and the water layer extracted twice with 100-ml. portions of chloroform. The combined chloroform extracts were washed once with 50 ml. of water and then dried over anhydrous sodium sulfate. The chloroform was removed *in vacuo* and the residue distilled at less than 1 mm. The fore run was unchanged veratrole and then the 4-chloromethylveratrole distilled at 100–103°. It crystallized on cooling the receiver; m. p. 48–50°; yield, 62 g. (54%), based on recovered veratrole.

Further preparatory studies and kinetic studies on the mechanism of the general chloromethylation reaction are in progress.

## Substituted Quinolyl Dodecyl Sulfides

BY HENRY GILMAN AND SAMUEL P. MASSIE

The therapeutic activities of some quinoline ethers and the germicidal activities of some aryl sulfides[1] suggested the preparation of some quinoline sulfides for pharmacological testing. It was also considered desirable to incorporate a fat-soluble group into the molecule, so as to increase the possibility of absorption of the drug by the animal body. These considerations initiated the preparation of some high-molecular weight alkyl quinolyl sulfides for therapeutic investigation.

[a] This amine would not form a derivative with salicylaldehyde or acetonylacetone. [b] The dihydrochloride melted at 156–157°. Calcd. for $C_{21}H_{34}N_2Cl_2S$: S, 7.67. Found: S, 7.67. [c] This amine could not be purified, but the acetamido derivative gave the correct analysis. [d] Calcd. for $C_{25}H_{37}O_2N_3S$: N, 9.48. Found: N, 9.48.

A series of substituted quinolyl dodecyl sulfides was prepared from activated chloroquinolines and sodium dodecyl mercaptide in methyl cellosolve. The quinoline compounds used were 5-nitro-6-chloroquinoline,[2] 5-nitro-6-chloro-8-acetamidoquinoline,[3] 4,7-dichloroquinoline[4] and 6-methoxy-2-chlorolepidine.[5] The nitroquinolyl sulfides were then reduced to the amino derivatives and these, in turn, were acetylated to the acetamido derivatives.

These compounds were tested against tuberculosis; reports on their activities will be published elsewhere. The authors are grateful to Parke, Davis and Co. for arranging for the tests, and to William Meikle for assistance.

### Experimental

**Quinolyl Dodecyl Sulfides.**—The general method of preparation was to add a solution of sodium dodecyl mercaptide in methyl cellosolve to the chloroquinoline in hot methyl cellosolve.[6] The mixture was refluxed for an hour, cooled, poured into 200 ml. of water, acidified with acetic acid, filtered, and the precipitate recrystallized from methanol.

**Aminoquinolyl Dodecyl Sulfides.**—The nitroquinolyl dodecyl sulfides were reduced with hydrogen and Raney nickel in absolute ethanol. Recrystallization was not necessary. The amines were yellow solids.

**Acetamidoquinolyl Dodecyl Sulfides.**—The acetamido derivatives were prepared by heating the amine and acetic anhydride in glacial acetic acid. The mixture was poured into water, filtered and recrystallized from absolute ethanol.

The results are given in Tables I, II and III.

## A New Synthesis of 2,4-Dihydroxyquinoline

BY E. H. HUNTRESS AND J. BORNSTEIN

A recent review[1] of 4-hydroxyquinolines prompts us to report a synthesis of 2,4-dihydroxyquinoline from isatin, giving better results by simpler procedure than prior methods.

The most widely used method for the preparation of 2,4-dihydroxyquinoline has been the treatment of the esters of N-acetylanthranilic acid with sodium metal in toluene or xylene.[2,3,4] Although Camps[2] reported 60% crude yield, subsequent investigators[2,3,4] (including ourselves) have been unable to obtain more than 28–40%.

Reaction of isatin with chloroacetyl chloride gave N-(chloroacetyl)-isatin which on refluxing with aqueous potassium hydroxide, followed by acidification of the reaction mixture with hydrochloric acid, precipitated 2,4-dihydroxyquinoline with the simultaneous evolution of carbon dioxide.

### Experimental

**N-(Chloroacetyl)-isatin.**—Isatin (10 g., 0.068 mole) was vigorously refluxed with chloroacetyl chloride (70 ml., 100 g., 0.89 mole) for five hours. The dark brown reaction mixture was cooled for two hours in an ice-bath

and the precipitate filtered. The filtrate was saved and the solid washed twice with 20 ml. portions of ether and air-dried. The N-(chloroacetyl)-isatin (10.0 g., 66%) consisted of fine-golden-yellow needles, m. p. 210–211° cor., suitable for use without additional purification. The reaction filtrate was replenished with fresh chloroacetyl chloride (10 ml.) and the run repeated with additional isatin (10 g.) giving more equally pure product (12.0 g., 78%). For analysis the N-(chloroacetyl)-isatin was recrystallized from ethyl acetate.

*Anal.* Calcd. for $C_{10}H_6O_3NCl$: C, 53.71; H, 2.71; N, 6.26; Cl, 15.85. Found: C, 53.32; H, 2.91; N, 6.41; Cl, 15.79.

On recrystallization from methanol the yellow N-(chloroacetyl)-isatin separated with one mole of solvent as fine, *colorless* needles, m. p. 83.0–83.5° cor.

*Anal.* Calcd. for $C_{11}H_{10}O_4NCl$: C, 51.68; H, 3.95; N, 5.48; Cl, 13.88. Found: C, 51.52; H, 4.09; N, 5.46; Cl, 14.02.

**2,4-Dihydroxyquinoline.**—Into 150 ml. of an aqueous boiling solution of potassium hydroxide (5.0 g., 0.09 mole) was added all at once 5.0 g. (0.022 mole) of yellow N-(chloroacetyl)-isatin. The straw-colored solution was refluxed for two hours and then cooled to room temperature. On acidification of the reaction mixture with concentrated hydrochloric acid a cream-colored solid separated which was filtered and washed three times with 10-ml. portions of cold water. The crude yield was 2.0–2.5 g., 56–70%. From the filtrate small amounts of isatin were isolated. The 2,4-dihydroxyquinoline was purified by dissolving in the minimum amount of 10% sodium carbonate solution, filtering, boiling the filtrate with Darco for five minutes, filtering, and then reacidifying. On recrystallizing from methanol the compound separated as fine, colorless needles; m. p. 352–354° cor., recorded m. p. 355°.[5]

*Anal.* Calcd. for $C_9H_7O_2N$: C, 67.08; H, 4.38; N, 8.69. Found: C, 67.21; H, 4.63; N, 8.65.

The identity of the 2,4-dihydroxyquinoline was confirmed by means of its nitroso derivative, m. p. 208° dec., uncor. (recorded 208°[6]), which melted at the same temperature when mixed with an authentic sample. In addition, the (mono) acetyl derivative was prepared; m. p. 215.0–215.5° uncor. (recorded 214–215°[3]), mixed melting point with authentic sample was 215.0–215.5° uncor.

## The Synthesis of Boron Trichloride

BY DALLAS T. HURD

A well known and convenient method for preparing small amounts of boron trichloride or boron tribromide comprises passing boron trifluoride gas over aluminum chloride or aluminum bromide.[1] I recently have found that a reaction may occur at elevated temperatures between aluminum chloride and boric oxide to produce boron trichloride.

**Experimental.**—120 grams of anhydrous boric acid and 440 g. of aluminum chloride were ground together and placed in a steel pressure vessel. The reaction mixture was heated at 350° for sixteen hours. The bomb then was cooled and the gaseous reaction product was bled off and caught in a trap held at −80°. The collected product was a clear colorless liquid boiling at 12° (reported boiling point of boron trichloride +12.5°). This material fumed in moist air, reacting with the moisture to produce white solid boric acid. A small amount of the liquid was dissolved in water to give a solution which, when tested with silver nitrate, gave a strong test for chloride.

The total amount of product collected was 30 g. or about 7.5% yield based on a complete conversion of boric oxide to boron trichloride.

It also was observed that a molten mixture of boric oxide and calcium chloride at 800–900° evolved boron trichloride very slowly and became more viscous, precipitating an infusible residue in the magma. This solid residue was treated with water after it was cool and a strongly alkaline solution resulted, indicating a conversion of some of the calcium chloride to calcium oxide.

**Discussion.**—The low yields of boron trichloride are ascribed to: (1) the reaction between aluminum chloride and boric oxide to form aluminum oxide and boron trichloride may be an equilibrium reaction which did not go to completion in the sealed bomb; and/or (2) part of the boric oxide may become bound chemically as aluminum borate by reaction with the aluminum oxide as this material is formed. It is noteworthy that attempts to prepare boron trichloride by a reaction of sodium borate or tetraborate with aluminum chloride were unsuccessful at reaction temperatures up to 350°.

## Reactions of Polyhaloparaffins with Grignard Reagents. 1,1,1-Trichloropentane

BY CORLISS R. KINNEY AND WILLIAM L. SPLIETHOFF

Binaghi[1] has shown that chloroform and carbon tetrachloride react readily with ethylmagnesium bromide, but that gaseous reduction products are formed for the most part. We have reëxamined the reaction from the point of view of controlling its course for the production of tri- and tetrasubstituted paraffins. However, even at −78°, using the less reactive *n*-butylmagnesium chloride, and carrying the halide into the reaction flask vaporized in a stream of dry nitrogen, a vigorous reaction occurs and the products are largely gaseous.

On the other hand, the reaction may be controlled to a certain extent by using the inverse Grignard technique. Thus, adding *n*-butylmagnesium chloride to a solution of carbon tetrachloride in ether gives a small yield of the first step in the reaction, 1,1,1-trichloropentane. The new compound loses hydrogen chloride at about 140° but could be vacuum distilled without decomposition. This thermal instability further indicates activity of the vicinal chlorine atoms. No attempt was made to treat this compound with additional Grignard reagent, but instead the more available 1,1,1-trichloroethane was investigated. This compound, like chloroform, gave largely

(1) Binaghi, *Gazz. chim. ital.*, **52**, II, 132–138 (1922); **53**, 879 (1923).

gaseous products and the reaction appeared to be unsuited as a synthetic method. To complete the series, methylene chloride also was tried but did not react at the boiling point of ether. These results indicate a marked difference in the reactivity of vicinal chlorides at the trichloro level. This is of interest in connection with the behavior of chloral for which only reduction at the carbonyl group with aliphatic Grignard reagents containing β-hydrogen atoms has been reported[2] and the behavior of monochloroacetone which was found to react with isoamylmagnesium bromide at the chlorine atom as well as adding on the reagent at the carbonyl group.[3]

Considering the violence of the reaction of carbon tetrachloride, even at −78°, carbon tetrafluoride was also treated with *n*-butylmagnesium chloride at the boiling point of ether. However, no reaction was observed.

### Experimental

**1,1,1-Trichloropentane.**—*n*-Butylmagnesium chloride was prepared from one mole of *n*-butyl chloride, one gram atom of magnesium and 300 ml. of dry ether. The solution was forced by means of dry nitrogen under pressure, into a stirred mixture of 2 moles of carbon tetrachloride and 300 ml. of dry ether cooled in a bath of Dry Ice and acetone. A vigorous reaction occurred with the formation of a white precipitate and a gas which decolorized bromine in carbon tetrachloride. White fumes were also formed which settled on the walls of the flask as a white solid. Since this was very soluble in water it was concluded that it was magnesium chloride. After the reagent had been added the cooling bath was removed and the mixture allowed to come to room temperature and stand for two hours. It was then refluxed gently for forty-five minutes and after cooling was decomposed with ice-water. Some basic magnesium precipitate was filtered out with suction and the organic layer separated, dried with calcium chloride and distilled to 100° to remove ether and excess carbon tetrachloride. The residue weighed about 30 g. and constituted a crude yield of 16.5%. On continuing the distillation, hydrogen chloride was evolved copiously at about 140°; consequently, the residue was vacuum distilled. Refractionation at 20 mm. through a 10-plate column packed with glass helices gave a heart-cut boiling at 56–57°. The index of refraction was $n^{20}D$ 1.4540.

## Decomposition of Aliphatic Azo Compounds

BY FREDERICK M. LEWIS AND MAX S. MATHESON

Certain aliphatic azo compounds have several properties which make them especially suitable as sources of free radicals for kinetic investigations. These properties include stability, clean first order decompositions nearly independent of reaction media, and the ability to act as efficient photosensitizers in the near ultraviolet.

The decomposition rates (Table I) as measured by nitrogen evolution, were in all cases first order after a short induction period, probably due to a thermal adjustment after sample addition and to the disappearance of oxygen traces introduced with the sample. Thiele and Heuser[1] and Dox[2] have described the method of preparation of these compounds. Further, it has been shown that 2-azo-bis-isobutyronitrile heated at 110° in high boiling petroleum ether quantitatively splits out nitrogen, tetramethyl succinonitrile being formed in 50% yield.[1] Of course such fragments of the azo compound as initiate polymerization in the presence of monomer will not appear as tetramethyl succinonitrile.

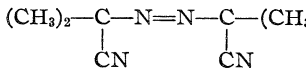

TABLE I

DECOMPOSITION OF AZO COMPOUNDS IN XYLENE AT 80°

| Material, 0.1–0.3 mole/l. | *k*, min.$^{-1}$ | *Ea*, kcal. |
|---|---|---|
| 2-Azo-bis-isobutyronitrile | 0.0092 | 31.3 |
| 2-Azo-bis-2-methylbutyronitrile | .00598 | 29.4 |
| 2-Azo-bis-2-methylheptonitrile | .0107 | 30.2 |
| 1-Azo-bis-1-cyclohexanecarbonitrile | .000282 | 39.9 |
| Dimethyl-2-azo-bis-isobutyrate | .00653 | 35.8 |
| 4-Azo-bis-4-cyanopentanoic acid | .00538[a] | 34.0 |

[a] In water, insoluble in xylene.

Table II shows that there is little change in rate for 2-azo-bis-isobutyronitrile (sold as Porofor N by Naugatuck Chemical Division of U. S. Rubber Co.) with widely different reaction solvents, and

even a powerful inhibitor (tetrachloroquinone) has little effect. Accordingly these materials offer several advantages over peroxides as free radical sources when a constant rate of production of radicals is desired. (As an example of free radical activity 0.096 g./l. of Porofor N in purified vinyl acetate induces 4.7% polymerization per hour at 50°.) Several authors[3] have shown that

the rate of decomposition of benzoyl peroxide varies widely with solvent and concentration.

These compounds are highly efficient photosensitizers as well as thermal initiators for free radical reactions. An absorption band has its peak at 3500 Å. (measurements on 2-azo-bis-isobutyronitrile) so that the compounds are especially suited for work using the 3660 Å. line of the mercury arc. Table III illustrates some results obtained in irradiations with Type A Hanovia mercury arc light filtered through Pyrex. Because of the characteristics of the absorption, the absorbed light is >80% 3660 Å. Slightly smaller values than those given in the Table have been found for 2-azo-bis-isobutyronitrile using monochromatic 3660 Å. radiation. The quantum yields show the aliphatic azo nitriles to be superior in efficiency to such a photosensitizer as biacetyl.[4] The first six compounds in the table vary little in efficiency in styrene, and the variations in vinyl acetate are probably less than shown, as it is believed the reactions with vinyl acetate overheated several degrees. These polymerizations were carried out *in vacuo* to eliminate the effects of oxygen. Light intensities were measured with the uranyl oxalate actinometer.

## Reaction of Hydrogen Bromide with Di-*t*-butyl Peroxide

BY NICHOLAS A. MILAS AND CHARLES N. WINNICK[1]

Vaughan and Rust[2] claimed the preparation of di-*t*-butyl peroxide by the vapor oxidation of isobutane in the presence of hydrogen bromide. More recently Raley, Rust and Vaughan[3] reported that hydrogen chloride sensitizes the vapor phase decomposition of di-*t*-butyl peroxide, but that under comparable conditions hydrogen bromide has little effect on this decomposition. However, the behavior of hydrogen bromide with liquid di-*t*-butyl peroxide is different. We have found recently that at 0° it reacts rapidly and exothermically with di-*t*-butyl peroxide in accordance with the equations

$$(CH_3)_3COOC(CH_3)_3 + 4HBr \longrightarrow 2(CH_3)_3CBr + Br_2 + 2H_2O \quad (1)$$

$$(CH_3)_3CBr + Br_2 \text{ (peroxide)} \longrightarrow (CH_3)_2CBrCH_2Br + HBr \quad (2)$$

The validity of the second reaction was determined experimentally by allowing *t*-butyl bromide to react with bromine in the presence of di-*t*-butyl peroxide as a catalyst. A yield of 64% of isobutylene dibromide was obtained.

### Experimental

**Reaction of Di-*t*-butyl Peroxide with Hydrogen Bromide.**—A sample (16.4 g., 0.181 mole) of di-*t*-butyl peroxide prepared and purified according to directions given elsewhere[4] was cooled to 0° and a slow stream of hydrogen bromide (Dow Chemical Co.) from a tank was allowed to come in contact with the peroxide. The reaction, which was immediate and exothermic, was continued for three hours, the temperature being kept as close to 0° as possible. At the end of this period the mixture separated into two distinct layers which were separated and weighed. The bromine was estimated in each layer iodimetrically and the hydrogen bromide plus bromine by titration against standard alkali. The water in the aqueous layer was estimated by difference. The remainder of the non-aqueous layer was washed with concentrated sodium bisulfite solution, dried over anhydrous magnesium sulfate, then fractionated. A fraction (24 g.) boiling at 72–73° was collected; $n^{25}D$ 1.426. This was identified as *t*-butyl bromide. Another fraction (21.4 g.) was collected at 143–145° which was refractionated through a six-plate Podbielniak column; b. p. 145–148°; $n^{25}D$ 1.5050; $d^{25}_{25}$ 1.7426. From the analysis and physical constants, this fraction was identified as isobutylene dibromide. *Anal.* Calcd. for $C_4H_8Br_2$: C, 22.22; H, 3.70; Br, 74.07. Found: C, 22.44; H, 3.87; Br, 74.62. In addition to the two bromides, a black residue remained in the distillation flask.

From 26.4 g. (0.181 mole) of di-*t*-butyl peroxide and excess hydrogen bromide, we obtained 0.1685 mole (92.2%) of bromine (free 0.0695 mole; reacted, 0.099 mole), 0.35 mole of water (96.6%), and 0.274 mole of *t*-butyl bromide (0.175 mole) plus isobutylene dibromide (0.099 mole).

**Catalyzed Bromination of *t*-Butyl Bromide.**—A mixture of 50 g. of *t*-butyl bromide and 5 g. of di-*t*-butyl peroxide was cooled to 0° and to it was added slowly with frequent shaking 58 g. of liquid bromine. No apparent reaction was noticed during the first few minutes of bromine addition, then a vigorous reaction set in with copious evolution of hydrogen bromide. The reaction mixture was allowed to stand overnight at 0°, then shaken with anhydrous potassium carbonate and distilled. Only 7 g. distilled below 90°, 76 g. between 90–160° and a small tarry residue remained in the distilling flask. The main product was fractionated and the fraction (51 g., 64%) boiling at 148–151° collected and identified as isobutylene dibromide; $n^{26}D$ 1.5075.

## Base Strength of Urea and Thiourea in Methanol

BY RALPH G. PEARSON AND JAMES TUCKER

In some work with solutions containing thiourea and strong acids dissolved in methanol it became apparent that salt formation was appreciable even though thiourea is generally considered too weak a base to form salts stable in solution. The explanation lies in the inherent weak basicity of methanol which causes other bases to appear abnormally strong in this solvent.[1]

The hydrolysis constants for thiourea and urea in dry methanol were determined by a conductimetric method essentially the same as that used by Goldschmidt and Dahlls[1a] to find the base strength of water in methanol. β-Naphthalenesulfonic acid was recrystallized from water and dried to the composition of the monohydrate in a vacuum oven at 60°. Methanol was dried by the use of magnesium turnings.[2] C. P. thiourea and urea were used.

Resistances were measured at 25.0 ± 0.03° on a Jones bridge of solutions containing a fixed amount of acid and varying amounts of base. If $R_0$ is the resistance of the solution containing only acid and $R$ the resistance of a solution with added base, then $R/(R - R_0)$ plotted against the reciprocal of the base concentration[3] gave straight lines which could be extrapolated to infinite base concentration. From this a value of $R_\infty$ could be found corresponding to the resistance of a solution completely converted to the salt of the base. From $R_0$, $R_\infty$ and $R$ the fraction of acid converted to salt could be found for each solution and the concentration equilibrium constant, $K_h$, for the reaction could be determined.

$$BH^+ + CH_3OH \rightleftharpoons B + CH_3OH_2^+ \qquad (1)$$

Table I shows the experimental results, the calculated values of $R_\infty$ and the average value of $K_h$ for each base. The effect of urea and thiourea on the resistances of methanolic solutions of lithium acetate and potassium chloride was checked and found to be negligible except for the more concentrated urea solutions. Assuming the effect here to be due to viscosity, an equivalent correction was made on the measured conductances of the acid solutions before any calculations were made.

## Isomerization of Saturated Hydrocarbons. VI.[1] Effect of Benzene upon the Isomerization of Methylcyclopentane

BY HERMAN PINES, EUGENE ARISTOFF[2] AND V. N. IPATIEFF

The study of the isomerization of *n*-butane[3] and cyclohexane and methylcyclopentane[1] in the presence of aluminum bromide–hydrogen bromide catalyst using a high vacuum technique and highly purified materials has been reported recently. This work has shown that under certain carefully controlled conditions the isomerization of saturated hydrocarbons does not proceed unless a small amount of an olefin or an alkyl or cycloalkyl halide is present.

In the study of isomerization of methylcyclopentane it was found that small amounts of impurities which are present commonly in this hydrocarbon, such as benzene, have a profound effect upon the rate of isomerization. By fractional distillation it is difficult to eliminate the last traces of benzene; this can, however, be accom-

(1) For paper V of this series see H. Pines, B. M. Abraham and V. N. Ipatieff, THIS JOURNAL, **70**, 1742 (1948).

plished by passing methylcyclopentane over silica gel.[4]

The following table shows the inhibiting effect of benzene upon the isomerization of methylcyclopentane promoted by *s*-butyl bromide. The experiments were carried out by a general procedure described previously[3]; the reaction temperature was 25° and the duration of each experiment was two hours. On the average about 0.04 mole of methylcyclopentane was used in each experiment.

TABLE I

EFFECT OF BENZENE UPON THE ISOMERIZATION OF METHYLCYCLOPENTANE

| Expt. | Reagents used: moles per 100 moles of methylcyclopentane $AlBr_3$ | HBr | *s*-$C_4H_9Br$ | Benzene | Cyclohexane formed, mole % |
|---|---|---|---|---|---|
| 1 | 2 | 1.0 | 0.0 | 0.000 | 0 |
| 2 | 2 | 0.9 | .1 | .000 | 51 |
| 3 | 2 | .9 | .1 | .022 | 22 |
| 4 | 2 | .9 | .1 | .072 | 5 |
| 5 | 2 | .9 | .1 | .140 | 3 |
| 6 | 2 | 1.0 | .0 | .140 | 0 |

The concentration of benzene in methylcyclopentane was determined by ultraviolet analysis. Experiment 4 was made by the addition of benzene to a purified sample of methylcyclopentane.

The inhibiting effect of benzene upon the isomerization, which was also observed to occur in the case of *n*-pentane,[5] is probably due to the ease with which the benzene reacts with the chain initiator. The ultraviolet absorption spectra taken of the hydrocarbons obtained from experiment 5 after removal of the catalyst by washing show that probably a mono-alkylbenzene was formed during the reaction. The absorption spectrum of the methylcyclopentane containing 0.14% of benzene and that of the reaction product was taken. The spectrum of the product showed a slight peak at 258.5 mμ where *s*-butylbenzene has a strong absorption band.

In expt. 3 the benzene caused only a partial inhibition of isomerization. This is not surprising since the molal ratio of *s*-butyl bromide to benzene used was over four, and the alkylation usually does not proceed beyond the formation of a tributylbenzene. There was therefore still some *s*-butyl bromide left to act as a chain initiator.

It was also noticed that in the experiments 3, 4, and 5 where benzene and *s*-butyl bromide were used an oily-yellow layer deposited on the walls of the reaction tube; in all the other experiments the product was homogeneous and free of color.[6] It is probable that the alkylbenzenes or cycloalkylbenzenes produced in the reaction formed a complex with the aluminum bromide and hydrogen bromide, similar to the type reported by Norris and Rubinstein.[7]

The inhibition of the isomerization of methylcyclopentane by benzene is in accordance with the proposed chain mechanism of isomerization.[1,8]

In the presence of benzene the chain may break by the reaction

$$[R^+AlBr_4^-] + \bigcirc \longrightarrow \bigcirc\!\!-R + AlBr_3 + HBr$$

$R^+$ may correspond to the carbonium ion obtained from the original olefin or from the product resulting from an exchange reaction between methylcyclopentane or cyclohexane formed and the *s*-butylcarbonium ion.

(5) J. M. Mavity, H. Pines, R. C. Wackher, and J. A. Brooks, *Ind. Eng. Chem.*, **40**, 2374 (1948).

(6) In the last paper of this series[1] it was reported that the isomerization of methylcyclopentane to cyclohexane was usually accompanied by the formation of an oily layer even though the methylcyclopentane used did not contain any traces of benzene. It was observed now that when methylcyclopentane is further purified by passing it over silica gel certain impurities not detectable by spectrographic analysis and responsible for the formation of an oily layer are removed.

## Synthesis of 7-Chloro-4-[1-methyl-(1-pyrrolidyl)-butylamino]-quinoline

BY ROBERT H. REITSEMA AND JAMES H. HUNTER

Studies on the effects resulting from an exchange of a pyrrolidyl group for a dialkylamino substituent in various chemotherapeutic agents[1] has now been extended briefly into the field of antimalarials. The synthesis of 7-chloro-4-[1-methyl-4-(1-pyrrolidyl)-butylamino]-quinoline (I), the pyrrolidyl analog of Chloroquine (II) was undertaken in consequence of the utility reported[2] for the latter in the control of malaria.

(2) Wiselogle, "A Survey of Antimalarial Drugs," Vol. I, J. W. Edwards, Ann Arbor, 1946, pp. 388-392.

Preparation of 5-(1-pyrrolidyl)-2-aminopentane (III) from ethyl acetoacetate and β-1-pyrrolidylethyl chloride[1a] was patterned after the synthesis used for noval diamine.[3] Alkylation of III with 4,7-dichloroquinoline occurred smoothly to give the desired aminoquinoline (I).

In suppressive tests on *p. gallinaceum* in the chick, the order of activity and toxicity of I was analogous to that of Chloroquine.[4]

### Experimental

**5-(1-Pyrrolidyl)-3-carbethoxypentanone-2.**—A solution of 400 g. (2.35 moles) of pyrrolidylethyl chloride hydrochloride in 200 ml. of water was treated with Nuchar C twice. The resulting light yellow solution was covered with 200 ml. of benzene, cooled to 5° and cold 50% potassium hydroxide was added with stirring and cooling below 12°. The upper organic layer was separated and the aqueous layer extracted twice with 100-ml. portions of benzene. Titration of a sample of the combined layers indicated 2.25 moles of base in solution or 96% of theory.

The sodium salt of 172 g. of acetoacetic ester in 1 l. of dry benzene was prepared with 26.0 g. of sodium sand. After addition of the ester was complete the mixture was boiled under reflux for one hour. One half of the above benzene solution of pyrrolidylethyl chloride was added dropwise. No reaction was apparent and the mixture was boiled under reflux for ten hours. After two hours nearly all the material was in solution.

**5-Pyrrolidylpentanone-2.**—To the above solution was added dilute sulfuric acid (from 160 ml. of water, 140 g. of ice, and 75 ml. of sulfuric acid). When about two-thirds of the acid had been added the solution was filtered and the layers separated. The remainder of the acid was used to dissolve the solid on the filter and to wash the benzene layer. The combined aqueous layers were washed with 100 ml. of benzene. The benzene was removed by distillation and the residual solution was boiled under reflux for seventeen hours. To the cooled solution was added 430 ml. of 30% sodium hydroxide with cooling and an organic layer of 184 g. was removed. The aqueous layer was extracted three times with 100-ml. portions of benzene. The dried organic layer was distilled to give 129 g. (74%) of material boiling at 92–98° (11–13 mm.). Redistillation of this gave a fraction which weighed 98.2 g.; b. p. 93–95° (11 mm.), $n^{20}D$ 1.4589.

*Anal.* Calcd. for $C_9H_{17}NO$: C, 69.63; H, 11.04; N, 9.02. Found: C, 70.10; H, 11.07; N, 8.35.

**5-Pyrrolidyl-2-aminopentane.**—A solution of 88.1 g. (0.568 mole) of 5-pyrrolidylpentanone-2, in a mixed solvent consisting of 100 ml. of dry ammonia and 100 ml. of dry methanol was reduced in two portions in the presence of Raney nickel catalyst. Reduction was complete after one and one-third to two hours at 100°. After filtration and removal of solvent the residue was distilled to give 86.8 g. of 5-pyrrolidyl-2-aminopentane, b. p. 92–97° (11–12 mm.), $n^{20}D$ 1.4665. This was purified through the dithiocarbamate[5] to give a product which boiled at 93–94° (11 mm.), $n^{20}D$ 1.4674.

*Anal.* Calcd. for $C_9H_{20}N_2$: C, 69.17; H, 12.89. Found: C, 69.45; H, 12.44.

The picrate after recrystallization from ethanol melted at 148–149°.

*Anal.* Calcd. for $C_{21}H_{26}N_8O_{14}$: C, 41.04; H, 4.27. Found: C, 41.06; H, 4.27.

**7-Chloro-4-[1-methyl-4-(1-pyrrolidyl)-butylamino]-quinoline.**—A mixture of 29.0 g. (0.147 mole) of 4,7-dichloroquinoline and 50.0 g. (0.322 mole) of 5-pyrrolidyl-2-aminopentane was heated with stirring for six hours at 160–170°. The cold mixture was taken up in 120 ml. of 50% acetic acid with cooling. After addition of 100 ml. of ether, 140 ml. of 30% sodium hydroxide was added to give a strongly basic solution. The mixture was shaken, the ether layer separated, and the aqueous layer was extracted with three 100-ml. portions of ether. The combined ether extracts were dried over magnesium sulfate. After removal of the solvent, 20.1 g. of an oil boiling at 93° (11 mm.) was obtained leaving a residue of 45.7 g. (98%). A portion (31 g.) of this dark green fluorescent residue was taken up in 100 ml. of hot methylcyclohexane. Upon cooling 28 g. of yellow solid, m. p. 98–107°, was obtained. Three recrystallizations from methylcyclohexane gave some oily solid as a first precipitate and 13 g. of white 7-chloro-4-[1-methyl-4-(1-pyrrolidyl)-butylamino]-quinoline, m. p. 110–111°.

*Anal.* Calcd. for $C_{18}H_{24}N_3Cl$: C, 68.01; H, 7.61; N, 13.22. Found: C, 68.11; H, 7.52; N, 12.68.

## The Preparation and Properties of *cis*-(0.3.3)-Bicycloöctane

BY A. W. RYTINA,[1] ROBERT W. SCHIESSLER AND FRANK C. WHITMORE[2]

*cis*-(0.3.3)-Bicycloöctane  was prepared previously in very small quantity by Linstead and Cook[3] by heating the semicarbazone of *cis*-α-(0.3.3)bicycloöctanone with potassium hydroxide at 200–210°. A small-scale trial of this method by the present workers resulted in a poor (less than 40%) yield of hydrocarbon, therefore the conversion of the ketone to hydrocarbon was accomplished by the modified Wolff–Kishner reaction.[4] A 68% yield of bicycloöctane was realized, based on carefully purified material.

The hydrocarbon was purified by fractional distillation through a 25-plate helix-packed column, and the following properties determined.

| °C. | Density,[a] g./ml. | Viscosity,[b] cp. |
|---|---|---|
| 0.0 | 0.8863 | 2.839 |
| 20.0 | .8695 | 1.859 |
| 37.8 | .8543 | 1.350 |
| 60.0 | .8353 | 0.9598 |

B. p.: 136.5° (±0.2°) at 738.3 mm.

M. p.: *ca.* −49° (much difficulty was encountered with glass formation)

$n^{20}D$: 1.4622

Mol. refraction (20°C.): found 34.85; calcd. 34.76

[a] ±0.0001; corrected for air buoyancy. [b] ±0.2%.

### Experimental

Following the method of Linstead,[3] a total of 300 g. of pure *cis*-α-(0.3.3)bicycloöctanone was prepared from indene by hydrogenation to hydrindene, sulfonation, fusion with potassium hydroxide of the resultant 5-hydrin-

denesulfonic acid, hydrogenation to 5-hydrindanol, nitric acid oxidation to 1-carboxy-2-cyclopentane-beta-propionic acid,[3] and cyclo-decarboxylation to the desired ketone over barium oxide.

To a 300-ml. Aminco hydrogenation bomb was charged 53 g. (0.43 mole) of purified *cis*-α-[0.3.3]bicycloöctanone, 43 g. (0.86 mole) of 100% hydrazine hydrate, 225 g. (4.0 moles) of potassium hydroxide and one liter of triethylene glycol.[4] The mixture was shaken at 195° for twenty-three hours in the sealed bomb. After cooling to room temperature, the reaction mixture was removed from the bomb (foaming), diluted with water, and the mixture steam-distilled. The two liters of steam distillate was acidified with 10% hydrochloric acid and extracted with 400 ml. of ethyl ether. The ether was removed from the separated, dried organic layer by distillation through a 20-plate fractionating column. To the residue was added 35 ml. of 2-octanone, and the mixture carefully fractionated through a 20-plate column to yield 32 g. of material boiling at 136–137° at 735 mm.

This product was combined with 19 g. of material prepared by the semicarbazone method[3] and distilled through a 25-plate column, yielding 49.5 g. of constant boiling, constant index *cis*-(0.3.3)bicycloöctane, b. p. 137° (735 mm.), $n^{20}D$ 1.4622. The hydrocarbon was filtered through a 2 × 20 cm. tube filled with activated silica gel (28–200 mesh), and the physical properties determined.

## The Preparation of α-Trifluoro-*p*-phenylacetophenone

BY J. H. SAUNDERS, R. J. SLOCOMBE AND EDGAR E. HARDY

Trifluoroacetic acid was converted to the acid chloride and this in turn to α-trifluoro-*p*-phenylacetophenone with an over-all yield of 53%. Recrystallization of this compound from methanol apparently gave the solvated ketone containing one molar equivalent of methanol.

**Trifluoroacetyl Chloride.**—A 1-liter 3-necked flask was equipped with a dropping funnel, stopper, and an 8-in. helix-packed column. A partial take-off still-head and a Hopkins type, Dry Ice-cooled condenser were attached to the column. The head and condenser gas outlet were then connected to a Dry Ice trap. Two hundred sixty grams (1.25 moles) of phosphorus pentachloride was placed in the flask and 96 g. (0.84 mole) of trifluoroacetic acid was added in 5-cc. portions. To ensure complete reaction the system was maintained under total reflux while the first 5 cc. of acid was added and for an additional ten minutes. Then all of the acid chloride produced from this portion of acid was distilled into the cold receiver before adding the next 5 cc. of acid. Proceeding in this manner about six hours were required for the entire reaction. When all of the acid had been added and had reacted the flask and its contents were warmed to 50° to drive out the last traces of acid chloride. The yield of the clear, straw-colored liquid, which contained some hydrogen chloride, was 119 g.

**α-Trifluoro-*p*-phenylacetophenone.**—The method of Simons and Ramler[1] was followed. From 205 g. (1.33 moles) of biphenyl, 178.5 g. (1.33 moles) of aluminum chloride, and the acid chloride from 96 g. (0.84 mole) of trifluoroacetic acid there was obtained 114 g. (55.6%) of recovered biphenyl and 112 g. (53.4% based on trifluoroacetic acid, 75.6% based on biphenyl consumed) of α-trifluoro-*p*-phenylacetophenone, b. p. 130–133° (3 mm.). After recrystallization from 60–70° petroleum solvent the compound melted at 51.2–51.4°.

*Anal.*[2] Calcd. for $C_{14}H_9OF_3$: C, 67.20; H, 3.62. Found: C, 67.48; H, 3.84.

When this product was recrystallized from methanol or methanol and water a new compound, m. p. 102.5–103.5°, was obtained. When this compound was heated above its melting point a condensable gas, presumably methanol, was evolved, and the residue again melted at 51.0–51.4°. Analysis indicated the presence of one mole of methanol per mole of ketone. The difficulty with which a solid of constant melting point was obtained indicated that this compound may have been unstable in methanol solution or that other states of solvation may have existed.

*Anal.* Calcd. for $C_{15}H_{13}O_2F_3$: C, 63.83; H, 4.64. Found: C, 64.03; H, 4.37.

The α-trifluoro-*p*-phenylacetophenone was insoluble in 10% sodium hydroxide solution but was rapidly hydrolyzed by warm alkali. The observed products were a gas, doubtless fluoroform,[1] and biphenyl-4-carboxylic acid, m. p. 226–228°. Gull and Turner reported m. p. 228° for this acid.[3]

## Chlorination of *t*-Butylbenzene to 1-Chloro-2-methyl-2-phenylpropane

BY WILLIAM E. TRUCE, E. T. MCBEE AND C. C. ALFIERI

The side chain of *t*-butylbenzene has been considered too inert to undergo reaction directly with the halogens. It was claimed that chlorination of *t*-butylbenzene in the presence of sunlight caused ring substitution only.[1] However, we chlorinated *t*-butylbenzene to 1-chloro-2-methyl-2-phenylpropane in 48% conversion. (This compound had been obtained previously by the peroxide-induced chlorination of *t*-butylbenzene with sulfuryl chloride.[2])

Proof of structure consisted of oxidizing the product to benzoic acid in small yield with alkaline potassium permanganate,[3] and carbonation of the corresponding Grignard reagent to the known 3-methyl-3-phenylbutyric acid[4] in 49% over-all conversion. The poor yield of benzoic acid in the above oxidation is to be anticipated for *t*-alkylbenzenes.[5] The preparation of the Grignard reagent was difficult to initiate. When the reaction started, it proceeded slowly but smoothly and an

82% conversion of halide to Grignard reagent was achieved as determined by titration.[6]

### Experimental

Three moles (402 g.) of *t*-butylbenzene was placed in a long reaction tube which was strongly illuminated. Chlorine, which was first bubbled through a sulfuric acid absorption tube, was slowly bubbled through the hydrocarbon over a period of three hours until a total of three moles had passed. Subsequent rectification yielded 90 g. (0.67 mole) of *t*-butylbenzene, 240 g. (1.42 moles) of 1-chloro-2-methyl-2-phenylpropane, 45 g. of polychlorinated material and 70 g. of still residue. The physical constants of 1-chloro-2-methyl-2-phenylpropane are b. p. 111–112° (18 mm.), $n^{20}D$ 1.5245, and $d^{20}_4$ 1.047.

## Condensation of Saturated Halides with Unsaturated Compounds. VII. Condensation of Neopentyl Chloride with Ethylene[1]

BY LOUIS SCHMERLING AND E. E. MEISINGER

The metal halide catalyzed condensation of ethylene with alkyl halides (particularly chlorides and bromides) containing at least three carbon atoms offers a means of preparing 1-halo-3,3-dialkylalkanes.[2] The reaction of typical primary alkyl halides may be illustrated as:

An example of the reaction of ethylene with a third type of primary alkyl halide, namely, a 1-halo-2,2-dialkylalkane, will now be described. The condensation of neopentyl chloride with ethylene proceeded smoothly at −14 to −20° in the presence of aluminum chloride. There was obtained a 38% yield of chloroheptane which was identified as 1-chloro-3,3-dimethylpentane which is also the product of the condensation of ethylene with *t*-pentyl chloride. Isomerization of the neopentyl group to *t*-pentyl apparently occurred

The dissociation of the neopentyl chloride into the unstable positive neopentyl ion and the negative chloride ion is probably brought about by formation of a complex with the catalyst, $(CH_3)_3CCH_2^+AlCl_4^-$.

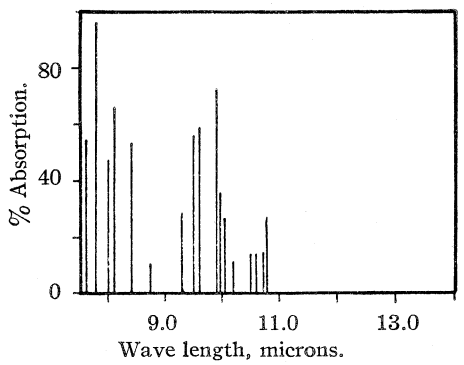

Fig. 1.—Infrared absorption spectrum of 1-chloro-3,3-dimethylpentane.

### Experimental

**Condensation of Neopentyl Chloride with Ethylene.**—A mixture of 40 g. (0.37 mole) of neopentyl chloride,[3] 50 g. of *n*-pentane diluent and 5 g. of aluminum chloride was placed in a three-necked flask immersed in a Dry Ice–acetone-bath. Ethylene was bubbled into the stirred mixture while the temperature was permitted to rise from −70 to −15° at which point absorption began (determined by difference of gas rates in inlet and outlet bubblers). The temperature was maintained at −14 to −20° for the duration of the addition of ethylene (three quarters of an hour) during which time the catalyst gradually coagulated. The liquid product was decanted from the 12 g. of yellow sludge and powder, washed with water, dried and distilled. There was obtained 19 g. (0.14 mole) of product b. p. 50–51° at 20 mm. pressure (150–151° at 760 mm.); $n^{20}D$ 1.4300. There was also obtained 22 g. of unidentified higher-boiling material which apparently consisted largely of chlorononane and chlorohendecane.

The product boiling at 50–51° at 20 mm. was shown to be 1-chloro-3,3-dimethylpentane by converting it to *β*-*t*-pentylpropionanilide by the method of Schwartz and Johnson[4]: m. p. 95–96°. This anilide did not depress the melting point of the analogous derivative of 1-chloro-3,3-dimethylpentane prepared by the condensation of *t*-pentyl chloride with ethylene.[2]

(1) Preceding paper in this series, THIS JOURNAL, **71**, 107 (1949).

(2) L. Schmerling, *ibid.*, **67**, 1152 (1945).

(3) Obtained by the chlorination of neopentane according to the method of F. C. Whitmore and G. H. Fleming, *ibid.*, **55**, 4161 (1933). We wish to thank Dr. Vladimir Haensel for the sample of neopentane which was prepared by the demethylation of neohexane: V. Haensel and V. N. Ipatieff, *Ind. Eng. Chem.*, **39**, 853 (1947).

Comparison of the infrared spectrum[5] (Fig. 1) of the product boiling at 50–51° at 20 mm. with that of the 1-chloro-3,3-dimethylpentane prepared from *t*-pentyl chloride and ethylene showed that samples contained at least 95% material in common.

(5) We are indebted to Dr. W. S. Gallaway, Physics Division, Universal Oil Products Company, for the infrared absorption analysis. For a description of the procedure used, see THIS JOURNAL, **69**, 1124 (1947).

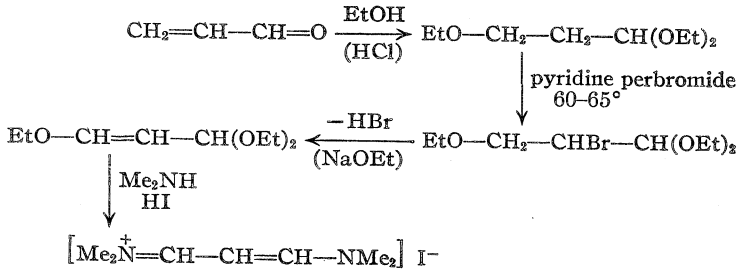
## Two Simple Amidinium Vinylogs[1]

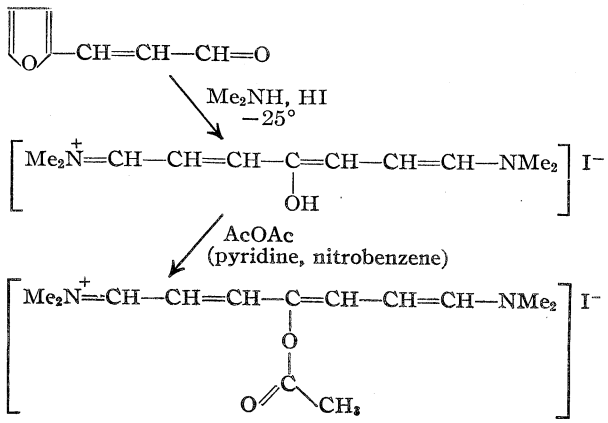
BY WILLIAM T. SIMPSON[2]



The vinylene homologous series

$$[Me_2\overset{+}{N}=CH-(CH=CH)_n-NMe_2]\ X^-$$

is interesting because of its simplicity[3] and yet its close relationship to several large families of dyestuffs. The second member ($n = 2$) was obtained by König and Regner.[4] Now the first member, ($n = 1$), N-methyl-(2-dimethylaminovinyl)-formimine methiodide, and a substance which is very closely related to the third member ($n = 3$) have been synthesized. The latter compound is N-methyl-(6-dimethylamino-3-acetoxy-1,3,5-hexatrienyl)-formimine methiodide



The former substance was prepared according to the scheme

The latter was synthesized by a splitting of the furan ring,[5] followed immediately by acetylation.

### Experimental

**β-Ethoxypropionaldehyde Diethylacetal.**—This material was prepared substantially as described by Pingert.[6] Since the yield of acrolein acetal is not important, the following changes in the procedure were made. The starting material, 80 g. (95 cc., 1.36 mole) of acrolein

(95% with stabilizer) was combined with 325 cc. (5.56 mole) of absolute ethanol (commercial). Approximately 0.7 g. of hydrochloric acid was used as a catalyst. The alcohol was removed under reduced pressure at 40–50°. The yield was 125.1 g. (52%); b. p. 95–97° (39 mm.). The material was used without further purification in the next step.

**Bromination of β-Ethoxypropionaldehyde Diethylacetal.**[7]—The acetal (67 g., 76 cc., 0.38 mole) and 30 g. (30.5 cc., 0.38 mole) of dry pyridine were combined. Then 61 g. (19.5 cc., 0.38 mole) of bromine was added at a rate of several drops a second. A mechanical stirrer operated continuously until the reaction was complete. After the bromine had been added the temperature was adjusted to 60–65°. The reaction was complete in two to four hours, as indicated by the disappearance of the red color of the pyridine perbromide. The reaction vessel was then washed with dry ether and the precipitate triturated with dry ether. Combined ether extracts were dried over anhydrous potassium carbonate and stored in an ice chest. Removal of the ether left 81 g. (83%) of the crude product. It was found that distillation of the crude material produced decomposition to the extent that a better yield in the next step was obtained if purification at this stage had been eliminated.

Dehydrobromination was carried out as described by Reitzenstein and Bonitsch.[8]

**N-Methyl-(2-dimethylamino-vinyl)-formimine Methiodide.**—Dimethylammonium iodide (6.0 g., 0.034 mole), 6.0 g. (0.034 mole) β-ethoxyacrolein diethylacetal, 4.8 g. (0.036 mole) 33% dimethylamine in methanol, and 10 cc. absolute methanol were sealed in a bomb tube. The tube was heated at 100° for five hours in the dark. The reaction mixture was washed with 200 cc. of ether; the precipitate which formed filtered and purified by several recrystallizations from acetic anhydride followed by ether throwdown. The material was dissolved in acetic anhydride at 100° and maintained at this temperature for five or ten minutes during each recrystallization. (This heating during recrystallization converted unchanged dimethylammonium iodide into ether soluble materials.) The yield after three recrystallizations was 3.8 g. (44%). An analytical sample was obtained after several additional recrystallizations from *n*-butyl alcohol. The pure material is crystalline, white with a faint suggestion of a metallic luster: m. p.[9] 188–188.5°.

**N-Methyl-(6-dimethylamino-3-acetoxy-1,3,5-hexatrienyl)-formimine Methiodide.**—Furylacrolein (1.0 g., 0.0082 mole) (Eastman Kodak Co., once recrystallized from ligroin), dissolved in 10 cc. of commercial isopropyl alcohol, was cooled to approximately −25°. A solution containing 1.4 g. (0.0079 mole) dimethylammonium iodide, 1.0 g. (0.0075 mole) of a 33% methanol solution of dimethylamine, and 5 cc. of isopropyl alcohol at room temperature was added to the furylacrolein suspension immediately upon its removal from the cooling bath. The addition, with shaking, required thirty seconds. The mixture was cooled immediately to −25° and kept at this temperature except for brief removal periods for stirring (at five-minute intervals). After thirty minutes the reaction mixture was removed from the cooling bath, 10 cc. of dry ether at 0° added, the solution stirred and filtered. The reaction flask and residue were washed with another cold 10-cc. ether portion. The residue was dried three minutes at the pump, and then transferred to a solution containing nitrobenzene (commercial) 100 cc., dry pyridine 10 cc., and acetic anhydride 10 cc. The solution was swirled until all of the crude material dissolved. The reaction required an hour at room temperature. The product was then thrown out with ether to give 1.2 g. (44%) of crude dye. Several recrystallizations from n-butyl alcohol gave an analytical sample with m. p. 191° (dec.). The crystals are a deep purple and possess a metallic luster.

*Anal.* Calcd. for $C_{13}H_{21}N_2O_2I$: C, 42.86; H, 5.81. Found: C, 42.89; H, 5.79.

of halogen compound and benzenesulfonhydrazide in the presence of one mole of hydrogen chloride (added as concentrated hydrochloric acid) increased the yields to 80–90%; the rate of condensation was also appreciably increased by this modification. The hydrochlorides were purified by crystallization from dilute or glacial acetic acid; excepting the pyrimidine derivative, the products were almost insoluble in water or dilute acids. Dilute bases produced the expected decomposition.[2]

1-Benzenesulfonyl-2-(7-chloroquinolyl-4)-hydrazine hydrochloride was also prepared, in 35% yield, by the action of benzenesulfonyl chloride on 7-chloro-4-hydrazinoquinoline in dry pyridine in the usual manner, followed by treatment of the product with dry hydrogen chloride in alcohol. The latter compound was prepared in 88.6% yield from 4,7-dichloroquinoline essentially by the general procedure of Koenigs and Loesch.[3] The compound formed white needles from alcohol, m. p. 231–232° (cor.) (dec.).

*Anal.* Calcd. for $C_9H_8ClN_3$: N, 21.70. Found: N, 21.68.

Surrey and Cutler[4] reported m. p. 220–221°.

1-Benzenesulfonyl-2-(5-nitropyridyl-2)-hydrazine was prepared from 2-hydrazino-5-nitropyridine[5] and benzenesulfonyl chloride in dry pyridine. This compound could not be prepared by the direct condensation of 2-chloro-5-nitropyridine with benzenesulfonhydrazide in either the presence or absence of hydrochloric acid.

The substituted hydrazines are listed in the accompanying table.

TABLE I

tetrachloride essentially as has recently been described by Whitmore.[2] In many runs we found it practical to dissolve the silicon tetrachloride in either pure benzene or a mixture of dry ether and benzene (recovered from previous runs) rather than in pure ether. Yields were ordinarily 20–45%. Isopropylmagnesium bromide, however, gave 5–6% yield of the trichloride,[3] together with an equal weight of the dichloride (11% yield, based on the Grignard reagent).

For the preparation of diisobutylsilicon dichloride equimolar quantities of the Grignard reagent and isobutylsilicon trichloride (in benzene) were placed in reaction. The yield was about 20%.

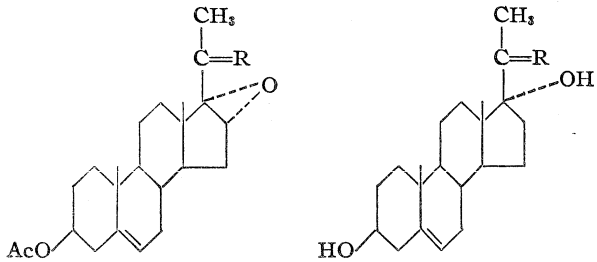
# COMMUNICATIONS TO THE EDITOR



## 17α-HYDROXYSTEROIDS

*Sir:*

The recent communication by Plattner, Heusser and Feurer[1] impels us to record certain work on the reduction of steroid oxides which has been under way in these Laboratories for some time.

We have likewise prepared Reichstein's substances J and O by the reduction of 16,17-oxido-allopregnane-3β-ol-20-one acetate with lithium aluminum hydride. Furthermore, we have investigated the lithium aluminum hydride reduction of 16,17-oxido-5-pregnene-3β-ol-20-one acetate. The nature of the resulting 3,17,20-triol mixture was confirmed by oxidation with periodic acid to dehydroisoandrosterone (m. p. 148–149°; acetate, m. p. 166–168°).

We wish, particularly at this time, to report a novel procedure for the preparation of 17α-hydroxy steroids bearing a ketone group at position 20. The focal point in the facile preparation of these derivatives has been the protection of the 20-keto group through the formation of cyclic ketals. The 16,17-oxido-20-ketals undergo smooth reduction with lithium aluminum hydride and the resulting products are readily cleaved to the desired 17α-ol-20-ones.

**16,17-Oxido-5-pregnene-3β-ol-20-one Acetate (I).**—Plates from methanol, m. p. 154–155°; $[\alpha]^{26}D$ −9.0° (chloroform). *Anal.* Calcd. for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66. Found: C, 74.43; H, 8.72. It was prepared by the action of perbenzoic acid on derivatives of 5,16-pregnadiene-3β-ol-20-one.

**Ketal of 16,17-Oxido-5-pregnene-3β-ol-20-one Acetate (II).**—From the oxido-pregnene (I) and ethylene glycol by refluxing a benzene solution with *p*-toluenesulfonic acid monohydrate as catalyst as thick, needle-like prisms from benzene-methanol, m. p. 195–197°; $[\alpha]^{27}D$ −37.8° (chloroform). *Anal.* Calcd. for $C_{25}H_{36}O_5$: C, 72.07; H, 8.71. Found: C, 71.92; H, 8.67.

**Ketal of 17α-Hydroxypregnenolone (III).**—From the reduction of the ketal (II) with lithium aluminum hydride in benzene–ether solution as plate-like prisms from acetone, m. p. 185–187°; $[\alpha]^{26}D$ −44.8° (chloroform). *Anal.* Calcd. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64. Found: C, 73.63; H, 9.70.

**17α-Hydroxypregnenolone (5-Pregnene-3β,17α-diol-20-one) (IV).**—From the ketal (III) by cleavage with sulfuric acid in aqueous methanol as fine prisms from methanol, m. p. 265°[2]; $[\alpha]^{23}D$ −34.4° (2 parts ethanol–1 part dioxane). *Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.42; H, 9.84. Acetylation of the 17α-hydroxypregnenolone with acetic anhydride-pyridine gave the acetate, needles from benzene–petroleum ether (b. p. 35–60°), m. p. 232–234°.[2]

By the Oppenauer oxidation of 16,17-oxidopregnenolone (16,17-oxido-5-prenene-3β-ol-20-one) we have incidentally prepared 16,17-oxidoprogesterone (16,17-oxido-4-pregnene-3,20-dione) as fine prisms from aqueous methanol, m. p. 205–207°; $[\alpha]^{27}D$ +160.8° (chloroform). *Anal.* Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59. Found: C, 76.50; H, 8.68.

The investigations are being continued.

## THE RESOLUTION OF SPARTEINE

*Sir:*

In consideration of the recently reported syntheses of sparteine[1,2] we wish to record herein the resolution of *dl*-sparteine, the total synthesis of which was first announced from this Laboratory.[3] Synthetic *dl*-sparteine was resolved by means of β-camphorsulfonic acid, and both *d*- and *l*-sparteine were isolated and identified.

Equimolar portions of racemic sparteine and *d*-β-camphorsulfonic acid in ethanol gave ***l*-sparteine *d*-β-camphorsulfonate.** After two recrystallizations from acetone the specific rotation remained constant, $[\alpha]^{29}D$ 24.8 ± 0.5° (*C*, 1.932 in chloroform), and consistent with that of an authentic sample of the *d*-β-camphorsulfonate of natural *l*-sparteine, $[\alpha]^{29}D$ 24.4 ± 0.5° (*C*, 2.298 in chloroform). Both natural and synthetic salts melted at 240–241°, as did a mixture of the two. ***l*-Sparteine dipicrate,** yellow needles, m. p. 207–208°, was prepared directly from the *d*-β-camphorsulfonate salt in ethanol by the addition of ethanolic picric acid (*Anal.* Calcd. for $C_{27}H_{32}N_8O_{14}$: C, 46.82; H, 4.66; N, 16.18. Found: C, 47.13; H, 4.54; N, 15.94). The melting point was depressed when the compound was mixed with *dl*-sparteine dipicrate, m. p. 208°, undepressed when mixed with natural *l*-sparteine dipicrate, m. p. 208°.[4]

Following the separation of the *l*-sparteine *d*-β-camphorsulfonate, *d*-sparteine-enriched base was freed from the mother liquor and was converted, by treatment with *l*-β-camphorsulfonic acid,[5] to ***d*-sparteine *l*-β-camphorsulfonate.** After three recrystallizations from acetone, this salt melted at 239–241° and exhibited a specific rotation, $[\alpha]^{22}D$ −24.0 ± 0.5° (*C*, 2.040 in chloroform), approximately equal and opposite to that of its antipode. ***d*-Sparteine dipicrate,** yellow needles, m. p. 208–209°, was prepared directly from the *l*-β-camphorsulfonate salt and showed no depression in melting point when mixed with the dipicrate of natural *d*-sparteine,[6] m. p. 208°.[7] ***d*-Sparteine monoperchlorate,** colorless needles, m. p. 174°, was prepared by dissolving *d*-sparteine *l*-β-camphorsulfonate in a small amount of water, acidifying to *p*H 1–2 with 65% perchloric acid, and then basifying with ammonium hydroxide. The perchlorate separated on cooling and was recrystallized from ethanol–ether. A mixture with the monoperchlorate of natural *d*-sparteine,[6] m. p. 173°,[7] was also 173°.

The infrared absorption spectra of natural *l*-, resolved *l*-, natural *d*-, and resolved *d*-sparteine dipicrates were determined[8] and were found to be identical for these samples in the crystalline state and very slightly different from that of crystalline *dl*-sparteine dipicrate.[3]

## CRYSTALLINE XYLAN AND MANNAN

*Sir:*

I wish to report the isolation of a crystalline xylan from barley straw and birchwood. The weaker linkages of the xylan-rich fraction of the hemicelluloses of these materials, purified by the method of Salkowski, were hydrolyzed under mild conditions (0.2% oxalic acid at 100°); the reducing value of the hydrolysate was virtually constant after five hours. The insoluble portion from the hydrolysis, on autoclaving at 120°, was soluble in water to the extent of about 0.2%; on cooling to 60–70°, hexagonal platelets with rounded corners separated. The xylan was purified by heating a water paste for five hours at 120°, readily filterable spherocrystals being obtained. Barley xylan is purified more readily than birch xylan. Aging of the amorphous xylan or contact with dilute alkali renders it insoluble in 3 *N* sodium hydroxide. Wet heat at 120° and *p*H 5 restores its solubility. Attempts to prepare a slash pine xylan failed. The crystals are doubly refractive and give typical crystalline X-ray diffraction patterns. Crystalline D-xylose was prepared in good yield and its identity confirmed. A diphenylhydrazine test for arabinose in the mother liquor was negative. This, coupled with the high pentosan analysis, indicates relatively pure xylan. Breddy–Jones and Wise–Appling xylose determinations on 3% nitric acid hydrolysates confirmed this finding. Osmotic pressure measurements on methylated barley xylan indicate a degree of polymerization of 39. A newly developed aldose end-group method gave the

| | Material from selective hydrolysis | | Repeatedly recrystallized xylan | |
|---|---|---|---|---|
| | Barley | Birch | Barley | Birch |
| Pentosans as xylan (cor. for uronic acids), % | 97.4 | 92.4 | 99.5 | 97.9 |
| Uronic anhydride (cor. for $CO_2$ from xylose), % | 2.4 | 6.4 | 0.38 | 2.39 |
| Ash, % | 0.85 | .. | 0.34 | 0.39 |

same value. Birch xylan, compared viscometrically with barley xylan, had a degree of polymerization of 35. Optical rotational measurements indicate a 1,4′,β-linkage. This is based on the rotational shift method of Reeves and comparisons with Haworth's esparto xylan.

Mannan "A" of ivory nut readily forms supersaturated solutions of 1% concentration. Such a solution crystallizes if heated to 60–70° for several days. The crystals initially are rods and gradually become dumb-bell shaped as growth continues. Slight double refraction is evident. A mannan-rich fraction from slash pine gave similar crystals. Repeated recrystallization did not alter the facility or habit of crystallization. The crystals assayed only 50% mannan and had a light tan color.

This work will be published in full at a later date.

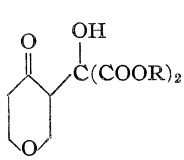
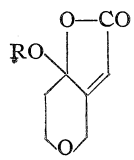
## THE STRUCTURE OF PATULIN

*Sir:*

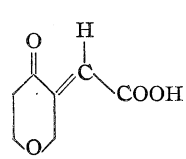
We are reporting elsewhere in detail the considerations which led us to reject the accepted structure[1] (I, *and/or* tautomers) for the well-known mold metabolite and antibiotic, patulin, in favor of a new expression (I, R = OH). Here we re-record the synthesis of (II, R = H), which we designate as *desoxypatulin*, since its relevant physical properties resemble those of patulin so closely as to provide very strong support for our structural views.



I



II



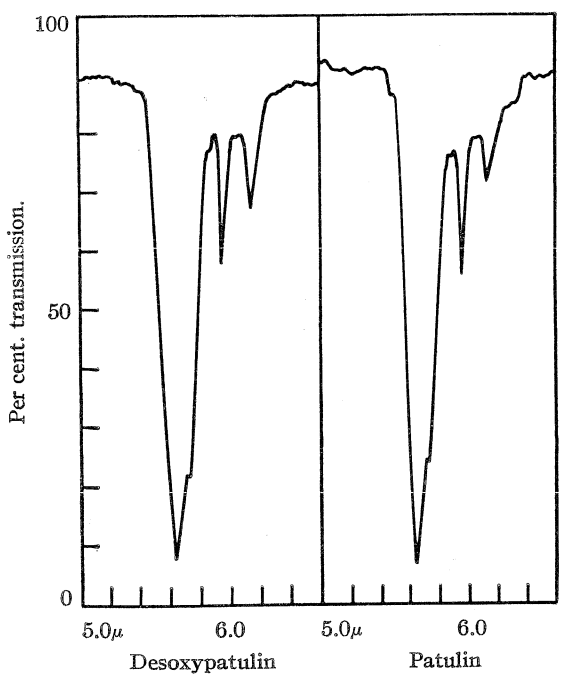
Condensation of tetrahydro-γ-pyrone with ethyl mesoxalate gave the ketol (III, R = Et), m. p. 58.5–60° (Calcd. for $C_{12}H_{18}O_7$: C, 52.55; H, 6.57. Found: C, 52.73; H, 6.67). When the corresponding acid (III, R = H) was heated with acetic anhydride and acetic acid, among the products obtained were: (i) the *cis*-acid (IV, R = H), m. p. 122–123° (Calcd. for $C_7H_8O_4$: C, 53.85; H, 5.13. Found: C, 53.77; H, 5.18), (ii) the lactol acetate (IV, R = Ac), m. p. 121.5–123° (Calcd. for $C_9H_{10}O_5$: C, 54.55; H, 5.05. Found: C, 54.64; H, 5.02), (iii) the *trans*-acid (V), m. p. 153° (Calcd. for $C_7H_8O_4$: C, 53.85; H, 5.13. Found: C, 53.89;

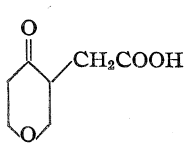
III

IV

V

H, 5.25). Treatment of (IV, R = Ac) with warm acetic anhydride–acetic acid–sulfuric acid[2] gave desoxypatulin (II, R = H), m. p. 46–48° (Calcd. for $C_7H_6O_3$: C, 60.80; H, 4.35. Found: C, 60.62; H, 4.37), whose ultraviolet spectrum possessed a single maximum at 273 mμ (log ε, 4.17) (patulin: $\lambda_{max.}$, 276 mμ (log ε, 4.22)), and whose infrared spectrum in the double bond region reproduced in detail the very characteristic spectrum of patulin in the same region (Fig. 1).





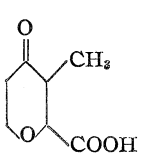


Fig. 1.—Spectra in $CH_2Cl_2$.

Further support for the structure (II, R = OH) was forthcoming when the oily acid (VI), obtained by the hydrogenation either of the *cis*-acid (IV, R = H) or the *trans*-acid (V), was shown to be identical, through comparison of the methyl ester 2,4-dinitrophenylhydrazones, m. p. 149–150°, with the acid $C_7H_{10}O_4$ originally obtained by Ber-

# NEW BOOK

**Carotinoide.** By PAUL KARRER AND ERNST JUCKER, Chemical Institute of the University of Zurich. (Lehrbücher und Monographien aus dem Gebiete der Exakten Wissenschaften, 17. Chemische Reihe, Band III.) Verlag Birkhäuser, Basel, Switzerland, 1948. 388 pp. 17 × 24.5 cm. Price, 39.-Swiss francs (paper binding); 43.-Swiss francs (linen binding).

With the rapid expansion of chemical research in the past twenty-five years, the organization and correlation of diverse observations in complex fields has become a great problem to all specialists, research workers, teachers and students. Although *Chemical Abstracts* and the numerous review journals provide leads to many isolated facts, there is as yet no satisfactory substitute for the comprehensive monograph written by an authority in the field. For this reason, there are widespread benefits when so productive research workers as Professor Karrer and his collaborator, Dr. Jucker, summarize the studies of the carotenoids, a highly specialized field in which they have made many significant contributions over a long period.

If a technical book is to be more than a handbook, the authors must select their material carefully, omitting the extraneous observations and including and emphasizing the pertinent facts that lead to progress in the field. The choice of material will of necessity reflect the aims, the interest and the experience of the writers. The readers, on the other hand, will examine the book from their particular points of view seeking new information often with a view toward further application in their own fields.

This new monograph on the carotenoids is divided into two parts; a general section of 100 pages and a special section of 231 pages. The general part contains rather brief descriptions of the state or condition of the carotenoids in plants and animals (4 pp.); the origin and physiological significance of the carotenoids in plants and animals (10 pp.); the isolation of the carotenoids (9 pp.); the chemical constitution of the carotenoids, represented by 31 formulas (8 pp.); *cis–trans* isomerization of the carotenoids (5 pp.); methods for determination of the chemical structure (10 pp.); relationship between constitution and color of the carotenoids (7 pp.); and partial syntheses of carotenoids (5 pp.). The last 35 pages of this general section are devoted to tables showing the occurrence of carotenoids in various species of plants and animals classified according to families. For these tables alone, 434 publications are cited. Here is a mass of information not readily available elsewhere.

The second part of this monograph describes the individual carotenoid pigments; particularly, their occurrence, with tables illustrating sources; methods for their preparation; their chemical constitution; their properties such as absorption maxima, solubility, optical activity, adsorbability, etc.; *cis–trans* isomers; and various derivatives of the pigments. Some 28 pigments of known structure and 37 pigments of unknown structure as well as numerous derivatives of these substances are described. Finally, there are 12 colored pictures of carotenoid crystals and 28 figures of spectral absorption curves determined in various solvents. Two indexes provide references to the plants and animals in which the pigments occur and to the usual subject matter.

All this diverse material has been brought together according to a carefully arranged outline, so that the included facts are readily found by readers with different points of view. As a result, this book provides a service to everyone interested in the carotenoid pigments, although at the price quoted ($13.50) it is rather expensive. Unfortunately, there are some omissions of important data; hence, this monograph cannot be relied upon as an impartial source of information.

All chemists, especially those in the food and fodder industries where determinations of the carotenoid pigments have contributed so much to the improvement of our food supply, will be amazed to find few if any references to the careful spectral absorption work carried out in the United States during the past fifteen years. Most of the American results, which have been obtained with different instruments calibrated in different ways and which are in remarkably good agreement, differ significantly from many of those presented in the monograph. As one example, Figure 28 showing lycopene with smaller absorption coefficients than carotenes is contrary to all this uncited experience and to the theories concerning the spectral absorption capacity of unsaturated compounds.

In view of Professor Karrer's contributions, chemists interested in the chromatographic adsorption method will not be surprised that so much emphasis has been placed upon the use of zinc carbonate as an adsorbent. They will be astonished, however, to find that so little attention has been devoted to other adsorbents which have been widely used and which occasionally have made possible separations and identifications not included in this monograph, specifically the separation of neoxanthin and violaxanthin and the confirmation of the identity of violaxanthin from leaves with violaxanthin from pansies. Variation of the adsorption sequence with variation of the solvent and adsorbent is not reported. For the one adsorption sequence of the carotenoids that is summarized in the form of a table, there is no record of the solvent and the adsorbent.

The universal occurrence of carotenoid pigments in the photosynthetic apparatus of green plants and the possible role of these pigments in the utilization of solar energy have stimulated a great deal of biological, physiological and chemical investigation in the past decade, but none of these publications are cited in the present monograph. This work on chloroplast pigments has led to the discovery of many new carotenoids that are not included in this book. Examples are: neoxanthin from leaves, dinoxanthin from dinoflagellates, diadinoxantin from diatoms and dinoflagellates, etc. The fact that fucoxanthin is the principal xanthophyll of diatoms is omitted as is also the universal occurrence of zeaxanthin in green leaves. No mention

is made of the fact that peridinin, the principal xanthophyll of dinoflagellates, is probably identical with the sulcatoxanthin from sea anemones or from the symbiotic algae of these anemones. Spirilloxanthin, the principal xanthophyll of many purple, chemo-autotrophic bacteria, does not appear in the index although it is admittedly identical with the subsequently discovered rhodoviolascin.

Apart from these omissions, the material in this monograph is extensive, and it is clearly presented. The book is certain to serve as a guide in this field for many years to come.

# The Synthesis of 5-Keto-1,3,4,5-tetrahydrobenz[cd]indole. A Synthesis of 4-Substituted Indoles

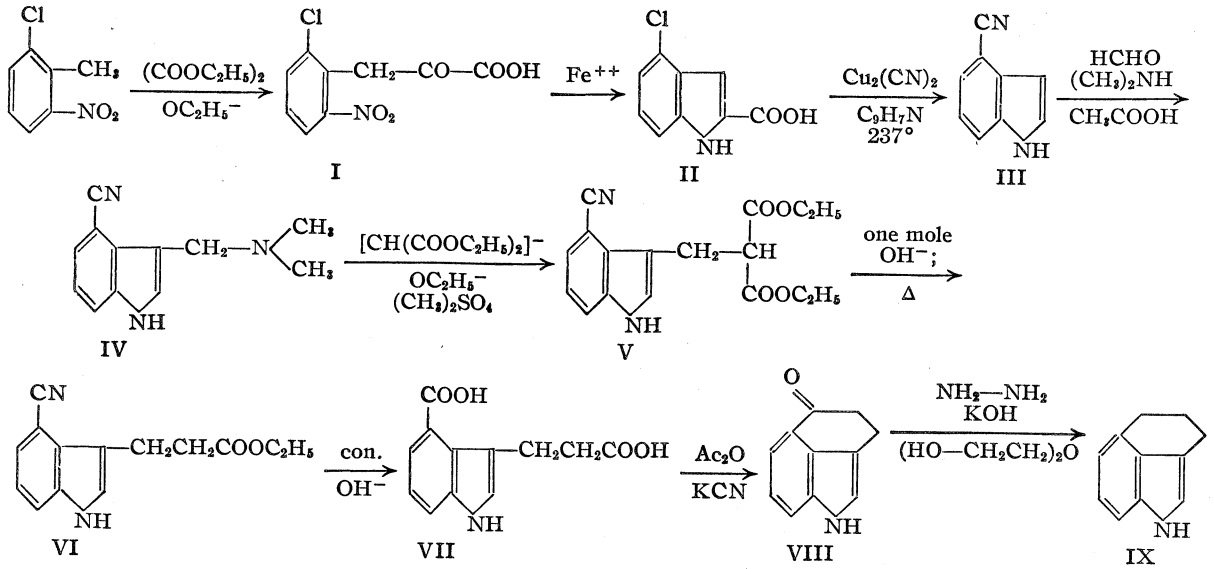
BY FREDERICK C. UHLE

The alkaloids isolated from *Claviceps purpurea* have been shown to be substances of polypeptide nature derived from certain $\alpha$-amino acids of relatively low molecular weight combined through amide linkage with a characteristic,complex indole derivative, lysergic acid.[1] More recently, the tetracyclic structure originally postulated on the basis of degradation studies for this characteristic ampholyte has been confirmed by the total syn-

Lysergic acid

thesis of dihydro-*dl*-lysergic acid.[2] The unprecedented *ergoline* ring system[3] encountered as this expression in the ergot alkaloids represents the only example of an indole derivative condensed in the 3,4-position to other nuclei which has been observed in nature or obtained by synthesis. Hitherto, the sole synthetic route to this novel type of structure has involved the sodium–butanol reduction of appropriately substituted naphthostyril derivatives and benzo[f]quinoline lactams. This procedure, while feasible in certain cases with simple derivatives, fails, or at best affords the indole in yields of less than ten per cent. in the case of naphthostyrils substituted with highly reactive functional groups, and attempts to synthesize lysergic acid by procedures involving reduction to the indole stage as one of the final steps have appeared most unpromising. New methods of approach to the synthesis of the ergoline type of ring structure are accordingly required to facilitate study of the chemistry of these interesting and unique indole derivatives, as well as to provide intermediates for the eventual synthesis of the alkaloids themselves.

Simple indoles substituted in the 4-position have been rarely reported in the literature, inasmuch as the only methods available for their synthesis have been those (such as the Fischer synthesis from meta-substituted phenylhydrazones) which give a mixture of the 4- and 6-isomers which are difficult to separate and identify, or those which with few exceptions yield compounds with substituents in the hetero-ring not readily eliminated in subsequent reactions.[4] A procedure has now been developed by which it is possible to prepare directly and in pure form, free from isomers, indoles substituted only in the 4-position in the benz-nucleus. The synthesis leads directly to the 4-chloro- and 4-cyanoindoles, and further functions are obtained by operation upon these groups. This new method has been extended to the preparation of $\beta$-(4-carboxy-3-indole)-propionic acid (VII), and ring closure under specific conditions has led to the synthesis of the tricyclic 5-keto-1,3,4,5-tetrahydrobenz[cd]indole (VIII).



The starting material chosen for the synthetic sequence, the readily available dyestuff intermedi-

(1) For example, four of the principal alkaloids yield the following hydrolysis products, respectively: ergotamine—lysergic acid, *d*-proline, *l*-phenylalanine, pyruvic acid, and ammonia; ergosine—lysergic acid, *d*-proline, *l*-leucine, pyruvic acid, and ammonia; ergocornine—lysergic acid, *d*-proline, *l*-valine, isobutyrylformic acid, and ammonia; ergonovine—the least complex of the series—lysergic acid and *d*-2-aminopropanol.

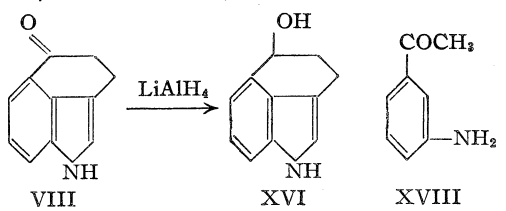
ate, 2-nitro-6-chlorotoluene, was condensed with ethyl oxalate, and the pyruvic acid derivative (I) reduced with ferrous hydroxide to 4-chloro-2-indolecarboxylic acid (II). Decarboxylation, as well as metathetical replacement of the halogen substituent occurred with cuprous cyanide in refluxing quinoline, and the 4-cyanoindole (III) isolated in good yield and characterized as 4-indolecarboxylic acid was converted through the Mannich base (IV) and the malonic ester derivative (V) to β-(4-carboxy-3-indole-)-propionic acid (VII).

The position of the substituent in the benz-nucleus was confirmed by the degradation of 4-chlorindole (X), obtained by decarboxylation of (II) with cuprous chloride in quinoline, to the known 6-chloroanthranilic acid (XIII) and 2,6-dichlorobenzoic acid (XIV).

Attempts to cyclize the dimethyl ester of the acid (VII) under the conditions of the Dieckmann condensation, using a wide variety of experimental variations and solvents, failed to give evidence of the formation of the desired tricyclic β-keto ester. Reaction with the metal occurred under some conditions leading to condensations involving presumably the indole nitrogen, but the products were difficult to isolate in a state of purity. N-Acetyl methyl-β-(4-carbomethoxy-3-indole)-propionate (XV) when allowed to react with sodium in re-



fluxing *p*-cymene gave no evidence of reaction. Ethyl β-(4-cyano-3-indole)-propionate (VI) likewise failed to exhibit tendency toward intramolecular condensation. Pyrolysis of the calcium or barium salt of β-(4-carboxy-3-indole)-propionic acid (VII) was not successful, and pyrolysis of the free dicarboxylic acid (VII) at 300° under diminished pressure led to decarboxylation of the nuclear carboxyl group, giving as the sublimate β-(3-indole)-propionic acid in low yield.

It was eventually found, however, that when a dilute solution of β-(4-carboxy-3-indole)-propionic acid (VII) in acetic anhydride containing a catalytic quantity of potassium cyanide was maintained at reflux temperature for an extended period and the reaction product hydrolyzed with alkali, a beautifully crystalline ketone was isolable in excellent yield. Uncyclized dicarboxylic acid was recovered from the alkaline filtrate, accounting for essentially the entire quantity of the compound used. The lemon-yellow keto-compound gave the usual carbonyl reactions and was characterized as the semicarbazone and as the *p*-nitrophenylhydrazone. A modified Wolff–Kishner

type reduction with hydrazine and potassium hydroxide in diethylene glycol, as well as a Clemmensen reduction, led to the formation of a compound which proved to be identical with 1,3,4,5-tetrahydrobenz[cd]indole (IX), prepared by sodium–butanol reduction of naphthostyril. The structure of the ketone is accordingly indicated to be 5-keto-1,3,4,5-tetrahydrobenz[cd]indole (VIII).

Hydrogenation of (VIII) by means of lithium aluminum hydride in ether solution gave 5-hydroxy-1,3,4,5-tetrahydrobenz[cd]indole (XVI) in excellent yield. Reduction of the carbonyl function in anhydrous isopropyl alcohol in the presence of aluminum isopropoxide led to the formation of a derivative with properties and analytical data which indicated it to be the isopropyl ether (XVII) of the alcohol (XVI).[5]

VIII XVI XVIII

The ultraviolet absorption spectrum[6] of the ketone (VIII), Fig. 1, exhibits maxima at 245 and 325 mμ and a minimum at 267 mμ, values suggesting those given by lysergic acid, which shows peaks at 230 and 315 mμ and a minimum at 270 mμ.[7] *m*-Aminoacetophenone (XVIII) gives a curve of similar form with maxima at 235 and 340 mμ and a minimum at 285 mμ. The 5-hydroxy compound (XVI) prepared by lithium aluminum hydride hydrogenation of the ketone (VIII), the isopropyl ether (XVII) formed in the Meerwein reduction, and the 1,3,4,5-tetrahydrobenz[cd]-indole (IX) prepared by hydrazine reduction of the ketone (VIII) as well as by sodium–butanol reduction of naphthostyril, gave practically superimposable curves with maxima at 230 and 280 mμ and a minimum at 254 mμ in conformity with data previously observed for certain indoles and for heterocyclic compounds derived from the indole nucleus.[7,8]

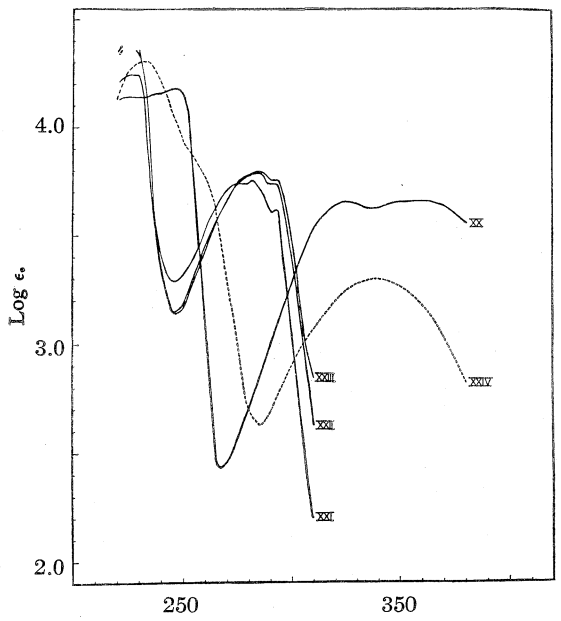
Additional reactions and properties of (VIII) and its utilization in further synthetic work, as well as an extension of the general methods, will be reported in subsequent communications.

## Experimental[9]

**2-Nitro-6-chlorophenylpyruvic Acid (I).**—To a solution of 23 g. (1.0 mole) of sodium in 350 ml. of absolute ethanol was added 146 g. (1.0 mole) of ethyl oxalate and 171.6 g. (1.0 mole) of 2-nitro-6-chlorotoluene and the mixture maintained at reflux temperature for forty minutes. The dark red solution was diluted with water and distilled with steam until starting material no longer collected in the distillate. The aqueous residue from the distillation was clarified by filtration and acidified with hydrochloric acid. The heavy precipitate which separated was collected by filtration and recrystallized from benzene. The compound gave the characteristic deep red color with alkali and a dark green color with ferric chloride solution. The yield was 102 g. (42%), and 70 g. (41%) of 2-nitro-6-chlorotoluene was recovered unchanged; m. p. 114–115°.

*Anal.* Calcd. for $C_9H_6NO_5Cl$: C, 44.38; H, 2.48. Found: C, 44.39; H, 2.84.

The semicarbazone was prepared in dilute ethanol and recrystallized from ethanol; m. p. 204–205°.



*Anal.* Calcd. for $C_{10}H_9N_4O_5Cl$: C, 39.95; H, 3.01. Found: C, 39.92; H, 3.05.

**4-Chloro-2-indolecarboxylic Acid (II).**—A solution of 81 g. (0.33 mole) of 2-nitro-6-chlorophenylpyruvic acid in dilute ammonium hydroxide solution was added to a suspension of ferrous hydroxide prepared from 560 g. (2.0 moles) of ferrous sulfate heptahydrate and 230 ml. of concentrated ammonium hydroxide solution in two liters of water and the mixture maintained at the boiling point for five minutes. The ferric hydroxide was separated by filtration, washed repeatedly with dilute ammonium hydroxide solution and water, and the filtrate acidified with dilute hydrochloric acid solution. The precipitate was recrystallized from a mixture of ethanol and water; yield 60 g. (92%); m. p. 259–260°.

*Anal.* Calcd. for $C_9H_6NO_2Cl$: C, 55.27; H, 3.09. Found: C, 55.38; H, 3.08.

The methyl ester was prepared by maintaining under reflux a solution of 3 g. of the acid in a mixture of 30 ml. of methanol and 3 ml. of concentrated sulfuric acid for fifteen hours. The solution was concentrated under diminished pressure, extracted with ether and aqueous sodium bicarbonate solution, and the residue from evaporation of the ether recrystallized from ethanol; yield 2.8 g. (87%); m. p. 146–147°.

*Anal.* Calcd. for $C_{10}H_8NO_2Cl$: C, 57.30; H, 3.84. Found: C, 57.42; H, 3.87.

Wave length in millimicrons.

Fig. 1.—Ultraviolet absorption spectra.

(5) Ether formation under the conditions of the Meerwein–Pondorff–Verley reduction has been observed in a few cases, Adams, *et al.*, "Org. Reactions," Vol. II, p. 190.

(6) The ultraviolet absorption spectra were determined on a Beckmann quartz spectrophotometer using a hydrogen discharge tube as a source of radiation, solvent, absolute ethanol; $\epsilon = 1/cd \log I/I_0$, $c = 0.0001$ molar, $d = 1$ cm.

(8) Ward, *Biochem. J.*, **17**, 891 (1923).

(9) All melting points are micro melting points. Microanalyses by Stephen Nagy of the Massachusetts Institute of Technology.

**4-Chloroindole (X).**—A mixture of 49 g. (0.25 mole) of 4-chloro-2-indolecarboxylic acid, 75 g. (0.125 mole) of cuprous chloride and 150 g. of quinoline was maintained under reflux for eight hours. The hot mixture was poured into ice and hydrochloric acid and repeatedly extracted with ether. The ether solution was washed with hydrochloric acid, water and sodium bicarbonate solution, dried over magnesium sulfate, and the residue from the distillation of the ether submitted to fractionation *in vacuo*. The yield of colorless oil was 30 g. (77.5%); b. p. 143° (10 mm.); $d^{20}_{20}$ 1.2485; $n^{20}D$ 1.6254; $M_D$ calcd. 42.43; $M_D$ found 42.93.

*Anal.* Calcd. for $C_8H_6NCl$: C, 63.38; H, 4.00. Found: C, 63.95; H, 4.15.

The picrate was prepared in ethanol solution and recrystallized from the same solvent; m. p. 171–173°.

*Anal.* Calcd. for $C_{14}H_9N_4O_7Cl$: C, 44.16; H, 2.38. Found: C, 44.31; H, 2.52.

**N-Benzoyl-4-chloroindole (XI).**—To a suspension of 1.15 g. (0.05 mole) of sodium sand in 20 ml. of dioxane was added 7.6 g. (0.05 mole) of 4-chloroindole and the mixture maintained under reflux for two hours to complete formation of the sodium derivative. A solution of 9.25 g. (0.05 mole) of benzoyl bromide in 5 ml. of dioxane was then added and the mixture maintained at reflux temperature for fifteen hours. The dioxane was distilled under diminished pressure, the residue extracted with a mixture of ether and water and the residue from the dried ether solution recrystallized from absolute ethanol; yield 6.2 g. (49%); m. p. 130–131°.

*Anal.* Calcd. for $C_{15}H_{10}NOCl$: C, 70.46; H, 3.94. Found: C, 70.36; H, 4.13.

**N-Benzoyl-6-chloroanthranilic Acid (XII).**—To a solution of 2.56 g. (0.01 mole) of N-benzoyl-4-chloroindole in 100 ml. of acetone was added, in portions, 10 g. (0.063 mole) of finely powdered potassium permanganate and the mixture stirred for fifteen hours. Fifty milliliters of ethanol was added and when the purple color had been discharged the manganese dioxide was separated by filtration and washed repeatedly with ethanol. The combined filtrates were concentrated to dryness under diminished pressure, dilute sodium hydroxide solution was added, 0.30 g. (14%) of unchanged starting compound removed by filtration, the filtrate acidified with hydrochloric acid, and the precipitate recrystallized from a mixture of ethanol and water; yield 1.38 g. (50%); m. p. 188–190°.

*Anal.* Calcd. for $C_{14}H_{10}NO_3Cl$: C, 61.00; H, 3.66. Found: C, 61.10; H, 3.79.

**6-Chloroanthranilic Acid (XIII).**—A solution of 1.38 g. (0.005 mole) of N-benzoyl-6-chloroanthranilic acid in 25 ml. of 10% sodium hydroxide solution was maintained under reflux for five hours, cooled, and acidified with dilute hydrochloric acid. The benzoic acid which separated weighed 500 mg. (82%). The filtrate was neutralized to *p*H 4 with solid sodium acetate and a solution of cupric acetate added dropwise. The copper salt which separated was collected by filtration, suspended in water, decomposed with hydrogen sulfide, and the filtrate from the copper sulfide concentrated to dryness *in vacuo*. The residue was recrystallized from benzene; yield 350 mg. (41%); m. p. 153–154°.[10]

*Anal.* Calcd. for $C_7H_6NO_2Cl$: C, 49.00; H, 3.52. Found: C, 49.10; H, 3.66.

The N-acetyl derivative was prepared by stirring a solution of 50 mg. of the sodium salt in 2 ml. of water with 0.5 ml. of acetic anhydride. The precipitate which separated after the solution had been chilled was recrystallized from water; m. p. 215–216°.[10]

**2,6-Dichlorobenzoic Acid (XIV).**—To a suspension at 0° of 86 mg. of 6-chloroanthranilic acid obtained from the oxidation of N-benzoyl-4-chloroindole in 1 ml. of 20% hydrochloric acid was added 35 mg. of sodium nitrite and the solution of the diazonium salt poured into a solution of 50 mg. of cuprous chloride in 20% hydrochloric acid and the solution allowed to come to room temperature. The precipitate was recrystallized from a mixture of equal quantities of benzene and ligroin; yield 72 mg. (76%); m. p. 143–144°.[11]

**4-Cyanoindole (III).**—A mixture of 9.78 g. (0.05 mole) of 4-chloro-2-indolecarboxylic acid (II), 6.7 g. (0.0375 mole) of cuprous cyanide, and 35 g. of quinoline was maintained at the reflux temperature of 237° for twenty hours. The hot dark-brown solution was poured into a mixture of 25 ml. of concentrated hydrochloric acid and ice and the well stirred precipitate collected by filtration and washed with water. The filtrate and precipitate were repeatedly extracted with ether, the ether solutions combined and washed with hydrochloric acid solution and water, dried over magnesium sulfate and concentrated under diminished pressure. The crystalline compound which remained was recrystallized from a large volume of water from which it separated in long, white silken needles; yield 3.6 g. (51%); m. p. 120–121°.

*Anal.* Calcd. for $C_9H_6N_2$: C, 76.04; H, 4.25; N, 19.71. Found: C, 75.94; H, 4.27; N, 19.53.

The picrate was prepared in methanol and recrystallized from the same solvent; m. p. 164–165°.

*Anal.* Calcd. for $C_{15}H_9N_5O_7$: C, 48.52; H, 2.44. Found: C, 48.32; H, 2.60.

**4-Indolecarboxylic Acid.**—A suspension of 1 g. of 4-cyanoindole in 10 ml. of 20% potassium hydroxide solution was maintained at reflux temperature for twenty hours. The alkaline solution was extracted with ether, the aqueous phase acidified with dilute hydrochloric acid solution and the precipitate recrystallized from water; yield 0.90 g. (80%); m. p. 213–214°.

*Anal.* Calcd. for $C_9H_7NO_2$: C, 67.07; H, 4.38. Found: C, 66.95; H, 4.57.

The methyl ester was prepared by maintaining at reflux temperature a solution of the acid in a mixture of 1 ml. of concentrated sulfuric acid in 10 ml. of methanol. The solution was concentrated under diminished pressure, extracted with ether and with dilute sodium bicarbonate solution and the residue from the ether recrystallized from methanol; m. p. 146–147°.

*Anal.* Calcd. for $C_{10}H_9NO_2$: C, 68.56; H, 5.18. Found: C, 68.20; H, 5.13.

**4-Cyanogramine (IV).**—To a solution of 71.0 g. (0.5 mole) of 4-cyanoindole in 250 ml. of acetic acid was added 41 g. (0.5 mole) of a 36.5% aqueous solution of formaldehyde and 90 g. (0.5 mole) of a 25% aqueous solution of dimethylamine and the mixture allowed to stand at room temperature for twelve hours. The acetic acid was distilled under diminished pressure, 500 ml. of water was added, the solution clarified by filtration, and the filtrate alkalinized with dilute sodium hydroxide solution. The crystalline base which separated was collected from the cold solution by filtration and recrystallized from acetone; yield 94.5 g. (95%). The compound appears to be somewhat unstable at elevated temperature but melts abruptly between 175 and 180° if the melting point is approached rapidly.

*Anal.* Calcd. for $C_{12}H_{13}N_3$: C, 72.32; H, 6.57. Found: C, 72.25; H, 6.83.

**Ethyl α-Carbethoxy-β-(4-cyano-3-indole)-propionate (V).**—To a solution of 2.30 g. (0.1 mole) of sodium in 150 ml. of absolute ethanol was added 16.0 g. (0.1 mole) of diethyl malonate, and 9.96 g. (0.05 mole) of 4-cyanogramine, and, while the mixture was cooled externally, 12.6 g. (0.1 mole) of dimethyl sulfate was added dropwise. The homogeneous solution was maintained at reflux temperature for five hours and the ethanol distilled *in vacuo*. Water and ether were added to the residue, and the product from the dried ether extract was stirred with petroleum ether. The crystalline solid which remained was recrystallized from ethanol; yield 10.2 g. (65%); m. p. 110–111°.

*Anal.* Calcd. for $C_{17}H_{18}N_2O_4$: C, 64.95; H, 5.77. Found: C, 64.67; H, 5.61.

**α-Carboxy-β-(4-cyano-3-indole)-propionic Acid.**—To a solution of 31.4 g. (0.1 mole) of ethyl α-carbethoxy-β-(4-cyano-3-indole)-propionate (V) in 250 ml. of ethanol was added a solution of 24 g. (0.4 mole) of potassium hydroxide in 25 ml. of water and the mixture maintained at reflux temperature for one-half hour. The solution was diluted with water, the ethanol removed under diminished pressure, the aqueous residue clarified by filtration, acidified with hydrochloric acid, and the precipitate collected by filtration and recrystallized from water; yield 24.6 g. (95%); m. p. 210–212°.

*Anal.* Calcd. for $C_{13}H_{10}N_2O_4$: C, 60.46; H, 3.90. Found: C, 60.06; H, 4.01.

**β-(4-Cyano-3-indole)-propionic Acid.**—(a) The malonic acid derivative was maintained at the melting point until the evolution of carbon dioxide had ceased and the crystalline residue recrystallized from a mixture of ethanol and water. (b) To a solution of 2.42 g. (0.01 mole) of ethyl β-(4-cyano-3-indole)-propionate (VI) in 20 ml. of ethanol was added 7 ml. of 10% sodium hydroxide solution and the mixture maintained under reflux for one hour. The ethanol was removed under diminished pressure, the residue extracted with ether, and the aqueous solution acidified with dilute hydrochloric acid. The precipitate was recrystallized from a mixture of ethanol and water; yield 2.0 g. (93.5%); m. p. 205–207°.

*Anal.* Calcd. for $C_{12}H_{16}N_2O_2$: C, 67.27; H, 4.70. Found: C, 67.17; H, 4.75.

The methyl ester was prepared by maintaining under reflux a solution of the acid in a solution of 1 ml. of concentrated sulfuric acid in 10 ml. of methanol. The ester was recrystallized from methanol; m. p. 138–139°.

*Anal.* Calcd. for $C_{13}H_{12}N_2O_2$: C, 68.40; H, 5.30. Found: C, 68.36; H, 5.35.

**Ethyl β-(4-Cyano-3-indolepropionate (VI).**—A solution of 15.7 g. (0.05 mole) of ethyl α-carbethoxy-β-(4-cyano-3-indole)-propionate (V) in a mixture of 18 ml. (0.05 mole) of 10% sodium hydroxide solution, 50 ml. of ethanol and 50 ml. of water was maintained under reflux for five hours. The ethanol was removed under diminished pressure, the aqueous solution extracted with ether and the acid precipitated by the addition of dilute hydrochloric acid, filtered and dried. The yield was 12.2 g. (85%). The acid was decarboxylated by maintaining at 200° for five minutes. The ester which crystallized when the melt had been allowed to cool was recrystallized from a mixture of ethanol and water, yield 9.8 g. (95%); m. p. 153–154°.

*Anal.* Calcd. for $C_{14}H_{14}N_2O_2$: C, 69.40; H, 5.82. Found: C, 69.38; H, 5.96.

**β-(4-Carboxy-3-indole)-propionic Acid (VII).**—To 20 ml. of 30% potassium hydroxide solution was added 2.42 g. (0.01 mole) of ethyl β-(4-cyano-3-indole)-propionate (VI) and the mixture was maintained under reflux for fifty hours by which time the evolution of ammonia had nearly ceased. The solution was brought to the neutral point with hydrochloric acid, clarified with Norite, and the filtrate acidified with hydrochloric acid. The precipitate was collected by filtration and recrystallized from water; yield 2.1 g. (90%); m. p. 188–189°; molecular weight calcd. 233.22; found, by neut. equiv., 233.

*Anal.* Calcd. for $C_{12}H_{11}NO_4$: C, 61.80, H, 4.76. Found: C, 61.65; H, 4.94.

**Methyl β-(4-Carbomethoxy-3-indole)-propionate.**—A solution of 2.33 g. (0.10 mole) of β-(4-carboxy-3-indole)-propionic acid (VII) in a mixture of 3 ml. of concentrated sulfuric acid and 30 ml. of methanol was maintained under reflux for fifteen hours. The solution was concentrated under diminished pressure, extracted with ether and sodium bicarbonate solution, and the crystalline residue from the ether extract recrystallized from ethanol; yield 1.96 g. (75%); m. p. 84–85°.

*Anal.* Calcd. for $C_{14}H_{15}NO_4$: C, 64.37; H, 5.79. Found: C, 64.30; H, 6.02.

The N-acetyl derivative (XV) was prepared by maintaining under reflux for ten hours an acetic anhydride solution of the ester, concentrating to dryness under diminished pressure, and recrystallizing from ethanol; m. p. 105–106°.

*Anal.* Calcd. for $C_{16}H_{17}NO_5$: C, 63.35; H, 5.65. Found: C, 63.12; H, 5.53.

**5-Keto-1,3,4,5-tetrahydrobenz[cd]indole (VIII).**—A solution of 2.33 g. (0.01 mole) of β-(4-carboxy-3-indole)-propionic acid (VII) and 0.20 g. of potassium cyanide in 100 ml. of acetic anhydride was maintained at reflux temperature for twenty hours. The acetic anhydride was distilled under diminished pressure, the residue dissolved in a mixture of 40 ml. of 10% potassium hydroxide solution and 40 ml. of ethanol and the solution maintained under reflux for one hour. The ethanol was distilled under diminished pressure and the crystalline product which separated was extracted with ether. The aqueous phase was acidified with dilute hydrochloric acid and 0.21 g. (9%) of unchanged dicarboxylic acid was collected by filtration. The washed and dried ether solution was concentrated and the crystalline residue recrystallized from ethanol; yield 1.37 g. (80%); m. p. 165–166°.

*Anal.* Calcd. for $C_{11}H_9NO$: C, 77.17; H, 5.30; N, 8.18. Found: C, 76.96; H, 5.37; N, 8.21.

The semicarbazone was prepared in aqueous ethanol and recrystallized from ethanol; m. p. 215–216°.

*Anal.* Calcd. for $C_{12}H_{12}N_4O$: C, 63.14; H, 5.31. Found: C, 63.21; H, 5.30.

The *p*-nitrophenylhydrazone was prepared in ethanol and recrystallized from the same solvent; m. p. 235–236°.

*Anal.* Calcd. for $C_{17}H_{14}N_4O_2$: C, 66.65; H, 4.61. Found: C, 66.68; H, 4.83.

**1,3,4,5-Tetrahydrobenz[cd]indole (IX).**—A mixture of 510 mg. (0.003 mole) of the ketone (VIII), 0.4 ml. of 85% hydrazine hydrate, 560 mg. of potassium hydroxide, and 4 ml. of diethylene glycol was maintained at 200° for four hours. The dark brown solution was poured into 10 ml. of water and extracted with ether. The residue from the washed ether extract was recrystallized from a mixture of ethanol and water. The glistening white plates melted at 55–56° and a mixed melting point with a sample of 1,3,4,5-tetrahydrobenz[cd]indole[12] prepared by sodium–butanol reduction of naphthostyril[13] was 55–56°; yield 300 mg. (64%).

*Anal.* Calcd. for $C_{11}H_{11}N$: C, 84.04; H, 7.05; N, 8.91. Found: C, 84.21; H, 7.11; N, 9.04.

The picrate was prepared in ethanol and recrystallized from the same solvent. The melting point was 164–166° and a mixed melting point with a sample prepared from the indole obtained by sodium–butanol reduction of naphthostyril was 164–166°.

*Anal.* Calcd. for $C_{17}H_{14}N_4O_7$: C, 52.85; H, 3.65. Found: C, 52.80, H, 3.64.

**5-Hydroxy-1,3,4,5-tetrahydrobenz[cd]indole (XVI).**—To a solution of 227 mg. (0.006 mole, twice the theoretical quantity) of lithium aluminum hydride in 30 ml. of absolute ether was added dropwise a solution of 1.03 g. (0.006 mole) of the ketone (VIII) in 20 ml. of absolute ether. The yellow color was at once discharged and the metal complex separated as a flocculent white precipitate. After the mixture had been maintained under reflux for ten minutes, water was added dropwise and the ether solution washed with 20% sulfuric acid, water, and sodium bicarbonate solution, and dried over magnesium sulfate. The crystalline residue from the ether was recrystallized from water; yield 780 mg. (75%); m. p. 126–127°.

*Anal.* Calcd. for $C_{11}H_{11}NO$: C, 76.27; H, 6.40. Found: C, 76.50; H, 6.63.

The *p*-nitrobenzoate was prepared with *p*-nitrobenzoyl chloride in pyridine and was recrystallized from methanol; m. p. 140–141°.

*Anal.* Calcd. for $C_{18}H_{14}N_2O_4$: C, 67.07; H, 4.38. Found: C, 66.80; H, 4.28.

## Summary

A synthesis of 4-substituted indoles has been developed. 4-Cyanoindole has been converted through the Mannich base to β-(4-carboxy-3-indole)-propionic acid, and cyclization of the dicarboxylic acid has afforded a new synthesis of the tricyclic 1,3,4,5-tetrahydrobenz[cd]indole ring system.

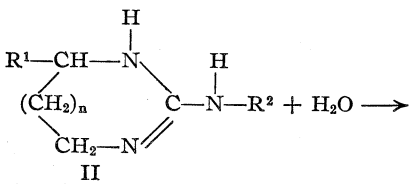
# The Reaction of Primary Amines with 2-Nitramino-$\Delta^2$-1,3-diazacycloalkenes



BY A. F. MCKAY, M. N. BUCHANAN AND GORDON A. GRANT

When 2-nitramino-$\Delta^2$-1,3-diazacycloalkenes[1] I are heated in the presence of primary amines a rapid evolution of gas occurs and the nitramino group is replaced by a substituted amino group. This reaction is analogous to the one described by Davis and Elderfield[2] in the preparation of *sym*-dibutylguanidine from N-butyl-N$^1$-nitroguanidine and butylamine in the presence of water. On the other hand, N-methyl-N$^1$-nitroguanidine and N-ethyl-N$^1$-nitroguanidine on heating with aqueous methylamine and aqueous ethylamine respectively gave the corresponding alkylureas. This would be expected because of the large volumes of water used by these authors. A. W. Hofmann[3] found that *sym*-triethylguanidine monohydrate on distillation decomposed into ethylamine and *sym*-diethylurea. Therefore, in order to eliminate the formation of cyclic ureas the 2-nitramino-$\Delta^2$-1,3-diazacycloalkenes I were heated with the anhydrous amines (reaction A). Water, however, is produced during this reaction in sufficient quantities to effect hydrolysis of part of the product II by reaction B.

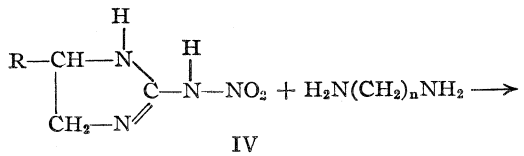
(B)

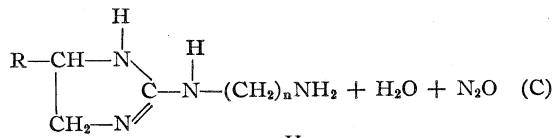
III

$R^1$ = $CH_3$ or H; $R^2$ = alkyl or aralkyl; $n$ = 0 or 1



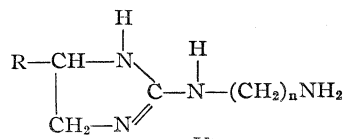
The 1,3-diazacyclopentene-2 I ($n$ = 0) compounds displayed less tendency to form urea derivatives than the 1,3-diazacyclohexene-2 I ($n$ = 1) compounds. On heating 2-nitramino-$\Delta^2$-1,3-diazacyclopentene or 2-nitramino-$\Delta^2$-1,3-diazacyclohexene with a primary amine until gas evolution ceased the former compound gave 4–8% 1,3-diazacyclopentanone-2 III ($n$ = 0, R′ = H) while the latter gave a 22% yield of 1,3-diazacyclohexanone-2 III ($n$ = 1; $R^1$ = H). These yields of cyclic ureas were decreased considerably by using a large excess (2–10 mole equivalents) of the amine which was slowly distilled during the course of the reaction. This excess amine on slow distillation carried with it the water produced during the reaction. The 2-alkylamino- and 2 aralkylamino-$\Delta^2$-1,3-diazacycloalkenes prepared in this manner are recorded along with their properties in Table I.

The formation of cyclic urea derivatives by the reaction of water with the 2-alkylamino- or 2-aralkylamino-$\Delta^2$-1,3-diazacycloalkenes II rather than with the corresponding 2-nitramino-$\Delta^2$-1,3-diazacycloalkenes I was verified by refluxing

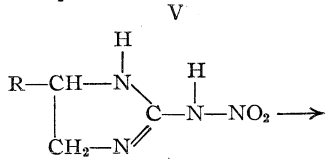


both types of compounds in water for a period of eight hours. 2-Nitramino-1,3-diazacyclohexene-2 was recovered unchanged while (4 or 6)-methyl-2-benzylamino-1,3-diazacyclohexene-2 gave a 58% yield of 4-methyl-1,3-diazacyclohexanone-2 III ($n = 1$, $R^1 = CH_3$).

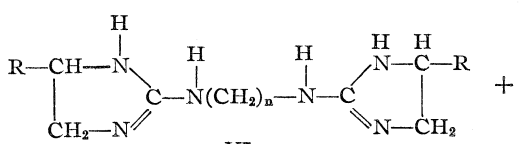
During the course of these studies 1,3-diazacyclohexanone-2 and 4-methyl-1,3-diazacyclohexanone-2 were isolated and characterized. 1,3-Diazacyclohexanone-2[4] and 4-methyl-1,3-diazacyclohexanone-2[5] have been described previously.



When diamines, *e. g.*, ethylenediamine, are used in place of primary amines, then two products may be obtained



IV



V (C)

V

IV

VI $H_2O + N_2O$ (D)

R = $CH_3$ or H

The expected compounds N-2-[4(or 5)-methyl-1,3-diazacyclopentene-2]-ethylenediamine V (R = $CH_3$) and N,N$^1$-2-[4(or 5)-methyl-1,3-diazacyclopentene-2]-ethylenediamine VI (R = $CH_3$) were obtained when ethylenediamine and 4 (or 5)-methyl-2-nitramino-1,3-diazacyclopentene-2 IV (R = $CH_3$) were heated together. On heating 2-nitramino-1,3-diazacyclopentene-2 IV (R = H) in a large excess of ethylenediamine N-2-(1,3-diazacyclopentene-2)-ethylenediamine V (R = H) was obtained. These compounds are described in Table I.

In the compounds prepared by reactions A, C and D, the double bond has been placed in the ring in agreement with the parent 2-nitramino-$\Delta^2$-1,3-diazacycloalkenes[1] and the results of the hydrolysis studies.

**Acknowledgment.**—The authors wish to thank Dr. A. S. Cook of Ayerst, McKenna and Harrison, Ltd., for a Grant-in-aid of this work and Miss C. Jockel of Ayerst, McKenna and Harrison Laboratories for the microanalyses.

## Experimental

**Preparation of 2-Alkylamino-$\Delta^2$-1,3-diazacyclopentenes.**—A mixture of the 2-nitramino-1,3-diazacyclopentene-2 with 1.1 to 4 mole equivalents of primary amine and xylene was heated under reflux for ten to thirty minutes. This was the time required for cessation of gas evolution which indicated that the reaction had gone to completion. The larger molar excesses of amines were used with the lower boiling amines. At the end of the reaction period the reaction mixture was distilled at atmospheric pressure until the vapor temperature reached 140°. The residue was then distilled at reduced pressure (0.1–5 mm.) to give the desired products as colorless crystalline solids or oils. The yields of 2-alkylamino-$\Delta^2$-1,3-diazacyclopentenes varied from 94.7–99% by theory. The picrates were formed by dissolving 0.5–1.0 g. of the 2-alkylamino-$\Delta^2$-1,3-diazacyclopentenes in a minimum of hot water and adding saturated picric acid solution until precipitation was complete. The crystalline picrates were recrystallized from water to a constant melting point and analyzed.

**2-Benzylamino-1,3-diazacyclopentene-2.**—A mixture of 74.6 g. (0.697 mole) of benzylamine and 46.5 g. (0.357 mole) of 2-nitramino-1,3-diazacyclopentene-2 was gently heated until the evolution of gas had ceased. The solution was then distilled *in vacuo* (1.0 mm.) to give a colorless oil which solidified on cooling, yield 60.7 g. (97%). The picrate of this compound was formed by dissolving 0.5 g. in a minimum amount of hot water and adding a saturated solution of picric acid. After two recrystallizations from water it melted at 150.5–151.5°.

**2-($\beta$-Phenylethylamino)-1,3-diazacyclopentene-2.**—Twenty-six grams (0.20 mole) of 2-nitramino-1,3-diazacyclopentene-2 and 48.5 g. (0.40 mole) of $\beta$-phenylethylamine were heated together cautiously to effect slow distillation of the excess amine. After the completion of gas evolution, the remaining liquid was distilled at reduced pressure. The distillate was a water-white oil which solidified on cooling, yield 35.6 g. (94.2%). The picrate was formed in the usual manner, and after two recrystallizations from water melted at 186.4–186.9°.

**N-$\alpha$-Naphthyl-N$^1$-1,3-diazacyclopentene-2-ethylenediamine.**—A suspension of 5.9 g. (0.045 mole) of 2-nitramino-1,3-diazacyclopentene-2 and 8.4 g. (0.045 mole) of N-$\alpha$-naphthylethylenediamine in 15 cc. of xylene was heated for twenty-five minutes. On cooling the reaction mixture solidified. This solid was triturated with ether (30 cc.) then filtered, washed with fresh ether (30 cc.) and dried. The crude yield was 9.2 g. (80.6%) which melted at 151–157°. A wasteful crystallization of 2.04 g. from 15 cc. of 95% ethanol raised the melting point to 175°. A sample of this material was converted to the picrate in the usual way and after two recrystallizations from water deep-red needles which melted at 144.8–145.6° were obtained.

**2-Benzylamino-1,3-diazacyclohexene-2.**—Seventy-two grams (0.50 mole) of 2-nitramino-1,3-diazacyclohexene-2 was added to 172 g. (1.60 mole) of benzylamine and heated to a temperature sufficient to maintain a slow rate of distillation of the excess benzylamine. This distillation at atmospheric pressure was continued until gas evolution ceased after which the residue was distilled *in vacuo*. A crystalline distillate of the desired product mixed with propylene urea (1,3-diazacyclohexanone-2) was obtained, yield 80.3 g. The cyclic urea by-product was separated by treating the distillate with sufficient chloroform to dis-

[a] Both compounds obtained in the same reaction, total yield 89.0%. [b] These boiling points are high because the pressure in the distillation apparatus was found to be higher than that recorded by the manometer. [c] All melting points uncorrected. [d] Dipicrates. [e] This picrate crystallized in two forms melting at 148–149° and 159–159.5°. [f] N. D. Not distilled.

solve the 2-benzylamino-1,3-diazacyclohexene-2. The chloroform-insoluble cyclic urea was then removed by filtration, washed with fresh chloroform (20 cc.), and dried, yield 7.0 g. (14%). This crude 1,3-diazacyclohexanone-2 melted at 260°. Two recrystallizations from 95% ethanol raised the melting point to 265–266°.

*Anal.* Calcd. for $C_4H_8N_2O$: C, 48.0; H, 8.00; N, 28.0. Found: C, 47.9; H, 8.02; N, 27.9.

The picrate was prepared by dissolving 0.6 g. of the cyclic urea in 15 cc. of water and adding 200 cc. of a saturated aqueous picric acid solution. The crystalline picrate (m. p. 188–189°) after two recrystallizations from water melted at 190–191°.

*Anal.* Calcd. for $C_{10}H_{11}N_5O_8$: C, 36.4; H, 3.34; N, 21.26. Found: C, 36.4; H, 3.30; N, 21.32.

Another aliquot of the cyclic urea on nitration by the method described by McKay and Wright[6] gave an 86.0% yield of 1,3-dinitro-1,3-diazacyclohexanone-2 (m. p. 120–121°). This latter product did not depress the melting point of an authentic sample of 1,3-dinitro-1,3-diazacyclohexanone-2 (m. p. 121–122°).

The chloroform filtrate from the cyclic urea on evaporation gave 73.3 g. (77.5%) of 2-benzylamino-1,3-diazacyclohexane-2. Its picrate, made in the usual manner, was found to exist in two forms. Both are needles and can be crystallized from water, although this procedure sometimes converts one form into the other. The more common form melts at 147–148°, while the other melts at 159–159.5°. Both forms gave analytical values in agreement with the theoretical for the monopicrate of 2-benzylamino-1,3-diazacyclohexene-2.

**4(or 6)-Methyl-2-benzylamino-1,3-diazacyclohexene-2.**—A large excess (36.9 g., 0.34 mole) of benzylamine was added to 6.5 g. (0.041 mole) of 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 in a Claisen flask having a six-cm. Vigreux column side-arm. The excess amine was then distilled at a rate sufficient to maintain the vapor temperature at 160° until the reaction was complete. This required thirty minutes. The residue was then distilled at reduced pressure. The distillate was a clear, viscous, light-yellow oil, yield 7.7 g. (92.5%). The monopicrate prepared in the usual way melted at 128.7–129° after two recrystallizations from water.

(6) A. F. McKay and G. F. Wright, This Journal, **70**, 3990 (1948).

**2-(β-Phenylethylamino)-1,3-diazacyclohexene-2.**—To 35 g. (0.289 mole) of boiling β-phenylethylamine, in the reaction flask of a distillation apparatus, was added 34.6 g. (0.240 mole) of 2-nitramino-1,3-diazacyclohexene-2 suspended in 73.1 g. (0.604 mole) of β-phenylethylamine. The sludge was added slowly, enough time being allowed between portions for the frothing from the previous addition to subside. After the addition was complete, the reaction mixture was slowly distilled until no further gassing could be observed. The residue was then distilled under reduced pressure. The main fraction contained some sublimed cyclic urea derivative. Separation of the 1,3-diazacyclohexanone-2 from the 2-(β-phenylethylamino)-1,3-diazacyclohexene-2 was effected by solution of the latter compound in xylene (3.25 cc./g.) and filtering off the insoluble cyclic urea. It melted at 263° alone and on admixture with an authentic sample of 1,3-diazacyclohexanone-2 (m. p. 265°), yield 2.7 g. (11.2%). After removal of the xylene from the filtrate 37.4 g. (76.8%) of 2-(β-phenylethylamino)-1,3-diazacyclohexene-2 was obtained. The picrate of this compound after six recrystallizations from water melted at 197–198°.

**4(or 6)-Methyl-2-(β-phenylethylamino)-1,3-diazacyclohexene-2.**—The distillation procedure was used in treating 30.9 g. (0.195 mole) of 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 with 48.5 g. (0.40 mole) of β-phenylethylamine. The slow distillation was continued for twenty-five minutes until gassing stopped. To the cooled (20°) reaction mixture ether (50 cc.) was added, and the insoluble 4-methyl-1,3-diazacyclohexanone-2 was filtered off and washed with ether (10 cc.). The white crystals which melted at 200.5–205°, were obtained in 18.46% yield (4.1 g.). The cyclic urea after two sublimations *in vacuo* (11 mm.) melted at 203.5–205°. A sample of the final sublimate was taken for analysis.

*Anal.* Calcd. for $C_5H_{10}N_2O$: C, 52.6; H, 8.77; N, 24.5. Found: C, 52.4; H, 8.92; N, 25.0.

After evaporation of the ether from the filtrate, it was distilled under reduced pressure. A viscous yellow oil was obtained, yield 32.2 g. (76%). The picrate was recrystallized four times from water and finally melted at 175.5–176.5°.

**4(or 6)-Methyl-2-(3-diethylaminopropylamino)-1,3-diazacyclohexene-2.**—A mixture of 23.7 g. (0.15 mole) of 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 and 52.1 g. (0.40 mole) of 3-diethylaminopropylamine was

heated to distillation temperature and a slow rate of distillation was maintained until the reaction had gone to completion. The remaining excess of 3-diethylaminopropylamine was distilled over and the cooled (20°) residue was triturated with ether (30 cc.). The insoluble cyclic urea by-product was removed by filtration and washed with ether (10 cc.), yield 3.2 g. (18.7%). It melted at 202–205° alone and on admixture with an authentic sample of 4-methyl-1,3-diazacyclohexanone-2 (m. p. 203.5–205°).

The ether was evaporated from the ethereal filtrate and the residue distilled under reduced pressure. A viscous oil was obtained yield 27.2 g. (78%). A portion of this oil (0.5 g.) was dissolved in 95% ethanol and treated with a saturated aqueous solution of picric acid. The crystalline dipicrate thus obtained melted at 141–142° after three recrystallizations from water.

**4(or 6)-Methyl-2-(β-hydroxyethylamino)-1,3-diazacyclohexene-2.**—The distillation technique was applied in the reaction of 7.9 g. (0.050 mole) of 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 with 18.3 g. (0.30 mole) of ethanolamine. The temperature of the distilling vapors was not allowed to drop below 150°. The reaction proceeded very rapidly, about four minutes being required for completion. The residual oil was distilled *in vacuo*. The distillate had a slight haziness due to the presence of a small amount (0.1 g.) of the cyclic urea by-product. The yield was 7.7 g. or 98.2%. The monopicrate prepared in the usual way melted at 135.4–136° after one recrystallization from water.

**N-2-(1,3-Diazacyclopentene-2)-ethylenediamine.**—Thirty grams (0.50 mole) of ethylenediamine (98–100%) was placed in a beaker and heated to 80–90°. This temperature was maintained during the portionwise addition of 6.5 g. (0.05 mole) of 2-nitramino-1,3-diazacyclopentene-2 which required twenty minutes. The reaction mixture was heated for a further five minutes and then transferred to a Claisen distilling flask and distilled *in vacuo*. After the excess ethylenediamine had distilled, a white crystalline distillate was obtained, yield 5 g. (78.1%). A portion (0.7 g.) of this product was dissolved in 15 cc. of warm water and 200 cc. of a saturated aqueous picric acid solution was added. The crystalline picrate (3.1 g.) melted at 179–181°. This melting point was raised to 199–200° by three recrystallizations from water (100 cc./g.).

**N-2-(4(or 5)-Methyl-1,3-diazacyclopentene-2)-ethylenediamine and N,N¹-2-(4(or 5)-Methyl-1,3-diazacyclopentene-2)-ethylenediamine.**—Forty grams (0.278 mole) of 4(or 5)-methyl-2-nitramino-1,3-diazacyclopentene-2 was added portionwise to 200 g. (3.33 mole) of ethylenediamine (98–100%) over a period of forty-five minutes. During the reaction period the temperature was held at 80–90°. After the addition of the 2-nitramino compound, the reaction mixture was heated for a further fifteen minutes until all signs of gas evolution disappeared. The unreacted ethylenediamine was removed by distilling the reaction mixture at atmospheric pressure until the vapor temperature reached 116°. The residue was then distilled *in vacuo* to give a main fraction consisting of a light-yellow oil (b. p. (0.05 mm.) 184–187°). This proved to be the mono-substituted ethylenediamine, yield 28.4 g. (71.9%). A second fraction (b. p. (0.2 mm.) 250–260°) was distilled over as an orange liquid which crystallized on cooling, yield 5.3 g. (17.0%). A sample (1 g.) of this latter fraction was dissolved in 15 cc. of water and treated with 200 cc. of a saturated aqueous picric acid solution. The crystalline picrate melted at 213–215°, yield 1.7 g. A constant melting point of 228–229° was obtained after four recrystallizations from water (700 cc./g.). The analytical values of this compound were in good agreement with the calculated for the dipicrate of N,N¹-2-(4(or 5) methyl-1,3-diazacyclopentene-2)-ethylenediamine.

An aliquot of the yellow oil (b. p. (0.05 mm.) 184–187°) gave a crystalline dipicrate which first melted at 190–192°. Six recrystallizations from water (60 cc./g.) raised the melting point to 200–201°.

**Hydrolysis of 4(or 6)-Methyl-2-benzylamino-1,3-diazacyclohexene-2.**—A solution of 9.2 g. (0.045 mole) of 4(or 6)-methyl-2-benzylamino-1,3-diazacyclohexene-2 in 30 cc. of 37% aqueous ethanol was refluxed for eight hours. After removal of the water and ethanol *in vacuo*, the residue was distilled. The main fraction consisted of unchanged starting material and 4-methyl-1,3-diazacyclohexanone-2. These compounds were separated by dissolving in 100 cc. of hot absolute ethanol, adding 20 cc. of absolute ether and cooling to −20°. The white precipitate of the cyclic urea was recovered by filtration, washed with ether and dried. This product was obtained in 58% yield and melted at 178–200°. One recrystallization from ethanol–ether followed by a sublimation *in vacuo* gave crystals melting at 200–204° alone and on admixture with an authentic sample of 4-methyl-1,3-diazacyclohexanone-2.

**Effect of Refluxing 4(or 6)-Methyl-2-nitramino-1,3-diazacyclohexene-2 with Water.**—Seven grams (0.044 mole) of 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 in 25 cc. of water was refluxed continuously for ten hours. It was then concentrated to 15 cc. and cooled to room temperature. The white crystals melted at 146–147.5°

alone and on admixture with the original 4(or 6)-methyl-2-nitramino-1,3-diazacyclohexene-2 (m. p. 147–148°). The recovery of original material was 6.2 g. (88% by weight).

## Summary

A new method of preparation of 2-alkylamino- and 2-aralkylaminoimidazolines and -tetrahydropyrimidines is described. The formation of cyclic ureas, *e. g.*, 1,3-diazacyclohexanone-2, as by-products in this reaction is discussed.

# Acylations of Certain α-Alkoxy and α-Aryloxy Ketones and Esters[1]

BY JON MUNCH-PETERSEN[2] AND CHARLES R. HAUSER

Although many acylations of ketones[3] and esters[4] have been described in the literature, relatively few successful acylations of α-alkoxy and α-aryloxy ketones and esters have been reported previously. The present paper describes some new contributions to this field. Various condensing agents have been employed.

**Acylations of α-Alkoxy and α-Aryloxy Ketones.**—Apparently the only acylations of this type effected previously are those reported by Malkin and Robinson[5] who acylated α-methoxy and α-4-dimethoxyacetophenone with ethyl formate using sodium ethoxide. The copper salts of the resulting β-ketoaldehydes (named as enols) were obtained in yields of 16 and 81%, respectively.[6]

We have found that, in contrast to acetophenone, α-methoxyacetophenone fails to be acylated with ethyl acetate, ethyl propionate, or ethyl benzoate, and α-phenoxyacetophenone fails to be acylated with ethyl acetate, employing sodium amide under the usual conditions.[3a] Similarly α-methoxyacetophenone fails to be acylated with ethyl acetate employing potassium triphenylmethide[7] in refluxing ether. In each of these cases, the methoxy or phenoxy ketone was largely recovered. However, both of these ketones may be acylated with phenyl benzoate or phenyl propionate by means of sodium amide. The benzoylations of α-methoxyacetophenone and α-phenoxyacetophenone have been effected in yields of 26 and 59%, respectively.

$$C_6H_5COOC_6H_5 + C_6H_5OCH_2COC_6H_5 \xrightarrow{NaNH_2} C_6H_5COCHCOC_6H_5 + C_6H_5OH$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OC_6H_5$$

The benzoylation of α-methoxyacetophenone has also been effected with benzoyl chloride but the yield was only 11%. The propionylations of α-methoxyacetophenone and α-phenoxyacetophenone have been effected in yields of 25 and 50%, respectively; however, the latter yield is only for the copper salt.

$$C_2H_5COOC_6H_5 + CH_3OCH_2COC_6H_5 \xrightarrow{NaNH_2} C_2H_5COCHCOC_6H_5 + C_6H_5OH$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OCH_3$$

Since some starting materials were recovered in these cases, the yields of acylation products could probably be improved.

The acylation of α-methoxyacetophenone with acetic anhydride has been effected in 10% yield by means of boron trifluoride.

**Acylations of α-Alkoxy and α-Aryloxy Esters.**—The self-condensation of ethyl ethoxyacetate was first reported by Conrad[8] who used sodium, but no yield was given. Similarly, Pratt and Robinson[9] effected the self-condensation of methyl and ethyl methoxyacetate in yields of 40–50% using sodium. Darzens and Meyer[10] reported a 75% yield in the self-condensation of ethyl ethoxyacetate using sodium ethoxide. We have self-condensed isopropyl ethoxyacetate in 69% yield using potassium triphenylmethide and in 35% yield using sodium amide

$$2\ C_2H_5OCH_2COOCH(CH_3)_2 \xrightarrow[\text{or } NaNH_2]{KC(C_6H_5)_3} C_2H_5OCH_2COCHCOOCH(CH_3)_2 + (CH_3)_2CHOH$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OC_2H_5$$

The lower yield with the sodium amide may be accounted for on the basis that this reagent reacts

(6) We have verified this result with α-methoxyacetophenone, but the yield of the free β-ketoaldehyde was only 8%; most of the methoxy ketone was recovered. It should be pointed out that this reaction was carried out at 0° and that, when attempts were made to effect the formylation of the sodium derivative of α-methoxyacetophenone (prepared with sodium amide or potassium triphenylmethide) in refluxing ether, only the methoxy ketone was recovered.

not only with the α-hydrogen of the ester leading to condensation but also with the carbonyl carbon resulting in the formation of ethoxyacetamide which was isolated from the reaction mixture in 35% yield. Since sodium amide self-condenses isopropyl acetate in better yield (57%)[11] and apparently produces little if any acetamide,[12] the substitution of an α-hydrogen of this ester by the ethoxy group evidently activates the carbonyl carbon[13] relative to the α-hydrogen toward sodium amide.[14]

The self-condensation of ethyl α-ethoxypropionate could not be effected satisfactorily. With potassium triphenylmethide or sodium hydride only a small amount of product was obtained even though the ester anion appeared to be formed readily.[15] With di-isopropylaminomagnesium bromide a product was obtained but it was apparently contaminated with some of the di-isopropyl amide, giving a positive test for nitrogen. Since di-isopropylaminomagnesium bromide self-condenses ethyl *n*-butyrate and ethyl isobutyrate to form a nitrogen free β-ketoester,[16] the formation of some amide with the ethyl α-ethoxypropionate lends further support to the view expressed above, that the α-ethoxy group activates the carbonyl carbon relatively more than the α-hydrogen.

Ethyl phenoxyacetate was first self-condensed by Johnson and Hill[17] using sodium; the yield of the sodium derivative of the β-ketoester was good, but the free β-ketoester was not isolated. We have similarly obtained a good yield (76%) of the sodium derivative of the β-ketoester using di-isopropylaminomagnesium bromide. We also self-condensed methyl 2,4-dichlorophenoxyacetate; the free β-ketoester was obtained in a 65% yield

$$2Cl_2C_6H_3OCH_2COOCH_3 \xrightarrow{[(CH_3)_2CH]_2NMgBr} Cl_2C_6H_3OCH_2COCHCOOCH_3 + [(CH_3)_2CH]_2N + Mg(OCH_3)Br$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad OC_6H_3Cl_2$$

Ethyl α-phenoxypropionate and ethyl α-(2,4-dichlorophenoxy)-propionate apparently self-condensed in the presence of di-isopropylmagnesium bromide, but the pure products were not isolated.

Apparently an alkoxy ester has not previously been acylated with a different ester. In an attempt to acylate isopropyl ethoxyacetate with phenyl benzoate using sodium amide[11] or potassium triphenylmethide[7] we have obtained the self-condensation product of the ethoxyacetate (35%) even though the addition of the ethoxyacetate to the reagent was followed immediately by the addition of the phenyl benzoate.[18] Since isopropyl acetate has been benzoylated with phenyl benzoate by means of sodium amide under similar conditions,[11] either the anion of isopropyl ethoxyacetate is acylated more slowly by phenyl benzoate than the anion of isopropyl acetate or, more likely, isopropyl ethoxyacetate undergoes self-condensation more rapidly than isopropyl acetate. This again is an indication of the above-mentioned effect of the ethoxy group.

However, we have succeeded in acylating ethyl α-ethoxypropionate with isobutyryl chloride using potassium triphenylmethide. The yield was only 15% but it could probably be improved

$$(CH_3)_2CHCOCl + C_2H_5O\underset{\displaystyle CH_3}{\underset{|}{C}}HCOOC_2H_5 \xrightarrow{KC(C_6H_5)_3} (CH_3)_2CHCO\underset{\displaystyle CH_3}{\underset{|}{C}}COOC_2H_5 + HCl$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad OC_2H_5$$

Koelsch and Whitney[19] have acylated ethyl phenoxyacetate with ethyl oxalate and ethyl formate using sodium ethoxide. We have benzoylated ethyl α-phenoxypropionate with phenyl benzoate using sodium amide but, rather surprisingly, the β-ketoacid (13%) instead of the β-ketoester was obtained. Most of the ethyl α-phenoxypropionate was recovered.

**Acknowledgment.**—One of the authors (J. Munch-Petersen) wants to express his gratitude to The Academy of Technical Sciences, Denmark, Laurits Andersens Fond, Otto Monsteds Fond, The American-Danish Foundation and the Duke University Research Council for financial support, without which his participation in this work would have been impossible.

## Experimental[20]

α-Methoxyacetophenone[21] and α-phenoxyacetophenone[22] were prepared as described in the literature.

(11) Shivers, Dillon and Hauser, THIS JOURNAL, **69**, 120 (1947).

(12) Hauser, Levine and Kibler, *ibid.*, **68**, 26 (1946).

(13) That the carbonyl carbon is activated by the ethoxy group toward a basic anion is indicated by the six times larger rate of alkaline hydrolysis of methyl ethoxyacetate than methyl acetate. See Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., New York, N. Y., 1940, p. 212.

(14) In agreement with this, an attempt to carbonate isopropyl methoxyacetate after treatment with sodium amide failed; methoxyacetamide (m. p. 92–93°) was isolated in 70% yield. Under similar conditions isopropyl acetate gives the carbonation product (56%) and apparently none of the amide.[12]

(15) With potassium triphenylmethide, the color of the reagent was discharged immediately, see ref. 7. With sodium hydride the calculated amount of hydrogen was evolved when equivalent amounts of this reagent and the ester were refluxed in *n*-butyl ether (b. p. 140°). See Swamer and Hauser, THIS JOURNAL, **68**, 2647 (1946).

(17) Johnson and Hill, *Am. Chem. J.*, **48**, 296 (1912); THIS JOURNAL, **35**, 1026 (1913).

(18) In these experiments isopropyl benzoate was obtained in yields of 67 and 50%, respectively. This ester was identified by its boiling point and by hydrolysis to benzoic acid and isopropyl alcohol. In the experiment with sodium amide a 35% yield of ethoxyacetamide (m. p. 80°) was obtained. The isopropyl benzoate was formed, presumably, by reaction of the phenyl benzoate with the isopropoxide ion which was produced as a by-product in the self-condensation of isopropyl ethoxyacetate and, in the experiment with sodium amide, also in the formation of ethoxyacetamide.

(22) Mohlau, *Ber.*, **15**, 2498 (1882).

Isopropyl ethoxyacetate, b. p. 161°, was prepared according to the procedure for ethyl ethoxyacetate,[23] using isopropyl alcohol in the esterification of the ethoxyacetic acid.

Ethyl α-ethoxypropionate was prepared according to the same procedure,[23] using α-chloropropionic acid instead of chloroacetic acid; the ester boiled at 153–155° (reported b. p. 155°).[24] The over-all yield was 58%, the yield of α-ethoxypropionic acid, b. p. 89–93° at 10 mm., being 77%.

Ethyl phenoxyacetate, b. p. 247–249° (reported b. p. 250°)[25] and ethyl α-phenoxypropionate, b. p. 242–244°[26] and b. p. 96° at 4 mm., were obtained in 80% yields from the corresponding acids by the general method involving the saturation of an ethanolic solution of the acid with hydrogen chloride.

Ethyl α-(2,4-dichlorophenoxy)-propionate, b. p. 129–130° at 4 mm. (reported b. p. 173–176° at 12 mm.)[27] was prepared by esterification of α-(2,4-dichlorophenoxy)-propionic acid, m. p. 115–116° (reported m. p. 117–118°),[27] which was obtained in 31% yield following the procedure given by Pakorny[28] for 2,4-dichlorophenoxyacetic acid.

**Acylations of α-Methoxy- and α-Phenoxyacetophenone by the Sodium Amide Method. Table I.**—The general procedure described previously[3a,29] has been modified. To a stirred suspension of 0.2 mole of sodium amide was added an ether solution of 0.1 mole of the ketone. After ten minutes, an ether solution of the ester was added. The mixture was refluxed for two hours and then poured onto ice. The water layer, after washing with ether, was acidified and extracted with ether. The ether layer, after washing with saturated sodium bicarbonate solution and water, was dried and the solvent distilled. Treatment of the residue varied.

TABLE I

ACYLATIONS OF $ROCH_2COC_6H_5$ USING SODIUM AMIDE

| R | Acylating compound | β-Diketone | M. p., °C. | Yield, % |
|---|---|---|---|---|
| $CH_3$ | PhBz | α-Methoxydibenzoylmethane[a] | 77–78 | 26 |
| $C_6H_5$ | PhBz | α-Phenoxydibenzoylmethane[b] | 97–100 | 59 |
| $CH_3$ | BzCl | α-Methoxydibenzoylmethane | 77–78 | 11 |
| $CH_3$ | PhPr | α-Methoxy-α-propionyl acetophenone[c] | B. p. 129–130 at 6 mm. | 25 |
| $C_6H_5$ | PhPr | α-Phenoxy-α-propionyl acetophenone | | 50[d] |

[a] *Anal.* Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.78; H, 5.20. [b] *Anal.* Calcd. for $C_{21}H_{16}O_3$: C, 79.73; H, 5.10. Found: C, 79.91; H, 4.90. [c] *Anal.* Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84. Found: C, 69.68; H, 6.65. [d] Obtained as the copper salt.

In the benzoylation of α-methoxyacetophenone with phenyl benzoate the β-diketone was isolated by the copper salt method[3a] and recrystallized from methanol.

In the benzoylation of α-phenoxyacetophenone most of the phenol was distilled off *in vacuo*. The residue, which crystallized, was brought into solution in 2 *N* sodium hydroxide. By acidifying, the β-diketone was precipitated, filtered, washed with water and a little ice-cold ethanol and finally recrystallized from ethanol.

In the benzoylation of α-methoxyacetophenone with benzoyl chloride equivalent amounts of sodium amide, the ketone and benzoyl chloride were used; before adding the ketone, the ether suspension of sodium amide was refluxed for several hours.

In the propionylation of α-methoxyacetophenone with phenyl propionate the β-diketone was separated from the phenol by fractional distillation *in vacuo*.

In the propionylation of the α-phenoxyacetophenone with phenyl propionate most of the phenol was removed by heating *in vacuo* (4 mm.) in an oil-bath kept at 200° for thirty minutes. The residue, which gave a strong red enol test with ferric chloride, was treated with a saturated copper acetate solution and the copper salt[3a] of the β-diketone crystallized by standing overnight. After washing, the yield of the copper salt was 50%. From the copper salt, the β-diketone was recovered as a brown oil, the over-all yield being 37%, but it did not crystallize.

**Acetylation of α-Methoxyacetophenone by the Boron Trifluoride Method.**—The general procedure described previously[3c] has been modified. The reaction mixture of 0.2 mole of the ketone and 0.4 mole of acetic anhydride, after saturation with boron trifluoride at temperatures between −10 and 0°, was kept at 0° for one hour and at room temperature (28–30°) for another hour. The mixture was refluxed with sodium acetate for thirty minutes and cooled. After neutralization of most of the acetic acid with sodium hydroxide, the mixture was extracted with ether and the ether solution washed with sodium bicarbonate solution and water. α-Methoxybenzoyl acetone, isolated by the copper salt method, was obtained as a yellow liquid, boiling at 110–111° at 4 mm.

*Anal.* Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29. Found: C, 68.78; H, 6.12.

None of the ketone was recovered and a considerable amount of tar was obtained.

When the reaction mixture was worked up within twenty minutes after saturation below 0° as described for other ketones,[3c] no β-diketone was obtained and the ketone was largely recovered.

**Self-condensation of α-Alkoxy and α-Aryloxy Esters. Table II.**—The self-condensation of isopropyl ethoxyacetate with potassium triphenylmethide was carried out according to the general procedure,[7] except that the reaction mixture was refluxed for three hours. The condensation was also effected by sodium amide[11]; in this experiment ethoxyacetamide (m. p. 80°) was isolated.

Ethyl phenoxyacetate and methyl 2,4-dichlorophenoxyacetate (m. p. 39–40°)[30] were self-condensed by diisopropylaminomagnesium bromide by adaptation of the procedure for the condensation of certain esters using diethylaminomagnesium bromide.[31] The reactions were generally carried out on a 0.1 or 0.2 mole scale.

To the stirred solution of ethylmagnesium bromide was added an ether solution of an equivalent of diisopropylamine, b. p. 83–84°,[32] and after twenty minutes an ether solution of an equivalent of the ester was added. After spontaneous refluxing ceased, the mixture was refluxed on the steam-bath for one and one-half hours. After cooling in an ice–salt-bath, crushed ice and concentrated hydrochloric acid were added and the mixture stirred until no solid was left. The ether phase, after combining with an ether extract of the aqueous phase, was stirred with 2 *N* sodium hydroxide. The white precipitate of the sodium derivative of the β-ketoester was filtered off, washed with water and dried in the air.

In the experiment with ethyl phenoxyacetate the sodium derivative of the β-ketoester was a white powder, which melted under slight decomposition at 199°. It was converted into the free β-ketoester by shaking in a separatory funnel with ether and hydrochloric acid. The water layer was extracted with ether, the combined ether ex-

TABLE II

SELF-CONDENSATION OF ALKOXY- AND ARYLOXYESTERS

| Ester | Condensing agent | β-Ketoester | B. p. °C. | Mm. | Yield % |
|---|---|---|---|---|---|
| Isopropyl ethoxyacetate | $NaNH_2$ | Isopropyl α,γ-diethoxyacetoacetate | 107–108 | 5 | 35 |
| Isopropyl ethoxyacetate | $KC(C_6H_5)_3$ | Isopropyl α,γ-diethoxyacetoacetate[a] | 103–104 | 4 | 69 |
| Ethyl phenoxyacetate | $(i\text{-Pr})_2NMgBr$ | Ethyl α,γ-diphenoxyacetoacetate[b] | | | 63[c] |
| Methyl 2,4-dichlorophenoxyacetate | $(i\text{-Pr})_2MgBr$ | Methyl α,γ-di-(2,4-dichlorophenoxy)-acetoacetate[b,d] | 102–104 (m. p.) | | 65 |

[a] *Anal.* Calcd. for $C_{11}H_{20}O_5$: C, 56.88; H, 8.68. Found: C, 56.59; H, 8.82. [b] No nitrogen was found by the sodium fusion test. [c] The sodium derivative was obtained in 76% yield. [d] *Anal.* Calcd. for $C_{17}H_{12}O_5Cl_4$: C, 46.60; H, 2.76; Cl, 32.37. Found: C, 46.92; H, 2.78; Cl, 32.10.

tracts washed with a saturated sodium bicarbonate solution and water, and dried. After evaporation of the solvent, the β-ketoester was obtained as a yellow oil, which, however, did not crystallize. Attempts to distil the β-ketoester *in vacuo* (3 mm.) resulted in decomposition. Attempts to effect ketonic cleavage in acid[33] and slightly alkaline[9] solution gave phenol and tar.

In the experiment with methyl 2,4-dichlorophenoxyacetate, the sodium derivative of the β-ketoester was similarly converted into the free keto ester, and this, after evaporation of the ether, crystallized, and was recrystallized from ethanol.

**Acylation of Ethyl α-Ethoxypropionate with Isobutyryl Chloride.**—To an ether suspension of 0.2 mole of potassium triphenylmethide (freed from ammonia by refluxing the mixture for four hours followed by purging the apparatus with nitrogen) was added 29.2 g. (0.2 mole) of ethyl α-ethoxypropionate. The red color disappeared immediately. After ten minutes, 21.2 g. (0.2 mole) of isobutyryl chloride was added. After refluxing on the steam-bath for three hours, the mixture was poured onto ice and 5 ml. of glacial acetic acid. The ether layer, after combining with an ethereal extract of the aqueous phase, was washed with saturated sodium bicarbonate solution, then with water, and dried. The solvent was distilled and the residue fractionated *in vacuo*, yielding 53% of the original ester and 10 g. of crude β-ketoester. Redistillation gave 6.5 g. (15%) of ethyl α-isobutyryl-α-ethoxypropionate, b. p. 75–76° at 4 mm.

*Anal.* Calcd. for $C_{11}H_{20}O_4$: C, 61.08; H, 9.32. Found: C, 61.31; H, 9.41.

**Benzoylation of Ethyl α-Phenoxypropionate with Phenyl Benzoate.**—To the stirred suspension of 0.1 mole of sodium amide was added an ether solution of 19.4 g. (0.1 mole) of ethyl α-phenoxypropionate. After fifteen minutes, an ether solution of 19.8 g. (0.1 mole) of phenyl benzoate was added. The mixture was refluxed on the steam-bath for one hour and then poured onto ice and hydrochloric acid. The water layer was extracted with ether. The combined ether phase was extracted with sodium hydroxide solution. From the ether phase there was recovered 70% of ethyl α-phenoxypropionate, b. p. 241–248° and 20% of the phenyl benzoate, m. p. 68°. Acidification of the alkaline extract yielded a precipitate from which, after fractional crystallization, there was obtained 0.3 g. of α-phenoxypropionic acid, m. p. 114–115° (reported m. p. 115–116°)[34] and 3.5 g. (13%) of α-benzoyl-α-phenoxypropionic acid, m. p. 136–137°, neutr. equiv.: Calcd. 270.3; found 270.3 and 270.8.

*Anal.* Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.47; H, 5.35.

## Summary

1. Although α-methoxy- and α-phenoxyacetophenone failed to be acylated with ethyl acetate, ethyl propionate, and ethyl benzoate by the sodium amide method, these ketones have been acylated with phenyl propionate and phenyl benzoate. α-Methoxyacetophenone has been acetylated by the boron trifluoride method.

2. Isopropyl ethoxyacetate has been self-condensed by potassium triphenylmethide and by sodium amide; ethyl phenoxyacetate and methyl 2,4-dichlorophenoxyacetate have been self-condensed by diisopropylaminomagnesium bromide.

3. Ethyl α-ethoxypropionate has been acylated with isobutyryl chloride by potassium triphenylmethide.

4. Certain related condensations have been studied. The effect of the α-ethoxy group on the relative reactivities of the carbonyl carbon and the α-hydrogen of esters has been considered.

# The Action of Grignard Reagents on Ethyl Ethylenetetracarboxylate. A General Method for Preparation of Monoalkylated and Monoarylated Succinic Acids

BY CHI-YI HSING[1] AND LIEN-TANG LI

The addition of Grignard reagents to $\alpha,\beta$-unsaturated carboxylic esters was studied intensively by Kohler and his co-workers.[2] The addition takes place either 1:2 or 1:4 depending on the character of the Grignard reagent and on the substituents in the unsaturated ester.[3] Kohler noted that by substituting a cyano or another carboxylic ester group on the $\alpha$-carbon atom, the addition of the Grignard reagent takes place exclusively 1:4. For instance, the reaction of benzal malonic ester with methylmagnesium iodide gives $\alpha$-phenethyl malonic ester. When an excess of Grignard reagent is used the ester groups are not further attacked. It is the object of the present investigation to test whether the generalization made by Kohler can be equally well applied to the action of Grignard reagents on ethyl ethylenetetracarboxylate. If one mole of Grignard reagent adds 1:4 to ethyl ethylenetetracarboxylate, a general method for the preparation of monosubstituted succinic acids will be available. The reactions are given as follows

$$(C_2H_5O_2C)_2C{=}C(CO_2C_2H_5)_2 \xrightarrow{RMgX}$$

$$(C_2H_5O_2C)_2C(R)-C(OMgX)=C(CO_2C_2H_5)-OC_2H_5 \xrightarrow{H_2O}$$

$$(C_2H_5O_2C)CR-CH(CO_2C_2H_5)_2 \longrightarrow$$

$$(HO_2C)_2CR-CH(CO_2H)_2 \xrightarrow{-CO_2} HO_2C-CHR-CH_2CO_2H$$

Bischoff[4] has also made monoalkylated succinic acids from monoalkylated $\alpha,\alpha,\beta,\beta$-ethanetetracarboxylic acid esters. The tetra-esters were obtained in poor yield by the alkylation of ethyl ethane-$\alpha,\alpha,\beta,\beta$-tetracarboxylate with an alkyl halide in the presence of sodium ethylate. The monoalkylated succinic acids were isolated as the final products by saponifying the crude esters. Arylated succinic acids could not be prepared by the method of Bischoff.

It was found that both aryl and alkylmagnesium bromide add to ethyl ethylenetetracarboxylate. When phenylmagnesium bromide was used, some coupling of the Grignard reagent with the formation of biphenyl was observed, while in the case of ethylmagnesium bromide, some reduction of ethyl ethylenetetracarboxylate took place. The reduced compound was isolated as ethyl ethane-$\alpha,\alpha,\beta,\beta$-tetracarboxylate. In general the yields were good, varying from 56–79%. The saponification of the tetra-ester and the decarboxylation of the poly-acid were carried out by the usual methods. The yield was satisfactory in the case of ethyl phenylethane-$\alpha,\alpha,\beta,\beta$-tetracarboxylate but poor in the case of ethyl methylethane-$\alpha$ $\alpha,\beta,\beta$-tetracarboxylate. It is our hope to extend the present investigation and to improve the experimental conditions in order to make the method useful for general synthetic purposes when more material is available for the investigation. No attempt was made to isolate the tetracarboxylic acids in the pure state; they were decarboxylated directly. When ethyl phenylethane-$\alpha,\alpha,\beta,\beta$-tetracarboxylate was saponified, an acid melting unsharply around 160° with decomposition was obtained. If the compound was heated at a temperature of 170° for some time until the decomposition ceased, the product melted sharply at 168°. This is the reported melting point of phenylsuccinic acid.[5,6] The identity between the methylsuccinic acid synthesized by our method and an authentic specimen was established.

Although a number of methods[7] for the preparation of monosubstituted succinic acids are available, the present method has the advantage of starting with readily prepared[8] material. Certain monosubstituted succinic acids may be prepared by the present method that can be prepared only with great difficulty by any other method.

**Acknowledgment.**—The authors are grateful to Mr. Y. S. Kao of the Institute of Materia Medica, National Academy of Peiping, Shanghai, for his kindness in doing the micro-analyses in the present paper.

## Experimental

**Ethyl Ethylenetetracarboxylate.**—Ethyl ethylenetetracarboxylate was prepared as described by Corson and Benson.[8]

**Ethyl $\alpha$-Phenylethane-$\alpha,\alpha,\beta,\beta$-tetracarboxylate.**—In a 200-cc. 3-necked flask equipped with a dropping funnel, a mechanical stirrer through a mercury seal and a reflux condenser to the upper end of which was attached a calcium chloride tube, was placed 1.8 g. of magnesium shavings and 10 cc. of absolute ether. A mixture of 11.8 g. of bromobenzene in 15 cc. of absolute ether was added drop by drop through the funnel. When all the bromobenzene solution had been added, the mixture was refluxed for thirty minutes. A mixture of 4.7 g. of ethyl ethylene-

tetracarboxylate dissolved in 40–50 cc. of absolute ether was dropped in through the funnel in thirty to forty minutes. The mixture was refluxed and stirred for an hour. The reaction flask was then cooled with ice water and 25 cc. of 25% ammonium chloride solution was added gradually. Stirring was continued for thirty minutes after all the ammonium chloride solution had been added. The ethereal layer was separated and the aqueous layer containing much solid matter was dissolved in a proper amount of 10% acetic acid and extracted several times with ether. The combined ethereal extracts were evaporated and the residue was then steam-distilled in order to remove most of the biphenyl formed during the reaction. The amount of biphenyl formed (m. p. 67–69°) varied from 0.6–1.2 g. The oil remaining in the distilling flask was extracted with ether and dried over sodium sulfate. The ether was removed and the residual oil was fractionated under reduced pressure. The fraction boiling at 208–210° (5 mm.) was collected. The yield was 4.2 g. (71%).

*Anal.* Calcd. for $C_{20}H_{26}O_8$: C, 60.9; H, 6.5. Found: C, 61.1; H, 6.2.

**Saponification of Ethyl α-Phenylethane-α,α,β,β-tetracarboxylate.**—Forty cc. of 25% potassium hydroxide was refluxed with 1.7 g. of ethyl phenylethane-α,α,β,β-tetracarboxylate in an oil-bath until the oil had disappeared completely (twelve hours). The aqueous solution was once extracted with ether in order to remove all traces of biphenyl remaining in the ester, then cooled in ice water and acidified with 20% sulfuric acid. An amorphous solid separated. It was filtered and dried on a steam-bath and then pulverized. The white powder was heated in dilute sulfuric acid until complete solution occurred. The solution was combined with the former filtrate and extracted several times with ether. After drying and removing the ether a crystalline substance (0.96 g.) was obtained. The crude acid was crystallized from hot water using a little charcoal. A yield of 0.82 g. of crystals was obtained. It decomposed at about 160°.

**Phenylsuccinic Acid.**—The acid obtained above was placed in a small glass tube and heated in a sulfuric acid bath keeping the temperature at 170–175° while the carbon dioxide evolved briskly. When the evolution of gas had ceased, 0.77 g. (86% based on the tetra-ester) of crude phenylsuccinic acid was obtained. After one crystallization from water, the pure acid was obtained as fine needles weighing 0.73 g., m. p. 168° (Thorpe reported 168°; Lapworth reported 167°).[6]

*Anal.* Calcd. for $C_{10}H_{10}O_4$: neut. equiv., 97. Found: neut. equiv., 96.

**Ethyl α-Methylethane-α,α,β,β-tetracarboxylate.**—The procedure was similar to that used for the preparation of ethyl phenyl-ethanetetracarboxylate. From 4.7 g. of ethyl ethylenetetracarboxylate 3.8 g. (79%) of ethyl methyl ethanetetracarboxylate was obtained as a slightly yellowish oil boiling at 165–166° (5 mm.).

*Anal.* Calcd. for $C_{15}H_{24}O_8$: C, 54.2; H, 7.2. Found: C, 54.4; H, 7.8.

**Methylsuccinic Acid.**—In a 150-cc. 2-necked round-bottomed flask, which was fitted with a reflux condenser and a mechanical stirrer, 2.4 g. of ethyl methylethanetetracarboxylate and 40 cc. of 20% potassium hydroxide were heated under reflux with stirring for seven hours. The solution was acidified and then extracted with ether. The aqueous layer was further extracted with ether in a continuous extraction apparatus. The ethereal extracts were combined and dried. After the solvent had been removed, an oil was obtained which was then heated at a temperature 150–160° until no more carbon dioxide was evolved. The residue was dissolved in water, decolorized, and evaporated to dryness. The residual oil solidified slowly in the desiccator. It was crystallized from a mixture of petroleum ether and chloroform. The pure acid was obtained as beautiful crystals, m. p. 110–111° (Boettinger reported 112.5°; Bone and Sprankling reported 110°).[9] The melting point was not depressed by mixing with an authentic specimen.

**Ethyl α-Ethylethane-α,α,β,β-tetracarboxylate.**—The procedure was similar to that used in the previous experiment. The Grignard reagent was prepared from 6.5 g. of ethyl bromide and 1.4 g. of magnesium shavings and allowed to react with 4.2 g. of ethyl ethylenetetracarboxylate. The crude product was obtained as a yellowish oil. The oil was allowed to stand for a few days. The crystals which separated were filtered and washed with a small amount of cold alcohol. On further standing a second crop of crystals was obtained. The process was repeated until no more crystals separated. The total amount of crystals weighed about 1.8 g., m. p. 76°. The melting point was not depressed by mixing with ethyl ethane-α,α,β,β-tetracarboxylate. The oil, freed from the reduced compound, was fractionated under reduced pressure. The fraction boiling at 180–183° (6 mm.) was collected. The product was of pale yellow color and weighed 2.6 g. (56%).

*Anal.* Calcd. for $C_{16}H_{26}O_8$: C, 55.5; H, 7.5. Found: C, 54.8; H, 7.9.

**Ethylsuccinic Acid.**—The saponification of the ester was similar to that of the ethyl methylethanetetracarboxylate. The decarboxylation was carried out at a temperature of 150–160° for thirty minutes. The product was decolorized in hot water. On evaporation, 0.37 g. (36% of the theoretical amount based on the tetra-ester) of oil remained. The oil solidified completely on standing. It was crystallized from chloroform–petroleum ether mixture, and the pure ethyl succinic acid melting at 96–98° (Huggenberg reported 98°; Polk reported 97°)[10] was obtained as fine crystals.

*Anal.* Calcd. for $C_6H_{10}O_4$: neut. equiv., 73. Found: neut. equiv., 73.

## Summary

1. The mode of addition of both aryl and alkylmagnesium bromide to ethyl ethylenetetracarboxylate has been shown to take place exclusively 1:4.

2. A general method for the preparation of monosubstituted succinic acids has been described and phenyl-, methyl- and ethyl-succinic acids were synthesized in this way.

# The Catalytic Reduction of Bromobenzene to Biphenyl[1,2]

BY FRANK R. MAYO[3] AND MELVIN D. HURWITZ[4]

Busch and co-workers[5] have shown that bromobenzene and some other aromatic halides could be reduced in the presence of a palladium catalyst to yield both benzene and biphenyl. The latter reaction was unique in that only partial reduction of the carbon–halogen bond occurred, and a new carbon–carbon bond was formed. The object of the present work was to determine the effect of experimental conditions on the yield of biphenyl in the hope that it would extend knowledge of the mechanism of catalytic reduction, and might also make possible new applications of semi-reduction methods in organic synthesis.

**Standard Experiment.**—A set of experimental conditions was chosen as a standard of comparison for reagents and for the effect of varied conditions. Methanol served as both solvent and reducing agent.

In a 200-cc., 3-necked, round-bottomed flask, equipped with an oil-sealed stirrer and reflux condenser, 7.85 g., 0.05 m., of bromobenzene, 3 g. of 1% palladium-on-calcium carbonate (Pd–$CaCO_3$) catalyst, 10 cc. of 10 *N* aqueous potassium hydroxide, and 90 cc. of methanol were mixed and refluxed until the catalyst was completely black or reduced. The catalyst was then separated by filtration, and the filtrate evaporated on a steam-bath to a volume of 25 cc. Water was then added to precipitate the biphenyl which was collected on a filter, dried in a vacuum desiccator, and weighed. The filtrate was made up to 500 cc., and an aliquot was titrated for bromide by the Volhard method to determine the extent to which bromobenzene had been reduced.

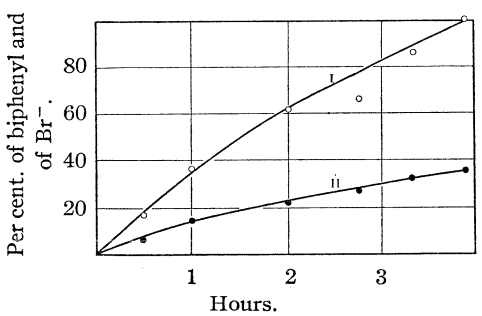

Fig. 1.—Reduction of bromobenzene to biphenyl and to $Br^-$ as a function of time: I, biphenyl; II, $Br^-$.

The two reactions occurring may be represented by the equations

$$C_6H_5Br + KOH + CH_3OH \longrightarrow C_6H_6 + KBr + H_2O + CH_2O \quad (1)$$

$$2C_6H_5Br + 2KOH + CH_3OH \longrightarrow (C_6H_5)_2 + 2KBr + 2H_2O + CH_2O \quad (2)$$

**End-Point of Reduction.**—The light brown palladium oxide catalyst was reduced to black palladium during the course of the reaction.

Six batches of 1% Pd–$CaCO_3$ catalyst, designated A to F, were prepared according to a modification of Busch's[5a] procedure by adding an aqueous solution of palladium chloride to the calculated amount of C. P. calcium carbonate in a water suspension and heating to complete the precipitation of palladium oxide. The product was then washed with water until free of chloride, and dried *in vacuo* over concentrated sulfuric acid.

Since the bromobenzene protected the metal oxide from reduction, the color change indicating complete reduction of the catalyst was sharp and indicated complete reduction of the bromobenzene. Catalyst B, which required 2.75 hours for complete reduction in a standard reaction mixture, was reduced in four minutes when the bromobenzene was omitted. Results of standard experiments with fresh portions of catalyst C are summarized in Fig. 1, which shows the correlation of yield of biphenyl and reduction of the bromobenzene with time.

As already indicated, the time for completion of a standard experiment, recorded in Table I, varied with the batch of catalyst. Although the reduction times varied over a wide range, the yields of biphenyl were constant within experimental error.

TABLE I

TIME FOR COMPLETE REDUCTION OF VARIOUS CATALYST BATCHES

| Catalyst | Reduction time, hr. | Found, % $Br^-$ | Found, % $(C_6H_5)_2$ |
|---|---|---|---|
| A | 0.50 | 96.4 | 34.0 |
| B | 2.75 | 98.8 | 35.6 |
| C | 3.91 | 100.6 | 35.3 |
| D | 1.00 | 99.0 | 35.3 |
| E | 2.00 | 100.5 | 35.0 |
| F | 6.50 | 99.8 | 34.0 |

**Properties of the Reduced Catalyst.**—The reduced catalyst was more active for reducing the halide, but less active for biphenyl production than the unreduced catalyst. This enhanced activity decreased with re-use, with the activity for biphenyl formation dropping off more sharply. A catalyst reduced originally in the absence of bromobenzene exhibited the same characteristics.

In a series of standard experiments Catalyst C was reused in seven successive runs. The time was held constant at 1.33 hours, since after the first run there was no indicator to give the end-point of the reduction. The fresh Catalyst C required 3.91 hours for complete reduction (see Fig. 1). In the second run 88.6% of the halide was

Chem.*, 232 (1918); (c) Busch, *ibid.*, **38**, 519 (1926); **47**, 536 (1934); (d) Busch and Schultz, *Ber.*, **62**, 1458 (1929); (e) Busch and Schmidt, *ibid.*, **62**, 2612 (1929); (f) Busch and Weber, *J. prakt. Chem.*, **146**, 1 (1936).

reduced in 1.33 hours. This state of reduction would have taken about 3.5 hours with fresh catalyst, and indicated that the reduced catalyst was about 2.6 times more active. The activity of the reduced catalyst fell off, so that in the eighth run only 67.4% of the halide was reduced in 1.33 hours—or only 2.1 times as fast as with the unreduced catalyst. The yield of biphenyl decreased more rapidly, from 20.2% in the second to 11.4% in the eighth.

**Effect of Water.**—Water up to a concentration of 50% by volume increased the yield of biphenyl. Above 50%, where the reaction liquids separated into two phases, the biphenyl yield fell off rapidly.

TABLE II

EFFECT OF WATER ON BIPHENYL YIELD[a]

| % $H_2O$ by vol.[b] | Reduction time, hr. | Found, % $Br^-$ | Found, % $(C_6H_5)_2$ |
|---|---|---|---|
| 0.0 | 5.0 | 101.0 | 27.0 |
| 9.0[c] | 2.75 | 98.8 | 35.6 |
| 16.0 | 2.0 | 87.8 | 40.3 |
| 25.0 | 2.0 | 100.9 | 42.7 |
| 50.0 | 2.0 | 98.8 | 50.4 |
| 68.0 | 2.0 | 98.0 | 20.8 |

[a] Catalyst B. [b] In alcohol–water–KOH reaction mixture. [c] Standard experiment.

**Effect of Bases.**—To obtain the maximum yield of biphenyl, at least one equivalent of potassium hydroxide was required per mole of bromobenzene. The effect of additional alkali on the yield was small, but the rate of reduction was accelerated. Potassium carbonate, pyridine, aniline, and sodium methoxide were substituted for potassium hydroxide in the standard experiment. The reduction with potassium carbonate required about six times as long as with potassium hydroxide and only about half the usual yield was obtained. There was no reduction of the halide in the presence of pyridine or aniline unless potassium hydroxide was present, in which case they greatly retarded the rate of reduction and decreased the yield of biphenyl. With sodium methoxide there was no reduction in twenty hours of refluxing. Biphenyl and benzene were the only reduction products formed. These results are summarized in Table III.

TABLE III

EFFECT OF BASES ON REDUCTION[a]

| Ratio moles base/$C_6H_5Br$ | Reduction time, hr. | Found, % $Br^-$ | Found, % $(C_6H_5)_2$ |

| 1.0 MeONa | 20.0[b] | 0.0 | 0.0 |

[a] Catalyst B. [b] Catalyst not fully reduced. [c] Standard Experiment.

**Effect of Hydrogen Gas.**—In runs where hydrogen gas was bubbled through a standard reaction mixture, at reflux, the reduction of the halide was accelerated but the yield of biphenyl was decreased.

Catalyst F, requiring 6.5 hours for complete reduction in the absence of hydrogen, required only an hour in its presence; the biphenyl yield dropped to less than 2%. Re-use of the reduced catalyst gave the same results as the fresh catalyst.

**Effect of Solvent.**—Three other solvents, ethanol, isopropyl alcohol, and dioxane, were substituted for methanol in the standard experiment. Reduction was negligible; no biphenyl was isolated, and tars were formed.

**Other Catalysts.**—Metals other than palladium were tried as catalysts to check Busch's[5f] conclusion that palladium was truly specific for biphenyl formation. Nickel and copper catalyst, prepared like the standard Pd–$CaCO_3$ catalyst were found to be totally inert with or without hydrogen. Platinum oxide catalyst was inert in the absence of hydrogen and very sluggish with hydrogen in the standard aqueous-alcohol reaction mixture or in alcohol alone. No trace of biphenyl was found in any of the experiments described above. Raney nickel catalyst was active in reducing the halide in the presence of hydrogen only, but again there was no trace of biphenyl formed.

A colloidal palladium-on-polyvinyl alcohol catalyst (Pd-PVA), prepared according to the directions of Rampino and Nord,[6] was completely inert in the Standard Experiment, but very active in reducing the halide in the presence of hydrogen, yielding no biphenyl.

The reductions with the Pd-PVA catalyst with hydrogen were carried out in a conventional low pressure hydrogenator, at a hydrogen pressure of about 2 atmospheres. While this catalyst was not reduced readily if the bromobenzene was added before its reduction in the presence of hydrogen, the rate of the reduction of the bromobenzene was not affected.

**Vapor Phase Experiments.**—No biphenyl was produced in any of the vapor phase experiments using palladium catalysts, with or without hydrogen. The essentially quantitative recovery of the bromobenzene in all runs indicated little reaction.

Catalysts were prepared in the following manner: (a) Potassium hydroxide, 3.0 g., was powdered by grinding under ether and mixed there with 1.5 g. of the Pd–$CaCO_3$ catalyst. The powder left after evaporation of the ether was dispersed in glass wool which filled the 1.4 × 20 cm. U-tube reaction vessel. Each filling of the reaction vessel contained 0.05 g. of palladium metal. (b) Solutions of palladium chloride, with and without potassium hydroxide, were dried on clay chips and on asbestos fibers, used as catalyst carriers.

The reaction vessel was immersed in an oil-bath held at 195–200°, 50 cc. of methanol solution containing 0.05 m. of bromobenzene was dropped in from a separatory funnel at such a rate that complete addition took two

(6) Rampino and Nord, THIS JOURNAL, **63**, 2745, 3268 (1941).

hours. The solution volatilized on reaching the hot portion of the tube, and the gases that passed through the tube were condensed and collected at the other end.

**Effect of Catalyst Poisons.**—Catalytic amounts of nickel and copper salts had no significant effect on the rate of reduction of the bromobenzene in the standard experiment, but the biphenyl yield dropped to less than 5%. The stronger hydrogenation catalyst poisons, arsenic trioxide, and sulfides, completely inhibited all reaction.

**Miscellaneous Experiments.**—Analyses of the reduction products of each group of experiments showed only biphenyl, less than 1% of higher polyphenyls, and benzene. The biphenyl fractions of all runs were combined, and subjected to a sodium fusion. Only a trace of halide was found.

Benzene and biphenyl were added to standard runs without affecting either the expected yield of biphenyl, the rate of reaction, or the products. In runs using a standard reaction mixture with added biphenyl, but without bromobenzene, the recovery of biphenyl was the same as in a control run without catalyst after four hours of refluxing. Only biphenyl was recovered.

In a standard run using *p*-bromobiphenyl in place of bromobenzene, the reaction rate approximated that of the reaction with bromobenzene. The yield of quaterphenyl was 30.8%, biphenyl 61.0%.

## Discussion

In view of the fact that detailed mechanisms have not yet been formulated for common catalytic reductions, it would be surprising if the present work could present a detailed mechanism for a very unusual type of catalytic reduction, the formation of biphenyl from bromobenzene. This work, however, has produced evidence that this unusual reaction required a palladium catalyst in a fairly specific state, a reducing agent with specific properties, and experimental conditions favorable to the adsorption of bromobenzene on the catalyst.

Repeated recovery and re-use of a catalyst sample led to a gradual diminishing rate of reduction, but the rate of formation of the biphenyl decreased faster than the rate of formation of benzene. These effects suggest that the two reductions are at least partially independent, the biphenyl formation being more sensitive to poisons or the state of the catalyst. This conclusion is further indicated in that copper and nickel salts suppress the formation of biphenyl but do not affect the reduction to benzene. The fact that no biphenyl could be obtained with nickel, platinum, or even colloidal palladium indicated that biphenyl formation is a reaction probably highly specific for certain palladium surfaces.

A highly specific reducing agent also seems to be required for biphenyl formation. The only successful reducing agent employed in the present work was methanol in the presence of strong base, at least equivalent to the amount of bromobenzene used. If insufficient alkali was used in the standard experiment, the solution approached neutrality and the reduction stopped. These proportions suggest but do not prove, that methylate ion was the reducing agent. Ethanol and isopropyl alcohol were found to be ineffective reducing agents. Busch suggested that the differences between these alcohols were related to their dielectric constants, but the latter differ little. A more probable explanation depends on the relative ease of dehydrogenation of the alcohols and the effect of aldehyde or ketone condensation products on the catalyst. Hydrogen gas, by accelerating the formation of benzene, inhibited the formation of biphenyl. These observations suggested that the bromobenzene was reduced by the alcohol or alcoholate ion to phenyl radicals on the active centers on the surface of the catalyst. If further reduction did not occur too easily, the phenyl radicals combined to give biphenyl. In the presence of hydrogen, even at atmospheric pressure, practically all were reduced to benzene.

The effect of water and amines in the standard experiment can be explained on the basis of the probable effect of these factors on the ease of adsorption of the halobenzene on the catalyst. Increasing the proportion of water in the alcohol solution increased the yield of biphenyl, presumably by decreasing the solubility of the bromobenzene and increasing its adsorption on the catalyst. Addition of pyridine or aniline decreased the rate of reduction without greatly affecting the proportions of products formed by being preferentially adsorbed on the catalyst.

Failure of added benzene to increase the yield of biphenyl from bromobenzene or of biphenyl to yield terphenyl, showed that biphenyl and benzene were not intermediates in terphenyl and biphenyl formation, respectively. The fact that *p*-bromobiphenyl gave considerable quaterphenyl on reduction, and that only traces of quaterphenyl were formed from bromobenzene, showed that bromobiphenyls are probably not intermediates in the formation of biphenyl. All the evidence seems consistent with the view that the reduction of bromobenzene to biphenyl is a surface reaction probably proceeding through adsorbed phenyl radicals.

## Summary

The reduction of bromobenzene was studied using methanol as solvent and reducing agent, and palladium on calcium carbonate as catalyst. In the presence of strong base, up to 50% yield of biphenyl was obtained, benzene being the other reduction product. The effects of solvents, quantity and kind of base, other catalysts, hydrogen, metal salts, and end-products on the rate of reduction and on the benzene–biphenyl ratio were determined. Most changes in procedure reduced or eliminated the formation of biphenyl, often

without appreciably affecting the rate of formation of benzene. Biphenyl seems to be formed by coupling of adsorbed phenyl radicals on a specific surface in the absence of a more adequate source of hydrogen.

# Arsenoso Derivatives of Phenyl-substituted Fatty Acids[1]

BY LEON D. FREEDMAN[2] AND G. O. DOAK[3]

The substitution of an acidic group in arsenosobenzene or its derivatives generally inhibits the activity and decreases the potential therapeutic utility of this class of compound.[4] An exception has been found in γ-(*p*-arsenosophenyl)-butyric acid which possesses marked trypanocidal activity and has undergone extensive therapeutic trial.[5] This unusual activity is not shown by the homologous *p*-arsenosophenylacetic and β-(*p*-arsenosophenyl)-propionic acids.

The present paper describes the preparation and properties of two higher homologs, one isomer and one derivative of γ-(*p*-arsenosophenyl)-butyric acid, as well as two other acid-substituted derivatives of arsenosobenzene.

For the preparation of several of these compounds, the *p*-nitro- and *p*-aminophenyl derivatives of the corresponding fatty acids were required as intermediates. The method of Van der Scheer[6] was previously used in this Laboratory for the preparation of γ-(*p*-nitrophenyl)- and γ-*p*-aminophenyl)-butyric acids, necessary for the synthesis of γ-(*p*-arsenosophenyl)-butyric acid.[7] The nitration procedure gave poor yields, probably due to oxidation of the side chain at the temperature employed. In an attempt to improve the yield, γ-phenylbutyric acid was nitrated under a variety of conditions. The most satisfactory yield was obtained by a procedure described in the Experimental Part. This procedure was also used for the nitration of δ-phenylvaleric acid. An improved method for the reduction of these nitro compounds to the desired amino compounds is also described.

For the preparation of *m*-arsonocinnamic acid the Scheller reaction was used.[8] The remaining arsonic acids were synthesized by the method of Palmer and Adams.[9] Since *p*-arsonomandelic acid was obtained as a sirup, which could not be crystallized, it was converted to the disodium salt which was readily crystallized from alcohol.

The arsenoso compounds were prepared by reduction of the corresponding arsonic acids with sulfur dioxide and hydriodic acid in the presence of hydrochloric acid, followed by hydrolysis of the resulting dichloroarsines with sodium bicarbonate. We were unable to isolate *p*-arsenosomandelic and γ-(2-amino-4-arsenosophenyl)-butyric acids because of their solubility in water. Therefore these two compounds were isolated as the dichloroarsines and neutralized in solution just prior to therapeutic testing.

The chemotherapeutic activity of these compounds has been reported previously.[5,10] δ-(*p*-Arsenosophenyl)-valeric acid was one-half as active against *T. equiperdum* as γ-(*p*-arsenosophenyl)-butyric acid, while none of the remaining compounds possessed any appreciable activity.

## Experimental Part

**δ-Phenylvaleric Acid.**—This compound has previously been described by Ali, *et al.*,[11] but no yield was reported. Using a somewhat similar procedure[12] we reduced γ-benzoylbutyric acid to the desired compound, which was purified by distillation under reduced pressure. The yield was 63%; b. p. 164–168° (5 mm.); m. p. 51–53° (cor.).

**ε-Phenylcaproic Acid.**—The method used for the preparation of this compound differed from that previously described by Grateau[13] in that δ-benzoylvaleric acid, rather than the corresponding ethyl ester, was reduced by the Clemmensen method.[12] The yield was 86%; b. p. 165° (1 mm.); f. p. 10–11°.

**Nitration of γ-Phenylbutyric Acid.**—γ-Phenylbutyric acid (140 g.) was added in small portions to 250 ml. of fuming nitric acid (d. 1.50) which was maintained at a temperature between −20 and −30° by means of an alcohol–Dry Ice-bath. The time of addition was two to three hours and the mixture was stirred mechanically throughout this period. A further 10 ml. of acid was then used to wash down the sides of the reaction vessel and the temperature was kept at −10° for a further one-half hour. The clear solution was poured into a four-liter beaker filled with cracked ice. The oil which precipitated solidified on standing for fifteen minutes. The mixture was allowed to stand in the ice-box overnight after which the solid was removed by filtration and washed with cold water.

| γ-(2-Amino-4-R-phenyl)-butyric, hydrochloride[h] | 163–164 | 27 | $C_{10}H_{12}AsCl_2NO_2.HCl$ | 20.8 | 20.7 |

[a] Water was used as the solvent in the recrystallization of all arsonic acids. [b] The melting points were determined by the method described in paper VI of this series, Steinman, Doak and Eagle, THIS JOURNAL, **66**, 192 (1944), or by the method of Morgan and Hamilton, *ibid.*, **66**, 874 (1944). [c] All analyses are the average of two or more determinations. [d] Calcd: N, 4.21. Found: N, 4.21. [e] Calcd.: N, 4.36. Found: N, 4.44. [f] The arsenoso compounds were obtained in an amorphous form and could not be crystallized from common solvents. [g] The dichloroarsines were obtained in crystalline form by solution in water, followed by the addition of concentrated hydrochloric acid. [h] Calcd.: N, 3.89. Found: N, 3.86.

It was then recrystallized twice from benzene. The yield of pure γ-(*p*-nitrophenyl)-butyric acid was 74 g. (42%); m. p. 93°. From the benzene mother liquors, a solid was obtained which melted at 55–56° after repeated recrystallization from benzene. Oxidation of this fraction with alkaline permanganate gave a mixture of *o*- and *p*-nitrobenzoic acids (52% of the para isomer) which were easily separated by their differential solubility, and were identified by mixed melting points with authentic samples of the two substances. No attempt was made to further separate the two isomeric nitrophenylbutyric acids.

**δ-(*p*-Nitrophenyl)-valeric Acid.**—δ-Phenylvaleric acid (58.9 g.), nitrated by the above procedure, gave 29.0 g. (40%) of pure δ-(*p*-nitrophenyl)-valeric acid after three recrystallizations from benzene. It was obtained as light-yellow hexagonal needles; m. p. 83.8–84.4° (cor.). The structure was proved by oxidation to *p*-nitrobenzoic acid with alkaline permanganate.

*Anal.* Calcd. for $C_{11}H_{13}NO_4$: N, 6.28; neut. equiv., 223. Found: N, 6.04; neut. equiv., 224.

**ε-(*p*-Nitrophenyl)-caproic Acid.**—The above nitration procedure yielded an oil which could not be crystallized; accordingly the procedure of Van der Scheer[6] was used for the preparation of this compound.

**γ-(*p*-Aminophenyl)-butyric Acid.**—The corresponding nitro acid (20.9 g.) was dissolved in 25 ml. of alcohol and reduced catalytically at 40 lb. gage pressure, using Raney nickel as catalyst. The reduction was rapid and complete. After recrystallization from water, the amino compound (16.1 g., 90%) melted at 130–131° (cor.).

**δ-(*p*-Aminophenyl)-valeric Acid.**—This compound was prepared in 93% yield by a similar procedure. It crystallized from water in white needles; m. p. 111–112.3° (cor.).

*Anal.* Calcd. for $C_{11}H_{15}NO_2$: N, 7.25; neut. equiv., 193.2. Found: N, 7.18, 7.04; neut. equiv., 193.4.

**ε-(*p*-Aminophenyl)-caproic Acid.**[6]—Catalytic reduction of the corresponding nitro acid gave this compound in 67% yield; m. p. 105–107° (cor.).

**α-(*p*-Aminophenyl)-butyric Acid.**—Catalytic reduction gave the amino compound in 75% yield; m. p. 142° (cor.). It has previously been prepared by Fourneau and Sandulesco who used a different procedure.[14]

***p*-Aminomandelic Acid.**—Catalytic reduction of *p*-nitromandelic acid with Raney nickel as catalyst gave a red product, insoluble in acids, which was not further characterized. The desired amino compound was obtained by the method of Heller.[15]

**γ-(2-Nitro-4-arsonophenyl)-butyric Acid.**—γ-(*p*-Arsonophenyl)-butyric acid (14.4 g., 0.05 mole) was added in small portions to 16 ml. of concentrated sulfuric acid maintained at −10°. When no undissolved material remained, 3.8 g. of fuming nitric acid (sp. gr. 1.5) were added dropwise. The solution was stirred for one-half hour and then placed in a bath at 36°. The temperature of the mixture rose to 42°, then fell to bath temperature. After being stirred a further fifteen minutes it was poured onto ice. An oil separated which quickly solidified. The crude material as recrystallized from hot water.

**γ-(2-Amino-4-arsonophenyl)-butyric Acid.**—Catalytic reduction of the above nitro compound, using Raney nickel as catalyst, was not successful. The nitro compound was reduced by the method of Jacobs, Heidelberger and Rolf.[16] The resulting amino compound was recrystallized from alcohol and then from water. It crystallized with one molecular equivalent of water of crystallization.

## Summary

Several new arsenoso derivatives of phenyl-substituted fatty acids have been prepared. None of these compounds possess the unusual trypanocidal activity of γ-(*p*-arsenosophenyl)-butyric acid. Improvements in the preparation of the latter compound are also described.

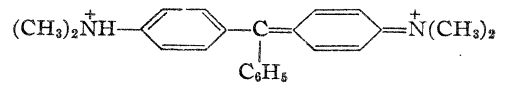
# The Spectra of Some Diaminotriphenylmethane Dyes in Concentrated Sulfuric Acid

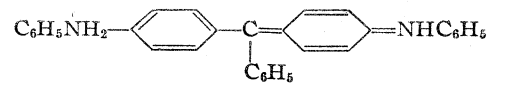
BY GERALD E. K. BRANCH AND BERT M. TOLBERT

A diaminotriphenylcarbinol has three basic structures, namely, the two amino groups and the triphenylcarbinol structure. Under sufficiently acidic conditions it should neutralize three equivalents of acid. The final product would be a disubstituted triphenylmethyl ion. The substituent radicals are aminium not amino groups. The aminium group is not an auxochrome, and hence the third ion of the dye should not absorb light of long wave lengths. Triphenylmethyl ion absorbs very little light at wave lengths longer than 450 mμ.



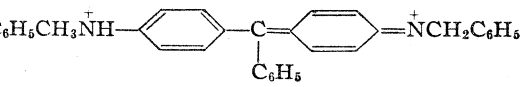
However Hill, Branch and Patapoff[1] observed a band at 678 mμ in the spectrum of viridine green (II) in concentrated sulfuric acid. This band could belong to neither the first nor the second ion, for under less acidic conditions the first ion is entirely converted to the second ion, whose longest band has its maximum at 495 mμ. Nor can one believe that a simple derivative of triphenylmethyl ion could have a strong absorption band with a maximum at 678 mμ. The authors of the above mentioned paper suggested that the band at 678 mμ was due to an intermediate product in the sulfonation of the dye, for on standing the band at 678 mμ was replaced by another at 580 mμ.

For further study of this phenomenon, the spectra of several diaminotriphenylmethane dyes were measured in a mixture of two volumes of acetic acid and ninety-eight volumes of concentrated sulfuric acid (d. 1.84 g./ml.). The spectra were measured immediately after making up the solutions, and after the solutions had stood twenty-six days at room temperature. In general the spectra changed on standing. No attempts were made to measure the rates and extents of these changes.



The formation of an ion of the dye, or an addition of sulfuric acid to the dye would be reversed when a solution in sulfuric acid is diluted with acetic acid. Sulfonation and decompositions would not be reversed. To study the nature of the irreversible changes, solutions in concentrated sulfuric acid were allowed to stand for a week, diluted with acetic acid, and their spectra compared with those of freshly prepared solutions in the same mixture of sulfuric acid and acetic acid. Generally sulfonation does not produce a large change in the spectra of the first and second ions of these dyes, but it must greatly reduce the basicity of the dye. When the spectra of a dye and its sulfonation derivative are measured at an acidity at which either the dye or the derivative exists as a mixture of first and second ions, the ratio of absorption by the first ion to that by the second ion is greater for the derivative than for the parent dye, and the two spectra differ markedly, and in an expected way.

(1) Hill, Branch and Patapoff, THIS JOURNAL, **67**, 545 (1945).

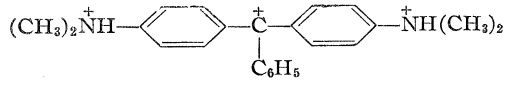


We think that the most illuminating results we obtained were those with malachite green (I), viridine green (II) and the N,N-dimethyl derivative of viridine green (III). The formulas of these dyes as their second ions are shown below

I

II

III



The results obtained with I were in sharp contrast with those obtained with II and III. We shall first describe and discuss the results with these three dyes, treating II and III as a unit. We shall then present and briefly discuss the spectra of five other dyes.

**Malachite Green** (I).—The spectrum of malachite green in concentrated sulfuric acid is shown in Fig. 1. This spectrum changed in no detectable way after standing for twenty-six days at room temperature. When a solution in concentrated sulfuric acid was allowed to stand for a week, and then diluted with acetic acid, the molecular extinction coefficients were, within experimental error, the same as those of a freshly prepared solution of (I) in the same solvent over the entire range of wave lengths measured (700 mμ to 300 mμ). Apparently no sulfonation or other irreversible reaction occurred.

The spectrum of malachite green in concentrated sulfuric acid is very similar to that of triphenylmethyl ion, and quite unlike that of the second ion of malachite green. This can be seen from the following comparison of the spectral data: For malachite green in concentrated sulfuric acid, $\lambda_1 = 434$ mμ, $\epsilon_1 = 3.2 \times 10^4$, $\lambda_2 = 388$ mμ, $\epsilon_2 = 2.7 \times 10^4$, $\lambda_3 = 288$ mμ, $\epsilon_3 = 2.3 \times 10^3$; for triphenylmethyl ion,[2] $\lambda_1 = 431$ mμ, $\epsilon_1 = 4 \times 10^4$, $\lambda_2 = 404$ mμ, $\epsilon_2 = 4 \times 10^4$, $\lambda_3 = 289$ mμ, $\epsilon_3 = 2 \times 10^3$; for the second ion of malachite green,[3] $\lambda_1 = 450$ mμ, $\epsilon_1 = 3.0 \times 10^4$, $\lambda_2 = 322$ mμ, $\epsilon_2 = 5.5 \times 10^3$, $\lambda_3 = 262$ mμ, $\epsilon_3 = 9.5 \times 10^3$. There seems little doubt that in concentrated sulfuric acid malachite green changes to an ion very similar to triphenylmethyl ion. The formula of this ion is IV.

(2) Orndorf, Gibbs, McNulty and Shapiro, *ibid.*, **49**, 1545 (1927).

(3) Tolbert and Branch, *ibid.*, **69**, 1083 (1947).

IV

In Fig. 1 the spectrum is not shown further toward the red than 560 mμ. The measurements were made beyond 700 mμ, but there was no absorption in this region. Malachite green does not show the phenomenon observed by Hill, Branch and Patapoff with viridine green.

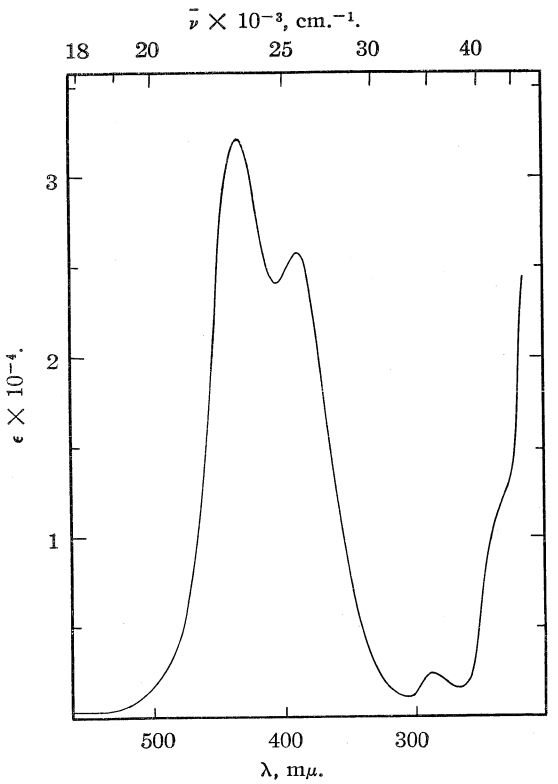


Fig. 1.—Spectrum of malachite green (I) in concentrated sulfuric acid.

**Viridine Green and its Dimethyl Derivative.**—The spectra of freshly prepared concentrated sulfuric acid solutions of II and III are shown in Fig. 2. The data for these spectra are $\lambda_1 = 677$ mμ, $\epsilon_1 = 1.9 \times 10^4$, $\lambda_2 = 512$ mμ, $\epsilon_2 = 2.1 \times 10^4$, $\lambda_3 = 349$ mμ, $\epsilon_3 = 1.1 \times 10^4$, $\lambda_4 = 269$ mμ, $\epsilon_4 = 1.3 \times 10^4$ for II, and $\lambda_1 = 710$ mμ, $\epsilon_1 = 2.25 \times 10^4$, $\lambda_2 = 485$ mμ, $\epsilon_2 = 2.3 \times 10^4$, $\lambda_3 = 270$ mμ, $\epsilon_3 = 1.3 \times 10^4$ with shoulders in the neighborhoods of 580 mμ, 450 mμ, and 350 mμ for III. The data for the second ions of these dyes are $\lambda_1 = 495$ mμ, $\epsilon_1 = 2.5 \times 10^4$, $\lambda_2 = 350$ mμ, $\epsilon_2 = 1.3 \times 10^4$, $\lambda_3 = 266$ mμ, $\epsilon_3 = 1.95 \times 10^4$ for II, and $\lambda_1 = 485$ mμ, $\epsilon_1 = 3.2 \times 10^4$, $\lambda_2 = 330$ mμ, $\epsilon_2 = 8.6 \times 10^3$, $\lambda_3 = 270$ mμ, $\epsilon_3 = 1.3 \times 10^4$ for III. The spectra in concentrated sulfuric acid are evidently those of the second ions with the spectra of other molecular species of the dyes superimposed on them. In both cases the new species have strong absorption bands in the neighborhood of 700 mμ.

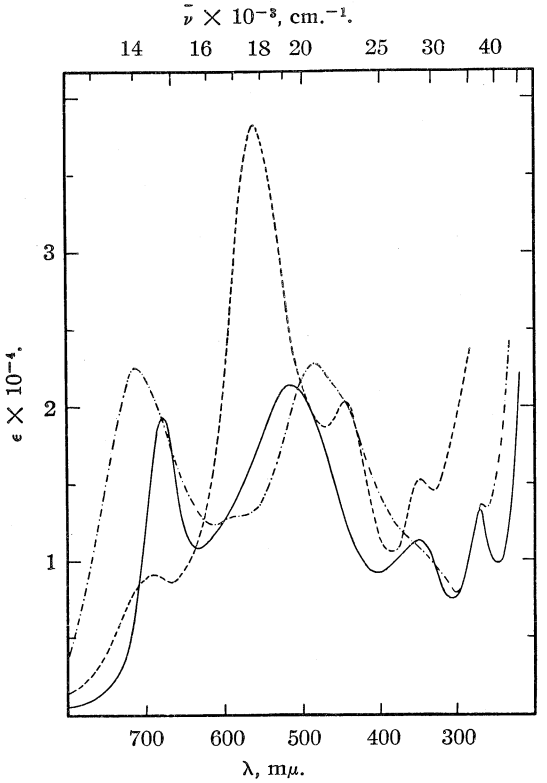

Fig. 2.—Spectra of dyes II, III and VIII in concentrated sulfuric acid: — dye II, -·-·- dye III, - - - dye VIII.

When solutions of II and III in concentrated sulfuric acid were allowed to stand and then diluted with acetic acid, the spectra of the resulting solutions were typical of first ions of diaminotriphenylmethane dyes, though at the same concentration of sulfuric acid the spectra of the parent dyes were those of mixtures of the first and second ions. This is illustrated in Fig. 3 for the case of II, at two volume per cent. of sulfuric acid. This is shown by the following data. For the first ion of II, $\lambda_x = 637$ mμ, $\epsilon_x = 4.7 \times 10^4$, $\lambda_y = 447$ mμ, $\epsilon_y = 1.3 \times 10^4$. With two per cent. of sulfuric acid $\lambda_x = 638$ mμ, $\epsilon_x = 2.9 \times 10^4$, and there was absorption covering the regions of the *x*-band of the second ion ($\lambda = 495$ mμ) and the *y*-band of the first ion ($\lambda = 447$ mμ). At this acidity an appreciable amount of the parent dye was converted to its second ion. But when II was allowed to stand for a week in concentrated sulfuric, the spectral data for the solution after it had been diluted to two per cent. sulfuric acid was $\lambda_x = 630$ mμ, $\epsilon_x = 4.4 \times 10^4$, $\lambda_y = 454$ mμ, $\epsilon_y = 1.6 \times 10^4$. This spectrum is very similar to that of the first ion of II. The irreversible change produced on standing in sulfuric acid was one that produces only small changes in the spectrum, but markedly decreases the basicity of the first ion. Evidently the irreversible reaction was sulfonation of benzene rings.

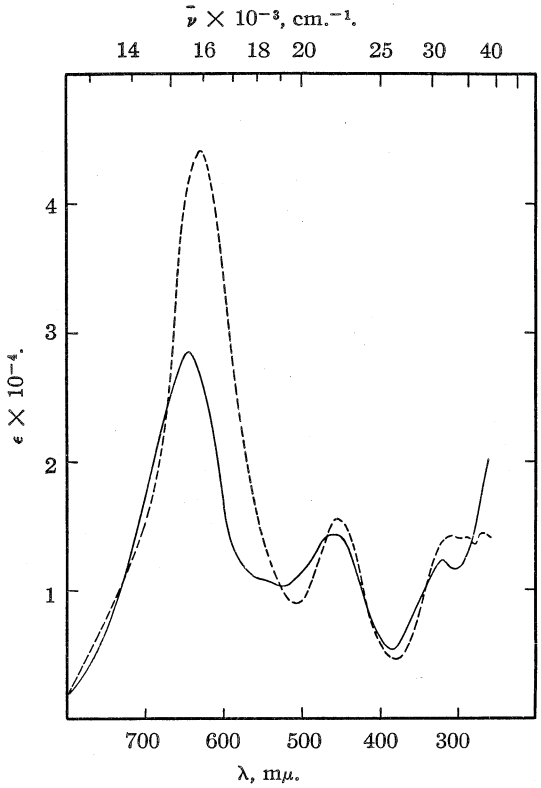

Fig. 3.—Spectra of dye II in acetic acid with 2% of sulfuric acid, before and after standing in concentrated sulfuric acid for a week: — after, - - - before.

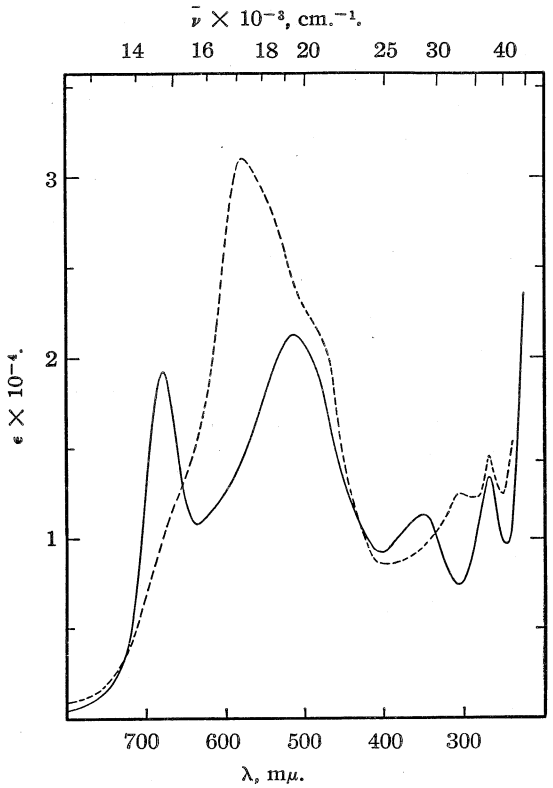

Fig. 4.—Spectra of dye II in concentrated sulfuric acid before and after standing for twenty-six days: — before, - - - after.

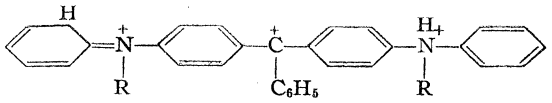
The spectrum of a freshly prepared solution of III in concentrated sulfuric had two regions of strong absorption. One of these was in the neighborhood of 700 mμ, and the other in the neighborhood of 500 mμ. The latter was due chiefly to the second ion, the former to a new species. The absorptions in the two regions were approximately equal. When the solution was allowed to stand the absorption in the neighborhood of 500 mμ grew at the expense of that at 700 mμ. During this period sulfonation of benzene rings occurred. Evidently sulfonation reduces the conversion of second ions to forms that absorb in the neighborhood of 700 mμ. This suggests that the forms absorbing at 700 mμ are higher ions, and that their disappearance is due to the reduction of basicity normally resulting from sulfonation.

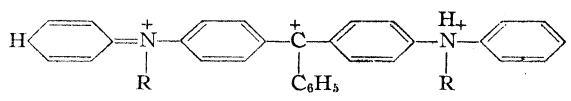
The spectrum of II in concentrated sulfuric acid changed in a quite different way on standing. This change is shown in Fig. 4. The spectrum was measured after twenty-six days, but visual observation showed that the change was nearly complete in a day. The chief feature of the spectrum after standing is a strong band with $\lambda = 580$ mμ, and $\epsilon = 3.1 \times 10^4$. The same phenomenon was observed by Hill, Branch and Patapoff.[1]

To whatever compound the absorption at 580 mμ was due, it was evidently formed in good yield, but was entirely destroyed when the solution was diluted with acetic acid.

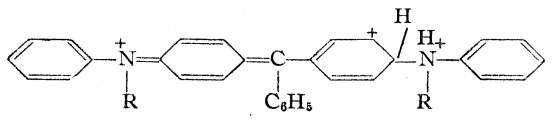
The chief difference between II and III is that II is a secondary amine while III is a tertiary amine. The difference observed in the spectra of the two dyes on standing is best explained as due to N-sulfonation. This reaction could occur with the secondary amine II, but not with the tertiary amine III. However there is no reason to believe that the second ion of any sulfonated product of II can have a band with $\lambda_{max}$ as great as 580 mμ. Sulfonation at the nitrogen atoms would greatly reduce the basicity of the dye, and hence could cause the reversion of the second ion to a first ion even in concentrated sulfuric acid. That $\lambda_x$ for the first ion of the N-sulfonated dye should be markedly smaller than that for the parent dye is to be expected. The value of $\lambda_x$ for the first ion of the N,N-diacetyl derivative of II is 539 mμ.



The acetyl groups are easily removed from the N-acetyl derivatives of II by hydrolysis in acid solution. By analogy one would expect that sulfonic acid groups are easily removed from N-sulfonic acid derivatives of II, by the lytic action of acetic acid. It is therefore not surprising that the band at 580 mμ disappeared when the solution was diluted. That C- as well as N-sulfonation occurred was shown by the spectrum of the diluted solution.



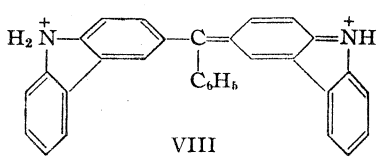
The value of the $\lambda_{max}$ of a diaminotriphenylmethane dye alternately increases and decreases by 100–200 m$\mu$ as protons are removed from or added to the nitrogen atoms, the greater $\lambda_{max}$ values occurring when the two nitrogen atoms have similar basicities. This alternation does not normally continue after the second ion has been reached, for on the next step both nitrogen atoms become neutralized by protons, thus insulating them from the chromophore and reducing $\lambda_{max}$. When as in II and III the alternation continues beyond the second ion, one might suppose that the amino groups have lost basicity, and the second ion has reverted to a first ion in spite of the increase in the acidity. But so great a reduction of the basicity of the amino groups would have a strong hypsochromic effect, and consequently such an explanation is not a valid explanation of the bands observed in the neighborhood of 700 m$\mu$, for the first ions of the parent dyes have $\lambda_{max}$ values a little smaller than 640 m$\mu$. It would appear therefore that the acid reacts to form a third ion in which the terminal rings extend the chromophoric conjugated system beyond the triphenylmethyl structure.



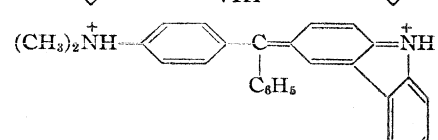
To assume that the band near 700 m$\mu$ is due to an addition of the acid to the $\pi$ electrons of a ring as a whole is begging the question. There is no known reason why such an addition should be strongly bathochromic. We shall assume an addition of the acid to a particular atom. For such an assumption to be acceptable it is necessary that the carbonium ion charge of the product should have a greater linear range of location than is found in triphenylmethyl ion in which the linear range for the charge is from the para position of one ring to the para position of another ring (9 atoms). Otherwise $\lambda_{max}$ would not be much greater than it is in triphenylmethyl ion (430 m$\mu$). Further it is also necessary that the carbonium ion charge of the addition product shall be locatable at more atoms than it is in triphenylmethyl ion (10 atoms). Otherwise, since the product has fewer benzenoidal rings than its type IV tautomer, and is for that reason very unstable with respect to its tautomer, it could not exist in appreciable quantities without the compensating factor of greater resonance of the charge.

We shall consider only the three product whose formulas are shown below. Other possibilities either could not absorb in the 700 m$\mu$ region, or are not acceptable for the same reasons that lead us to reject VII. In the formulas the added acid is represented by an H, and R is a methyl group when the parent dye is III, and a hydrogen atom when the parent dye is II.

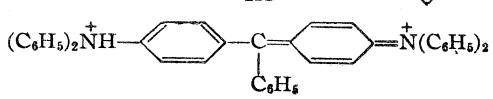
In VII, the charge may vibrate over thirteen atoms, and consequently such a product might account for the high value of $\lambda_{max}$. But there are only ten locations for the charge in VII, and these do not include the favored central carbon atom, but do include an already positively charged nitrogen atom. Consequently VII must be rejected as being too unstable with respect to its type-IV tautomer. One cannot assume that the equilibrium between VII and IV is not achieved, for the formation of the addition product is a rapid reversible reaction, and a type-IV compound is formed rapidly and reversibly from malachite green.



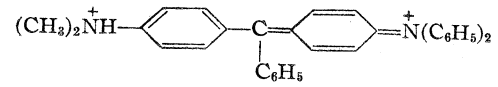
V



VI

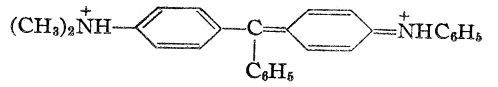


VII



The charge of V or VI vibrates linearly over 13 atoms. In V the number is 15 if the atoms are counted round the terminal ring. In VI there is the additional bathochromic factor of a branched system of double bonds in the terminal ring. If these carbonium ions are treated by the same rules as the cyanines, $\lambda_{max}$ of V or VI should be between 200 and 300 m$\mu$, greater than $\lambda_{max}$ of triphenylmethyl ion. That is, $\lambda_{max}$ should be between 650 and 750 m$\mu$. Both V and VI have thirteen locations for the charge, including the favored location on the central carbon atom. It is therefore possible that V and VI are stable with respect to their type IV tautomers. Since we have no preference between structures V and VI, we shall use V to mean V and/or VI.

**Other Phenylated Dyes.**—Experiments similar to those already described were done with some other phenylated diaminotriphenylmethane dyes. We shall use formula numbers instead of the complicated names to indicate these dyes. The formulas of the second ions are given below



VIII

IX

X

XI

XII

The change of the spectrum on ageing the solutions in concentrated sulfuric acid was not investigated for VIII and IX. The results obtained with X (Fig. 5) were inconclusive. The first ion of this dye is so weakly basic that in a 50–50 mixture of acetic and sulfuric acids there was no sign of the second ion. Hence there is a probability that the first ion was present in the sulfuric acid solution, which contained a considerable amount of the second ion. The *x*-bands of the first ions of II and III are greatly affected by the presence of the second ion. Although the absorption by X at long wave lengths was greatly changed in going from fifty per cent. to ninety-eight per cent. sulfuric acid, one cannot say whether the change was due to the effect of the second ion on the *x*-band of the first ion, or the production of higher than second ions. On standing, the sulfuric acid solution of X lost its optical clarity, and no conclusion could be drawn from the spectrum.

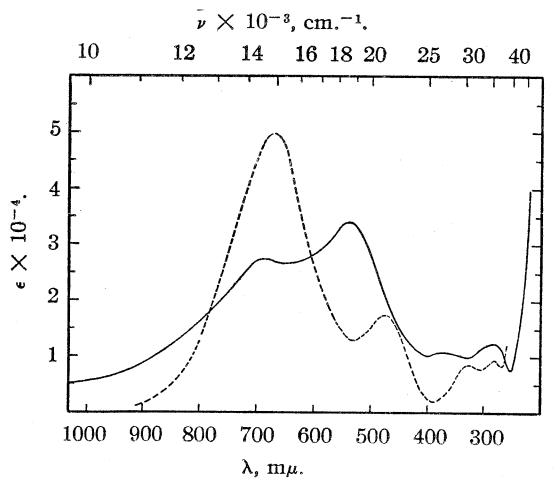


Fig. 5.—Spectra of dye X in a fifty–fifty mixture of acetic and sulfuric acids, and in concentrated sulfuric acid: — in concentrated sulfuric acid, – – – in fifty–fifty mixture.

The spectra observed for IX and XI indicated the presence of nothing but the second ions. The spectrum of IX in concentrated sulfuric acid was an exact replica of that shown for the second ion in reference 3. A shift of the bands toward the red was observed in XI. This is presumably a solvent effect. The spectral data for XI in sulfuric acid (Fig. 6) are $\lambda_1 = 538$ mμ, $\epsilon_1 = 3.7 \times 10^4$; $\lambda_2 = 355$ mμ, $\epsilon_2 = 1.1 \times 10^4$; $\lambda_3 = 270$ mμ, $\epsilon_3 = 1.3 \times 10^4$. The data in ten per cent. sulfuric acid are $\lambda_1 = 515$ mμ, $\epsilon_1 = 3.3 \times 10^4$; $\lambda_2 = 343$ mμ, $\epsilon_2 = 1.0 \times 10^4$, $\lambda_3 = 270$, $\epsilon_3 = 1.2 \times 10^4$.

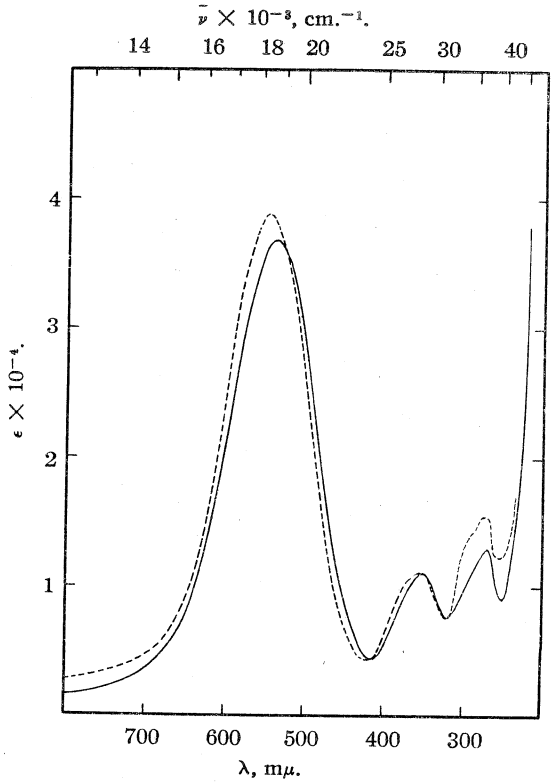

Fig. 6.—Spectra of dye XI in concentrated sulfuric acid before and after standing for twenty-six days: — before, – – – after.

The other two dyes VIII and XII (Figs. 2 and 7) showed the presence of type V ions. A definite band, $\lambda_{max} = 680$ mμ and $\epsilon = 9 + 10^3$, was obtained with VIII. A shoulder 680–700 mμ was obtained with XII.

The spectra of III, VIII and XII cannot be accounted for by bands in the neighborhood of 700 mμ and absorption by the second ions. In all three dyes some of this extra absorption was in the neighborhood of 450 mμ. This extra absorption appeared as a shoulder on the *x*-band of the second ion in III, as a small band, with $\lambda = 446$ mμ in VIII and as the most intense band ($\lambda = 440$ mμ) in the spectrum of XII. Since the strengths of these absorptions are related inversely to the intensity of the absorption by type V ions, presumably they are not due to type V ions; but to some other species, which we think is the type IV ion.

Terminal aryl groups on both nitrogen atoms are insulated in a type IV ion, but those on only one of the nitrogen atoms of a second ion are insulated. Hence the basicity of the second ion depends chiefly on the terminal groups on one nitrogen atom. Hence the relative basicities of the second ions should be correlated to the relative basicities of the less basic of the pair of amines out

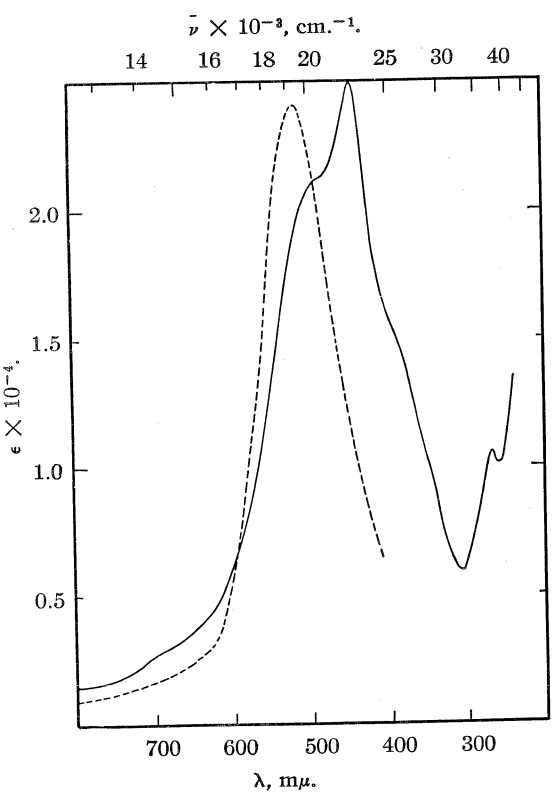

Fig. 7.—Spectra of dye XII in concentrated sulfuric acid before and after standing for twenty-six days: — before, – – – after.

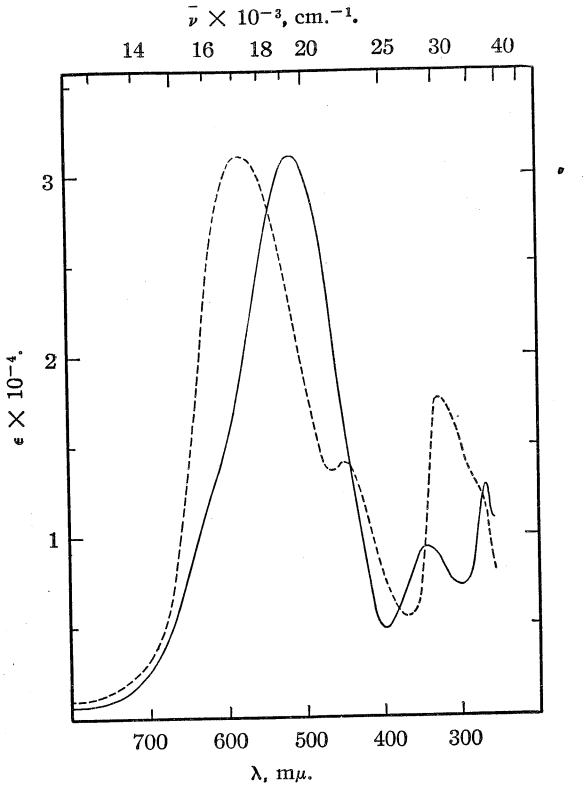

Fig. 8.—Spectra of dye XI in acetic acid with 2% sulfuric acid, before and after standing in concentrated sulfuric acid for a week: — before, – – – after.

of which the dye is made, the terminal groups from the more basic amine being insulated by the addition of the proton to form the second ion from the first. To obtain a type V ion one terminal aryl group is necessary. Other terminal aryl groups are either insulated or have only a small interaction with the rest of the molecule. Hence extra aryl groups or resonance either should have only a small effect on the amount of type V ion, or if located on the already phenylated nitrogen atom should reduce the conversion of the second ion to the type V ion.

Assuming that the relative intensities of the bands roughly mirror the relative concentrations of the three species the above deductions were to some extent confirmed by the experiments. Thus the second ion of I, which is derived from dimethylaniline, was completely neutralized, the second ions of VIII, IX and XI, which are derived in part or *in toto* from the very weakly basic amines, triphenylamine and carbazole, were the least affected by sulfuric acid, and II, III and XIII were of intermediate basicity. However, the agreement between deduction and experiment was far from perfect. The insulated aryl group has the effect of stabilizing the type V ion. Thus the type V ion was abundant in II and III, but only a trace was present in XII. The type V ion of VII was found, but at the same acidity no type V ion was observed in IX. Apparently the insulation is not complete. Tolbert and Branch[3] found bathochromic effects on the *x*-bands of the second ions leaking through the insulation.

The main thesis of this article is that the bands observed in the neighborhood of 700 mμ could have been due to a third ion that is tautomeric with the type IV ion, and derivable from it by a tautomeric shift of a proton from a nitrogen atom to an ortho or para position of a terminal aryl group. The arguments for this conclusion apply equally to a shift of this type from both nitrogen atoms. Against this double shift it can be argued that the band in the red was also found in the sulfuric acid solution of XII, which has only one terminal aryl group, and that calculation of $\lambda_{max}$ of the product of a double shift, by methods used to predict $\lambda_{max}$ values in cyanines, gives too large a value. Neither of these arguments is conclusive. The absorption in the red observed in XII was so small that it could have been due to an impurity with terminal groups on both nitrogen atoms. The amount needed would be too small to detect by analysis, or in the spectra of the first and second ions. Such an impurity could have been formed by disproportionation. Indeed Tolbert and Branch actually separated from the crude preparation of some of these dyes small amounts of dyes with spectra characteristic of triaminotriphenyl-

methane dyes. Although there is little doubt that structures like V represent oscillators very similar to the cyanines, it is not known that the constant for the increase of $\lambda_{max}$ with the number of interpolated double bonds would be the same as that found in cyanines. Were this constant half of what it is in the cyanines, the observed $\lambda_{max}$ would indicate the double shift.

With the exception of I, in all solutions in sulfuric acid that had stood, absorption due to third ions diminished. On dilution, such solutions, again with the exception of I, gave spectra that were characteristic of a diaminotriphenylmethane dye, but of one whose first ion was less basic than the first ion of the corresponding parent dye. It is natural that sulfonation should decrease the basicities of both first and second ions.

On standing, the spectra of XI changed very little (Fig. 6). That it had sulfonated was shown by the spectrum after dilution (Fig. 8). This spectrum was chiefly that of a first ion as can be seen from the bands in the far ultraviolet. However the main band comes at a wave length that is short for a phenylated dye. In dye XI the two amino groups are sufficiently different in basicities for the Brooker effect to be appreciable, on sulfonation of the terminal phenyl groups the difference of basicities of the two amino groups is increased, and the hypsochromic Brooker effect becomes accentuated. The appearance of the spectrum showed that there was a mixture in the solution as would be expected, since sulfonation would have reached different degrees in different molecules. Some second ions were probably present, but their bands were obscured by those of the first ions.

## Experimental

The spectra were measured with a Beckman spectrophotometer. The experimental details and the materials were all the same as those described or given by reference in the author's paper on the spectra of the second ions.[3] One detail should be repeated because of its special importance in this work. The mixtures of acetic and sulfuric acids in the comparison cell of the spectrophotometer were compounded and aged in the same way as the liquid in which the dye was dissolved. This was necessary to compensate for absorption, especially in the ultraviolet, that developed when mixtures of the two acids were aged. The absorption developed especially fast in mixtures of approximately equal proportions. In general the method of compensating for the charring appears to have been successful. The greatest error would have arisen when solutions that were treated with concentrated sulfuric acid were diluted. Heating was not always avoided during dilution. In solutions made in this way, the spectra at wave lengths less than 300 m$\mu$ should be considered dubious.

## Summary

The spectra in concentrated sulfuric acid of malachite green and some more phenylated diaminotriphenylmethane dyes were measured.

The spectrum of malachite green was so similar to that of triphenylmethyl ion, that it was assumed that, in concentrated sulfuric acid, malachite green exists as a triply charged ion with a structure similar to that of triphenylmethyl ion except for two dimethylaminium ion groups at the $p$ and $p'$ positions.

With some of the phenylated dyes bands were observed in the neighborhood of 700 m$\mu$. These bands have been attributed to the addition of a proton to one of the terminal benzene rings, resulting in a carbonium ion compounded of a large number of mesomers, differing from each other in the location of the charge, and the distribution of the double bonds. This mesomeric ion can be considered as a triphenylmethyl ion in which the conjugate system has been extended by three more double bonds. Bands attributed to this type of ion were found mixed with bands due to the second ion and to ions of the simple triphenylmethyl type. They were prominent only when both amino groups were phenylated, though a small band in the neighborhood of 700 m$\mu$ were found in one case in which only one of the amino groups was phenylated.

# Maintenance of Near Equilibrium during Isentropic Expansions through a Nozzle*

BY S. S. PENNER

## Introduction

The rates of homogeneous gas reactions in flow systems have been discussed by Benton,[1] Hulburt,[2] and Harris.[3] Brinkley and Weller[4] have recently reported a generalized form of the reaction-rate law in flow systems.

The rates of reactions in flow systems are of considerable importance in the determination of rocket performance.[5,6] During the flow through a rocket nozzle, many chemical reactions occur so slowly, relative to the rate of cooling of the gases, that the chemical composition (mole fraction of each constituent) remains nearly unchanged, thus leading to near-constant-composition flow. On the other hand, some reactions involving atoms or free radicals take place very rapidly, and nearly complete chemical equilibrium may be reached with respect to these rapid reactions at each temperature; *i.e.*, near-equilibrium flow obtains. In general, the rates of all of the chemical reactions which may occur are not sufficient to maintain nearly complete chemical equilibrium during flow, and the flow process as a whole is therefore intermediate between the two extremes mentioned above.

If thermodynamic equilibrium is reached for the chemical reactions in the combustion chamber, then the thrust on the rocket motor will reach a maximum value if complete equilibrium is also maintained during flow through the nozzle. The nature of the flow process can always be determined by a laborious numerical analysis, provided the necessary kinetics data are available.[5,6] Because of the importance of the nature of the flow process through the rocket nozzle on the performance of rockets, it is desirable to derive a simple criterion for determining the existence of near-equilibrium flow and thus obviate the necessity of laborious calculation for many reactions. Accordingly, the present paper is devoted to a discussion of a criterion for near equilibrium during isentropic expansion similar to the criterion developed by Schaefer.[7]

## Requirements for Thermodynamic Equilibrium

The present analysis is restricted to a discussion of triple-body collisions[8] which lead to the combination of atoms A and B to form the molecule AB

$$M + A + B \underset{k_b}{\overset{k_f}{\rightleftharpoons}} AB + M \qquad (1)$$

where $k_f$ and $k_b$ denote, respectively, the rates of the recombination and dissociation reactions. Assuming the validity of the perfect gas law, the equilibrium constant $K_c$ for reaction 1 is

$$K_c = (AB)/(A)(B) = K_p RT = k_f/k_b \qquad (2)$$

where (A), (B), and (AB) represent the respective concentrations, $K_p$ is the equilibrium constant defined by the relation

$$K_p = P_{AB}/P_A P_B \qquad (3)$$

$P_A$, $P_B$ and $P_{AB}$ denote the partial pressures of components A, B, and AB, respectively, $T$ is the absolute temperature, and $R$ is the molar gas constant. From equation 2 it can now be seen that flow under conditions of thermodynamic equilibrium is characterized by the relation

$$d \ln K_c/dt = d \ln (AB)/dt - d \ln (A)/dt - d \ln(B)/dt \qquad (4)$$

where $t$ represents the time.

Flow through a rocket nozzle is accompanied by changes in pressure and temperature. The concentrations of the reacting components A, B, and AB therefore change for two reasons during flow through the rocket nozzle: (1) a concentration change associated with the change in pressure and temperature (this concentration change occurs without time lag since it depends only on the physical state of the system); (2) a concentration change associated with chemical reaction according to equation 1 [this concentration change depends on the reaction rate constants $k_f$ and $k_b$ and cannot exceed in magnitude the concentration change which has to be added to (1) in order to make the sum of the concentration changes of (1) and (2) equal to the concentration changes required to maintain thermodynamic equilibrium as specified by equation (4)].

It is now necessary to derive analytic relations for the concentration changes defined by (1) and (2).

(8) The recombination of free atoms as the result of collision between two atoms, without the presence of a third body, does not make an appreciable contribution to the number of molecules actually formed, at least not for small atoms such as hydrogen. Chemical reactions other than atomic recombinations generally occur too slowly to allow near-equilibrium flow during expansions through a rocket nozzle. For this reason, only reaction 1 will be considered in this discussion.

## Concentration Change Caused by a Change in Temperature and Pressure

The concentration of an idealized gas is a function of pressure and temperature. Only the concentration changes associated with a change of state are considered in this section.

The concentration of the $j$'th constituent of a system whose physical state is changing is

$$c_j = c_j[p(t),T(t)]$$

where $p$ is the total pressure.

Differentiation with respect to time leads to the result

$$dc_j/dt = (\partial c_j/\partial p)(dp/dt) + (\partial c_j/\partial T)(dT/dt) \quad (5)$$

Adiabatic flow of ideal gases is characterized by the relation[9]

$$dp/dT = \gamma p/T(\gamma - 1) \quad (6)$$

where $\gamma$ is the instantaneous ratio of the specific heat at constant pressure to the specific heat at constant volume. Introducing equation 6 into equation 5 leads to the result

$$dc_j/dt = \{[p\gamma/T(\gamma - 1)](\partial c_j/\partial p) + (\partial c_j/\partial T)\}(dT/dt) \quad (7)$$

Equation 7 will be used only for ideal systems[10] in the present discussion.

The partial pressure $p_j$ of the $j$'th constituent is

$$p_j = c_j RT = n_j p/n$$

where $n_j/n$ represents the mole fraction of the $j$'th component. Hence

$$\partial c_j/\partial T = -p_j/RT^2$$

and

$$p(\partial c_j/\partial p) = p[\partial c_j/\partial(np_j/n_j)] = p_j(\partial c_j/\partial p_j) = p_j/RT$$

Replacing $p(\partial c_j/\partial p)$ and $(\partial c_j/\partial T)$ in equation 7, the desired result is obtained

$$dc_j/dt = (\gamma - 1)^{-1}(p_j/RT^2)(dT/dt) \quad (8)$$

Equation 8 shows the instantaneous concentration change of ideal gases which accompanies a change in pressure and temperature during adiabatic flow.

## Concentration Change Caused by Chemical Reaction

For the recombination of atoms according to equation 1, the rate of change of concentration with time for components A, B, and AB is given by the relation

$$\begin{aligned} -d(A)/dt &= -d(B)/dt = +d(AB)/dt \\ &= k_f(A)(B)(M) - k_b(AB)(M) \\ &= k_f(A)(B)(M)[1 - (AB)/(A)(B)K_c] \end{aligned} \quad (9)$$

From equation 9 it is evident that the rates of concentration change of ideal gases caused by chemical reaction according to equation 1 depend on the rate constants $k_f$ and $k_b$.

(9) Equation 6 is valid even if the composition changes as the result of chemical reaction, provided the heat capacity ratio $\gamma$ is changed appropriately. The effective heat capacity of the system is redefined to include a term involving the heat release associated with chemical reaction.[6]

(10) An ideal system is defined as a system for which the activity coefficient of each constituent is unity at all times.

## A Criterion for Near-Equilibrium Flow

Flow through a rocket nozzle occurs under conditions where concentration changes are caused by changes in the physical state of the system as well as by chemical reaction. It is therefore necessary to equate the total concentration changes $d \ln (AB)/dt$, $-d \ln (A)/dt$, and $-d \ln (B)/dt$ in equation 4 to the sum of the concentration changes given by equations 8 and 9. Thus

$$d \ln (AB)/dt = [(\gamma - 1)T]^{-1}(dT/dt) + k_f[(A)(B)(M)/(AB)][1 - (AB)/(A)(B)K_c] \quad (10)$$

$$-d \ln (A)\, dt = -[(\gamma - 1)T]^{-1}(dT/dt) + k_f(B)(M)[1 - (AB)/(A)(B)K_c] \quad (10a)$$

$$-d \ln (B)/dt = -[(\gamma - 1)T]^{-1}(dT/dt) + k_f(A)(M)[1 - (AB)/(A)(B)K_c] \quad (10b)$$

where use has been made of the ideal gas relations

$$P_{AB}/(AB)RT^2 = P_A/(A)RT^2 = P_B/(B)RT^2 = 1/T$$

Introducing equations 10, 10a and 10b into equation 4 leads to an equation as requirement for thermodynamic equilibrium

$$(d \ln K_c/dT)(dT/dt) = -[(\gamma - 1)T]^{-1}(dT/dt) + k_f(M)[(A) + (B) + (A)(B)/(AB)] \times [1 - (AB)/(A)(B)K_c] \quad (11)$$

It is evident from equation 11 that complete thermodynamic equilibrium during expansion, which exists only if

$$(AB)/(A)(B) = K_c$$

leads to the requirement that $k_f$ is infinite unless

$$-d \ln K_c/dT = [(\gamma - 1)T]^{-1}$$

*i.e.*, unless the concentration change associated with a change of state is just sufficient to fulfill the requirements of thermodynamic equilibrium.

The ratio $(AB)/(A)(B)$ at any temperature $T$ may be replaced by the equilibrium constant $K_c'$ at the temperature $T'$. For equilibrium flow $T' = T$, whereas for near-equilibrium flow $|T' - T|$ is a small number which will be chosen arbitrarily later on. Replacing $(AB)/(A)(B)$ by $K_c'$ in equation 11 leads to the result

$$k_f(M)[(A) + (B) + 1/K_c'][1 - K_c'/K_c] = \{d \ln K_c/dT + [(\gamma - 1)T]^{-1}\}(dT/dt) \quad (12)$$

Equation 12 can be simplified by making use of the same artifice employed previously by Schaefer.[7] Thus for sufficiently small values of $x$, $\ln (1 - x) \simeq -x$. Hence

$$\ln (K_c'/K_c) = \ln [1 - (1 - K_c'/K_c)] \simeq -(1 - K_c'/K_c)$$

or

$$1 - K_c'/K_c \simeq -\ln (K_c'/K_c) \simeq (-d \ln K_c/dT)(T' - T) \quad (13)$$

where the approximate equation 13 is the more nearly valid the more closely $T'$ approaches $T$. From equations 12 and 13 it follows that

$$k_f(M)[(A) + (B) + 1/K_c'] = \{1 + [(d \ln K_c/dT) \times (\gamma - 1)T]^{-1}\}(-dT/dt)/(T' - T) \quad (14)$$

Following Schaefer,[7] near-equilibrium flow

through the rocket nozzle is arbitrarily defined by the relation

$$(T' - T) \leqslant 50°\text{K.} \quad (15)$$

*i.e.*, flow through the rocket nozzle is considered to be near-equilibrium flow if the ratio (AB)/(A)·(B) at the actual temperature $T$ corresponds to the equilibrium ratio at the temperature $T'$ where $T'$ does not differ from $T$ by more than 50°K. Equation 14 thus leads to the following criterion for near-equilibrium flow

$$k_f(\text{M})[(\text{A}) + (\text{B}) + 1/K_c'] \geqslant 2 \times 10^{-2}\{1 + [(\text{d} \ln K_c/\text{d}T)(\gamma - 1)T]^{-1}\}(-\text{d}T/\text{d}t) \quad (16)$$

Equation 16 differs from the result obtained by Schaefer, who does not consider explicitly the concentration change associated with changes of pressure and temperature. However, criterion 16 can be replaced by Schaefer's criterion in most of the cases which are of interest in connection with adiabatic expansion through a rocket nozzle. Thus the term

$$[(\text{d} \ln K_c/\text{d}T)(\gamma - 1)T]^{-1}$$

is usually negative and smaller than unity. Therefore if

$$k_f(\text{M})[(\text{A}) + (\text{B}) + 1/K_c'] \geqslant 2 \times 10^{-2}(-\text{d}T/\text{d}t) \quad (17)$$

then inequality 16 is certainly satisfied. Inequality 17 is identical with Schaefer's criterion for near-equilibrium flow. For a more complete discussion of equation 16 it is convenient to note that

$$\text{d} \ln K_c/\text{d}T = \text{d} \ln K_p/\text{d}T + 1/T = \Delta H/RT^2 + 1/T$$

where $\Delta H$ is negative for the formation of molecules, since heat is evolved during the combination of atoms. Thus equation 16 becomes

$$k_f(\text{M})[(\text{A}) + (\text{B}) + 1/K_c'] \geqslant 2 \times 10^{-2}\{1 - [(Q/RT - 1)(\gamma - 1)]^{-1}\}(-\text{d}T/\text{d}t) \quad (18)$$

where $Q = -\Delta H$.

The following special cases arise:

Case 1. If $Q/RT > 1$ but $[(Q/RT - 1)(\gamma - 1)]^{-1} < 1$, then Schaefer's criterion 17 is applicable. This is the case for most practical applications to adiabatic expansion through a rocket nozzle since $Q \simeq 10^5$ cal./mole, $T \simeq 3000°$K., and $\gamma \simeq 1.2$.

Case 2. If $Q/RT = 1$, then $\text{d} \ln K_c/\text{d}T = 0$.[11] In this case equation 11 leads to the expression

$$k_f(\text{M})[(\text{A}) + (\text{B}) + (\text{A})(\text{B})/(\text{AB})] \times [1 - (\text{AB})/(\text{A})(\text{B})K_c] = [(\gamma - 1)T]^{-1}(\text{d}T/\text{d}t)$$

which requires a definition of near-equilibrium flow different from equation 15. A useful near-equilibrium criterion is obtained by imposing the condition $|(\text{AB})/(\text{A})(\text{B})K_c| \geqslant 0.99$.

Case 3. If $Q/RT < 1$, then equation 18 must be used directly. In particular, if $Q/RT$ is only very slightly less than unity, then the term $[(1 - Q/RT)(\gamma - 1)]^{-1}$ may become very large, and the requirements of inequality 18 are far more stringent than those of inequality 17. This case may be encountered in the future with rocket motors operating at exceedingly high temperatures.

Case 4. If $Q/RT > 1$ and also $[(Q/RT - 1)(\gamma - 1)]^{-1} > 1$, then the right-hand side of equation 18 becomes negative and criterion 18 is no longer applicable. The physical reason for this situation is the fact that the concentration change caused by the change of state is larger than the concentration change required to maintain chemical equilibrium, and therefore reaction according to equation 1 proceeds now from right to left; *i.e.*, molecules must dissociate in order to maintain chemical equilibrium. This case is of no practical importance at present.

As was noted previously, the conditions $Q/RT > 1$ and $[(Q/RT - 1)(\gamma - 1)]^{-1} < 1$ are usually fulfilled during expansion through a rocket nozzle. Therefore Schaefer's criterion 17 is usually applicable and can be used to test for the existence of near-equilibrium flow. Near equilibrium during the entire expansion can be shown to exist if the requirements of equation 17 are fulfilled at each point during flow. In practice, it is sufficient to show that equation 17 holds at a few representative points in the rocket nozzle.

Schaefer's discussion[7] of equation 17 is not applicable for expansions through the nozzles of small rockets[5,6] since $-\text{d}T/\text{d}t \simeq 3 \times 10^7$ (°K./sec.), rather than $-\text{d}T/\text{d}t \simeq 5 \times 10^6$ (°K./sec.), as used by Schaefer.[12] For atomic recombinations as the result of triple collisions, $k_f$ is of the order[7,13] of $10^{11}$ liter$^2$ × sec.$^{-1}$ × mole$^{-2}$ at temperatures close to 3000°K.[14] Equation 17 permits determination of the minimum atomic concentrations required for near-equilibrium flow with respect to atomic reactions. Thus if $[(\text{A}) + (\text{B})] \geqslant 3 \times 10^7/50 \times 10^{11}(\text{M})$, then near-equilibrium flow will occur. For the adiabatic expansion of gases from a rocket chamber at a pressure of about 20 atm., the total concentration of atoms and molecules = $\text{M} \simeq 3 \times 10^{-2}$ (mole/liter) and therefore, $[(\text{A}) + (\text{B})] \geqslant 2 \times 10^{-4}$ (mole/liter); *i.e.*, a mole fraction of about $1.5 \times 10^{-2}$ or greater is required to assure near-equilibrium flow with respect to atomic recombinations. This value for the required mole fraction of atoms is, of course, appreciably greater than the value of $1 \times 10^{-3}$ arrived at by Schaefer[7] by using too small a value for $(-\text{d}T/\text{d}t)$. Thus the conclusion is reached that near equilibrium during flow with respect to atomic reactions is strongly dependent on atomic concentrations. Application of the near-equilibrium criterion given in equation 17 to the flow of hydrogen gas through the rocket nozzle for the conditions

(11) This condition can be satisfied at only one point if the temperature changes continuously with time.

(12) $-\text{d}T/\text{d}t$ is decreased as the rocket motor size is increased. Schaefer's value probably refers to the V-2 rocket.

(13) I. Amdur, THIS JOURNAL, **60**, 2347 (1935).

(14) The values of $k_f$ have been measured only at low pressures and for a limited number of reactants A, B, and M. The assumptions that similar rate constants can be used at high pressures for all atomic recombinations in gaseous mixtures, and that the activation energy for the recombination of atoms is zero, are highly questionable and justified only by the lack of better data.

considered previously[6] shows that near equilibrium during flow is maintained in this special case.

## Summary

A criterion for near-equilibrium flow during isentropic expansion through a rocket nozzle has been derived. Schaefer's result[7] is shown to be valid for atomic recombinations in a system in which temperature and pressure changes produce concentration changes which are superimposed on the concentration changes associated with chemical reaction provided $-\Delta H/RT > 1$ and $\{[(-\Delta H/RT) - 1](\gamma - 1)\}^{-1} < 1$. These conditions are satisfied in the rocket motors usually encountered. Criteria for near-equilibrium flow under conditions which may be encountered in future work with rockets operating at exceedingly high temperatures are also discussed.

# Extrapolation of Adsorption Isotherms to High Relative Pressures and the Determination of the Surface Pressure of Adsorbed Films on Solids

BY MELVIN A. COOK AND DOUGLAS H. PACK[1]

A recent publication[2] outlined the development of the equation for the unrestricted multimolecular

$$v/v_m = \sum_1^\infty ix^i d_i \Big/ \left(1 + \sum_1^\infty x^i d_i\right) \qquad (1)$$

adsorption of gases on solids. Here the $d_i$'s are a series of interrelated constants different for each adsorbed layer and made up of $\alpha_i$ and $\beta_i$ components such that $d_i = \alpha_i\beta_i$. The $\alpha_i$'s are factors determined by the energies of interaction of the adsorbate with the surface of the adsorbent, and the $\beta_i$'s account for the interactions between the adsorbate molecules in the film. Equation (1) differs from the BET[3] equation only in the fact that the $d_i$'s are all the same constant $c$ in the BET theory; the theoretical basis for (1) differs from that of the BET equation only in the description of the adsorption forces.

In reference (2) only the important van der Waals attraction term for the adsorbate–adsorbent interactions, varying as $r_i^{-3}$ ($r_i$ = distance of the $i^{th}$ layer from the surface of the solid), was taken into account, the repulsive and second and higher order attractive terms being neglected. In this approximation the $\alpha_i$'s were defined by the equation

$$\alpha_i = \text{exp. } E_1(1 + 1/8 + 1/27 + \ldots + 1/i^3)/RT \qquad (2)$$

where $E_1$ is the (final) adsorbate–adsorbent interaction energy in the (nearly filled) first layer evaluated as an empirical constant. The $\beta_i$'s were defined as

$$\beta_i = \text{exp. } E_L(c_1 + c_2 + c_3 + \ldots c_i - i)/RT \equiv \text{exp. } E_L(c_1 - 1)(1 + 1/2 + 1/3 + \ldots + 1/i)/RT \qquad (3)$$

where $E_L$ is the heat of condensation in the corresponding bulk liquid state of the adsorbate and the $c_i$'s are constants related to the empirical constant $c_1$ as shown. Equation (3) was developed semi-empirically from the consideration that entropy variations in the various layers of the adsorbed film may be related to the average coördination number ratios between an *i-layer* film and the bulk liquid.

On the above basis equation (1) was found to reproduce quite accurately four experimental isotherms over the range from 0.05 to about 0.7–0.8 in relative pressure $x = p/p_0$, the experimental data in these cases being taken only in this range. More recently equation (1) has been examined by comparing it with some experimental isotherms in which the experimental data covered the entire range of relative pressures ($0 < x < 1.0$). Employing the definitions of $d_i$ (equations (2) and (3)), equation (1) was found to reproduce the isotherm over the range from $x = 0.05$ to $x \cong 0.8$, but it predicted too much adsorption for $x > 0.9$ and too little adsorption for $x < 0.05$. It is considered that the discrepancies in the very low pressure region involve a fundamental weakness of the theory incurred by its failure to take account of (1) surface heterogeneities, and (2) the non-constancy of $\beta_1$ for various stages of filling of the first adsorbed layer. The discrepancies in the very high relative pressure region on the other hand apparently involve only the deliberate approximations in $\alpha_i$ and evidently may be largely eliminated by simply taking into account the repulsive term.

The present article introduces a simple modification of equation (2) including a theoretical repulsive term, and illustrates the utility of equation (1) in extrapolating isotherms to the relative pressure $x = 1.0$. Also, it seemed worth while to discuss in this article some of the convergence–divergence characteristics of equation (1) and to outline some methods designed to render the equation tractable in practical applications.

**Repulsive Term in $\alpha_i$.**—According to approximate quantum mechanical treatments, the repulsive term in the van der Waals interaction should have the form $B_r e^{-r/\rho}$ ($B_r$ and $\rho$ being

(1) This work was supported by a grant from the University of Utah Research Fund.

(2) M. A. Cook, THIS JOURNAL, **70**, 2925 (1948).

(3) S. Brunauer, P. H. Emmett and E. Teller, *ibid.*, **60**, 309 (1938).

empirical constants). The form $B_r r^{-n}$ is, however, more frequently used and, because of its simplicity for the present purpose, it will be adopted here. Irrespective of the particular form adopted for the repulsive term, however, it is clear that it must show a much more rapid variation with distance than the $r^{-6}$ (bulk matter) and $r^{-3}$ (surface) attractive term. Consequently, this term will need to be included only in accounting for the binding energy in the first layer of the film. One may thus show that the inclusion of the repulsive term in $\alpha_i$ simply introduces a constant $a$ as follows

$$\alpha_i = \text{exp. } E_1(1 + a/8 + a/27 + \ldots + a/i^3)/RT \quad (4)$$

in which $a$ is related to $n$ in the term $B_r r^{-n}$ by the equation

$$3a/(a - 1) = n \quad (4a)$$

While $n$ will probably not be the same constant for all adsorbate–adsorbent systems, Hill[4] has suggested applying Lennard–Jones' formula for the van der Waals interaction in the bulk state from which he obtained an adsorbate–adsorbent interaction of the form (using the present notations)

$$E_i = A/r_i^3 - B/r_i^9 \quad (5)$$

Here $A$ and $B_r$ are constants which may be related by taking the derivative of (5) with respect to $r_i$ and equating $(dE_i/dr_i)\ r_i = r_1$ to zero. This gives

$$E_i = A/r_i^3 - Ar_1^6/3r_i^9 \quad (6a)$$

the more general case being

$$E_i = A/r_i^3 - \frac{3Ar_1^{n-3}}{nr_i^n} \quad (6b)$$

from which equations (4) and (4a) are derived. Using Hill's equation (6a) with $n = 9$, we obtain $a = 1.5$. Hill suggests applying (6a) to each separate adsorbate atom, taking account of the fact that the distance $r_i$ will not be the same for each atom in the molecule. Here, however, we shall assume that (6a or 6b) may be applied with sufficient accuracy to the whole molecule assuming that $r_i$ represents the distance from the effective center of the molecule to the active center on the solid surface, any greater refinement in $E_i$ being unjustified at this stage in the present theory.

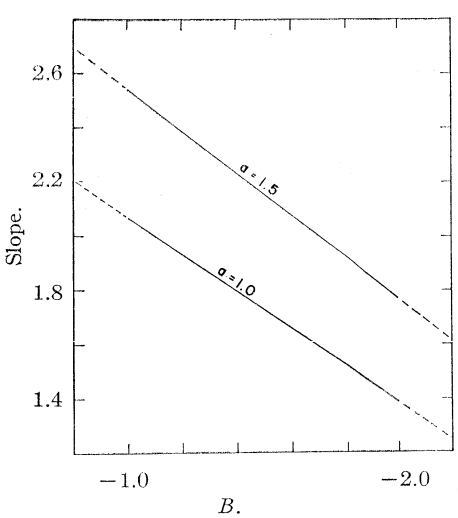

Fig. 1.—Slope $(v/v_m \div x)$ of linear part of $S$-curve *vs.* $B$.

(4) T. L. Hill, *J. Chem. Phys.*, **16**, 181 (1948).

**Manipulation of Equations at Large x.**—The application of the equation (1) requires the evaluation of the two (major) infinite series $\sum_1^\infty ix^i d_i$ and $\sum_1^\infty x^i d_i$ which are further complicated by the two (minor) series in the $d_i$'s. In view of the rapid convergence of the major series for small $x$, the solution of (1) offers no serious difficulties in the low relative pressure regions, and even up to relative pressures around $x = 0.8$. However, for $x > 0.8$ the series converge so slowly that their evaluation becomes very tedious. Fortunately, it is possible to shorten the labor considerably by replacing the summations beyond a certain number of terms by suitable integrals without incurring appreciable error.

The two empirical constants, $E_1$ and $c_1$ may be evaluated at small values of $x$ (preferably for $x < 0.5$) by the methods outlined in reference (2) no problems of convergence being encountered in this region. In spite of this the evaluation of these constants would be quite tedious unless one were to make use of various labor saving devices such as tables of $ix^i$, $x^i$, etc. It is of interest to note in this connection that one seldom needs to carry through the process of iteration for $c_1$ and $E_1$ more than three times if the fact is taken into consideration that $t_2 (= v_2/v_m$ ref. 2) varies approximately linearly with $c_1$. Thus, after calculations have been made for two assumed values of $c_1$, one may nearly always pick out the true value by means of a linear $c_1$ *vs.* $v_2/v_m$ plot, unless either, or both, of the first two assumed values of $c_1$ should happen to be selected too far from the true value. This can be easily avoided, and, as a matter of fact, the correct value of $c_1$ may sometimes be selected in the first trial by making use of Fig. 1 in which $B$, defined by the equation

$$B \equiv E_L\ (c_1 - 1)/RT \quad (7)$$

is plotted against the slope (in reduced $-\ v/v_m\ -$ units) of the essentially straight line portion of the sigmoid isotherms (usually extending from about 0.1 to perhaps 0.5 in $x$). Figure 1 was obtained by drawing the best straight lines through all of the points for $a = 1.0$ and $a = 1.5$, respectively, obtained in this and the previous study. It will be shown below that for $|B| > 2.0$ equation (1) is not properly divergent at $x = 1.0$. To avoid this difficulty when it occurs one might simply calculate $c_1$ directly from equation (7) for $B = -2.0$ (assuming that $|B|$ will never be appreciably greater than 2.0) leaving only a two empirical con-

stant ($v_m$ and $E_1$) equation to fit the curve. If it should turn out in some cases that $|B| >> 2$, $B$ could be fixed at $-2.0$, and the $a$ adjusted to be consistent with Figure 1 (by extrapolating or interpolating linearly between the two straight lines of Fig. 1) again leaving only the two constants ($v_m$ and $E_1$) to be evaluated. That this procedure evidently leads to results generally in good agreement with observed isotherms even as $x$ approaches closely to unity, and the further fact that values of $B$ evidently hover around $-2.0$ for $a = 1.5$, are of possible interest in regard to the general validity of the theory.

The previous paper (ref. 2) outlined the evaluation of $c_1$ and $B$. As a further remark in connection with the evaluation of the constants of equation (1), it is convenient in computing $E_1$, after selecting an appropriate value for $c_1$ or $B$, to make use of tables of $\alpha_1/\alpha_2$ for various values of $\alpha_2$ and of the equation

$$\alpha_2 = 1 \Big/ \left\{ \sum_2^\infty (i-1) x_m^i \beta_i \, (\alpha_i/\alpha_2) \right\} \qquad (8)$$

where $x_m$ is the relative pressure at which $v = v_m$, ($v_m$ being evaluated[2] by the method of BET.).

For solving equation (1) all but the first $q - 1$ terms may be evaluated by replacing $\sum_q^\infty i x^i d_i$ and $\sum_q^\infty x^i d_i$ by suitable integrals. The accuracy of this approximation will, of course, depend on the magnitude of $q$. With suitable tables of functions at hand it is convenient to select $q$, e. g., equal to 20, in which case the integral approximation will be well within tolerable limits of accuracy. For $q = 20$, $\alpha_i$ will have become substantially constant, hence

$$\sum_q^\infty i x^i d_i \cong \alpha_q \int_q^\infty i x^i \, e^{B \sum_1^i 1/i} \, di \cong \alpha_q \, \beta_{q-1} \, q^{-B} \int_q^\infty x^i \, i^{(B+1)} \, di \qquad (9)$$

$x$ being a particular relative pressure and $i$ the variable.

Making the substitution $i \ln x = -y$, (9) becomes

$$\sum_q^\infty i x^i d_i \cong \alpha_q \, \beta_{q-1} \, q^{-B} \frac{1}{(-\ln x)^{(B+2)}} \int_{y=-q \ln x}^\infty e^{-y} y^{(B+1)} \, dy$$

For $B = -2$, this becomes

$$\sum_q^\infty i x^i d_i \cong d_{q-1} \, q^2 \int_{-q \ln x}^\infty \frac{e^{-y}}{y} \, dy \qquad (9a)$$

which may be evaluated from tables by Jahnke and Emde,[5a] or W.P.A. tables.[5b] For values of $B$ from $-1$ to $-2$ (the allowable range as shown below) (9) may be evaluated from tables of gamma functions $\Gamma(n)$ as follows:

$$\sum_1^\infty i x^i d_i \cong d_{q-1} \, q^2 (-q \ln x)^{-(B+2)} \left[ \int_0^\infty e^{-y} \, y^{B+1} \, dy - \int_0^{-q \ln x} e^{-y} \, y^{B+1} \, dy \right] = d_{q-1} \, q^2 \, (-q \ln x)^{(-B+2)} \left\{ \Gamma(B+2) - \int_0^{-q \ln x} \left[ 1 - y + \frac{y^2}{2!} - \frac{y^3}{3!} + \frac{y^4}{4!} - \ldots \right] y^{B+1} \, dy \right\} =$$

$$d_{q-1} q^2 (-q \ln x)^{-(B+2)} \Gamma(B+2) - d_{q-1} q^2 \left\{ \frac{1}{B+2} + \frac{q \ln x}{B+3} + \frac{(q \ln x)^2}{(B+4)\,2!} + \frac{(q \ln x)^3}{(B+5)\,3!} + \frac{(q \ln x)^4}{(B+6)\,4!} + \ldots \right\} \qquad (9b)$$

Values of $\Gamma(B+2)$ may be obtained, for example, from Dwight[6] and the relation $\Gamma(n+1) = n\,\Gamma(n)$.

Similarly we obtain

$$\sum_q^\infty x^i d_i \cong d_{q-1} \, q^{-B} \int_q^\infty x^i i^B di \qquad (10)$$

which, for $B = -2.0$, becomes

$$\sum_q^\infty x^i d_i \cong d_{q-1} \, q^2 \left\{ \frac{e^{q \ln x}}{q} + \ln x \int_{-q \ln x}^\infty \frac{e^{-y}}{y} \, dy \right. \qquad (10a)$$

and for $-1 > B > -2.0$

$$\sum_q^\infty x^i d_i \cong d_{q-1} \, q (-q \ln x)^{-(B+1)} \left\{ \Gamma(B+1) - \int_0^{-q \ln x} \left( 1 - y + \frac{y^2}{2!} - \frac{y^3}{3!} + \frac{y^4}{4!} + \ldots \right) y^B dy \right\} =$$

$$d_{q-1} q (-q \ln x)^{-(B+1)} \Gamma(B+1) - d_{q-1} q \left\{ \frac{1}{B+1} + \frac{q \ln x}{B+2} + \frac{(q \ln x)^2}{(B+3)\,2!} + \frac{(q \ln x)^3}{(B+4)\,3!} + \ldots \right\} \qquad (10b)$$

Equation (1) for $B = -2$ thus becomes

$$v/v_m = \frac{\left( \sum_1^{q-1} i x^i d_i \right) + d_{q-1} q^2 \int_{-q \ln x}^\infty \frac{e^{-y}}{y} \, dy}{1 + \left( \sum_1^{q-1} x^i d_i \right) + d_{q-1} q^2 \left\{ \frac{e^{q \ln x}}{q} + \ln x \int_{-q \ln x}^\infty \frac{e^{-y}}{y} \, dy \right.} \qquad (1b)$$

and for $-1 > B > -2$, (1) may be written

(5) (a) Jahnke and Emde, "Tables of Functions," Dover Publications, New York, N. Y., 4th ed., 1945, pp. 1, 6–9. (b) Federal Works Agency, W. P. A., New York City, "Tables of Sine, Cosine and Exponential Integrals" (1940).

(6) H. B. Dwight, "Tables of Integrals and other Mathematical Data," The Macmillan Co., New York, N. Y., 1947.

$$v/v_m = \frac{\left(\sum_1^{q-1} ix^i d_i\right) + d_{q-1}q^2(-q\ln x)^{-(B+2)}\Gamma(B+2) - d_{q-1}q^2\left\{\frac{1}{B+2} + \frac{(q\ln x)}{B+3} + \frac{(q\ln x)^2}{(B+4)\,2!} + \frac{(q\ln x)^3}{(B+5)\,3!} + \cdots\right\}}{1 + \left(\sum_1^{q-1} x^i d_i\right) + d_{q-1}q(-q\ln x)^{-(B+1)}\Gamma(B+1) - d_{q-1}q\left\{\frac{1}{B+1} + \frac{q\ln x}{B+2} + \frac{(q\ln x)^2}{(B+3)\,2!} + \frac{(q\ln x)^3}{(B+4)\,3!} + \cdots\right\}} \quad (1c)$$

**Limits on $B$.**—For $x = 1.0$ we have

$$v/v_m = \frac{\left(\sum_1^{q-1} id_i\right) + d_{q-1}q^{-B}\int_q^\infty i^{B+1}\,di}{1 + \left(\sum_1^{q-1} d_i\right) + d_{q-1}q^{-B}\int_q^\infty i^B\,di} = \infty \quad (11)$$

From (7) we see that $B < 0$, since $c_1 < 1.0$. Moreover, from (11) $B \gtrsim -2$ in order that $v/v_m \to \infty$ as $x \to 1.0$. Also, (11) becomes indeterminate for $B \gtrsim -1$. In fact, it will be shown that values of $B \gtrsim -1$ are unacceptable because they lead to infinite values of the surface pressure $\pi$ of the adsorbed film. We thus conclude that $B$ will be restricted by the physical conditions of the problem to the region $-1.0 > B \gtrsim -2.0$. In view of uncertainties in the theory of $a$ and the fact that errors in $E_1$ will in general be largely compensated in $c_1$ (and $B$) one has little reason, however, to be disturbed if $B$ should sometimes turn out to be a little less than $-2.0$ (for we are still assured of the fact that $v$ will be infinite for $x >$ 1.0). One could, of course, avoid this technical difficulty by adjusting $a$ to make $B = -2.0$ and this should perhaps be done if the discrepancy should turn out to be quite large, (*e.g.*, $-B = 2.5$).

**High Relative Pressure Extrapolations.**—Jura and Harkins[7] have published several type II isotherms admirably suited for a careful evaluation of equations (1), (4) and (4a) in that their data extend over the entire region $0 < x < 1.0$. Figure 2 presents their experimental data for nitrogen (at 77.3°K.) on anatase, together with theoretical curves for $a$ values of 1.0, 1.3 and 1.5. It is quite significant that, while the agreement between the observed and calculated curves is independent of $a$ for $x < 0.8$, excellent agreement is obtained only for $a = 1.5$ as $x \to 1.0$ in agreement with Hill's form (6a) of $E_i$. Calculations were also made for water, *n*-butane and *n*-heptane on anatase only for $a = 1.5$, and, except for *n*-heptane, the agreement is excellent over the entire range $0.05 < x < 1.0$ as shown in Fig. 3. In *n*-heptane a large discrepancy between the experimental and calculated data are encountered for $x > 0.9$. There seems to be no way of resolving this difficulty except that perhaps the saturation pressure used in

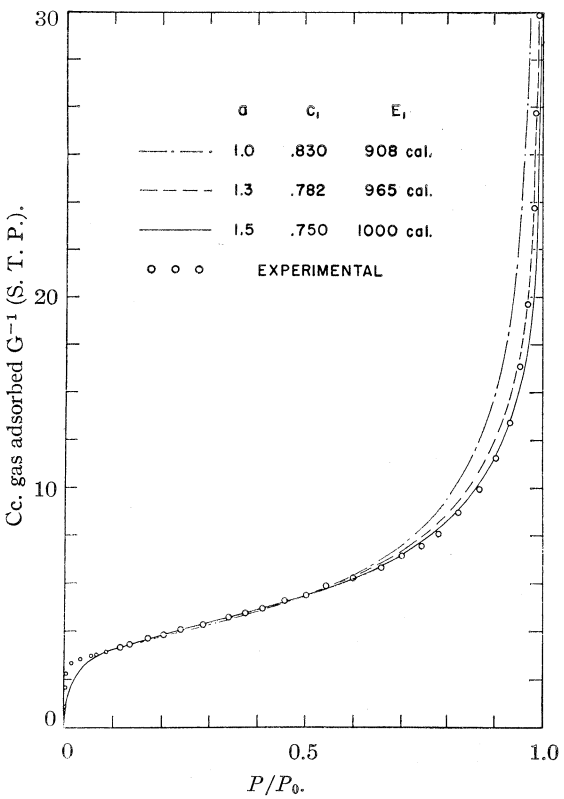

Fig. 2.—Influence of the repulsive term on the calculated adsorption isotherm of nitrogen on anatase—comparison with experimental.

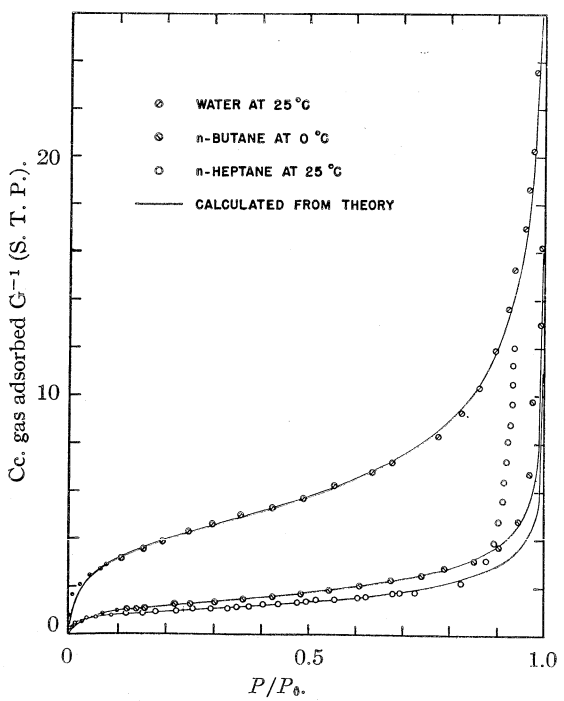

Fig. 3.—Comparison of theoretical and experimental adsorption isotherms.

TABLE I

CONSTANTS OF EQUATION (1) FROM SEVERAL ADSORPTION ISOTHERMS

| Adsorbate | Adsorbent | $T$, °K. | $v_m$, cc./g. | $a$ | $c_1$ | $-B$ | $E_1$, cal./mole | Constants from data of |
|---|---|---|---|---|---|---|---|---|
| Nitrogen | Anatase | 77.3 | 3.23 | 1.0 | 0.830 | 1.473 | 908 | Jura and Harkins |
| Nitrogen | Anatase | 77.3 | 3.23 | 1.3 | .782 | 1.888 | 965 | Jura and Harkins |
| Nitrogen | Anatase | 77.3 | 3.23 | 1.5 | .750 | 2.166 | 1000 | Jura and Harkins |
| Water | Anatase | 298.1 | 3.50 | 1.5 | .884 | 2.056 | 3420 | Jura and Harkins |
| *n*-Butane | Anatase | 273.1 | 1.07 | 1.5 | .796 | 2.00 | 3030 | Jura and Harkins |
| *n*-Heptane | Anatase | 298.1 | .776 | 1.5 | .863 | 2.00 | 3800 | Jura and Harkins |
| Methyl acetate | Vitrous | 298.1 | 1.12 | 1.0 | .952 | .675 | 2410 | Palmer and |
| Methyl acetate | silica | 298.1 | 1.12 | 1.5 | .912 | 1.250 | 2730 | Clark[8] |
| Nitrogen | Fe-$Al_2O_3$ | 77.3 | 135 | 1.0 | .862 | 1.200 | 898 | Emmett and |
| Nitrogen | catalyst | 77.3 | 135 | 1.5 | .775 | 1.950 | 998 | Brunauer[9] |
| Argon | Fe-$Al_2O_3$ | 90.1 | 126 | 1.0 | .884 | 0.970 | 852 | Emmett and |
| Argon | catalyst | 90.1 | 126 | 1.5 | .823 | 1.49 | 918 | Brunauer[9] |

computing the experimental data may have been in error. This is indicated from the fact that the experimental curve seems to be approaching about $x = 0.94$ asymptotically rather than $x = 1.0$ as one would expect. In fact, assuming this to be the case there is no difficulty in fitting the experimental curve with equation (1) with $a = 1.5$. It is interesting that no indication of this strange occurrence is to be found in any part of the curve below a relative pressure of 0.9. Table I lists values of the various constants of equation (1) for the cases illustrated in Figs. 2 and 3 together with others studied in reference (2) which are here recalculated for $a = 1.5$, previous calculations being carried out only for $a = 1.0$. While, as shown in Table I, $B < -2.0$ in nitrogen and water on anatase for $a = 1.5$, this discrepancy is not considered significant. The divergence difficulty at $x = 1.0$ would be cleared up by taking $B = -2.0$ and $a = 1.38$, but the agreement in the range $0.85 - 0.95$ in $x$ would not be as good as when the values $B = -2.166$ and $a = 1.5$ are used. It is of interest that the use of $a = 1.5$ tends to change the values of $E_1$ and $c_1$ in the right direction to agree with experimental differential net heats and expected theoretical coördination ratios, respectively, although several extraneous factors must still be operating to give values of $c_1$ which from theory seem peculiarly high.

**Surface Pressure of the Adsorbed Film.**—Bangham's[10,11] equation for the surface pressure $\pi$ of an adsorbed film of gas on a solid obtained by the integration of Gibbs' adsorption equation in terms of data from the adsorption isotherm may be written

$$\pi = \gamma_s - \gamma_{sf} = \frac{RT}{V\Sigma}\int_0^{x_v} \frac{dx}{x} \qquad (12)$$

where $\gamma_s$ is the surface tension of the solid, $\gamma_{sf}$ that of the film covered solid, $V$ is the molar volume of the gas, $\Sigma$ the specific area of the solid, $v$ the volume of gas adsorbed per gram of adsorbent, and $x$ the relative pressure $p/p_0$ of the gas. Evaluating the integral (12) between zero and the saturation pressure $p_0$, we obtain in cases of perfect wettability

$$\pi_{0-1} = \gamma_s - \gamma_{Ls} - \gamma_L \qquad (13)$$

where $\gamma_{Ls}$ is the interfacial tension between the solid and the film, and $\gamma_L$ is the surface tension of the adsorbate in the liquid state, the subscripts on $\pi$ indicating the limits of integration. Equation (13) is useful, as shown by Jura and Harkins,[12] in determining the work of adhesion $W_A$, the spreading coefficient $S_{L/s}$, and the free energy of emersion $f_E$. It may also be used to establish a lower limit to the surface tension of the solid which, when a sufficiently polar adsorbate is used, may, in some cases, approach quite closely the true surface tension $\gamma_s$. By correlating this with theoretical data, from which one may establish an upper limit to $\gamma_s$, one may be able to bracket $\gamma_s$ in some cases within quite close limits. Equations (12) and (13) are of further considerable interest in that they may be used to provide a critical test of the validity of the various theoretical adsorption equations. In this connection Jura and Harkins[12] have carried out graphical integrations of (12) for several of their own experimental isotherms. Their method is complicated by two troublesome extrapolations, one in the region where $x$ approaches zero and the other in the region where $x$ approaches unity. They minimized the difficulties inherent in these extrapolations, however, by obtaining experimental adsorption data covering as completely as possible the entire adsorption isotherm. Their work thus provides valuable data for an evaluation of our theoretical adsorption equation.

**Integration of Surface Pressure Equation.**—The validity of the theoretical adsorption equation (1) with

$$d_i = \alpha_i\beta_i = \exp\left\{E_1\left(1 + \frac{1.5}{8} + \ldots + \frac{1.5}{i^3}\right) + E_L(c_1 - 1)\left(1 + 1/2 + \ldots + \frac{1}{i}\right)\right\}\Big/RT \qquad (14)$$

(12) G. Jura and W. D. Harkins, THIS JOURNAL, **66**, 1356 (1944)

may be evaluated by means of equation (12) and the results of Jura and Harkins. Substituting (1) and (14) in (12) and integrating we obtain

$$\pi_{x_1-x_2} = \frac{RTv_m}{V\Sigma}\int_{x_1}^{x_2}\frac{\sum_1^\infty (ix^{i-1}d_i)dx}{1+\sum_1^\infty x^i d_i} \equiv \frac{2.303RTv_m}{V\Sigma}\left|\log\left(1+\sum_1^\infty x^i d_i\right)\right|_{x_1}^{x_2} \quad (15)$$

This integration is performed by making use of the identity

$$\sum_1^\infty ix^i d_i \equiv x\frac{d}{dx}\left(1+\sum_1^\infty x^i d_i\right) \quad (16)$$

(Whenever it is necessary to evaluate $\sum_1^\infty x^i d_i$ where $x$ is less than unity but still large enough that the series converges very slowly, one may make use of the integral approximations of equation (10)). Equation (15) integrated over the entire isotherm becomes

$$\pi_{0-1.0} = 2.303\frac{RTv_m}{V\Sigma}\log\left(1+\sum_1^\infty d_i\right) \quad (17)$$

The term $\sum_1^\infty d_i$ may be evaluated as accurately as desired by means of the approximation

$$\sum_1^\infty d_i \cong \sum_1^{q-1} d_i + \alpha_q\int_q^\infty \beta_i\,di \cong \alpha_q\,\beta_{q-1}q^{-B}\int_q^\infty i^B\,d_i = d_{q-1}q^{-B}\left|\frac{i^{(B+1)}}{B+1}\right|_q^\infty \quad (18)$$

where $B = E_L\,(c_1 - 1)/RT$ and the integer $q$ is chosen large enough that $\alpha_q$ is, within close limits, the limiting value of the series $\alpha_i$. Hence, (17) becomes

$$\pi_{0-1} = \frac{2.303RTv_m}{V\Sigma}\log\left\{1+\sum_1^{q-1} d_i + d_{q-1}q^{-B}\left|\frac{i^{(B+1)}}{B+1}\right|_q^\infty\right\} \quad (19)$$

It is evident that $B$ must be less than minus one in order that $\pi_{0-1}$ will remain finite. This and the fact that $v \to \infty$ as $x \to 1.0$, show that the acceptable limits on $B$ are $-1 > B \geqslant -2$. For $B < -1.0$, (19) gives

$$\pi_{0-1} = 2.303\frac{RTv_m}{V\Sigma}\log\left(1+\left(\sum_1^{q-1} d_i\right)\frac{-d_{q-1}\,q}{B+1}\right) \quad (19a)$$

In the BET equation (ref. 3)

$$v/v_m = c\sum_1^\infty ix^i \Big/ \left(1+c\sum_1^\infty x^i\right) \quad (20)$$

$B$ is zero. The BET equation is, therefore, unsatisfactory from the viewpoint of the Gibbs adsorption equation. This situation was pointed out by Cassel.[13] The same argument of course, applies to the various modifications of the BET equation (*e.g.*, Anderson's[14] and Pickett's[15] equations in which attempts are made to apply the BET equation at high relative pressures). In the low relative pressure region ($x < 0.35$) one can, of course, justify the BET equation and various modifications of it[16,17] from the viewpoint of the Gibbs theorem. Moreover, in this region the present theory is consistent with the BET equation because of the very rapid convergence of the series of equation (14) at low $x$.

## Results

Since (14) is not in agreement in most cases with experimental isotherms for $x < 0.05$, the integration of (12) by application of (1) and (14) can logically be carried out only over the range $0.05 < x < 1.0$. Thus, it is still necessary to employ a graphical integration such as that of Jura and Harkins[12,18,19] to evaluate $\pi_{0-0.05}$. Our evaluations of $\pi_{0-1.0}$, therefore make use of the equations

$$\pi_{0-1.0} = \pi_{0-.05} + \frac{2.303RTv_m}{V\Sigma}\log\left\{\frac{1+\left(\sum_1^{q-1} d_i\right) - d_{q-1}q/(B+1)}{\left(1+\sum_1^\infty (0.05)^i\,d_i\right)}\right\} \quad (21)$$

in which $\pi_{0-.05}$ is taken from the work of Jura and Harkins. Table II gives values of $\pi_{0.05-1.0}$ calculated from (15) for $x_1 = 0.05$ and $x_2 = 1.0$. Values of $\pi_{0-.05}$ shown in Table II were taken from Jura and Harkins[12] (Fig. 8). The values $\pi_{0-1.0}$ obtained from (21) are compared with $\pi_{0-1.0}$ data obtained by Jura and Harkins using the graphical method.

The results in Table I show that the theoretical adsorption isotherm (1) not only has the correct form required by the Gibbs adsorption theorem but also that it yields quite accurate data on surface tension lowering for relative pressures above about 0.05. It should perhaps be noted, however, that this is true in all cases studied only when the repulsive term in the adsorbate–adsorbent interaction is taken into account, two examples being found (Table I, in which equation (1), with $a = 1.0$ instead of 1.5, leads to an improper ($B > -1$) solution of the Gibbs equation.

The method developed in this paper for calculating $\pi_{0.5-1.0}$ is not necessarily restricted to type II (and III) isotherms; it may be applied equally well to isotherms (types IV and V) in which capillary condensation occurs, since the surface pressure $\pi$ will not be affected by the pore structure of the solid. It is necessary only that the isotherm have a large enough free or unrestricted adsorption region for $x > 0.05$, *e.g.*, $0.05 < x < 0.2$ or $0.05 < x < 0.5$, etc.), to allow one to evaluate the constants $E_1, c_1$, and $v_m$.

One will observe that the surface pressure of the film which forms at $x = 0.05$, *i.e.*, $\pi_{0-0.05}$, is generally a large part of the surface pressure of the film at saturation pressures, *i.e.*, $\pi_{0-1.0}$. For example, Table II shows that $\pi_{0-0.05}/\pi_{0-1.0}$ is 0.43 for nitrogen on anatase. Moreover, one cannot be sure of the accuracy of $\pi_{0-0.05}$ determined graphically in view of the uncertainties in the graphical method of extrapolation to $x = 0$ and necessary experimental errors in the adsorption data in the low $x$ region. These considerations thus emphasize the need for further theoretical developments for handling problems in the $0 < x < 0.05$ region.

## Summary

The theory of adsorption developed in an earlier publication including, however, the repulsive term previously neglected is shown to agree with several type II isotherms over the entire range of relative pressures from 0.05 to 1.0. Methods are outlined for handling the complex infinite series of the theoretical equation, and the convergence and divergence properties of the equation are discussed.

The Bangham equation derived from the Gibbs adsorption equation for the surface pressure $\pi$ of an adsorbed film is integrated by means of the theoretical adsorption isotherm. The calculated surface pressures are shown to be in excellent agreement with data determined by Jura and Harkins from graphical integration of the Bangham equation employing the experimental adsorption isotherms. The theory offers a method for evaluation of surface pressure from all types of physical adsorption isotherms including those exhibiting capillary condensation.

# Thermodynamic Properties of Thiophene[1]

BY GUY WADDINGTON, J. W. KNOWLTON,[2] D. W. SCOTT, G. D. OLIVER,[3] S. S. TODD,[4] W. N. HUBBARD, J. C. SMITH AND HUGH M. HUFFMAN

The thermodynamic properties of sulfur compounds are of interest for several reasons. From a practical point of view, the increasing interest in the sulfur compounds occurring in or derivable from petroleum makes it important to have an extensive knowledge of the properties of these substances. Such information would be useful in the refining of petroleum and in the preparation of sulfur derivatives of hydrocarbons. Also, the thermodynamic properties of the simpler sulfur compounds are of interest because of the information such data would yield with respect to their molecular structures. Finally, as in the case of hydrocarbons, a study of representative members of a homologous series of sulfur compounds would yield relationships permitting the estimation of properties of compounds which had not been studied.

The study of some sulfur compounds of interest to the petroleum industry has recently been added to the Bureau of Mines program of thermodynamic research. Thiophene, because of its importance and intrinsic interest, was chosen as the first compound to be studied in this field. Listed below, in their order of presentation in this paper, are the several types of investigation carried out: Section (1), low-temperature heat capacity; Section (2), vapor pressure; Section (3), heat of vaporization, vapor heat capacity, gas imperfection, and entropy of the ideal gas; Section (4), heat of combustion and heat of formation; Section (5), thermodynamic functions from spectroscopic and molecular structure data. From these investigations, relatively complete thermodynamic information about thiophene in the low pressure region has been obtained.

**The Material.**—Two samples of thiophene differing somewhat in their histories were used

(1) Portions of this paper were presented at the Atlantic City Meeting of the American Chemical Society, April, 1947.

(2) Deceased.

in the several investigations. Sample I was a selected cut from the Socony Vacuum Oil Company's pilot plant at Paulsboro, N. J., and was used without further purification for measurements of vapor heat capacities, heats of vaporization, and vapor pressures by the ebulliometric method. The apparent purity of this sample deduced from melting point studies by the time–temperature method was approximately 99.96 mole per cent. Sample II, used for the low-temperature studies, for the measurements of vapor pressures by the static method, and for the measurement of the heat of combustion, was prepared from material similar to Sample I by distillation in an efficient fractionating column at the Laramie Station of the Bureau of Mines.

TABLE I

| Impurity = 0.045 mole % | | |

[a] Computation based on these 2 points.

A mass spectrometer analysis, which was carried out at the Socony Vacuum laboratories, showed Sample II to have the composition: thiophene 99.954 mole %, benzene 0.030 mole %, carbon bisulfide 0.008 mole % and methylthiophene 0.008 mole %.[5] Melting point studies were made in this laboratory by the calorimetric method. The results of these investigations are summarized in Table I. Since thiophene and benzene are known to form solid solutions, too much reliance should not be placed on the value of the purity obtained from the melting point data. Direct determinations of sulfur made during the combustion measurements indicated that the sulfur content was in substantial agreement with theory.

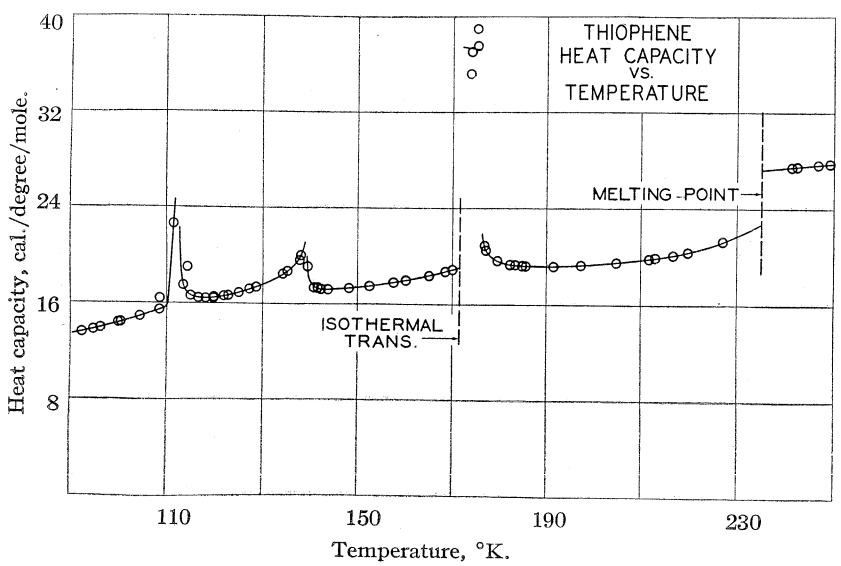

Fig. 1.—Plot of the heat capacity against temperature in the region of anomalous behavior.

## Section 1: Low-Temperature Heat Capacity

**The Apparatus.**—The measurements were made in the apparatus described by Ruehrwein and Huffman.[6] Very briefly, the method was as follows: About 0.5 mole of the material under investigation was contained in a sealed copper calorimeter, which was mounted in the adiabatic calorimetric system. A measured amount of electrical energy was supplied to the calorimeter, and at all times the temperature of the environment was maintained at that of the calorimeter to prevent heat interchange. The initial and final temperatures of the calorimeter were measured by means of a platinum resistance thermometer. The electrical measurements required for the determination of the resistance of the thermometer and the electrical energy were made on a "White" double potentiometer in conjunction with a high-sensitivity galvanometer and accurately calibrated resistances. The potential was in terms of a bank of six thermostated saturated cadmium cells, which had been certified by the National Bureau of Standards. Time measurements were made with an electric stop clock, which was operated by an a. c. power supply, the frequency of which was accurate to 0.001%. The precision of the measurements was, in general, better than 0.1%, and above 30° K. it is believed that the accuracy uncertainty should not be greater than 0.2%. The energy measurements were made in terms of the international joule and were converted to calories by dividing by 4.1833.

**The Results.**—The results of the heat capacity measurements are given in Table II and shown graphically in Fig. 1 over the region 90 to 250° K. Inspection of this figure shows that the thermal properties of thiophene vary with temperature in an unusual manner. The material appears to undergo two second-order transitions of the lambda type

having maxima at approximately 112 and 138° K., both transitions involving only small amounts of energy. At approximately 171.6° K. the crystals undergo an isothermal transition involving about 150 calories per mole. Immediately following this isothermal absorption of energy, the heat capacity is abnormally high, but drops rapidly to the normal level in a manner similar to the high temperature side of a lambda-type transition. Similar behavior was observed in an unpublished investigation in the organic laboratory at Stanford University.[7]

Because of this unusual behavior, the transition zones were investigated with considerable care in order to define the shape of the heat-capacity curve as definitely as possible. From the experimental data there can be no doubt of the negative slope of the heat-capacity curve on the high-temperature side of the transitions. Since it was thought that the shape of the curve might be characteristic of the crystals formed at low temperatures, measurements were made on the high-temperature side of each transition without allowing the material to cool below the temperature of maximum heat capacity. The usual practice is to cool the material to a suitably low temperature and then to make measurements at progressively higher temperatures. In the present case a reversal of this procedure was attempted, *i. e.*, measurements of heat capacity were made at progressively lower temperatures. In laboratory parlance this is described as "backing into a transition." These experiments demonstrated that the heat capacity was independent of the history of the sample.

Because of the peculiar behavior between 171 and 184° K., a time–temperature study was made over this region. In this study, electrical energy was supplied to the calorimeter at an approximately steady rate and the temperature of the resistance thermometer recorded at integral minutes. These data have been plotted in Fig. 2 and are in agreement qualitatively and semi-quantitatively with the deductions made from the heat-capacity measurements. [These measurements are inherently less reliable than the usual heat capacity measurements for two reasons: (1) Because of the location of the thermometer coil next to the heater coil, in the combination thermometer and heater, the temperature of the thermometer coil would always be higher than the contents of the calorimeter during energy input. However, if the rate of energy input to the heater is constant and the conduction and radiation paths are also constant, this temperature

(7) Private communication from G. S. Parks.

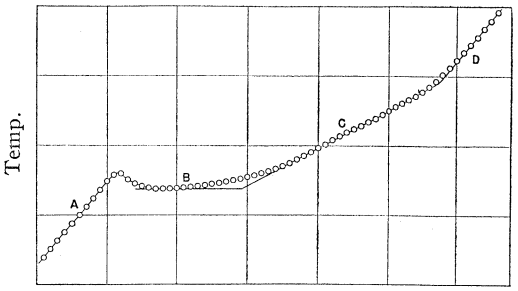

Fig. 2.—Time–temperature study of thiophene between 171 and 184°K. This study includes isothermal transition and the region of abnormally high heat capacity. Units are arbitrary.

head should be constant and the above investigation should give a good picture of the relative temperature change. (2) There will be another uncertainty due to the fact that the system is not in thermodynamic equilibrium during the heating process.] The initial portion of the curve shows a nearly uniform slope which is inversely proportional to $\Delta E/\Delta T$, the heat capacity. The low temperature material tends to superheat, and when the transition begins, the excess energy is absorbed by the transition process and the temperature drops rapidly. For some time thereafter the temperature remains nearly constant, then begins to increase slowly, forming another portion of the curve having a slope which is nearly uniform but considerably smaller than the slope of the initial part of the curve. The curve finally breaks again into another portion of uniform but higher slope. By drawing straight lines through the uniform portions of the curve it may be divided into four parts. In portion (A) the energy absorbed raises the temperature of the low-temperature crystals. In this region the heat capacity calculated from the time–temperature curve is in good agreement with the observed heat capacity values. Portion (B), which is almost flat, corresponds to an isothermal absorption of energy. This is followed by portion (C), which has a small slope and corresponds to the short temperature interval of high heat capacity. Portion (D) corresponds to the temperature range in which the heat capacity of the crystals has an apparently normal value. All of the data are in agreement, so there can be little question in regard to the thermal behavior of the material upon which the measurements were made. Because this behavior is so unusual, the question of the purity of the material has been carefully considered. All of the evidence at this time indicates that the amount of impurity was so small that it would probably have no significant effect on the thermal properties. For this reason it must be concluded that the observed behavior is characteristic of thiophene.

The value for the heat of the isothermal transition at 171.6° K. is rather arbitrary because of the uncertainties in the heat capacity of the high-temperature form and also of the temperature of transition. Check measurements were made of the energy requirements over a selected temperature interval, including the isothermal transition and the high heat capacities, and good agreement was obtained. This indicates that the transition was reproducible. The arbitrary distribution of the energy absorbed as heat of transition and heat capacity should have no significant effect on the entropy. The value assigned for the heat of transition is 152.4 cal./mole.

Two measurements were made of the heat of fusion. The experimental values were 1214.4 and 1216.6 giving a mean value $\Delta H^\circ = 1215.5 \pm 1.1$ cal./mole.

**Section 2: Vapor Pressure.**—The vapor pressure of thiophene was measured from 0 to 40° by a static method and from 40 to 120° by an ebulliometric method.

The apparatus used for the static vapor pressure measurements is shown schematically in Fig. 3. A sample container, A, and a mercury manometer, B (shown in isometric projection in the insert of Fig. 3), are contained in a constant-temperature water-bath, C, having a plate glass window, D, through which the manometer may be observed. When a sample is to be introduced into or removed from the sample container, the mercury in the manometer may be lowered into the mercury reservoir, E, by applying suction through the stopcock, F. The glass tube connecting the mercury reservoir with the manometer enters the bottom of the constant-temperature bath

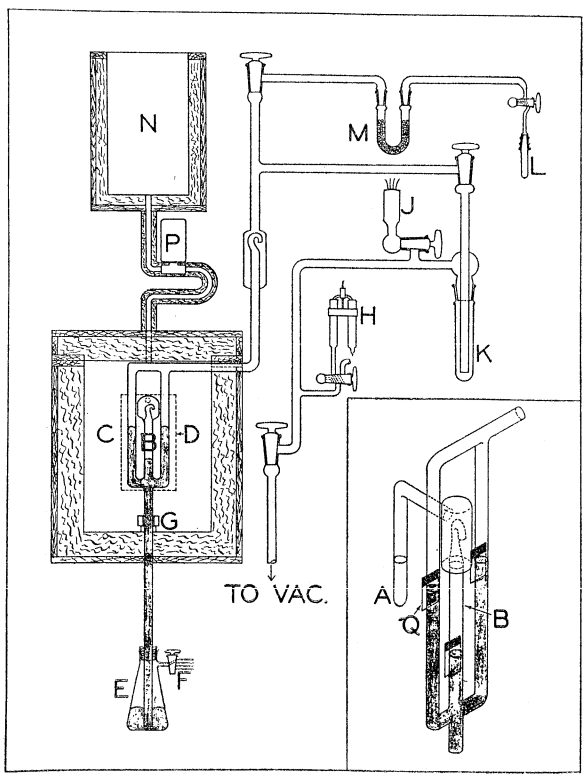

Fig. 3.—Apparatus for vapor pressure measurements by the static method.

through the packing gland, G. The two outer arms of the manometer are connected to a high-vacuum system. The Pirani gage, H, and ionization gage, J, included in this high-vacuum system, may be isolated by stopcocks when not in use and are protected from mercury vapor and other condensible materials by the refrigerated trap, K.

The procedure used for introducing and outgassing the sample is as follows: Approximately 5 ml. of the substance to be investigated is placed in the bulb, L, where it is frozen. The space over the solid is evacuated to a pressure of $10^{-5}$ mm. or less. The material is then distilled under its own vapor pressure into the sample container, A, during which operation the vapor passes through the U-tube, M, containing a suitable drying agent. The sample is again frozen and the space over it evacuated. The material is subjected to several additional bulb-to-bulb distillations between the sample container, A, and the bulb, L, and back again, and after each of these distillations it is frozen and any residual gas is pumped out. After the final distillation into the sample container, the material is melted, and about 20% of it is pumped off and caught in the trap, K (from where it is subsequently transferred to bulb L for storage). A series of vapor-pressure measurements is now made with the 80% of the sample remaining. Following these measurements, an additional 60% of the original sample is pumped off and a second series of vapor-pressure measurements is made with the 20% of the sample remaining. If the vapor pressures measured on 80% of the sample and on 20% are found to be in good agreement, this is taken as evidence that the sample was adequately outgassed and contained only negligible amounts of impurities of different volatility.

The constant-temperature bath is controlled by electrical heating when operating above room temperature and by intermittent addition of cold water from the container, N, by means of the solenoid valve, P, when operating below room temperature. In this type of apparatus, with both the sample container and manometer in the same constant-temperature bath, it is essential that there be no temperature gradients which will cause sample to distill from the sample container to the mercury surface of the manometer. For this reason, the various elements in the constant-temperature bath are so arranged that any small gradients, not eliminated by vigorous stirring, are in such a direction that the manometer is never colder than the sample container. The tube for addition of cold water is in the rear of the bath. Two immersion heaters, one a steady heater for compensating most of the heat loss of the bath, and the other an auxiliary heater used in heating the bath rapidly from one operating temperature to another, are located in the front of the bath, between the window and the manometer (but not obscuring the view of the mercury columns). The intermittent heater used for controlling the bath temperature and the stirrer are located in a 3-inch-diameter tower in one corner of the bath (not shown). A sensitive mercury-in-glass thermoregulator and a calorimetric-type platinum resistance thermometer, calibrated and certified by the National Bureau of Standards, are both in close proximity to the sample container. The resistance of the thermometer is measured by means of a G-2 Mueller bridge and a sensitive galvanometer. The bath is controlled to $\pm$ 0.01° at 15°, $\pm$ 0.005° at 40°, and $\pm$ 0.01° at 75°. When making measurements at 0°, the water is drained from the bath, and the sample container is surrounded by a Dewar flask containing crushed ice.

The manometer is read by means of a Gaertner M904 cathetometer certified by the National Bureau of Standards. The vernier of the cathetometer scale is graduated in 0.05-mm. divisions, and it is possible to estimate visually between vernier divisions to 0.01 mm. Each meniscus is observed against a background, Q, made from a rectangle of white plastic with a black strip across the top. The black reflects in the mercury surface and makes the outline of the meniscus clearly visible against the white background. The backgrounds are so mounted that they may be adjusted for vertical height by means of rods extending through the lid of the constant-temperature bath. The manometer is illuminated by "Lumiline" incandescent lamps on each side of the window.

To test the window of the constant-temperature bath for any optical imperfections that would introduce errors into the pressure readings, a standard meter bar was mounted behind the window in the place ordinarily occupied by the manometer. Cathetometer readings of the distance between graduations on the standard meter bar showed that there were no optical imperfections in the window that would affect the pressure readings significantly. The walls of the manometer arms were also tested for optical imperfections by taking "blank" pressure readings with the sample container evacuated. The pressure readings obtained did not differ significantly from zero.

When taking pressure readings, the meniscus heights are always read in order from one side to the other at approximately equal time intervals and the readings for the two outer arms are averaged. This procedure automatically corrects for any regular variation of meniscus height with time or with position, such as might be caused by a temperature drift of the mercury reservoir or by failure of the axis of the cathetometer telescope to rotate in an exactly horizontal plane. Capillary depression corrections, taken from the tables of Cawood and Patterson,[8] are applied and the readings are reduced to 0° and standard acceleration of gravity. The acceleration of gravity at this location is calculated from the latitude and altitude to be 979.82 cm./sec.$^2$, and the standard acceleration of gravity is taken as 980.665 cm./sec.$^2$. Corrections for the vapor pressure of mercury are applied to the values obtained at the higher temperatures where this correction becomes significant.

To test the performance of the apparatus, the vapor pressure of benzene was measured at six temperatures between 0° and 35°. The results obtained, when compared with values calculated from the equation given in the A.P.I. Tables,[9] showed an average deviation of 0.03 mm. of Hg and a maximum deviation of 0.06 mm.

The results obtained for thiophene are listed in the first part of Table III. Each value listed is the average of five or more pressure readings taken within a period of about an hour. Three readings of the bath temperature were taken within the same period, and if these were significantly different from the integral temperature, the appropriate corrections were applied to the pressure readings.

In the ebulliometric vapor-pressure measurements, the boiling temperature of thiophene was compared directly with the boiling temperature of water in a closed system filled with nitrogen gas, the pressure of which could be adjusted to any predetermined value between 100 and 2500 mm. The boiling temperature of each liquid was measured in a differential ebulliometer, Fig. 4, which is a modification of one described by Swietoslawski.[10] The strain-free platinum resistance thermometer used to measure the boiling points had been calibrated and certified by the National Bureau of Standards. Its resistance was measured with the same bridge and galvanometer used with the static vapor pressure apparatus.

At atmospheric pressure, the boiling and condensation temperatures of the thiophene sample

differed by only 0.003°. This result indicates that the sample did not contain sufficient impurities of different volatility to have any significant effect on the boiling point measurements.

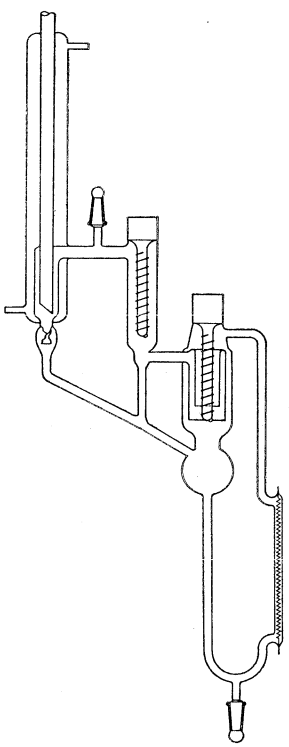

Fig. 4.—Differential ebulliometer.

The vapor pressure data obtained by the ebulliometric method are listed in the second part of Table IV. The pressures corresponding to the observed boiling points of water were obtained from the tables of Osborne, Stimson and Ginnings.[11]

The vapor pressure data obtained by both methods were fitted to an Antoine equation by the least squares treatment of Willingham, Taylor, Pignocco, and Rossini.[12] In weighting the individual points, the expected standard deviation of each temperature measurement was arbitrarily taken as 0.01° and the expected standard deviation of each pressure measurement by the static method was arbitrarily taken as 0.10 mm. The equation obtained is

$$\log_{10} P = 6.95926 - 1246.038/(221.354 + t) \quad (1)$$

Values of the vapor pressure calculated by means of this equation are included in Table III for comparison with the observed values. In the deviation plot, Fig. 5, the results of prior investigations of the vapor pressure of thiophene[13] are compared with those reported here.

## Section 3: Heat of Vaporization, Vapor Heat Capacity, Gas Imperfection, and Entropy of the Ideal Gas

**Heat of Vaporization and Vapor Heat Capacity.**—The heat of vaporization of thiophene was determined at three temperatures, and the heat capacity of the vapor was measured at two or more pressures at each of five temperatures between 70 and 200°. The cycling vaporizer and flow calorimeter, described in previous publications from this laboratory,[14] were used for these measurements. The heat of vaporization data are given in Table IV; the accuracy of these values is estimated to be about 0.1%. The following empirical equation may be used for interpolation over the temperature range of the experiments

$$\Delta H_{vap.} = 9543 + 2.740T - 0.02349T^2 \quad (2)$$

Table V lists the vapor heat-capacity data. The values of $C_p°$ (obs.) were obtained at each temperature by linear extrapolation to zero pressure, of plots of heat capacity *vs.* pressure. Al-

though the accuracy of vapor heat capacity measurements of polyatomic molecules is difficult to assess, the accuracy uncertainty of the $C_p^\circ$ values given here is believed to be about $\pm 0.2\%$. Over the range of temperatures studied, $C_p^\circ$ is given without significant loss of accuracy by the empirical relationship

$$C_p^\circ = -7.017 + 0.10045T - 6.325 \times 10^{-5}T^2 \quad (3)$$

**Gas Imperfection and the Second Virial Coefficient.**—Values of the second virial coefficient, $B$, in the equation of state $PV = RT + BP$ were calculated from the heat of vaporization and vapor pressure data by means of the relation

$$B = \frac{\Delta H_{vap.}}{T(dP/dT)} - \frac{RT}{P} + V_l \quad (4)$$

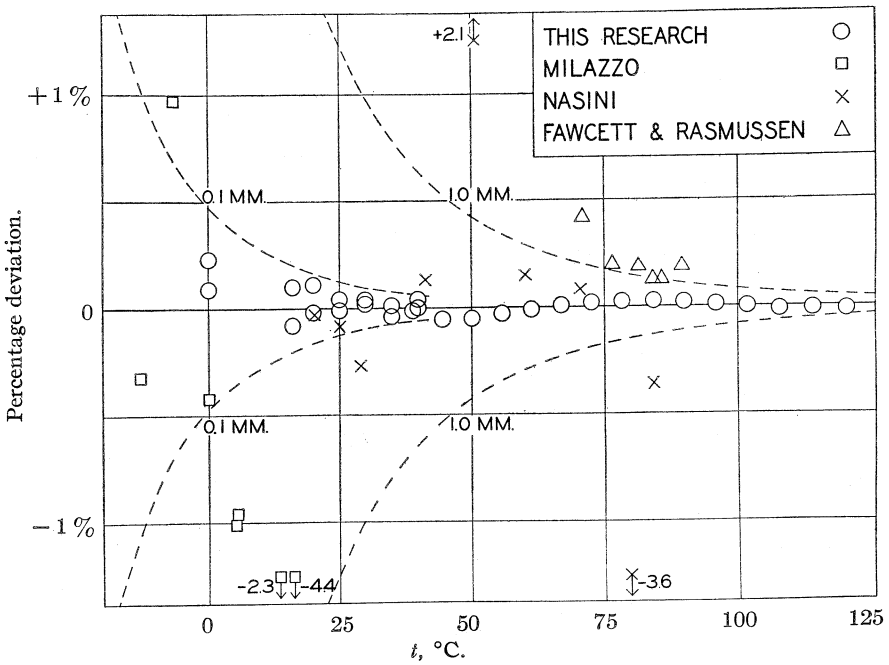

Fig. 5.—Deviation plot of vapor pressure data for thiophene, comparing the results of this research with those of previous investigators (ref. 13). Equation 1 was used for the base line. The dashed lines represent the percentage deviations arising from absolute deviations of 0.1 mm. and 1.0 mm., respectively.

where $V_l$ is the molal volume of the liquid. Use of the experimental data for the pressure dependence of the vapor heat capacity in the equation $(\partial Cp/\partial P)_T = -T(\partial^2 B/\partial T^2)_P$ yielded values of the second derivative of $B$ with respect to temperature. These results were used to obtain the following empirical equation for the second virial coefficient of thiophene vapor

$$B(\text{liters}) = -0.435 - 0.0172 \exp.\ (1200/T) \quad (5)$$

The method of evaluating the constants has been discussed previously.[15]

In Table VI the observed values of the second virial coefficient and of $(\partial Cp/\partial P)_T$ are compared with those calculated from Eq. 5.

**Entropy from Calorimetric Data.**—The calorimetric data have been used to calculate the entropy in the usual way. In the transition regions the heat capacity curves are not necessarily accurate because of rapid curvature. However, the curves have been made in such a way that $\int_{T_x}^{T_y} C_p dT$ gives the observed enthalpy change; hence there will be no significant error in the entropy.

Since the heat-capacity measurements were carried out up to 340° K., it was possible, with a small extrapolation, to obtain the entropy of the liquid at the temperatures corresponding to those at which the heat of vaporization had been measured. The entropy calculations are summarized in Table VII.

(15) Scott, Waddington, Smith and Huffman, *J. Chem. Phys.*, **15**, 565 (1947).

The uncertainties in the experimental heat capacity measurements in certain temperature regions are probably higher than usual because of the rapid curvature and slow approach to equilibrium. Nevertheless it is believed that the experimentally determined entropy of the liquid is reliable to ±0.1 cal./deg./mole, and that of the gas is reliable to ± 0.20 cal./deg./mole.

## Section 4: Heat of Combustion and Heat of Formation

**Calorimetric Method.**—The calorimetric method has been described previously.[16]

Certain modifications in the apparatus as described by Hubbard, Knowlton and Huffman[17] had been made, but the operating principles were unchanged. All of the combustions were carried out in a platinum-lined bomb having a volume of 0.330 liter. The general method of Huffman and Ellis[16] for the combustion of sulfur compounds was followed; that is, an atmosphere of air was left in the bomb to supply nitrogen required for the complete oxidation of sulfur to sulfur trioxide and no (liquid) water was introduced into the bomb before the combustion. The combustion samples were contained in thin-walled glass ampules drawn down to a capillary neck which was not sealed.

The ampules were filled by the following procedure. The weighed empty ampules were placed neck down in the receiver of an all-glass distilling apparatus. The system was then evacuated and the thiophene allowed to distill into the receiver under its own vapor pressure. When a sufficient quantity had been distilled, air was admitted to the system and the pressure forced liquid into the ampules. Shortly before a combustion experiment an ampule was taken from the receiver, external material was removed, and a small amount of thiophene was forced out of the ampule so as to bring the liquid level, at room temperature, below the fine part of the capillary, to avoid losses due to expansion caused by temperature fluctuations subsequent to weighing. Because of the fineness of the opening and the small surface exposed, there appeared to be no significant evaporation of sample or solution of air during the experimental period. The method was tested by burning benzene in both sealed and unsealed ampules. In both cases very satisfactory agreement was obtained with the accepted value for its heat of combustion.

**Calibration.**—The energy equivalent of the system was determined by the combustion of benzoic acid NBS standard sample #39f having the certified value of 26,428.4 NBS international joules per gram for the isothermal heat of combustion under standard conditions.[18] Since the conditions of this investigation were not quite standard, this value was corrected to 26,426.6 NBS int. joules/g. Joules were converted to conventional calories by dividing by 4.1833. The average value of the energy equivalent of the system, from eight calibration experiments, was found to be 3225.7 cal./degree, with an average deviation of 0.004% and a maximum deviation of 0.017%.

**Corrections and Analytical Procedures.**—The reactions involved in the combustion of sulfur compounds are rather complex and require corrections not usually applied in C, H, O combustions. Under the conditions of the experiment, part of the nitrogen in the bomb is fixed. Hence it is necessary to determine both the type of nitrogen compound and the quantity so that proper calorific corrections may be applied for these secondary reactions. Because of the large heat of dilution of sulfuric acid, it is necessary to know its concentration with considerable certainty. Finally, because there is a difference in the amount of water vapor initially present in the bomb and the amount existing over the sulfuric acid solution in the final state, a correction must be applied for its condensation.

Qualitative tests indicated that nitrogen was fixed in the form of nitric acid and nitrous acid. The $NO_2^-$ ion was determined by the colorimetric method of Treadwell and Hall[19] and the total nitrogen was determined as ammonia after reduction by Devarda's method.[20] It was assumed that all of the nitrogen was in the form of nitrous and nitric acid; hence nitric acid was taken as the difference between total nitrogen and nitrous acid nitrogen. The heat effects ($\Delta E$) associated with the formation of nitrous and nitric acid were taken as 6.4 and −14.96 kcal. per mole, respectively.

The concentration of the sulfuric acid was calculated from the stoichiometric relations of the materials entering into the reaction. In a number of cases the sulfate ion was determined gravimetrically and the amount found was on the average 99.8% of the calculated amount. The data of Huffman and Ellis[16] were used to correct the observed heats to one corresponding to a standard sulfuric acid concentration. The correction for the condensation of water vapor was determined from measurements of the humidity, the volume of the bomb, the known heat of vaporization of water, and the vapor pressure of aqueous sulfuric acid.[21]

The results of the six combustions are summarized in Table VIII. In addition to the final results this table shows the magnitude of the various correction terms used.

[a] $Q_{diln.}$ = correction for dilution of $H_2SO_4$, $Q_{cond.}$ = correction for condensation of water, $Q_{HNO_2}$ = correction for nitrous acid, $Q_{HNO_3}$ = correction for nitric acid.

In Table IX are given the derived data for thiophene. It should be borne in mind that $-\Delta U_R$ and $-\Delta H_R$ apply to the combustions only when the composition of the aqueous sulfuric acid corresponds to $H_2SO_4 \cdot 1.7H_2O$ and that the Washburn correction has not been applied.

TABLE IX

THIOPHENE, MOL. WT. = 84.132; DERIVED DATA AT 298.16°

| in kcal./mole | | | |
|---|---|---|---|
| $\Delta U_R$ | $\Delta H_R$ | $\Delta H°_f$(liq.) | $\Delta H°_f$(gas) |
| −665.71 | −667.19 | 19.52 | 27.82 |

$\Delta U_R$ and $\Delta H_R$ refer to the reaction in which $H_2O/H_2SO_4 = 1.7$. $\Delta H_f°$ refers to the formation from the elements.

**Discussion.**—The above value for the heat of formation of thiophene is to be looked upon as a preliminary value only, for several reasons that will be discussed below. The corrections for the fixed nitrogen were based on the assumption of the formation of aqueous nitrous acid and nitric acid. Actually this assumption may not be warranted as is borne out by the following evidence. According to the above assumption the products of the combustion of the sulfur and the nitrogen are all acidic. Hence from the total nitrogen and sulfur known to be present it is possible to calculate the moles of acid to be expected. This calculated value was always greater than the value found from titration by approximately 0.4–0.5 millimole or 2 to 3%. Because the gravimetric sulfur analyses accounted for practically 100% of the theoretical $SO_4^{--}$ ion and no known cations were present, it is believed that the discrepancy is due to nitrogen being fixed in some form other than nitrous acid or nitric acid. This problem is being investigated.

Furthermore, a small amount of solid material is found after each combustion when the solutions formed in the combustion are evaporated to dryness. Presumably this solid residue comes from the reaction of the products of combustion with either platinum or glass or both. The amount of residue is far too small to account for the discrepancy between calculated and found hydrogen ion. A series of combustions made in an illium bomb showed about twice as much residue and the combustion values were definitely higher.

The heat of combustion of thiophene has also been studied by Moore, Renquist and Parks[22] in an illium bomb. Their value for $-\Delta U_B/M$ corrected for the change in the heat of combustion of benzoic acid[18] and a change in calibration[23] is 7918.3 ± 2.5 calories per gram and in good agreement with the value 7916.8 obtained in this laboratory using an illium bomb.

In the opinion of the authors, the data obtained in this Laboratory using the platinum bomb are probably the most reliable. In spite of the uncertainty attached to their experimental quantities, it seems desirable to publish these results as being the best available and because of the need of a value of the heat of formation for thermodynamic calculations.

## Section 5: Thermodynamic Functions from Spectroscopic and Molecular Structure Data

**Vibrational Assignment.**—With the aid of the vapor-heat-capacity data, a complete, although not entirely certain, vibrational assignment for thiophene was made. No complete vibrational assignment has been proposed heretofore, but Thompson and Temple[24] have assigned 14 of the 21 fundamental frequencies. The assignment given here is based primarily on the Raman data of Reitz[25] and the infrared data of Thompson and Temple, as given in Table X, although all of the other available spectroscopic data[26] were consid-

| 7 | 2996 | | | | | 17 | (3093) |
| 8 | 3093 | | | | | | |

[a] Parentheses denote frequencies used for the second time.

In class $A_1$, the assignment of the frequencies below 1600 cm.$^{-1}$ follows that of Thompson and Temple. These frequencies appear as strong polarized lines in the Raman effect, and their assignment is unambiguous. There are two C–H stretching frequencies in this symmetry class, but three polarized Raman lines are observed in the 3000 cm.$^{-1}$ region of the spectrum. The frequency 2996 cm.$^{-1}$ was assigned to $\nu_7$ and the doublet 3078–3108 cm.$^{-1}$ was interpreted as Fermi resonance between $\nu_8$ and $3(\nu_2)$. The average value, 3093 cm.$^{-1}$, was used for $\nu_8$.

In assigning the frequencies in class $A_2$, use was made of the fact that the vibrations in this symmetry class do not involve motion of the sulfur atom, and consequently the frequencies should not differ greatly from those of the corresponding vibrations in pyrrole. The $A_2$ frequencies in pyrrole occur at 510, 711, and 868 cm.$^{-1}$;[27] the evident choices for thiophene are the frequencies 565, 686 and 748 cm.$^{-1}$ observed in the Raman effect. In conformity with the selection rules for $A_2$ frequencies, these do not appear in the infrared.

In class $B_2$, Thompson and Temple assigned the strong infrared band at 710 cm.$^{-1}$ to $\nu_{22}$. The out-of-plane ring bending frequency, $\nu_{23}$, would be expected in the region of the spectrum below 500 cm.$^{-1}$; the choice is between the Raman lines at 375 and 453 cm.$^{-1}$. Thompson and Temple suggest that the former is the difference tone 832 − 453 = 379 cm.$^{-1}$. Additional evidence for this interpretation is the fact that if 375 cm.$^{-1}$ is assumed to be a fundamental frequency, no reasonable assignment of the other frequencies can be made to agree with the gas heat capacity data. This leaves the 453 cm.$^{-1}$ Raman line for $\nu_{23}$. The remaining $B_2$ frequency, $\nu_{24}$, arises from an out-of-plane hydrogen bending mode which would be expected to involve little motion of the heteroatom or group in the series pyrrole, pyrrole-N-d, furan and thiophene. Hence it would be expected to have roughly the same value in all of these molecules. In pyrrole and pyrrole-N-d, $\nu_{24}$ is found at 838 and 833 cm.$^{-1}$, respectively,[28] and the $B_2$ frequency of furan at 837 cm.$^{-1}$ is very likely also $\nu_{24}$. In thiophene a $B_2$ frequency in this region of the spectrum would be obscured in both the Raman and infrared spectra by the $A_1$ frequency, $\nu_3$, at 832 cm.$^{-1}$, and the value 832 cm.$^{-1}$ was used for $\nu_{24}$, as well as for $\nu_3$.

Thompson and Temple have assigned the observed frequencies 872, 1252, and 1590 cm.$^{-1}$ to class $B_1$; these probably are the ring frequencies $\nu_{10}$, $\nu_{14}$, and $\nu_{15}$. As all the C–H stretching frequencies of thiophene have not been resolved, the same values were used for $\nu_{16}$ and $\nu_{17}$ in class $B_1$ as for $\nu_7$ and $\nu_8$ in class $A_1$, namely, 2996 and 3093 cm.$^{-1}$. This leaves only the two C–H bending frequencies, $\nu_{11}$ and $\nu_{12}$, to be assigned. The weak Raman line at 898 cm.$^{-1}$ (corresponding to the infrared band for thiophene vapor at 909 cm.$^{-1}$) was used for $\nu_{11}$; it is depolarized and hence cannot be the overtone of $\nu_{23}$. To fix the remaining frequency, $\nu_{12}$, use was made of the gas heat capacity data. Assuming all the other frequencies assigned correctly, the gas heat capacity data require $\nu_{12}$ to be approximately 1300 cm.$^{-1}$. Liquid thiophene has a weak infrared band at 1290 cm.$^{-1}$. Although this can be interpreted as a combination band (453 + 832 = 1285) it seems more probable that it is the fundamental frequency, $\nu_{12}$, and it was so assigned.

In Table V the observed values of $C_p°$ are compared with those calculated by means of the harmonic oscillator-rigid rotator approximation, using the vibrational assignment of Table XI. If the

(27) Lord and Miller, *J. Chem. Phys.*, **10**, 328 (1942).

(28) Actually, Lord and Miller assign these frequencies to $\nu_{23}$, but it seems more probable that they correspond to $\nu_{24}$, and that the lowest $B_2$ frequencies, 565 and 450 cm.$^{-1}$, correspond to $\nu_{23}$.

vibrational assignment is correct, the values of $C_p°$(obs.) − $C_p°$ (calcd.) in the last line of Table V represent the contribution to the heat capacity of anharmonicity and other factors neglected in the harmonic oscillator–rigid rotator treatment. In the case of benzene,[15] for which there can be little doubt as to the correctness of the vibrational assignment, values of $C_p°$(obs.) − $C_p°$ (calcd.) were found which were similar both in magnitude and in temperature dependence to those found here for thiophene.

**Entropy from Molecular Structure Data.**—The calorimetric values of the entropy are compared in Table XII with those calculated from molecular structure data. In these calculations the values of the fundamental constants given by Wagman, *et al.*[29] were used. The moments of inertia, calculated from the geometrical data of Schomaker and Pauling[30] and 1941 atomic weights, are $I_x = 156.5 \times 10^{-40}$, $I_y = 262.1 \times 10^{-40}$, and $I_z = 105.6 \times 10^{-40}$ g. sq. cm. The symmetry number is 2. The vibrational assignment of Table XI was used.

TABLE XII

| $T$, °K. | Entropy, cal./deg./mole: Calorimetric | Molecular structure |
|---|---|---|
| 318.52 | 67.83 | 67.81 |
| 336.24 | 68.88 | 68.84 |
| 357.32 | 70.04 | 70.05 |

The close agreement of the two sets of entropy values shows that crystalline thiophene approaches zero entropy at the absolute zero. It is also a confirmation of the planar structure ($C_{2v}$ symmetry) for the thiophene molecule.

**Statistically Calculated Thermodynamic Functions.**—The free-energy function, heat-content function, entropy, and heat capacity of gaseous thiophene have been calculated for various temperatures up to 1500° K. The values obtained are listed in Table XIII.

TABLE XIII

THERMODYNAMIC FUNCTIONS OF THIOPHENE

| $T$, °K. | $(H_0^0 - FT^0)/T$, cal./deg./mole | $HT^0 - H_0^0$, kcal./mole | $ST^0$, cal./deg./mole | $C_p{}^0T$, cal./deg./mole |
|---|---|---|---|---|
| 298.16 | 55.98 | 3.172 | 66.62 | 17.32 |
| 300 | 56.05 | 3.204 | 66.72 | 17.43 |
| 400 | 59.45 | 5.224 | 72.51 | 22.81 |
| 500 | 62.62 | 7.728 | 78.08 | 27.10 |
| 600 | 65.64 | 10.59 | 83.32 | 30.46 |
| 800 | 71.27 | 17.22 | 92.80 | 35.27 |
| 1000 | 76.42 | 24.61 | 101.03 | 38.56 |
| 1500 | 87.52 | 45.24 | 117.68 | 43.33 |

These thermodynamic functions were calculated on the basis of the harmonic oscillator–rigid rotator approximation and may be somewhat in error, especially at the higher temperatures, because of neglect of the contributions of anharmonicity and other factors. Some values in the table are given to more significant figures than are warranted by their absolute accuracy, in order to retain the internal consistency of the several thermodynamic functions.

**Acknowledgments.**—The authors are indebted to J. S. Ball of the Petroleum and Oil-Shale Experiment Station, Bureau of Mines, Laramie, Wyo., and to the Socony Vacuum Oil Co., Paulsboro, N. J., for the samples of purified thiophene used in this work, and for analytical data on the samples. Helpful discussion of certain features of the vibrational assignment with Dr. Kenneth S. Pitzer of the University of California is gratefully acknowledged.

## Summary

The heat capacity of thiophene was measured over the temperature range 11–340° K. The solid has two lambda-type transitions at approximately 112 and 138° K., an isothermal transition at approximately 171.6° K., and a short region of anomalously high heat capacity on the high-temperature side of the latter transition. The heat of transition (152.4 cal./mole), heat of fusion (1215.5 ± 1.1 cal./mole), and the triple point (234.95 ± 0.05° K.) were measured.

The vapor pressure of thiophene was measured over the temperature range 0 to 120°, and the following equation was found to fit the vapor-pressure data: $\log_{10} P(\text{mm.}) = 6.95926 - 1246.038/(221.354 + t)$. The normal boiling point is 84.16°.

The heat of vaporization was measured at three different temperatures, and the values found were 8032, 7808 and 7522 cal./mole at 45.36, 63.08 and 84.16°, respectively.

The heat capacity of thiophene vapor was measured at five different temperatures in the range 343 to 472° K. The experimental values for $Cp°$, the heat capacity in the ideal gas state, may be represented by the equation $Cp° = -7.017 + 0.10045T - 6.325 \times 10^{-5}T^2$. An equation for the second virial coefficient, $B$, in the equation of state $PV = RT + BP$, was obtained from thermal data. The equation is $B$ (liters) $= -0.435 - 0.0172 \exp.(1200/T)$.

The entropy of liquid thiophene at 298.16° K. is 43.30 ± 0.10 cal./deg./mole. The entropy of the ideal gas at the normal boiling point (357.32° K.) and 1 atmosphere pressure is 70.04 ± 0.20 cal./deg./mole.

The heat of combustion of thiophene was determined. For the reaction at 298.16° K., $C_4H_4S(l) + 13/2\ O_2(g) + 0.7H_2O = 4\ CO_2(g) + H_2SO_4 \cdot 1.7H_2O$, $\Delta H_R = -667.19$ kcal./mole. The heat of formation of liquid thiophene is 19.52 kcal./mole and the heat of formation of the gas is 27.82 kcal./mole, both at 298.16° K.

A complete vibrational assignment was proposed for thiophene. Using this vibrational as-

# Solubilization of Polar–Non-polar Substances in Solutions of Long Chain Electrolytes[1a]

BY WILLIAM D. HARKINS AND HANS OPPENHEIMER

## I. Introduction

Earlier work in this Laboratory[1b,2] on the effects of long chain alcohols and amines on both the X-ray bands and the critical micelle concentration of soap solutions indicates that their effects are very different from those of the hydrocarbons. This suggests that the locus in which the alcohols dissolve is also different, and thus that the relations exhibited in the solubilization of the alcohols should be different from those of the hydrocarbons.

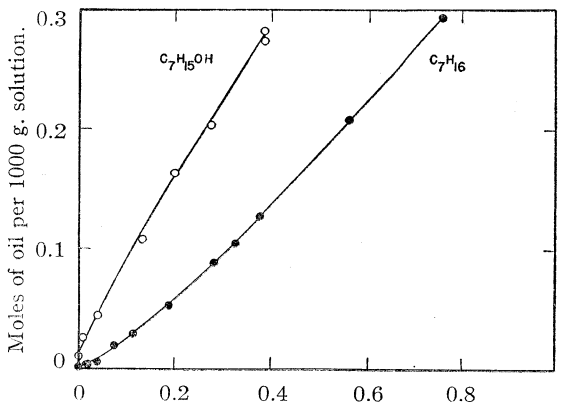

Fig. 1a.—Solubility of normal primary heptyl alcohol and of normal heptane in solutions of potassium dodecanate.

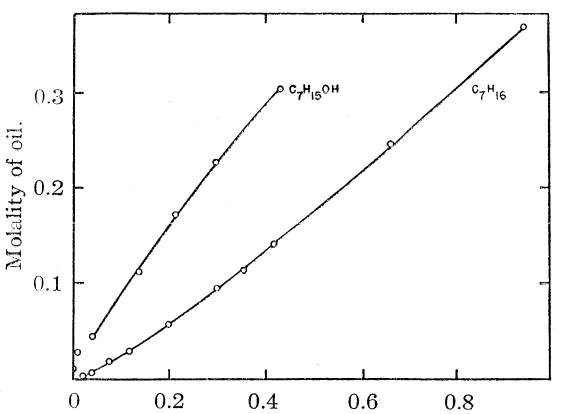

Fig. 1b.—Solubility of normal primary heptyl alcohol and of normal heptane in solutions of potassium tetradecanoate.

In Fig. 1a it is shown that the solubility in aqueous solutions of heptanol in aqueous solutions of potassium dodecanoate is twice as great as that of heptane at the higher soap concentrations. At low concentrations the ratio is much larger. In this figure the concentrations are given in moles per 1000 g. of the solution, but since the density of the soap solutions is, at all concentrations, very close to unity, these are very close to the molar concentrations. In Fig. 1b the concentrations are expressed in terms of molality, but the general relations remain as before.

The curve which represents the *non-polar* solubilization is, in both figures, convex toward the concentration axis. This is the usual relationship: the rate of increase of the non-polar solubilization with soap concentration, increases with soap concentration.

That which represents heptanol is concave toward the axis. Both curves are most highly curved just above the critical micelle concentration.

These curves indicate that, according to expectation, these two types of compounds exhibit two types of solubilization. These are considered further in a later section.

## II. Experimental Methods

The solubility of the mercaptans was determined by an amperometric method, according to Kolthoff.[3]

That of the amines, alcohols and acids was found by use of a turbidimetric method, in which a photometer was used to determine the turbidity. It was assumed as a criterion of solubility that as the saturation point is exceeded, the excess oil is emulsified and the solutions therefore become increasingly turbid.

To determine the solubility of an alcohol in a soap solution at one given concentration the following procedure was adopted. The soap solution was weighed into a glass ampule, a weighed amount of oil was added, and the ampule was sealed. At a constant soap concentration a series of ampules was prepared, each successive ampule

(3) I. M. Kolthoff and V. A. Stanger, "Volumetric Analysis," Interscience Pub., New York, N. Y., 1942, p. 264.

containing an increasing amount of the alcohol. The samples were shaken vigorously for forty-eight hours or more in order to attain equilibrium. That equilibrium was actually obtained was shown by approaching saturation from both undersaturation and supersaturation in enough instances to make certain that the times allotted were more than sufficient.

At the end of the time the turbidity of the solutions was measured by the use of a photometer. For those samples in which the amount of alcohol added was below the saturation value the turbidity was equal to that of the original soap solution. When an excess of alcohol was present, the solutions exhibited a rapid increase of turbidity, caused by the appearance of emulsion droplets, with increase in the amount of alcohol. A plot was made of the turbidity against the amount of alcohol added, and the sharp break in the curve was considered as the saturation point. Fig. 2 shows the type of curve obtained upon addition of benzene to a 6.89% solution of potassium laurate. The method works well if there is a large difference between the refractive index of the alcohol and that of the soap solution.

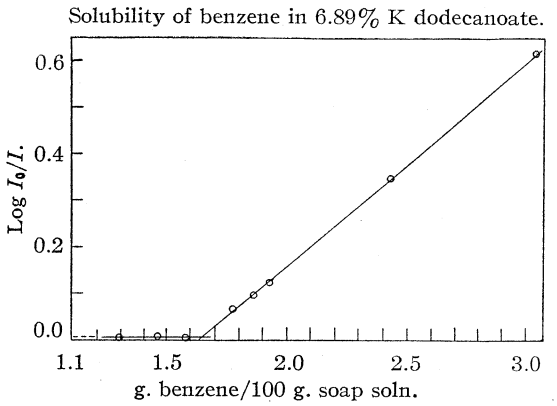

Fig. 2.—Turbidity of solutions of benzene in 6.89% potassium dodecanoate. The solubility is given by the intersection of the two straight lines.

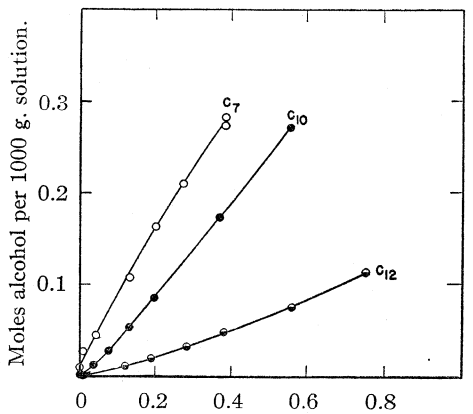
The **soaps** were prepared as follows: No commercial soaps were used. The fatty acid (Eastman Kodak Co.) was dissolved in ethyl alcohol. This solution was slowly added to a hot solution of the base (usually KOH) in ethanol. The amount of base was about 10% more than the theoretical amount necessary for neutralization. On cooling, the soap crystallized. It was allowed to stand overnight and then was filtered off. It was purified by two or three recrystallizations from a mixture of ethyl alcohol and acetone. The final drying was done *in vacuo* over potassium hydroxide.

**Sodium dodecyl sulfate** (Procter and Gamble) was extracted with ether once or twice until it had lost its yellow appearance. Then it was recrystallized from 95% ethyl alcohol for two or three times. The crystals were very well formed. The drying was done *in vacuo* over potash.

The **alcohols** were obtained from Eastman Kodak Co. and Connecticut Hard Rubber Company, and were purified by fractional distillation, with the higher alcohols at a low pressure.

**III. Effect of Length of the Hydrocarbon Chain.**—The solubility of the *n*-long chain alcohols in solutions of potassium tetradecanoate is found to fall rapidly in the series, 7, 10, and 12 carbon atoms (Fig. 3). This is the general relation found for the hydrocarbons, but the solubilities exhibited here are in all cases much greater at the same chain length as pointed out earlier for heptane and heptanol.



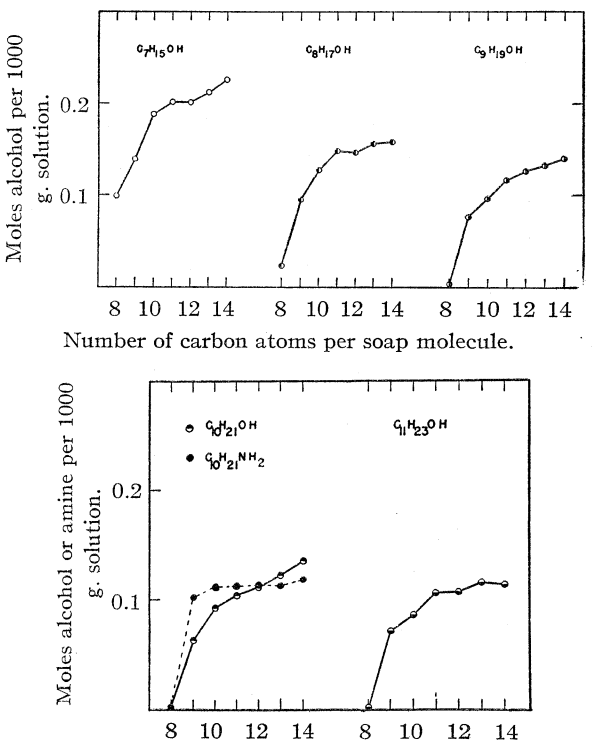


Fig. 3.—Solubility of heptanol, decanol and dodecanol (normal primary alcohols) in solutions of potassium tetradecanoate.

A general increase in the solubility of alcohols with chain length of the soap is exhibited in Figs. 4a and b, with soaps of from 8 to 14 carbon atoms. All alcohols, except heptanol, show by far the greatest increase between the 8 and the 9 carbon atom soap.

Figs. 4a and b.—Solubility of normal primary alcohols of 7 to 11 carbon atoms in solutions of soaps from 8 to 14 carbon atoms at 0.3 molar concentration.

A decrease in solubility with length of the hydrocarbon chain of the alcohol is brought out in

ture is not so different from that in non-polar solubilization as with 7 C atoms.

**IV. Discussion. Solubilization of Polar-Nonpolar Long Chain Molecules.**—Papers on solubilization alone, such as that presented here and those of others,[5,6] give no evidence whatever to show where in the micelle polar–non-polar molecules are solubilized.

However, earlier work in this Laboratory[1b,2] and extensive X-ray investigations[7] give evidence, on the basis of the effects of long chain alcohols and amines on the X-ray bands and on the critical micelle concentration, which shows that the position and orientation of a polar–non-polar molecule is similar to that of a soap molecule. Thus the long polar–non-polar molecules are found to lie with their chains between those of the soap molecules, and their polar-hydrogen-bonding groups toward the water.

## Summary

The solubility relations exhibited by polar–non-polar long chain substances in solutions of long chain electrolytes are found to be different from those with non-polar compounds. The former are in general more soluble than the latter. The curve for *n*-heptanol is concave, that for *n*-heptane convex, toward the concentration axis. Curves which relate polar–non-polar solubility are given for all of the ordinary soaps of from 7 to 14 C atoms for all of the *n*-primary alcohols of from 7 to 11 C atoms.

The effects of long chain polar–non-polar molecules on the X-ray bands and on the critical micelle concentration as presented in other communications from this Laboratory indicate the locus of such molecules in the micelle. Their position is like that of the soap molecules in that their polar groups are oriented toward the water and their hydrocarbon chains lie between those of the soap.

No work on solubilization gives evidence for this point of view. It shows merely that whereas two types of solubility behavior are expected on the above basis, they are also found.

# Infrared Absorption of Hydroxy Compounds in Autoxidizing Linseed Oil[1]

BY F. J. HONN, I. I. BEZMAN AND B. F. DAUBERT

Infrared absorption measurements have been rather widely employed for routine analysis, industrial process control, and the elucidation of molecular structure and reaction mechanisms. Although the deterioration of rubber and other high polymers has been studied with the aid of infrared techniques,[2] there has been little information published demonstrating the application of these techniques to the problem of drying oil oxidation.[3]

Preliminary examination of the infrared spectrum of raw linseed oil before and after vigorous oxidation reveals a marked increase in the intensity of two absorption bands (Fig. 1). The first, a rather broad band at 10.2 $\mu$, is known to be characteristic of the general configuration R—CH=CH—R.[4] Its appearance during the oxidation process may result from the production of geometric isomers of the naturally occurring unsaturated fatty acids.[5] The second, a far more distinct band at 2.9 $\mu$, is said to be characteristic of the bonded hydroxyl group. In this instance, as in the many others, the wave length of the infrared absorption band is indicative of the nature of the absorbing group or configuration, while the intensity of absorption is dependent upon the concentration of that group.[6]

Because of its role in the autoxidation process, the hydroxyl band at 2.9 $\mu$ has been selected for further study. The degree of absorption at 2.9 $\mu$ and therefore the hydroxyl content of a drying oil do not vary uniformly with oxidation time. In Fig. 2, the 2.0–3.0 $\mu$ region has been scanned at several stages throughout the oxidation process.

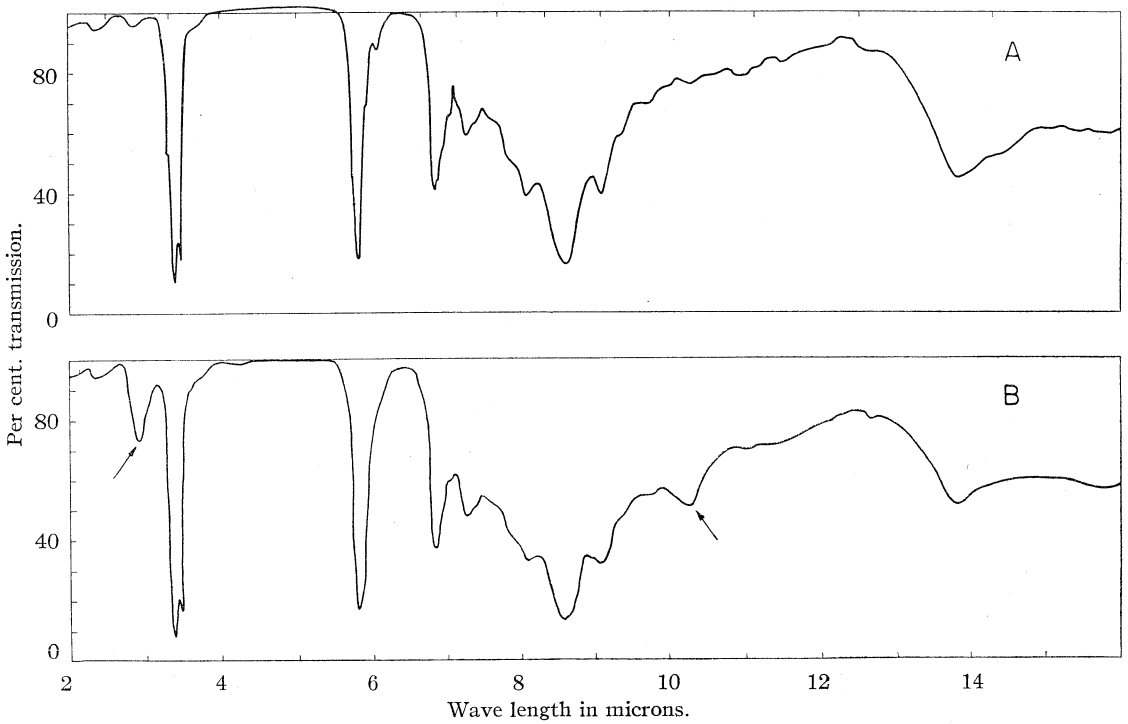

Fig. 1.—Infrared spectra of raw linseed oil: A, before oxidation; B, after oxidation.

During the induction period (zero to four hours), when oxygen uptake and peroxide formation are sluggish, the increase in intensity of absorption at 2.9 $\mu$ is correspondingly slow. At the end of the induction period, however, the 2.9 $\mu$ band quickly increases in intensity as the various oxidation reactions proceed at a rapidly accelerating pace.

In the autoxidation process there are formed several functionally distinct groups containing the (O–H) linkage, which can contribute to 2.9 $\mu$ absorption. They are (1) the hydroperoxide group (O–O–H), (2) the carboxy group (–CO–

OH), (3) the simple alcoholic group (–C–OH), and (4) possibly other groups, such as that found in free liquid water (H–O–H). Classes (3) and (4) may be grouped conveniently as the "R–OH fraction."

Each of these hydroxy compounds can be accounted for by mechanisms usually advanced to explain drying oil autoxidation.[7–11] Farmer and co-workers[7–8] have demonstrated the formation of hydroperoxides by the attack of molecular oxygen upon the carbon alpha to a double bond. They have indicated, moreover, that such hydroperoxides may undergo further reaction with a carbon–carbon double bond to form epoxy and hydroxy derivatives.[9] More vigorous oxidation of the C=C linkage, of course, may result in its complete rupture, with the formation of carboxylic acids. Later in the oxidation process, particularly at elevated temperatures, water is released by the condensation of hydroxy derivatives to form polymers.[10] Other hydroxy substances, such as phospholipids and mucilages, are to be found in unrefined drying oils.[11]

Where associated in a mixture as complex as a raw drying oil, the various hydroxy components appear only as the single, broad 2.9 $\mu$ absorption band. Their individual peaks, occurring at closely neighboring wave lengths, are not resolved even by a high dispersion calcium fluoride prism.

Because the spectroscopic approach alone has failed to delineate the relative concentrations of the various hydroxy compounds, we have devised a combined chemical–spectroscopic method. Of the three types of hydroxy compounds mentioned, two can be estimated with considerable accuracy by chemical means. Hydroperoxides can be determined iodometrically and carboxylic acids by acid–base titration. In contrast, alcoholic hydroxyl analyses, such as the acetyl or Zerewitinoff procedures, do not yield reliable, unequivocal data in the presence of hydroperoxides. Furthermore, drying oils in the process of oxidation contain unstable substances, so that milder analytical techniques are desirable.

By means of the chemical–spectroscopic method, the so-called ROH fraction can be calculated by subtracting the sum of the hydroperoxide and carboxylic acid contributions, measured chemically, from the total hydroxyl content, measured optically. To perform this subtraction, the specific absorption coefficients of the (–OOH) and (–COOH) groups must be known, to permit conversion of their chemical concentrations to "optical concentrations."

From measurements of the optical densities of representative hydroxy compounds at several concentrations, it has been demonstrated that these compounds, in the range of concentrations encountered in an autoxidizing drying oil, obey Beer's law: $-\log T$ = optical density = $kcl$, where $k$ is specific absorption coefficient, a proportionality constant; $c$ is concentration of absorbing group, in g./l.; and $l$ is thickness of absorbing medium, in cm. From the data plotted in Fig. 3, these absorption coefficients have been calculated and expressed in appropriate units.

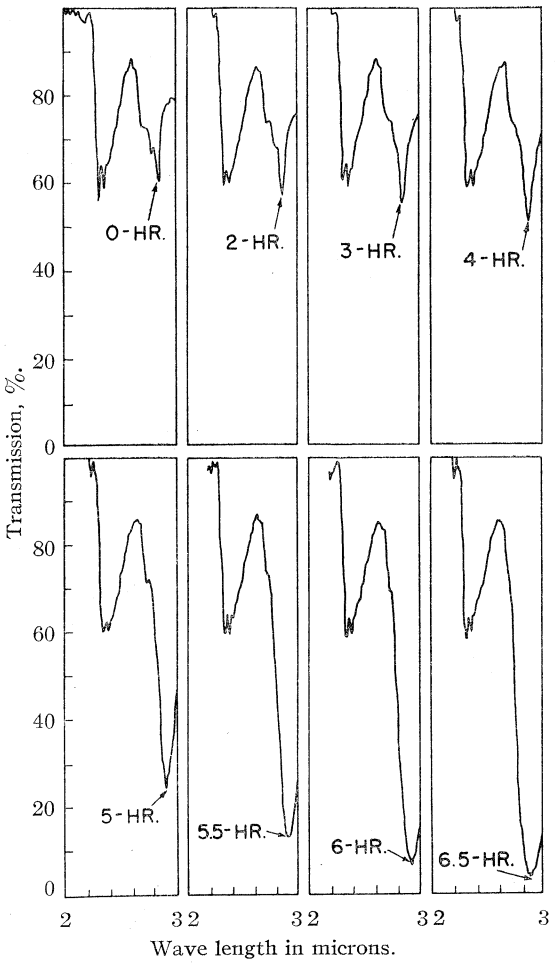

Fig. 2.—Changes in 2.9$\mu$ hydroxyl band during linseed oil autoxidation.

## Experimental

**Apparatus.**—All spectroscopic measurements for which data are presented were made on a Baird infrared recording spectrophotometer, equipped with a rock salt prism. Experiments involving the use of a calcium fluoride prism, however, were conducted with a Perkin–Elmer spectrometer. A quartz cell, of fixed 0.187 mm. thickness, proved convenient for autoxidized oils as well as solutions of representative hydroxy compounds. Because only the hydroxyl band at 2.9 $\mu$ was of immediate concern, the quartz cut-off near 4.0 $\mu$ did not interfere.

**Hydroxy Compounds.**—Ethyl myristate (Eastman Kodak Co., m.p. 10–12°) was employed as a stable, inert ester solvent for the various hydroxy compounds. Methyl

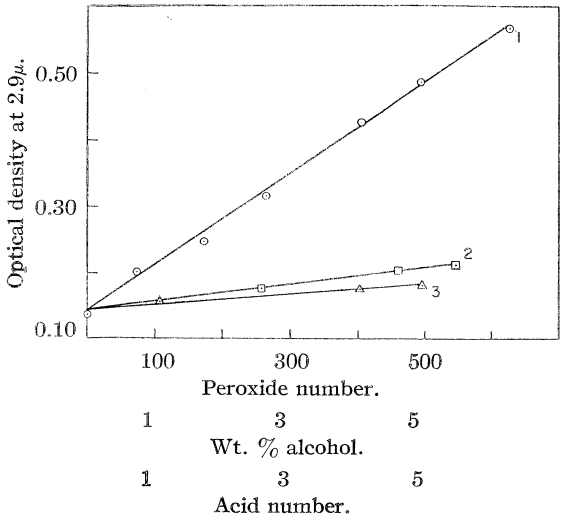

Fig. 3.—Optical densities of solutions of hydroxy compounds in ethyl myristate as a function of their concentrations: 1, methyl hydroperoxide oleate; 2, *n*-octadecanol; 3, palmitic acid.

hydroperoxide oleate was prepared[12] by ultraviolet irradiation and autoxidation of pure methyl oleate, and isolated by low-temperature crystallization. Its Wheeler peroxide number of 4200 indicated a purity of about 69%. The balance of the material was substantially unreacted methyl oleate. Palmitic acid (m.p., 61–62°) was highly purified by recrystallization from acetone. The alcohol employed was *n*-octadecanol, an Eastman Kodak Co. product of m.p. 56.5–58°.

**Procedure of Absorption Coefficient Measurement.**—Solutions of each of the hydroxy compounds were made to several known concentrations. The optical density of each solution was then determined at 2.9 μ (Table I); for each compound, optical density was plotted as a function of a concentration. The resulting linear relationships are shown in Fig. 3. Absorption coefficients were calculated from the slopes of these straight lines. By preparing several mixtures, calculating their total hydroxyl contents from the appropriate coefficients and comparing the values so obtained with observed optical densities (Table II), infrared absorption of the three compounds at 2.9 μ was shown to be an additive function of their concentrations. In every case, the deviation lay close to or within the ± 1% transmission error normally expected of the Baird instrument.

**Linseed Oil Oxidation.**—Raw linseed oil, in 1500-ml. quantities, was oxidized in a glass and stainless steel apparatus at 85° by passing dry air through the oil at the rate of 4000 ml./min. and vigorously agitating the oil with a beater rotating at 1725 r.p.m.

## Results and Discussion

The absorption coefficients determined for three representative hydroxy compounds are: (1) Palmitic acid, $k$ = 0.375/acid no.-cm.; (2) methyl hydroperoxido oleate, $k$ = 0.0364/peroxide no.-cm.; (3) *n*-octadecanol, $k$ = 0.675/wt. per cent.-cm.

In Fig. 4, a typical linseed oil autoxidation has been analyzed by means of the chemical–spectroscopic method. The total hydroxyl content has been divided into its three major components: R–OOH, R–COOH, R–OH. The concentration of each component, expressed in optical density, has been plotted as a function of oxidation time. The data from which the curves are drawn are assembled in Table III.

Curve 1 represents the change in total hydroxyl content, measured by infrared absorption at 2.9 μ. Curve 4 depicts the change in hydroperoxide concentration, determined chemically by the Wheeler method and converted to optical units by means of the absorption coefficient. Carboxylic acid optical concentrations, obtained similarly and then added to the hydroperoxide concentrations, yield curve 3. If curve 3 is subtracted point by point from curve 1, the resultant curve 2 indicates the change in the R–OH component.

Initially the R–OH fraction in a raw drying oil is a complex mixture of alcoholic hydroxy compounds, phospholipids, mucilages and water. As autoxidation proceeds, however, the increase in the R–OH component depicted in Fig. 4 can be ascribed only to an increase in the concentration of alcoholic hydroxy compounds. Although water is liberated in the process, its contribution to the 2.9 μ absorption band seems to be negligible. During the first stages of oxidation, linseed oil is

TABLE III

[a] Values for peroxide optical density include the constant cell absorption of 0.02. [b] Net ROH = (total OH) − (peroxide O.D. + acid O.D.)

not sufficiently hydrophilic to dissolve an appreciable quantity of water. In one instance saturation of an unoxidized linseed oil with water raised the water content from 0.14 to 0.33% and the optical density at 2.9 $\mu$ from 0.276 to 0.284—a difference within the limits of error of the spectrophotometer. Saturation of an oxidized linseed oil, on the other hand, lifted the water content form 0.37 to 0.95%. But in this case the optical density at 2.9 $\mu$ was already so great that no increment could be detected.

During the induction period in a typical linseed oil autoxidation (zero to six hours in Fig. 4), no carboxylic acids are formed. Curves 3 and 4, therefore, are parallel. Since these curves rise at the same rate as the total hydroxyl content, the R–OH component remains substantially constant. It appears, on the basis of this evidence, that those peroxides formed during the induction period are essentially all hydroperoxides.

Later in the oxidation process, however, there is not as much assurance that all peroxides formed are of R–OOH type, because the Wheeler iodometric procedure, from which the R–OOH is derived, measures the sum total of all oxidizing compounds in the oil. The hydroperoxide values should then be regarded as maximum values.

During the "transition" period (six to eight hours in Fig. 4), the R–COOH contribution begins to increase, while the R–OOH component rises rapidly to a maximum. At the same time the total hydroxyl content rises even more rapidly, causing a sharp increase in the R–OH fraction. The transition period, then, is a time of rapid peroxide formation and decomposition.

As the drying oil begins to polymerize (over eight hours in Fig. 4), the rate of peroxide decomposition exceeds that of formation, while carboxylic acids continue to form. Curves 3 and 4, therefore, diverge, while the R–OH component rises even more sharply.

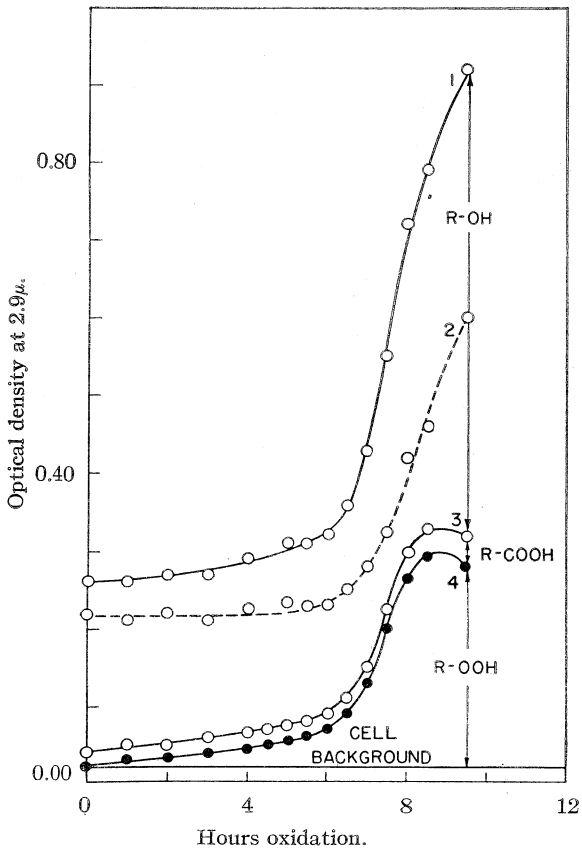

Fig. 4.—Analysis of a typical linseed autoxidation process: 1, total hydroxyl content; 2, net R–OH component; 3, sum of hydroperoxide and acid contributions; and 4, hydroperoxide contribution.

Infrared absorption measurements of autoxidizing drying oils at 2.9 $\mu$ serve as a rapid means of determining the end of the induction period, since the total hydroxyl content rises sharply at that point. In conjunction with chemical analyses, infrared techniques offer further confirmation of the role of hydroperoxides in autoxidation. It should now be possible to make use of the absorption coefficient reported for the alcoholic hydroxyl group and so determine the reaction products of peroxide decomposition.

**Acknowledgment.**—We wish to thank Messrs. J. H. Lieblich and R. B. Hannan of the Department of Research in Chemical Physics of Mellon Institute for their aid in making spectroscopic measurements.

## Summary

1. A combined chemical–spectroscopic analytical method has been devised to permit a detailed breakdown of the autoxidation reaction.

2. Infrared absorption coefficients have been

determined for three representative hydroxy compounds.

3. The role of hydroperoxides and their decomposition products in autoxidation has been further investigated.

# Pyrolysis and Chlorinolysis of Some Perchlorinated Unsaturated Hydrocarbons[1]

BY J. A. KRYNITSKY AND H. W. CARHART

In earlier work,[2] it was shown that the pyrolysis of octachlorocyclopentene yields hexachlorocyclopentadiene, chlorine and small amounts of hexachlorobenzene. It has been reported[3] that both hexachloroethane and octachloropropane give carbon tetrachloride and tetrachloroethylene on thermal decomposition. Carbon tetrachloride and tetrachloroethylene have been reported[4] as being highly stable.

Prins[6,7] has shown that one mole of chlorine adds rapidly and quantitatively in sunlight to tetrachloroethylene, hexachloropropene and hexachlorocyclopentadiene without causing rupture of the carbon chain. On the other hand, hexachloroethane,[3] hexachloro-1,3-butadiene,[5] octachloro-1,3-pentadiene,[7,8] and octachlorocyclopentene,[2,8,9,10] have been reported either to resist the action of chlorine or, under drastic conditions, to be cleaved by it.

In the present work, tetrachloroethylene, hexachloropropene, hexachloro-1,3-butadiene and octachloro-1,3-pentadiene were subjected both to vapor phase pyrolysis and to the action of chlorine at temperatures up to 500°. In addition, hexachloropropene and octachloro-1,3-pentadiene were exposed to prolonged heating in the liquid state at their reflux temperatures and to chlorination under similar conditions. Small samples of two isomeric $C_6Cl_8$ compounds having melting points of 43–44° and 182–183° were also decomposed at 500°, and a sample of hexachloro-1,3-butadiene was treated with chlorine in bright sunlight for an extended period of time.

## Results and Discussion

**Pyrolyses.**—Both tetrachloroethylene and hexachloro-1,3-butadiene were found to be quite thermostable as no pyrolysis products were found on heating at 500°.

Hexachloropropene was recovered unchanged after a six-hour reflux (210–213° pot temperature). Vapor phase pyrolysis became appreciable at temperatures over 400° and yielded carbon tetrachloride, tetrachloroethylene and hexachloroethane as the major products. The amounts of these products obtained are summarized in Table I. In addition to these, a minor quantity of hexachlorobenzene was isolated from the 490–500° pyrolysis but not at the lower temperatures. A compound, $C_6Cl_8$ (m. p. 43–44°), was also obtained from the products of pyrolysis at 450–460° and 490–500°. It is believed that this compound is the same as the $C_6Cl_8$ (m. p. 45°) prepared by Prins[11] to which he assigns the structure 1-(trichloromethyl)-pentachloro-2,4-cyclopentadiene. In the pyrolysis of hexachloropropene, carbonization was insignificant and very little, if any, chlorine was evolved. In contrast to hexachloropropene, prolonged refluxing decomposed octachloro-1,3-pentadiene completely. The principal products of the reflux and vapor phase pyrolyses were carbon tetrachloride, hexachloro-1,3-butadiene and hexachlorocyclopentadiene. The amounts of these compounds and hexachlorobenzene found are given in Table II. Small amounts of hexachloroethane were obtained from the vapor phase but not from the reflux pyrolyses. Traces of tetrachloroethylene were found in all but the 400–410° pyrolyses. Two other compounds, octachlorocyclopentene and $C_6Cl_8$ (m. p. 182–183°) were isolated from the products of the reflux pyrolysis. The latter compound was shown to be identical with a $C_6Cl_8$ compound prepared by Prins[6] to which he assigns the probable structure 1-(dichloromethylene)-hexachloro-2-cyclo-

pentene.[11] In the pyrolyses of octachloro-1,3-pentadiene, small amounts of chlorine were evolved; however, carbonization was insignificant.

When small samples of the two $C_6Cl_8$ isomers (m. p. 43–44° and 182–183°) were heated at 500°, hexachlorobenzene and chlorine were found to be the major products. However, the pyrolysis of the 43–44° compound was not as complete as that of the 182–183° isomer.

**Chlorinolyses.**—Tetrachloroethylene was found to be stable toward chlorinolysis at temperatures up to 500° as no carbon tetrachloride was found. However, as shown in Table III, addition of chlorine did occur to a limited extent.

Hexachloro-1,3-butadiene was found to be inert to chlorination in the dark since no reaction products were found even at 500°. On the other hand, prolonged exposure to chlorine in bright sunlight at 10–20° cleaved this compound to hexachloroethane.

As may be seen in Table IV, the principal products of both the reflux and vapor phase chlorinolyses of hexachloropropene were found to be carbon tetrachloride and tetrachloroethylene. The vapor phase reaction became appreciable at temperatures above 300° and was complete at 400–410°. Small amounts of hexachloroethane were also found at the higher temperatures. In addition to the compounds mentioned, the reflux chlorinolysis produced a small amount of higher boiling material which was not identified.

Both reflux and vapor phase chlorinolyses of octachloro-1,3-pentadiene yielded carbon tetrachloride and hexachloro-1,3-butadiene as the major products. Lesser amounts of hexachlorocyclopentadiene and octachlorocyclopentene were also isolated from these reactions. The amounts of products obtained are summarized in Table V. In addition to these compounds, small quantities of tetrachloroethylene were found in all but the 350–360° reaction. Small amounts of hexachlorobenzene were also isolated from the reflux and 490–500° chlorinolyses.

In all reactions involving chlorine, carbonization was insignificant. The vapor phase chlorinolyses of both hexachloropropene and octachloro-1,3-pentadiene were observed to be exothermic. It is noteworthy that the chlorinolysis of these compounds is essentially complete at 400–410°. This is in contrast to their simple pyrolysis where decomposition is only slight at this temperature. There is insufficient evidence to substantiate complete mechanisms for these reactions; however, the results indicate that they probably proceed through free radical chain reactions involving several steps.

It was observed that hexachlorocyclopentadiene has a strong tendency to supercool. By using a Dry Ice-bath, however, two different crystalline forms may be obtained. One of these melts at 10–10.8° and the other at −0.8 to −0.2°. The lower melting form is converted to the higher melting form by sudden strong cooling (liquid air) or by seeding with a small crystal of the latter. In view of this and the fact that the higher melting form is the one more frequently obtained on freezing, it is indicated that it is the more stable form. Samples of both crystalline forms have remained unchanged when kept for several months at a temperature a few degrees below their melting points.

## Experimental

**Materials.**—Hexachloropropene (b.p. 140–142° at 100 mm.) and octachloro-1,3-pentadiene (b.p. 139–140° at 10 mm.) were prepared through condensation and dehydrohalogenation reactions from chloroform, tetrachloroethylene and trichloroethylene as described by Prins.[6,7,12] Hexachloro-1,3-butadiene (b.p. 142–144° at 100 mm.) was obtained from the pyrolysis and chlorinolysis products

(12) H. J. Prins, *ibid.*, **51**, 1065 (1932).

of octachloro-1,3-pentadiene. The two $C_6Cl_8$ compounds (m. p. 43–44° and 182–183°) were obtained from the pyrolysis products of hexachloropropene and octachloro-1,3-pentadiene.

**Vapor Phase Pyrolyses.**—In general, the vapor phase pyrolyses of tetrachloroethylene, hexachloropropene, hexachloro-1,3-butadiene and octachloro-1,3-pentadiene were carried out at 400, 450 and 500° by passing approximately 200 g. of compound through a 20-mm. Pyrex tube heated over a 30-cm. zone. The rate was adjusted so that the passage was between 70 and 120 g. per hour. This resulted in contact times which varied from twelve to fifteen seconds for the first three compounds and sixteen to twenty-four seconds for the last. All pyrolyses involving hexachloropropene and octachloro-1,3-pentadiene were carried out in the dark to prevent photocatalytic action of chlorine should it be formed. When evolution of chlorine was detected, it was removed from the warmed products by air aspiration in the dark using suitable traps for retaining volatile components. The pyrolysis of hexachloropropene at 500° will serve to illustrate the method used.

Two hundred grams of hexachloropropene was passed dropwise, in the dark, over a period of two hours through the tube set at a slight incline and electrically heated to 490–500°. The product which was collected in an ice-cooled receiver weighed 199 g., was red in color and contained some solid material. During the pyrolysis, tests of the exit vapors with potassium iodide paper showed that very little, if any, chlorine was evolved. Fractionation of the product through a 17 mm. × 60 cm. helix-packed column gave the following principal fractions: (1) 14 g. b.p. 77–78°, (2) 6 g. b.p. 78–120°, (3) 90 g. b.p. 120–122°, (4) 44 g. (solid) b.p. 123–130° (100 mm.), (5) 5 g. b.p. 130–150° (100 mm.), and (6) 17 g. b.p. 164–165° (20 mm.).

Fraction 1 was carbon tetrachloride and fraction 3 was tetrachloroethylene. Refractive index measurements showed fraction 2 to be composed of approximately 3 g. each of carbon tetrachloride and tetrachloroethylene. Fraction 4 was hexachloroethane which was collected as a solid in the still head. An additional 2 g. of hexachloroethane was obtained by cooling the intermediate fraction 5. Fraction 6 solidified on standing to a reddish-orange solid melting at 36–40°. Two recrystallizations from ethanol yielded 10 g. of a white compound melting at 43–44°, which was not changed by further treatment. Analyses showed this compound to be $C_6Cl_8$. *Anal.* Calcd. for $C_6Cl_8$: Cl, 79.74; mol. wt., 355.8. Found: Cl 79.7, 79.4; mol. wt., 354.

Ten grams of hexachlorobenzene was isolated from the fractionation residue by crystallization using carbon tetrachloride and ethanol.

**Reflux Pyrolysis.**—Octachloro-1,3-pentadiene (152 g.) was placed in a still pot fitted to a 17 mm. × 60 cm. helix-packed column connected to an ice-cooled receiver. The column jacket was maintained at 200–215° by an external heater. The material was heated for five hours in the dark at the end of which time reaction seemed to be complete. During this period, the pot temperature varied between 261 and 279° and a slight amount of chlorine was detected in the exit vapors. The free chlorine was removed from the warmed distillate (in the dark) by aspirating dry air through it until the effluent air gave a negative test for chlorine. A reflux condenser and efficient ice-cooled trap was used to prevent loss of volatile materials. The product obtained was combined with the residue in the still pot. Fractionation yielded the following principal fractions: (1) 22 g. b.p. 77–78°, (2) 1 g. b.p. 58–65° (100 mm.), (3) 58 g. b.p. 141–145° (100 mm.), (4) 8 g. b.p. 145–160° (100 mm.), (5) 7 g. b.p. 117–121° (20 mm.), (6) 12 g. b.p. 157–163° (20 mm.), and (7) 28 g. residue.

Fraction 1 was carbon tetrachloride. Fraction 2 was shown to be chiefly tetrachloroethylene by chlorination to hexachloroethane. On refractionation of fraction 3, the main bulk distilled at 143.0–143.1° (100 mm.). This was identified as hexachloro-1,3-butadiene through its physical constants which are in good agreement with those previously reported[5] and by analyses: b.p. 213° (775 mm.), 123° (50 mm.), 101° (20 mm.); m.p. −20 to −19°; $n^{20}D$ 1.5558, $n^{25}D$ 1.5535; $d^{20}_4$ 1.6804. *Anal.* Calcd. for $C_4Cl_6$; Cl, 81.58; mol. wt., 260.8; *MR*, 48.94.[13] Found: Cl, 81.3, 81.6; mol. wt., 262; *MR*, 49.87.

Fraction 5 was identified as hexachlorocyclopentadiene by comparison with a known sample. Purified hexachlorocyclopentadiene has the following properties in addition to those given previously:[2,7,14] b.p. 163.6–163.8° (100 mm.), m.p. 10–10.8° and −0.8 to −0.2°, $n^{20}D$ 1.5647.

Refractive index measurements of fraction 4 showed it to be composed of approximately 5 g. hexachloro-1,3-butadiene and 3 g. hexachlorocyclopentadiene. On crystallizing fraction 6 from ethanol and carbon tetrachloride, there was obtained 3 g. of a compound m. p. 182–183° and 7 g. of octachlorocyclopentene. The 182–183° compound was shown to be identical to the $C_6Cl_8$ compound obtained by the action of copper on hexachloropropene, by a mixed melting point and by hydrolysis to a diketone[6] which melted at 226–228° (sealed tube).

Fractional crystallization of the 28 g. of residue from ethanol–carbon tetrachloride yielded several grams each of the $C_6Cl_8$ compound and hexachlorobenzene.

**Pyrolyses of $C_6Cl_8$ Compounds at 500°.**—Four grams of the 43–44° isomer was melted over four to five minutes into the heated zone (8 mm. × 30 cm.) of a Pyrex tube set at a slight incline. During this time, the exit vapors gave a strong test for chlorine. The pyrolysis product was a solid which when worked up with ethanol–carbon tetrachloride yielded approximately 1 g. of hexachlorobenzene. In addition, approximately 1.5 g. of $C_6Cl_8$ was recovered.

In a like fashion, 4 g. of the 182–183° isomer evolved chlorine and yielded approximately 2 g. of hexachlorobenzene and a very small amount of liquid which was not identified. None of the original $C_6Cl_8$ could be recovered.

**Photochlorinolysis of Hexachloro-1,3-butadiene.**—A 12.7-g. sample of hexachloro-1,3-butadiene was placed in a Pyrex test-tube fitted with a gas bubbler tube. The system was exposed to direct sunlight and chlorine was admitted in a slow stream. During this time, the ambient temperature varied from 10 to 20°. The reaction was stopped after a total of sixteen hours as the material had become semisolid. After removal of the unreacted chlorine by air aspiration through the warmed mixture, the sample showed a gain in weight of 6.3 g. The solid reaction product was identified as hexachloroethane.

**Vapor Phase Chlorinolyses.**—In general the vapor phase chlorinolyses of tetrachloroethylene, hexachloropropene, hexachloro-1,3-butadiene and octachloro-1,3-pentadiene were carried out in the dark at various temperatures up to 500° by passing approximately 200 g. of compound through a 20-mm. Pyrex tube heated over a 30 cm. zone. An ice-cooled receiver was used for collection of the products. Chlorine gas was admitted at a rate such that a bubbler at the end of the system indicated that an excess was always present. The rate of compound addition was between 70 and 120 g. per hour. Unreacted chlorine was removed from the warmed products (in the dark) by air aspiration using suitable traps to retain volatile components. The methods used for separation and identification of the products were the same as those given earlier.

**Reflux Chlorinolyses.**—The reflux chlorinolyses of hexachloropropene and octachloro-1,3-pentadiene were carried out in a manner similar to the reflux pyrolysis of the latter compound except that an excess of chlorine was maintained in the system by bubbling the gas into the liquid. The products were analyzed by methods already described.

## Summary

1. Tetrachloroethylene and hexachloro-1,3-

(13) Does not include value for exaltation due to conjugation.

(14) The melting point in ref. 2 was listed erroneously as −10 to −9° rather than 9–10°.

butadiene were found to be stable at a temperature of 500°.

2. The pyrolysis of hexachloropropene yielded principally carbon tetrachloride, tetrachloroethylene, and hexachloroethane. Smaller amounts of hexachlorobenzene and a compound $C_6Cl_8$ (m. p. 43–44°) were obtained under some conditions.

3. The pyrolysis of octachloro-1,3-pentadiene yielded principally carbon tetrachloride, hexachloro-1,3-butadiene and hexachlorocyclopentadiene. Smaller amounts of tetrachloroethylene, hexachloroethane, octachlorocyclopentene, hexachlorobenzene and a compound $C_6Cl_8$ (m. p. 182–183°) were obtained under some conditions.

4. The pyrolysis of two $C_6Cl_8$ compounds (m. p. 43–44° and 182–183°) yielded chiefly hexachlorobenzene and chlorine.

5. Hexachloro-1,3-butadiene yielded hexachloroethane slowly on chlorinolysis in sunlight at 10–20°. In the dark, it was found to resist the action of chlorine at a temperature of 500°.

6. Tetrachloroethylene was found to be stable to thermal chlorinolysis at temperatures up to 500°; however, small amounts of hexachloroethane were produced by addition of the halogen.

7. Thermal chlorinolysis of hexachloropropene yielded principally carbon tetrachloride and tetrachloroethylene and smaller amounts of hexachloroethane.

8. Thermal chlorinolysis of octachloro-1,3-pentadiene yielded carbon tetrachloride and hexachloro-1,3-butadiene as the principal products and lesser amounts of hexachlorocyclopentadiene and octachlorocyclopentene. Small amounts of tetrachloroethylene and hexachlorobenzene were also obtained under some conditions.

# Hydrocarbons. IX.[1] 2,2,4-Trimethylheptane, 2,2,4-Trimethyloctane, 2,2,4,6-Tetramethylheptane and 2,2,4,5,5-Pentamethylhexane

BY GEORGE W. MOERSCH[2] AND FRANK C. WHITMORE[3]

In a continuation of previous work the present paper reports the syntheses of a decane and three undecanes containing the neopentyl system, and the determination of several of their physical constants.

With some exceptions, the hydrocarbons were prepared by catalytic hydrogenation of the olefins resulting from dehydration of the tertiary alcohols, 2,2,4-trimethyl-4-heptanol, 2,2,4-trimethyl-4-octanol, 2,2,4,6-tetramethyl-4-heptanol, and 2,2,3,-5,5-pentamethyl-3-hexanol. In the case of 2,2,-3,5,5-pentamethylhexane, the alcohol was prepared by two different methods and the olefins were also obtained by a Kolbe electrolysis of Butlerow's beta acid, methyl-*t*-butylneopentylacetic acid.

The reactions involved in these syntheses are not of the type usually accompanied by rearrangement[4] except for the dehydration of 2,2,3,5,5-pentamethyl-3-heptanol.[5] Structures similar to the latter,

always rearrange to a small degree, about 5% under the conditions employed here,[4] and it is therefore reasonable to assume that the 2,2,3,5,5-pentamethylheptane contains some 2,3,3,5,5-pentamethylheptane. This contamination from a closely related isomer could not be expected to affect appreciably the physical properties of the compound. This was substantiated when the electrolysis of Butlerow's beta acid gave material that checked the product made by dehydration of the alcohol.

The decane, 2,2,4-trimethylheptane, is mentioned in the literature[6] in connection with the investigation of impurities in isoöctane. From still residues there was isolated a material of b. p. 151.97° at 760 mm., $d^{20}$ 0.7349, $n^{20}_D$ 1.41278. It was suggested that this compound was either 2,2,4- or 2,2,5-trimethylheptane. The physical properties of the 2,2,4-trimethylheptane reported in this paper are not in agreement with the values found for the above material.

## Experimental

Distillations were made through columns of the adiabatic, total reflux, variable take-off type, packed with (A) one-eighth inch glass helices, packed section 1.7 × 67 cm., 11 theoretical plates, (B) three thirty-second inch stainless steel helices, 1.0 × 100 cm., 25 theoretical plates, and (C) one-sixteenth inch stainless steel helices, 1.0 × 100 cm., 65 theoretical plates.

**2,2,4-Trimethylheptane.**—A typical preparation of methyl neopentyl ketone is given.[7] Sodium dichromate

dihydrate, 59 kg., diisobutylene (Rohm & Haas), 207 kg. and 80 liters of water were charged to a 50-gallon glass-lined Pfaudler kettle. Sulfuric acid, 45 liters, was added over a period of thirty-six hours while cold water was passed through the jacket of the reactor, keeping the temperature at 30–40°. Stirring was continued for an additional two hours and then the oxidation product steam-distilled from the kettle, giving 13.4 kg. of organic material. The oil layer was treated with 1.82 kg. of sodium hydroxide, the neutral products siphoned off, 10.22 kg., and the organic acids regenerated with sulfuric acid, yield 2.85 kg. The neutral products were fractionated to give 8.03 kg. (38%) of methyl neopentyl ketone, b. p. 126°, $n^{20}D$ 1.4030–1.4036.

Five moles, 120 g., of magnesium turnings was weighed into a three-liter flask and four moles, 492 g., of *n*-propyl bromide added in four portions of 500 ml. of anhydrous ether each. Addition was completed in five and a half hours, yield 98%. Two moles, 228 g., of methyl neopentyl ketone was added with stirring during one and a half hours, the mixture refluxed for three hours and then decomposed by pouring into 2 l. of cracked ice. A fine suspension resulted which was coagulated by distilling of about 1.5 l. of ether. The entire mass of precipitated salts was washed by decantation with four portions of ether totalling 2.5 l. The ether solution was concentrated by distillation through a modified Vigreux column. The residue was dried over potassium carbonate and distilled from 10 g. of potassium carbonate through Column A, giving a 58% yield of 2,2,4-trimethyl-4-heptanol, b. p. 119.8° at 100 mm., 59.6° at 7 mm., $d^{20}$ 0.833, $n^{20}D$ 1.4373.

The carbinol, 585 g., was dropped onto a mixture of 25 g. of anhydrous copper sulfate and 10 g. of powdered pumice heated to 200° at 200 mm. After separating the water layer, 35 ml., the olefin product was dried over potassium carbonate and distilled. About half was found to be unchanged carbinol and was dehydrated in Column A by distilling with 25 g. of copper sulfate and 10 g. of pumice at atmospheric pressure. The water layer was 18 ml. The olefin mixture was dried over potassium carbonate and distilled to give 454 g., 88% yield, b. p. 149–150° at 741 mm., $n^{20}D$ 1.4255–1.4277.

The olefin mixture, 202 g., was hydrogenated over 20 g. of UOP nickel on kieselguhr at 110–130° at 1200 p. s. i. The product was filtered and fractionated through Column C and constant index material rehydrogenated and then fractionated again through Column C, giving only constant boiling, constant index material.

**2,2,4-Trimethyloctane.**—Methyl neopentyl ketone was added to *n*-butylmagnesium bromide in the usual way and the product distilled under reduced pressure to give 57% yield of 2,2,4-trimethyl-4-octanol,[8] b. p. 137.1° at 100 mm., 79.8° at 8 mm., $n^{20}D$ 1.4405, $d^{20}$ 0.835.

The alcohol was dehydrated with copper sulfate and pumice as previously described to give an 84% yield of olefin mixture. Ozonolysis of the product showed no rearrangement of the carbon skeleton.[9]

The olefins were hydrogenated in glacial acetic acid using platinum oxide at 3 atm. and room temperature.

The saturated hydrocarbon was also obtained by hydrogenation of the alcohol over Raney nickel at 200° and 150 atm.

**2,2,4,6-Tetramethylheptane.**—Methyl neopentyl ketone was added to isobutylmagnesium bromide in the usual way. The product was distilled at reduced pressure to give a 29% yield of 2,2,4,6-tetramethyl-4-heptanol, b. p. 126.8° at 100 mm., 64.0° at 7 mm., $d^{20}$ 0.828, $n^{20}D$ 1.4368.

The alcohol was dehydrated by dropping onto copper sulfate and pumice at 200° giving a 77% yield of olefins, b. p. 159–161°, $n^{20}D$ 1.4260–61. The mixture was ozonized in olefin-free, low-boiling (0–30°) hydrocarbon solvent and the ozonide decomposed with zinc dust and water in the presence of traces of hydroquinone and silver nitrate. The products obtained were: formaldehyde (dimetol deriv. m. p. 189–190°), isobutyraldehyde (dimetol deriv. m. p. 147–148°, 2,4-dinitrophenylhydrazone m. p. 182–183°), methyl neopentyl ketone (semicarbazide m. p. 173–173.5°), and isobutyl neopenyl ketone. Isobutyl neopentyl ketone failed to yield a carbonyl derivative but when reduced with sodium in moist benzene gave isobutylneopentylcarbinol (α-naphthylurethan m. p. 99–100°). Mixed melting points were made in all cases. These products show no rearrangement of the carbon skeleton, the olefins being 2,2-dimethyl-4-isobutyl-4-pentene and 2,2,4,6-tetramethyl-4-heptene.

The olefin mixture was hydrogenated over a nickel–kieselguhr catalyst at 120–135° and 1700 p. s. i.

**2,2,4,5,5-Pentamethylhexane.**—(A) *t*-Butylacetic acid was prepared in 77% yield by the bromoform reaction with methyl neopentyl ketone.[10] The acid was converted to the chloride in 91% yield with thionyl chloride. The *t*-butylacetyl chloride was treated with *t*-butylmagnesium chloride in equi-molar quantity and the complex then treated with an equal amount of methylmagnesium chloride. The reaction mixture was decomposed and the 2,2,4,5,5-pentamethyl-4-hexanol distilled under reduced pressure, 13% yield, b. p. 124.1° at 100 mm., 60.2° at 7 mm., $d^{20}$ 0.841, $n^{20}D$ 1.4412, m. p. 11.4°. (B) The same alcohol was also prepared by adding methyl neopentyl ketone to *t*-butylmagnesium chloride in the usual way, yield 7.5%.

The alcohol was dehydrated with copper sulfate and pumice at 180° in 98% yield, and the products fractionated through Column C, b. p. 152–162°, $n^{20}D$ 1.4309–1.4333. The olefins were ozonized and the products identified as: formaldehyde (dimetol deriv. m. p. 189–90°), trimethylacetaldehyde (2,4-dinitrophenylhydrazone, m. p. 206–207°), pinacolone (2,4-dinitrophenylhydrazone m. p. 122–124°, semicarbazone m. p. 156–156.5°), and *t*-butyl neopentyl ketone which was identified by reduction with sodium in moist benzene to the corresponding alcohol (phenylurethan m. p. 124–126°). These products indicate the olefins as 4,4-dimethyl-2-*t*-butyl-1-pentene and 2,2,4,5,5-pentamethyl-3-hexene. Hydrogenation of the olefins gave material of b. p. 165°, $n^{20}D$ 1.4216.

Although no rearranged product was identified, it is quite certain that a small amount, about 5%, of 2,3,3,5,5-pentamethyl-1-hexene was formed during the dehydration.

A mixture of these same olefins was obtained by dissolving one mole of Butlerow's beta acid, methyl-*t*-butylneopentylacetic acid,[11] m. p. 125.5–127.5°, in 1.2 moles of potassium hydroxide in 500 ml. of water and electrolyzing between smooth platinum electrodes at 8.2 to 8.5 amp. for eight hours. The oil layer (50% yield) was separated

and distilled into two portions, (I) b. p. 156–161, $n^{20}D$ 1.4247–1.4320; (II) b. p. 162–165, $n^{20}D$ 1.4325–1.4380.

Refractionation of the lower boiling fractions (I) through Column A gave material boiling at 152–162°, $n^{20}D$ 1.4297–1.4336. Ozonolysis of this material gave formaldehyde, trimethylacetaldehyde and pinacolone, identified as their 2,4-dinitrophenylhydrazones.[12] Hydrogenation of these lower boiling fractions gave material boiling mainly at 165°, $n^{20}D$ 1.4216.

Refractionation of the higher boiling portion (II) through Column B gave material of b. p. 162–166°, $n^{20}D$ 1.4314–1.4396. This when hydrogenated gave material boiling mainly at 171°, $n^{20}D$ 1.4278–90, having a mol. wt. of 166 (dodecane = 168) and which was insoluble in cold concd. sulfuric acid.

**Physical Properties.**—The constants determined for the hydrocarbons are given the accompanying table. The boiling points were measured in a Cottrell-type apparatus using a thermometer with 0.2° divisions checked against a Bureau of Standards calibrated Anschutz thermometer. Refractive indices were read on a Valentine No. 454 refractometer. Densities were measured in pycnometers; and viscosities, with the Ostwald-type viscometer recommended by Cannon and Fenske[13] for use with non-viscous liquids.

The physical properties were determined by N. C. Cook and Andrew Carson; some of the hydrogenations were performed by R. E. Meyer and N. C. Cook.

(12) Identification by H. H. Johnson, Ph.D. Thesis, Penn State, 1940.

## Summary

Four highly branched hydrocarbons, 2,2,4-trimethylheptane, 2,2,4-trimethyloctane, 2,2,4,6-tetramethylheptane, and 2,2,4,5,5-pentamethylhexane have been synthesized and a number of their physical properties determined.

# Substituted 1,10-Phenanthrolines. II. Di- and Tri-methyl Phenanthrolines Related to 5-Methyl-1,10-phenanthroline[1]

BY FRANCIS H. CASE

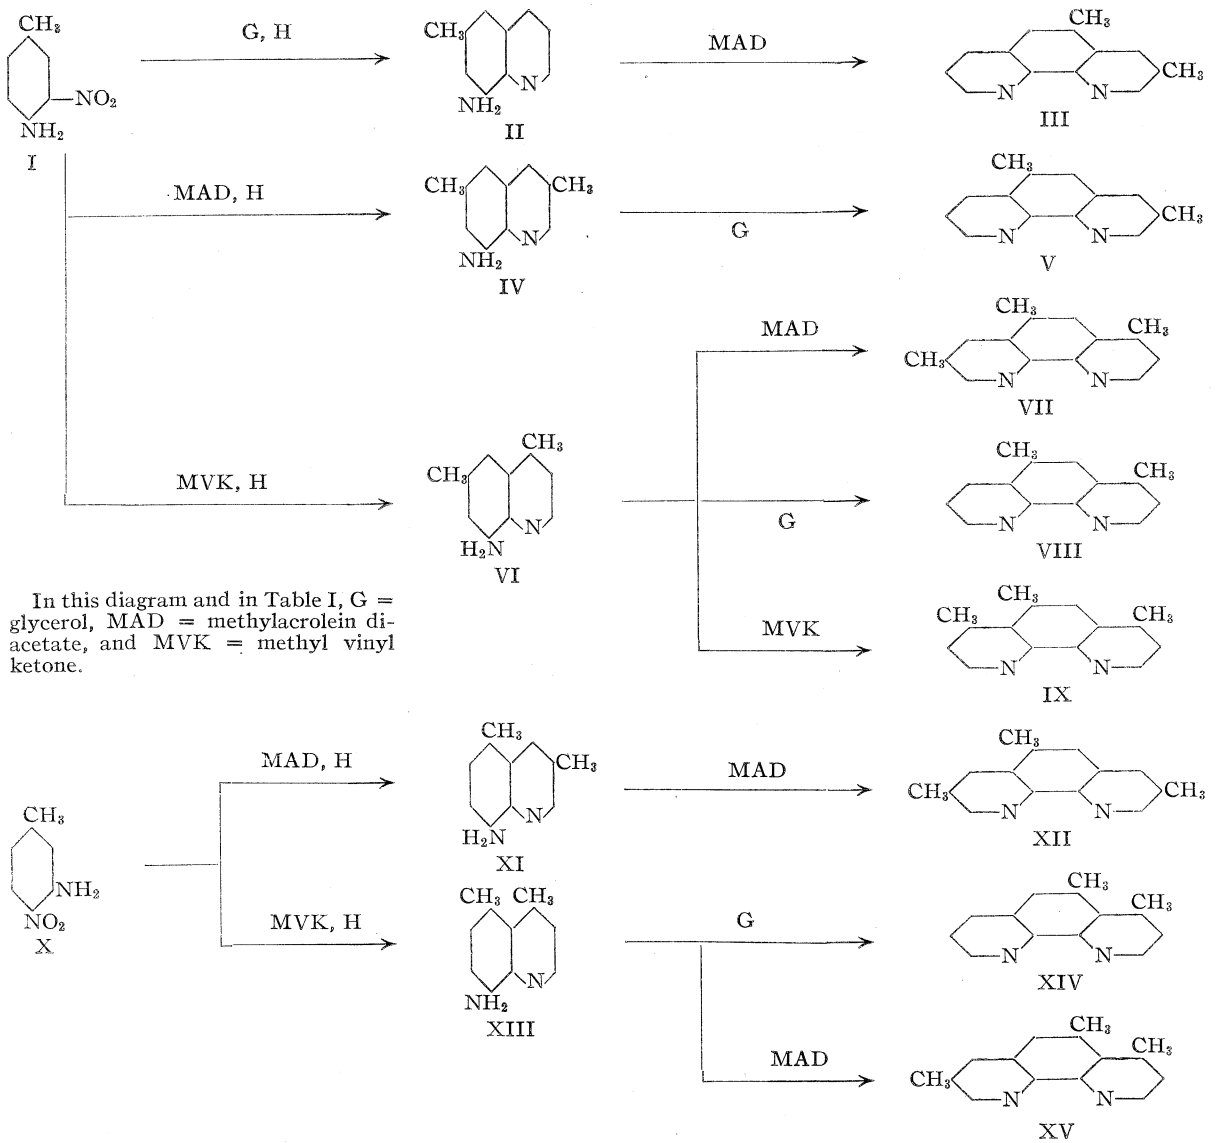
Continuing the work described in the first article of this series[2] with the object of preparing a series of substituted phenanthrolines which in the form of their ferrous complexes would be suitable for use as oxidation–reduction indicators, all possible di- and tri-methyl-1,10-phenanthrolines were synthesized in which one methyl group is in the 5- or 6- position and each of the others in a different ring, but none adjacent to nitrogen. The quinolines and phenanthrolines described here were synthesized from a substituted aniline or aminoquinoline by a Skraup reaction using arsenic acid as oxidizing agent and either glycerol, α-methylacrolein diacetate (2-methyl-2-propene-1,1-diol diacetate) or methyl vinyl ketone as the second component. In the case of 3,5-dimethyl-8-nitroquinoline this method proved much more satisfactory than that previously described,[3] while with 4,5-dimethyl-8-nitroquinoline no improvement in yield was noted.

Under these conditions 3,5-dimethyl-1,10-phenanthroline (III) was obtained from 6-methyl-8-aminoquinoline[4] (II) and α-methylacrolein diacetate.

The action of α-methylacrolein diacetate and 3-nitro-4-aminotoluene (I) yielded, in a two-step reaction, 3,6-dimethyl-8-aminoquinoline (IV) which with glycerol was converted to 3,6-dimethyl-1,10-phenanthroline (V).

I, with methyl vinyl ketone under Skraup conditions yielded in a two-step reaction 4,6-dimethyl-8-aminoquinoline (VI) from which the following compounds were made: 3,5,7-trimethyl-1,10-phenanthroline (VII) (with α-methylacrolein diacetate); 4,6-dimethyl-1,10-phenanthroline (VIII) (with glycerol); 4,5,7-trimethyl-1,10-phenanthroline (IX) (with methyl vinyl ketone). From 3,5-dimethyl-8-aminoquinoline (XI) and α-methylacrolein diacetate, 3,5,8-trimethyl-1,10-phenanthroline (XII) was obtained. This also resulted in very small yield if 3,6-dimethyl-8-aminoquinoline (IV) were used as the base. From 4,5-dimethyl-8-aminoquinoline (XIII) and glycerol, 4,5-dimethyl-1,10-phenanthroline (XIV) resulted, while if α-methylacrolein diacetate were used as the second component, 3,6,7-trimethyl-1,10-phenanthroline (XV) was formed.

It should be noted that in the synthesis of each substituted phenanthroline two possible methods were available. For example, 4,5-dimethyl-1,10-phenanthroline might theoretically be prepared by the action of 4,5-dimethyl-8-aminoquinoline with glycerol or of 6-methyl-8-aminoquinoline with methyl vinyl ketone. Both methods were tried, but in the latter case, no yield was obtained. The choice of methods was conditioned by the availability of the starting aminoquinoline as well as by the fact that the yield is highest when glycerol is used as the second component, less with α-methylacrolein diacetate and least with methyl vinyl ketone. When both possible methods were attempted this fact is indicated by a footnote in Table I.



All the phenanthrolines described in this paper give a positive ferroin reaction.

In this diagram and in Table I, G = glycerol, MAD = methylacrolein diacetate, and MVK = methyl vinyl ketone.

## Experimental

**Methyl Vinyl Ketone.**—The cooled azeotrope obtained from du Pont containing 15% water, was shaken with anhydrous potassium carbonate, dried over calcium chloride and distilled *in vacuo*. The resulting liquid nearly all boiled at 34–40° (150 mm.).

**4,6-Dimethyl-8-nitroquinoline.**—A mixture of 25.3 g. of 2-nitro-4-methylaniline, 36 ml. of concentrated sulfuric acid, 12 ml. of water and 25.0 g. of arsenic oxide was warmed to 100°. Methyl vinyl ketone (17 g.) was then added at such a rate that the temperature did not exceed 140°. The mixture was maintained at this temperature for two hours with stirring, then poured on ice, and made alkaline with sodium hydroxide. The resulting precipitate was removed by filtration, dried, and extracted with hot benzene. Removal of the benzene and crystallization from the same solvent yielded 12 g. of pure product, m.p. 147–148°; yield, 35.6%.

*Anal.* Calcd. for $C_{11}H_{10}N_2O_2$: C, 65.33; H, 4.98. Found: C, 65.24; H, 4.76.

**4,6-Dimethyl-8-aminoquinoline.**—This compound was obtained by reduction of the nitro compound (67 g.) with 229 g. of $SnCl_2 \cdot 2H_2O$ in 1200 ml. of boiling ethanol; yield, 51 g., b.p. 195–205° (9 mm.). The pure substance, on crystallization from petroleum ether, melts at 85–86°.

*Anal.* Calcd. for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02. Found: C, 77.18; H, 6.99.

**3,6-Dimethyl-8-nitroquinoline.**—The preparation of this compound was identical with that of 4,6-dimethyl-8-nitroquinoline, the same amounts of materials being used except that 50 g. of $\alpha$-methylacrolein diacetate was substituted for methyl vinyl ketone. The yield of product, melting at 163–164° after crystallization from benzene was 11.5 g. or 34.2%.

*Anal.* Calcd. for $C_{11}H_{10}N_2O_2$: C, 65.33; H, 4.98. Found: C, 65.75; H, 4.97.

**3,6-Dimethyl-8-aminoquinoline.**—Reduction of 57 g. of the corresponding nitro compound by 193 g. of $SnCl_2 \cdot 2H_2O$ in 1100 ml. of boiling ethanol yielded 32 g. of 3,6-dimethyl-8-aminoquinoline, b.p. 202–220° (5 mm.). The pure product melts at 107–108° after crystallization from benzene–petroleum ether.

*Anal.* Calcd. for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02. Found: C, 76.95; H, 7.47.

TABLE I

| 1,10-Phenanthroline | 1st component, quinoline | 2nd component | M. p., °C. | Yield, % | Analyses,[d] % Calcd. C | Calcd. H | Found C | Found H |

| 4,5,7-Trimethyl | 4,6-Dimethyl-8-amino- | MVK | 184–185 | 1.3 | 81.05 | 6.35 | 80.84 | 6.37 |

[a] These samples are hygroscopic. [b] Crystallized from benzene–petroleum ether. [c] Alternate method tried, but yield of phenanthroline negligible. [d] Analyses were done by the Clark Microanalytical Laboratory, Urbana, Illinois.

**3,5-Dimethyl-8-nitroquinoline.**[3]—The preparation of this compound was similar to that of 3,6-dimethyl-8-nitroquinoline except that 2-nitro-5-methylaniline was used as the first component; yield, 9.5 g. or 28.0%, m.p. 189–190° (from 25.5 g. of 2-nitro-5-methylaniline).

**4,5-Dimethyl-8-nitroquinoline.**[3]—This compound was prepared exactly as in the case of 4,6-dimethyl-8-nitroquinoline except that 2-nitro-5-methylaniline was used as the first component; yield, 3 g. or 8.9%, m.p. 139–140° (from 25.3 g. of 2-nitro-5-methylaniline).

**General Procedure for the Synthesis of Di- and Trimethyl-1,10-Phenanthrolines.**—A mixture of one molar proportion of the appropriate methyl- or dimethyl-8-aminoquinoline, 0.65 mole of arsenic oxide, 4 moles of sulfuric acid in 96.8% solution and a volume of water equal to one third of the volume of sulfuric acid used was heated to 100° and treated with glycerol (3.6 moles), α-methylacrolein diacetate (1.8 moles), or methyl vinyl ketone (1.8 moles) at such a rate that the temperature did not exceed 140°. It was then heated with stirring for two more hours at this temperature. The mixture was then poured into water, made alkaline, and the tarry precipitate removed by filtration. The filtrate was extracted three times with hot benzene, which was then used to extract the phenanthroline from the solid material. After removal of the benzene the phenanthroline was crystallized from benzene. The results are shown in Table I.

## Summary

The following phenanthrolines have been synthesized: 3,5-, 4,5-, 3,6-, 4,6-dimethyl- and 3,5,7-, 3,5,8-, 3,6,7- and 4,5,7-trimethyl-1,10-phenanthrolines.

3,6- and 4,6-dimethyl-8-nitroquinolines and the corresponding amino derivatives have been prepared.

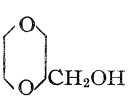
# Formation of a Seven-membered Cyclic Disulfide from 1,2-Dibromohydrin and a 1,2-Dithiol

BY REYNOLD C. FUSON AND A. JOHN SPEZIALE[1]



In connection with other studies, an attempt was made to prepare 2-hydroxymethyl-1,4-dithiane (I) and 6-hydroxy-1,4-dithiacycloheptane (II) by condensing ethanedithiol with 2,3-dibromo-1-propanol and 1,3-dibromo-2-propanol, respectively. It was found that the two reactions yielded the same product—the carbinol with the seven-membered ring (II).

It had been observed that, in the preparation of acyclic diethers from 1,2- or 1,3-dihalohydrins or from epihalohydrins, the 1,3-diethers are produced in preference to the 1,2-diethers.[2] In the formation of cyclic ethers, however, it was to be expected that a six-membered ring would be produced to the exclusion of a seven-membered ring as observed in the synthesis of 2-hydroxymethyl-1,4-benzodioxane (III) from pyrocatechol and the dihalohydrins,[3] and of 2-hydroxymethyl-1,4-dioxane (IV) from ethylene glycol and epichlorohy-

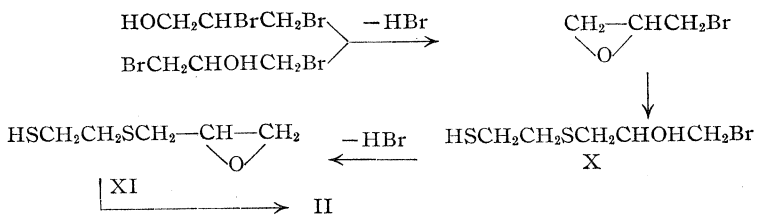
drin.[4] Our observation that a seven-membered ring (II) is produced with either 2,3-dibromo-1-propanol or 1,3-dibromo-2-propanol appears, accordingly, to be anomalous.

The low yield (average 30%) of the 6-hydroxy-1,4-dithiacycloheptane (II) may be attributed to the predominance of intermolecular condensation; large amounts of polymer were formed.



Proof of the structure of this carbinol is afforded by the following transformations.

Careful oxidation of 6-hydroxy-1,4-dithiacycloheptane tetroxide (VI) with potassium dichromate and sulfuric acid led to the keto sulfone (VII) from which a phenylhydrazone was prepared. Dehydration of the tetroxide (VI) with phosphorus oxychloride in pyridine produced the cycloheptene tetroxide (VIII) which gave the known[5,6,7] 1,4-dithiacycloheptane tetroxide (IX, m. p. 279–280° (dec.)) when hydrogenated catalytically with 10% palladium chloride on carbon.

If the initial condensation product had been 2-hydroxymethyl-1,4-dithiane (I), oxidation of its sulfone would have given the corresponding acid, and dehydration and hydrogenation of the sulfone would have produced 2-methyl-1,4-dithiane tetroxide. 2-Methyl-1,4-dithiane, prepared from ethanedithiol and propylene bromide, had a melting point which was in agreement with that reported.[5] The disulfone, not previously described, was obtained by treating 2-methyl-1,4-dithiane with 30% hydrogen peroxide in glacial acetic acid. It had a melting point of 304–306°.

The cyclization can be accounted for by assuming the following changes, involving two epoxide intermediates.

Kharasch and Nudenberg[4] reported the formation of the oxygen analogs of X and XI by the reaction between ethylene glycol and epichlorohydrin.

## Experimental

**6-Hydroxy-1,4-dithiacycloheptane (II).**—A modification of the method of Tucker and Reid[5] was adopted. To 500 ml. of absolute ethanol, 24 g. of clean sodium was added. After the reaction was completed, 48.9 g. of freshly distilled ethanedithiol[8] was added dropwise over a period of one-half hour at 20°. The sodium mercaptide solution and a solution of 113.3 g. of freshly distilled 2,3-dibromo-1-propanol in 500 ml. of absolute ethanol were added dropwise and at approximately the same rate to 500 ml. of absolute ethanol in a 2-l. flask equipped with a stirrer. The temperature was maintained at 20–25° during the addition, which required seven hours. The mixture was stirred overnight at room temperature. The white solid consisting of sodium bromide and polymeric material was discarded. The volume of the alcohol solution was reduced to about 150 ml. by evaporation under slightly diminished pressure. One liter of benzene was added, the insoluble material separated by filtration and the benzene filtrate dried over anhydrous magnesium sulfate. Evaporation of the solvent left an oil which crystallized when allowed to stand in the cold. After recrystallization from a cyclohexane–ethanol mixture (9:1), the hydroxy sulfide melted at 64.5–65.5°; yield 25 g. (32%).

*Anal.* Calcd. for $C_5H_{10}OS_2$: C, 39.96; H, 6.71; S, 42.67. Found: C, 40.13; H, 6.64; S, 42.33.

The same compound was formed when 1,3-dibromo-2-propanol was used in place of the 1,2-dibromohydrin.[9]

**The benzoate,** made in the usual manner and recrystallized from ethanol, melted at 75–76°; yield 76%.

*Anal.* Calcd. for $C_{12}H_{14}O_2S_2$: C, 56.66; H, 5.55. Found: C, 56.63; H, 5.54.

**The disulfone** (V) was produced by dissolving 0.4 g. of the benzoate in 10 ml. of glacial acetic acid and adding to the mixture slowly and with stirring, 0.11 g. of hydrogen peroxide (30%). After the exothermic reaction had subsided, 0.22 g. of hydrogen peroxide was added rapidly. The reaction mixture was stirred at 60° for 24 hours and the white, matted crystals of the sulfone benzoate were collected on a filter; m. p. 229–230°; yield 0.43 g. (86.5%). Repeated recrystallization of the sulfone from acetone did not change its melting point.

*Anal.* Calcd. for $C_{12}H_{14}O_6S_2$: C, 45.27; H, 4.43. Found: C, 45.32; H, 4.46.

**6-Hydroxy-1,4-dithiacycloheptane Tetroxide (VI).**—This compound was prepared in the usual manner from 1.35 g. of 6-hydroxy-1,4-dithiacycloheptane in 25 ml. of glacial acetic acid and 1.8 g. of hydrogen peroxide (30%). After the mixture had been stirred at 70° for twenty-four hours, the white, needle-like crystals (VI) were collected

(9) The melting points of the *p*-nitrobenzoates of these dibromohydrins, prepared according to the procedures of Fairbourne and Foster (*J. Chem. Soc.*, 3146, 3148 (1926)) and Conant and Quayle, (THIS JOURNAL, **45**, 2771 (1923)) were in agreement with the reported values.

on a filter, washed with cold water and dried over potassium hydroxide in a vacuum desiccator; m. p. 230–231°; yield 1.40 g. (72.5%). Removal of the solvent left a solid which weighed 0.3 g. and melted at 209–210°. Recrystallization of these solids from water raised their melting points to 233–234° and 210–211°, respectively.

**The benzoate** of the higher melting material, prepared in the usual manner, melted at 228–230° after recrystallization from acetone. A mixture melting point with the benzoate of 6-hydroxy-1,4-dithiacycloheptane tetroxide (V) showed no depression. Attempts to prepare the benzoate of the lower melting material failed.

**1,4-Dithia-6-cycloheptanone Tetroxide (VII).**—One gram of the hydroxy sulfone (VI) was suspended in 10 ml. of water to which had been added 0.92 g. of potassium dichromate. Concentrated sulfuric acid (10 ml.) was added dropwise over a period of one-half hour at 20–25°. Stirring was continued for one hour after which 50 ml. of water was added to the green reaction mixture. The ketone was collected on a filter and recrystallized from dioxane or water; yield 0.72 g. (72.7%); m. p. 252–253° (dec.).

*Anal.* Calcd. for $C_5H_6O_5S_2$: C, 28.29; H, 3.79; S, 30.21. Found: C, 28.68, 28.71; H, 3.66, 3.42; S, 30.07.

**The phenylhydrazone** was prepared by dissolving 0.2 g. of the ketone in 10 ml. of hot dioxane, cooling the solution and adding 1 ml. of phenylhydrazine and two drops of glacial acetic acid. The mixture was then heated on the steam-bath for ten minutes and cooled in ice. The addition of 20 ml. of water caused the immediate precipitation of the phenylhydrazone; m. p. 235–236° (dec.); yield 0.2 g. (70%). Recrystallization of the derivative from a dioxane–water mixture did not change its melting point.

*Anal.* Calcd. for $C_{11}H_{14}N_2O_4S_2$: C, 43.69; H, 4.66; N, 9.26; S, 21.21. Found: C, 43.95; H, 4.93; N, 9.24; S, 21.09.

**1,4-Dithia-5-cycloheptene Tetroxide (VIII).**—Five grams of 6-hydroxy-1,4-dithiacycloheptane tetroxide was dissolved in 75 ml. of hot anhydrous pyridine. The mixture was cooled in an ice-bath, and 4.6 ml. of phosphorus oxychloride was added dropwise with stirring. The reaction mixture was allowed to come to room temperature and then stirred at 60–70° for three hours. The slightly colored cycloheptene tetroxide was collected on a filter and washed well with ice-water; m. p. 279–280° (dec.); yield 3.4 g. (74%). Repeated recrystallization of the unsaturated sulfone from water raised its melting point to 280–280.5° (dec.). An aqueous solution of potassium permanganate was instantly decolorized when added to a dioxane solution of this compound.

*Anal.* Calcd. for $C_5H_8O_4S_2$: C, 30.60; H, 4.11. Found: C, 30.80, 30.75; H, 3.78, 3.71.

**1,4-Dithiacycloheptane Tetroxide (IX).**—Five grams of 10% palladium chloride on carbon[10] was reduced in 25 ml. of anhydrous dioxane at three atmospheres pressure. To the reduced catalyst a solution of 0.6 g. of the cycloheptene tetroxide (VIII) in 75 ml. of dioxane was added. The hydrogenation was completed after seven hours at three atmospheres pressure. The contents were transferred to a flask, boiled and filtered. Two additional extractions of the catalyst were carried out with 100-ml. portions of dioxane. The 1,4-dithiacycloheptane tetroxide, which separated when the combined extracts were allowed to stand in the cold, was recrystallized from water; m. p. 279–280° (dec.); yield 0.4 g. (66%).

*Anal.* Calcd. for $C_5H_{10}O_4S_2$: C, 30.29; H, 5.08. Found: C, 30.41; H, 5.38.

1,4-Dithiacycloheptane was synthesized in 7.9% yield (m. p. 47°) according to the procedure of Reid,[5,6] who reported the same melting point and a yield of 8.2%. The sulfone was prepared with 30% hydrogen peroxide in glacial acetic acid in a yield of 59%; m. p. 277.5–278.5° (dec.). A mixture of this sulfone with that prepared in the preceding experiment decomposed at 278–279°. The melting point of the sulfone has been given as 282°[7] and 287–288°[5,8].

*Anal.* Calcd. for $C_5H_{10}O_4S_2$: C, 30.29; H, 5.08. Found: C, 30.41; H, 5.00.

**2-Methyl-1,4-dithiane Tetroxide.**—2-Methyl-1,4-dithiane, prepared according to the method of Tucker and Reid,[5] melted at 20–22°. The reported melting point is 20°. After two sublimations at low pressure, the clear, colorless sulfide was converted to the sulfone by the usual method. It was recrystallized from water; m. p. 304–306° (dec.).

*Anal.* Calcd. for $C_5H_{10}O_4S_2$: C, 30.29; H, 5.08. Found: C, 30.09; H, 5.11.

## Summary

Ethanedithiol has been found to react with 2,3-dibromo-1-propanol or 1,3-dibromo-2-propanol to give 6-hydroxy-1,4-dithiacycloheptane. The structure of the product has been established by unequivocal methods.

# A Polymer-homologous Series of Sugar Acetates from the Acetolysis of Cellulose[1]

BY E. E. DICKEY[2] AND M. L. WOLFROM

The chain scission of cellulose by hydrolysis in mineral acids and by acetolysis has yielded, in addition to D-glucose and cellobiose, specific sugars composed of three, four and six D-glucopyranose units as fragments of the original cellulose chains.[3] We wish to report herein the isolation of such a polymer-homologous series of sugars (as the α-D form of the acetates) complete from α-D-glucopyranose pentaacetate through a α-cellohexaose eicosaacetate (Table I). This has been accomplished through the application of the general method for the chromatography of sugar acetates as developed in this Laboratory.[4,5]

α-D-Glucopyranose pentaacetate, *aldehydo*-D-glucose heptaacetate[6] and α-cellobiose octaacetate

[a] All melting points were taken on a Fisher–Johns melting point block, Fisher Scientific Co., Pittsburgh, Pa., and are uncorrected. [b] The precautions cited by J. H. C. Smith and W. G. Young, *J. Biol. Chem.*, **75**, 289 (1927), and W. B. Meldrum, L. P. Saxer and T. O. Jones, THIS JOURNAL, **65**, 2023 (1943), were followed in the determination of molecular weights by the method of Rast. [c] Accepted values as reported by Hudson and Johnson, ref. 15. [d] Specific rotation and melting point reported by Hess and Dziengel, ref. 10. [e] Accepted values.

are known products of the acetolysis of cellulose.[7] The trisaccharide, "procellulose," was first obtained by Bertrand and Mlle. Benoist,[8] as an amorphous solid after saponification and fractionation of a cellulose acetolyzate. By a similar procedure, Ost[9] succeeded in isolating the crystalline trisaccharide and named it cellotriose. By the acetolysis of cotton linters followed by saponification and fractionation, Hess and Dziengel[10] prepared a carefully purified sample of cellotriose which evidently crystallized as the α-form, $[\alpha]_D$ +32.0°, initial → +23.2°, final (in water). α-Cellotriose hendecaacetate was then prepared by acetylating the free sugar in pyridine and acetic anhydride, and repeatedly crystallizing the acetate to maximum purity (Table I). Crystalline cellotetraose was obtained by Willstätter and Zechmeister[11] from wood cellulose by hydrolysis in fuming hydrochloric acid ($d^{15}_4$ 1.21), and later, crystalline cellohexaose was isolated from the hydrolyzate by Zechmeister and Tóth.[12] Crystalline cellotriose hendecaacetate and cellotetraose tetradecaacetate were prepared by Zechmeister and Tóth[12] by acetylating the free sugars in acetic anhydride and pyridine, but cellohexaose failed to yield a crystalline acetate. As indicated by the specific rotation, the acetates prepared by Zechmesiter and Tóth were undoubtedly mixtures of both the α- and β-forms. The viscosity and molecular weight (Rast) of the cellohexaose acetate,[13] along with the lower members of the series, were determined by Staudinger and Leupold[14] who believed that the hexaose was actually a cellopentaose heptadecaacetate. Until all the free sugars of this series have been prepared and characterized, the identity of Zechmeister and Tóth's hexaose will remain somewhat in question. The triose and the tetraose have been obtained, also, in the form of their crystalline methyl ethers and phenylosazones.[3]

As shown by Hudson and Johnson,[15] mainly the α-form of a sugar acetate exists in an acetylating mixture of acetic anhydride and sulfuric acid. Since, in the present investigations, a cellulose acetolyzate was resolved directly into the polymer-homologous series, the preponderance of the α-form of each sugar acetate is to be expected (Table I).

| Total recovered | 9.47 | .. | ... | 1965 | ..... |

In the work herein described, cellulose in the form of filter paper was subjected to the procedure of Hess and Dziengel[10] for mild acetolysis. The cellulose acetolyzate was chromatographed on "Silene EF"[5] to effect a preliminary fractionation of the mixture. Three zones, as shown in Table II and Fig. 1, subsequently yielded the tetraose, pentaose and hexaose acetates, respectively. The

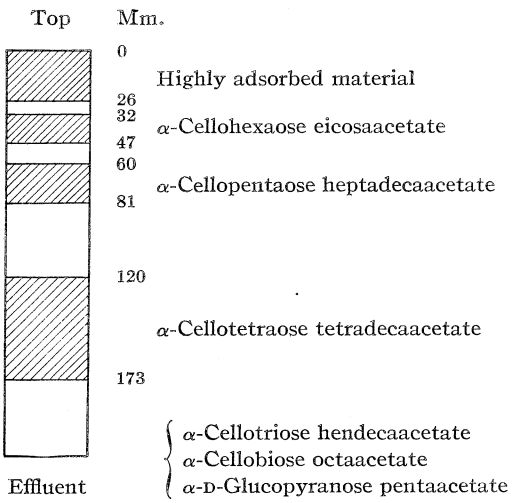

Fig. 1.—Cross section of a typical chromatogram of 1.5 g. of cellulose acetolyzate in 30 ml. of chloroform adsorbed on a column of adsorbent (44 mm. in diameter and 215 mm. long) composed of 5 parts by wt. of "Silene EF"[19] and 1 part of "Celite"[20] as developed with 1.4 liters of benzene–ethanol (100:1 by vol.).

highly adsorbed material at the top of the column is under further investigation. The solids recovered from the effluent were then chromatographed on "Magnesol"[4] to yield the three lower sugar acetates (Table II and Fig. 2) as well as two unidentified, crystalline substances under further investigation. It is probable that these substances represent impurities originating in the wood which was the source of the cellulose used. Corresponding zones from several chromatograms were combined, rechromatographed on "Magnesol" or "Silene EF" and crystallized from a suitable solvent (Table II). The data for the purified samples of specific sugars obtained from the cellulose acetolyzate are summarized in Table I and Fig. 3.

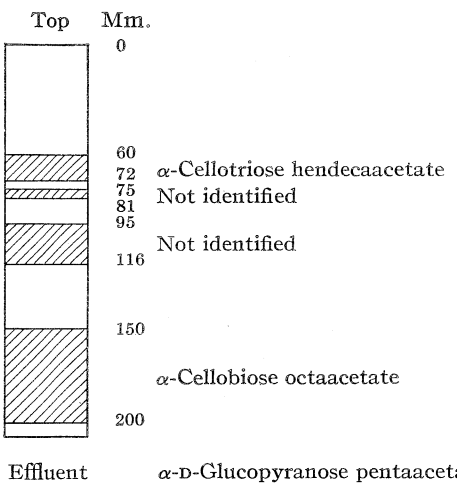

Fig. 2.—Cross section of a typical chromatogram of 1.8 g. of solids from the "Silene EF" effluent (*cf.* Fig. 1) in 30 ml. of chloroform adsorbed on a column of absorbent (44 mm. in diameter and 220 mm. long) composed of 5 parts by wt. of "Magnesol"[22] and 1 part of "Celite"[20] as developed with 1.5 liters of benzene–ethanol (100:1 by vol.).

The trend of melting points and specific rotations (Table I) is toward the constants for cellulose triacetate, $[\alpha]_D$ *ca.* −20°[16] and m. p. (softening point) *ca.* 295°.[17] Such a trend was found by Zechmeister and Tóth[12] for the corresponding series of free sugars, excluding the cellopentaose.

Freudenberg and co-workers[18] have shown that if the type of linkage in a polymer-homologous series is uniform, the expression $[M]_n/n$ plotted against $(n-1)/n$ (where $[M]$ is the molecular rotation and $n$ is the degree of polymerization)

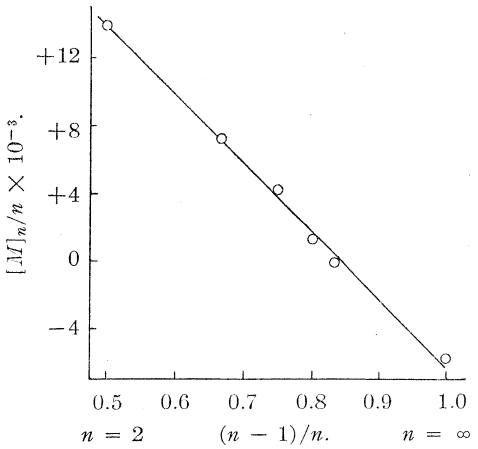

Fig. 3.—Relation between D. P. and molecular rotation.

should yield a straight line for $n \geqq 2$. Figure 3 shows that this linear relation holds for the α-D acetates of this series.

The determination of molecular weight by the method of Rast, Table I, tends to decrease in reliability as the molecular weight is increased. However, when the experimental molecular weights were correlated with specific rotations, melting points and relative positions on the chromatographic columns (Figs. 1–3) agreement with the proposed series was evident. As more material of better quality becomes available, the physical properties herein reported may be somewhat revised.

## Experimental

**Cellulose Acetolyzate.**—Using the general procedure of Hess and Dziengel,[10] 90 g. of filter paper (no. 1, prepared by W. &. R. Balston, Ltd., England) was dissolved with mechanical stirring in a mixture of 340 ml. of glacial acetic acid, 340 ml. of acetic anhydride and 36 ml. of concentrated sulfuric acid. The temperature of the reaction mixture was held at *ca.* 40° by external cooling with ice-water during the addition of the filter paper. After standing at room temperature for sixty hours, the clear, yellow solution was filtered through a sintered glass funnel and the filtrate poured slowly and with efficient mechanical stirring into 3 liters of cold water. The mixture was neutralized with sodium bicarbonate until just acid to congo red paper and allowed to stand overnight. The white precipitate was removed by filtration, washed on the filter with water until the filtrate was neutral to litmus and dried to constant weight in a vacuum desiccator over anhydrous calcium chloride; yield *ca.* 140 g. The product was powdered in a mortar and stored in a desiccator over solid sodium hydroxide and anhydrous calcium chloride.

**First Chromatographic Fractionation of Cellulose Acetolyzate.**—Using the general procedure of Georges, Bower and Wolfrom[5] for the chromatographic separation of sugar acetates on "Silene EF"[19] and "Celite,"[20] the cellulose acetolyzate was fractionated as shown in Fig. 1 and Table II. The extruded column was brushed with the streak reagent[21] and showed three zones in addition to the strongly adsorbed material at the top of the column (Fig. 1). The zones were separated, eluted with acetone and the eluates evaporated to dryness. The effluent from the chromatogram was also evaporated to dryness; the yields obtained are shown in Table II.

**Chromatographic Resolution of the Effluent Fraction on "Magnesol."**—Following the general procedure of McNeely, Binkley and Wolfrom,[4] the effluent fraction of solids was chromatographed on "Magnesol"[22] as shown in Fig. 2 and Table II. The column was extruded and brushed with the streak reagent. The α-D-glucopyranose pentaacetate was washed from the column and was recovered from the effluent by evaporating the solvent. α-Cellobiose octaacetate and α-cellotriose hendecaacetate along with the two unidentified substances were obtained by sectioning the column and eluting with acetone (Fig. 2 and Table II).

**Final Purification of Fractions.**—The α-D-glucopyranose pentaacetate and α-cellobiose octaacetate were not rechromatographed but were crystallized twice as shown in Table II. α-Cellotriose hendecaacetate was rechromatographed twice in the above-described manner on "Magnesol" and was then chromatographically pure. The product was finally crystallized twice. α-Cellotetraose tetradecaacetate was rechromatographed twice in the above-described manner on "Silene EF" and was finally crystallized as shown. α-Cellopentaose heptadecaacetate and α-cellohexaose eicosaacetate were each rechromatographed once on "Silene EF" and were crystallized as shown (Table II). The constants and elementary analyses obtained on these finally purified fractions are shown in Table I and are plotted in Fig. 3.

**Acknowledgment.**—This work was supported by the Ordnance Department under contract (W-33-019ord-3978, supervising agency Ballistic Research Laboratories, Aberdeen Proving Ground, Maryland) with The Ohio State University Research Foundation (Project 212). We wish to express our appreciation to Dr. W. W. Binkley and Mr. R. S. Bower of this Laboratory for their interest and coöperation in developing the chromatographic procedures used in this investigation.

## Summary

1. A product obtained by the acetolysis of cellulose has been resolved by a chromatographic technique into a polymer-homologous series of crystalline α-D acetates ranging in D. P. (degree of polymerization) from 1 to 6, inclusive.

2. A correlation of melting points and specific rotations with degrees of polymerization has been made.

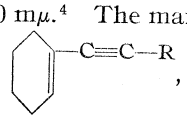
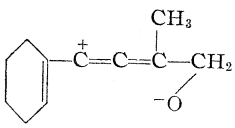
# Synthesis and Properties of Spiranes Containing Oxygen Heterocycles

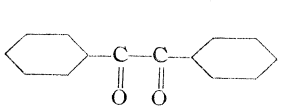


BY J. D. CHANLEY

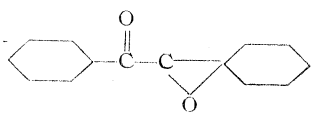


This investigation[1e] concerns itself with the preparation and properties of the *dl*-bis-epoxide of symmetric dicyclohexylethane (IV). This compound contains a new and interesting dispirane system. Numerous investigations of the ultraviolet absorption spectra of compounds containing a cyclopropyl group[1d] or epoxy group,[1c,2] adjacent to an unsaturated grouping, such as an ethylenic linkage, a carbonyl, phenyl, or pyridyl group, have shown that such compounds exhibit a shift of absorption to the longer wave lengths. This phenomenon as well as chemical evidence[3] indicates that three-membered rings resemble in many respects the ethylenic linkage. In these systems, the observed shift in the spectrum is commonly attributed to the participation of the three-membered ring in some of the excited (ionic) states of the molecule.[1a-d] It was of interest to investigate whether an epoxy-group, adjacent to a second one or to an acetylenic linkage, would display similar spectral properties. The *dl*-bis-epoxide of *sym*-dicyclohexylethane (IV) was prepared and proved to be completely transparent down to $\lambda = 214$ m$\mu$. A possible explanation is that such excited states as

which presumably would favor a shift in the spectrum toward the longer wave lengths, are extremely improbable. In this connection, it is of interest to know that the maximum of the 3,4-epoxide of 1-cyclohexenyl-3-methyl-1-butyne is



as low as 230 m$\mu$.[4] The max. values[4] for systems of the type , with R denoting a saturated group, lie in the range 227–229 m$\mu$. The epoxy group in this instance does not appear to possess double bond character. It is extremely unlikely that hypothetical excited states as



which would produce a shift of absorption to longer wave lengths, occur.

The synthesis and proof of structure of the bis-epoxide (IV) are outlined in the Scheme. The assigned *cis* configuration for 1,1′-vinylene-bis-cyclohexanol (II) is based on the general experience that mild catalytic hydrogenation of an acetylenic linkage produces the *cis* ethylenic derivative.[5] The $\alpha,\beta$-(1,1′-dihydroxycyclohexyl)-$\alpha,\beta$-dibromoethane (III), obtained by bromination of the ethylenic compound (II), is a racemate since bromine adds *trans* to ethylenic linkages.[6] The assigned structure for compound III was further confirmed by catalytic reduction of the dibromide to the *sym*-1,1′-ethylene bis-cyclohexanol (XII), identical with the product resulting from the complete catalytic reduction of 1,1′-ethynylene-bis-cyclohexanol (I), or of 1,1′-vinylene-bis-cyclohexanol (II).

Dehydrohalogenation of the double bromohydrin III yielded the *dl*-bis-epoxide of *sym*-dicyclohexylethane (IV). Since it is generally accepted that, both in the opening and in the formation of epoxy rings, an inversion at one of the carbon atoms ensues,[7a-h] it is therefore postulated that the racemic form only of the bis-epoxide IV may be expected from the racemic double bromohydrin III, since inversion would occur at each of the carbon atoms,[7d,g,h] bearing bromine atoms in III. Other conceivable structures for the new compound with the correct empirical elementary composition such as

(A)

(B) and VII

were considered at the time, but eliminated for the following reasons: (a) Compound IV gave no ketonic derivatives; (b) Compound A has been

SCHEME

synthesized[8] and its properties bear no resemblance to those of compound IV; (c) compound VII was prepared in the course of the present investigation and proved to be different from compound IV. Confirmatory evidence for the assigned structure was obtained when the bis-epoxide yielded, on catalytic hydrogenation, the *dl*-$\alpha,\beta$-dicyclohexylethylene glycol (V). Since the oxygen atoms remain attached to the same carbon atom after hydrogenolysis of the racemic bis-epoxide, the glycol of m. p. 154° must necessarily be a racemate. This compound is identical with the so-called "iso-$\alpha,\beta$-dicyclohexylethylene-glycol" of m. p. 153°, prepared by Buck and Ide[9] by condensation of glyoxal and cyclohexylmagnesium bromide. Thus, the *meso* configuration should be assigned to the isomeric $\alpha,\beta$-dicyclohexylethylene glycol, m. p. 194°, obtained by the catalytic reduction of benzoin.[10]

Treatment of the bis-epoxide IV with water in a sealed tube did not give the tetrahydroxy compound, but rather the 3,4-dihydroxy-dispiro[dicyclohexane-tetrahydrofuran] (VIII).[11,12] This was confirmed by the following synthesis; di-

(12) This designation follows rule 23 for nomenclature of spiro systems, Patterson and Capell, "Ring Index," Reinhold Publ. Corp., New York, N. Y., 1940, p. 27. Under rule 22 this compound would be named 7,8-dihydroxy-15-oxa-trispiro[5,2,5,1]-pentadecane.

spiro[dicyclohexane-2,5-dihydrofuran] (VI), was prepared from compound II according to Burkhardt and Hindley.[13] This compound, when treated with perbenzoic acid, yielded the 3,4-epoxide (VII). This epoxide, on hydrolysis with a trace of acid, gave the expected *trans*-glycol, 3,4-dihydroxy-dispiro[dicyclohexane-2,5-tetrahydrofuran] (VIII). The *trans* position of the hydroxy groups with reference to the plane of the furan ring is anticipated since oxide rings open with inversion.[7]

This compound (VIII), on treatment with an equivalent amount of periodic acid, gave a quantitative yield of a new compound of elementary composition and molecular weight $C_{14}H_{24}O_4$. It gave no fuchsin test for aldehyde nor is it soluble in strong base, thus excluding a lactone formulation; therefore it is tentatively formulated as an internal acetal of a dialdehyde with a *p*-dioxane structure (IX). On oxidation of compound VIII with potassium permanganate in water or pyridine, a new acid $C_{13}H_{22}O_4$ was formed which has been tentatively assigned the structure X.

The bromination of 1,1′-vinylene-dicyclohexanol (II) yielded, in addition to the main product (III), relatively minor quantities of two by-products. One of them was free of bromine and proved to be identical with the dihydrofuran derivative VI. Evidently, the hydrobromic acid, whose evolution was observed during the bromination and must be ascribed to some minor side-reaction, is responsible for the furan formation from the 1,4-glycol (II). This is in analogy to the cyclizing effect of oxalic acid, leading to the same product.[13]

As the second by-product in the bromination, we have found *dl*-3,4-*trans*-dibromo-dispiro[cyclohexane-2,5-tetrahydrofuran] (XI). This substance was also obtained by bromination of the dihydrofuran (VI), which as stated in the preceding paragraph, was obtained in two ways: by the procedure of Burkhardt and Hindley and as the first by product in the above reaction. The transformation of compound III into compound XI by boiling with oxalic acid could not be effected.

## Experimental

**1,1′-Ethynylene-bis-cyclohexanol (I).**—This was prepared from acetylenedimagnesium bromide[14] and cyclohexanone according to the procedure of Du Pont[15] and Marvel[8] m. p. 108–109°; reported[8] m. p. 108–110°.

**1,1′-Vinylene-bis-cyclohexanol (II).**—Forty grams of compound I was dissolved in 100 cc. of absolute ethanol and hydrogenated at 2–3 atm. pressure in the presence of 0.5 g. of platinum oxide as catalyst. Hydrogenation was interrupted after 1 mole of hydrogen had been absorbed after twenty to thirty minutes, hydrogen uptake then slackened perceptibly and the product precipitated in the hydrogenation flask. The mixture was boiled down to 35 cc., filtered, cooled and the product recrystallized from ethanol; yield, 60–70%, m. p. 150–151°; reported 153–154[16]; 152°.[17] The same product was obtained when hydrogenation was carried out in the presence of a 5% palladium on barium sulfate catalyst at atmospheric pressure.

*Anal.* Calcd. for $C_{14}H_{24}O_2$: C, 74.95; H, 10.79. Found: C, 75.00; H, 10.88.[18]

***dl*-α,β-(1,1′-Dihydroxycyclohexyl)-α,β-dibromoethane (III).—Dispiro[dicyclohexane-2,5-dihydrofuran] (VI). 3,4-*trans*-Dibromo-dispiro[dicyclohexane-2,5-tetrahydrofuran] (XI).**—A solution of 64.8 g. (0.4 mole) of bromine in 600 cc. of dry carbon tetrachloride was added over a period of three hours to a vigorously stirred, ice cooled, illuminated (light bulb or sunlight) suspension of 90 g. (0.4 mole) compound II in 600 cc. of dry carbon tetrachloride. The reaction was allowed to continue for an additional forty-five minutes at the end of which time the evolution of hydrogen bromide became particularly evident. The precipitated product, after filtration and washing with small portions of cold carbon tetrachloride (the filtrates and washings were combined and will henceforth be referred to as filtrate A), was immediately refluxed for sixteen hours with 1000 cc. of carbontetrachloride, at the end of this refluxing period the evolution of hydrogen bromide ceased and formation of water droplets in the condenser was noted. The refluxing is necessary because attempts to purify the product by recrystallization alone gave material contaminated with an impurity which turned purple on standing. The carbon tetrachloride solution was decanted from precipitated tar, evaporated to 450 cc., cooled and the dibromohydrin collected. (The filtrate will henceforth be referred to as B.) Recrystallization from carbon tetrachloride gave product III m. p. 128–130° (decomposition) in 50% yield.

*Anal.* Calcd. for $C_{14}H_{24}O_2Br_2$: C, 43.74; H, 6.30; Br, 41.61. Found: C, 43.54; H, 6.19; Br, 40.78.

Filtrate A after refluxing for sixteen hours, during which time a copious evolution of hydrogen bromide and formation of water was noted, was then combined with filtrate B and the burgundy-colored solution was evaporated to dryness. The residue was treated with 500 cc. of petroleum ether (40–60° b. p.), cooled in ice and filtered from a dark violet solid (unidentified) (5–7 g.). The petroleum ether solution after two successive passages through a column (16 cm. length and 1.5 cm. internal diam.) of activated aluminum oxide (−80 mesh ALCOA) was evaporated to dryness. The partially crystalline residue (30 g.) was triturated with 100 cc. of cold 95% ethanol and filtered. Four grams of compound VI was obtained on recrystallization from ethanol m. p. 95–96°; it showed no depression of m. p. on admixture with an authentic sample of m. p. 95–96°.[13]

Distillation of the alcohol soluble portion gave 3 g. of the pure dihydrofuran VI b. p. 117–118° (9.5 mm.); $n^{25}D$ 1.4915. Reported 116–118° (10 mm.).[13] The identity of this fraction was confirmed by the preparation of its dibromo derivative which melted at 95–96° and showed no depression of melting point on admixture with the authentic sample. Four grams of unidentified high boiling material was present in the alcohol soluble portion.

**Hydrogenation of *dl*-α,β-(1,1′-Dihydroxycyclohexyl)-α,β-dibromoethane (III) to 1,1′-Ethylene-bis-cyclohexanol (XII).**—One hundred and ninety-eight mg. of compound XII in 25 cc. of ethanol was hydrogenated at atmospheric pressure employing 200 mg. of 5% palladium on calcium carbonate as catalyst. Hydrogenation ceased after the theoretical quantity (2 mole) of hydrogen was absorbed. The saturated glycol, obtained in quantitative yield, was recrystallized from petroleum ether (40–60°). It melted at 128–129° and showed no depression in m. p. on admixture with an authentic sample m. p. 128–129°

prepared by the hydrogenation of 1,1′-vinylenebiscyclohexanol (II) in glacial acetic acid at atmospheric pressure in the presence of $PtO_2$ as catalyst. Reported 128–129°.[16]

*dl*-**Bis-epoxide of *sym*-Dicyclohexylethane (IV).**—A solution of 17.2 g. (0.45 mole) of sodium hydroxide in 600 cc. of ethanol was added over a period of five minutes to a solution of 68 g. (0.177 mole) of the double bromohydrin (III) and set aside to stand for one to two days. After removal of the precipitated sodium bromide, the alcohol solution was evaporated almost to dryness *in vacuo* and the residue was treated with 400 cc. of ice water. The solid product was collected by filtration and recrystallized from petroleum ether (40–60°); colorless crystals, m. p. 58–58.7°; yield, 35–36 g. (90%).

*Anal.* Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.98. Found: C, 75.91; H, 10.02.

*dl*-$\alpha,\beta$-**Dicyclohexylethylene Glycol (V).**—Two and three-tenths grams of the bis-epoxide IV dissolved in 30 cc. of purified glacial acetic acid was hydrogenated at atmospheric pressure in the presence of 200 mg. of platinum oxide as catalyst. It was necessary to add an additional 200 mg. of catalyst to bring the hydrogenation to completion (2 mole of hydrogen were absorbed). Evaporation of the solvent and recrystallization of the residue from Skellysolve L (b. p. 93–129°) gave crystals of m. p. 153–154°; reported 153°.[9]

*Anal.* Calcd. for $C_{14}H_{26}O_2$: C, 74.30; H, 11.58. Found: C, 74.18; H, 11.49.

**3,4-Expoxide of Dispiro[dicyclohexane-2,5-tetrahydrofuran] (VII).**—Compound VI (b. p. 116–118° (10 mm.) $n^{25}D$ 1.4900) was prepared according to the method of Burkhardt and Hindley[13] by boiling compound II with oxalic acid. It gave the authentic dibromide, m. p. 95–96°, on bromination according to the procedure of the same authors.

A solution of 16 g. (0.077 mole) compound (VI) was allowed to stand for one week at room temperature with 275 cc. of perbenzoic acid solution in carbon tetrachloride which contained 1.58 g. (0.1 mole) of active oxygen. At the end of this time the theoretical amount of oxygen had been absorbed. The carbon tetrachloride solution was washed thoroughly with 10% sodium hydroxide, water and dried over anhydrous sodium sulfate. Distillation gave a slight forerun of starting material and 10 g. of pure compound (VII) b. p. 143° (10 mm.) $n^{25}D$ 1.4930.

*Anal.* Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.98. Found: C, 75.58; H, 10.06.

*dl*-**3,4-Dihydroxy-dispiro[dicyclohexane-2,5-tetrahydrofuran] (VIII).** (a) **From Compound (IV).**—A sealed tube containing 25 g. of the bis-epoxide (IV) and 75 cc. of water was heated at 120° for two to three days. After separating the water by decantation the residual viscous oil was mixed with 300 cc. of petroleum ether (40–60°) and cooled in ice; the product crystallized in felt-like needles. Recrystallization from Skellysolve L, b. p. 93–129° gave 7 g. of pure material m. p. 145–146°.

*Anal.* Calcd. for $C_{14}H_{24}O_3$: C, 70.07; H, 10.00. Found: C, 70.18; H, 9.67.

The residue after evaporation of the original petroleum ether was evaporatively distilled at 0.1 mm. and the fraction collected at 50–60° was redistilled to yield 4 g. of starting material boiling at 118–119° (0.5 mm.) $n^{25}D$ 1.4940 which solidified on standing. After recrystallization from petroleum ether (40–60°) it melted at 57–58° and showed no depression in melting point on admixture with the bis-epoxide (IV). The remainder of the petroleum ether solution were intractable polymers; yield, 30–35% based on recovered starting material.

(b) **From Compound (VII).**—One gram of compound (VII) was mixed with 10 cc. of water, containing three drops of dilute hydrochloric acid (hydrolysis did not occur with water alone) and heated in a sealed tube for two days at 120°. The reaction mixture was worked up as described above. Three-tenths of a gram of product, m. p. 145–146°, was obtained which showed no depression in m. p. when mixed with the glycol (VIII) as obtained above.

**Compound $C_{14}H_{24}O_4$ (IX).**—A suspension of 1.23 g. (0.005 mole) of the glycol (VIII) in 35 cc. of the solution of periodic acid containing 0.0054 equivalent of oxidizing agent was shaken mechanically for sixteen hours. The product was collected by filtration and recrystallized from 35% aqueous ethanol; yield 90% m. p. 133° (dec.). Molecular weight determination by Rast: 243 (camphor); average of four determinations (pinene dibromide): 260, calcd. 256.

*Anal.* Calcd. for $C_{14}H_{24}O_4$: C, 65.59; H, 9.45. Found: 65.76; H, 9.46.

**Compound $C_{13}H_{22}O_4$ (X).**—A mixture of 700 mg. (0.0029 mole) of compound (VIII), 1.05 g. (0.006 equivalent) of potassium permanganate in 30 cc. of 3.3% sodium hydroxide solution was heated on steam-bath with occasional shaking for fifteen to twenty minutes. The mixture was cooled and filtered. Acidification with dilute hydrochloric acid of the filtrate yielded the acid which after recrystallization from Skellysolve C (86–100°) melted with decomposition at 132–134°. The same product was obtained by oxidation of compound (VIII) by potassium permanganate in dried pyridine.

*Anal.* Calcd. for $C_{13}H_{22}O_4$: C, 64.42; H, 9.15. Found: C, 63.96; H, 9.02.

**Acknowledgment.**—The author wishes to express his gratitude to Dr. Harry Sobotka, Chief Chemist of the Mount Sinai Hospital, for his many valuable suggestions and interest in this work; and to acknowledge the able technical assistance of Miss Bernice Hamerman.

## Summary

The preparation and properties of the *dl*-bis-epoxide of symmetric dicyclohexylethane and of the isomeric 3,4-epoxide of dispiro[dicyclohexane-2,5-tetrahydrofuran] are described and discussed.

# Steroid Acids and Their Transformation Products. V. 24-Phenyl-5,23-choladien-3β-ol and Derivatives

BY GEORGE B. SPERO, A. VERN MCINTOSH, JR., AND ROBERT H. LEVIN

The preparation of two 24-phenyl-5-cholen-3β,24-diols (I), epimeric at C-24, has been reported recently.[1] When the mixture of epimeric diols, or either pure isomer, was treated with anhydrous oxalic acid in refluxing Dowtherm A[2] selective dehydration occurred, giving a choladiene in 60–75% yield. The dehydration product (II) was precipitable with digitonin and readily formed a monoacetate which, on treatment with excess bromine in carbon tetrachloride, gave a tetrabromide. The acetate of II exhibited an ultraviolet absorption curve having a principal peak at 251 mμ and two smaller maxima at 285 mμ and 293 mμ, respectively. This is in good agreement with published data for substituted phenylethylene,[3] indicating that the dehydration product is 24-phenyl-5,23-choladien-3β-ol (II). If dehydration had occurred at C-3 the product would have been a derivative of 2,4-cholestadiene, or 3,5-cholestadiene, having absorption maxima in the region 267–275 mμ and 234–240 mμ, respectively.[4]

I II III IV V VI

An Oppenauer oxidation of 24-phenyl-5,23-choladien-3β-ol (II) with aluminum isopropoxide and cyclohexanone gave 24-phenyl-4,23-choladien-3-one (III), whose absorption curve exhibited maxima at 247, 285 and 293 mμ. The same ketone (III) was obtained by oxidizing the tetrabromide of II with chromic acid in acetic acid, debrominating with zinc, and isomerizing the 5,6 double bond with alkali. To complete the structure proof of these compounds, the ketone (III) was oxidized with chromic acid to give 3-keto-nor-4-cholenic acid (VI) in 50% yield. This keto acid, which has not been recorded previously in the literature, was also obtained, in 25% yield, by a similar oxidation of the corresponding diphenylethylene (V).

The acetate of the dehydration product (II) was treated at 0° with a saturated solution of hydrogen chloride in chloroform and acetic acid (1:1). The product of this reaction was characterized as 5-chloro-24-phenyl-23-cholene-3β-ol acetate (IV) on the basis of analysis and the fact that its ultraviolet absorption spectrum is identical with that of compound (II). When the acetate of 24-phenyl-5,23-choladien-3β-ol (II) was treated with hydrogen chloride in acetic acid–ether (1:16) at 0°, a mixture of mono- and dihydrohalogenated products was formed, as indicated by analysis and ultraviolet absorption data. Attempts to separate the components by fractional crystallization were not successful.

When cholesterol was treated with anhydrous oxalic acid in refluxing Dowtherm A for a period four times as long as the optimum time for the dehydration of the diol (I), better than 70% of the cholesterol was recovered unchanged. The selectivity of the dehydrating action of the oxalic

acid on these secondary alcohols may be due to the influence of activating groups adjacent to the hydroxyl. Experiments designed to study and extend this reaction are now under way.

**Acknowledgment.**—We wish to express our appreciation to Dr. George Pish for the ultraviolet absorption data reported in this paper.

## Experimental[5]

**24-Phenyl-5,23-choladien-3β-ol Acetate (II).**—Eight grams (0.018 mole) of a mixture of the two epimers of 24-phenyl-5-cholen-3β,24-diol (I)[1] was allowed to reflux for ninety minutes with 16 g. of anhydrous oxalic acid[6] and 160 ml. of Dowtherm A. Most of the Dowtherm A was then removed by distillation *in vacuo*. During the distillation the oxalic acid sublimed out of the reaction mixture. The residue was cooled, dissolved in 200 ml. of ether and washed with 2% sodium bicarbonate solution and water. The ether solution was dried over anhydrous sodium sulfate and the solvent removed. The residue was dissolved in 200 ml. of hexane and passed over 230 g. of alumina[7] in a column 5 cm. in diameter. Elution with 700 ml. of hexane–benzene (1:1) removed the Dowtherm A, and the product (II) was obtained by the use of 800 ml. of benzene–methanol (92:8). The benzene–methanol eluate was taken to dryness and the residue crystallized from ether, giving 5.28 g. (69%) of 24-phenyl-5,23-choladien-3β-ol, m.p. 105–118°. This material could not be crystallized to a sharper melting point because of its tendency to solvate. It was heated for three hours on the steam-bath with acetic anhydride and pyridine, giving 4.88 g. (87%) of the acetate, m.p. 172–176°. Recrystallization from methanol–ether gave pure material, m.p. 176.5–177.5°; $[\alpha]^{24}D$ −31.4° (62.1 mg. in 10 ml. of chloroform; 2-dm. tube: $\alpha_D$ −0.39°). Absorption spectrum: maxima at 251 mμ (log *E*, 4.29), 285 mμ (log *E*, 3.25), 293 mμ (log *E*, 2.97), taken in 95% alcohol (*c*, 2.210 mg. in 100 ml.).

*Anal.* Calcd. for $C_{32}H_{44}O_2$: C, 83.43; H, 9.63; $CH_3CO$, 9.3. Found: C, 83.10; H, 9.60; $CH_3CO$, 9.5.

**The tetrabromide** was formed by treating 60 mg. of the acetate in 2 ml. of carbon tetrachloride with an excess of bromine in the same solvent. After standing at room temperature the solution was evaporated to dryness and the residue crystallized from methanol–ether, m.p. 168–175°. Recrystallization gave the tetrabromide of 24-phenyl-5,23-choladien-3β-ol acetate, m.p. 171–175°.

*Anal.* Calcd. for $C_{32}H_{44}O_2Br_4$: Br, 40.96. Found: Br, 40.56, 40.88.

Saponification of 3.94 g. of the acetate in 225 ml. of methanol with 3.9 g. of potassium hydroxide in 9 ml. of water gave 3.12 g. (84%) of recrystallized hydroxy compound (II), m.p. 107–113°. Numerous recrystallizations from ether, benzene, alcohol, acetone and other solvents failed to give sharper melting material. Analysis indicated varying degrees of solvation.

**24-Phenyl-4,23-choladien-3-one (III). A. By Oppenauer Oxidation.**—Three grams (0.007 mole) of 24-phenyl-5,23-choladien-3β-ol was dissolved in 90 ml. of toluene and 60 ml. of cyclohexanone. Ten ml. of the solution was distilled to remove traces of moisture and 3 g. of aluminum isoproxide was added. The mixture was heated under reflux for two and one-half hours, cooled, and diluted with a mixture of 200 ml. of 5% hydrochloric acid and 100 ml. of ether. The aqueous phase was separated and extracted with 100 ml. of fresh ether. The combined ether solution was washed with 5% hydrochloric acid and water, then dried and concentrated *in vacuo*. The residue was crystallized from methanol giving 2.6 g. (86%) of the keto diene (III), m.p. 130–154°. Recrystallization from ether–methanol gave 76% of pure material, m.p. 159–160.5°; $[\alpha]^{25}D$ +99.8° (52.6 mg. in 5 ml. of chloroform; 2-dm. tube; $\alpha_D$ +2.10°. Absorption spectrum: maxima at 244 mμ (log *E*, 4.50), 285 mμ (log *E*, 3.24), 293 mμ (log *E*, 2.98) taken in 95% alcohol (*c*, 2.192 mg. in 100 ml.).

*Anal.* Calcd. for $C_{30}H_{40}O$: C, 86.47; H, 9.68. Found: C, 86.51; H, 9.43.

**B. By Chromic Acid Oxidation of the Tetrabromide of II.**—The tetrabromide prepared from 270 mg. of 24-phenyl-5,23-choladien-3β-ol was oxidized with chromic anhydride in acetic acid, debrominated with zinc dust and acetic acid in ether, and isomerized with alkali to give 55 mg. (32%) of crystals melting at 159–163°. The 3-keto compounds (III) prepared by the two methods gave the same melting point on admixture.

**5-Chloro-24-phenyl-23-cholen-3β-ol Acetate (IV).**—A solution of 2.25 g. (0.005 mole) of 24-phenyl-5,23-choladien-3β-ol acetate in 9 ml. of chloroform and 4.5 ml. of glacial acetic acid was cooled to 0° and saturated with dry hydrogen chloride. After standing at 0° for twelve days, the solution was evaporated to dryness *in vacuo*. The residue was crystallized from ether, giving 0.8 g. (33%) of the 5-chloro compound (IV), m.p. 160–188°. Several recrystallizations from acetone gave a small recovery of pure material, m.p. 194–198° (dec.). Absorption spectrum: maxima at 251 mμ (log *E*, 4.30), 285 mμ (log *E*, 3.27), 295 mμ (log *E*, 2.99), taken in 95% alcohol (*C*, 2.171 mg. in 100 ml.); $[\alpha]^{25}D$ +21.4° (163.8 mg. in 10 ml. of chloroform; $\alpha_D$ +0.35°).

*Anal.* Calcd. for $C_{32}H_{45}O_2Cl$: C, 77.31; H, 9.12; Cl, 7.13. Found: C, 77.30; H, 9.05; Cl, 6.99.

When 4.7 g. of 24-phenyl-5,23-choladien-3β-ol acetate was dissolved in 800 ml. of ether and 50 ml. of acetic acid and similarly treated with dry hydrogen chloride, 4.3 g. of material, m.p. 178–186°, was obtained. Repeated crystallizations gave material with a constant m.p. of 185–187°. Analyses indicated it was essentially the dichloro compound, contaminated with some of the monochloro derivative. On refluxing this mixture with quinoline pure 24-phenyl-5,23-choladien-3β-ol acetate, m.p. and mixed m.p. 175–176.5°, was recovered in poor yield. Similar treatment with pyridine and dimethylaniline gave intractable mixtures.

**3-Keto-nor-4-cholenic Acid (VI).**—A solution of 700 mg. of chromic anhydride in 0.7 ml. of water and 7 ml. of acetic acid was added over a period of an hour to 400 mg. (0.0009 mole) of 24-phenyl-4,23-choladien-3-one (III) dissolved in 15 ml. of acetic acid at room temperature. The mixture was allowed to stand one hour, then the excess chromic acid was decomposed with 3 ml. of methanol. The solution was poured into 4 volumes of water, extracted with ether, and the ether solution washed with dilute hydrochloric acid and with water. On extraction of the ether solution with 5% aqueous sodium carbonate an insoluble sodium salt was formed. The aqueous suspension was separated and acidified with 3 *N* hydrochloric acid, giving 187.5 mg. (54%) of the keto acid (VI), m.p. 190–200°. Several crystallizations from acetone–water (1:1) brought the melting point to 208–211°.

*Anal.* Calcd. for $C_{23}H_{34}O_3$: C, 77.05; H, 9.56. Found: C, 77.29; H, 9.64.

**The methyl ester** of 3-keto-nor-4-cholenic acid was prepared with diazomethane and was crystallized from alcohol–water, m.p. 140–142°; $[\alpha]^{25}D$ +96.2° (15.6 mg. in 2 ml. chloroform; $\alpha_D$ +0.75°). Absorption spectrum: maximum at 241 mμ (log *E*, 4.20 in absolute alcohol).

*Anal.* Calcd. for $C_{24}H_{36}O_3$: C, 77.38; H, 9.74. Found: C, 77.58; H, 9.58.

Oxidation of 350 mg. of 24,24-diphenyl-4,23-choladien-3-one (V)[8] with 500 mg. of chromic anhydride under similar conditions over a period of three hours gave a

(8) Meystre, Wettstein and Miescher, *Helv. Chim. Acta*, **30**, 1022 (1947).

gummy acid fraction, which on crystallization from acetone–water yielded 66.6 mg. of 3-keto-nor-4-cholenic acid, m.p. 200–207°; methyl ester, m.p. 139–142°. A mixture of the methyl esters obtained from the monophenylethylene (III), and the diphenylethylene (V) gave no depression of the melting point.

**Treatment of Cholesterol with Oxalic Acid.**—A mixture of 1.0 g. of cholesterol, 4.0 g. of anhydrous oxalic acid, and 30 ml. of Dowtherm A was heated under reflux for five hours in an atmosphere of nitrogen. The Dowtherm was removed by steam distillation, and the water insoluble residue was adsorbed on 116 g. of chromatographic alumina from petroleum ether solution. Elution with petroleum ether–benzene (3:2) gave 90 mg. of material which was not further investigated. Elution with benzene–methanol (96:4) gave 727 mg. of cholesterol which after one recrystallization from 95% alcohol melted at 148–149°.

## Summary

24-Phenyl-5-cholen-3β,24 diols, epimeric at C-24, have been dehydrated by anhydrous oxalic acid to give 24-phenyl-5,23-choladien-3β-ol.

24-Phenyl-4,23-choladien-3-one has been prepared and oxidized to 3-keto-nor-4-cholenic acid.

The addition of hydrogen chloride to 24-phenyl-5,23-choladien-3β-ol acetate has been studied.

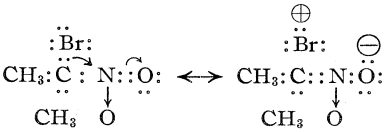
# The Malonic Ester Reaction with 1-Halo-nitroparaffins

BY EUGENE E. VAN TAMELEN[1] AND GERRIT VAN ZYL

In view of the present availability of the nitroparaffins, the reaction of the readily prepared 1-halo-nitroparaffins with malonic ester was undertaken with the purpose of determining the effect, if any, of the highly electronegative nitro group upon the course of the reaction. In only one instance was a normal alkylation accomplished which resulted in a 1-nitroalkyl malonic ester.



2-Bromo-2-nitropropane, Ia, was selected as a model for the bromo series, since there is no acidic hydrogen present to complicate the reaction. Upon carrying out the reaction of Ia with sodium malonic ester, IIa, under the usual conditions, two organic products were isolated: 2,3-dinitro-2,3-dimethylbutane, V, and ethane tetracarboxylic ester, VI. Since bromomalonic ester, IVa, is known to react rapidly with IIa to yield VI, IVa was postulated as an intermediate.

According to this series, one-half mole of Ia should be sufficient to convert IIa completely to VI, provided the known reaction (B) is slow.[2] It was found that the rapid addition of one-half mole of Ia to IIa gave 73% VI, with no detectable amount of V.

Since the reaction of alkyl bromomalonic esters with sodium alkyl malonic esters is not nearly as rapid as that of IVa and IIa,[3] it seemed likely that an intermediate, IVb, could be isolated if sodium ethyl malonic ester, IIb, were employed instead of IIa. Indeed, a 69% yield of IVb was obtained in this way. No matter how rapidly Ia was added to IIb, however, the formation of V could not be completely avoided—a reflection of the less rapid reaction rate of alkyl malonic esters. Increased time of addition of Ia and prolonged stirring may result in as high a yield as 30% of V.

Reaction (A) may probably be best interpreted in terms of a positively charged bromine ion. Similar reactions have been recorded in which one of the reactants possesses a halogen atom attached to the same carbon atom as one or more highly negative groups.[3] The displacement of halogen as a positive ion may be attributed to two causes: (1) the higher attraction of electrons by the nitro group as illustrated in the resonance forms

and (2) the stabilization of the resulting nitro carbanion through resonance.

The mixture of sodium salts which precipitated from the alcoholic medium during the course of the reaction was shown to consist of sodium 2-nitropropane, III, sodium bromide and sodium nitrite VII. The presence of VII along with III was unexpected, but is paralleled by the observations of Meyer[4] and Nygaard, *et al.*[5]

Whereas the reaction of Ia and II proceeds *via* the positive bromine route, 2-chloro-2-nitropropane, Ib, and II result in a normal nucleophilic displacement on carbon. This is somewhat surprising in view of the foregoing, since the chlorine substituent, like the bromine, is less electronegative than the nitro group. The treatment of IIa with Ib resulted in the production of two esters: isopropylidene malonic ester, X, and isopropylidene dimalonic ester, XI

The nitro group in IXa is labilized by the acidic hydrogen in the 2-position; in the presence of strong base, sodium nitrite is easily lost with the formation of X. The addition of IIa to X yields XI.

*A priori*, it was not possible to determine at this point whether the series of reactions actually proceeded as outlined above; displacement of the nitro group in (D), yielding 1-chloro-1-methylethylmalonic ester, followed by loss of sodium chloride would also account for the formation of X. The question was simply solved by employing sodium ethyl malonic ester, which would yield a stable, substituted ester with no reactive hydrogen. 1-Nitro-1-methylethyl ethylmalonic ester, IXb, was obtained in a 68% yield along with 13% ethyl isopropyl malonic ester. The mechanism by which the latter compound is formed is not obvious, but a similar malonic ester alkylation is known in which one of the chlorine atoms in carbon tetrachloride is replaced by hydrogen during reaction.[6]

An attempt to synthesize IXb by refluxing a suspension of dry sodium 2-nitropropane in a xylene solution of IVb was unsuccessful; only starting materials were recovered.

As a model of a 1-halo-nitroparaffin with an acidic hydrogen, 1-chloronitroethane, XII, was selected for reaction with sodium malonic ester. Under conditions similar to those described above for the reaction with Ia, the preponderant part of the ester was recovered, in spite of the fact that a great deal of solid material was precipitated during an exothermic reaction. Apparently the initial reaction is merely the regeneration of malonic ester from its sodium salt by the stronger acid XII. XII could not be regained, however, upon acidification of the salt material, which proved to be mainly sodium chloride rather than the expected sodium 1-chloronitroethane.

## Experimental[7]

**2-Bromo-2-nitropropane.**[8]—The following procedure was used for the preparation of a pure starting material. 2-Nitropropane[9] (178 g., 2 moles) was dissolved, with external cooling, in a solution of 132 g. 85% potassium hydroxide pellets in 500 cc. of water. The resulting solution of sodium 2-nitropropane was cooled in an ice-bath while bromine (320 g., 2 moles) was dropped in with stirring at such a rate as to maintain the temperature at 35–40°. After the addition was complete, the reaction mixture was usually colored red; solid sodium sulfite was added with vigorous stirring until the mixture became colorless. The heavy, oily layer of the bromonitroparaffin was separated from the water layer and washed twice with 100-cc. portions of water. The product, after drying over sodium sulfate, was essentially pure, since 99% distilled at 151.7–151.8° (745 mm.) forerun: 150.5–151.7°); yield 89%. Many of the 1-halonitroparaffins are lachrymators, and care should be exercised in their use.

**The Reaction of 2-Bromo-2-nitropropane with Sodium Malonic Ester.**—Sodium malonic ester (0.4 mole) was prepared in 200 cc. of absolute alcohol contained in a 500-cc. three-neck flask equipped with a stirrer, thermometer, dropping funnel and reflux condenser with calcium chloride tube attached (a similar set-up was used in the subsequently described experiments). 2-Bromo-2-nitropropane (33.6 g., 0.2 mole) was dropped in with stirring over a period of twenty-five minutes; the temperature of the contents was maintained at 35° by external cooling. Stirring was continued at room temperature for four hours. Petroleum ether (50 cc.) was added and the flask cooled in an ice-bath and the contents filtered. The colorless material collected was washed with petroleum ether and was then added to 200 cc. of water. The salts dissolved, and the white needles of ethane tetracarboxylic ester which floated on top were filtered off and dried at 60°; yield, 41.6 g., m.p. 72–73°. After two recrystallizations from alcohol–petroleum ether, the melting point was 75.0–75.3°, which was not depressed upon admixture with an authentic sample (m.p. 75.0–75.3°).[10] Approximately five additional g. of the ester may be obtained from the initial alcoholic mother liquor by removing the excess alcohol and adding an excess of water; the thick oil which comes down is redistilled under reduced pressure.

The identity of the sodium 2-nitropropane which was obtained mixed with the ester was indicated in the following way. The aqueous solution obtained when the mixture was added to water was acidified with sodium bisulfite, the resulting 2-nitropropane extracted with ether and identified by its boiling point and conversion to the blue monomeric isopropylpseudonitrole, $(CH_3)_2C(NO)NO_2$, by means of nitrous acid (red, white and blue test).

**Reaction of 2-Bromo-2-nitropropane with Sodium Ethyl Malonic Ester.**—2-Bromo-2-nitropropane (50.4 g., 0.3 mole) was added dropwise over a period of four minutes to a solution of 0.32 mole sodium ethyl malonic ester in 175 cc. absolute alcohol maintained at 40° by external cooling. Stirring was continued for ten minutes. The thick mush of sodium 2-nitropropane and sodium bromide which had formed was filtered off with suction and washed

(7) All melting points corrected. All yields based upon the amount of starting material consumed.

(9) Eastman Kodak Co. practical grade was redistilled with a Todd column: b. p. range, 119.7–120.0° (745 mm.)

(10) H. F. Finkelstein, *Ber.*, **43**, 1532 (1910).

with 50 cc. of ether. The salt mixture was then triturated with 200 cc. of ether and again filtered. The ether washings were added to the main filtrate. The excess ether and alcohol was removed by distillation under reduced pressure using a heating mantle; the internal temperature was not allowed to rise above 95°. After cooling to room temperature, 100 cc. of water was added and the two phases were allowed to stand overnight. After this time, a small amount of snow-white crystals had separated from the ethyl bromomalonic ester layer. It was filtered off, washed with a few cc. of ether and dried at room temperature (1.5 g.). The melting point 215.0–215.5° was not lowered upon mixing with 2,3-dinitro-2,3-dimethylbutane[2] (m.p. 215.5–216.0°, purified by sublimation). The halomalonic ester was separated from the water layer and the latter extracted with 50 cc. of ether. The combined ester and extract were dried over sodium sulfate. Fractionation was begun in a Todd column but had to be discontinued after a forerun of 14.5 g. ethyl malonic ester had been collected, since the dinitrohexane which sublimed at the same time clogged the narrow takeoff passage. Distillation was continued from a Claisen flask. Two rectifications gave 44.0 g. of ethyl bromomalonic ester, b.p. 121–124° (12 mm.). The product was contaminated with small amounts of the dinitrohexane, which could not be completely removed by further fractionation. The infrared spectrum of a middle cut was identical with that of an authentic sample[11] (b.p. 124.0° (11.5 mm.) cor.) which had been saturated with dinitrohexane for comparison purposes.

**Reaction of 2-Chloro-2-nitropropane with Sodium Malonic Ester.**—2-Chloro-2-nitropropane (24.7 g., 0.2 mole), b.p. 88.5–88.7° (174 mm.), was added in one lot to 0.4 mole of sodium malonic ester dissolved in 200 cc. absolute alcohol. Stirring was continued for sixty-five hours while the internal temperature was maintained at 40–45° by a heating mantle. Stirring was discontinued, and the mixture of salts which had precipitated was filtered out. The excess alcohol was then removed under reduced pressure and 100 cc. of water added. The ester layer was separated and one ether extract of the water layer added to it. After drying over sodium sulfate, fractionation was begun in a Todd column. After a forerun of malonic ester, 17.6 g. (44%) of isopropylidene malonic ester was collected. The remainder was distilled from a Claisen flask, yielding 19.6 (27%) of isopropylidene dimalonic ester (b.p. 195–200° (12 mm.)). The unsaturated ester was identified by a characteristic, known reaction:[12] the concomitant ammonation and hydrolytic cleavage to acetone (isolated as the semicarbazone, m.p. 190.0–191.5°) and malonamide (m.p. 173.2–173.6°; mixed m.p. 173.2–173.6°). The reported melting points of these compounds are, respectively, 190–191° and 170°.[13] The tetra-ester was hydrolyzed to 2,2-dimethyl-1,5-pentanedioic acid (m.p. 99.8–100.0°); the anhydride (m.p. 125.0–125.5°) and the monoanilide (m.p. 135.0–135.5°) were prepared. The melting points given in the literature are, respectively, 100–101°[14] (103–104°[15]), 124°[14] and 131°.[16]

**1-Nitro-1-methylethyl Ethyl Malonic Ester.**—2-Chloro-2-nitropropane (123.5 g., one mole) was added dropwise over a period of four to five hours to a refluxing, stirred solution of one mole of sodium ethyl malonic ester in 550 cc. of dry ether. Refluxing and stirring were continued for thirty-six hours. The excess ether was removed by distillation under diminished pressure and the crude ester isolated in the manner previously described. Fractionation with a Todd column gave 47 g. unreacted 2-chloro-2-nitropropane and 18.5 g. ethyl isopropyl malonic ester (b.p 129.5–132.0° (20 mm.); 231–234° (742 mm.)). Crossley and Le Sueur[17] give 232–233° as the boiling point of the latter compound. The remaining, undistilled ester was transferred to a Claisen flask and 116 g. of 1-nitro-1-methylethyl ethyl malonic ester collected at 161–165° (14.0 mm.). A middle cut boiling at 164.0° (14.0 mm.) was used for analysis.

*Anal.* Calcd. for $C_{12}H_{21}O_6N$: C, 52.42; H, 7.69; N, 5.09; mol. wt., 275; sapn. equiv., 91.8.[18] Found: C, 52.68, 52.56; H, 7.17, 7.06; N, 5.17; mol. wt. (Rast), 276; sapn. equiv., 89.8; $n^{22}D$ 1.4335. The Bose[19] method for the detection of a nitrite or nitro group was positive. The infrared spectrum of the ester showed distinct absorption maxima at 1550 and 1350 $cm.^{-1}$; the characteristic maxima of the nitro group are at 1550 and 1380 $cm.^{-1}$ whereas those of the nitrite group fall at 1660–1730 and 1160 $cm.^{-1}$.[20]

The infrared spectrum of the ethyl isopropylmalonic ester was not identical with that of an authentic sample; however, they were so nearly so that the slight discrepancy may be assumed to be due to an impurity in the experimental product.

**Acknowledgment.**—The authors wish to express their gratitude to the Commercial Solvents Corporation, who supplied the chloronitroparaffins used in this investigation.

## Summary

2-Bromo-2-nitropropane reacts with sodium malonic esters to give, as the initial products, sodium 2-nitropropane and bromomalonic esters. Additional products encountered are described. A "positive bromine ion" mechanism is proposed.

2-Chloro-2-nitropropane reacts normally with sodium malonic esters to give 1-nitro-1-methylethyl malonic esters as the initial products. In the case of the reaction with unsubstituted malonic ester, the nitroalkyl malonic ester is unstable and loses the elements of nitrous acid to yield isopropylidene malonic ester.

# Stereochemical Equilibration of Alcohols[1]

BY W. VON E. DOERING AND T. C. ASCHNER

From many examples in the literature,[2,3,4] it is apparent that alcohols of the general structure I may be brought to stereochemical equilibrium[5] by treatment with alkoxide ion. Both Wagner-Jauregg[2] and Hückel[3] have suggested that the equilibration is initiated by the dehydrogenation of sodium alcoholate to aldehyde or ketone which then takes part in a Meerwein–Ponndorf–Verley reduction and Oppenauer oxidation. Wagner-Jauregg has formulated

the reaction in general terms (A) and has left an explanation of the stereochemical equilibration of alcohols of type I to the more specific suggestions of Hückel (B) although, as has been pointed out,[4] recognition of the inevitable enolization of the carbonyl compounds related to alcohols of type I suffices to accommodate the stereochemical equilibration of the latter (C).

Doering, Cortes and Knox[4] have presented considerable evidence in support of the modified mechanism (A and C) but have been unable to demonstrate (in the case of quinine) the striking consequence of the mechanism, that optically active alcohols should not be racemized in the complete absence of oxidants. In the present work, it is shown that the racemization of (−)-phenylmethylcarbinol by potassium *t*-butoxide at 100° can be completely inhibited by excluding oxygen, potassium peroxides and carbonyl compounds, and that, under otherwise non-racemizing conditions, the addition of the rapid oxidation–reduction system,[6] fluorenone (3 mole %)–fluorenol (6 mole %), causes 56% racemization. In another example, (−)-2-methylbutanol-1, stable to boiling for twenty hours with 5 mole % of sodium, is racemized in a few hours by adding 5 mole % of benzophenone.[7] Similarly with aluminum isopropoxide as catalyst, no racemization occurs until an oxidant, benzophenone, is added.

These experiments establish with considerable certainty that the presence of carbonyl compound is a necessary condition for effecting the stereochemical equilibration of alcohols of type I and can be interpreted to mean that a reversible oxidation–reduction process is the essential mechanism of the equilibration. The further conclusion can be drawn that no initiating carbonyl compound is formed by the elimination of hydrogen gas as proposed by both Wagner-Jauregg and Hückel, at least not at the comparatively low temperature of these equilibrations, although at higher temperatures where alkoxide ion is known to decompose to hydrogen,[8] dehydrogenation may serve as a way of introducing initiating carbonyl compound.

The unique structural consequence of mechanism B, that it should be impossible stereochemically to equilibrate those secondary alcohols in which lack of α-hydrogen prohibits dehydrogenation to a related enolate ion, has been given temporary confirmation in the negative observation that α- and β-fenchol cannot be epimerized, even under conditions drastic enough to form the corresponding ketone, fenchone.[9] Contrarywise it has now been established that both α- and β-fenchol can be epimerized when the rapid oxidation–reduction system, fluorenol–fluorenone, is added. Coupled with the ability of non-enolizable ketones such as benzophenone and fluorenone to initiate stereochemical equilibration, the successful epimerization of the fenchols invalidates direct dehydrogenation to an enolate ion as the mechanism of the effectual oxidation–reduction process. Hückel's mechanism (B) is presumably generally incorrect in that it limits the reaction to alcohol–carbonyl systems having alpha hydrogen.

(1) This work, taken from a dissertation submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science of Columbia University, was presented at the 112th meeting of the American Chemical Society, September 7, 1947, New York, N. Y., by T. C. Aschner, present address, Smith, Kline and French Laboratories, Philadelphia, Pa.

(5) The term "stereochemical equilibration" is defined to embrace racemization, partial racemization, epimerization, and *cis-trans* interconversion, the specific process depending on the detailed structure of the alcohol under consideration.

(6) Baker and Adkins, THIS JOURNAL, **62**, 3305 (1940).

(7) In the absence of consciously added oxidant, Stevens [*ibid.*, **54**, 3732 (1932)] has observed a much slower rate of racemization.

(8) Hückel cites the Guerbet reaction and the inversion of *cis-cis*-α-decalol [Hückel and Naab, *Ber.*, **64**, 2137 (1931)]. Compare footnote 18 of ref. 4.

(9) Hückel, Kindler and Wolowski, *ibid.*, **77**, 220 (1944).

The failure to epimerize the fenchols in the presence of fenchone and the vain attempt to effect the partial racemization of quinine in the presence of quininone[4] clearly indicate that excessively slow rates of oxidation–reduction may conspire to make the necessary presence of carbonyl compound an insufficient condition for stereochemical equilibration. In these, as well as in less extreme cases, the stereochemical equilibration can be catalyzed by adding a much more rapid oxidation–reduction system.[6] For example, in the very slowly reacting fenchol–fenchone system (1), the addition of fluorenol and fluorenone, which interact very rapidly (2), introduces a cross reaction (3) of intermediate rate that results in the more rapid establishment of equilibrium (1).[10]

Fenchone* + Fenchol $\underset{\leftarrow}{\overset{\rightarrow}{(1)}}$ Fenchol* + Fenchone

Fluorenol* + Fluorenone $\underset{\leftarrow}{\overset{\rightarrow}{(2)}}$ Fluorenone* + Fluorenol

Fluorenol + Fenchone $\underset{\leftarrow}{\overset{\rightarrow}{(3)}}$ Fluorenone + Fenchol

## Experimental[11]

**Racemization of Phenylmethylcarbinol.**—(−)-Phenylmethylcarbinol, $[\alpha]^{27}D$ −50.6° ($c$ = 3, toluene), b.p. 86.5–87.5° (8 mm.), was obtained by resolution of the acid phthalate according to Downer and Kenyon.[12] Decomposition of the active acid phthalate and distillation of the active alcohol were carried out under nitrogen. The racemizations were effected in thiophene-free toluene which had been distilled repeatedly from sodium under nitrogen. Potassium $t$-butylate was prepared by dissolving freshly cut and carefully washed potassium in $t$-butyl alcohol in a nitrogen atmosphere. $t$-Butyl alcohol was purified by refluxing over potassium permanganate and twice distilling from sodium under nitrogen. Preliminary experiments, carried out in the simple apparatus customarily used to avoid contact with air, led to considerable and unpreventable racemization even in the absence of added oxidant. The more complicated apparatus shown in Fig. 1 prevented contamination by oxidants when employed according to the following procedure: After the system had been flushed with nitrogen, 10 cc. of toluene from flask A, containing purified toluene and 1 g. of sodium, was distilled under nitrogen into D. The remaining system was closed at G and E, D was detached and potassium, freshly cut and weighed under toluene, was quickly dropped into D which was then reattached to G and flushed with nitrogen through L, F and E. L and I were closed, G was opened and toluene was forced through E into F by nitrogen pressure. Five drops of $t$-butyl alcohol was added through B to A and was distilled with 10 cc. of toluene into D. All liquid was forced out of D into F as before and the surface of the potassium was further cleaned by rinsing with two additional 10-cc. portions of toluene distilled from A; $t$-butyl alcohol (3.0 g.) was added through B to A and was distilled into D with 10 cc. of toluene. Still under positive nitrogen pressure, D was heated in an oil-bath until all the potassium had reacted. A weighed amount of (−)-phenylmethylcarbinol was added through H to D and the volume in D was adjusted to 30 cc. by distilling additional toluene from A. All reagents added through H or B were forced into the system by applying excess nitrogen pressure. Finally D was heated in an oil-bath at 99–100°. In experiments 1 and 4, fluorenol and fluorenone in toluene were added to D through H prior to the final heating. After being cooled, the reaction mixture was forced into the cleaned flask F, and neutralized under nitrogen with dilute hydrochloric acid added through J. Phenylmethylcarbinol was isolated from reactions 1 to 3 by fractionation of the washed reaction mixtures through a 10-cm. Vigreux column, the specific rotation of the main fraction b.p. 203–204° (760 mm.), being determined at 27° ($c$ = 3, toluene). Partly racemized phenylmethylcarbinol from reaction 4 was separated from non-alcoholic impurities by conversion to the acid phthalate. Treatment of alkali-insoluble compounds extracted from the alkaline solution of the acid phthalate with 2,4-dinitrophenylhydrazine, yielded only 0.04 g. of acetophenone-2,4-dinitrophenylhydrazone. The results of these experiments are compiled in Table I.

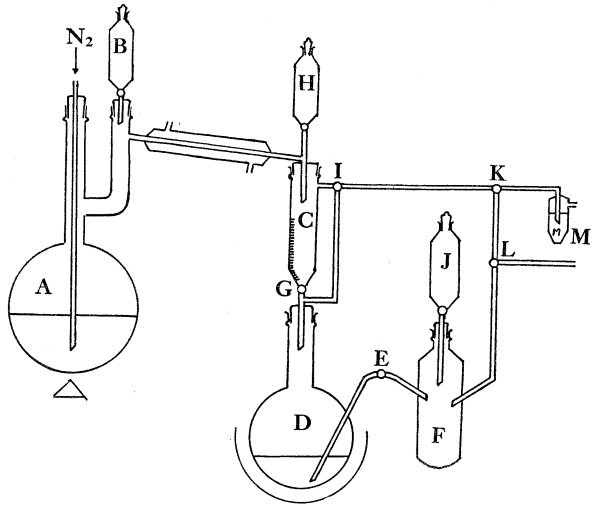

Fig. 1.

TABLE I

| Expt. | Potassium in mole % | $t$-Butyl alcohol in mole % | Phenylmethylcarbinol, g. | Reaction time, hours | $[\alpha]^{27}D$ of phenylmethylcarbinol | % Racemization |
|---|---|---|---|---|---|---|
| 1 | 20 | 100 | 2.0 | 19 | −49.3° | 2 |
| 2[a] | 20 | 100 | 2.0 | 17 | −27.5° | 46.5 |
| 3[b] | 20 | 100 | 4.0 | 17 | −49.4° | 2 |
| 4[b] | | | | 17 | −22.4° | 56 |

[a] Prior to the start of heating, 1 mole % of fluorenone and 2 mole % of fluorenol were added to the reaction mixture; [b] One-half of reaction 3 was forced into flask F after seventeen hours of heating and phenylmethylcarbinol was isolated; to the remaining reaction mixture, 3 mole % of fluorenone and 6 mole % of fluorenol were added and heating was continued seventeen hours longer (reaction 4).

**Racemization of (−)-2-Methylbutanol-1.**—From a commercially available fraction of fusel oil containing about 17% of (−)-2-methylbutanol-1, and about 80% of 3-methylbutanol-1, various fractions of (−)-2-methylbutanol-1 (75–100% optically active) were obtained by two fractionations (at a reflux ratio of 1:100) through a four-foot adiabatic column packed with metal helices.

From 2.2 to 8.8 g. of optically active alcohol was treated with sodium under an atmosphere of nitrogen or, in other experiments, was added to aluminum isopropoxide. The resulting alkoxide solution was then heated at 120° with or without previous addition of oxidants, for various periods of time under positive nitrogen pressure. After being cooled, the reaction mixture, made weakly acidic by adding hydrochloric acid, was extracted with 100 cc. of ether. The ether extract was washed with water, dried over

(10) It may be mentioned that the acceleration depends in no way on oxidation-reduction potentials; in fact, equilibrium concentrations could be chosen so that no concentration changes would accompany the acceleration of (1).

(11) All melting points are corrected.

(12) Downer and Kenyon, *J. Chem. Soc.*, 1156 (1939).

magnesium sulfate and fractionated through a 10 cm. Vigreux column. The fraction boiling at 127–128° was collected, the specific rotation being measured in methanol at 27°. From blank runs it was established that further purification of the recovered alcohol was not necessary. The results of various experiments are compiled in Table II.

TABLE II

| Catalyst in mole % | Added reagents in mole % | Reaction time, hours[a] | $[\alpha]^{27}D$ starting alcohol[b] | $[\alpha]^{27}D$ recovered alcohol | Racemization in % |
|---|---|---|---|---|---|

[a] Reaction temperature was 120°. [b] The specific rotations were measured in methanol ($c$ = 3). Starting materials with identical specific rotations were obtained from the same sample. [c] Sodium. [d] Aluminum isopropoxide.

**Epimerization of α- and β-Fenchol.**—α-Fenchol was prepared from purified $d$-fenchone by reduction with sodium and amyl alcohol[13]; m.p. 43.6–44.5°, $[\alpha]^{27}D$ −12.7° ($c$ = 3, 95% ethanol); acid phthalate, m.p. 145–146°, $[\alpha]^{27}D$ + 20.2° ($c$ = 5, methanol). β-Fenchol was prepared by catalytic reduction of $d$-fenchone with copper chromite catalyst in ethanol at 100 atmospheres and 110°.[14] The alcohol was isolated from the reduction mixture via the acid phthalate (twice crystallized from $n$-hexane), m.p. 151–151.6° $[\alpha]^{22}D$ + 11.7° ($c$ = 4, ethanol), which yielded upon hydrolysis and fractionation of the hydrolysate in a molecular still, 94.4% pure β-fenchol, $[\alpha]^{27}D$ −21.8° ($c$ = 4, ethanol).

A mixture of 7.7 g. of β-fenchol (0.05 mole), 9.1 g. of fluorenol (0.05 mole) and 0.91 g. of fluorenone (0.005 mole) in 38 cc. of $t$-butyl alcohol containing 0.12 g. of sodium (0.005 mole) was heated in a bomb-tube under nitrogen for seventy hours at 165°. The high-boiling fraction [7 g., b.p. 83–86° (20 mm.)] of the neutralized reaction mixture was heated twenty-five hours with 7.0 g. of phthalic anhydride in 8.5 g. of pyridine at 100° to give 9.6 g. of crude fenchyl acid phthalate, which was crystallized from glacial acetic acid. The first crop (4.8 g., m.p. 139–141°, $[\alpha]^{27}D$ +17.2°) yielded after two recrystallizations from the same solvent, 3.0 g. of α-fenchyl acid phthalate, m.p. 145–145.6°, $[\alpha]^{27}D$ +20.8° ($c$ = 3, ethanol); the second crop (3.0 g., m.p. 138–143.5°, $[\alpha]^{27}D$ + 14.1°) yielded after three recrystallizations from glacial acetic acid an additional 0.48 g., m.p. 143–145.2°, $[\alpha]^{27}D$ + 19.1°. Hydrolysis and sublimation of the combined samples of α-fenchyl acid phthalate yielded 1.1 g. of α-fenchol, $[\alpha]^{27}D$ −12.2° ($c$ = 4, ethanol), m.p. 43.5–44.6°, mixed m.p. 43.5–44.5°. The combined acid phthalate mother liquors yielded after three recrystallizations from $n$-hexane 3.0 g. of solid, m.p. 148–149.5°, $[\alpha]^{27}D$ + 13.8° ($c$ = 3, ethanol), from which 1.1 g. of β-fenchol was recovered upon hydrolysis, $[\alpha]^{27}D$ −19.0° ($c$ = 3, ethanol).

A mixture of 6.1 g. of α-fenchol (0.04 mole), 7.3 g. of fluorenol (0.04 mole) and 0.75 g. of fluorenone (0.004 mole) in 30 g. of butyl alcohol containing 0.09 g. of sodium (0.004 mole) was heated in a bomb-tube under nitrogen for thirty-five hours at 160–180°. After removal of solvent from the neutralized reaction mixture, fenchol was co-distilled with 12 cc. of decalin from the residue of fluorenol and fluorenone. From the distillate, b.p. 118–119° (100 mm.), fenchol (3.6 g., $[\alpha]^{22}D$ −14.9°) was separated by conversion to the acid phthalate, extraction of neutral impurities, hydrolysis, steam distillation and fractionation. Upon redistillation through a molecular still, some α-fenchol crystallized on the cold finger and the distillate was thus further enriched in β-fenchol[15], $[\alpha]^{27}D$ −15.7° ($c$ = 2, ethanol).

## Summary

From the fact that (−)-phenylmethylcarbinol and (−)-2-methylbutanol-1 are not racemized by alkoxide ion in the complete absence of oxidants but are racemized in the presence of ketones, it is concluded that the stereochemical equilibration of alcohols () is accomplished through an oxidation–reduction mechanism. α- and β-fenchols, thought previously to be unepimerizable because of lack of α-hydrogen, have now been epimerized.

NEW YORK 27, N. Y. RECEIVED SEPTEMBER 20, 1948

(13) Gardner, *J. Chem. Soc.*, **73**, 276 (1898).

(14) We are grateful to Dr. H. R. Snyder for suggesting and carrying out, in the laboratories of the University of Illinois, the reduction of $d$-fenchone with copper chromite catalyst, when Raney nickel failed.

(15) In agreement with Hückel's findings,[9] we were unable to isolate pure β-fenchol from the mixture which contained a substantial excess of α-fenchol. However, the change in specific rotation from −12.7° to −15.7° can only be assigned to the formation of β-fenchol, since the likely optically active contaminant, fenchone ($[\alpha]^{27}D$ +62°), would have changed the rotation in the opposite direction.

# Some Observations on the Dakin–West Reaction

BY GEORGE H. CLELAND AND CARL NIEMANN

The reaction of α-amino acids with acetic anhydride in the presence of a base to give α-acetamidoalkyl methyl ketones[1,2] was recognized as an aldol reaction by Dakin and West[2] and it appears[1–3] that the over-all reaction proceeds through acetylation of the amino acid, cyclization to the azlactone, reaction of the latter compound with base to give a resonance stabilized carbanion, the reaction of this ion with acetic anhydride to give the azlactone of an α-acetamido-β-keto acid and acetate ion, and the subsequent conversion of this azlactone to the acetamido ketone and carbon dioxide. The mechanism of the last transformation is obscure though it is probable that it may be dependent upon an attack by acetate ion upon the azlactone of the α-acetamido-β-keto acid.

Although many α-acetamidoalkyl methyl ketones have been prepared *via* the Dakin–West reaction[1–5] the applicability of this reaction to the preparation of ketones other than methyl ketones has not been explored beyond Dakin and West's observation that "the homologues of acetic anhydride are much less reactive than the latter substance" and the recent report of Wiley and Borum[6] relative to the formation of 1-phenyl-1-propionamido-2-butanone from α-aminophenylacetic acid and propionic anhydride. The fact that a number of α-amino acids react smoothly in the presence of pyridine with such diverse acid anhydrides as propionic, butyric, methoxyacetic, and benzoic anhydrides to give the corresponding acylamidoalkylethyl, propyl, methoxymethyl, and phenyl ketones indicates that the reaction is generally applicable to acyclic alkyl and aryl acid anhydrides. The reaction of acetyl chloride with α-amino acids in the presence of pyridine[2] was found difficult to control and with both acetyl and benzoyl chloride the ketones were obtained in poor yield. However benzoyl fluoride was found to react smoothly in the presence of pyridine with the single α-amino acid investigated to give good yields of the corresponding acylamidoalkylphenyl ketone and it appears that the acyl fluoride may be used in lieu of the acid anhydride in the Dakin–West reaction.

The preparation of oxazoles by the dehydration of the crude reaction product obtained by treating an α-amino acid with acetic anhydride and sodium acetate[7,8] has been interpreted by Wiley[6,9] as proceeding through the intermediate α-acetamidoalkyl methyl ketone. In view of the above observations and those of Attenburrow, *et al.*,[3] it was not surprising to find that with an α-amino acid such as phenylalanine comparable yields of the α-acetamidobenzyl methyl ketone were obtained by using either pyridine or sodium acetate as a condensing agent. The difference in the behavior of pyridine and of acylate ion noted by Attenburrow, *et al.*,[3] in the case of glycine may be explained on the basis of the greater basic strength of the acylate ion favoring more complete formation of the ion, which would be expected to be more inert toward ring cleavage and subsequent decarboxylation than the corresponding acid. The difference noted by Dakin and West[2] and by Wiley and Borum[6] in the behavior of glycine and the other α-amino acids is also explainable in terms of the formation of the above resonance stabilized ion in the case of glycine and the impossibility of its formation in the case of the other α-amino acids.

From Dakin and West's observations[2] one would expect that a dipeptide would react with acetic anhydride in the presence of a base to give one equivalent of carbon dioxide and that the corresponding diketopiperazine would not react at all. These expectations have been realized and it may be concluded that all evidence is consistent with the previously stated proposition[2] that only those α-amino acids or their derivatives which are capable of forming azlactones containing an active α-hydrogen atom will undergo the Dakin-West reaction. Complicating competitive reactions are to be found in the case of the β-hydroxy-α-amino acids where the base catalyzed intermolecular dehydration reaction takes obvious precedence over the intramolecular carbonyl addition reaction and in the case of glutamic acid where pyrrolidone carboxylic acid formation limits azlactone formation.[2]

## Experimental[10]

**1-Phenyl-2-acetamido-3-butanone.**[2]—(A) A mixture of 12.4 g. (0.075 mole) of DL-phenylalanine, 39.3 g. (0.5 mole) of pyridine and 65.2 g. (0.64 mole) of acetic anhydride was heated on a steam-bath for five hours, steam distilled until free of pyridine, the residue treated with an excess of aqueous sodium bicarbonate, and extracted with six 100-ml. portions of ether. The ethereal extract was dried, the solvent removed and the waxy orange-yellow solid recrystallized twice from xylene to give 12.1 g. (79%) of 1-phenyl-2-acetamido-3-butanone,[2] colorless needles, m. p. 98–99° (cor.).

(B) A mixture of 1.65 g. (0.01 mole) of DL-phenylalanine, 4 g. (0.05 mole) of anhydrous sodium acetate and 10.8 g. (0.11 mole) of acetic anhydride was heated with stirring for thirty minutes at 130–135°, and the reaction product worked up substantially as described in (A) to give 0.94 g. (46%) of acetamidoketone, colorless needles, m.p. 98–99° (cor.).

(C) A mixture of 2 g. (0.012 mole) of DL-phenylalanine, 7.9 g. (0.1 mole) of pyridine and 8.8 g. (0.11 mole) of acetyl chloride was heated with stirring for one hour at 60° and the reaction mixture worked up as described previously to give 0.15 g. (8%) of 1-phenyl-2-acetamido-3-butanone, colorless needles, m. p. 97–99° (cor.) after one recrystallization from xylene.

**1-Phenyl-2-propionamido-3-pentanone.**—A mixture of 3.3 g. (0.02 mole) of DL-phenylalanine, 16 g. (0.2 mole) of pyridine and 26 g. (0.2 mole) of propionic anhydride was refluxed at 140–145° for thirty minutes, the solution concentrated *in vacuo*, treated with an excess of aqueous sodium bicarbonate, extracted successively with two 100-ml. portions of ether and of chloroform, the non-aqueous phases combined, dried, and the solvents evaporated to give approx. 5 g. of a light-orange oil. The oil was taken up in hot ligroin, b. p. 90–130°, filtered, the volume reduced to 25 ml., and the solution stored at 5° overnight. The colorless needles so obtained were recrystallized first from ligroin and then from aqueous-acetone to give 1.7 g. (36%) of 1-phenyl-2-propionamido-3-pentanone, colorless needles, m. p. 67–68° (cor.). In a second experiment the reaction mixture resulting from heating 5 g. (0.03 mole) of DL-phenylalanine, 16 g. (0.2 mole) of pyridine and 26 g. (0.2 mole) of propionic anhydride at 135° for one and one-half hours was fractionally distilled to give 2.9 g. (41%) of 1-phenyl-2-propionamido-3-pentanone, colorless needles, m. p. 67–68° (cor.).

*Anal.* Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2; N, 6.0. Found: C, 71.9; H, 8.2; N, 5.9.

The oxime, colorless needles, m. p. 152–153° (cor.), was recrystallized from 95% ethanol.

*Anal.* Calcd. for $C_{14}H_{20}O_2N_2$: C, 67.7; H, 8.1; N, 11.3. Found: C, 67.6; H, 8.4; N, 11.1.

The 2,4-dinitrophenylhydrazone, yellow needles, m. p. 153–154° (cor.), was recrystallized alternately from ethyl acetate and 95% ethanol.

*Anal.* Calcd. for $C_{20}H_{23}O_5N_5$: N, 16.9. Found: N, 16.8.

**1-Phenyl-2-butyramido-3-hexanone.**—A mixture of 3.3 g. (0.02 mole) of DL-phenylalanine, 16 g. (0.2 mole) of pyridine and 40 g. (0.25 mole) of butyric anhydride was heated for three hours at 145–150°, and the reaction product worked up as described for the preceding preparation to give a light-orange oil which crystallized upon standing at 5°. This product was recrystallized successively from xylene and ligroin, 30–60°, to give 1.4 g. (27%) of 1-phenyl-2-butyramido-3-hexanone, colorless needles, m. p. 59–60° (cor.).

*Anal.* Calcd. for $C_{16}H_{23}O_2N$: C, 73.5; H, 8.9; N, 5.4. Found: C, 73.6; H, 8.7; N, 5.4.

The oxime, colorless needles, m. p. 145–146° (cor.) was recrystallized twice from water.

*Anal.* Calcd. for $C_{16}H_{24}O_2N_3$: C, 69.5; H, 8.8; N, 10.1. Found: C, 69.3; H, 8.7; N, 10.1.

The 2,4-dinitrophenylhydrazone, bright yellow needles, m. p. 173–174° (cor.) was obtained after successive recrystallization from ethanol and ethyl acetate.

*Anal.* Calcd. for $C_{22}H_{27}O_5N_5$: C, 59.9; H, 6.2; N, 15.9. Found: C, 60.1; H, 6.4; N, 16.0.

**1-Methoxy-3-methoxyacetamido-4-phenyl-2-butanone.**—A mixture of 5 g. (0.03 mole) of DL-phenylalanine, 12 g. (0.15 mole) of pyridine and 24 g. (0.15 mole) of methoxyacetic anhydride[11] was heated with stirring at 115° for one hour, the solution evaporated *in vacuo*, the residue treated with an excess of aqueous sodium bicarbonate, extracted successively with two 100-ml. portions of ether and of chloroform, the non-aqueous phases combined, dried, the solvents removed, the residual oil taken up in 60% ethanol, the solution treated with Norite, filtered, and the solvents evaporated to give 6.2 g. (78%) of a neutral light-yellow oil which could not be induced to crystallize. A portion of the oil was treated with *p*-nitrophenylhydrazine to give a *p*-nitrophenylhydrazone, stout orange rhombs, m. p. 179–181° (cor.) after two recrystallizations from 95% ethanol.

*Anal.* Calcd. for $C_{20}H_{24}O_5N_4$: C, 60.0; H, 6.0; N, 14.0. Found: C, 60.2; H, 6.1; N, 14.1.

The 2,4-dinitrophenylhydrazone was obtained as light-yellow needles, m. p. 168–169° (cor.) after two recrystallizations from chloroform.

*Anal.* Calcd. for $C_{20}H_{23}O_7N_5$: C, 53.9; H, 5.2; N, 15.7. Found: C, 53.8; H, 5.2; N, 15.8.

The semicarbazone, rosettes of colorless needles, m. p. 116–117° (cor.), was recrystallized twice from water.

*Anal.* Calcd. for $C_{15}H_{22}O_4N_4$: C, 55.9; H, 6.9; N, 17.4. Found: C, 55.7; H, 7.0; N, 17.5.

**α-Benzamidopropiophenone.**—A mixture of 3 g. (0.034 mole) of DL-alanine, 12 g. (0.15 mole) of pyridine and 34 g. (0.15 mole) of benzoic anhydride[12] was heated with stirring at 130–135° for two and one-half hours, and the reaction product worked up as previously described. The solid obtained was recrystallized once from ligroin and twice from aqueous ethanol to give 3.6 g. (42%) of α-benzamidopropiophenone, colorless prisms, m. p. 104–105° (cor.). α-Benzamidopropiophenone has been reported to have a m. p. of 103°[13] and 104–105°.[14]

*Anal.* Calcd. for $C_{16}H_{15}O_2N$: C, 75.9; H, 6.0; N, 5.5. Found: C, 76.0; H, 6.0; N, 5.4.

The oxime, rosettes of colorless needles, m. p. 157–158° (cor.), was recrystallized twice from aqueous ethanol.

*Anal.* Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.6; H, 6.0; N, 10.4. Found: C, 71.9; H, 6.2; N, 10.3.

The ketone (3 g.) in 3 ml. of cold concd. sulfuric acid was diluted with ice water, the solid collected, washed with water and recrystallized twice from ligroin to give 2,5-diphenyl-4-methyl-oxazole, prisms, m. p. 81–82° (cor.). Lister and Robinson[14] give a m. p. of 82°.

*Anal.* Calcd. for $C_{16}H_{13}ON$: C, 81.7; H, 5.6; N, 6.0. Found: C, 81.8; H, 5.7; N, 5.8.

**α-Benzamido-β-phenyl-propiophenone.**—(A) A stirred mixture of 2.5 g. (0.015 mole) of DL-phenylalanine, 8 g. (0.10 mole) of pyridine, and 22.5 g. of benzoic anhydride (0.10 mole) was heated at 140–145° for two hours. The reaction mixture was worked up as described for α-benzamidopropiophenone to give 2.2 g. (44%) of α-benzamido-β-phenyl-propiophenone, long colorless needles, m. p. 146–147° (cor.) after two recrystallizations from aqueous-ethanol.

*Anal.* Calcd. for $C_{22}H_{19}O_2N$: C, 80.2; H, 5.8; N, 4.3. Found: C, 80.3; H, 5.8; N, 4.3.

(10) In the following experiments no attempt has been made to determine the conditions leading to maximum yields.

(11) Prepared by a method similar to that described by Allen, *et al.*, "Organic Syntheses," **26**, 1 (1946).

(12) Clarke, *et al.*, "Organic Syntheses," Coll. Vol. **1**, 91 (1941).

(13) Behr-Bregowski, *Ber.*, **30**, 1515 (1897).

(14) Lister and Robinson, *J. Chem. Soc.*, **101**, 1297 (1912).

The oxime was obtained after two recrystallizations from 95% ethanol as colorless needles, m. p. 188–189° (cor.).

*Anal.* Calcd. for $C_{22}H_{20}O_2N_2$: C, 76.7; H, 5.8; N, 8.1. Found: C, 76.7; H, 6.0; N, 8.0.

A solution of 0.4 g. of α-benzamido-β-phenyl-propiophenone in 30 ml. of 6 *N* hydrochloric acid and 10 ml. of ethanol was refluxed for three hours, the solvents removed, the residue extracted with ether, and dissolved in 10 ml. of ethanol. The addition of 25 ml. of ether gave the hydrochloride of α-amino-β-phenylpropiophenone, lustrous needles, m. p. > 200° with decomposition.

*Anal.* Calcd. for $C_{15}H_{16}ONCl$: C, 68.8; H, 6.2; N, 5.4; Cl,13.6. Found: C, 68.6; H, 6.4; N, 5.2; Cl, 13.8.

(B) A mixture of 2.7 g. (0.01 mole) of N-benzoyl-DL-phenylalanine, 5.9 g. (0.075 mole) of pyridine and 11.3 g. (0.05 mole) of benzoic anhydride heated at 135–140° for two hours with stirring when treated as described above gave 1.2 g. (36%) of α-benzamido-β-phenylpropiophenone, colorless needles, m. p. 146–147° (cor.).

(C) When 2 g. (0.012 mole) of DL-phenylalanine, 7.9 g. (0.1 mole) of pyridine, and 17 g. (0.12 mole) of benzoyl chloride was heated for one hour at 135–140°, 39–42% of the anticipated quantity of carbon dioxide was evolved but on working up the dark tarry reaction product only 0.36 g. (9%) of α-benzamido-β-phenyl-propiophenone, m. p. 146–147° (cor.), was obtained.

(D) A mixture of 2 g. (0.012 mole) of DL-phenylalanine, 7.9 g. (0.1 mole) of pyridine and 12.5 g. (0.1 mole) of benzoyl fluoride[15] was heated for two hours at 135–140° with stirring and from the reaction mixture there was obtained 1.55 g. (39%) of α-benzamido-β-phenylpropiophenone, m. p. 146–147° (cor.).

(15) Meslans and Girardet, *Bull. soc. chim.*, [3] **15**, 877 (1896).

**Studies Based upon Evolution of Carbon Dioxide.**—A mechanically stirred mixture of 0.7 g. (0.0044 mole) of DL-alanylalanine, 3.6 g. (0.045 mole) of pyridine, and 4.6 g. (0.045 mole) of acetic anhydride heated for two hours at 110–115° gave 0.004 mole of carbon dioxide. In a second experiment heating for one and one-half hours at 115° gave 92% of the anticipated amount of carbon dioxide (one equivalent) and when the reaction mixture was refluxed with 6 *N* hydrochloric acid no more carbon dioxide was obtained.

A mixture of 0.44 g. (0.004 mole) dimethyldiketopiperazine, 2 g. (0.025 mole) of pyridine and 3.6 g. (0.035 mole) of acetic anhydride was heated with stirring at 120° for two hours. No carbon dioxide was evolved during this period nor after refluxing with 6 *N* hydrochloric acid.

## Summary

The Dakin–West reaction has been shown to be applicable to the synthesis of α-acylamidoalkyl aryl ketones as well as to the synthesis of α-acylamidoalkyl alkyl ketones other than methyl ketones. It has been found that acetate ion may be used in lieu of pyridine as a condensing agent and that the acid anhydride may be replaced by the corresponding acyl fluoride. The nature of the base catalyzed reaction involving a dipeptide and an acid anhydride has been considered in a preliminary manner.

# The Use of Carbon-14 in the Determination of the Structures of Aldoketene Dimers[1,2]

BY JOHN D. ROBERTS, ROSE ARMSTRONG, R. F. TRIMBLE, JR., AND MARION BURG

The structures of aldoketene dimers prepared by the dehydrohalogenation of acyl halides have not been conclusively established. Recent infrared spectroscopic studies by Miller and Koch[3] indicate that the parent compound, diketene, is probably an equilibrium mixture of compounds having structures II and III although IV could not be excluded as a component of the mixture by the infrared data.

It was considered that I and V were unlikely because of the absence of absorption at the characteristic hydroxyl and C=C=O frequencies.

(1) Assisted by the joint program of the Office of Naval Research and the Atomic Energy Commission.

(2) Presented at the St. Louis Meeting of the American Chemical Society, September 7, 1948.

(3) Miller and Koch, THIS JOURNAL, **70**, 1890 (1948).

The higher aldoketene dimers prepared from acyl halides by the Wedekind procedure[4,5,6,7] have chemical and physical properties which are generally similar to those of diketene and presumably present a similar structural problem.[8] It is apparently agreed that the dimers of dialkyl-substituted ketenes (ketoketene dimers) have tetraalkylcyclobutanedione-1,3 structures.[6]

In the present investigation the isotopic tracer

(8) Two seemingly isomeric forms have been reported for methylketene dimer. A liquid, b. p. 50–52° (9 mm.), has been prepared from the dehydrohalogenation of propionyl chloride[5,7] having properties similar to those of diketene and a solid form, m. p. 140°, has been obtained from the polymerization of methylketene prepared from the debromination of α-bromopropionyl bromide with zinc by Staudinger and Klever, *Ber.*, **41**, 906 (1908); Staudinger, *ibid.*, **44**, 533 (1911). The solid compound has also been synthesized by Schroeter, *ibid.*, **49**, 2697 (1916); **53**, 1917 (1920); **59**, 977 (1926), from diethyl α,α′-dimethylacetonedicarboxylate. The structure, 1,3-dimethylcyclobutene-2-ol-4-one was assigned to the solid compound by Staudinger on the basis of its pronounced enolic properties. However, this assignment can only be regarded as tentative in the absence of a molecular weight determination.

technique was used to show that a mixed dimer of methyl- and hexylketenes which was convertible to alkylacetoacetic esters with alcohol probably does not have a structure similar to IV or V. The method utilized the mixed dimer[7] prepared by the Wedekind reaction from $C^{14}$ carbonyl-labeled propionyl and unlabeled capryloyl chlorides and was based on the fact that IV is unique among the five structures proposed for ketene dimers in having two equivalent carbonyl groups. If any of the mixed dimer had the cyclobutanedione-1,3 structure (VI), treatment of this material with alcohol would be expected to give a mixture of four different substituted acetoacetic esters, VII, VIII, IX, and X.

The esters constitute two pairs (VII and X or VIII and IX) comprised of chemically but not isotopically equivalent components. Regardless of the ratio of formation, (VII + X)/(VIII + IX), the equivalence of the carbonyl groups in VI would be expected to make VII/X and VIII/IX equal to unity.[9] Cleavage of the $\beta$-ketoester mixture derived from the dimer with sodium ethoxide would result in the formation of *radioactive* ethyl caprylate. If all of the mixed dimer had the structure VI then the radioactive carbon atoms would be expected to be distributed equally between the ethyl propionate and ethyl caprylate fractions. Similar results should be obtained from a structure like V since this form should be formed from VI and possess for an instant, at least, the symmetry of VI.

If the mixed dimer had a structure related to I, II or III it could exist in two forms depending on which ketene furnished the C=C=O group of a structure like I, or the carbonyl groups of the lactonic structures similar to II or III. Regardless of the mixture of dimers, degradation through the substituted acetoacetic esters should give only *non-radioactive* caprylic acid derivatives. These reactions are illustrated below using structure II as an example.

In the present investigation, the carbonyl-labeled propionyl chloride was prepared from carboxyl-labeled propionic acid which was made from ethylmagnesium chloride and radioactive carbon dioxide.[10] The mixed dimer was made following the directions of Sauer[7] and was separated from the simultaneously formed methyl- and hexylketene dimers by fractional distillation. The mixed dimer was degraded through the substituted acetoacetic esters as outlined above. Since the separation of a small amount of ethyl propionate from ethyl alcohol is not possible by

(9) It is recognized that differences in the zero-point energies of $C^{12}$–$C^{14}$ and $C^{12}$–$C^{12}$ bonds may prevent the bonds of an isotopic cyclobutanedione-1,3 ring from cleaving so as to give exactly the expected product ratios. An effect of this type has been reported by Calvin (paper presented at the Chicago Meeting of the American Chemical Society, April 21, 1948) for the decarboxylation of carboxyl-labeled malonic acid. In the present case, the error so introduced should probably not amount to more than 5%.

(10) The carbon dioxide was prepared from $C^{14}$-barium carbonate supplied by the Clinton Laboratories, Oak Ridge, Tenn., and obtained on allocation from the U. S. Atomic Energy Commission.

distillation the mixture of esters was saponified and the resulting propionic and caprylic acids separated by fractional distillation. The radioactivity analyses were made by the previously reported procedure.[11] The results are summarized in Table I.

TABLE I

RADIOACTIVITY ANALYSES

| Compound | Measured activity, counts/min.[a] | No. of tagged positions per molecule | Counts/min./mg. of $BaCO_3$/tagged position[b] |
|---|---|---|---|
| Methylketene dimer | 372 | 2 | 390 |
| Hexylketene dimer | 10[c] | 2[d] | 28 |
| $CO_2$ from decarboxylation of ethyl α-capryloylcaprylate | 5 | 1[e] | 2 |
| Mixed dimer (methyl- and hexyl- ketenes) | 105 | 1 | 400 |
| Acetoacetic esters from mixed dimer | 94 | 1 | 420 |
| $CO_2$ from decarboxylation of acetoacetic ester mixture | 806 | 1 | 280 |
| Propionic acid | 374 | 1 | 390 |
| Caprylic acid (Frac. 1) | 8.6 (2)[f] | 1 | 6[g] |
| (Frac. 2) | 9.7 (3)[f] | 1 | 8[g] |
| (Frac. 3) | 8.8 (2)[f] | 1 | 6[g] |
| Propionic acid[h] | 294 | | |
| Caprylic acid[h] (Frac. 1) | 6.2 | | |
| (Frac. 2) | 4.1 | | |

[a] Activity (corrected for background) of "infinitely thick" barium carbonate samples having a cross-sectional area of 2.90 cm.² measured with a Lauritsen electroscope (see Ref. 11) or a methane-filled windowless counter ("Nucleometer") manufactured by the Radiation Counter Laboratories. [b] Corrected for self absorption, calculated from (specific activity) × (number of carbon atoms)/(number of labeled positions). [c] The activity of this material must be due to impurities since the activity of the carbon dioxide from the decarboxylation of a sample of ethyl α-capryloylcaprylate prepared from the dimer was much lower. [d] Two tagged positions were assumed since the carbonyl groups are equivalent in this compound. [e] The number of tagged positions is taken as unity since the specific activity of the carbonyl positions is the important consideration and the activity would not be increased even if both carbonyl positions were decarbonylated at once. [f] Values in parentheses are corrected for the efficiency of the separation of the propionic and caprylic acids. The correction factor was taken as (6.2 + 4.1) (374)/2 (294) = 6.6 counts/min. [g] Corrected for efficiency of the separation process. [h] Blank separation using radioactive and non-radioactive caprylic acids.

The activity of the caprylic acid (corrected for the efficiency of the separation of propionic and caprylic acids in the apparatus used) from the degradation of the mixed dimer was 1.5% of the activity per labeled carbon atom of the mixed dimer. From this value, the maximum amount of the material in the mixed dimer with structure VI which is convertible to acetoacetic esters with alcohol is 3%.

With the knowledge that practically none of the mixed dimer has the VI structure it is possible to determine the composition of the forms XI and XII (or the corresponding unsymmetrical compounds derived from I or III) of the dimer by radioactive analysis of the carbon dioxide formed by decarboxylation of the acetoacetic acids resulting from the hydrolysis of the mixture of esters, VIII and X. The carbon dioxide so formed had 67% of the activity of the acetoacetic ester mixture and hence the composition of the original mixed dimers must be 33% of XI and 67% of XII.

In order to effectively utilize the information obtained from the radiochemical work a comparison was made between the physical properties of diketene, methylketene dimer, hexylketene dimer and the mixed dimer. The dipole moments (Table II) which were determined in benzene solution are large and quite close together. If the hypothesis is accepted that all of the compounds have similar structures the increase in moment (0.25 *D*) in going up the series from diketene to hexylketene dimer may well be due to induced moments in the long alkyl side chains. The molar refractivities of the compounds (Table II) are in best agreement with the lactone structures although some exaltation is noticed as might be expected for small ring structures.

The ultraviolet absorption spectra (Fig. 1) were determined in cyclohexane and may be taken as indicating that diketene is different in structure from the other aldoketene dimers. The spectrum of diketene has previously been interpreted by Calvin, Magel and Hurd[12] as being in agreement with expectations for form II. The differences in

[a] Non-radioactive materials prepared by the methods of Sauer (ref. 7). [b] Data for calculation of $P_\infty$ given in Table III [c] Oesper and Smyth, THIS JOURNAL, **64**, 768 (1942), report 3.31 $D$ in benzene solution.

ultraviolet spectra between diketene and the higher aldoketene dimers might be due to considerably higher proportions of substances corresponding to III in the higher dimers although this conclusion may not be safe in view of the small extinction coefficient of the 312 mμ absorption maximum of diketene and the unknown influence which substitution of alkyl groups might have on the spectrum of II.

The infrared and Raman spectra of all four dimers have been obtained by Dr. R. C. Lord, Jr., Mr. R. S. McDonald, and Mr. E. J. Slowinski, to whom we are much indebted. The spectra, which will be published in detail later, are in satisfactory agreement with those previously reported[3,13,14] although the infrared spectrum of diketene shows a double peak at about 1060 cm.$^{-1}$ which has been reported earlier as a single shoulder on the 1020 cm.$^{-1}$ bond by Whiffen and Thompson.[13]

The infrared and Raman absorption of all of the dimers are similar and seem to be consistent with the lactone structures, II and III. The absence of absorption at 2153 cm.$^{-1}$ and above 3200 cm.$^{-1}$ typical of C=C=O and OH groups, respectively, appears to exclude structures I and V for all of the compounds. The presence of three widely separated C—H stretching frequencies at 2972, 3024 and 3120 cm.$^{-1}$ is in agreement with the conclusion that diketene is not a single pure compound since none of the structures I–V have more than two different varieties of C–H bonds.

The physical evidence is generally consistent with the hypothesis that the aldoketene dimers prepared in the present work have similar structures. The physical evidence in conjunction with the tracer study favors the assignment of structures of the type II or III which may be in equilibrium as suggested by Miller and Koch.[3]

**Acknowledgment.**—We wish to acknowledge the assistance of Miss Winifred Bennett with the radioactivity analyses and Mr. D. R. Smith with the preparation of the radioactive propionyl chloride.

## Experimental

**Preparation of Mixed Dimer of Methyl- and Hexylketenes.**—The preparation was carried out as described by Sauer.[7] The procedure is described in detail since consistent yields were not always obtained using other conditions. A solution containing 37 g. (0.4 mole) of carbonyl-labeled propionyl chloride (0.015 mc. of $C^{14}$) and 65 g. (0.4 mole) of capryloyl chloride in 500 ml. of dry ether was placed under nitrogen in a 2-l. three-necked flask equipped with Dry Ice condenser, efficient sealed stirrer and dropping funnel. To the stirred solution was added dropwise 80.9 g. (0.8 mole) of purified triethylamine[7] over a period of three hours. The reaction mixture was allowed to stand at room temperature for three days and the solution of the ketene dimers separated from the amine salt by inverted filtration. The ethereal solution was concentrated under reduced pressure and finally distilled at 0.1 mm. using a Dry Ice-cooled receiver. The distillate was fractionated under reduced pressure using a 1.5 × 35 cm. Vigreux column equipped with a total condensation partial take-off distilling head. The yields were: methylketene dimer, b. p. 41–49° (11.5 mm.), 5.5 g. (24.5%); hexylketene dimer, b. p. 148° (1.3 mm.), 12.0 g. (24%); and mixed dimer, b. p. 86–89.5° (1.3 mm.), 18.6 g. (25.5%). Intermediate fractions amounted to 7.1 g. and 5.2 g. of brown viscous residue remained.

**Degradation of Mixed Dimer.**—The mixed dimer (10.4 g., 0.057 mole) was refluxed with 23 g. of absolute alcohol containing dry hydrogen chloride for five hours. The alcohol was removed by distillation and the residual mixture of ethyl α-propionylcaprylate and ethyl α-capryloylpropionate distilled under reduced pressure. After collection of a forerun of 1.9 g., b. p. 60–105° (0.5 mm.), the ester mixture distilled at 105° (0.5 mm.). The yield was 9.1 g. (70%). The mixture of ethyl α-propionylcaprylate and ethyl α-capryloylpropionate was analyzed.

*Anal.* Calcd. for $C_{13}H_{24}O_3$: C, 68.38; H, 10.60; $OC_2H_5$, 19.74. Found: C, 68.53; H, 10.37; $OC_2H_5$, 19.55.

The mixture of ethyl α-propionylcaprylate and ethyl α-capryloylpropionate (4.5 g., 0.0197 mole) was refluxed with a solution of 0.3 g. of sodium in 50 ml. of dry alcohol for five hours. Sodium hydroxide solution was added and the mixture was refluxed for an additional two hours to hydrolyze the ethyl propionate and ethyl caprylate. The solution was evaporated under reduced pressure and the residue acidified with phosphoric acid and boiled for an hour. The solution was made basic and any non-acidic material steam-distilled. The residual solution was acidified and extracted continuously for three days with methylene chloride. The methylene chloride solution was dried over calcium sulfate and the solvent removed through a glass helices-packed column. The residue was transferred to a small flask and fractionated through a small center-tube column.[15] The yield of propionic acid, b. p. 135–136°, was 0.62 g. (43%). The yield of caprylic acid, b. p. 231–227°, was 1.34 g. (47%). Intermediate fractions amounted to 0.07 g.

As a test of the efficiency of the column, a mixture of 1.3 g. of radioactive propionic acid and 2.0 g. of caprylic acid was fractionated. The recoveries were: 1.03 g. (80%) of propionic acid and 0.91 g. (45%) of caprylic acid. Radioactivity analyses of the products are given in Table I.

[a] Hartshorn and Oliver, *Proc. Roy. Soc.* (*London*), **A123**, 664 (1929).

g. of the mixture of ethyl $\alpha$-propionylcaprylate and ethyl $\alpha$-caprylylpropionate was hydrolyzed by refluxing with a carbon dioxide-free solution of sodium hydroxide prepared by dissolving 0.05 g. of clean sodium in 10 ml. of boiled alcohol and diluting with 10 ml. of boiled water. The hydrolysis mixture was acidified with dilute perchloric acid and heated to boiling. The evolved carbon dioxide was swept out with nitrogen and precipitated as barium carbonate which was analyzed in the usual manner.[11]

**Ultraviolet Absorption Spectra.**—The ultraviolet spectra were determined in purified cyclohexane solution using a Beckman Quartz Spectrophotometer.[16]

**Dipole Moments.**—The dielectric constants were measured at a frequency of 954 kilocycles using a modification of the heterodyne heat apparatus described by Smyth.[17] The standard condenser was a General Radio Type 722-N. The dielectric cell was similar to the one described previously.[18] The replaceable capacity of the cell at 25° was 123.50 $\mu\mu$ fd. and the volume about 40 ml. The pycnometers were of the graduated type described by Robertson.[19]

The dipole moments were obtained from the dielectric constants and densities of dilute solutions using the customary equations.[17] Values of $P_\infty$ were obtained by least squares extrapolation of $P_2$ to infinite dilution and the sum of the electronic and atomic polarizations at infinite wave length was assumed to be equal to the experimental value of the molar refraction for the sodium D line, $MR_D$. The data are given in Tables II and III.

## Summary

The isotopic tracer technique has been used to demonstrate that the mixed aldoketene dimer of methyl- and hexylketenes prepared by the Wedekind reaction does not have a cyclobutanedione-1,3 structure.

The physical properties of several aldoketene dimers indicate that these substances probably have structures similar to diketene and are best formulated as vinylaceto-$\beta$-lactone or $\beta$-crotonolactone derivatives.

# The Binding of Organic Ions by Proteins. Effect of Temperature

BY IRVING M. KLOTZ AND JEAN M. URQUHART

The affinity of serum albumin for organic ions has been found to depend on the charge and structure of the anion, as well as on the *p*H and nature of the buffer and on the concentration of the protein.[1-6] From the magnitude of the effects of these different factors, it has been possible to obtain some insight into the molecular nature of the anion–protein complex. Since entropy and enthalpy changes accompanying a chemical transformation are frequently also very illuminating in this respect, it has seemed appropriate to examine also the temperature dependence of the binding process.

In his exploratory work on sulfonamide–plasma protein complexes, Davis[1] observed no marked change in degree of binding with rise in temperature. Similarly Putnam and Neurath[7] in their electrophoretic investigations of complexes between albumin and sodium dodecyl sulfate obtained no indication of a temperature dependence.

Boyer, Ballou and Luck[8] also have reported a zero temperature coefficient in the binding of caprylate by serum albumin.

The results of the present investigation indicate that the temperature dependence is indeed quite small. At least for methyl orange and azosulfathiazole, however, significant differences in binding by albumin are observed at 0 and 25°, and these can be used to calculate values for the appropriate thermodynamic functions. These quantities, in turn, lead to some pertinent conclusions on the nature of the binding process.

## Experimental

The extent of binding of the reference anions by bovine serum albumin was measured by the differential dialysis technique described in detail previously.[3] Experiments were carried out, with mechanical shaking for an eighteen-hour period, in an ice-bath at 0.0 ± 0.1° for the low temperature measurements and at 25.00 ± 0.05° for the upper temperature results.

As in past work, the reference anions used were monovalent methyl orange and divalent azosulfathiazole of high purity.[3] Analyses were made by optical density, as measured by the Beckman spectrophotometer.

Buffers were prepared from reagent grade salts and acid. The acetate buffer of *p*H 5.00 had an ionic strength of 0.1000. The phosphate buffer of *p*H 6.83 had an ionic strength of 0.132.

The bovine serum albumin was a crystallized product of Armour and Company. Its water content was determined by drying a separate portion in an oven at 110°. Binding was measured with solutions containing near 0.2% of the protein.

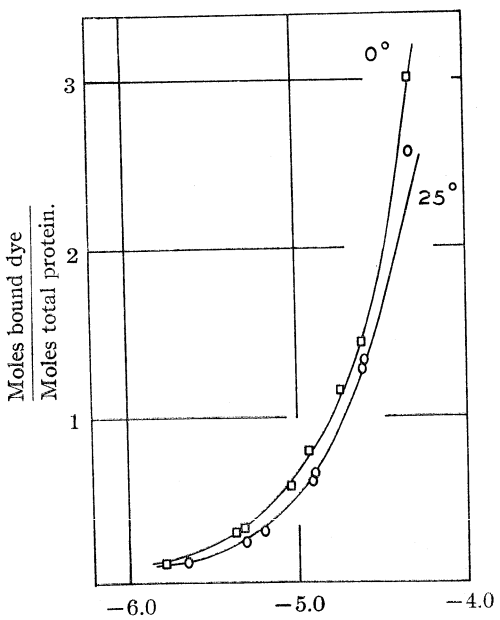

Fig. 1.—Effect of temperature on binding of methyl orange by bovine serum albumin at *p*H 6.8.

(8) P. D. Boyer, G. A. Ballou and J. M. Luck, *ibid.*, **167**, 407 (1947).

## Results

The data on the binding of the monovalent anion, methyl orange, by bovine serum albumin in phosphate buffer are presented in Fig. 1. As in the past, the moles of bound ion per mole of protein, $r$, have been plotted as a function of the concentration of the free ion (A), in equilibrium with the protein complex. Phosphate buffer has been used since previous work[6] has indicated that competition with buffer anions is small in this system.

Corresponding data on the binding of azosulfathiazole, the divalent anion, are assembled in Fig. 2. Acetate buffer at *p*H 5, rather than phosphate at *p*H 6.8, was used in this case, in order to prevent the dissociation of the dye into a trivalent species.

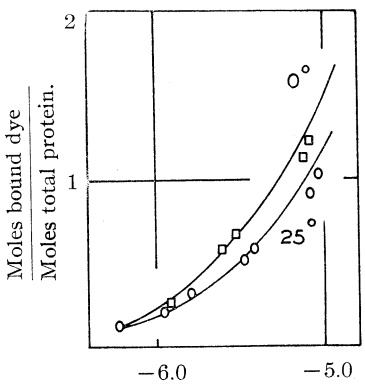

Fig. 2.—Effect of temperature on binding of azosulfathiazole by bovine serum albumin at *p*H 5.0.

## Discussion

A cursory glance at the data shows that the extent of binding is not a sensitive function of the temperature. One can conclude immediately, then, that the enthalpy change for the binding process must be small (since $\Delta H = RT^2 \, \mathrm{d} \ln K/\mathrm{d}T$) and that the major contribution to the favorable free energy change comes from the entropy term (since $\Delta F = \Delta H - T\Delta S$). To present these considerations in a more precise and quantitative form, however, requires further calculations.

**Calculation of Binding Constants for First Complex.**—A method of evaluation of free energies of formation of anion–protein complexes, $PA_i$, from the experimental data on binding has been presented previously.[3] Depending on the application of the law of mass action to the multiple equilibria

$$PA_{i-1} + A = PA \qquad (1)$$

this method enables one to calculate the successive equilibrium constants, $k_i$, and, in princi-

ple, $n$, the maximum number of sites on the protein available to the anion.

In practice, however, the determination of $n$ with assurance is a very difficult problem. In previous work, an approach has been made by a plot of $1/r$ *vs.* $1/(A)$. As (A) approaches infinite concentration, $r$ should approach $n$. Hence the intercept on the ordinate in a graph of $1/r$ *vs.* $1/(A)$ should be $1/n$, since the value (of zero) for $1/(A)$ at that point corresponds to infinite (A). Such extrapolations have been limited largely to situations where electrostatic factors are negligible, and hence where the binding data can be expressed by the linear function[3]

$$\frac{1}{r} = \frac{1}{kn}\frac{1}{(A)} + \frac{1}{n} \qquad (2)$$

In equation (2), $k$ is the intrinsic binding constant and is related to $k_i$ by the expression

$$k_i = \frac{n - (i - 1)}{i} k \qquad (3)$$

However, as has been pointed out recently by Scatchard,[9] this type of extrapolation tends to obscure non-statistical, interaction effects, particularly when data at high anion concentrations are lacking, and may lead to incorrect values of $n$. An alternative method of plotting has been proposed by Scatchard and is based on the use of the function

$$\frac{r}{(A)} = kn - kr \qquad (4)$$

when electrostatic factors are negligible, and of an appropriately modified expression when such factors must be taken into account. As is evident from equation (4), the intercept on the *abscissa* of a graph of $r/(A)$ *vs.* $r$, must be $n$, since $r/(A)$ at this point is zero. This type of graph shows one quite clearly the length of the extrapolation from the region of experimental data, and hence gives a good indication of the reliability of the value obtained for $n$.

An analysis of our present data by the Scatchard method indicates that no reliable value of $n$ can be obtained. Nevertheless, for our present purpose, an investigation of the effect of temperature on binding by albumin, it is unnecessary to know $n$, for the thermodynamic changes accompanying the formation of $PA_i$ can be evaluated readily *for small values of* $i$ by the following procedure.

From data on the extent of binding at low values of (A), it is possible to evaluate $k_1$ quite readily. It is evident from equation (3) that for $i = 1$

$$k_1 = nk \qquad (5)$$

Thus $k_1$ can be obtained from a knowledge of the product $nk$ even if the individual factors are unknown. This product can be obtained in turn from equation (4), for it corresponds to the intercept on the *ordinate* in a graph of $r/(A)$ *vs.* $r$. This intercept, in contrast to that on the abscissa, can be evaluated readily, for it can be obtained by an extrapolation in the region of low values of $r$, and hence low concentrations of (A), a region in which adequate experimental data are available.

This procedure has been used to obtain values of $k_1$ for albumin complexes with each of the two anions, methyl orange and azosulfathiazole, at each of the two temperatures, 0 and 25°. The results obtained are listed in Table I.

TABLE I

BINDING CONSTANTS FOR COMPLEXES WITH BOVINE ALBUMIN

| Anion | Constant | Temperature 0° | Temperature 25° |
|---|---|---|---|
| | $k_1$ | $6.9 \times 10^4$ | $5.0 \times 10^4$ |
| Methyl orange | $k_2$ | $3.4 \times 10^4$ | $2.5 \times 10^4$ |
| | $k_3$ | $2.2 \times 10^4$ | $1.6 \times 10^4$ |
| Azosulfathiazole | $k_1$ | $2.4 \times 10^5$ | $1.75 \times 10^5$ |
| | $k_2$ | $0.88 \times 10^5$ | $0.64 \times 10^5$ |
| | $k_3$ | $0.43 \times 10^5$ | $0.31 \times 10^5$ |

**Calculation of Binding Constants for Higher Complexes.**—Since the binding data in the present series cover complexes with an average value of $i$ as high as nearly 3, it has seemed pertinent to attempt to calculate binding constants up to $k_3$. Strictly speaking this cannot be done without a knowledge of $n$ since an evaluation of the statistical contribution from equation (3), or its equivalent, depends on the value of $n$. However, if we assume that $n$ is large, for example 20 or more, it can be shown readily that the magnitude of the statistical contribution is not sensitive to the specific value chosen for $n$ so long as only small values of $i$ are considered.

Starting from known values of $k_1$, one can obtain succeeding equilibrium constants by means of the equation[3]

$$RT \ln (k_{i-1}/k_i) = RT \ln \left[\frac{n - (i - 2)}{n - (i - 1)}\frac{i}{i - 1}\right] - \Delta F_{elect.} \qquad (6)$$

where $\Delta F_{elect.}$ is the change in electrostatic free energy in the reaction

$$PA_i + PA_{i-2} = 2PA_{i-1} \qquad (7)$$

The term in the brackets on the right-hand side of equation (6) is the statistical factor. That it is not sensitive to the value of $n$, so long as $n$ is large, is shown by the comparison of numerical values listed in Table II. In a more general fashion, this characteristic of the statistical contribution is evident also from the fact that the first factor,

TABLE II

COMPARISON OF STATISTICAL FACTOR FOR DIFFERENT VALUES OF $n$

| | $\frac{n - (i - 2)}{n - (i - 1)}\frac{i}{i - 1}$ | |
|---|---|---|
| | $n = 22$ | $n = 50$ |
| 2 | 2.10 | 2.04 |
| 3 | 1.58 | 1.53 |
| 4 | 1.40 | 1.36 |
| 5 | 1.32 | 1.28 |
| 6 | 1.27 | 1.23 |

(9) G. Scatchard, *Annals N. Y. Acad. Sci.*, in press.

$n(i-2)/n-(i-1)$, will be close to unity for different values of $i$, so long as $n$ is large, and $i$ is kept to the first few integers. Thus the numerical value of the bracket in equation (6) is determined essentially by the second factor $i/(i-1)$, which is obviously independent of $n$.

For the data on the binding of methyl orange, $\Delta F_{\text{elect.}}$ was assumed to be zero, as in previous work, because the results did fit a linear presentation in terms of equation (2). The constants $k_2$ and $k_3$ can then be evaluated readily at each temperature by application of equation (6). The results obtained have been included in Table I. The corresponding free energy changes can be expressed in the form of the following equations (in units of calories/mole)

$$\text{At } 0°: \quad \Delta F_i^0 = -6049 + \sum_{j=2}^{j=i} RT \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} \tag{8}$$

$$\text{At } 25°: \quad \Delta F_i^0 = -6411 + \sum_{j=2}^{j=i} RT \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} \tag{9}$$

In complexes between serum albumin and azosulfathiazole, on the other hand, electrostatic interactions between successively bound anions do not seem to be negligible. The term $\Delta F_{\text{elect.}}$ in equation (6) was calculated, as previously,[3] on the assumption of a spherical protein molecule of radius 30 Å., and a value of 4 Å. for the radius of the dye anion. At 0°, $\Delta F_{\text{elect.}}$ turns out to be 160 cal./mole, and at 25°, 177 cal./mole. With these values, $k_2$ and $k_3$ can be calculated readily from equation (6), and the results obtained have also been placed in Table I. The corresponding free energy changes may be expressed by the following equations (in units of calories/mole)

$$\text{At } 0°: \quad \Delta F_i^0 = -6725 + \sum_{j=2}^{j=i} RT \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} + 160(i-1) \tag{10}$$

$$\text{At } 25°: \quad \Delta F_i^0 = -7151 + \sum_{j=2}^{j=i} RT \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} + 177(i-1) \tag{11}$$

The additional term in each of the equations (10) and (11), in comparison with (8) and (9), represents the contribution of the electrostatic interaction factor.

**Calculation of Enthalpies and Entropies of Binding.**—From the equations for the free energy changes it is possible to deduce expressions for the enthalpy and entropy changes accompanying the formation of the respective protein–anion complexes by standard thermodynamic procedures. These functions can be summarized as follows (the units for $\Delta H$ being calories/mole, those for $\Delta S$ being calories/mole degree)

Methyl orange–albumin complexes

$$\Delta H^0 = -2100 \tag{12}$$

$$\Delta S_i^0 = 14.5 - \sum_{j=2}^{j=i} R \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} \tag{13}$$

Azosulfathiazole–albumin complexes

$$\Delta H^0 = -2000 \tag{14}$$

$$\Delta S_i^0 = 17.1 - \sum_{j=2}^{j=i} R \ln \frac{n-(j-2)}{n-(j-1)} \frac{j}{j-1} \tag{15}$$

Strictly speaking, the $\Delta H^0$ for azosulfathiazole complexes should have two additional terms, one containing the factor $\Delta F_{\text{elect.}}$ and the second its temperature coefficient. In practice, however, it turns out that these terms balance each other approximately, so that $\Delta H^0$ does not vary significantly for different values of $i$.

**Significance of the Thermodynamic Changes in Binding.**—In considering the magnitudes of the thermodynamic changes associated with the binding process, one is struck particularly by the positive entropy values. Despite the fact that the formation of the complex, as represented by the simple expression in equation (1), is an association reaction, the entropy of the system does not drop, but increases. Thus the formation of albumin–anion complexes stands in direct contrast with that of cellulose–anion complexes, where the association reactions are accompanied by negative entropy changes,[10] as one would expect from a simple molecular picture. The difference between these two systems may be, however, in the use of fibers, rather than soluble macromolecules, in the cellulose investigations; for the values of the equilibrium constants and temperature coefficients for anion–wool fiber combinations reported by Steinhardt[11] indicate a decrease in entropy for the uptake of organic ions.

The positive entropies associated with many reactions involving proteins are attributed frequently to disorientation and unfolding of the protein molecule, and a similar explanation might be offered here. Such a picture in connection with anion–protein complexes seems unlikely, however, since the enthalpy changes involved are negative and small, whereas a process of unfolding presumably requires the breaking of several bonds and hence should be an endothermic reaction of appreciable magnitude.

An alternative explanation, which is consistent with both the observed entropy and enthalpy changes, would focus attention on the electrostatic nature of the species involved in the formation of these anion–protein complexes. Though the anion may be indicated merely by the symbol $A^-$, it is recognized that this ion has several polarized water molecules "frozen" to it in the aqueous solution. Similarly the protein molecule is highly hydrated, particularly, perhaps, around the charged loci of the free carboxyl groups and the quaternary nitrogen atoms. Recent evidence from measurements of the decrease in binding with increasing $p$H,[12] as well as from observations of

(10) W. J. Marshall and R. H. Peters, *J. Soc. Dyers Colourists*, **63**, 446 (1947).

(11) J. Steinhardt, *Annals N. Y. Acad. Sci.*, **41**, 287 (1941).

(12) I. M. Klotz and F. M. Walker, THIS JOURNAL, **69**, 1609 (1947).

loss in binding ability on acetylation of the amino groups of albumin,[13] points to the participation of the charged nitrogen loci in the bond with the anion. The formation of such an electrostatic bond would release some of the "frozen" water molecules from the constituent ions. Thus there would be an *increase* in the number of molecular species upon formation of the anion–protein complex, rather than a decrease, as indicated by equation (1), and hence one would reasonably expect an increase in entropy for the process. It is of interest in connection with this interpretation that Lundgren[14] has observed an increase in the volume of the solution when an alkylsulfonate anion is bound by egg albumin.

This view of the mechanism of the binding process makes it analogous to the ionization process of organic carboxylic acids. Written as an association reaction, the ionic changes in these acids may be represented by the equation

$$H^+ + A^- \rightleftarrows HA \qquad (16)$$

For the aliphatic organic acids the entropy change accompanying the reaction shown is around 20 calories/mole degree and the enthalpy change of the order of several hundred calories/mole.[15] Here too, then, there is an increase in entropy in a reaction which superficially involves a reduction in the number of molecular species. When one recognizes, however, that the disappearance of the free ions is accompanied by the release of fixed water molecules, the positive entropy for reaction (16) becomes reasonable.

The volume changes accompanying the ionization processes of organic acids also parallel those for anion–protein complexes. Thus it has been observed[16] in several different ionic systems that reaction (16) is associated with an increase in volume of the order of 20 cc./mole. While corresponding quantitative data for the binding process by albumin are not available, the qualitative observations of Lundgren[14] are of the correct sign. In both cases, an increase in volume fits the assumption that water molecules are released in the association reaction.

The analogy between these two processes may be pursued even further by a comparison of the changes in the thermodynamic quantities for the association process with variation in the structure of the anion. It is of interest to note that the change of 1369 calories/mole[15] in $\Delta F^0$ for reaction (16) in going from formic to acetic acid is due almost entirely to the 4.5 calories/mole degree difference in $\Delta S^0$ for the reaction with hydrogen ion, a difference which may be attributed to the greater degree of hydration of the neutral molecule with the single carbon atom. Correspondingly, in the present investigation with a protein, a comparison of the thermodynamic changes in the formation of the first[17] complex, $PA_1$, with methyl orange and azosulfathiazole, respectively, reveals that the more favorable free energy of binding of the latter ion is due to the greater change in entropy in the formation of the protein complex. On the molecular level, then, these characteristics of the thermodynamic quantities associated with the binding process indicate that the higher affinity for some of the larger anions is not due so much to increased van der Waals interaction, but rather to a greater degree of dehydration of the complex.

**Conclusion.**—While the present investigations have been carried out with a single type of molecule, sulfonated azo compounds, the qualitative observations on other anions[1,7,8] of very different atomic structure indicate that here too the heat of binding is quite small and that the favorable free energy for association is due primarily to the positive entropy term. It is of interest to note also that substantially the same conclusions have been reached in a study of metallic cation–albumin complexes.[18] It becomes apparent, then, that in comparisons of changes in binding energy with variations in structure of the small ion, greater attention should be paid to the ability of the ion to force the release of frozen water molecules on the ion–protein complex.

**Acknowledgments.**—This investigation was supported in part by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service. The authors are indebted also to Dr. Fred Karush of New York University Medical School, and to Dr. Ralph Pearson of Northwestern University for numerous profitable discussions.

## Summary

The binding of methyl orange and of azosulfathiazole, respectively, by bovine serum albumin has been examined quantitatively at 0 and at 25°. For the formation of the first anion-protein complex, the following thermodynamic changes have been calculated: Methyl orange; $\Delta F_0^0 = -6049$ cal./mole, $\Delta F_{25}^0 = -6411$ cal./mole, $\Delta H^0 = -2100$ cal./mole, $\Delta S^0 = 14.5$ cal./mole deg.; azosulfathiazole: $\Delta F_0^0 = -6725$ cal./mole, $\Delta F_{25}^0 = -7151$ cal./mole, $\Delta H^0 = -2000$ cal./mole, $\Delta S^0 = 17.1$ cal./mole deg.

The large positive entropy of binding, coupled with the small enthalpy of binding, have been interpreted to mean that the major contribution to the free energy of binding comes from the release of solvent molecules from the anion–protein complex.

# Dielectric Properties and Ultraviolet Absorption Spectra of Addition Compounds of Sulfur Dioxide and Sulfur Trioxide with Tertiary Amines[1]

BY J. A. MOEDE[2] AND COLUMBA CURRAN[3]

Studies on the addition compounds of tertiary amines with sulfur dioxide have been summarized by Bateman, Hughes and Ingold.[4] Later work includes the phase equilibrium studies of VanderWerf and co-workers.[5] An adequate discussion of the type of bonding in these compounds has been given by Burg.[6]

The addition compounds of amines with sulfur trioxide have been less extensively studied. They are higher melting, more stable, less reactive and much less soluble in inert solvents than their sulfur dioxide analogs.[6]

The present investigation was undertaken to evaluate the N–S bond moment, to study the effect of the formation of this bond on ultraviolet absorption spectra, and to determine the extent of dissociation of the addition compounds in solution. Dielectric constant and absorption measurements complement each other in that the latter may be made at solute mole fractions of about one-thousandth of the concentrations required for the former measurements.

## Experimental

**Preparation and Purification of Compounds.**—**Sulfur dioxide,** an Ohio Chemical Company product, was dried by passing through two phosphoric anhydride towers.

**Sulfur trioxide** was obtained by distillation from a mixture of fuming sulfuric acid and phosphoric anhydride.

**Trimethylamine,** an Eastman Kodak Co. product, was purified by passing through sodium hydroxide. Analysis by titration indicated a purity of 99.3%.

**Triethylamine** and **tri-*n*-butylamine,** Eastman Kodak Co. white label products, were refluxed over sodium and distilled. The following constants were obtained for tri-*n*-butylamine: b. p. 219° (750 mm.), $d^{25}_4$ 0.7743, $n^{25}D$ 1.4278.

**Pyridine** was refluxed over calcium oxide and distilled.

**Dimethylaniline,** a Merck product, was distilled and stored over activated alumina in an atmosphere of nitrogen.

**Trimethylamine–sulfur dioxide** was prepared under moisture-free conditions by the method of Burg[6]; m. p. 77°.

**Pyridine–sulfur dioxide,** m. p. −7.0°, was prepared by the addition of sulfur dioxide to pyridine at −20°.

**Pyridine–sulfur trioxide,** m. p. 137°, was prepared by a variation of the method of Baumgarten.[7]

**Dimethylaniline–sulfur trioxide** was prepared by the method of Willcox.[8] The dried product melted between 85 and 90° and solutions were prepared immediately after drying, as the compound is not stable over long periods.

**Trimethylamine–sulfur trioxide,** m. p. 240°, was prepared in the same manner as dimethylaniline–sulfur trioxide and purified by washing with water.

**Triethylamine–sulfur trioxide,** m. p. 91.5°, was prepared in the same manner as pyridine–sulfur trioxide, using carbon tetrachloride as a solvent. The product was crystallized from acetone and the crystals were dried in a vacuum desiccator over phosphoric anhydride.

**Tri-*n*-butylamine–sulfur trioxide** was prepared by adding 5 ml. of liquid sulfur trioxide with stirring to 30 ml. of tri-*n*-butylamine in 300 ml. of carbon tetrachloride at 0°. The lower layer was washed with cold concentrated hydrochloric acid and then with water, dried over calcium chloride and decolorized with activated charcoal. The solvent was evacuated off and the product crystallized from acetone, m. p. 94°. Its molecular weight was determined cryoscopically in benzene as 266, compared to the calculated value, 265.4.

**Dimethylaniline hydrochloride** was prepared as described by Scholl and Escales.[9]

*trans*-**Dichloroethylene,** obtained from the Columbia Organic Chemicals Company, was washed successively with silver nitrate, hydrochloric acid, sodium carbonate and water and partially dried with calcium chloride. It was then refluxed over phosphoric anhydride and twice fractionally distilled through a 1 meter Fenske column in an atmosphere of nitrogen.

**Triethylamine–sulfur dioxide** and **tri-*n*-butylamine–sulfur dioxide** were prepared in solution. For the absorption measurements, all sulfur dioxide addition compounds were prepared in solution.

**Chloroform,** a U. S. P. grade, was dried over activated alumina. Where alcohol-free chloroform was necessary a technical grade was washed with water, dried over activated alumina and activated silica and used as soon as possible after drying.

*n*-**Butyl chloride,** an Eastman product, was washed with water and dried with activated alumina and activated silica. Other solvents were purified as in earlier work.

**Preparation of Solutions.**—Solutions for dielectric constant measurements were prepared in a dry air box and were introduced into the dielectric cell without contacting moist air. The master solutions for absorption measurements were prepared in a similar manner, but dilutions were made outside the box and the Beckman absorption cells were not sealed. Small amounts of a white solid, probably the bisulfite, formed on the addition of sulfur dioxide to butyl chloride solutions of triethylamine, preventing a quantitative treatment of the absorption measurements on these solutions.

Solutions of sulfur dioxide in *trans*-dichloroethylene were prepared by direct addition of sulfur dioxide gas to the solvent. Concentrations were determined by the addition of excess sodium hydroxide, titration with hydrochloric acid to the phenolphthalein end-point, oxidation of the sulfite with hydrogen peroxide and continued titration to the methyl orange end-point.

**Physical Measurements.**—Dielectric constants were obtained at radio frequencies using a modified Armstrong oscillator in the tuning circuit, constructed with the aid of a circuit diagram kindly furnished by Professor W. D. Kumler. The dielectric cell was similar to that described by Svirbely and co-workers,[10] having a capacity of 110 $\mu\mu$f. As the dielectric constants of dioxane solutions of the sulfur trioxide addition compounds varied with time, capacity readings on these solutions were taken as soon as possible after preparation. The 20-ml. pycnometer used to obtain densities was a modification of that described by

Lipkin.[11] Absorption measurements were made with a Beckman DU quartz spectrophotometer. All extinctions were corrected for the difference in transparency of the two 1-cm. fused silica cells. The precision limit of the molar extinction coefficients is estimated as 3%.

## Calculations

The dissociation constant of trimethylamine–sulfur dioxide in chloroform and *n*-butyl chloride was calculated from the variation of the extinction of the solution with solute concentration, assuming Beer's law. For the equilibrium mixture, using 1-cm. cells, the observed extinction $E = \epsilon_C c_C + \epsilon_A c_A + \epsilon_B c_B$, where $\epsilon$ is the molar extinction coefficient, $c$ is the molar concentration and the subscripts A, B and C refer to the amine, sulfur dioxide and the addition compound, respectively. The molar extinction coefficient of the undissociated addition compound could not be obtained experimentally. That value of $\epsilon_C$ was chosen, by trial and error, which gave the smallest variation with concentration of $K_c = c_A^2/c_2 - c_A$ where $c_2$ is solute molarity considering no dissociation. The value of the molar extinction coefficient of trimethylaminesulfur dioxide yielding the most consistent set of $K_c$ values was the same in both solvents, 6250. The dissociation constant of dimethylaniline hydrochloride was calculated in a similar manner; the molar extinction coefficient of this compound was taken as the experimental value obtained in a solution containing a large excess of hydrogen chloride, where the extent of dissociation is negligible.

The solute polarizations at infinite dilution reported in Table II were calculated by the method of Hedestrand. The distortion polarizations were taken as 1.05 $MR_D$, with the exception of tri-*n*-butylamine for which the atomic polarization was assumed to be zero.[12] The electric moment of trimethylamine–sulfur dioxide in benzene calculated from the data for the three most concentrated solutions listed in Table I is 4.90. The moment calculated assuming a dissociation constant equal to that obtained from spectral measurements in chloroform is 5.0. Dissociation in benzene is expected to be less than in chloroform, and the change in polarization with concentration likewise indicates a smaller degree of dissociation in benzene. Therefore, a mean value, 4.95, has been taken as the moment of this addition compound.

(11) Lipkin, Davison, Harvey and Kurtz, *Ind. Eng. Chem., Anal. Ed.*, **16**, 55 (1944).

(12) Le Fevre and Russel, *Trans. Faraday Soc.*, **43**, 374 (1947).

Both the $\Delta D/N_2$ and $\Delta d/N_2$ ratios for benzene solutions of the addition compounds of triethylamine, tri-*n*-butylamine and pyridine with sulfur dioxide decreased sharply with decreasing solute concentration, indicating appreciable dissociation. Assuming that these compounds were in equilibrium in solution with the amines and sulfur dioxide, dissociation constants were calculated in the following manner: The electric moments of triethylamine–sulfur dioxide and tri-*n*-butylamine–sulfur dioxide were assumed to be 0.05 and 0.10 debyes greater than the moment of trimethylamine–sulfur dioxide. The calculation of the moment of pyridine–sulfur dioxide is indicated in the Discussion. The polarizations at infinite dilution of these compounds were calculated from the moments and molar refractions. The polarizations of tri-*n*-butylamine and sulfur dioxide are listed in Table II.

TABLE II

POLARIZATIONS AND ELECTRIC MOMENTS

| Compound | $P_{2\infty}$ | $MR_D$ | $\mu$ |
|---|---|---|---|
| Sulfur dioxide | 63.2 | 11.5 | 1.6 |

Table II. The values for triethylamine and pyridine were taken from the literature. It was assumed that at the low solute concentrations listed in Table III the polarization of each component was independent of concentration. The concentration of each component and the value of $K_N$ were calculated from the total polarization of each solution by relations similar to those used by Earp and Glasstone.[13] Values of $K_c$ were obtained from the equation $K_c = K_N/V$ where $V$ is the molar volume of the solution in liters.

## Discussion of Results

The low moment obtained for tri-*n*-butylamine in benzene, 0.77, compared to the values reported[12] for triethylamine, 0.90, and trimethylamine, 0.86, suggest a slight increase in the nitrogen valence angle in tri-*n*-butylamine due to steric hindrance.

A consideration of the configurations of sulfur dioxide,[14] thionyl chloride[15] and sulfuryl chloride[15] has led the authors to choose 55° as the angle between the N → S and $SO_2$ moment vectors in the

amine–sulfur dioxide addition compounds. Assuming the moments of the amine, 0.86, and sulfur dioxide, 1.6, each to be increased by 0.2 in the addition compound, the moment calculated for the N → S bond from the moment of trimethylamine–sulfur dioxide, 4.95, is 2.7 ± 0.4.

This N → S moment is appreciably lower than the N → O bond moment, 4.2, in amine oxides,[16] and the difference is greater than expected from a comparison of the C–S and C–O bond moments. It has been suggested by one of the authors[17] that a coördinate bond may result from resonance between a dipole–dipole bond, $R_3N\text{--}SO_2$, and a purely covalent bond in which the electrons are equally shared, $R_3\overset{+}{N}—\overset{-}{S}O_2$. The dipole–dipole structure should make an appreciable contribution to the amine–sulfur dioxide molecule and thus reduce the N → S moment appreciably below the N → O moment in amine oxides, as the latter bond can have practically no dipole–dipole character.

The moment of pyridine–sulfur dioxide, 6.2 ± 0.7, used in calculating the dissociation constant for this compound in benzene listed in Table III was approximated as the vector sum of the pyridine, N → S and $SO_2$ moments.

Compound formation between trimethylamine and sulfur dioxide is accompanied by a marked increase in ultraviolet absorption, as is evident from Fig. 1. The lower absorption maxima of the addition compounds of sulfur dioxide with triethylamine and tri-*n*-butylamine are attributed to the greater dissociation of these compounds at corresponding concentrations. The absorption maxima for these two compounds shifted with decreasing concentration and the absorption curves approached the envelopes of the amine and sulfur dioxide curves at very low concentrations. The variation of the molar extinction coefficients with concentration is illustrated in Fig. 2. The dissociation constant calculated for trimethylamine–sulfur dioxide from spectral data is $1.9 \times 10^{-4}$ in both chloroform and butyl chloride, compared to the values 0.007, 0.013 and 4 calculated for the sulfur dioxide addition compounds of triethylamine, tri-*n*-butylamine and pyridine from the changes in polarization with concentration in benzene. The variation with time of the extinction values observed for U.S.P. chloroform, alcohol-free chloroform and *n*-butyl chloride solutions of triethylamine–sulfur dioxide and tri-*n*-butylamine–sulfur dioxide prevented the calculation of dissociation constants for these compounds from spectral data. It is evident from Fig. 3 that pyridine–sulfur dioxide is practically completely dissociated at concentrations of the order of $10^{-4}$ molar.

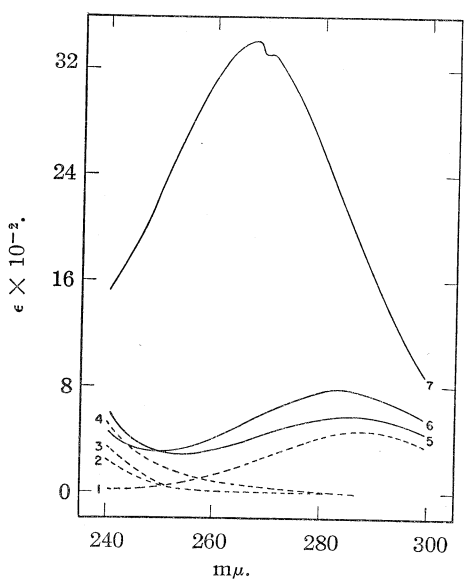

Fig. 1.—Absorption spectra in *n*-butyl chloride: (1) sulfur dioxide; (2) trimethylamine; (3) triethylamine; (4) tri-*n*-butylamine; (5) tri-*n*-butylamine–sulfur dioxide, $c = 5.1 \times 10^{-4}$; (6) triethylamine–sulfur dioxide, $c = 2.9 \times 10^{-4}$; (7) trimethylamine–sulfur dioxide, $c = 5.6 \times 10^{-4}$.

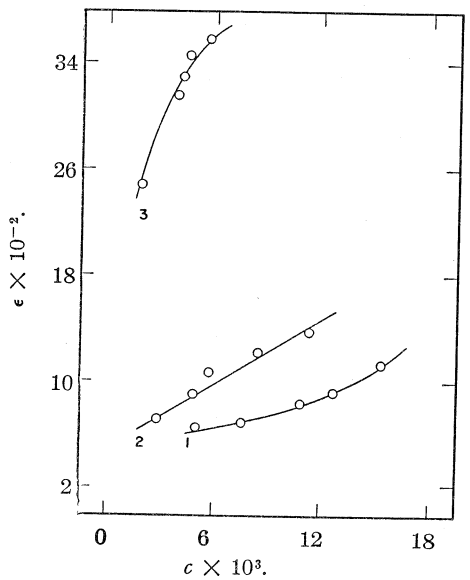

Fig. 2.—Change in molar extinction coefficient in *n*-butyl chloride with concentration: (1) tri-*n*-butylamine–sulfur dioxide at 284 mμ; (2) triethylamine–sulfur dioxide at 284 mμ; (3) trimethylamine–sulfur dioxide at 267 mμ.

Both the dielectric and absorption data reveal that the order of decreasing dissociation of the sulfur dioxide addition compounds is pyridine > tri-*n*-butylamine > triethylamine > trimethylamine. The chief factors determining this order appear to be the weak basicity of pyridine and the steric effects of alkyl groups. The steric factors affecting the stability of this type of compound have been characterized by Brown.[18]

The dielectric and density data reveal that the sulfur trioxide addition compounds of triethylam-

ine and tri-*n*-butylamine do not dissociate in benzene solution. This lack of dissociation is also evidenced by the molecular weight obtained for tri-*n*-butylamine–sulfur trioxide from a freezing point measurement on a benzene solution. Association of this compound in carbon tetrachloride at solute mole fractions in excess of 0.001 is indicated by the large $\Delta D/N_2$ ratios that increase with increasing concentration. To illustrate this effect the electric moment of tri-*n*-butylamine–sulfur trioxide has been calculated from $\Delta D/N_2$ ratios for two concentrations in carbon tetrachloride and listed in Table II. The solubilities of the addition compounds of sulfur trioxide with trimethyl amine, pyridine and dimethylaniline in non-polar solvents were too low for dielectric constant measurements.

Assuming tetrahedral valence angles in sulfur trioxide addition compounds and an increase of 0.3 in the triethylamine moment, the sum of the N → S and S–O bond moments in triethylamine–sulfur trioxide is 5.6. As a fair approximation a value of 3.6 is assigned to the N → S vector and 2.0 to the S–O bond moment. The increase in the N → S moment from the sulfur dioxide to the sulfur trioxide addition compounds is probably due to the greater residual positive charge on the trioxide sulfur and to the distorted character of the sulfur bond angles in the $R_3N{-}{-}SO_3$ dipole–dipole structure, resulting in an increased contribution of the $R_3\overset{+}{N}—\overset{-}{S}O_3$ structure to the molecule. The large moment of the S–O bond in this addition compound indicates a decrease in the S=O double bond character compared to that in sulfur dioxide.

The transparency of sulfur trioxide in the near ultraviolet limits the study of compound formation from absorption spectra to a comparison of the spectrum of the addition compound with that of the amine. Trimethylamine–sulfur trioxide and triethylamine–sulfur trioxide were observed to be transparent in the region available with chloroform, above 240 mμ, indicating, in support of the interpretation of dielectric data, that these compounds are not dissociated in solution. The absorption of tri-*n*-butylamine-sulfur trioxide, Fig. 4, is about 0.2% of that of the amine at 243 mμ, suggesting the possibility of a small amount of dissociation. The molar extinction coefficient of this compound increased slightly with decreasing concentration, but the change was less than the precision error of the measurements at these low extinction values.

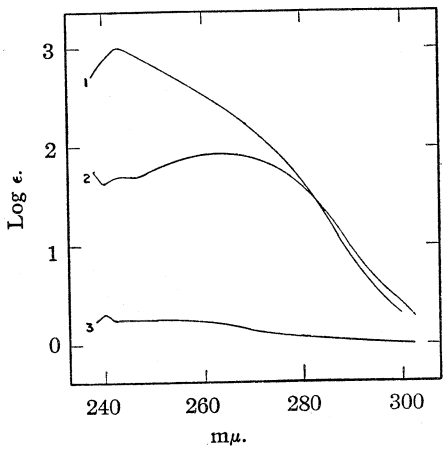

Fig. 4.—Absorption spectra in chloroform: (1) tri-*n*-butylamine; (2) tri-*n*-butylamine + 0.04 molar hydrogen chloride; (3) tri-*n*-butylamine–sulfur trioxide, $c = 0.1$.

The transparency of sulfur trioxide and its addition compounds compared to the absorption by sulfur dioxide and the amines and the strong absorption by the sulfur dioxide addition compounds suggests that absorption by these compounds is associated with excitation of the unshared nitrogen and sulfur electrons. This view is consistent with the decrease in the absorption by butylamine in acid solution illustrated in Fig. 4. The very strong absorption by trimethylamine–sulfur dioxide suggests that compound formation results in a loosening of the unshared sulfur electrons, perhaps by increasing the $sp^3$ hybrid character of the orbitals of these electrons.

The addition of a proton to pyridine increases the electron demand of the nitrogen atom and thus facilitates electron migration from the ortho and para carbon atoms, resulting in stronger absorption. The addition of sulfur trioxide alters the pyridine spectrum in a similar manner, as illustrated in Fig. 5. Lewis and Bigeleisen have shown a similar relation between the proton and stannic chloride in altering the spectrum of methylene blue.[19] The slightly lower maximum of pyridine–

(19) Lewis and Bigeleisen, *ibid.*, **65**, 1144 (1943).

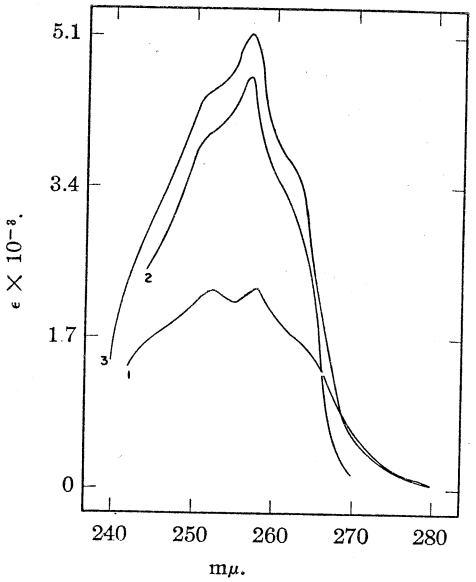

Fig. 5.—Absorption spectra in chloroform: (1) pyridine; (2) pyridine–sulfur trioxide +1% ethyl alcohol; (3) pyridine + 0.1 molar hydrogen chloride.

sulfur trioxide compared to the pyridinium ion may result from the action of the alcohol required to dissolve the addition compound. The very low solubility of this compound prevented a study of the effect of concentration on the molar extinction coefficient.

The addition of a proton to dimethylaniline prevents the migration of the nitrogen electrons to the ring and decreases sharply the absorption maximum at 255 mμ.[20] Figure 6 reveals that sulfur trioxide addition has a similar effect on the spectrum of dimethylaniline. The change in the molar extinction coefficient with concentration in U.S.P. chloroform indicates appreciable dissociation of the addition compound in this solvent. In alcohol-free chloroform, as illustrated in Fig. 7, this dissociation is decreased considerably; the extent of dissociation of the sulfur trioxide complex is very little different from that of the dimethylanilinium ion in this solvent. The absorption maxima for dimethylaniline–sulfur trioxide at varying concentrations in alcohol-free chloroform could not be determined with sufficient precision (the extinction values changed slightly with time) to obtain a reliable dissociation constant for this compound.

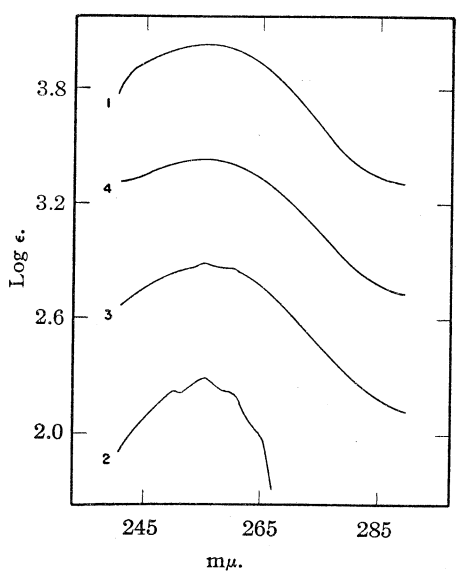

Fig. 6.—Absorption spectra of (1) dimethylaniline in chloroform and (2) dimethylaniline hydrochloride in chloroform + 0.1 molar hydrogen chloride compared with (3) $1.2 \times 10^{-3}$ molar and (4) $2.0 \times 10^{-4}$ molar dimethylaniline–sulfur trioxide in U. S. P. chloroform.

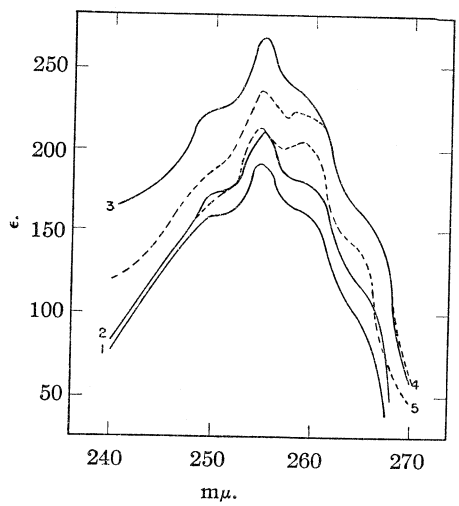

Fig. 7.—Absorption spectra in alcohol-free chloroform: (1) dimethylaniline hydrochloride + 0.1 molar hydrogen chloride; (2) 0.0081 *M* and (3) 0.0012 *M* dimethylaniline hydrochloride; (4) 0.0017 *M* and (5) 0.0069 *M* dimethylaniline–sulfur trioxide.

The values of the dissociation constant calculated for dimethylaniline hydrochloride in chloroform from observed extinctions at different concentrations increased with decreasing concentration. Dr. W. H. Hamill suggested to the authors that this increase might be due to the salt effect of the hydrochloride. The conductance of a 0.1 molar solution of dimethylaniline hydrochloride in chloroform was observed to be about a thousand times that of hydrogen chloride in chloroform. The dissociation constant was therefore calculated considering the equilibrium to be $C_8H_{11}NH^+ + Cl^- \rightleftarrows C_8H_{11}N + HCl$. The values of $K_c$ are given in Table V. From the Debye–Hückel limiting law it follows that $-\log K_c = -\log K_a + 2k\sqrt{\mu}$, where $k$ for chloroform at 25° is 32.8. The plot of

(20) This is actually a comparison of the primary band of dimethylaniline with the secondary band of the ion. For simplicity of illustration the shift of the dimethylaniline secondary band to higher frequencies on ionization is ignored. See Doub and Vandenbelt, *ibid.*, **69**, 2714 (1947).

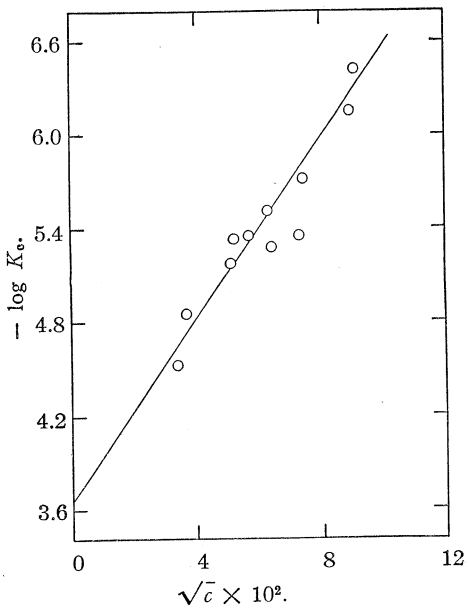

Fig. 8.—Variation of $-\log K_c$ for the reaction $C_8H_{11}NH^+ + Cl^- \rightleftharpoons C_8H_{11}N + HCl$ with concentration of dimethylanilinium ions.

$-\log K_c$ *versus* $\sqrt{c}$ given in Fig. 8, where $c$ is the concentration of dimethylanilinium ions calculated from the spectral data, yielded a value of $K_a = 2 \times 10^{-4}$ and a value of $k = 14$. Other authors have reported low values of $k$ for solvents of low dielectric constant from conductance measurements. In this instance the low value appears to be due in part to the presence of a large number of $C_8H_{11}NH^+ \cdots Cl^-$ ion pairs, which reduces the ionic strength below the calculated value.

## Summary

Electric moments have been determined for sulfur dioxide, tri-*n*-butylamine, trimethylamine–sulfur dioxide, triethylamine–sulfur trioxide and tri-*n*-butylamine–sulfur trioxide. The N → S bond moments in these addition compounds have been evaluated.

Dissociation constants have been calculated for trimethylamine–sulfur dioxide and dimethylaniline hydrochloride in chloroform from ultraviolet absorption measurements, and for the sulfur dioxide addition compounds of pyridine, triethylamine, and tri-*n*-butylamine in benzene from dielectric constant and density measurements. Both absorption and dielectric constant measurements reveal that the order of decreasing stability of the sulfur dioxide addition compounds is trimethylamine > triethylamine > tri-*n*-butylamine > pyridine. The sulfur trioxide addition compounds of trimethylamine and triethylamine appear to be undissociated in benzene and chloroform solutions.

Interaction of trialkylamines with sulfur dioxide results in a very large increase in absorption in the 270 mμ region. The addition compounds of sulfur trioxide with trialkylamines are transparent in this region. Sulfur trioxide shows an effect similar to that of the proton in altering the spectra of pyridine and dimethylaniline.

# Rate of Adsorption of Barium Ions in Extreme Dilution, by Hydrous Ferric Oxide

BY M. H. KURBATOV

## Introduction

In earlier work it was realized that the extent of adsorption of divalent ions from very dilute solutions on hydrous ferric oxide depended not only on the usually recognized factors of temperature, *p*H, amount of adsorbent, volume and salt concentration but also on the duration of adsorption. It was observed that adsorption was not discontinued with the separation of the solid adsorbent, but that when the co-precipitation procedure was used in the case of very dilute solutions, there was an observable adsorption rate. Particularly was this true when the amount of adsorbate was less than $10^{-6}$ gram atom, the volume of solution of the order of 10–30 ml. and the quantity of adsorbent 1 or $2 \times 10^{-5}$ gram atom of iron, the effect being more pronounced with decreased amounts of adsorbate. From this observation there arose the possibility of determining a rate of ion adsorption from solution.

## Procedure

The adsorption procedure and the preparation of barium 133 as carrier-free tracer are described in a previously published paper.[1] For the rate studies, $2 \times 10^{-5}$ gram mole ferric chloride was mixed with the chosen quantity of stable barium chloride and tracer, all in acid solution, and the mixture titrated rapidly with ammonium hydroxide to the selected *p*H. Thus, the so-called co-precipitation procedure, in which hydrous ferric oxide was precipitated in the presence of barium ions, was used. Some barium was adsorbed during titration in the *p*H interval from the formation of the solid phase to the selected *p*H of a particular series of experiments, the amount adsorbed during titration increasing with *p*H (see Table II).

The co-precipitation procedure has some advantage over the "real" adsorption procedure (in

(1) M. H. Kurbatov, Fu-Chun Yu and J. D. Kurbatov, *J. Chem. Phys.*, **16**, 87 (1948).

which latter case barium ions in solution are added to a solution containing the previously precipitated hydrous ferric oxide) in that the selected conditions such as salt concentration, volume of liquid phase, etc., are more reproducible and these conditions are of significance in the rate of adsorption in this liquid–solid system.

The time intervals at which adsorption was measured were from one to several hours; the zero time being taken as that at which the final *p*H was reached. Each determination was made on a separate sample, the rate of adsorption being found from a series of samples, initially prepared, under experimentally identical conditions.

## Experimental

**Rate of Adsorption of Barium Ions in Concentrations of $3 \times 10^{-6}$ and $3 \times 10^{-10}$ Gram Atom per Liter.**—In studies of adsorption isotherms it has been established that the fraction of barium adsorbed (under specified conditions) in a given time interval of, for instance, one, two or four hours, increases with dilution down to a concentration of $10^{-8}$ gram atom per liter. Below this concentration the fraction adsorbed becomes experimentally constant for the given time interval.[2]

Therefore, it is possible to study the rate of adsorption after titration is completed in concentration ranges in which the fraction adsorbed is either independent or not independent of the changing concentration. To exemplify these two conditions and to observe the variation in rate due to concentration, the barium quantities selected were $1 \times 10^{-11}$ gram atom and $1 \times 10^{-7}$ gram atom per 32 ml. of liquid phase. The results are given in Table I.

It can be seen that in equal time intervals the fraction of barium adsorbed is higher for the lower concentration in agreement with the previous isotherm studies. Also the rate of change with time of the fraction of barium adsorbed is greater for the lower concentration.

After sixty hours the quantity of adsorbed barium, within the limits of experimental observation, remains constant for both concentrations.

**The Dependence of Rate of Adsorption on Hydrogen Ion and Ammonium Chloride Concentrations.**—The procedure used in securing the data in Tables II, III, and IV differed from that used in obtaining the data in Table I in that the volume of liquid phase (~32 ml. initially) decreased at each successive measurement. That is, the five determinations of barium adsorbed at a given *p*H and salt concentration in the time interval from 0.5 to 30, 50 and 45 hours, respectively, were obtained by successive removals

of portions of solution from one original sample. This procedure so reduced the number of individual samples as to allow simultaneous study of several different hydrogen ion concentrations and salt concentrations. The main distinction between Tables II, III and IV is the ammonium chloride concentration, $3.8 \times 10^{-3}$, $3.3 \times 10^{-2}$ and $3.0 \times 10^{-1}$ $N$, respectively.

These experiments even though they involved repeated removals of the liquid phase resulted in a continued increase in adsorption in consecutive periods.

From Table II ($3.8 \times 10^{-3}$ $N$ $NH_4Cl$) it may be seen that the rate of change of adsorbed barium increases as the *p*H increases from *p*H 7.6 to 8.7 but then the rate drops off at *p*H 9.0.

A similar though not so marked trend may be seen in Table III ($3.3 \times 10^{-2}$ $N$ $NH_4Cl$). The change in the amount adsorbed between 0.5 and 30.0 hours increases with *p*H from *p*H 7.7 to 8.1 but then appears to decrease as the *p*H is increased farther. In the experiments represented in Table IV the salt concentration was $3 \times 10^{-1}$ $N$ and the tracer measurements consequently less accurate. However, the data show similar trends to those in Tables II and III.

If Tables II, III and IV are compared (recognizing the more approximate nature of the data in Table IV) using the change in the amount adsorbed from 0.5 to 25 or 30 hours at similar *p*H values it can be seen that:

(a) At *p*H 9, changing the ammonium chloride concentration from $3.8 \times 10^{-3}$ to $3.0 \times 10^{-1}$ $N$ has no significant effect on the rate of adsorption after titration although the amount adsorbed initially (during titration) is decreased by increased salt.

(b) At *p*H 8.5 or 8.6 there is little difference in the effect of $3.8 \times 10^{-3}$ and $3.3 \times 10^{-2}$ $N$ salt on the rate.

(c) At *p*H 8 and 7.5 the change in adsorption with time is increased as the salt concentration is increased from $3.8 \times 10^{-3}$ to $3.3 \times 10^{-2}$ $N$.

(d) The difference in the rate referred to in (c) results largely from decreased initial adsorption with increased salt, the total adsorption after 30 hours being essentially the same for $3.8 \times 10^{-3}$ $N$ or $3.3 \times 10^{-2}$ $N$ salt at approximately *p*H 7.5 or 8.

The following data selected from Tables II and III show the direction and greatest observed extent of the effects of salt and hydrogen ion concentration on rate of adsorption (after titration)

| $(H^+)$ | $NH_4Cl$ concn., $N$ | Change in g. at. Ba adsorbed in interval from 0.5 to 30 hours after titration $\times 10^{12}$ |
|---|---|---|
| $2.5 \times 10^{-8}$ | $3.8 \times 10^{-3}$ | $2.46 - 1.50 = 0.96$ |
| $2.7 \times 10^{-9}$ | $3.8 \times 10^{-3}$ | $7.92 - 5.95 = 1.97$ |
| $2.1 \times 10^{-8}$ | $3.3 \times 10^{-2}$ | $2.46 - 0.47 = 1.99$ |

## Discussion of Results

It has been established that, in spite of extreme dilution ($1 \times 10^{-11}$ gram atom of Ba per 32 ml.) barium is not completely adsorbed by $2 \times 10^{-5}$ gram atom of hydrous ferric oxide under the conditions used though this quantity of adsorbent can remove $4 \times 10^{-8}$ gram atom barium from a solution originally containing $1 \times 10^{-7}$ gram atom barium, other conditions being comparable. The maximum adsorption observed for the two above quantities of barium was 54 and 39%, respectively, and was obtained within forty to sixty hours.

It has also been found that the *p*H of the solution and salt concentration not only affect the initial amount of adsorption (from a solution containing $1 \times 10^{-11}$ gram atom barium), but affect the rates as well. In the interval from *p*H 7.5 to 8.0 or 8.5 the rate (after the initial adsorption) increases with decrease in hydrogen ion concentration and the quantity adsorbed, at any given time interval, increases with decreased hydrogen ion concentration. In the range of ammonium chloride concentrations from $3.8 \times 10^{-3}$ to $3 \times 10^{-2}$ $N$ the rate (after the initial adsorption) increases with increase in salt concentration where the *p*H is 7.5 or 8.0 although the quantity adsorbed at any given time decreases with increased salt concentration.

In considering these rate studies several possible mechanisms suggest themselves as rate-determining processes.

Since the adsorption system used involves initial mixing followed by rapid settling of the solid phase and no further stirring, ionic diffusion through solution might be considered as the rate-determining process after settling. However, if the usual equation for diffusion of ions through solution to a solid electrode is applied the fraction left in solution is found to decrease from 83 to 1% in 100 hours while experimentally it decreases from 82% to only 60% in that time. The equation indicates as much adsorption in four hours as is observed in 100 hours.

Diffusion in and through solid particles[3] has similarly been ruled out as the major process since that equation contains a constant ratio[4] which when evaluated from the above data is not constant but varies from a value of 0.19 at $t = 1$ to 0.07 at $t = 10$.

The adsorption of divalent cations may be considered as competitive[1] with adsorption of monovalent cations, $H^+ + NH_4^+$. To treat this more specifically an ionic displacement reaction can be written as

$$Ba^{++} + S_2Ad \underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2S^+ + BaAd$$

in which $Ba^{++}$ represents the moles of $Ba^{++}$ in solution, $S_2Ad$ represents the adsorbent with $H^+$ and/or $NH_4^+$ ions adsorbed, $S^+$ represents $H^+$ and/or $NH_4^+$ in the solution and BaAd the adsorbent with adsorbed barium. It is not intended to imply here that $H^+$ and $NH_4^+$ ion effects are directly additive, nor of magnitude proportional to their concentrations, but the effect of both, though they may be competitive with each other, is assumed to be in opposite direction to that of the divalent ion.

In the systems studied experimentally the initial $Ba^{++}$ concentrations were $3 \times 10^{-6}$ and $3 \times 10^{-10}$ gram atom per liter ($1 \times 10^{-7}$ and $1 \times 10^{-11}$ g. at. per 32 ml.) while the salt concentration was $10^{-2}$ $N$ and the $H^+$ concentration $10^{-8}$ $N$.

It may be postulated that in the initial rapid adsorption—the rate of which has not been measured because of changing conditions—both monovalent and divalent ions are adsorbed and that the slow measured rate represents the subsequent desorption of monovalent ions and preferential adsorption of divalent ions.

The rate of formation of BaAd would then be

$$d[BaAd]/dt = k_1[Ba^{++}][S_2Ad] - k_2[S^+]^2[BaAd]$$

which may be rewritten in the form

$$d[BaAd]/dt = -[BaAd](k_1[Ba^{++}] + k_2[S^+]^2) + k_1[Ba^{++}G]$$

in which G is a constant equal to the sum of $S_2Ad$ and BaAd.

It has been shown experimentally[2] that the fraction of barium adsorbed is independent of the original concentration if the latter is below $10^{-7}$ gram atom per liter so the *effect* of the $Ba^{++}$ concentration in solution can be considered constant for the lower concentration of barium used in the rate studies (*i. e.*, $3 \times 10^{-10}$ g. at./liter). With an initial salt concentration of the order of $10^{-2}$ $N$ any $H^+$ or $NH_4^+$ ion desorbed (being of the order of magnitude of $10^{-10}$) would represent a negligible change in $S^+$ concentration during its desorption.

Therefore $k_1[Ba^{++}] + k_2[S^+]^2$ can be considered as a constant D and the equation can be simplified to

$$d[BaAd]/dt = -[DBaAd] + k_1[Ba^{++}G]$$

which on integration gives

$$[BaAd] = \frac{k_1[Ba^{++}G]}{(k_1[Ba^{++}] + k_2[S^+]^2)}[1 - Ke^{-Dt}] \quad (1)$$

If the value of [BaAd] is $Q$ at $t$, is $Q_0$ at $t_0$ and is $Q_\infty$ at $t_\infty$ then Equation (1) can be shortened to

$$Q = Q_\infty - Ke^{-Dt}Q_\infty$$

and if the fraction of Ba adsorbed at $t = Q/Q_\infty = F$ and at $t_0 = Q_0/Q_\infty = F_0$ the expression becomes

(3) C. E. Boyd, A. W. Adamson and L. S. Myers, Jr., THIS JOURNAL, **69**, 2836 (1947).

(4) $D^i\pi^2/r_0^2$ in which $D^i$ is diffusion coefficient in the solid and $r_0$ the radius of solid particles.

$$\log (1 - F) = \frac{-D}{2.303} t + \log (1 - F_0) \qquad (1a)$$

$(1 - F_0)$ being constant for any given set of conditions.

This equation indicates that a straight line should result from a plot of log $(1 - F)$ against $t$ when the conditions assumed in the derivation are met. Accordingly it was found that the rate of adsorption of barium from the lower concentration studied gives the straight semi log plot while the higher concentration does not give a straight line (Fig. 1).

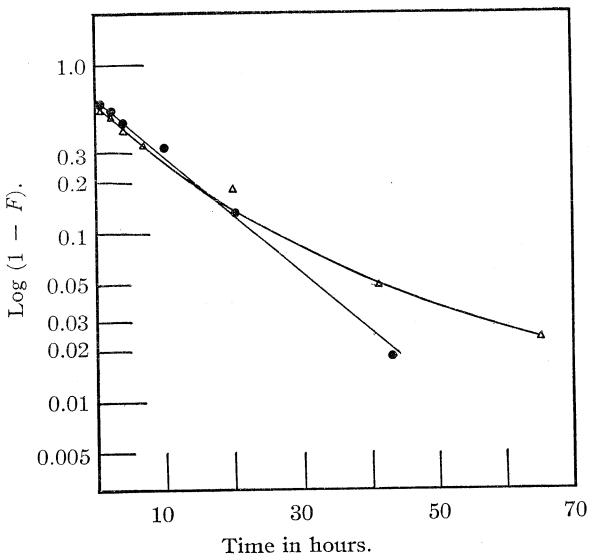

Fig. 1.—Adsorption of barium on hydrous ferric oxide represented as ion exchange rate: O, Ba = $1 \times 10^{-11}$ g. at.; △, Ba = $1 \times 10^{-7}$ g. at.; $p$H = 8.00 ± 0.01; Fe = $2 \times 10^{-5}$ g. at.; vol. = 32.00 ± 0.05 ml.; $NH_4Cl$ = $3.5 \times 10^{-2}$ $N$.

Although this equation is essentially the same as the equation for diffusion through a thin liquid film[3] the displacement mechanism is favored because the equation based on displacement shows several relations which are compatible with previous experimental observations. Some of these are:

(1) The fraction of barium adsorbed at any given time with a constant quantity of adsorbent is independent of total barium when the concentration of $Ba^{++}$ used is less than $10^{-7}$ g at./liter with a salt concentration of $6 \times 10^{-3}$ $N$. When this is true the ratio of adsorbed barium to barium left in solution is also constant. Equation (1) indicates that $[BaAd]/[Ba^{++}]$ is dependent upon the sum of $k_1[Ba^{++}]$ and $k_2[S^+]^2$. If $k_1[Ba^{++}]$ is insignificant as compared to $k_2[S^+]^2$ the fraction $[BaAd]/[Ba^{++}]$ is independent of $Ba^{++}$ concentration but when $k_1[Ba^{++}]$ becomes significant when added to $k_2[S^+]^2$ the fraction $[BaAd]/[Ba^{++}]$ not only changes but decreases as has been observed.

(2) The fraction $[BaAd]/[Ba^{++}]$ (at constant time) decreases as salt or hydrogen ion concentration ($S^+$) increases which is consistent with the $[S^+]^2$ factor being in the denominator of equation (1).

(3) The quantity adsorbed from a given concentration of barium (at constant time) increases with increased quantities of hydrous ferric oxide. This is consistent with the G factor being in the numerator of equation (1).

(4) The rate of change with time of the quantity of barium adsorbed under the conditions described above increases with increased salt concentration. Increase in $S^+$ should decrease the rate if $K$ were constant for all conditions but it is not. $K$ which is $(1 - F_0)$ increases with salt concentration in such a manner as to more than balance the effect of increased $S^{+2}$.

(5) An increase in hydrogen ion concentration from $p$H 8.5 or 8.0 to $p$H 7.6 (other factors being constant) decreases the rate after the initial coagulation. This is in accord with the equation if the change in $K$ is neglected. Actually, $K$ increases in value with increased hydrogen ion concentration but the change (in the case of $3.8 \times 10^{-3}$ salt) may be approximated as from 0.25 to 0.40 for a change from $p$H 8.6 to 7.6 while a change from $3.8 \times 10^{-3}$ $N$ to $3.3 \times 10^{-2}$ $N$ $NH_4Cl$ at $p$H 7.6 results in a change of $K$ from 0.40 to 0.83.

In conclusion it may be said that while the observed rate of attachment of barium ions to hydrous ferric oxide after the initial co-precipitation adsorption may involve more than one mechanism the rate for very dilute solutions is well expressed by a simple chemical equilibrium. The equation derived on this basis is consistent with both current and previous observations on the effect of salt, hydrogen ion concentration and quantity of adsorbent on quantities adsorbed at constant time and on rate of adsorption.

**Acknowledgment.**—It is a pleasure to express thanks to Prof. Edward Mack, Jr., whose stimulating support of nuculear chemistry research made this work possible.

A grant, for instruments, made by the Ohio State University Development Fund, is greatly appreciated by the author.

## Summary

The rate of adsorption of barium ions has been studied with the purpose of selecting optimum conditions for carrier-free target chemistry relative to the nuclear reactions $Cs(dn)Ba^{133}$ and $Cs(d2n)Ba.^{134}$

At a concentration of barium ions of $3 \times 10^{-10}$ gram atom per liter with $1 \times 10^{-5}$ gram mole of hydrous ferric oxide as adsorbent, other conditions being as described, the rate of adsorption was observed in an interval from one to 100 hours. It was found that in spite of the extreme dilution of barium its adsorption did not proceed to complete removal of the divalent ions from solution but reached its highest value within forty to sixty hours.

From studies of the dependence of rate of adsorption (after titration) on *p*H and salt concentration it was established that a decrease in hydrogen ion concentration from *p*H 7.5 to 8.0 or 8.5 increased the rate while an increase in ammonium chloride concentration from $3.8 \times 10^{-3}$ to $3.0 \times 10^{-1}$ *N* increased the rate.

A rate equation has been derived postulating a displacement of adsorbed monovalent cations by divalent cations. The experimental data on rate of adsorption of barium ions from dilute solution ($3 \times 10^{-10}$ gram atom per liter) were found to fit this equation.

# The Adsorption of Helium on Carbon Black at Liquid Helium Temperatures[1]

BY W. D. SCHAEFFER, W. R. SMITH AND C. B. WENDELL

Previous investigators[2,3,4,5] have studied the adsorption of helium on various adsorbents of poorly defined total surface area. In one investigation[4] the heat of adsorption of helium on charcoal (Carbotax) was calculated from isotherms at liquid and solid hydrogen temperatures. Values ranging from 416 to 127 calories were reported. van Dingenen[3] reported heats of 93 to 52 cal./mole calculated from the isotherms of helium on glass at and below the temperature of liquid helium. Stout and Giauque[2b] report values of 131 to 148 calories for the heat of adsorption of helium on $NiSO_4 \cdot 7H_2O$ at 4.23°K. These values were computed from the Sackur–Tetrode equation, assuming zero entropy for the adsorbed helium. Keesom and Schweers[2a] measured the quantity of helium adsorbed in the temperature range, 4 to 1°K., on layers of hydrogen, neon, nitrogen and oxygen all solidified on glass. Isosteric heats of adsorption varied from 100 to 29 cal./mole, and led to the conclusion of multimolecular adsorption since the adsorption energy rapidly decreased at adsorbate concentrations representative of completed layers.

The Brunauer, Emmett and Teller procedure[6] for determining surface area from low temperature adsorption isotherms has been widely used in determining the area of commercial carbon blacks,[7,8,9] and has been particularly successful when the isotherms were determined at 78°K. with nitrogen as the adsorbate. The question as to the nature of the isotherm and the atomic area which might be revealed when helium was used as the adsorbate at 4.2°K. has interested us for some time. In addition to evaluating the B.E.T. expression at 4.2°K., adsorption studies with helium on carbon black of well defined area provide a simple system for observing the vigor of the van der Waals association between a simple atom and an essentially graphitic surface.[10]

Since a supply of liquid helium has recently become available in close proximity to our laboratory we have been able to determine the helium isotherms on two samples of commercial carbon black, Spheron 6 and Spheron C, at 4.2°K.

## Experimental

By arrangement with Arthur D. Little, Inc., of Cambridge, Massachusetts, a supply of 2 to 3 liters of liquid helium per day was assured. The helium was liquefied in the Little laboratories in the Collins cryostat.[11] A system of double Dewar flasks, the outer containing liquid nitrogen, served to transport the liquid helium, and also provided the bath for the adsorption system. The inner helium Dewar flask of 1100 cc. capacity was constructed of unsilvered Pyrex and was 71 mm. in diameter and 267 mm. deep. The neck was constricted to 33 mm.; 250 mm. of 15-mm. Pyrex tubing ending in a well-ground stopcock was sealed to the neck of the flask. There was, of course, no need to evacuate the interspace of this Dewar flask since when the stopcock was closed and the flask filled with liquid helium the air in the interspace rapidly solidified, providing an excellent vacuum. This arrangement also facilitates the precooling of the entire system with liquid nitrogen prior to filling with liquid helium. The "helium Dewar" was immersed to the neck in liquid nitrogen contained in a tall 9-liter stainless steel Dewar flask. The inner flask, after cooling to −195° C., was then filled to the neck with liquid helium by siphoning directly from the Collins cryostat, and the mouth of the flask closed with a plug of glass wool. It was possible to transport the helium in this system by car to the authors' laboratory, a matter of five miles, without appreciable loss of liquid helium.

The familiar type of constant pressure adsorption apparatus used in surface area determinations was employed.[9] The adsorption cell was only 1 cc. in volume in order to keep the "dead" space to a minimum. To insure rapid cooling with a minimum loss of liquid helium the walls of the adsorption cell were made as thin as possible. As shown in Fig. 1, the cell was joined to the adsorption line through a Pyrex capillary about 1 mm. in diameter. The cell was immersed some 35 cm. into the helium bath. During a run the level of the liquid helium dropped 2 to 3 cm. Since the liquid helium in the bath could not be replenished by any of the usual siphon arrangements, the variations in temperature of the exposed capillary dead

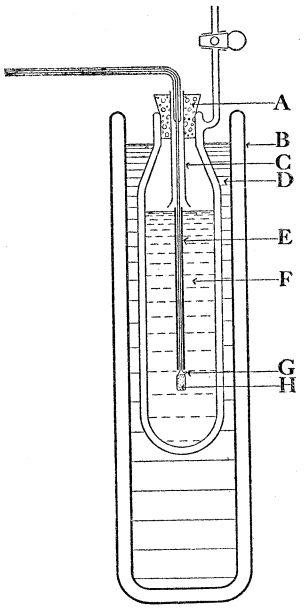

Fig. 1.—Helium bath and adsorption cell: A, cork stopper; B, stainless-steel Dewar flask; C, flared glass tube for exciting gases; D, liquid nitrogen; E, copper tube; F, liquid helium; G, stem for filling adsorbent cell; H, adsorbent.

space were reduced by encasing the capillary stem in a copper sheath which extended well below the level of the liquid helium. A section of Pyrex tubing with one end belled out as shown served to guide the helium vapors boiling off the bath around the upper portion of the stem.

Helium at liquid nitrogen temperatures was used to determine the dead space for the nitrogen isotherms. The volume of helium in the dead space at 4.2°K. was calculated from $PVT$ relations.

Spheron 6, a medium processing rubber grade of channel black, and Spheron C, a much smaller particle size rubber black, were used as adsorbents. Spheron 6 had a surface area as determined by nitrogen adsorption of 113 sq. m./g. Its mean diameter, as observed under the electron microscope, is 285 Å. Spheron C had an area of 227 sq.m./g. and a mean diameter of 190 Å., 0.2-g. samples of each black were employed. The blacks were introduced and removed from the Pyrex adsorption cell through the small stem G which could be sealed and unsealed without causing observable changes in the dead space of the system. Prepurified grades of nitrogen and helium obtained from the Matheson Company were used without further treatment, while the helium was passed through degassed, evacuated charcoal at 78°K. prior to use.

The carbon black samples were degassed at 200 ± 10°C. for two hours. Nitrogen surface areas were first obtained at 78°K. The nitrogen was then pumped off, and the sample degassed for another hour at 200°C. After precooling with liquid nitrogen, the liquid helium bath, as shown in Fig. 1 was slowly lifted over the cell until the latter was immersed some 35 cm. in the bath. The system was then allowed to equilibrate for approximately fifteen minutes before starting the adsorption. Over the entire pressure range the adsorption was characterized by rapid approach to equilibrium. Ten minutes was sufficient to attain this condition in all instances. Pressures lower than 10 mm. must be viewed with reservations due to the possibility of thermal transpiration[12] at the gas outlet inducing non-equilibrium pressures between adsorbent and manometer.

## Discussion

Figure 2 presents the helium isotherms at 4.2°K. on Spheron 6 and Spheron C. The isotherms are of the sigmoid type normally encountered with non-polar gases on carbon black.[13,9] The adsorption fits the simple B.E.T. expression

$$\frac{x}{V(1-x)} = \frac{1}{V_m C} + \frac{C-1}{V_m C}\,x \qquad (1)$$

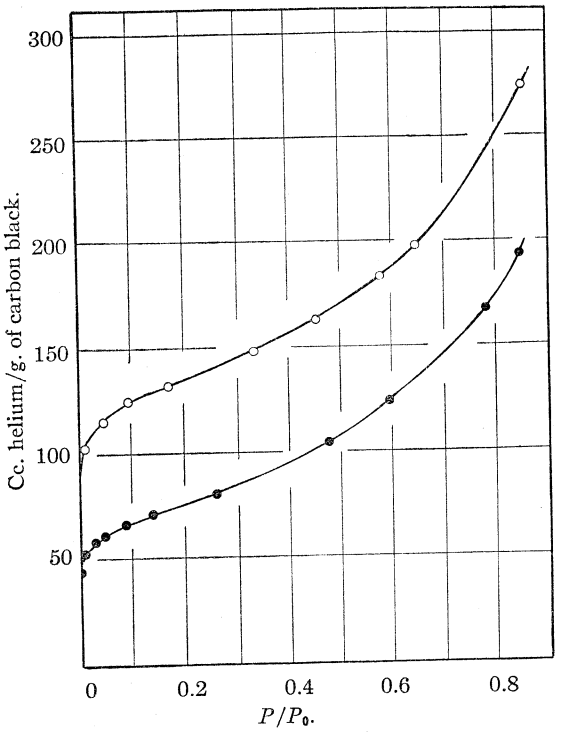

Fig. 2.—Adsorption isotherms of helium at 4.2°K. on O, Spheron 6 and ●, Spheron C.

in which $V_m$ is the volume of adsorbate (S.T.P.) required to form a monolayer, $V$ is the volume of gas (S.T.P.) adsorbed at the relative pressure, $x$, and $C$ is a constant peculiar to the adsorbent, adsorbate and temperature employed. The B.E.T. plots are illustrated in Fig. 3. At relative pressures larger than 0.25 there is some deviation from linearity as is generally encountered when the simple B.E.T. expression is employed. The $V_m$ and $c$ values obtained by least squares treatment of these data are summarized in Table I.

in which $A$ is the average area occupied by each adsorbed molecule, $M$ is the molecular weight of

(14) P. H. Emmett and S. Brunauer, THIS JOURNAL, **59**, 1558 (1937).

the gas, $D_L$ is the density of the normal liquid or solid, $N_a$ is Avogadro's number, and the molecules are assumed to be hexagonally close-packed in a face-centered cubic lattice. The cross sectional area of the helium atom, as computed from its liquid density of 0.125 g./ml.[15] is 15.4 Å.$^2$; consequently, the volume of helium required to fill a monolayer on a non-porous carbon black should be only slightly larger than that for nitrogen. Experimentally, however, the expectation of similar $V_m$'s for the adsorption of nitrogen and helium is not realized.

Two obvious explanations of the anomalous $V_m$'s may be offered. Either the carbon blacks have a large percentage of pores which accommodate the helium atoms, but are too small to admit the nitrogen molecules, or the cross sectional area of the helium atom as calculated from the liquid density is much larger than the space actually occupied by an adsorbed helium atom. The first interpretation appears rather improbable in view of the substantial agreement of the ratios of helium to nitrogen $V_m$'s on Spheron 6 and Spheron C; the possibility of similar pore size as well as pore size distributions for two carbon blacks of markedly different average diameters being extremely remote. Moreover, electron micrographs and nitrogen adsorption at high relative pressures[13] indicate negligible porosity. It appears more logical to assume that the greater volume of helium adsorbed is due to a cross sectional area much smaller than that computed from the liquid helium density. If the cross sectional area of the hexagonally-packed helium atom is modified to yield surface areas of the two carbon blacks in agreement with those obtained with nitrogen, values of 6.77 and 7.43 Å.$^2$ are obtained. These areas correspond to interatomic distances of 2.80 Å. and 2.92 Å. X-Ray diffraction patterns of solid helium[16] at 1.45°K. and 37 atmospheres indicate a close-packed hexagonal structure with interatomic distances of 3.07 Å. in the (100) plane and 2.75 Å. in the (101) plane, and a density of 0.207 g./c. Thus, the interatomic distance of 2.80 Å. calculated above for the adsorbed helium is nearly identical to that for solid helium.

The possibility of penetration of helium atoms of 1.40 Å. radius between the planes of the quasi-graphitic crystallites constituting the carbon black particles was considered. A calculation similar to that of Barrer's[17] indicates an energy barrier of only 34 cal./mole to the migration of a helium atom across the graphite hexagon, and slightly less than 68 cal./mole for penetration between the graphite planes. Although the heats of adsorption of helium at low surface coverage are unquestionably greater than 68 cal./mole, the work of Rossman and Smith[18] demonstrates that even at 25° C. no significant penetration of helium into graphite lattices could be detected. If, on the other hand, adsorbed helium at 4.2°K. were to partake to a certain degree the energy and physical characteristics of helium II, the enhanced helium adsorption on carbon black could probably be attributed to diffusion into the graphite lattice. The phase diagram does not permit the presence of He II at 4.2°K., and until possible phase changes of helium in the adsorbed state have been investigated this consideration remains purely speculative.

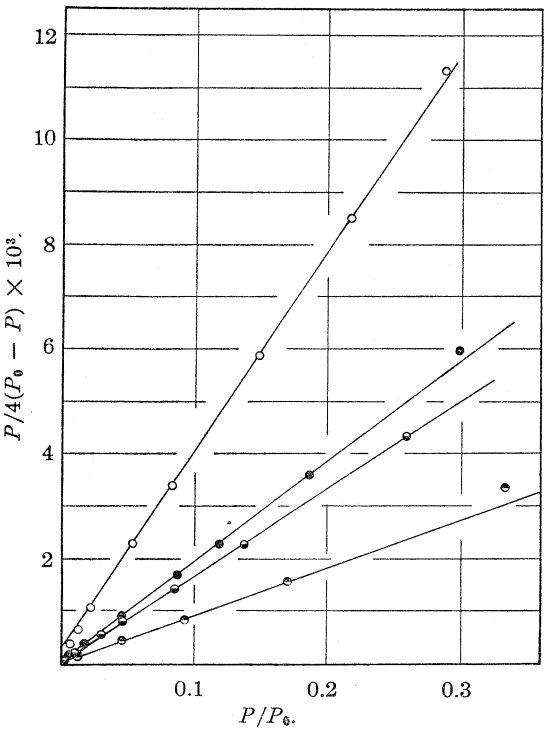

Fig. 3.—B. E. T. plots of helium and nitrogen: ○, nitrogen on Spheron 6 at 78°; ●, nitrogen on Spheron C at 78°; ◒, helium on Spheron 6 at 4.2°; ◓, helium on Spheron C at 4.2°.

The relatively large compressibility of liquid and solid helium suggests that the force field at the carbon black surface compresses or distorts the filled electron shell of the atom, resulting in a diminished cross sectional area for the adsorbed helium atoms. The electron shells of the other inert gases might be expected to behave similarly; however, Emmett, *et al.*,[19] have found it necessary to revise the area of the krypton atom upward when adsorbed as a solid at 78°K. on various surfaces. The differences in behavior of these inert gases can probably be ascribed to the influence of residual motion or zero point energy magnified in the case of helium by its low atomic weight.[20]

A calculation of the heat of adsorption for he-

(20) W. H. Keesom, "Helium," Elsevier, Amsterdam, Holland, 331 (1942).

lium on carbon black at 4.2°K. has been carried out according to the method described by Giauque and Stout.[2] They calculated the heats of adsorption of helium on $NiSO_4 \cdot 7H_2O$ at 4.2°K. from the Sackur–Tetrode equation assuming a negligible entropy for the adsorbed phase and the ideality of helium at the pressures employed. Thus, the entropy of adsorption becomes equal to the entropy of the gas at 4.2°K.

$$\Delta S_{ads} = S_{gas} = R \ln \frac{M^{3/2}T^{5/2}}{P} - 2.317 \qquad (2)$$

The expression for $\Delta H$ is then

$$\Delta H = T\Delta S \qquad (3)$$

since $\Delta F$ is zero for the isothermal process, gaseous helium at equilibrium pressure, $P$, to adsorbed helium at pressure, $P$. Since the pressures (1–650 mm.) employed in the present investigation are considerably higher than those used by Stout and Giauque ($10^{-2}$–$10^{-3}$ mm.), the assumption of ideality is somewhat suspect. However, heats have been calculated in the manner described above, and are compared in Fig. 4 with those computed from entropies obtained by interpolation of Keesom's data.[21] The latter $\Delta H$ values are significantly lower than those calculated on the assumption of ideality only for surface coverages in the second and successive multilayers. Near $V/V_m$ equal to 2.5 the heats approach a limiting value of 33.7 cal./mole, some 12.7 calories greater than the heat of vaporization of 21 cal. mole. If the limiting value of 33.7 cal./mole is used as the heat of vaporization, in conjunction with the B.E.T. $c$ value reported in Table I, a heat of adsorption ($E_1$) of 56 ± 2 cal./mole is obtained, surprisingly close to the heat of adsorption at the completion of the monolayer as calculated from the aforementioned entropy considerations.

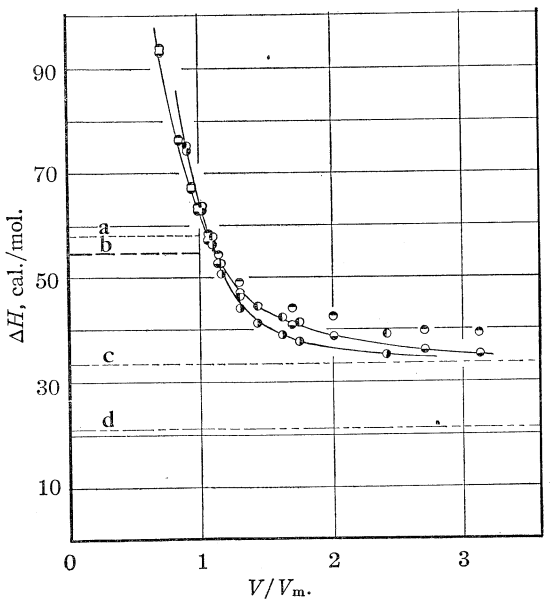

Fig. 4.—Heats of adsorption of helium on Spheron 6 and Spheron C: ◐, Spheron C, $\Delta H$ calculated from Sackur–Tetrode equation; ◑, Spheron C, $\Delta H$ calculated from Keesom[21]; ◓, Spheron 6, $\Delta H$ calculated from Sackur–Tetrode equation; ◒, Spheron 6, $\Delta H$ calculated from Keesom[21]; a, ———, B. E. T. "heat of adsorption" ($E_1$), for Spheron C; b, — — —, B. E. T. "heat of adsorption," ($E_1$), for Spheron 6; c, — — —, limiting value of heat of adsorption; d, — · — ·, helium heat of vaporization.

(21) W. H. Keesom, *ibid.*, p. 247.

The oxygen chemisorbed on the surface of Spheron 6 carbon black in the form of various complexes[22] is generally considered sufficient (23 cc. S.T.P.) to constitute a monolayer; thus, a comparison of these results with those of Keesom and Schweers[11] employing a glass surface covered with frozen oxygen proves instructive. The calculated differential heats of adsorption of helium at the completion of the first, second, and third layers ($V/V_m$) on Spheron 6 are 62, 39 and 35 cal./mole, respectively. Keesom and Schweers report heats, determined from the Clausius–Clapeyron equation, on oxygen covered glass to be 62 and 42 cal./mole at the completion of the second and third layers. The agreement is good. In fact, since they assumed a helium diameter of 4.04 Å. in computing surface coverage while 2.80 Å. was employed in the present work, one is perhaps justified in comparing Keesom and Schweers' second and third layer values of 62 and 42 cal./mole with our first and second layer values of 62 and 39 cal./mole. While agreement of this order is doubtless fortuitous, it does lend support to our assumption of negligible entropy for the adsorbed helium.

The fact that both Keesom's and our values for the heat of adsorption of helium remain considerably in excess of the heat of vaporization after a two or three layer coverage, while puzzling, is at least reproducible.

## Summary

1. A system of Dewar flasks successfully used for transporting liquid helium with negligible losses is described.

2. The helium isotherms at 4.2°K. on the carbon blacks, Spheron 6 and Spheron C, have been determined, and the application of the B.E.T. equation has been extended to liquid helium temperature.

3. The area of the helium atom adsorbed on carbon black at 4.2°K. is 7.0 ± 0.3 square ångström units.

4. The calculated heats of adsorption of he-

(22) W. R. Smith and W. D. Schaeffer, "Proceedings Rubber Technology Conference," London, England, 1948.

lium on Spheron 6 and Spheron C range from 93 to 34 cal./mole.

5. The heat of adsorption, as defined by the B.E.T. "*c*" value is in substantial agreement with the calculated heat curves.

# A Polarographic Study of Cobalt Cyanide Complexes[1]

BY DAVID N. HUME[2] AND I. M. KOLTHOFF

The characteristic properties of a solution of a cobaltous salt in excess alkali cyanide have frequently been attributed to the presence of hexacyanocobalt(II)ate ions.[3] There is much evidence, however, that in at least moderately concentrated solutions the complex which is formed is a pentacyanide rather than a hexacyanide.[4] The oxidation state of the cobalt in these solutions has never been definitely established. In the present investigation, a study of the reduction at the dropping mercury electrode of various cobalt complexes in cyanide medium has led to an understanding of the nature and identity of the complex cobalt ions formed in cyanide medium.

## Experimental

The usual polarographic technique was employed. Details of the apparatus and methods have been described in a previous communication.[5] The capillary had a drop time of 3.18 sec. and a value of 1.98 for $m^{2/3}t^{1/6}$ in 0.1 *M* potassium chloride at a potential of 0.0 v. against the saturated calomel electrode.

The reduction of cobalt(II) salts in potassium cyanide as a supporting electrolyte was first studied. In agreement with previous investigators[3d,3e] well-defined reduction waves were found for 0.002 *M* cobalt solutions in 0.1 *M* and 1.0 *M* potassium cyanide. The height of these waves was observed to be almost exactly one half that of the corresponding wave in potassium chloride, implying a one-electron reduction (Fig. 1). The shape of the waves obviously indicated irreversibility and no effort was made at analysis. It was also noted that the half wave potential was shifted to more positive values with increasing cyanide concentration, a confirmation of the irreversibility of the electrode reaction. The solutions obtained were yellow-green in color.

Previous investigators had interpreted the apparent one-electron reaction as a reduction of cobalt(III) hexacyanide ion produced spontaneously by water-oxidation of the cobalt(II) hexacyanide ion initially formed. In order to test this hypothesis, pure potassium hexacyanocobalt (III)ate (cobalticyanide) was prepared by the method of Benedetti-Pichler.[6] The product was obtained in large, clear, very pale yellow crystals which dissolved readily in water giving a clear solution. Polarograms were taken on millimolar solutions of the pure complex salt in 0.1 *M* and 1.0 *M* potassium cyanide as a supporting electrolyte.

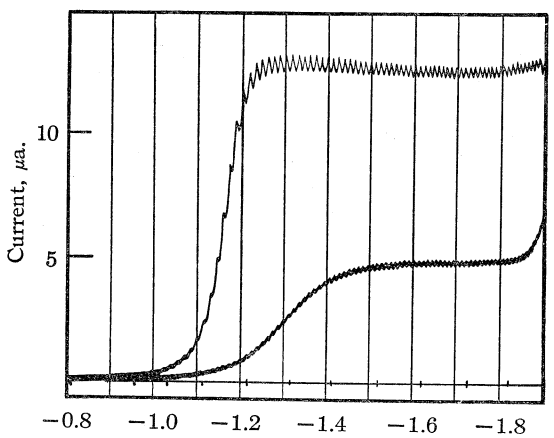

Fig. 1.—Polarograms of 0.002 *M* $CoCl_2$: upper curve in 0.1 *M* KCl; lower curve 1.0 *M* KCN.

No reduction of the cobalt complex could be observed prior to the discharge of potassium ion; the polarograms were identical with the residual current of the cyanide supporting electrolyte. The following experiments were therefore devised to determine the nature of the complex formed by solution of cobaltous salts in alkali cyanide.

A solution of 0.200 millimole of cobaltous chloride in 50 ml. of 1.0 *M* potassium cyanide was titrated amperometrically with 0.100 *M* potassium ferricyanide with exclusion of oxygen. After each addition of reagent and a wait of 2 or 3 minutes, the current at cathode potentials of −0.8 v. and −1.7 v. was measured. The cobalt is not reduced at −0.8 v. but gives a diffusion current at −1.7 v. Ferricyanide is reduced in cyanide medium at all attainable potentials of the dropping electrode, while ferrocyanide gives no wave. Hence any current at −0.8 v. must be due to unreacted ferricyanide. The result is shown in Fig. 2. The ferricyanide was consumed until one mole had been added per mole of cobalt. During the titration, the color of the solution changed from pale yellow-green to deep yellow and the diffusion current at −1.7 v. increased steadily, being approximately doubled by the end of the titration. The wave of the cobalt compound became more drawn-out and the half-wave potential shifted to more negative values (approximately −1.4 v.). The experiment clearly showed, therefore, that cobalt (II) chloride dissolved in excess potassium cyanide solution in the absence of air remains in the divalent state. Furthermore, the oxidized product obtained by treatment with ferricyanide is definitely not cobalt(III) hexacyanide ion, as the latter gives no wave.

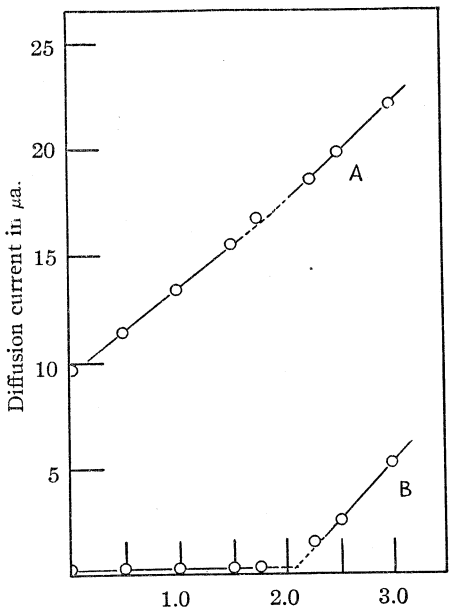

Fig. 2.—Amperometric titration of cobalt chloride with potassium ferricyanide in 1 *M* cyanide medium: (A) diffusion current at −1.7 v.; (B) diffusion current at −0.8 v.

Further experiments were performed in which 0.05 *M* cobaltous chloride solutions 1 *M* in potassium cyanide were heated in boiling water and samples taken in intervals for polarographic analysis. It was observed that the solutions first changed to an orange-yellow color while the polarographic wave decreased and became more drawn out. Amperometric titrations with ferricyanide showed that most of the cobalt had been oxidized after one hour. After three hours heating or standing overnight at room temperature, the solutions became almost colorless and yielded no polarographic wave. From this it was concluded that heating or standing in excess alkali cyanide ultimately converts the cobalt to the hexacyanocobalt(III)ate ion.

In order to establish the nature of the cobalt(II)cyanide complex first formed, experiments were performed in which cobalt chloride solutions were titrated with potassium cyanide, and *vice versa*. In agreement with previous investigators,[4] it was observed that good endpoints were obtained at a ratio of one cobalt to five cyanide ions regardless of whether the endpoint was located potentiometrically or by observation of the appearance or disappearance of the precipitate of cobalt cyanide. From this it would appear that the initial product obtained on dissolving cobalt(II) salts in excess potassium cyanide is the $[Co(H_2O)(CN)_5]^{=}$ ion. Since direct oxidation should result in the $[Co(H_2O)(CN)_5]^{-}$ ion, which can be obtained unambiguously by another method, proof of the identity of the two products would establish the structure of the cobalt(II) complex. A solution of pure potassium aquopentacyanocobalt(III)ate was therefore prepared. It was obtained without difficulty by the method of Ray[7] and Ray and Dutt[8] from cobaltous chloride through thiosulfato pentammine cobalt(III) chloride, potassium thiosulfato pentacyano cobalt(III) ate and silver aquopentacyanocobalt(III)ate, and found to have the properties described by them. In 1.0 *M* potassium cyanide as a supporting electrolyte, it gave a single wave, identical in shape with that obtained after oxidation of divalent cobalt with ferricyanide in the same medium (Fig. 3). The observed half wave potential of −1.45 v. is in satisfactory agreement with that obtained from the other product.

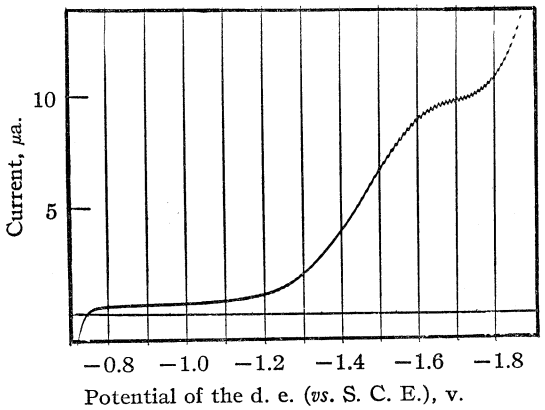

Fig. 3.—Polarogram of $[Co(H_2O)(CN)_5]^{-}$ ion in 1 *M* KCN.

An attempt was made to study the polarographic characteristics of the hexacyanocobalt(II)ate ion. Potassium hexacyanocobalt(II)ate was obtained as a finely crystalline violet precipitate by addition of a slight excess of potassium cyanide to a 0.1 *M* cobalt nitrate solution at −20°.[9] On transferring a sample of the solid to a 1 *M* potassium cyanide solution in the polarograph cell the solid immediately dissolved giving a clear pale yellow-green solution and the polarogram obtained was the same as that found on direct addition of cobalt nitrate to 1.0 *M* potassium cyanide.

The one-electron reduction of the cobalt(II) cyanide complex and the two-electron reduction of the cobalt (III) cyanide complex imply the existence of cobalt(I) as a cyanide complex formed at the surface of the dropping electrode. Grube and Schächterle[3a] in 1926 reported evidence for the formation of univalent cobalt by reduction of alkaline potassium hexacyanocobalt(III)ate solution at a cobalt cathode and with potassium amalgam. We observed a similar result when sodium amalgam was used as the reducing agent. The initially colorless solution slowly changed to red-orange with very little evolution of hydrogen. The same effect was observed when cobalt nitrate with five equivalents of cyanide added was used as the starting material. Samples of these reduced solutions were examined polarographically in 1.0 *M* potassium cyanide as a supporting electrolyte. In each case a small wave characteristic of the pentacyanocobalt(II)ate ion was observed. The height corresponded to only 5–10% of the total cobalt present. Addition of ferricyanide increased the height of the wave and gradually shifted it, ending with the characteristic wave of the pentacyanocobalt(III)ate ion. The cobalt(I) complex was not oxidizible anodically at the dropping electrode.

## Discussion

The most striking characteristic of the cobalt cyanide complexes is the irreversibility of the oxidation and reduction steps involved. None of the complex ions studied were reversibly reduced at the dropping electrode, and none were oxidized at all. The potential of a quiet mercury electrode in the cobalt(II) solutions was the same as that of a mercury electrode in a cyanide solution of the same concentration but with cobalt absent. For the measurement of the potential of cobalt(II)–cobalt(III) couple in cyanide medium, the mer-

(7) P. R. Ray, *J. Indian Chem. Soc.*, **4**, 64, 325 (1927).

(8) P. R. Ray and N. K. Dutt, *Z. anorg. allgem. Chem.*, **234**, 65 (1937).

(9) A. Descamps, *Ann. Chim. Phys.*, [5] **24**, 78 (1881).

cury electrode whether dropping or quiet is completely useless. The value commonly accepted[10] for the oxidation potential of that couple is due to Grube and Schächterle.[3a] From the potential of a platinized platinum electrode in a strongly alkaline solution of cobalt(III)hexacyanide partially reduced at a cobalt cathode, they calculated a result in terms of a hypothetical hexacyanocobalt(II)ate–hexacyanocobalt(III)ate electrode reaction. In addition to the error in formulation of the electrode reaction, a more serious difficulty exists. Both hydroxide ions and platinum are known to catalyze the water oxidation of the cobalt(II) cyanide complex. The potential which was measured differed from the potential of a hydrogen electrode in a solution of the same alkalinity by only a few millivolts: undoubtedly no more than experimental error. The potential which was reported (−0.81 v. on the hydrogen scale, European sign convention) must therefore be considered only as a lower limit on the reducing strength of the couple involved.

## Summary

Polarographic investigation of the reduction of cobalt cyanide complexes has led to the following conclusions.

1. Addition of excess alkali cyanide to a solution of a cobalt(II) salt results in the immediate formation of the aquopentacyanocobalt(II)ate ion, reducible at the dropping electrode to a cobalt(I) complex.
2. Oxidation of the cobalt(II) complex yields aquopentacyanocobalt(III)ate, also reducible at the dropping electrode to a cobalt(I) complex.
3. Prolonged treatment of the aquopentacyano complexes with excess cyanide ultimately yields the hexacyanocobalt(III)ate ion, not reducible at the dropping electrode.
4. The cobalt(I) complex is neither reducible nor oxidizable at the dropping electrode.
5. The commonly accepted value for the potential of the cobalt(II)–cobalt(III) couple in cyanide medium cannot be considered valid.

# The Behavior of Oxygenated Organic Compounds in Acid Media[1]

BY MELVIN S. NEWMAN, RAYMOND A. CRAIG[2] AND ALFRED B. GARRETT

When oxygenated organic compounds are dissolved in strong protonic acids they generally accept a proton from the solvent to form a positively charged intermediate which may or may not undergo further change.[3] Evidence as to the fate of these conjugate acids has been obtained, among other sources, from the measurements of freezing point depression of solvent sulfuric acid[3,4] and from the nature of the reaction products isolated when the sulfuric acid solutions were poured into water or certain alcohols.[4] The further behavior of the species $BH^+$ forms the topic for the present discussion.

$$B + HA \longrightarrow BH^+ + A^- \qquad (1)$$

## Alcohols[5]

In the case of solutions of alcohols in sulfuric acid three types of cryoscopic behavior have been noted.

$$ROH + H_2SO_4 \rightleftharpoons ROH_2^+ + HSO_4^- \quad [i = 2][6] \qquad (2)$$

$$ROH + 2H_2SO_4 \rightleftharpoons RHSO_4 + H_3O^+ + HSO_4^- \quad [i = 3] \qquad (3)$$

$$ROH + 2H_2SO_4 \rightleftharpoons R^+ + H_3O^+ + 2HSO_4^- \quad [i = 4] \qquad (4)$$

For example, *i*-factors of 2 have reported for *t*-butyl and *t*-amyl alcohols[7]; *i*-factors of about 3 for several primary alcohols,[7] and an *i*-factor of 4 for triphenylcarbinol.[3,8] It appears reasonable to suppose that the first step in each of these cases involves a proton transfer to yield an oxonium compound, $ROH_2^+$. Two questions arose as to the further behavior of such oxonium compounds. (1) Why should an *i*-factor of only 2 be obtained with *t*-alcohols[7] when in reactions in acid media *t*-compounds often react most rapidly? (2) Are the conjugate acids of alcohols, $ROH_2^+$, thermally unstable at ordinary temperatures, or is some solvent effect operative?

In order to obtain information on the first topic, we have re-investigated the behavior of *t*-butyl alcohol in sulfuric acid and have also studied triethylcarbinol. When these alcohols are *carefully* (see Experimental Part for details) dissolved in sulfuric acid initial *i*-factors of slightly

(5) In this paper monofunctional compounds containing only carbon, hydrogen and oxygen and a few silicon organic compounds will be considered.

(6) The *i* refers to the van't Hoff *i* factor which means essentially the number of particles produced from one particle of solute.

(7) Oddo and Scandola, *Gazz. chim. ital.*, **39**, II, 1 (1909).

(8) Hammett and Deyrup, THIS JOURNAL, **55**, 1900 (1933).

over 2 are obtained. On standing, however, these values gradually increase and eventually go over 5. If roughly extrapolated back to zero time, *i*-factors of 2.1 and 2.4 are obtained. On standing, sulfuric acid solutions of these alcohols gradually develop a hydrocarbon layer. The presence of sulfur dioxide was also established. The above findings are interpreted further below.

As for the second question, we have found that *n*-propyl and *t*-butyl alcohols each give *i*-factors of about 1.7 in methanesulfonic acid.[9] We interpret this to mean that the reaction indicated in equation 5 is only partly complete and that the oxonium salts, $ROH_2^+$, are not unstable *per se*.

$$ROH + CH_3SO_3H \rightleftharpoons ROH_2^+ + CH_3SO_3^- \quad (5)$$

The importance of the solvent in the further reactions of the species $ROH_2^+$ is attested by the fact that the *i*-factor of 1.7 for *t*-butyl alcohol is only slightly increased by heating the solution in question to 60° for fifteen minutes[9] (compare the behavior of *t*-butyl alcohol in sulfuric acid).

It is interesting to note that, in their further reactions with sulfuric acid, the oxonium compounds, $ROH_2^+$, appear to react analogously to the corresponding alkyl halides, RX, in nucleophilic displacement reactions.[10] For example, most primary alkyl halides react by the $S_N2$ mechanism,[10] which involves a backside approach.[11] The *i*-factors of 3 generally observed for primary (and some secondary) alcohols may be explained by the backside approach of a bisulfate ion to displace a water molecule from the oxonium salt of the alcohol, followed by the further ionization of water in sulfuric acid, as shown below.

$$ROH + H_2SO_4 \rightleftharpoons ROH_2^+ + HSO_4^- \quad (6)$$

$$HSO_4^- + ROH_2^+ \rightleftharpoons RHSO_4 + H_2O \quad (7)$$

$$H_2O + H_2SO_4 \rightleftharpoons H_3O^+ + HSO_4^- \quad (8)$$

Summation of equations 6, 7, and 8 yields equation 3.

*t*-Halides undergo displacement reactions at an appreciable rate only by a first order mechanism (S1 type) in which the rate determining step involves ionization of the halide.[10] The rate is slow for *t*-butyl halides but quite rapid for triphenylmethyl halides. When *t*-butyl alcohol and triethylcarbinol are carefully dissolved in cold sulfuric acid, the first measurement of *i*-factor gives values of slightly over two. Successive measurements give increasing *i*-factors which eventually reach over 5. We interpret these results as evidence that the oxonium salts formed in accordance with equation 6 undergo a slow spontaneous ionization as shown in equation 9.

$$ROH_2^+ \rightleftharpoons R^+ + H_2O \quad (9)$$

If nothing further happened the summation of equations 6, 9, and 8 would yield equation 4 and an *i*-factor of 4 would result. In the case where R is triphenylmethyl, this is actually the case.[8]

However, complicating side reactions set in with the aliphatic *t*-alcohols. These side reactions include polymerization (*i*-factor lowering), general oxidation (*i*-factor raising) and possibly others. The fact that triphenylcarbinol gives an immediate *i*-factor of 4 is not surprizing in view of the fact that triarylcarbinyl halides ionize much more readily than trialkylcarbinyl halides. In this connection it is interesting to note that in methanesulfonic acid we have shown[9] that triphenylcarbinol gives an *i*-factor of 3.8.

The inability of *t*-halides to undergo $S_N2$ type reactions is commonly attributed to steric effects which hinder the approach of a substituting group from the face of the tetrahedron directly opposite to the carbon–halogen bond.[12] However, if the central atom involved were silicon instead of carbon, the steric effect should be less. We have found that triethylsilanol gives an *i*-factor of 3 in sulfuric acid and thus approximates the behavior of primary alcohols. We interpret this fact as support for the view that a bisulfate ion makes a backside attack to displace a water molecule from the initially formed silicon-containing oxonium salt, as shown below.

$$(R)_3SiOH + H_2SO_4 \rightleftharpoons (R)_3SiOH_2^+ + HSO_4^- \quad (9)$$

$$HSO_4^- + (R)_3SiOH_2^+ \rightleftharpoons (R)_3SiHSO_4 + H_2O \quad (10)$$

Summation of equations 9, 10, and 8 results in a calculated *i*-factor of 3.

In addition we have found that hexamethyldisiloxane,[13] hexaethyldisiloxane, and triethylethoxysilicon yield *i*-factors of about 4. The over-all equations are given below and may be derived by following the principles above outlined.

$$(R)_3SiOSi(R)_3 + 3H_2SO_4 \rightleftharpoons 2(R)_3SiHSO_4 + H_3O^+ + HSO_4^- \quad (11)$$

$$(C_2H_5)_3SiOC_2H_5 + 3H_2SO_4 \rightleftharpoons (C_2H_5)_3SiHSO_4 + C_2H_5HSO_4 + H_3O^+ + HSO_4^- \quad (12)$$

When added to water the trialkylsilicon bisulfate present in these solutions probably reacts with water as shown by the reverse of equation 10. In the acid medium the trialkylsilanols rapidly form disiloxanes and these compounds were obtained in high yield on pouring the sulfuric acid solutions above mentioned into water.[14]

The formation of trialkylsilicon chloride[15] by adding ammonium chloride to solutions which contain trialkylsilicon bisulfate probably involves the displacement of the bisulfate ion by a back-

(9) A more complete discussion of our work in methanesulfonic acid is being prepared for publication.

side attack of chloride ion.[16] Because of the insolubility of the trialkylsilicon chlorides in sulfuric acid the reaction goes to completion and constitutes an excellent method of preparation for these chlorides.

$$Cl^- + (R)_3SiHSO_4 \rightleftharpoons (R)_3SiCl + HSO_4^- \quad (13)$$

## Esters[17]

Two types of behavior have been noted for solutions of methyl esters in sulfuric acid.

$$RCOOCH_3 + H_2SO_4 \rightleftharpoons RCO_2CH_3{\cdot}H^+ + HSO_4^- \; [i = 2] \quad (14)$$

$$RCOOCH_3 + 3H_2SO_4 \rightleftharpoons RC^+O + H_3O^+ + CH_3HSO_4 + 2HSO_4^- \; [i = 5] \quad (15)$$

Some factors tending to cause esters to behave according to either of these courses have been discussed.[4a,b] In seeking to determine the effect of heating the sulfuric acid solution of methyl benzoate, a new type of behavior has been noted, as shown in equation 16.

$$RCOOCH_3 + 2H_2SO_4 \rightleftharpoons RCO_2H_2^+ + CH_3HSO_4 + HSO_4^- \; [i = 3] \quad (16)$$

When solutions of methyl benzoate in sulfuric acid were heated to 45° or above for short times and then cooled for freezing point depression determinations, *i*-factors of about 3 were obtained. This behavior may be explained by postulating a backside attack of bisulfate ion on the conjugate acid of methyl benzoate as shown below.

$$RCOOCH_3 + H_2SO_4 \rightleftharpoons RCO_2CH_3H^+ + HSO_4^- \quad (17)$$

$$HSO_4^- + CH_3O_2CR{\cdot}H^+ \rightleftharpoons CH_3HSO_4 + RCOOH \quad (18)$$

$$RCOOH + H_2SO_4 \rightleftharpoons RCO_2H_2^+ + HSO_4^- \quad (19)$$

Summations of equations 17, 18, and 19 yields equation 16.

The conjugate acids of *t*-butyl esters undoubtedly undergo ionization as follows

$$RCO_2C(CH_3)_3{\cdot}H^+ \rightleftharpoons RCOOH + (CH_3)_3C^+ \quad (20)$$

Evidence for this type of reaction has been obtained in the formation of *t*-butyl methyl ether by the acid catalyzed decomposition of *t*-butyl esters in methanol.[18]

It is thus evident that the behavior of the conjugate acids of methyl and *t*-butyl esters in acid media can be compared to the behavior of the conjugate acids of methanol and *t*-butyl alcohol. How complete the analogy may be must await further experimentation.

It is a fact that *i*-factors of about 3 can be obtained from methyl benzoate on heating or on long standing at 25°. This might be explained by postulating an amount of ionization according to equation 15 sufficient to account for the *i*-factors observed. That such ionization does not occur is indicated by the fact that the amount of benzoic acid recovered on pouring the sulfuric acid solutions of methyl benzoate into water is far greater than that which would have been found if ionization according to equation 15 were taking place. Thus, when a solution of methyl benzoate in sulfuric acid was heated to 90° for fifteen minutes and then cooled, an *i*-factor of 3.32 was obtained. When an aliquot of this solution was poured into water 81% of the original ester was isolated as benzoic acid. If the benzoic acid had been formed by the reaction of the $C_6H_5CO^+$ ion (equation 15) with water, an *i*-factor of over 4 would have been expected. We have ruled out possible abnormalities derivable from the action of sulfuric acid on methanol by showing that *i*-factors of solutions of methanol in sulfuric acid do not change appreciably on heating to 90° for twenty minutes.

(16) In line with the above concept, it was predicted that the alkaline hydrolysis of trialkylsilicon halides should be first order with respect to the base used. This prediction appears to be confirmed by a statement of Dr. Gardner Swain of M. I. T. made at the Chicago meeting, April, 1948, to one of us (M.S.N.) that he had observed kinetics in such replacement reactions to be first order with respect to alkali.

(17) In this discussion only the behavior of methyl esters will be discussed.

## Experimental

### Reagents

**Sulfuric Acid.**—C. P. concentrated sulfuric acid and thirty per cent. fuming sulfuric acid were mixed in the ratio twenty to thirteen by weight and sufficient water added to make the solution slightly less than 100% sulfuric acid. Acid with a freezing point between 10.2 and 9.6° was used in cryoscopic determinations.

**Solutes.**—All solutes were carefully purified and dried before use. Where the material was not otherwise available, preparation was by previously reported procedures. Physical constants were as follows:

Benzoic acid: m.p. 122.1–122.3° (uncor.)
Hexaethyldisiloxane: b.p. 103° (11 mm.); $n^{20}D$ 1.4338
Hexamethyldisiloxane: $n^{20}D$ 1.3780. Received through the courtesy of General Electric Research Labs.
Methyl alcohol: $n^{20}D$ 1.3294
Methyl benzoate: b.p. 112.5° (53 mm.); $n^{20}D$ 1.5170
Triethylcarbinol: b.p. 80° (70 mm.); $n^{20}D$ 1.4300
Triethylethoxysilicon: b.p. 152° (740 mm.); $n^{20}D$ 1.4135
Triethylsilanol: b.p. 74.5° (26 mm.); $n^{20}D$ 1.4329
*t*-Butyl alcohol: m.p. 25.43° (cor.)

**Apparatus and Procedure.**—Except where indicated in the data section, the apparatus used and procedures followed are essentially those previously described.[4a]

## Data

**A. Tertiary Alcohols.**—Preliminary runs with *t*-butyl alcohol indicated that its *i*-factor rose rapidly with time, the rate of rise being temperature dependent. Care was taken in subsequent determinations to note the rate of this rise, making possible extrapolation of *i*-factor values to zero time. In all runs herein reported the solute was added after the freezing point apparatus and sulfuric acid had been in the cooling bath for some time, the addition being made when the temperature of the acid was about 13°. Use of this technique facilitated calculation of the *i*-factor at zero time since it not only cut the time that the alcohol was in the acid prior to the freezing

point determination, but also minimized the rate of *i*-factor change by maintaining a relatively constant low temperature.

The second column gives the time elapsing between addition of the solute and the time crystallization started in each run.

## I. Alcohols

### A. *t*-Butyl Alcohol (0.03509 Molal Solution)

Temperature of solution rose to a maximum of 180° between runs

| No. | Time, min. | F. p., °C. | *T* | *i* |
|---|---|---|---|---|
| 1 | Pure solvent | 10.024 | ... | .. |
| 2 | 20 | 9.473 | 0.551 | 2.56 |
| 3 | 76 | 9.322 | .702 | 3.27 |
| 4 | 205 | 9.168 | .856 | 3.99 |
| 5 | 1650 | 9.068 | .956 | 4.46 |

Highest *i*-value observed was 5.46. Rough extrapolation to zero time gives $i = 2.1$.

A second solution of *t*-butyl alcohol (0.3411 molal), in which the temperature never was above 14°, gave *i*-factors of 2.30, 3.08 and 3.85 for the time intervals of 15, 86 and 312 minutes, respectively.

### B. Triethylcarbinol (0.08017 Molal Solution)

Temperature was below 16° for runs 1–4; at room temperature for runs 5–7

| No. | Time | F. p., °C. | T | *i* |
|---|---|---|---|---|
| 1 | Pure solvent | 9.686 | ... | .. |
| 2 | 25 minutes | 8.432 | 1.254 | 2.55 |
| 3 | 63 minutes | 8.360 | 1.326 | 2.71 |
| 4 | 252 minutes | 8.201 | 1.485 | 3.04 |
| 5 | 27 hours | 7.759 | 1.927 | 3.96 |
| 6 | 40 hours | 7.412 | 2.274 | 4.68 |
| 7 | 160 hours | 6.902 | 2.784 | 5.74 |

Extrapolation to zero times gives $i = 2.4$.

## II. Organo-silicon Compounds

**A. Triethylethoxysilicon.**—The *i*-factors for 5 different increments of solute ranged in value from 3.98 to 4.44 with an average of 4.3. The time intervals ranged from a few minutes to fourteen hours and no drift in the value of *i* was noted with time.

**B. Hexamethyldisiloxane.**—The *i*-factors for 3 different increments of solute ranged in value from 3.98 to 4.23 with an average of 3.1. The time intervals ranged from a few minutes to twelve hours and no drift in the value of *i* was noted with time.

**C. Hexaethyldisiloxane.**—The *i*-factors for three different increments of solute ranged in value from 3.92 to 4.04 with an average of 4.0.

**D. Triethylsilanol.**—The *i* factors for 3 different increments of solute ranged in value from 2.84 to 3.10 with an average of 3.0. The time intervals ranged from a few minutes to three hours and no drift in the value of *i* was noted with time.

## Summary

*i*-Factors, calculated from measurements of the freezing point depression in sulfuric acid caused by solution of a number of organic compounds, have been determined.

The *i*-factors for *t*-butyl alcohol and triethylcarbinol are shown to change with time; extrapolation to zero time gives values of 2.1 and 2.4, respectively. An explanation of this phenomenon is proposed.

An hypothesis which attempts to correlate the behavior of oxonium salts, $ROH_2^+$, of alcohols in acid media with the nucleophilic displacement reactions of the analogous alkyl halides, RCl, is stated.

It is shown that the *i*-factor of a solution of methyl benzoate in sulfuric acid is raised from a value of 2 to 3 by heating at 90° for fifteen minutes. This *i*-factor is accounted for by postulating the following reaction

$$C_6H_5CO_2CH_3 + 2H_2SO_4 \rightleftharpoons C_6H_5CO_2H_2^+ + CH_3HSO_4 + HSO_4^-$$

Experimental evidence supporting this equation is presented.

Triethylethoxysilicon, hexamethyldisiloxane, hexaethyldisiloxane, and triethylsilanol were shown to give *i*-factors of about 4.3, 4.1, 3.9, and 3.0, respectively, in sulfuric acid.

# *o-*, *m-* and *p-t*-Butyltoluenes

BY KASPER T. SERIJAN, HAROLD F. HIPSHER AND LOUIS C. GIBBONS

The fuel evaluation program conducted at this Laboratory involving the synthesis and purification of aromatic hydrocarbons included the preparation of five-gallon quantities of *m-* and *p-t*-butyltoluenes. One reference was found in the literature on *o-t*-butyltoluene[1] and the physical properties attributed to this compound were not in accordance with expectations. Accordingly, a smaller scale preparation of this hydrocarbon was undertaken in order to obtain physical constants data for the three isomeric compounds, including a brief analysis of the infrared spectra.

The alkylation of monoalkylbenzenes by the alcohol–boron trifluoride method has been described in the preparation of some *p*-dialkylbenzenes.[2] This procedure was followed in the present work in several relatively large-scale runs and an analysis of the resulting product by careful fractionation using a distillation column rated above 100-theoretical plates indicated that nearly equal amounts of the *m-* and *p*-isomers were obtained. This result is not in agreement with the earlier work and the formation of the *m*-isomer may possibly be attributed to some slight deviation in the experimental conditions when applied on a larger scale. However, the refractive index value reported in the previous work for *p-t*-butyltoluene indicates a mixture of both isomers of nearly identical composition with that obtained in this investigation. The proximity of the boiling points of the two isomers as shown in Table I indicates that complete separation would require a precise fractionation.

The use of aluminum chloride in the alkylation of toluene with *t*-butyl alcohol[3] similarly resulted in mixtures which upon fractionation indicated the presence of both isomers. The total yield of dialkylbenzenes was nearly identical in both procedures as shown in Table I but the *m*-isomer was obtained in appreciably higher yield when aluminum chloride was used. Both procedures gave substantial yields of higher boiling material which was not investigated further at this time.

No trace of the *o*-isomer was apparent in the reaction products of these two methods of preparation. This compound was obtained by the condensation of *t*-butyl chloride with *o*-methylphenylmagnesium bromide and the physical properties of the three isomeric hydrocarbons are summarized in Table I. A high state of purity of each compound was indicated by the time–temperature freezing or melting curves. The physical properties were obtained by methods previously described[4] with the exception of the density values which were measured by means of apparatus described by Forziati, *et al.*[5]

equivalents and melting points of the acids are shown in Table II.

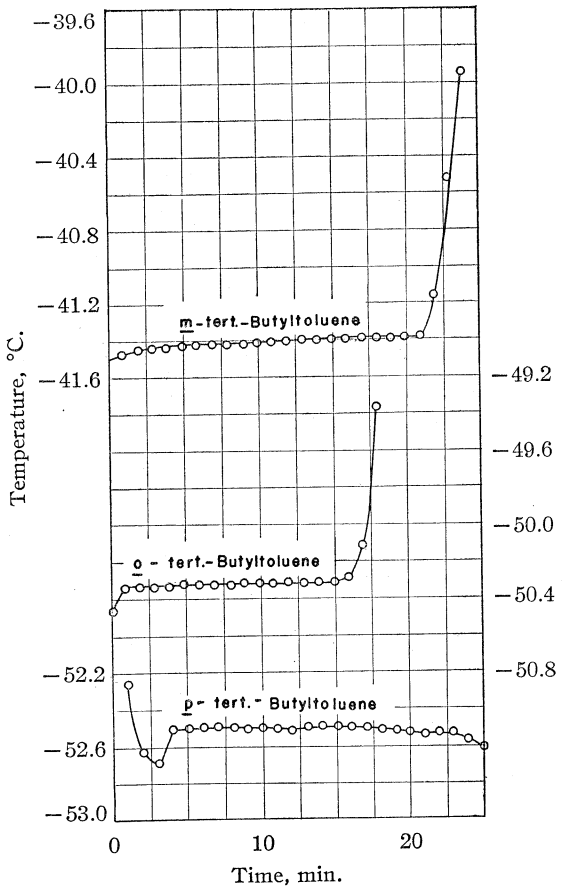

Fig. 1.—Time–temperature freezing or melting curves of *o*-, *m*- and *p*-*t*-butyltoluenes.

The infrared absorption spectra of the three hydrocarbons were obtained by the use of a spectrometer previously described[8] with the photoelectric amplifier of McAlister, *et al.*[9] The data are given in Table III with the intensity of absorption arbitrarily indicated as shown. The wave length certainty is estimated to be ±0.05 μ. Since the only purpose for the analysis of the absorption spectra of these compounds was to supplement the conclusions with respect to *o*-, *m*- and *p*-isomerism[10] a limited portion of the spectra is presented. The wave length regions 8.20–9.25 μ and 11.90–13.90 μ are of particular significance in the analysis of structure for the di-substituted aromatics[11] and Table IV is a summary from a portion of the data in the cited reference. The indicated wave length regions in the table are characterized by relatively high absorption for *o*-, *m*- and *p*-substituted compounds. The infrared data for the designated *t*-butyltoluenes show fairly good agreement as indicated by a comparison between Tables III and IV.

## Experimental

**Alkylation of Toluene Using Boron Trifluoride.**—The reaction vessel consisted of a 10-gal., copper-lined reactor equipped with a stirrer, reflux condensor and a copper inlet tube in the form of a perforated coil submerged below the liquid level. An ice-chilled brine solution was circulated through the outer jacket of the reaction vessel by means of a pump. A typical run consisted of 25 moles of *t*-butyl alcohol and 100 moles of toluene cooled to approximately 5° after which 25 moles of boron trifluoride was bubbled through the coil in approximately two hours. The reaction mixture was stirred at 5–15° for four hours and then allowed to come to room temperature. The reaction product was then transferred to a stainless steel reactor and heated for six hours at 70–80°. After cooling, the hydrocarbon layer was separated off, washed twice with water, then with dilute sodium carbonate solution and again with water. The combined material from several such runs was dried by passage through alumina. The unreacted toluene was then stripped off and the remainder was fractionated on a Fenske-type column as previously mentioned.

**Alkylation of Toluene Using Aluminum Chloride.**—The Friedel–Crafts reaction was carried out in a 30-gal., glass-lined reactor. The quantities of reactants and reaction conditions closely followed the general procedure.[3] A mixture of 500 moles of toluene and 150 moles of aluminum chloride was cooled by cold water circulating through the jacket. To this was gradually added 150 moles of *t*-butyl alcohol dissolved in 250 moles of toluene, the total addition time being six hours. The reaction mixture was stirred for twelve hours and the complex was then hydrolyzed by passing it through a pipe to a second reactor which

was partially filled with water and ice and located one floor-level below. After a short period of stirring, the hydrocarbon layer was removed and worked up as in the previous procedure. Final purification was effected by a second fractionation of the individual isomers accumulated from both syntheses.

*o-t*-**Butyltoluene.**—The Grignard reagent was made using 85 moles of magnesium covered with 12 liters of dry ether to which was added over a period of five hours 80 moles of *o*-bromotoluene (f.p. −26.91° and $n^{20}D$ 1.5563) dissolved in 5 liters of dry ether. This was condensed with 72 moles of *t*-butyl chloride dissolved in 5 liters of dry ether and the reaction mixture was stirred overnight. After hydrolysis with dilute hydrochloric acid, the hydrocarbon layer was separated and the ether was evaporated.

The crude product was then dried over sodium sulfate and fractionated on a 15-theoretical plate column. Halogen impurities were removed by treatment with sodium in liquid ammonia. It was finally fractionated on a six-foot Podbielniak column and the yield of pure hydrocarbon based on the *t*-butyl chloride is shown in Table I.

**Oxidation of *t*-Butyltoluenes.**—No difficulty was encountered in the oxidation of the *m*- and *p*-isomers. The *t*-butylbenzoic acids obtained by the alkaline-permanganate method were found to be identical with those obtained by dilute nitric acid oxidation after maximum purity was attained by successive recrystallizations out of ethyl alcohol. Several attempted oxidations of the *o*-isomer using alkaline permanganate resulted in an oil which could not be crystallized. When the oil was purified by distillation at reduced pressure, a solid product was obtained which was recrystallized out of neohexane and found upon analysis to be *o-t*-butylbenzoic acid. The data on these acids are shown in Table II.

The oxidation of *o-t*-butyltoluene was also carried out in a sealed tube using dilute nitric acid and heating at 170° for twelve hours. Phthalic acid was precipitated out by the addition of chloroform to the oil resulting in this procedure and this was sublimed to phthalic anhydride, which gave no depression in melting point when mixed with an authentic sample (m.p. 130.8°).

**Acknowledgment.**—The authors wish to thank Mr. R. R. Hibbard for the infrared measurements, Mr. D. E. Grant for the carbon–hydrogen analyses and Mr. J. F. Thompson for the determination of the physical properties reported.

## Summary

1. The use of boron trifluoride as an alkylation catalyst has been shown to result in mixtures of *p*- and *m-t*-butyltoluenes in the reaction between toluene and *t*-butyl alcohol. The yield of each isomer is nearly the same but when aluminum chloride is used as the catalyst the *m*-isomer is appreciably greater with a corresponding decrease in yield of the *p*-compound.

2. The preparation and characterization of *o-t*-butyltoluene has been described. The physical properties have been shown to differ from those reported in the only earlier work on the synthesis of this hydrocarbon.

3. The physical properties of the three isomeric *t*-butyltoluenes in high purity have been described and time–temperature freezing or melting curves for these compounds are shown.

4. The oxidation of *o*-, *m*- and *p-t*-butyltoluenes to the corresponding *t*-butylbenzoic acids has been described and *o-t*-butylbenzoic acid has been reported for the first time.

5. Partial infrared absorption data for the *t*-butyltoluenes have been determined for purposes of gross structural analysis and the data have been shown to be in good agreement with previous work wherein characteristic absorption spectra for disubstituted aromatic compounds have been evaluated.

# Erythrina Alkaloids. XVI. Studies on the Constitution of Erysodine, Erysovine and Erysopine[1]

BY FRANK KONIUSZY, PAUL F. WILEY AND KARL FOLKERS

Structure studies on erysodine, erysovine and erysopine have elucidated the functional groups and the number of rings of each alkaloid, and have shown that each has the same ring system.

These three *Erythrina* alkaloids[2,3,4] have interesting curare-like pharmacologic action.[5] Erysodine and erysovine have the same molecular formula, $C_{18}H_{21}NO_3$; each has two methoxyl groups and one phenolic hydroxyl group. Therefore, the functional groups containing all the oxygen atoms of erysodine and erysovine are known.[2] Erysopine[2] has the formula $C_{17}H_{19}NO_3$, one methoxyl group, and two phenolic hydroxyl groups which are ortho as indicated by a color reaction with ferric chloride. None of these three alkaloids showed the presence of an N-methyl group or a C-methyl group. The presence of methoxyl groups, and particularly the phenolic hydroxyl groups, implies the presence of at least one benzenoid nucleus in all three alkaloids.

A facile reaction between erysodine and methyl iodide to give the crystalline quaternary salt, erysodine methiodide, proved the tertiary nature of the nitrogen atom in erysodine.

Erysodine reacted with two molar equivalents of hydrogen with Adams platinum catalyst at atmospheric pressure. The ease of hydrogenation was

typical of that of semi-saturated cyclic alkaloidal structures. The tetrahydroerysodine was isolated as a crystalline free base and hydrobromide. The fact that this hydrogenation reaction involved two >C=C< groups and not one >C=C< group and one >C=N— group was shown by the reaction of the tetrahydroerysodine with acetic anhydride to give crystalline O-acetyltetrahydroerysodine. The reduction of a >C=N— group to a >CH—NH— group would be expected to lead to an O-acetyl-N-acetyl derivative upon acetylation. On the basis of these data, the nitrogen atom of erysodine appears to be shared by two nuclei.

Erysopine was hydrogenated under similar conditions to give tetrahydroerysopine, which was isolated as a crystalline hydrobromide.

"Erysocine,"[6] which is a "complex" of erysodine and erysovine, absorbed two molar equivalents of hydrogen, similarly. The hydrogenation product yielded a crystalline tetrahydro-"erysocine" hydrobromide which did not separate into its components on crystallization.

It was observed[2] before that a characteristic property of erysodine, erysovine and erysopine is their weakly basic nature. For example, erysodine crystallizes from ethanol containing excess hydrogen chloride. Although erysodine dissolves in aqueous hydrochloric acid, it can be nearly completely removed by several chloroform extractions. Erysovine was converted into a crystalline hydrobromide and hydroiodide. Erysodine is also weakly acidic and could be removed from 2% aqueous sodium hydroxide solution by repeated chloroform extraction.

Since erysodine has two methoxyl groups, one phenolic hydroxyl group, a tertiary nitrogen atom shared by two nuclei, two "ethylenic" double bonds, and a benzenoid nucleus, it is now evident that erysodine has four nuclei in its ring system.

It appeared probable that erysodine, erysovine and erysopine have the same ring system, that the three oxygen atoms of each are in the same position and that each differs in the position or number of the O-methyl groups. This relationship between the alkaloids was investigated by methylation reactions.

Erysodine and erysopine reacted with dimethyl sulfate in alkaline aqueous solution to give identical crystalline products of the formula $C_{21}H_{29}NO_7S$. This composition corresponds to the methomethylsulfate of O-methylerysodine and O-dimethylerysopine, respectively. For simplicity of nomenclature, the fully oxygen-methylated alkaloid is designated "erysotrine"; hence, this new product, $C_{21}H_{29}NO_7S$, is erysotrine methomethylsulfate. As other data prove, this product should also be produced from erysovine.

It was desirable to methylate the free phenolic hydroxyl group of these *Erythrina* alkaloids without methylating the tertiary nitrogen atom. The methylation of the phenolic hydroxyl groups of alkaloids by dimethyl sulfate is frequently accompanied by methylation of the nitrogen atom. Thus, the reaction of morphine with dimethyl sulfate in sodium hydroxide solution gave codeine methomethylsulfate.[7] To circumvent this difficulty, morphine was methylated by reaction with phenyltrimethylammonium hydroxide in alcohol at 110° and codeine was obtained.[8] Our experiments with this method, including several modifications, for the methylation of erysodine were not satisfactory. Tetramethylammonium hydroxide has been used[9] for methylating sterically hindered acids, but treatment of erysodine with this reagent was unsatisfactory. The result of treating erysodine with diazomethane was also unsatisfactory since much erysodine was recovered.

The nitrogen atom of morphine was "protected" in the methylation of morphine N-oxide; codeine was obtained by reduction of the oxide with sulfurous acid.[10] We have found that the N-oxides of these *Erythrina* alkaloids could be made readily and, after methylation, reduction with zinc dust and hydrochloric acid gave the fully oxygen-methylated tertiary alkaloid which could be extracted readily from an ammoniacal solution. It was shown separately that erysodine N-oxide could be reduced to erysodine with zinc and hydrochloric acid.

Treatment of erysodine N-oxide with dimethyl sulfate gave a non-crystalline erysotrine N-oxide which was reduced with zinc and hydrochloric acid to erysotrine. This fully oxygen-methylated tertiary base did not crystallize, but it did sublime *in vacuo* to give a gum of the expected composition, $C_{19}H_{23}NO_3$, and it gave a crystalline picrate. It may be that some erysotrine was produced in the above-mentioned unsatisfactory methylation experiments, but was not isolated because of its non-crystalline character.

Conversion of both erysovine and erysopine into their N-oxides, followed by methylation, reduction, and treatment with picric acid, gave crystalline picrates which were identical with the one derived from erysodine.

Erysonine[11] has the molecular formula $C_{17}H_{19}NO_3$, which is the same as that of erysopine. Erysonine does not give a green color with ferric chloride in aqueous solution as does erysopine showing that erysonine apparently does not have two ortho phenolic hydroxyl groups. The series of reactions used to obtain erysotrine picrate was applied to erysonine. Although 20 mg. of gummy product was obtained from 127 mg. of erysonine, it did not give a crystalline picrate even after additional manipulation and storage.

The conversion of erysodine and erysopine into erysotrine methomethylsulfate, and the conversion of erysodine, erysovine and erysopine into erysotrine picrate prove that all three alkaloids have the same oxygenated ring system and differ only in the position or number of O-methyl groups. Furthermore, all three alkaloids have four nuclei in their ring system.

## Experimental

**Erysodine Methiodide.**—A solution prepared from 150 mg. of erysodine, 1 ml. of methyl iodide, and 2 ml. of absolute methanol was refrigerated for twelve hours. The crystals, which were obtained, weighed 68 mg. and melted at 229–229.5°. Recrystallization of this product from 95% ethanol did not alter the melting point. The crystals were dried at 100° *in vacuo* for one hour.

*Anal.* Calcd. for $C_{18}H_{21}NO_3 \cdot CH_3I$: C, 51.70; H, 5.48; N, 3.18. Found: C, 51.82, 51.78; H, 5.62, 5.62; N, 3.27.

**Tetrahydroerysodine.**—A 508-mg. sample of erysodine was dissolved in 100 ml. of water to which 4 drops of concentrated hydrochloric acid had been previously added. The hydrogenation was carried out with 51 mg. of Adams platinum catalyst at atmospheric pressure and 2 moles of hydrogen was absorbed. After removal of the catalyst, the filtrate was made alkaline with sodium bicarbonate. The solution was extracted continuously with chloroform for eighteen hours. The chloroform extract was distilled under reduced pressure and 327 mg. of a gummy base was obtained; it crystallized after dissolving in 2 ml. of absolute ethanol. The crystals melted at 148–150°, and after three recrystallizations from ethanol, the melting point was constant at 152–153°. The tetrahydroerysodine was dried at 2 mm. and 25°.

*Anal.* Calcd. for $C_{18}H_{25}NO_3$: C, 71.25; H, 8.30; N, 4.61. Found: C, 71.10; H, 8.20; N, 4.78.

After a 2-g. sample of erysodine was hydrogenated, the chloroform residue of crude tetrahydroerysodine weighed 1.884 g. It was dissolved in 100 ml. of absolute ether and the solution was filtered to remove amorphous insoluble impurities. The filtrate was concentrated by distillation before crystallization, and 1.422 g. of tetrahydroerysodine was obtained; m. p. 150°. Recrystallization of this product from ether yielded crystals melting at 152–153° which is the same melting point observed for the product recrystallized from ethanol.

**Tetrahydroerysodine Hydrobromide.**—A 200-mg. sample of tetrahydroerysodine was dissolved in 2 ml. of absolute ethanol. After adding two drops of 40% aqueous hydrobromic acid, anhydrous ethyl ether (about ten drops) was added until incipient turbidity was observed. The crystals which were obtained melted at 247.5–248.5° and, after two recrystallizations from ethanol, the melting point was constant at 251–251.5° (dec.). The melting point was not changed by drying at 100° *in vacuo*.

*Anal.* Calcd. for $C_{18}H_{25}NO_3 \cdot HBr$: C, 56.25; H, 6.81. Found: C, 56.05; H, 6.65.

**O-Acetyltetrahydroerysodine.**—A 104-mg. sample of tetrahydroerysodine was added to 5 ml. of acetic anhydride and the solution was refluxed for ten minutes. After cooling, the solution was poured into 100 ml. of ice and water. When the excess anhydride had hydrolyzed, the solution was made alkaline with sodium bicarbonate and extracted six times with chloroform. Distillation of the chloroform extract yielded 109 mg. of colorless gum. A solution of this residue in 50 ml. of anhydrous ethyl ether was diluted with 5 ml. of petroleum ether, filtered, and concentrated to a volume of 12 ml. After refrigeration, 89 mg. of O-acetyltetrahydroerysodine, m. p. 135–136°, was obtained.

*Anal.* Calcd. for $C_{20}H_{27}NO_4$: C, 69.54; H, 7.87; $CH_3CO$-, 12.46. Found: C, 69.43, 69.63; H, 7.86, 7.91; $CH_3CO$-, 12.21.

**Tetrahydroerysopine Hydrobromide.**—One gram of erysopine was dissolved in a mixture of 25 ml. of water and 1.5 ml. of 40% aqueous hydrobromic acid. After the addition of 124 mg. of Adams platinum catalyst, the hydrogenation was carried out at atmospheric pressure, and 2 moles of hydrogen was absorbed. After removal of the catalyst, the filtrate was concentrated to dryness at 30° under reduced pressure in an atmosphere of nitrogen. The colorless gum was dissolved in 5 ml. of hot absolute ethanol and crystals quickly formed in the hot solution. The solution was cooled in the refrigerator. After the crystallization was complete, the yield of tetrahydroerysopine hydrobromide was 1.024 g.; m. p. 242–244°. Two recrystallizations of this product from ethanol yielded 900 mg. of tetrahydroerysopine hydrobromide which melted constantly at 244–245°.

*Anal.* Calcd. for $C_{17}H_{23}NO_3 \cdot HBr$: C, 55.15; H, 6.53. Found: C, 55.19; H, 6.50.

**Tetrahydro-"erysocine" Hydrobromide.**—A sample of "erysocine" was hydrogenated under conditions similar to that described for erysopine. The first crop of tetrahydro-"erysocine" hydrobromide melted at 223–224°. After recrystallization from absolute ethanol and ether, the melting point of the product was unchanged.

*Anal.* Calcd. for $C_{18}H_{25}NO_3 \cdot HBr$: C, 56.25; H, 6.91. Found: C, 56.11; H, 6.64.

It was interesting that this product showed no ready tendency to separate into tetrahydroerysodine hydrobromide and tetrahydroerysovine hydrobromide.

**Erysovine Hydrobromide Hemi-hydrate.**—To 5 ml. of absolute alcohol containing 300 mg. of erysovine was added 80 mg. of anhydrous gaseous hydrogen bromide in 2 ml. of alcohol. This solution was diluted with 4 ml. of anhydrous ethyl ether and refrigerated. Crystals separated slowly during three days; they weighed 197 mg. and melted at 150–151° (dec.). One recrystallization of this product did not alter the melting point.

*Anal.* Calcd for $C_{18}H_{21}NO_3 \cdot HBr \cdot 0.5H_2O$: C, 55.54; H, 5.95; N, 3.59. Found: C, 55.48; H, 6.06; N, 3.68.

**Erysovine Hydriodide Hydrate.**—A 300-mg. sample of erysovine was dissolved in 5 ml. of absolute ethanol and 150 mg. of sodium iodide was added. The solution was acidified with two drops of glacial acetic acid, diluted with 3 ml. of ethyl ether, and refrigerated. After one week, 121 mg. of crystals melting at 159–160° was obtained. Recrystallization of this product from ethanol and ether yielded 63 mg. of hydriodide melting at 162°.

*Anal.* Calcd. for $C_{18}H_{21}NO_3 \cdot HI \cdot H_2O$: C, 48.54; H, 5.43; N, 3.14. Found: C, 48.76; H, 5.52; N, 3.22.

**Conversion of Erysodine into Erysotrine Methomethylsulfate.**—A mixture of 20 ml. of 5% sodium hydroxide solution, 150 mg. of erysodine, and 1 ml. of dimethyl sulfate was shaken for five minutes at 25°. The excess dimethyl sulfate was hydrolyzed by warming the solution and the cooled clear alkaline solution was extracted four times with chloroform. Distillation of the solvent left 143 mg. of a clear gum which was dissolved in 1 ml. of absolute ethanol. The crystals, which formed during refrigeration, melted at 60°. The melting point was constant at 61° after two recrystallizations of the product from ethanol. The crystals were somewhat hygroscopic.

*Anal.* Calcd. for $C_{21}H_{29}NO_7S$: C, 57.39; H, 6.65; N, 3.16. Found: C, 57.46, 57.47; H, 6.96, 6.90; N, 3.15.

**Conversion of Erysopine into Erysotrine Methomethylsulfate.**—A 1.087-g. sample of erysopine was dissolved in 50 ml. of 10% sodium hydroxide solution and 2 ml. of dimethyl sulfate was added. After shaking the mixture vigorously for twenty-five minutes with cooling, the excess dimethyl sulfate was hydrolyzed by heating the solution to 50°. After cooling, the alkaline solution was extracted five times with chloroform. Distillation of the solvent left 1.313 g. of residue which crystallized when it was dissolved in 2 ml. of absolute ethanol. The crystals melted at 60–61° and when mixed with the substance de-

rived from erysodine, the melting point of the mixture was not depressed. A sample was dried four hours at 25° *in vacuo* for analyses.

*Anal.* Calcd. for $C_{21}H_{29}NO_7S$: C, 57.39; H, 6.65. Found: C, 57.75; H, 6.43.

**Conversion of Erysodine N-Oxide to Erysodine.**—A 470-mg. sample of erysodine was added to 5 ml. of superoxol and the mixture was heated forty-five minutes on the steam-bath. After standing overnight, the solution was concentrated *in vacuo*. The residue, 596 mg., was dissolved in 10 ml. of 15% hydrochloric acid. Two grams of zinc dust was added in small portions and after the reaction had subsided the solution was filtered. The filtrate was made alkaline with ammonium hydroxide and extracted five times with 10-ml. portions of chloroform. Distillation of the chloroform left 143 mg. (30%) of product, m. p. 189°. One recrystallization of this product from ether gave erysodine, m. p. 200–202°. A mixture of this product and the original erysodine showed no depression of melting point.

**Conversion of Erysodine into Erysotrine and Erysotrine Picrate.**—A 2-g. sample of erysodine was added to 20 ml. of superoxol (30% hydrogen peroxide), and the solution was heated for one hour on the steam-bath. Concentration of the solution at 18 mm. pressure yielded 3.093 g. of a thick oil. This crude N-oxide was dissolved in 50 ml. of 2% sodium hydroxide solution, and 5 ml. of dimethyl sulfate was added. The mixture was shaken for one hour, with occasional addition of alkali to keep the solution alkaline. The solution was extracted six times with chloroform, and distillation of the solvent *in vacuo* left 1.308 g. of crude erysotrine N-oxide. This product was dissolved in 50 ml. of 15% hydrochloric acid solution and reduced by gradual addition of 5 g. of zinc dust. After hydrogen evolution had practically ceased, the zinc sludge was collected on a filter and the filtrate was made alkaline with ammonium hydroxide. The solution was extracted six times with chloroform, and distillation of the solvent *in vacuo* left 963 mg. of crude erysotrine as a gum. This product did not crystallize from ether, so a 599-mg. portion was dissolved in 5 ml. of absolute ethanol and 500 mg. of picric acid was added. After standing, the clear yellow solution deposited crystals; m. p. 157°. Five recrystallizations from ethanol yielded pure erysotrine picrate, which melted constantly at 160–161°; $[\alpha]^{25}D$ + 138.1° (*c*, 0.35 in ethanol).

*Anal.* Calcd. for $C_{19}H_{23}NO_3 \cdot C_6H_3N_3O_7$: C, 55.39; H, 4.83; 3 $CH_3O$-, 17.17. Found: C, 55.48; H, 4.70; $CH_3O$-, 16.42.

The gummy erysotrine was sublimed in a molecular still at a bath temperature of 100–105° and a pressure of $2.5 \times 10^{-4}$ mm. The sublimate was gummy and showed no tendency to crystallize.

*Anal.* Calcd. for $C_{19}H_{23}NO_3$: C, 72.81; H, 7.39, 3 $CH_3O$-, 29.74. Found: C, 72.46; H, 7.64.

Resublimation gave a product of unaltered composition. Found: C, 72.46; H, 7.35; $CH_3O$-, 26.45.

**Conversion of Erysovine into Erysotrine Picrate.**—To 20 ml. of superoxol was added 276 mg. of erysovine and the solution was warmed to 90°. It was then cooled and maintained at 10° for six hours. After concentration *in vacuo*, 285 mg. of crude erysovine N-oxide remained. It was dissolved in 25 ml. of 4% sodium hydroxide solution and 5 ml. of dimethyl sulfate was added. The mixture was mechanically agitated for one hour; alkali was added to maintain an alkaline reaction. The solution was then extracted with chloroform ten times and distillation of the solvent left 270 mg. of crude erysotrine N-oxide. It was dissolved in 25 ml. of dilute hydrochloric acid and reduced by the gradual addition of 5 g. of zinc dust. When the reduction was complete, the zinc sludge was removed and the filtrate was made alkaline with ammonium hydroxide and extracted ten times with chloroform. Removal of the solvent *in vacuo* yielded 169 mg. of crude erysotrine. It was dissolved in 5 ml. of warm ethanol and treated with 5 ml. of warm ethanol containing 129 mg. of picric acid. The solution was maintained at 50–60° for six hours for crystallization. Filtration yielded 122 mg. of yellow crystals; m. p., 158–160°, $[\alpha]^{25}D$ + 137°. Recrystallization of this product yielded 65 mg. of erysotrine picrate, m. p. 160–161°. The melting point of a mixture of this picrate and the corresponding picrate derived from erysodine was not depressed. The rotation, $[\alpha]^{25}D$ + 139°, checked that of erysotrine picrate from erysodine.

**Conversion of Erysopine into Erysotrine Picrate.**—A 272-mg. sample of erysopine was added to 20 ml. of superoxol and the mixture was heated at 100° for thirty minutes. The insoluble alkaloid was filtered (32 mg.) and discarded. Concentration of the filtrate *in vacuo* left 282 mg. of crude erysopine N-oxide. It was dissolved in 50 ml. of 4% sodium hydroxide solution and after adding 5 ml. of dimethyl sulfate, the mixture was shaken one hour. After extraction eight times with chloroform, the combined extracts were concentrated *in vacuo;* 30.7 mg. of erysotrine N-oxide remained. Eight more extractions yielded only 6.5 mg. of oxide. The combined product was dissolved in 25 ml. of dilute hydrochloric acid, and reduced with 3 g. of zinc dust. The filtrate from the residual zinc was made ammoniacal and extracted eight times with chloroform. Distillation of the solvent *in vacuo* left 14 mg. of crude erysotrine, and further extractions yielded 4 mg. The 18 mg. of erysotrine was dissolved in 1 ml. of ethanol and treated with 15 mg. of picric acid dissolved in 1 ml. of ethanol. After addition of 2 drops of petroleum ether, crystals formed slowly and crystallization was allowed to continue overnight at 10°. The yield of crystals was 14 mg. and two recrystallizations from ethanol and petroleum ether gave 7 mg. of pure erysotrine picrate, m. p. 160–161°, $[\alpha]^{25}D$ + 138°. A mixture of this picrate and the one derived similarly from erysodine did not show a depressed melting point.

**Acknowledgment.**—We are indebted to Messrs. D. F. Hayman, W. Reiss, and H. C. Clark for the microanalytical data.

## Summary

Erysodine, erysovine and erysopine have the same four-nuclei ring system; each has three oxygen atoms at the same positions on the ring system, but each differs in the position or number of O-methyl groups. These deductions are based essentially upon the results of analytical, hydrogenation and methylation experiments.

# Curariform Activity and Chemical Structure. V.[1] Syntheses in the Quinolizidine Series[2]

BY V. BOEKELHEIDE AND SEYMOUR ROTHCHILD[3]

An examination of the compounds possessing curariform activity reveals that a fused bicyclic ring system with nitrogen common to both rings is a structural feature present in many of the highly active compounds.[4] For example, such a ring system is present, or thought to be present, in members of the erythrina, calabash curare, and canadine alkaloids as well as in certain active synthetic compounds.[5] In view of this coincidence between curariform activity and the presence of a bicyclic, fused, nitrogen-containing ring system, model compounds based on the quinolizidine[6] nucleus have been prepared and tested to determine whether this structural unit, by itself, is sufficient for curariform activity. The results of testing the various derivatives, which are described in this paper, indicate that simple quinolizidines, either as tertiary or quaternary amine salts, do not possess appreciable curariform activity.

Although the simple quinolizidines did not have the desired physiological activity, the chemistry of their preparation proved to be quite interesting. Despite the number of syntheses of quinolizidine derivatives which have been reported,[7] particularly in investigations of the lupinane alkaloids, it seemed desirable to find a method which would be simpler and of more general applicability than those available. The development of such a method was facilitated by the discovery that 2-vinylpyridine can be employed effectively in the Michael reaction.[8a,b] It has now been found that the addition products of 2-vinylpyridine with active methylene compounds are particularly well suited for conversion to quinolizidines by reductive cyclization. Thus, the combination of Michael addition followed by reduction represents a two-step synthesis for a variety of quinolizidine derivatives.

In the present study the Michael additions of diethyl malonate, diethyl ethylmalonate, ethyl acetoacetate and acetylacetone to 2-vinylpyridine have been utilized to obtain I, II, III and IV, respectively. With the exception of acetylacetone, the additions proceeded readily and gave good yields of product.

I, X = $-CO_2Et$, Y = $-CO_2Et$, R = $-H$
II, X = $-CO_2Et$, Y = $-CO_2Et$, R = $-Et$
III, X = $-CO_2Et$, Y = $-COCH_3$, R = $-H$
IV, X = $-COCH_3$, Y = $-COCH_3$, R = $-H$
V, X = $-CO_2Et$, Y = $-H$, R = $-Et$
VI, X = $-COCH_3$, Y = $-H$, R = $-H$

The addition reactions of 2-vinylpyridine have been pictured by Doering and Weil[8a] as an attack by nucleophilic reagents on the electrophilic 2-vinylpyridine. In agreement with this picture it was found that the additions of the active methylene compounds, mentioned above, were most effectively catalyzed by bases, such as sodium or sodium ethoxide, which act by producing the nucleophilic anion of the active methylene compound. However, with ethyl acetoacetate, the addition could also be accomplished in good yield by the use of an acidic catalyst, dry hydrogen chloride. In this case the reaction probably involves an attack by the electrophilic 2-vinylpyridinium ion on the neutral ethyl acetoacetate molecule.

When basic catalysts were employed, it was necessary to control the reaction conditions carefully to avoid the side reactions typical of Michael additions. For example, the addition of diethyl ethylmalonate in the absence of solvent gave the expected adduct, II, but, when alcohol was employed as solvent, the main product was V. Apparently II is dissociated by base in the presence

(6) The name quinolizidine is employed in this paper to designate the saturated compound shown at the right. This compound has been referred to in the literature by various names including octahydroquinolizine, quinolizidine, octahydropyridoccoline, norlupinane, and 1-azabicyclo-(0,4,4)decane. *Chemical Abstracts* lists both octahydroquinolizine and norlupinane. The name quinolizidine seems superior and has been chosen for the following reasons: (1) The corresponding unsaturated compound is generally called quinolizine, and so quinolizidine has a structural basis which norlupinane does not have. (2) Although octahydroquinolizine is indicative of structure, it is too unwieldy for referring to large numbers of compounds. (3) The use of quinolizidine is consistent with the use of pyrrolizidine, which is commonly accepted for 1-azabicyclo(0,3,3)octane. The system of numbering used for quinolizidine is that employed by *Chemical Abstracts*.

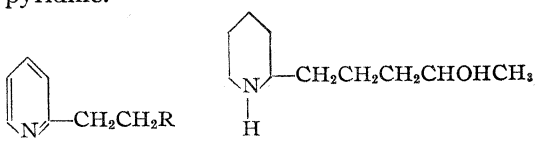
of alcohol to give diethyl carbonate and V.[9] Likewise, the addition of acetylacetone gave both IV and VI, although under the proper conditions IV was the primary product. The formation of adducts, corresponding to two molecules of 2-vinylpyridine to one of active methylene compound, occurred to an appreciable extent only in the case when 2-vinylpyridine and diethyl malonate were employed in a 1:1 molar ratio.

The reductive cyclization of the addition products of 2-vinylpyridine to give quinolizidine derivatives was investigated under various conditions using as catalysts, Raney nickel, platinum oxide, and copper chromite, respectively. A few experiments were also carried out using lithium aluminum hydride. Inasmuch as the nature of the products differed under different catalytic conditions, the reductive cyclizations are discussed according to the catalyst employed.

**Raney Nickel Reductions.**—When substituted γ-(2′-pyridyl)-butyric esters were treated with Raney nickel catalyst at 125–150° under hydrogen pressures of one hundred atmospheres or more, it was found that reduction and cyclization occurred simultaneously to give the corresponding 4-ketoquinolizidines in high yields. By this method I, II, III, and V were converted to VII, VIII, IX and X, respectively, in yields ranging from 75 to 97%.

VII, R = —H, Y = —$CO_2Et$
VIII, R = —Et, Y = —$CO_2Et$
IX, R = —H, Y = —$CHOHCH_3$
X, R = —Et, Y = —H
XI, R = —H, Y = —H

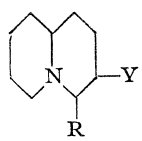


The structure of VII was established by its conversion on hydrolysis and decarboxylation to 4-ketoquinolizidine, XI, which was identified by the preparation of the hydrochloride[10] and also by its reduction with copper chromite to quinolizidine, XV. The structures of VIII, IX and X were assumed on the basis of analogy and because their subsequent reactions were consistent with these structures.

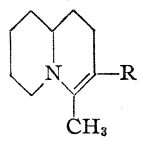
The reduction with Raney nickel of 1-(2′-pyridyl)-4-pentanone, VI, which was obtained from III by hydrolysis and decarboxylation, followed a different course at low temperatures than at high. At 120°, VI gave primarily XIV, whereas at 200° the product was almost entirely XVI. Since the reductive cyclization of 1-(2′-piperidyl)-4-pentanone would be expected to occur very readily, it can be concluded that the carbonyl group was reduced prior to the pyridine ring. The reaction must proceed by reduction of the intermediate 1-(2′-pyridyl)-4-pentanol, XII, to XIV, which at low temperatures is stable but which at higher temperatures undergoes cyclodehydration to give XVI.

(9) Similar reverse Claisen condensations have been frequently observed; see Cope and McElvain, THIS JOURNAL, **54**, 4319 (1932); and Connor, *ibid.*, **55**, 4597 (1933).

(10) For previous identifications of 4-ketoquinolizidine, see Ochiai, Tsuda and Yokoyama, *Ber.*, **68**, 2291 (1935), and ref. 8.



In support of this it was found that treatment of XIV with Raney nickel at 200° gave XVI. This is in agreement with the results previously found for the reductive cyclization of 2-(γ-hydroxypropyl)-pyridine.[11]



XII, R = —$CH_2CHOHCH_3$
XIII, R = —$CH(CH_2OH)_2$

XIV

Further evidence that the carbonyl group was reduced prior to the pyridine ring was obtained from a study of the reduction of III. If the pyridine ring were reduced first, it would be expected that cyclization would occur with the carbonyl group rather than the ester, and the product would be XVII. However, at 115°, III gave a 75% yield of IX and only 14% of XVII. The formation of XVII occurred in better yield at higher temperatures, though. At 200° there was obtained a 35% yield of XVII, a 15% yield of IX, and a small amount of XVI.

XV, R = —H, Y = —H
XVI, R = —$CH_3$, Y = —H
XVII, R = —$CH_3$, Y = —$CO_2Et$
XVIII, R = —H, Y = —Et
XIX, R = —$CH_3$, Y = —$CHOHCH_3$
XX, R = —$CH_3$, Y = —$CO_2H$
XXI, R = —$CH_3$, Y = —$CH_2OH$
XXII, R = —$CO_2Et$
XXIII, R = —$CHOHCH_3$

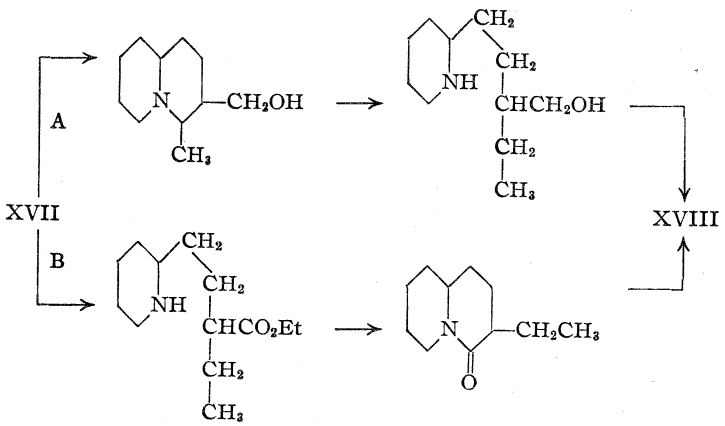
**Platinum Oxide Reductions.**—Since the pyridine ring is readily reduced in acid with platinum oxide at room temperature under an atmospheric pressure of hydrogen, this method was applied to several pyridyl ketones in an attempt to obtain cyclization of the pyridine ring with the carbonyl group. When III was reduced in this way, there was obtained a 42% yield of XVII plus a 38% yield of XXII.

The relationship of XXII to XVII was clearly established by the fact that XXII, on reduction in alcohol with platinum oxide catalyst, gave XVII in excellent yield. The presence of unsaturation in XXII was also shown by a test with permanganate solution. Since XXII is much less basic than XVII, the double bond must be adjacent to the nitrogen.

Although the structure of XVII was not rigorously established, there can be little doubt as to its correctness. XVII underwent the reactions to be expected of it and was readily shown to possess a carbethoxyl group. On hydrolysis, it gave the corresponding acid, XX, and by reduction with lithium aluminum hydride it was converted to the corresponding alcohol, XXI.

(11) Boekelheide and Rothchild, THIS JOURNAL, **70**, 864 (1948).

The formation of incompletely reduced products, such as XXII, during reductive cyclization with platinum oxide in acid is apparently a common behavior. When IV was reduced in acid solution, there was obtained in excellent yield an unsaturated compound, to which structure XXIII is assigned. In support of this structure, it was found that the compound reduced permanganate solution, did not react with carbonyl reagents, did not form a picrate, and decomposed on standing. Furthermore XXIII was readily reduced in neutral solution with platinum oxide to give the corresponding saturated derivative, XIX. As would be expected, XIX was a stable, colorless oil, which readily formed a picrate.



In agreement with the work of Galinovsky and Stern,[12] it was found that, with platinum oxide in acid, 4-ketoquinolizidines were reduced to the corresponding saturated derivatives. In this manner 3-ethyl-4-ketoquinolizidine, X, was reduced to 3-ethylquinolizidine, XVIII.

**Copper Chromite Reductions.**—The use of copper chromite at 250° was first attempted in order to convert the 4-ketoquinolizidines, obtained by Raney nickel reduction, to the corresponding saturated derivatives. In this way XI was readily reduced to quinolizidine, XV, in 75% yield. Also it was found that the reduction of V gave XVIII in good yield, illustrating that γ-pyridylbutyric esters can be converted in one step by copper chromite reduction to the corresponding saturated, cyclic derivatives. However, when the reduction of VII was attempted in the hope of preparing 3-hydroxymethylquinolizidine, an isomer of lupinine, there was obtained mainly quinolizidine plus a small amount of XI.

The loss of the carbethoxyl group in the reduction of VII is not surprising, though, in view of the well-known cleavages of substituted malonic esters by copper chromite.[13] Actually the copper chromite cleavage may be utilized for the preparation of quinolizidine on a practical scale.[8b] The direct copper chromite reduction of I gave a 65% yield of quinolizidine.

When reduction with copper chromite was tried with III, it was again found that cleavage occurred and from the reaction there was isolated quinolizidine and 3-ethylquinolizidine. However, the reaction product represented a complex mixture of which at least one of the components was not identified. In an attempt to simplify the number of reaction products, copper chromite reductions of IX and XVII, the intermediate cyclization products of III, were investigated. It was found that IX gave mainly 3-ethylquinolizidine plus some quinolizidine and a small amount of material which was not identified. On the other hand XVII was reduced with copper chromite to give a fair yield of 3-ethylquinolizidine.

Although the formation of 3-ethylquinolizidine would be expected from IX, its formation from XVII can only be accomplished by rearrangement. Two plausible routes for such a rearrangement are as follows:

The cleavage of a carbon to nitrogen bond during reduction of a β-amino ester, which is the essential step in route B, seems quite likely since Folkers and Adkins have found that this type of cleavage occurs during the reduction of ethyl N-ethyl nipecotate.[14] However, the reductive cleavage of a β-amino alcohol, which is the essential step in route A, has also been reported.[15] At present it is not possible to decide between the two routes.

**Lithium Aluminum Hydride.**—Lithium aluminum hydride was found to be of value chiefly for the reduction of esters to the corresponding carbinols. Thus, I with an excess of lithium aluminum hydride gave only the corresponding glycol, 2-hydroxymethyl-4-(2′-pyridyl)-1-butanol (XIII). Reduction of the pyridine ring did not occur. Similarly, XVII on reduction with lithium aluminum hydride gave XXI in good yield.

When VII was treated with an excess of lithium aluminum hydride, the reaction took an unusual course and the only product to be isolated was XI. Apparently, lithium aluminum hydride can cause cleavages similar to those which occur during copper chromite reductions.

The compounds in this series were tested by intraperitoneal injection into mice. Compounds VII, VIII, IX and XXI were tested as aqueous emulsions, whereas the hydrochloride salts of XV, XVII, XIX, XXI, 5-methylquinolizidinium iodide and 5-benzyl-3-hydroxymethyl-4-methylquinolizidinium bromide were tested as aqueous solutions. None of these compounds exhibited curariform activity.

## Experimental[16]

### Michael Additions to 2-Vinylpyridine

**Diethyl β-(2-Pyridyl)-ethylmalonate, I.**—Diethyl malonate (375 g., 2.35 moles) was added to a solution of sodium ethoxide (23 g. of sodium in 225 ml. of absolute alcohol) in a 1-liter flask equipped with condenser, drying tube, and a dropping funnel. To the boiling mixture, freshly distilled 2-vinylpyridine (106 g., 1.0 mole) in 175 ml. of absolute alcohol was added slowly. After the mixture had boiled under reflux for two hours, the alcohol was removed by distillation and the residue was acidified with dilute hydrochloric acid. The unreacted malonic ester was extracted with ether, the aqueous phase was made basic with dilute sodium hydroxide, and the basic organic layer was extracted with ether. After the ethereal solution had been dried over Drierite, the ether and recovered 2-vinylpyridine (b. p. 58° at 16 mm.) were removed *in vacuo*. The residue on distillation yielded 140 g. (53%) of a clear yellow oil; b. p. 135–140° at 0.02 mm.; $n^{25}D$ 1.4845.

*Anal.* Calcd. for $C_{14}H_{19}NO_4$: C, 63.38; H, 7.22; N, 5.28. Found: C, 63.35; H, 7.26; N, 5.27.

The **picrate** of I formed slowly in ethanol over a period of several days and was obtained after recrystallization from ethanol as yellow needles, m. p. 85.0–85.5.

*Anal.* Calcd. for $C_{20}H_{22}O_{11}N_4$: C, 48.73; H, 4.24. Found: C, 48.58; H, 4.48.

**Diethyl Di-(β-(2-pyridyl)-ethyl)-malonate.**—When the preparation of I was carried out as above with equimolar quantities of 2-vinylpyridine and diethyl malonate, the maximum yield of I was only 15%. The major product was a dark viscous oil which was obtained by molecular distillation at above 190° at 1 mm. The dark oil formed a picrate in ethanol and, after crystallization from ethanol, the picrate was obtained as yellow crystals, m. p. 171–172°. The composition of the picrate, as revealed by analysis, agrees with that for the dipicrate of diethyl di-(β-(2-pyridyl)-ethyl)-malonate.

*Anal.* Calcd. for $C_{33}H_{32}N_8O_{18}$: C, 47.77; H, 3.89. Found: C, 47.95; H, 3.77.

**Diethyl Ethyl-β-(2-pyridyl)-ethylmalonate, II.**—A mixture of 2-vinylpyridine (31.5 g., 0.3 mole), diethyl ethylmalonate (84.7 g., 0.45 mole) and 2.3 g. of sodium was boiled under reflux for two hours. After the mixture had cooled, there was added 75 ml. of dilute hydrochloric acid. The product was then isolated according to the procedure given for the isolation of I, yielding 34.0 g. (39%) of a yellow oil; b. p., 138–150° at 0.2 mm.; $n^{20}D$ 1.4894.

*Anal.* Calcd. for $C_{16}H_{23}NO_4$: C, 65.51; H, 7.91. Found: C, 65.11; H, 7.97.

The **picrate** of II formed in ethanol over a period of several days and was obtained by recrystallization from ethanol as yellow crystals, m. p. 88.5–89.5°.

*Anal.* Calcd. for $C_{22}H_{26}N_4O_{11}$: C, 50.57; H, 5.02. Found: C, 50.58; H, 4.84.

When a small amount of II was boiled with concentrated hydrochloric acid, both hydrolysis and decarboxylation occurred. By careful neutralization of the acidic solution there was obtained a white granular solid. After crystallization from dilute ethanol, the white solid, α-ethyl-γ-(2-pyridyl)-butyric acid, was found to melt at 126.5–128°. A sample of the acid, when mixed with a sample of the acid obtained from V (see below), melted at 127–128°.

**Ethyl α-Ethyl-γ-(2-pyridyl)-butyrate, V.**—When the addition of diethyl ethylmalonate to 2-vinylpyridine was carried out according to the procedure given for the preparation of I, there were obtained two fractions on distillation of the product. The higher boiling fraction, obtained in 28% yield, was shown to be II by preparation of the picrate. The lower boiling fraction, V, was obtained in 47% yield as a yellow oil; b. p. 115–122° at 0.5 mm.; $n^{22}D$ 1.4851.

*Anal.* Calcd. for $C_{13}H_{19}NO_2$: C, 70.55; H, 8.65. Found: C, 69.85; H, 8.59.

**α-Ethyl-γ-(2-pyridyl)-butyric Acid.**—A solution of V (5.9 g.) in 10 ml. of concentrated hydrochloric was boiled under reflux for three hours. The reaction mixture was evaporated to dryness, the residue was taken up in dilute sodium hydroxide solution, and the basic solution was extracted with ether. When the aqueous phase was acidified with acetic acid, a white granular solid (2.6 g.) separated from the solution. After several recrystallizations from dilute ethanol, the acid was obtained as white crystals, m. p. 129–129.5°.

*Anal.* Calcd. for $C_{11}H_{15}NO_2$: C, 68.38; H, 7.83. Found: C, 67.88; H, 7.90.

**Ethyl β-(2-Pyridyl)-ethylacetoacetate, III.**—Dry hydrogen chloride was bubbled rapidly into a mixture of 2-vinylpyridine (26.0 g.) and ethyl acetoacetate (65.0 g.) for ten minutes. The mixture was then boiled under reflux for three hours. After the mixture had cooled, there was added 100 ml. of 3 *N* hydrochloric acid. The product was then isolated according to the procedure given for the isolation of I, yielding 29.0 g. (50%) of III; b. p. 138–150° at 1.0 mm.; $n^{22}D$ 1.500.

III was also prepared by the method of Doering and Weil.[8a] The yields by their procedure varied from 57 to 62%.

In the preparation of III by the method of Doering and Weil, there was also obtained a small yield of a white, needle-like solid, m. p. 172–173°. It is presumed that this is the same compound as that obtained by Collie and Chrystall[17] by heating ethyl acetoacetate with sodium ethoxide.

**3-Acetyl-1-(2′-pyridyl)-4-pentanone, IV.**—The addition of acetylacetone to 2-vinylpyridine was carried out according to the procedure described for the preparation of I using 31.5 g. of 2-vinylpyridine, 60.0 g. of acetylacetone, 2.3 g. of sodium and 50 ml. of absolute ethanol. Two fractions were obtained on distillation of the product. The lower boiling fraction consisted of 3.7 g. (7%) of a light yellow oil; b. p. 89–116° at 0.05 mm.; $n^{22}D$ 1.5062. This was shown to be 1-(2′-pyridyl)-4-pentanone, VI, by preparation of the picrate, m. p. 111–112°. A mixture of the picrate with the picrate of an authentic sample of VI showed no depression of melting point.

The higher boiling fraction, IV, consisted of 10.8 g. (16%) of a light yellow oil; b. p. 116–122° at 0.05 mm.; $n^{22}D$ 1.5228.

*Anal.* Calcd. for $C_{12}H_{15}NO_2$: C, 70.20; H, 7.37. Found: C, 70.07; H, 7.42.

The **picrate** of IV formed readily in ethanol and was obtained by recrystallization from ethanol as yellow clusters, m. p. 117–118°.

*Anal.* Calcd. for $C_{18}H_{18}N_4O_9$: C, 49.77, H, 4.18. Found: C, 49.53; H, 4.18.

When the preparation of IV was attempted according to the method of Doering and Weil for the preparation of III, the only product was a small yield of VI. Also, when the preparation of IV as given above was altered by employing larger amounts of sodium and ethanol, the yield of IV was markedly decreased and the yield of VI was increased.

**1-(2′-Pyridyl)-4-pentanone, VI.**—This was prepared by the hydrolysis and decarboxylation of III according to the procedure of Doering and Weil.[8a] VI was obtained in yields of 87 to 90%.

(16) Analyses by Mrs. G. L. Sauvage and the Micro-Tech Laboratories: all melting points are corrected.

(17) Collie and Chrystall, *J. Chem. Soc.*, **91**, 1802 (1907).

### Reductions with Raney Nickel

**3-Carbethoxy-4-ketoquinolizidine, VII.**—A mixture of 27.2 g. of I, 15 ml. of ethanol, and 5 g. of Raney nickel was heated at 145° for one hour under a hydrogen pressure of 200 atmospheres. After separation of the catalyst by filtration, the solvent was removed *in vacuo* and the residue was distilled. There was obtained 22.2 g. (97%) of a pale yellow oil; b. p. 145–155° at 0.5 mm.; $n^{22}D$ 1.5022.

*Anal.* Calcd. for $C_{12}H_{19}NO_3$: C, 63.97; H, 8.50; N, 6.22. Found: C, 63.92; H, 8.47; N, 5.97.

**4-Ketoquinolizidine, XI.**—A solution of 13.4 g. of VII in 50 ml. of concentrated hydrochloric acid was boiled under reflux for three hours. The solution was evaporated to dryness, and the residue was treated according to the procedure which Ochiai, Tsuda and Yokoyama[10] employed for the conversion of γ-(2-pyridyl)-butyric acid hydrochloride to 4-ketoquinolizidine. On distillation there was obtained 5.2 g. (57%) of a colorless oil; b. p. 97° at 1.5 mm.

The identity of the 4-ketoquinolizidine was established by the preparation of the hydrochloride which melted at 143–145° (lit.,[10] m. p. 146–147°). Also the 4-ketoquinolizidine was reduced by copper chromite to quinolizidine (*vide infra*).

**3-Ethyl-3-carbethoxy-4-ketoquinolizidine, VIII.**—Following the procedure given above for the preparation of VII, the reductive cyclization of II was readily accomplished. Reduction was complete in three hours, and on working up the product there was obtained an 84% yield of a colorless oil; b. p. 140–145° at 0.8 mm.; $n^{22}D$ 1.4891.

*Anal.* Calcd. for $C_{14}H_{23}O_3N$: C, 66.38; H, 9.15. Found: C, 66.49; H, 9.06.

**3-Ethyl-4-ketoquinolizidine, X.**—The reductive cyclization of V was carried out according to the procedure given above for the preparation of VII. From 4.9 g. of V there was obtained 3.1 g. (78%) of a colorless oil; b. p. 125–128° at 0.5 mm.; $n^{23}D$ 1.4957.

*Anal.* Calcd. for $C_{11}H_{19}NO$: C, 72.87; H, 10.56. Found: C, 72.69; H, 10.54.

**Reduction of Ethyl β-(2-Pyridyl)-ethylacetoacetate.**—The reduction of ethyl β-(2-pyridyl)-ethylacetoacetate, III, was carried out according to the procedure previously given for the preparation of VII. On distillation there were obtained two products: 3-(α-hydroxyethyl)-4-ketoquinolizidine, IX, and 3-carbethoxy-4-methylquinolizidine, XVII. The reduction was repeated several times to find the effect of temperature on the relative yields of IX and XVII. The results are shown in Table I.

TABLE I

| Temperature, °C. | % of IX | % of XVII | Total yield, % |
|---|---|---|---|
| 115 | 75 | 14 | 89 |
| 140 | 73 | 20 | 93 |
| 200 | 15 | 36 | 56[a,b] |

[a] This includes a 5% yield of 4-methylquinolizidine, XVI, which was identified by its picrate, m. p. 191–194°. A mixed melting point determination with the picrate of an authentic sample of XVI showed no depression. [b] Total yield is low because of mechanical loss.

IX and XVII were characterized as follows:

**3-Carbethoxy-4-methylquinolizidine,** XVII, was obtained as a colorless oil; b. p. 105–120° at 1.5 mm.; $n^{22}D$ 1.4820.

*Anal.* Calcd. for $C_{13}H_{23}NO_2$: C, 69.30; H, 10.29. Found: C, 69.41; H, 10.45.

The **picrate** of XVII formed readily in ethanol and was obtained by recrystallization from ethanol as a yellow granular solid, m. p. 127.5–128.5°.

*Anal.* Calcd. for $C_{19}H_{26}N_4O_9$: C, 50.22; H, 5.77. Found: C, 50.65; H, 5.69.

**3-Carboxy-4-methylquinolizidine,** XX, was readily obtained by hydrolysis of a small amount of XVII with dilute hydrochloric acid. An attempt to isolate the acid as the hydrochloride was unsucessful, but the picrate was readily prepared. After crystallization from ethanol, the picrate of XX was obtained as a yellow amorphous solid, m. p. 203–205°.

*Anal.* Calcd. for $C_{17}H_{22}N_4O_9$: C, 47.88; H, 5.20. Found: C, 48.08; H, 5.32.

**3-(α-Hydroxyethyl)-4-ketoquinolizidine,** IX, was obtained as a viscous, slightly yellow oil; b. p. 145–155° at 1.5 mm.; $n^{20}D$ 1.5090.

*Anal.* Calcd. for $C_{11}H_{19}NO_2$: C, 66.96; H, 9.66. Found: C, 66.69; H, 9.26.

**Reduction of 1-(2′-Pyridyl)-4-pentanone.**—The reduction of 1-(2′-pyridyl)-4-pentanone, VI, was carried out according to the procedure previously given for the preparation of VII. On distillation there were obtained two products: 4-methylquinolizidine, XVI, and 1-(2′-piperidyl)-4-pentanol, XIV. The effect of temperature on the relative yields of XIV and XVI is shown in Table II.

TABLE II

| Temperature, °C. | % of XIV | % of XVI | Total yield, % |
|---|---|---|---|
| 125 | 67 | 9 | 76 |
| 150 | 55 | 26 | 81 |
| 200 | 15 | 69 | 84 |

XIV and XVI were characterized as follows:

**1-(2′-Piperidyl)-4-pentanol,** XIV, distilled as a colorless oil (b. p. 118° at 1.5 mm.) which crystallized in the receiver. After recrystallization from petroleum ether (60–70°), it was obtained as a hygroscopic, white solid, m. p. 64.5°.

*Anal.* Calcd. for $C_{10}H_{21}NO$: C, 70.11; H, 12.36. Found: C, 69.90; H, 12.31.

The **hydrochloride** of XIV was prepared in ether using dry hydrogen chloride. After recrystallization from a mixture of acetone and ethyl acetate, it was obtained as a white, crystalline solid, m. p. 107–108°.

*Anal.* Calcd. for $C_{10}H_{22}ClNO$: C, 57.81; H, 10.68. Found: C, 57.63; H, 10.74.

**4-Methylquinolizidine,** XVI, was obtained as a colorless oil; b. p. 79° at 13 mm.; $n^{19}D$ 1.4813.

*Anal.* Calcd. for $C_{10}H_{13}N$: C, 78.36; H, 12.50. Found: C, 78.21; H, 12.47.

The **picrate** of XVI formed readily in ethanol and was obtained by recrystallization from ethanol as yellow needles, m. p. 191–195°.

*Anal.* Calcd. for $C_{16}H_{22}N_4O_7$: C, 50.25; H, 5.80. Found: C, 50.29; H, 5.60.

Although there should be two diastereoisomeric forms of XVI, no other picrate was isolated. Similar results have been noted previously for compounds of this type.[18,19]

The cyclization of XIV to yield XVI was accomplished by heating 0.6 g. of XIV in 3 ml. of absolute alcohol in a bomb at 200° for one hour in an atmosphere of hydrogen and in the presence of Raney nickel catalyst. After removal of the catalyst, the product was isolated through the formation of the picrate. The picrate, which was isolated in good yield, was shown to be identical with the picrate of XVI by a mixed melting point determination.

### Reductions with Platinum Oxide

**Reduction of Ethyl β-(2-Pyridyl)-ethylacetoacetate.**—A mixture of 47.1 g. of ethyl β-(2-pyridyl)-ethylaceto-

(18) Clemo, Morgan and Raper, *J. Chem. Soc.*, 1743 (1935).

(19) While correcting proof of this manuscript, the article by Lukes and Sorm, *Coll. Czechoslov. Chem. Commun.*, **12**, 356 (1947); *Chem. Abst.*, **42**, 7780 (1948), in which they describe two picrates of the possible diastereoisomeric racemates of 4-methylquinolizidine (allolupinane), became available to us. Our picrate appears to correspond to the picrate which they describe as melting at 195°. In view of their results and the fact that the crude preparation of our picrate melted at 188–192°, it would seem that essentially only one racemate was produced by the reductive cyclization.

acetate, III, 200 ml. of dilute hydrochloric acid and 0.89 g. of platinum oxide was reduced under a hydrogen pressure of 3 atm. at room temperature for one hour. The catalyst was removed by filtration, the solution was made basic, and the organic layer was extracted with ether. After the ethereal solution had been dried over anhydrous sodium carbonate, the ether was removed *in vacuo* and the residue was distilled. By careful distillation through a column packed with glass helices, there were obtained two fractions. The lower boiling fraction consisted of 19.0 g. (42%) of an oil which by its physical properties (b. p. 116–122° at 1.3 mm.; $n^{22}D$ 1.4820) and by formation of the picrate (m. p. 127–128°, mixed melting point determination with the picrate of an authentic sample of XVII showed no depression) was shown to be XVII.

The higher boiling fraction, **3-carbethoxy-3-ene-4-methylquinolizidine** (XXII), consisted of 17.2 g. (38%) of a semi-viscous, colorless oil; b. p. 129–132° at 0.8 mm.; $n^{20}D$ 1.5426.

*Anal.* Calcd. for $C_{13}H_{21}NO_2$: C, 69.92; H, 9.48. Found: C, 69.72; H, 9.72.

XXII readily decolorized a solution of potassium permanganate in acetone. Although no hydrogen absorption was observed when 5.6 g. of XXII in 20 ml. of ethanol was shaken under a pressure of 3 atm. of hydrogen at 50° in the presence of Raney nickel catalyst, reduction occurred rapidly when 0.10 g. of platinum oxide was added. The product was isolated in the usual manner and on distillation there was obtained 4.6 g. (82%) of a colorless oil. In the same manner as given above, this oil was shown to be XVII.

**3-(α-Hydroxyethyl)-3-ene-4-methylquinolizidine, XXIII.**—The reduction of IV with platinum oxide as catalyst was carried out according to the procedure given above for the reduction of III. From 6.2 g. of IV there was obtained on distillation of the residual oil 4.9 g. (85%) of a colorless oil; b. p. 92–100° at 0.5 mm.; $n^{21}D$ 1.4931.

*Anal.* Calcd. for $C_{12}H_{21}NO$: C, 73.79; H, 10.84. Found: C, 73.55, 73.70; H, 10.92, 11.04.

XXIII decolorized a solution of potassium permanganate, and it did not form a semi-carbazone, a 2,4-dinitrophenylhydrazone, or a picrate.

**3-(α-Hydroxyethyl)-4-methylquinolizidine, XIX.**—The reduction of 1.40 g. of XXIII in 10 cc. of ethanol in the presence of 0.093 g. of platinum oxide took place under an atmospheric pressure of hydrogen at room temperature. The uptake of hydrogen was complete in twelve hours. A colorless oil, about 1 g., was isolated by distillation; bath temp. 110–120° at 1.5 mm.; $n^{23}D$ 1.4920.

*Anal.* Calcd. for $C_{12}H_{23}ON$: C, 73.05; H, 11.75. Found: C, 73.27; H, 11.65.

**The picrate** of XIX was obtained, after recrystallization from ethanol, as yellow crystals, m. p. 198–201°.

*Anal.* Calcd. for $C_{18}H_{26}O_8N_4$: C, 50.70; H, 6.15. Found: C, 50.78; H, 5.80.

**3-Ethylquinolizidine, XVIII.**—The reduction of X was carried out according to the procedure given by Galinovsky and Stern for the reduction of 4-ketoquinolizidine.[12] A mixture of 1.81 g. of X and 0.70 g. of platinum oxide in 50 ml. of a 1.5% solution of hydrochloric acid was shaken in an atmosphere of hydrogen at room temperature. After the mixture had been shaken for seventy-six hours, 88% of the calculated volume of hydrogen had been absorbed. The catalyst was removed and the solution was extracted with ether. The aqueous layer was then made basic and extracted again with ether. After the ethereal solution had been dried and the ether removed *in vacuo*, the residual oil was divided into two parts and converted directly to the corresponding picrate and hydrochloride. The picrate, after crystallization from ethanol, melted at 152–156°, and the hydrochloride, after crystallization from ethyl acetate, melted at 198–199°. The picrate and hydrochloride of 3-ethylquinolizidine were shown by the method of mixed melting points to be identical with the samples of these derivatives prepared previously (see the section on the copper chromite reduction of ethyl α-ethyl-γ-(2-pyridyl)-butyrate).

### Reductions with Copper Chromite

**Quinolizidine, XV, from 4-Ketoquinolizidine, XI.**—A mixture of 5.6 g. of XI and 1.5 g. of copper chromite in 20 cc. of ethanol was heated at 260° for five hours under a hydrogen pressure of 250 atm. After separation of the catalyst by filtration and removal of the ethanol *in vacuo*, the residual oil was distilled yielding 3.8 g. (75%) of a colorless oil; b. p. 79° at 18 mm.; $n^{20}D$ 1.4796. The oil was shown to be quinolizidine by the preparation of the picrate, which melted at 198–199° (lit.,[7,12] m. p. 194°, 196°; 199–200°), and the chloroaurate, which melted at 168–169° (lit.,[7] m. p. 171°).

The **methiodide** of XV formed readily and was obtained as white crystals, dec. 309–311° (lit.,[7,12] dec. 335°; 333°).

*Anal.* Calcd. for $C_{10}H_{20}IN$: C, 42.71; H, 7.17. Found: C, 42.50; H, 7.09.

The **hydrochloride** of XV formed readily in ether but it did not give a definite melting point.

*Anal.* Calcd. for $C_9H_{18}ClN$: C, 61.53; H, 10.32. Found: C, 61.20; H, 10.01.

**Quinolizidine, XV, from 3-Carbethoxy-4-ketoquinolizidine, VII.**—When the reduction of VII was carried out as given above for the reduction of XI, there was obtained on distillation a 76% yield of XV. The identity of XV was established through the preparation of the picrate, m. p. 198–199°, and the methiodide, dec. 309–311°. Mixtures of these derivatives with the corresponding derivatives of quinolizidine prepared previously (see above) showed no depression of melting point.

**Quinolizidine, XV, from Diethyl β-(2-Pyridyl)-ethylmalonate, I.**—The reduction of I was carried out on a 0.05 molar scale according to the procedure used for the reduction of XI. When the reduction was allowed to proceed overnight, there was obtained, on working up the product and distilling, a 65% yield of quinolizidine and a 13% yield of 4-ketoquinolizidine. The quinolizidine was identified in the same manner as described previously. The 4-ketoquinolizidine was identified by preparing the hydrochloride, m. p. 139–142°; no depression of melting point occurred when the hydrochloride was mixed with the hydrochloride of an authentic sample of 4-ketoquinolizidine. A sample of the 4-ketoquinolizidine was also converted by hydrolysis in dilute hydrochloric acid to the hydrochloride of γ-(2-piperidyl)-butyric acid, m. p. 191–192° (lit.,[10] m. p. 188–189°).

When the time of reduction was shortened to one-half hour, the yield of quinolizidine was only 42% but the yield of 4-ketoquinolizidine increased to 25%. In addition a small amount of a crystalline solid, m. p. 90–93°, separated during the distillation. The amount of solid was insufficient for further characterization.

**3-Ethylquinolizidine, XVIII, from Ethyl α-Ethyl-γ-(2-pyridyl)-butyrate, V.**—A mixture of 9.7 g. of V and 2.0 g. of copper chromite was heated at 250° for one hour under a hydrogen pressure of about 150 atm. After removal of the catalyst, the residual oil was fractionally distilled and there was obtained two fractions. The higher boiling fraction consisted of 2.8 g. (35%) of a colorless oil, which on the basis of its physical properties (b. p. 112–115° at 0.2 mm.; $n^{21}D$ 1.4933) must be 3-ethyl-4-ketoquinolizidine, a product which was obtained previously from the Raney nickel reduction of V.

The lower boiling fraction, XVIII, consisted of 3.1 g. (43%) of a colorless oil; b. p. 104–108° at 20 mm.; $n^{21}D$ 1.4735.

*Anal.* Calcd. for $C_{11}H_{21}N$: C, 78.97; H, 12.65. Found: C, 78.70; H, 12.65.

**The picrate** of XVIII was prepared in ethanol and, after several recrystallizations from ethanol, was obtained as yellow crystals, m. p. 156–157°.

*Anal.* Calcd. for $C_{17}H_{24}N_4O_7$: C, 51.51; H, 6.10. Found: C, 51.62; H, 6.08.

The **hydrochloride** of XVIII was prepared in ether with

dry hydrogen chloride and, after several recrystallizations from ethyl acetate, was obtained as white crystals, m. p. 198–199°.

*Anal.* Calcd. for $C_{11}H_{22}ClN$: C, 64.84; H, 10.88. Found: C, 64.53; H, 10.72.

The picrate and hydrochloride of XVIII were shown by the method of mixed melting points to be identical with the corresponding derivatives of the oil obtained by the platinum oxide reduction of X. Since any sort of rearrangement during platinum oxide reduction at room temperature would be extremely unlikely, there can be little doubt that XVIII is 3-ethylquinolizidine. Even though isomerism due to the nitrogen atom is neglected, there should be two diastereoisomeric forms of XVIII. The presence of two such forms was indicated by the fact that the crude derivatives of XVIII melted over a wide range. However, no pure derivative corresponding to a second diastereoisomer was isolated, even though several attempts to do so were made.

**Reduction of Ethyl β-(2-Pyridyl)-ethylacetoacetate, III.**—A mixture of 21.2 g. of III and 5.0 g. of copper chromite in 26 ml. of ethanol was shaken at 250° under a pressure of 150 atm. of hydrogen for three hours. After removal of the catalyst and solvent, the residual oil was fractionally distilled and there was obtained three fractions.

The first fraction consisted of 3.4 g. (27%) of a colorless oil, b. p. 66–70° at 10 mm., which was shown to be quinolizidine by a comparison of the picrate and methiodide with the corresponding derivatives of an authentic sample of quinolizidine.

The second fraction consisted of 4.6 g. (31%) of a colorless oil, b. p. 80–87° at 10 mm., which was shown to be 3-ethylquinolizidine by the preparation of the picrate, m. p. 155–157°. A mixture of this picrate with the picrate of an authentic sample of 3-ethyl-quinolizidine (see above) showed no depression of melting point. Since mixtures of picrates of related compounds in this series were found to give marked depressions of melting point, the method of mixed melting points is assumed to be a valid test for identity.

The third fraction consisted of 6.3 g. of a colorless oil; b. p. 113–116° at 1.5 mm.; $n^{21}D$ 1.4956. The composition of the oil, as indicated by analysis, does not agree with any logical formula. A portion of the oil was converted to the picrate, m. p. 204–206°, but no further identification was carried out.

**Reduction of 3-(α-Hydroxyethyl)-4-ketoquinolizidine, IX.**—When the reduction of 5.0 g. of IX was carried out according to the procedure given previously for the reduction of III, there was obtained, on distillation, three fractions. The first two fractions, which weighed 0.6 g. and 1.2 g. respectively, were shown to be quinolizidine and 3-ethylquinolizidine in the same manner as described above. The third fraction consisted of 1.1 g. of a colorless oil; b. p. 102–108° at 1.5 mm.; $n^{20}D$ 1.4963. A portion of the oil from the third fraction was converted to the picrate, m. p. 158–160°, but further identification was not carried out. A mixture of the picrate of the oil from the third fraction with the picrate of 3-ethylquinolizidine showed a marked depression in melting point. The composition of the oil, as indicated by analysis, does not agree with any logical formula.

**Reduction of 3-Carbethoxy-4-methylquinolizidine, XVII.**—A mixture of 6.7 g. of XVII, 1.5 g. of copper chromite and 8 ml. of absolute alcohol was heated at 250° for two hours under a pressure of 200 atm. of hydrogen. When the reaction mixture was worked up in the usual fashion, there was obtained two fractions on distillation.

The lower boiling fraction consisted of 2.1 g. (42%) of a colorless oil, b. p. 83–90° at 8 mm., which was shown by the preparation of the corresponding picrate, m. p. 155–157°, and hydrochloride, m. p. 197–199, to be 3-ethylquinolizidine, XVIII. Neither the picrate nor the hydrochloride, when mixed with authentic samples of these derivatives previously prepared from 3-ethylquinolizidine, showed any depression of melting point. In one attempt to prepare the hydrochloride of the lower boiling fraction, there was obtained a sample of white crystals, m. p. 179–180°, whose melting point was not raised by further recrystallization from ethyl acetate. The composition of this hydrochloride (*Anal.* Calcd. for $C_{11}H_{22}ClN$: C, 64.84; H, 10.88. Found: C, 64.60; H, 11.07.) agrees with that for 3-ethylquinolizidine, and it was thought, at first, that this hydrochloride represented a diastereoisomer of the hydrochloride previously isolated. However, when a supersaturated solution of the hydrochloride melting at 179–180° was seeded with crystals from the hydrochloride melting at 198–199°, the crystals, which separated, melted at 183–187°, indicating that the two hydrochlorides are probably different polymorphic forms of the same diastereoisomer.

The higher boiling fraction consisted of 2.2 g. of a colorless oil, b. p. 105–110° at 1 mm. The composition of the oil, as indicated by analysis, did not agree with any logical formula, and the oil was not further identified.

### Reductions with Lithium Aluminum Hydride

**2-Hydroxymethyl-4-(2′-pyridyl)-1-butanol, XIII.**—A solution of 13.3 g. of I in 30 ml. of dry ether was added dropwise with stirring to 100 ml. of a 0.6 molar solution of lithium aluminum hydride in ether. The reaction mixture was decomposed with water and then hydrolyzed with dilute sulfuric acid. The ether layer was separated, and the aqueous layer was made strongly basic with sodium hydroxide solution. The organic layer was extracted from the basic solution with *s*-amyl alcohol, the amyl alcohol was removed from the extract *in vacuo*, and the residual oil was distilled. There was obtained 2.2 g. (24%) of a slightly green oil; b. p. 165–170° at 0.4 mm. When the oil was triturated with acetone, it crystallized to give a white solid, m. p. 57–59°.

*Anal.* Calcd. for $C_{10}H_{15}NO_2$: C, 66.28; H, 8.35. Found: C, 66.66; H, 8.20.

**3-Hydroxymethyl-4-methylquinolizidine, XXI.**—The reduction of 4.7 g. of XVII was carried out according to the procedure given above for the reduction of I. In this case the basic oil was extracted with ether instead of amyl alcohol. On distillation of the residual oil there was obtained 1.9 g. (50%) of a viscous, colorless oil; b.p. 98–110° at 0.8 mm.; $n^{19}D$ 1.5072.

*Anal.* Calcd. for $C_{11}H_{21}NO$: C, 72.12; H, 11.52. Found: C, 72.24; H, 11.40.

The **benzyl bromide salt** of XXI was readily formed by heating a sample of XXI with benzyl bromide. After recrystallization from an ethanol–acetone mixture, the benzyl bromide salt was obtained as white crystals, m. p. 179.5–180.5°.

*Anal.* Calcd. for $C_{18}H_{28}BrNO$: C, 61.02; H, 7.97. Found: C, 60.75; H, 7.95.

**Reduction of 3-Carbethoxy-4-ketoquinolizidine, VII.**—The reduction of 2.1 g. of VII was carried out according to the procedure given above for the reduction of I. Extraction of the basic aqueous solution was done with ether instead of amyl alcohol. On distillation of the residual oil there was obtained 0.3 g. of 4-ketoquinolizidine, b. p. 100–105° at 1 mm.; $n^{22}D$ 1.5131. The identity of the 4-ketoquinolizidine was established by the preparation of the hydrochloride, m. p. 143–145°. When a sample of this hydrochloride was mixed with an authentic sample of the hydrochloride of 4-ketoquinolizidine, there was no depression of melting point.

## Summary

The Michael addition of active methylene compounds to 2-vinylpyridine followed by reductive cyclization has been found to be an easy and practical method of synthesis for a variety of quinolizidine derivatives. Several methods of reductive cyclization have been employed, and, depending on the method of reduction used, either substituted quinolizidines or 4-ketoquinoli-

zidines may be obtained. When copper chromite was employed as catalyst for reductive cyclizations, examples of both skeletal cleavage and rearrangement were found.

Compounds, having the simple quinolizidine nucleus, were found not to possess appreciable curariform activity.

# Quaternary Carbon Compounds. II. N,N-Dimethyl-N′-(2,2-dibutylhexyl)-N′-(2-pyridyl)-ethylenediamine and the Diethyl Homolog

BY NATHAN SPERBER AND DOMENICK PAPA

In a publication[1] describing the synthesis of N′-benzyl-N′-(2-pyridyl)-N,N-dimethylethylenediamine (I) and related compounds, several substances in which the benzyl group of I was replaced by lower alkyl radicals such as ethyl, isopropyl and propyl are reported. The latter substances showed a low order of antihistaminic activity in experimental animals as compared with the benzyl compound.

In the course of studies on trialkyl-substituted compounds of pharmacological importance,[2] we have prepared a highly branched compound related to I, namely, N,N-dimethyl-N′-(2,2-dibutylhexyl)-N′-(2-pyridyl)-ethylenediamine (II), in order to establish whether this type of substitution would show appreciably greater antihistaminic activity than the lower alkyl derivatives. In animal experiments, II has shown approximately $^1/_{250}$ the antihistaminic activity of I. The diethyl homolog (III) of II was also prepared and was $^1/_5$–$^1/_{10}$ as active as II.

II

The synthesis of II and the diethyl homolog was carried out in two steps. The condensation of 2-bromopyridine, (2,2-dibutylhexyl)-amine and anhydrous sodium carbonate in xylene or cymene yielded, after prolonged refluxing, N-(2,2-dibutylhexyl)-2-aminopyridine. The latter on alkylation with dimethylaminoethyl chloride or diethylaminoethyl chloride gave good yields of II and III, respectively.[3] Attempts to condense N,N-diethyl-N′-(2,2-dibutylhexyl)-ethylenediamine and 2-bromopyridine with sodamide were unsuccessful.

(3) These experiments were completed prior to the publication of Huttrer, *et al.*, and were based on the directions of Whitmore, Mosher, Goldsmith and Rytina, THIS JOURNAL, **67**, 393 (1945).

## Experimental

**(2,2-Dibutylhexyl)-amine.**—Capronitrile was dialkylated with butyl bromide and sodium amide according to the directions of Ziegler and Ohlinger.[4] The resulting 2,2-dibutylcapronitrile was reduced to (2,2-dibutylhexyl)-amine[2b]; yield 90%; b. p. 123–124° (4 mm.); hydrochloride m. p. 135°.

**N-(2,2-Dibutylhexyl)-2-aminopyridine.**[5]—A mixture of 32 g. of 2-bromopyridine, 50 g. of (2,2-dibutylhexyl)-amine and 21 g. of anhydrous sodium carbonate in 100 cc. of *p*-cymene was refluxed and stirred for sixty-seven hours. The mixture was poured into water, the cymene layer separated and, after drying, concentrated *in vacuo*. The residue was fractionated. After a forerun of 12.6 g., b. p. 95–163° (1 mm.), the substituted aminopyridine was obtained as a yellow viscous oil; yield 45 g., b. p. 172–174° (2 mm.); $n^{23}D$ 1.5045. Calcd. for $C_{19}H_{34}N_2$: N, 9.65. Found: N, 9.28.

**N,N-Dimethyl-N′-(2,2-dibutylhexyl)-N′-(2-pyridyl)-ethylenediamine.**—To a sodium amide suspension[6] (2.5 g. of sodium) in 75 cc. of dry toluene, was added 29 g. (0.1 mole) of N-(2,2-dibutylhexyl)-2-aminopyridine.[7] The mixture was heated with stirring for two hours on the steam-bath. A solution of 12 g. of dimethylaminoethyl chloride in 20 cc. of dry toluene was added dropwise to the stirred suspension and the reaction heated with stirring for twenty hours on the steam-bath. The reaction mixture was cooled and then decomposed with water. The organic layer was separated, dried and the solvent removed *in vacuo*. The residue distilled as a yellow viscous oil; yield 28.5 g., b. p. 175–177° (2 mm.), $n^{23}D$ 1.5002. Calcd. for $C_{23}H_{43}N_3$: C, 76.36; H, 11.99; N, 11.62. Found: C, 76.60; H, 11.99; N, 11.61.

**The dihydrochloride** was prepared as follows: A solution of 6 g. of the free base in 75 cc. of dry ethyl acetate was saturated with anhydrous hydrogen chloride. Upon cooling and scratching, a crystalline solid was obtained. Dry ether was added, the solid collected and washed with ether: recrystallized twice from alcohol–ether; yield 5.8 g.; m. p. 184.5–185.5°. Calcd. for $C_{23}H_{45}N_3Cl_2$: N, 9.67; Cl, 16.33. Found: N, 9.45; Cl, 16.00.

**N,N-Diethyl-N′-(2,2-dibutylhexyl)-N′-(2-pyridyl)-ethylenediamine.**—N-(2,2-Dibutylhexyl)-2-aminopyridine was alkylated with diethylaminoethyl chloride and sodium amide as described for the corresponding dimethyl compound; yield 70%; yellow viscous oil; b. p. 190–195° (2 mm.); $n^{21}D$ 1.5005. The free base was converted to

(4) Ziegler and Ohlinger, *Ann.*, **495**, 84 (1932).

(5) The reaction of 16 g. of 2-bromopyridine, 39 g. of (2,2-dibutylhexyl)-amine and 50 cc. of pyridine for ten hours at 155–160° essentially as described by Whitmore[3] did not yield any of the substituted aminopyridine.

(6) "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1942, p. 99.

(7) Although King, King and Muir (*J. Chem. Soc.*, 5 (1946)) alkylated diphenylamine with diethylaminoethyl chloride by means of the Grignard reagent, N-(2,2-dibutylhexyl)-2-aminopyridine with methylmagnesium iodide and dimethylaminoethyl chloride yielded none of the expected tertiary amine.

the dihydrochloride in ethyl acetate and was recrystallized twice from a mixture of alcohol–ether; m. p. 205–205.5°. Calcd. for $C_{25}H_{49}N_3Cl_2$: N, 9.08; Cl, 15.34. Found: N, 9.18; Cl, 15.76.

**N,N-Diethyl-N′-(2,2-dibutylhexyl)-ethylenediamine.**—A mixture of 21 g. (0.1 mole) of 2,2-dibutylhexylamine, 14 g. (0.1 mole) of diethylaminoethyl chloride and 11 g. of anhydrous sodium carbonate in 50 cc. of dry xylene was refluxed with stirring for sixty-five hours. The cooled reaction product was poured into water, the xylene layer separated, and the solvent removed *in vacuo*. The brown oily residue was distilled; yield 29 g.; b. p. 155–156° (2 mm.); $n^{23}D$ 1.4540. The analytical sample showed the following constants: b. p. 151–152° (1.5 mm.); $n^{23}D$ 1.4513. Calcd. for $C_{20}H_{44}N_2$: C, 76.82; H, 14.20; N, 8.97. Found: C, 76.71; H, 13.74; N, 9.26.

**Acknowledgment.**—We wish to express our appreciation to Dr. Richard Tislow and Mrs. Annette LaBelle of our Pharmacology Laboratory for the pharmacological data reported herein.

## Summary

Replacement of the benzyl group in N′-benzyl-N′-(2-pyridyl)-N,N-dimethylethylenediamine by a highly branched aliphatic radical resulted in a considerable decrease in antihistaminic activity.

# Pyridyl-Substituted Alkamine Ethers as Antihistaminic Agents[1]

BY NATHAN SPERBER, DOMENICK PAPA, ERWIN SCHWENK AND MARGARET SHERLOCK

Although Fourneau and co-workers[2] demonstrated that dialkylaminoalkylaryl ethers[3] possessed antihistaminic activity, these substances proved too toxic for general clinical use. Recently, a series of dialkylaminoalkylbenzhydryl ethers[4] have been reported[5] to be potent antihistaminic agents. One of the latter type of compounds, β-dimethylaminoethyl benzhydryl ether, is employed at present in anti-allergic therapy.

The extremely favorable change in therapeutic index which resulted from the replacement of the phenyl group by a pyridyl group[6] in N′-phenyl-N′-benzyl-N,N-dimethylethylenediamine seemed of sufficient interest to warrant the study of a similar substitution in the benzhydrylalkamine ether series. A number of substituted dialkylaminoalkylpyridylmethyl ethers of the general formula I (Table II) wherein R is a pyridyl radical, R′ is alkyl, aryl or heterocyclic, R″ is hydrogen or a lower alkyl group, $n$ is 2 or 3 and R‴ is a dialkylamino group, were synthesized by the condensation of the appropriately substituted carbinols with dialkylaminoalkyl halides and sodium amide in toluene. In general, the yields of ethers varied from about 45–88%. In the case of (2-pyridyl)-(2-thienyl)-methylcarbinol, only 22% of the dimethylaminoethyl ether was obtained.

I

The requisite carbinols (Table I) were synthesized by the following three methods[7]: (I) the reaction of aldehydes with 2-pyridylmagnesium bromide as described by Overhoff and Proost[8]: (II) The condensation of picolinic acid and aromatic aldehydes and ketones to yield the secondary and tertiary pyridylarylcarbinols,[9] respectively; (III) tertiary carbinols were also prepared by the reaction of 2- or 3-acetylpyridine with aryl or aralkylmagnesium halides.

Although method I is reported to give 40–55% of the carbinols, we have not been able to duplicate these yields. Furthermore, this synthesis required the use of large volumes of solvent for extraction and, frequently, troublesome emulsions were encountered.

A more satisfactory method for the preparation of the secondary substituted 2-pyridylcarbinols is based on the decarboxylation of picolinic acid in the presence of an aromatic aldehyde at a temperature above 140° (Method II). The products of

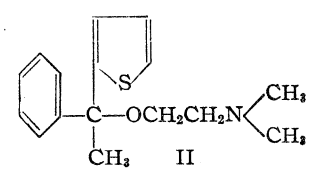
[a] Yields are based on a limited number of experiments and do not necessarily represent the maximum obtainable. [b] Ref. 9, m. p. 78°. [c] Ref. 9, m. p. 131.5°. [d] Ref. 9 described this compound as distilling at 152.5° (745 mm.); ref. 7b gives b. p. 301–303° and m. p. 32°. [e] Ref. 9, m. p. 105°.

this reaction are the desired carbinol, pyridine and carbon dioxide. Although the yields are reported to be rather low, the ease of operation and isolation of the carbinols renders the method a useful synthetic procedure. However, it appeared advisable to study the conditions for the preparation of a typical carbinol, since the published procedures make no mention of the effects of solvents or the ratio of reactants on yields.

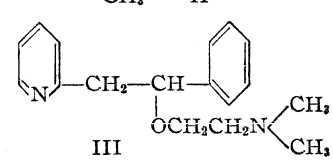
Method I: $2BrC_5H_4N + C_2H_5Br + Mg \longrightarrow 2C_5H_4N—MgBr$

Method II: $2\text{-}C_5H_4N—COOH + RCHO \longrightarrow C_5H_4N—\underset{\displaystyle R}{\underset{|}{C}}HOH$ (RCHO)



$2\text{-}C_5H_4N\text{-}COOH + RCOCH_3 \longrightarrow C_5H_4N—\underset{\displaystyle CH_2}{\underset{|}{\overset{\displaystyle R}{\overset{|}{C}}}}—OH$

Method III: $C_5H_4N—COCH_3 + RMgBr$



R = aryl or heterocyclic radical.

In the case of *p*-tolyl-2-pyridylcarbinol, the yield of carbinol is greatest when the ratio of aldehyde to picolinic acid is 6:1 and *p*-cymene at reflux temperature is used as solvent. Ashworth, *et al.*,[9] have used no solvent and a ratio of aldehyde to picolinic acid of 3:1 and 8:1 with no apparent increase in yield. It has been established that *p*-cymene is definitely superior to no solvent and to xylene. The optimum reaction time was found to be six hours and the yield of carbinol was not increased when the reaction was run for sixteen hours or when a nitrogen atmosphere was used.

In the course of this investigation, attempts to obtain 1-phenyl-1-(2-thienyl)-1-(β-dimethylaminoethoxy)-ethane (II) and 1-phenyl-1-(β-dimethylaminoethoxy)-2-(2-pyridyl)-ethane (III) were unsuccessful. In the case of II, instead of the expected tertiary carbinol, the Grignard reaction between bromobenzene and 2-acetylthiophene gave 1-phenyl-1-(2-thienyl)-ethylene, dehydration of the carbinol occurring notwithstanding precautions to remove traces of acid from the reaction product. The reaction of 1-phenyl-2-(2-pyridyl)-ethanol with β-dimethylaminoethyl chloride with sodium amide gave α-stilbazole and none of the expected ether, III.

II

III

**Pharmacology.**—The alkamine ethers listed in Table II have been tested for antihistaminic activity by the intravenous injections of lethal doses of histamine diphosphate one-half to one hour after the intravenous administration of the drug under test.

The most active compounds are the 2-pyridyl

[a] The yields are not calculated on the basis of recovered carbinol. [b] Low nitrogen analyses are due to traces of unreacted carbinol which could not be removed by repeated fractionation. [c] Some decomposition occurred during distillation. [d] At present in clinical use under the trade name "Decapryn." [e] The dialkylaminoalkyl residue is either $—CHCH_2N(CH_3)_2$ | $CH_3$ or $—CH_2—CH(CH_3)—N(CH_3)_2$ | $CH_3$ or both. Compare Schultz, Robb and Sprague, THIS JOURNAL, 69, 188 (1947); 69, 2454 (1947).

derivatives in which R′ is phenyl or an alkoxy, alkyl, halogen or dimethylamino substituted phenyl group, R″ is hydrogen or a methyl group and R‴ is methyl. These compounds, group I, (1, 3, 4, 5, 6, 7, 10, 19 and 20) have exhibited antihistaminic activity comparable to that of the presently available preparations. The oral LD/50 in mice was approximately 300–400 mg./kg.

Lower antihistaminic activity is exhibited by the 3-pyridyl compounds (2, 18 and 21) and the 2-pyridyl compounds wherein R′ is 3,4-methylenedioxybenzene (8), benzyl (11), phenethyl (12), 2-thienyl (13), *n*-propyl (14); or wherein R″ is $C_2H_5$ (15 and 16). Variations in the length of the carbon chain of the ether also result in decreased potency (17). In general, these compounds possess $^1/_5$ to $^1/_{100}$ the activity of the group I compounds. A detailed pharmacological report will appear elsewhere.

## Experimental

**Method I. 2-Pyridyl-*p*-isopropylphenylcarbinol.**[8]—In a one-liter, three-necked flask equipped with a Hershberg tantalum stirrer, condenser and dropping funnel, there were placed 19.2 g. (0.8 mole) of magnesium turnings and 200 cc. of anhydrous ether. To the stirred mixture was added 20 g. (0.2 mole) of ethyl bromide. After the ethyl bromide had reacted, 64 g. (0.4 mole) of 2-bromopyridine was added dropwise at a rate which produced rapid reflux. The suspension was refluxed and stirred for an additional three hours. To the brown reaction mixture was added 89.5 g. (0.6 mole) of *p*-isopropylbenzaldehyde in 100 cc. of ether and the mixture was refluxed for ten hours. After decomposing the complex with cold, dilute hydrochloric acid, the aqueous acid layer was separated, made alkaline with gaseous ammonia and extracted with ether. The ether layer was dried over sodium sulfate, filtered, the ether removed and the residue distilled.

**Method II. 2-Pyridyl-*p*-tolylcarbinol**[9].—In a five-liter, three-necked flask equipped with a stirrer, condenser and nitrogen inlet tube, there were placed 100 g. of picolinic acid, 600 g. of *p*-tolualdehyde and 600 cc. of *p*-cymene. The reaction mixture was refluxed and stirred for six hours under nitrogen. The initial vigorous evolution of carbon dioxide subsided within a few hours. The solution was cooled and extracted with several portions of dilute hydrochloric acid. The aqueous acid layer was made alkaline with gaseous ammonia and the oil which separated was extracted with ether. The alkamine ether was isolated as described under Method I.

**Method III. 2-Pyridylphenylmethylcarbinol.**—In a 500-cc., three-necked flask, equipped with a stirrer, condenser and dropping funnel, there were placed 200 cc. of anhydrous ether and 4.4 g. (0.18 mole) of magnesium turnings. To the stirred mixture was added dropwise 28.2 g. (0.18 mole) of bromobenzene in 50 cc. of ether. The reaction mixture was then stirred and refluxed for one hour. After cooling the mixture, 20 g. (0.17 mole) of 2-acetylpyridine was added and a heavy white precipitate separated. After refluxing for several hours, the reaction mixture was decomposed with dilute hydrochloric acid and ice. The acid layer was separated, made alkaline with gaseous ammonia and extracted with ether. Isolation of the alkamine ether was carried out as described under Method I.

The alkamine ethers listed in Table II were prepared essentially as described for phenyl-2-pyridylmethyl-β-

N,N-dimethylaminoethyl ether (19): In a 500-cc., three-necked flask equipped with a stirrer, condenser and dropping funnel, containing a suspension of sodium amide (from 6.74 g. (0.29 mole) of sodium) in 250 cc. of dry xylene, there was added cautiously at 0° 53 g. (0.286 mole) of phenyl-2-pyridylmethylcarbinol. A vigorous evolution of ammonia occurred and the resulting deep blue reaction mixture was heated for several hours on the steam-bath. Then 32.5 g. (0.30 mole) of β-N,N-dimethylaminoethyl chloride was added and the reaction mixture heated for approximately eighteen hours on the steam-bath. During this time, the deep blue color of the sodium salt of the carbinol was discharged and a turbid brown mixture resulted. The excess sodium amide was decomposed with water, the xylene layer was separated and, after drying, was evaporated *in vacuo*. The crude alkamine ether was fractionated.

The following procedures were used in an attempt to secure ethers II and III. To phenylmagnesium bromide (48.7 g. bromobenzene) in 150 cc. ether, there was added 37.8 g. of 2-acetylthiophene. The reaction product yielded 23.3 g. of a pale yellow liquid, b. p. 100–108° (0.5 mm.).

*Anal.* Calcd. for $C_{12}H_{10}S$: C, 77.35; H, 5.41. Found: C, 77.26; H, 5.44. The residue from the distillation yielded 13.1 g. of a viscous material, b. p. 185–245 (0.5 mm.) which resinified on standing.

To a sodium amide suspension, from 1.2 g. of a sodium in 250 cc. of toluene, there was added at room temperature 10 g. of 1-phenyl-2-(2-pyridyl)-ethanol. The reaction mixture was heated with stirring on the steam-bath for two hours and then 9 g. of β-dimethylaminoethyl chloride was added. The condensation was carried out in the usual manner and the product distilled; yield 8.4 g.; b. p. 158–162° (2.5 mm.); m. p. 90–91° after recrystallization from aqueous ethanol, mixed m. p. with an authentic sample of α-stilbazole, 90–91°.

**Acknowledgment.**—We are grateful to Dr. Richard Tislow and Mrs. Annette LaBelle for the pharmacological data reported herein.

## Summary

A series of pyridyl-substituted alkamine ethers has been synthesized from pyridyl substituted carbinols and dialkylaminoalkyl halides. In general, the 2-pyridyl substituted alkamine ethers showed a high order of antihistaminic activity whereas the corresponding 3-pyridyl compounds were relatively less active.

# Quinolines. VII. Some 3-Methylquinolines

BY EDGAR A. STECK AND LOUIS L. HALLOCK[1]

Potential antimalarials of the 4-amino-3-methylquinoline type have been the subject of considerable investigation in these laboratories.[2-6] The bulk of these studies[2,5] was concerned with the influence of the variation of substituents in the benzenoid moiety upon the schizontocidal action of 4-(4-diethylamino-1-methylbutylamino)-3-methylquinoline derivatives. In the present contribution there are presented data relating to the preparation of 4-(4-diethylamino-1-methylbutylamino)-7-ethoxy-3-methylquinoline and certain experiences in the synthesis of other 3-methylquinolines which were terminated prior to completion because other work intervened.

The preparation of 4-chloro-7-ethoxy-3-methylquinoline, required for reaction with 4-diethylamino-1-methylbutylamine, was accomplished by a modification of the Conrad-Limpach synthesis.[2d] In the cyclization of the anil from 3-phenetidine and ethyl α-ethoxalylpropionate, only one quinoline ester appeared to be formed (*cf.* ref. 2c, d and 5), as in the case of the related methoxy series.[7] The structure of the series (notice Table I) could not be proved unequivocally, for several attempts to oxidize[2c,d] the ethoxy-4-hydroxy-3-methylquinoline or related 2-carboxylic acid gave only 3-phenetidine. There was no comment as to difficulty in the proof of structure of the 7-methoxy analog by oxidation,[7] but the facile decarboxylation of several anthranilic acids has been recorded in the literature recently,[8,9] including 4-methoxyanthranilic acid. The 7-position is assigned to the ethoxy group on the basis that only one product resulted from the pyrolytic cyclization (*cf.* ref. 7) and the ease with which the oxidation product decarboxylated to 3-phenetidine (*cf.* ref. 9).

The work on 3,5/7-dimethylquinoline derivatives was halted when it was learned that Hauser, *et al.*,[7] were engaged in similar studies. 3-Toluidine was employed as the starting material in the Conrad-Limpach synthesis, and the preparation discontinued at the 4-chloro-3,5/7-dimethylquinoline stage. The structure of the series, shown in Table I, was proven by the catalytic dehalogenation of one of the 4-chloroquinoline derivatives to the corresponding dimethylquinoline, previously prepared by Manske.[10] It was of interest that the lower-melting isomer of the 4-chloroquinoline type, here an oil, was the one bearing a methyl group in position 7 (*cf.* ref. 5).

[a] Yield as employed in next step, being well-purified at ester stage. [b] Legend: Ac = acetone; E = ethanol; Pg = propylene glycol; S = sublimed; SA = Skellysolve A; a = aqueous. [c] Note reference 14; d. = decomposes. [d] Much tar formed during the cyclization. [e] Previously reported by Hauser, *et al.*; the 4-hydroxy compound was recorded as having m. p. 260–261° and the 4-chloro body had m. p. 59–60.5°. [f] Converted directly into the picrate, golden needles from acetone, m. p. 217–218°. *Anal.* Calcd. for $C_{11}H_{10}ClN$, $C_6H_3N_3O_6$: N, 13.36. Found: N, 13.10.

In the hope of obtaining some compounds bearing the 8-iodo-5-methoxy-3-methylquinoline nucleus, 3-amino-4-iodoanisole[11] was condensed with ethyl α-ethoxalylvalerate and cyclized in Dowtherm A.[12,2d] The loss of iodine was noted throughout all of the attempts to form the quinoline ring bearing the desired groups. Purification of the product of cyclization gave only ethyl 4-hydroxy-methoxy-3-methylquinoline-2-carboxylate, as indicated by analyses and comparison with a sample prepared after the method of Hauser.[7]

A re-examination of certain data relating to previous investigations on bz-iodo-3-methylquinolines[2d] was deemed of interest because the iodomethoxy type had a labile iodine atom. The compound formed by the action of 5% sodium hydroxide upon ethyl 4-hydroxy-5-iodo-3-methylquinoline-2-carboxylate was found to contain iodine when boiled with sodium and amyl alcohol. Analyses on this substance were not concordant, as earlier noted.[2d] When the acid was decarboxylated, a loss of iodine did occur, but the analyses indicated an impure substance. At last, treatment with phosphorus oxychloride gave a small amount of 4-chloro-3-methylquinoline[2a] after extensive purification by crystallization and sublimation.

The only compound herein reported which was screened as an antimalarial was 4-(4-diethylamino-1-methylbutylamino)-7-ethoxy-3-methylquinoline (SN-13,573[13]). This compound, although fairly low in activity, was superior to the related methoxy derivative (SN 10,566) and the 6- and 8-ethoxy-4(4-diethylamino-1-methylbutylamino)-3-methylquinolines[2a,b] (SN 9,082 and 12,348).

## Experimental[14]

**7-Ethoxy-3-methylquinolines.**—The application of the Conrad–Limpach synthesis to 3-phenetidine and ethyl α-ethoxalylpropionate followed the usual pattern, and data relating to the intermediates are presented in Table I. Several attempts to prove the structure of these compounds unequivocally by oxidative means[2c,d] failed because the resulting anthranilic acid decarboxylated readily to give only 3-phenetidine. The reaction of 4-chloro-7-ethoxy-3-methylquinoline with 4-diethylamino-1-methylbutylamine in phenol[2] at 170° led to a 76% yield of the 4-(4-diethylamino-1-methylbutylamino) compound. 4-(4-Diethylamino-1-methylbutylamino)-7-ethoxy-3-methylquinoline, SN-13,573, was obtained as a golden oil which boiled at 180–186° (0.05 mm.).

*Anal.* Calcd. for $C_{21}H_{33}N_3O$: C, 73.43; H, 9.68; N, 12.33. Found: C, 73.45; H, 9.58; N, 12.29.

**3,5/7-Dimethylquinolines.**—The synthesis of both the 3,5- and 3,7-dimethylquinolines here proceeded from 3-toluidine and ethyl α-ethoxalylpropionate in the customary manner. Hauser, *et al.*,[7] prepared several 3,5-dimethylquinoline derivatives through dehalogenation of 8-chloro-4-hydroxy-3,5-dimethylquinoline. In the present case, the isomeric ethyl 3,5- and 3,7-dimethyl-4-hydroxyquinoline-2-carboxylates proved to be rather recalcitrant of separation. The high-melting isomer, the 3,7-dimethyl compound, was less soluble in 70% acetone, while

(11) During the compilation of these data, the preparation of this compound was reported: Frank, Fanta and Tarbell, THIS JOURNAL, **70**, 2319 (1948).

(12) A commercial heat-transfer liquid consisting of 73.5% diphenyl ether and 26.5% diphenyl.

(13) All drugs identified by Survey Numbers (SN) in the files of the Antimalarial Survey have been systematically tabulated, together with the antimalarial activities, in "Antimalarial Drugs, 1941–1945" (F. Y. Wiselogle, editor), Edwards Bros., Ann Arbor, Mich., 1946.

(14) The melting points and boiling points reported are uncorrected values.

the other was best crystallized from alcohol. In Table I are listed the properties of the compounds involved in proceeding to the 3,5- and 3,7-dimethyl-4-chloroquinolines. The structure of the two series was clarified by dehalogenation of the 4-chloro compound of m.p. 59.5–60° in alcohol containing one equivalent of sodium hydroxide employing Busch–Stöve catalyst[15] under 50 lb./sq. in. hydrogen pressure. The crude product was directly converted to the picrate, which melted at 221° after crystallization from acetone. Manske, *et al.*[10] have given the melting point of 3,5-dimethylquinoline picrate as 220° while that salt of 3,7-dimethylquinoline melted at 244°.

**3-Amino-4-iodoanisole in the Conrad–Limpach Synthesis.**—4-Amino-3-nitroanisole was diazotized and treated with potassium iodide after the manner of Reverdin[11,16,17] to give 4-iodo-3-nitroanisole in 86–92% crude yield. It crystallized from Skellysolve C or aqueous alcohol as orange needles, m.p. 62.5–63°. The reduction of the nitro group was best accomplished by the method of West[11,18] using aqueous ethanol as the solvent. Crude yields of 65–73% resulted, the 3-amino-4-iodoanisole being a reddish-brown oil. The crude material was used in subsequent work, for while a trial batch gave a fair recovery of a reddish liquid, b.p. *ca.* 90–115° (0.2 mm.), another sample exploded when distillation was attempted, much iodine vapor being noted afterward. This occurrence has also been witnessed recently by Tarbell, *et al.*[11]

The condensation of crude 3-amino-4-iodoanisole with ethyl α-ethoxalylpropionate was carried out in the usual manner, the product resulting in 69–80% yield. All attempts to cyclize the anil in Dowtherm A led to copious evolution of iodine vapor. When the crude reaction product was crystallized from ethanol and from acetone several times, using Darco G-60 liberally, fine white needles were obtained, m.p. 192–192.5°. Analysis and mixed melting point with an authentic sample (prepared from 3-anisidine by the method described by Hauser, *et al.*[7]) showed this compound to be ethyl 4-hydroxy-7-methoxy-3-methylquinoline-2-carboxylate. The yields obtained (from the anil) were 52–66%.

*Anal.* Calcd. for $C_{14}H_{15}NO_4$: C, 64.35; H, 5.78; N, 5.37. Found: C, 64.45; H, 6.06; N, 5.36.

**Further Study of 5-Iodo-3-methylquinolines.**—In a previous contribution in this series,[2d] it was reported that a halogen-free compound, m.p. 251° dec., was obtained by the action of boiling 5% caustic upon ethyl 4-hydroxy-5-iodo-3-methylquinoline-2-carboxylate. This substance was re-examined and found to contain iodine when boiled with *n*-amyl alcohol and sodium for some while. The low solubility of the material in the common solvents led to the use of 2-methyl-2,4-pentanediol, but satisfactory analyses could not be obtained. Decarboxylation of the yellow acid in either Dowtherm A or mineral oil led to a white solid which melted vaguely around 286° after crystallization from alcohol. This alleged 4-hydroxy-5-iodo-3-methylquinoline failed to give concordant analyses, but merely indicated that more iodine was lost during the reaction. Ultimately, the 4-hydroxy-3-methylquinoline type so obtained was interacted with phosphorus oxychloride. The result of extensive purification of the product by crystallization from Skellysolve B and sublimation was a small quantity of white needles, m.p. 61.5–62.5°, which was free of iodine. A melting point of 60° has been reported for 4-chloro-3-methylquinoline.[2a]

**Acknowledgment.**—The authors wish to express their appreciation to Mrs. N. P. Gorman, Mr. E. V. Ryan and Mr. A. J. Holland for technical assistance. All analyses were carried out by the analytical staff of this Institute under the direction of Mr. M. E. Auerbach.

## Summary

The preparation of 4-(4-diethylamino-1-methylbutylamino)-7-ethoxy-3-methylquinoline from 3-phenetidine has been described.

The properties of a number of 3,5- and 3,7-dimethylquinoline derivatives have been reported and the structures proven. Certain experiences with iodinated compounds in the Conrad–Limpach synthesis have been described.

# Pteridines. IV. Derivatives of 2,4-Diamino-6,7-diphenylpteridine[1]

BY C. K. CAIN, E. C. TAYLOR, JR., AND LOUISE J. DANIEL

In the course of a study of substituted pteridines, it was found that those compounds which have amino groups in both the 2- and 4-positions of the pteridine nucleus exhibit a high degree of antifolic acid activity against several bacteria.[2,3] However, the diaminopteridines studied showed very low solubility in water and in all of the common organic solvents tested. Since it appeared desirable to have available for biological testing compounds of this type which could be administered in aqueous solution, several experiments have been carried out to modify these compounds in such a way that solubility in water or alcohol would result with the retention of a high degree of antifolic acid activity.

Of the various pteridines previously reported,[4] 2,4-diaminophenanthro(9,10-e)pteridine had the maximum antifolic acid activity against *S. faecalis*. The preparation of a derivative of this compound having a sulfonic acid group on the phenanthrene nucleus has been carried out. The resulting compound is fairly soluble in aqueous sodium bicarbonate solution but shows very little antifolic acid activity. Since it was thought for a variety of reasons that 2,4-diamino-6,7-diphenyl-

Solvents for absorption spectra

[a] Methyl alcohol. [b] Methyl alcohol made 0.1 *N* in hydrochloric acid. [c] Ethylene glycol made 0.1 *N* in hydrochloric acid. [d] 0.1 *N* Hydrochloric acid. [e] 0.1 *N* Sodium hydroxide. [f] Water. [g] 1 *N* Hydrochloric acid.

pteridine would be a more suitable molecule to modify for solubility, several compounds have been prepared which might be considered as derivatives of this parent molecule. These compounds, together with their absorption spectra in solution, some solubility characteristics and antifolic acid activity against *S. faecalis*, are listed in Tables I and II.

Inspection of Table I leads to several interesting conclusions in regard to the relation of structure and antifolic acid activity. First, there seems to be no direct correlation between alcohol solubility, which we assume is related to lipid solubility, and antifolic acid activity. Extreme examples of this may be found in Compounds 2 and 9 of Table I. Second, acetylation of the amino groups in either the 4- or both the 2- and 4-positions of the pteridine ring has very little effect on the activity, the difference between the mono- and the diacetate probably being one of ease of hydrolysis by the organism. Third, substitution on the phenyl group, regardless of the nature of the substituting group, decreases the activity. Moreover, the position of the substituent on the phenyl group also has a marked effect on the activity, as shown by Compounds 5 and 12. Fourth, the introduction of any of the various water-solubilizing groups employed results in a considerable decrease in the activity, as shown by Compounds 7, 8 and 13. Fifth, replacement of the 4-amino group by a 4-methylamino group lowers the activity, as shown by Compounds 1 and 4.

It is also of interest to point out that the replacement of phenyl groups in the 6- and 7-positions of the pteridine nucleus by *p*-aminophenyl groups affects the reactivity of the amino groups in the 2- and 4-positions. As described in the Experimental Section, acetylation of 2,4-diamino-6,7-bis-(*p*-aminophenyl)-pteridine under mild conditions gives the tetraacetyl derivative, all four of the amino groups present in the molecule being attacked. In contrast to this behavior, the acetylation of the 4-amino group of 2,4-diamino-6,7-diphenylpteridine requires rather vigorous conditions while the acetylation of both the 2- and 4-amino groups in this compound requires much more strenuous conditions.

The assignment of structure of the monoacetyl derivative of 2,4-diamino-6,7-diphenylpteridine as 2-amino-4-acetamido-6,7-diphenylpteridine is based upon a comparison of the absorption spectrum of this compound with that of 2-amino-4-methylamino-6,7-diphenylpteridine.

## Experimental

**2-Amino-4-acetamido-6,7-diphenylpteridine.**—A mixture of 1.0 g. of 2,4-diamino-6,7-diphenylpteridine and 50 ml. of acetic anhydride was heated under reflux for sixteen hours, the acetic anhydride removed by distillation under reduced pressure, and the residue taken up in 100 ml. of boiling alcohol and filtered. The dark orange filtrate was treated twice with Norit and the alcohol concentrated to 15 ml. on a steam-bath. Addition of 75 ml. of hot water and cooling gave 620 mg. (55%) of a light yellow microcrystalline solid. It was recrystallized by dissolving in alcohol, adding hot water to the point of precipitation, and allowing to cool slowly. On heating, the compound melts slowly at 140–150° to a clear red liquid.

*Anal.* Calcd. for $C_{20}H_{16}N_6O$: N, 23.6. Found: N, 23.6.

**2,4-Diacetamido-6,7-diphenylpteridine.**—A solution of 0.5 g. (0.0016 mole) of 2,4-diamino-6,7-diphenylpteridine in 3 ml. of concentrated sulfuric acid was treated with 10 ml. of acetic anhydride and the clear red solution heated on a steam-bath for one hour. It was then poured onto ice, diluted to 100 ml. with water and allowed to stand at 0° for one day. The light yellow solid was filtered off and washed first with water and then with alcohol. Recrystallization by dissolving in boiling dimethylformamide, adding hot water to precipitation and cooling gave 0.43 g. (68%) of a light yellow microcrystalline solid, which decomposed slowly on heating above 190°.

*Anal.* Calcd. for $C_{20}H_{18}N_6O_2$: C, 66.3; H, 4.6; N, 21.1. Found: C, 66.5; H, 4.8; N, 21.2.

**2-Amino-4-chloro-6,7-diphenylpteridine Hydrochloride.**—A suspension of 1.0 g. (0.0032 mole) of dry 2-amino-4-hydroxy-6,7-diphenylpteridine in 60 ml. of freshly distilled phosphorus oxychloride containing 5 g. of phosphorus pentachloride was refluxed for two hours in an oil-bath to give a clear red solution. After filtering through a sintered glass filter, the solvent was removed by distillation under diminished pressure and the excess phosphorus pentachloride destroyed by addition of ice. After standing for one-half hour, the bright yellow solid was filtered off and washed thoroughly with water to give 0.95 g. (81%). All attempts to recrystallize it resulted in the hydrolysis of the 4-chloro group to give 2-amino-4-hydroxy-6,7-diphenylpteridine.

**2-Amino-4-methylamino-6,7-diphenylpteridine.**—A mixture of 1.0 g. (0.002 mole) of 2-amino-4-chloro-6,7-diphenylpteridine hydrochloride, 30 ml. of alcohol, and 10 ml. of methylamine was heated in a glass bomb at 155° for sixteen hours. After cooling, the reaction mixture was filtered and the clear yellow filtrate evaporated to dryness under diminished pressure. The yellow residue was extracted with hot 0.5 *N* hydrochloric acid and filtered. The filtrate was treated with Norite and adjusted to *p*H 9 with ammonium hydroxide. The resulting precipitate was crystallized by dissolving in hot alcohol and adding hot water to the point of precipitation which gave 0.27 g. (27%) of bright yellow crystals in the form of rectangular platelets exhibiting parallel extinction and melting at 237–238° (cor.).

*Anal.* Calcd. for $C_{19}H_{16}N_6$: C, 69.5; H, 4.9; N, 25.6. Found: C, 69.6; H, 5.0; N, 25.8.

**2,4-Diamino-6,7-bis-(*p*-aminophenyl)-pteridine.**—To a solution of 2.00 g. (0.0084 mole) of 2,4,5,6-tetraminopyrimidine sulfate in 90 ml. of water was added 2.00 g. (0.0049 mole) of *p,p'*-diaminobenzil sulfate,[5] and the mixture refluxed for one hour to give a clear, cherry red solution. After treatment with Norit, it was poured into boiling dilute ammonium hydroxide of sufficient strength so that the final solution was distinctly alkaline (*p*H 11). Orange crystals of the desired product separated at once. After filtering, washing with water, and drying, 1.73 g. (quantitative) was obtained. Recrystallization from 50% ethanol gave bright orange prisms exhibiting parallel extinction, and decomposing sharply at 308–309° (cor.).

*Anal.* Calcd. for $C_{18}H_{16}N_8$: C, 62.8; H, 4.7; N, 32.6. Found: C, 63.0; H, 4.6; N, 32.6.

**2,4-Diamino-6,7-bis-(*p*-acetamidophenyl)-pteridine.**—A solution of 1.10 g. (0.00785 mole) of 2,4,5,6-tetraminopyrimidine in 75 ml. of water and a solution of 1.35 g. (0.00417 mole) of *p,p'*-diacetamidobenzil in 100 ml. of ethanol were mixed and refluxed for seven hours. After treatment with Norit, the ethanol was removed by dis-

(5) We should like to express our thanks to Calco Chemical Division of American Cyanamid Company for this material.

tillation under reduced pressure. Upon cooling and filtering, 1.46 g. (82%) of yellow crystals was obtained. Recrystallization from 50% aqueous acetic acid gave small, slender needles showing oblique extinction, m. p. 234–237° (cor.).

*Anal.* Calcd. for $C_{22}H_{20}N_8O_2$: C, 61.7; H, 4.7; N, 26.2. Found: C, 61.4; H, 4.8; N, 26.2.

**2,4-Diamino-6,7-bis-(*p*-hydroxymethylaminophenyl)-pteridine.**—To a suspension of 0.1 g. of 2,4-diamino-6,7-bis-(*p*-aminophenyl)-pteridine in 4 ml. of boiling water, sufficient concentrated hydrochloric acid was added to cause solution, and then 0.2 ml. of 40% formaldehyde was added slowly. The addition product separated at once. The mixture was adjusted to *p*H 7.5 with sodium bicarbonate, cooled to 0°, filtered, and washed thoroughly with water to give 115 mg. (quantitative) of the bright orange product. The solid did not melt below 300°.

**2,4-Diamino-6,7-bis-(*p*-sulfitomethylaminophenyl)-pteridine Disodium Salt.**—The product obtained above was suspended in 30 ml. of water and 0.15 g. of sodium bisulfite added. The mixture was refluxed for three hours to give a clear, light red solution. Removal of three-quarters of the water by distillation under reduced pressure and addition of two volumes of acetone precipitated 0.148 g. (88%) of the orange product. The solid did not melt below 300°.

**2,4-Diamino-6,7-bis-(*p*-sulfinomethylaminophenyl)-pteridine Disodium Salt.**—To a solution of 0.8 g. (0.00232 mole) of 2,4-diamino-6,7-bis-(*p*-aminophenyl)-pteridine in 200 ml. of ethanol was added 0.65 g. of finely powdered sodium formaldehyde sulfoxylate and 50 mg. of sodium hydroxide, and the mixture heated under reflux on a steam-bath for six hours. During this time, the sulfoxylate gradually dissolved and a bright orange solid separated. The reaction mixture was cooled to 0° and the product filtered off and washed thoroughly with hot alcohol to yield 0.96 g. (76%). The solid did not melt below 300°. No satisfactory method of recrystallization could be found. The structure is assigned on the basis of absorption spectrum and ready solubility in water.

**2,4-Diacetamido-6,7-bis-(*p*-acetamidophenyl)-pteridine.**—A mixture of 0.2 g. of 2,4-diamino-6,7-bis-(*p*-aminophenyl)-pteridine, 1.9 ml. of glacial acetic acid, and 3.2 ml. of acetic anhydride was heated for forty-five minutes at 80°. Addition of 100 ml. of water caused the separation of a flocculent, light yellow solid, which was collected by filtration, washed with ice cold water, and recrystallized from water to give 0.18 g. (56%). The product was dried for analysis at 140° under vacuum over phosphorus pentoxide, but retained one molecule of water of recrystallization.

*Anal.* Calcd. for $C_{26}H_{24}N_8O_4 \cdot H_2O$: C, 58.9; H, 4.9; N, 21.1. Found: C, 59.0; H, 4.8; N, 20.8.

**2,4-Diamino-6,7-bis-(*p*-hydroxyphenyl)-pteridine.**—(a) To an ice-cold solution of 0.2 g. of 2,4-diamino-6,7-bis-(*p*-aminophenyl)-pteridine in a mixture of 7 ml. of water and 0.8 ml. of concentrated sulfuric acid was added slowly a solution of sodium nitrite in water until an excess of nitrous acid was present (starch–iodide paper). The excess nitrous acid was destroyed with urea and the reaction mixture was immersed in a water-bath at 60° for fifteen minutes and finally at 100° for one hour. Five ml. of water was added, and the yellow solid filtered off and washed with water to give 0.14 g. (71%). It was purified by dissolving in dilute sodium hydroxide, treating with Norite, and pouring into hot dilute hydrochloric acid, and was finally recrystallized from water to give a yellow microcrystalline solid. (b) A solution of 0.5 g. (0.002 mole) of *p,p'*-dihydroxybenzil, 1.0 g. (0.0045 mole) of 2,4,5,6-tetraminopyrimidine bisulfite, 20 ml. of ethyl methyl ketone, 20 ml. of ethanol, 40 ml. of water, and 6 ml. of concentrated hydrochloric acid was refluxed for sixteen hours. The clear yellow solution was then treated with Norit and concentrated by distillation under reduced pressure until a bright yellow product separated out. It was filtered off, washed with cold water, and recrystallized from water to give 0.6 g. (84%) of a light yellow microcrystalline solid. The absorption spectrum of this product was identical with that obtained by method (a) above.

*Anal.* Calcd. for $C_{18}H_{14}N_6O_2$: C, 62.4; H, 4.1. Found: C, 62.7; H 4.1.

**2,4-Diamino-6,7-bis-(*m*-nitrophenyl)-pteridine.**—A solution of 3.0 g. (0.0214 mole) of 2,4,5,6-tetraminopyrimidine and 2.0 g. (0.0066 mole) of 3,3'-dinitrobenzil in a mixture of 70 ml. of ethanol and 15 ml. of ethyl methyl ketone was refluxed for three hours. The heavy yellow solid which had separated from the reaction mixture was filtered off, washed with boiling water, and recrystallized by dissolving in a small amount of glacial acetic acid, treating with Norit, and pouring into a ten-fold excess of boiling water. The product weighed 2.3 g. (quantitative). After two additional recrystallizations, the product was obtained in the form of thin rods and sheets showing oblique extinction, m. p., 307–308° (cor.).

*Anal.* Calcd. for $C_{18}H_{12}N_8O_4$: N, 27.7. Found: N, 27.5.

**2,4-Diamino-6,7-bis-(*m*-aminophenyl)-pteridine.**—A solution of 1.0 g. (0.0025 mole) of 2,4-diamino-6,7-bis-(*m*-nitrophenyl)-pteridine in 75 ml. of ethanol containing 5 drops of concentrated hydrochloric acid was shaken with hydrogen at 2.5 atmospheres pressure with platinum oxide catalyst at room temperature. After one hour, reduction was complete, and the yellow reaction mixture was filtered and evaporated to dryness. The residue was dissolved in 15 ml. of water, treated with Norit, and the product precipitated by addition of ammonium hydroxide to give 0.55 g. (65%). After a partial purification by redissolving in dilute hydrochloric acid and precipitating by addition of ammonium hydroxide, the compound was recrystallized from dilute ammonium hydroxide to give an orange-yellow microcrystalline solid. It slowly decomposed on heating above 180°.

*Anal.* Calcd. for $C_{18}H_{16}N_8$: C, 62.8; H, 4.7; N, 32.6. Found: C, 62.6; H, 4.6; N, 32.7.

**2,4-Diamino-6,7-bis-(*m*-sulfinomethylaminophenyl)-pteridine Disodium Salt.**—A boiling solution of 0.04 g. (0.000116 mole) of 2,4-diamino-6,7-bis-(*m*-aminophenyl)-pteridine in 75 ml. of absolute alcohol was treated with 0.013 g. (0.00011 mole) of sodium formaldehyde sulfoxylate, and the mixture refluxed for two hours. The white sodium formaldehyde sulfoxylate gradually disappeared, while at the same time an orange solid deposited. After cooling, filtering, and washing with boiling absolute alcohol, 51 mg. (85%) of the desired product was obtained. The material was hygroscopic and rapidly formed the trihydrate in contact with air.

*Anal.* Calcd. for $C_{20}H_{18}N_8Na_2O_4S_2 \cdot 3H_2O$: C, 40.1; H, 4.0; N, 18.7. Found: C, 39.7; H, 4.5; N, 18.7.

**2,4-Diaminophenanthro(9,10-e)pteridine-8-(or 11)-sulfonic Acid.**—A solution of 5.0 g. (0.0225 mole) of 2,4,5,6-tetraminopyrimidine bisulfite in 20 ml. of 0.5% sodium hydroxide was added to a solution of 5.0 g. (0.0174 mole) of phenanthrenequinone-3-sulfonic acid in 130 ml. of water and the resulting deep green mixture refluxed for thirty minutes. At the end of this time the color had changed to a deep cherry red. The reaction mixture was treated with Norit and acidified to *p*H 5 with concentrated hydrochloric acid. The bright yellow solid which separated was collected by filtration and washed with water followed by acetone to give 6.0 g. (88%). The product was purified by dissolving in dilute alkali, treating with Norit, and adding an equal volume of 40% sodium hydroxide. The crystalline sodium salt so obtained was dissolved in water and poured into hot dilute hydrochloric acid to give a light yellow microcrystalline product. It does not melt below 360°.

*Anal.* Calcd. for $C_{18}H_{12}N_6O_3S$: C, 55.1; H, 3.1. Found: C, 55.2; H, 3.0.

## Summary

1. A number of derivatives of 2,4-diamino-6,7-

diphenylpteridine have been prepared for the purpose of finding a soluble derivative which would retain a high degree of antifolic acid activity.

The absorption spectra of these compounds in solution, some of their solubility characteristics and their inhibitory indices against *S. faecalis* are reported.

2. It has been found that a sulfinomethylamino group confers water solubility with the retention of antifolic acid activity. The introduction into the 2,4-diamino-6,7-diphenylpteridine molecule of any of the solubilizing groups investigated results in some lowering of antifolic acid activity.

3. Several conclusions have been drawn regarding the effect on antifolic acid activity of certain structural changes in the 2,4-diamino-6,7-diphenylpteridine molecule.

# Piperidine Derivatives. XX. The Preparation and Reactions of 1-Methyl-3-piperidone

By S. M. McElvain and John F. Vozza

The recent report[1] on the reactions of 1-methyl-4-piperidone, particularly those with a variety of aromatic aldehydes, indicated a study of similar reactions with the unsymmetrical isomer, 1-methyl-3-piperidone (VI). The preparation of this latter compound from 1-methyl-4-carbethoxy-3-piperidone (V), obtained by the cyclization of the diester (IV) was reported earlier[2] from this Laboratory. It seemed of special interest to determine the reactivity of VI in the presence of basic catalysts inasmuch as the previous workers[2] had shown that, due to the relative inertness of the α-aminomethylene group, the cyclization of IV produced the keto-ester V rather than the isomer, 1-methyl-2-carbethoxy-3-piperidone.

In the earlier work[2] the diester IV was prepared by the interaction of ethyl γ-bromobutyrate with sarcosine ester. In the present work a more satisfactory preparation of IV has been developed from butyrolactone, which is now commercially available.[3] The complete series of reactions from this lactone to the piperidone VI is

$$\underset{\text{OCH}_2\text{CH}_2\text{CH}_2\text{CO}}{\text{OCH}_2\text{CH}_2\text{CH}_2\text{CO}} \xrightarrow[280°]{\text{CH}_3\text{NH}_2} \underset{\text{I (90–93\%)}}{\text{CH}_3\text{NCH}_2\text{CH}_2\text{CH}_2\text{CO}} \xrightarrow{\text{HCl}}$$

IV (37–46% from II)

V (74%) VI (100%)

The sequence from II to IV was found necessary, as it was not possible to obtain an ester of II; all attempts to prepare the ester gave the pyrrolidone (I). The amino-acid, however, is quite stable in the form of its salts II and III. The cyclization of IV was found to proceed most satisfactorily with sodium ethoxide; sodium hydride, which produced excellent yields of 1-methyl-3-carbethoxy-4-piperidone,[1] gave very poor yields (*ca.* 10%) of V.

The condensation of benzaldehyde with VI in alkaline, 60% ethanol was rapid and a crystalline product, which gave analytical values approximating an equimolecular mixture of the 4-carbinol (VII) and the 4-benzal derivative (VIII), was obtained in approximately 70% yield. No other products could be separated from this reaction. This mixture of VII and VIII could not be separated by recrystallization; a product with a constant melting range, 123–128°, was obtained. However, when this material was converted to the hydrochloride salts, the free bases liberated into ether, and the resulting solution concentrated, the benzal derivative VIII, m. p. 112–113°, separated. From the ether filtrate the carbinol VII was obtained as a glass, which gave a crystalline hydrochloride that melted at 192–202°, indicating that it was a mixture of the two possible racemates. Two other observations are worthy of note: (a) an ethereal solution of the carbinol VII containing a small amount of the benzal derivative (VIII) gave, on standing, a crystalline precipitate, m. p. 123–128°, and (b) this latter product also separated from an alkaline 60% ethanol solution of VII on

(3) From the Cliffs Dow Chemical Company, Marquette, Michigan.

standing. These results lead to the conclusion that this reaction product is a molecular complex of VII and VIII, which is destroyed when the components are converted to their hydrochlorides, and which forms sufficiently slowly to permit separation of the components immediately after their liberation from the non-associated salts.

Both VII and VIII show a similar instability (as indicated by rapid darkening) to light and air as has been noted[2] for the free base of VI. The structures of VII and VIII were shown by their reduction to 1-methyl-4-benzylpiperidine, derivatives of which were compared to those obtained from an authentic sample prepared from 4-benzylpyridine.

VII VIII IX

The carbinols VII are as resistant to dehydration as are those obtained from 1-methyl-4-piperidone.[1] The 4-benzal derivative (VIII), however, is readily hydrated to VII, treatment of a moist ethereal solution of VIII with hydrogen chloride being sufficient to effect the reaction. This peculiar reactivity of the benzal linkage of VIII was noticeable in its hydrogenation: in alcohol solution it absorbed hydrogen very slowly and incompletely, while in dioxane solution it was rapidly, but incompletely, hydrogenated, possibly because of a complex formation between a hydroxylic reduction product and unchanged VIII.

The condensation of benzaldehyde with VI in an ethanolic solution of hydrogen chloride was much slower than the base catalyzed reaction. The dark-colored reaction product was readily recrystallized to colorless crystals, m. p. 165–166°, the analyses of which were corresponded to a monobenzal derivative of VI. This purified material was obtained in 43% yield, and no other product could be isolated from the reaction mixture. In spite of the narrow melting range of this salt it was shown to be a mixture of the hydrochlorides of VIII and the isomeric 2-benzal derivative IX by the following reactions: (a) conversion of the salt to the free base produced a pale-yellow oil that could not be induced to crystallize (VIII melts at 112–113°), but was reconverted to the original hydrochloride mixture, m. p. 164–165°, by hydrogen chloride; (b) reduction failed to give a single 1-methyl-benzylpiperidine, but a product, the methiodide of which had properties similar to a mixture of the methiodides of 1-methyl-2- and 1-methyl-4-benzylpiperidines; (c) the picrate of the reduction product behaved as a mixture of authentic picrates of 1-methyl-2- and -4-benzylpiperidines that contained a higher proportion of the 4-isomer.

The exclusive formation of the 4-derivatives of 1-methyl-3-piperidone with an alkaline catalyst indicates that the reactivity of the 2-methylene group is inhibited by the attached basic nitrogen as is the acetic ester–methylene group[2] of IV in the Dieckmann cyclization. In acid medium, however, some of the 2-derivative (IX) is formed, which indicates that a positive charge on the nitrogen of the piperidone promotes reaction at the 2-position. It is also of interest to note that none of the dibenzal derivative, which was the main or exclusive product with 1-methyl-4-piperidone,[1] could not be isolated from any of the reactions of benzaldehyde with VI.

It also seemed of interest to determine the behavior of the 3-piperidone toward such a Grignard reagent as phenylmagnesium bromide. With this reagent, the isomeric 1-methyl-2-piperidone is reported[4] to yield the dehydration product, 1-methyl-2-phenyl-1,4,5,6-tetrahydropyridine, of the expected tertiary carbinol when the initial Grignard reaction product is decomposed with acids. Under these conditions, however, the 1-methyl-4-phenyl-4-hydroxypiperidine may be obtained from the 4-piperidone.[5] The 3-piperidone (VI) behaves as does its 4-isomer with phenylmagnesium bromide. The carbinol, 1-methyl-3-phenyl-3-hydroxypiperidine, was obtained in 59% yield as a viscous oil, which, because of its sensitivity to air, was analyzed in the form of the methiodide. The hydrochloride of this compound was readily acetylated to the corresponding 3-acetoxy derivative.

## Experimental

**1-Methyl-2-pyrrolidone (I).**—A steel bomb containing 172 g. (2 moles) of butyrolactone[3] was placed in a bath of acetone and Dry Ice. After the bomb and its contents were thoroughly cooled, 124 g. (4 moles) of liquid methylamine was added, the bomb closed and heated at 280° for four hours. After removing the excess methylamine with the aspirator, the reaction mixture was distilled, yielding 175–185 g. (90–93%) of 1-methyl-2-pyrrolidone,[6] b. p. 201–202°.

The hydrochloride of I, precipitated from ether with hydrogen chloride and recrystallized from absolute ethanol,[2] melted at 86–88°.

**γ-N-Methylaminobutyric Acid Hydrochloride (II).**—A solution containing 179 g. (1.8 moles) of 1-methyl-2-pyrrolidone and 250 ml. of concentrated hydrochloric acid was refluxed in an oil-bath for eight hours. The water and excess acid then were removed at diminished pressure on the steam-bath. The solid residue was shaken with 250 ml. of cold, dry acetone, which does not dissolve the amino-acid hydrochloride but facilitates its subsequent crystallization from ethanol. Crystallization from ethanol yielded 250 g. (90%) of colorless crystals, m. p. 120–121°.[7]

Several attempts to esterify the secondary amino-acid hydrochloride (II) by heating it in the presence of ethanolic hydrogen chloride failed to yield the desired ester. Also various attempts to form the N-benzoyl derivative of II by the Schotten–Baumann reaction and modified versions of this general procedure failed to give the desired product.

[a] Anker, Cook and Heilbron, *J. Chem. Soc.*, 917 (1945). [b] Ref. 4. [c] Bryans and Pyman, *J. Chem. Soc.*, 549 (1929). [d] This compound was obtained also when an ethereal solution of 2-benzylpiperidine was treated with methyl iodide. Anker, *et al.*,[a] p. 918, report a similar product, but state that they obtained 1-methyl-2-benzylpiperidine (A) from it on treatment with sodium hydroxide. This is obviously an error, as the methiodide, m. p. 226°, is not converted to A by alkali as is the hydroiodide, m. p. 120–121°.

**Ethyl γ-(Methyl-N-carbethoxymethylamino)-butyrate (IV).**—To a 5-l. three-necked flask, equipped with a dropping funnel and mechanical stirrer and immersed in an ice–salt-bath, was added a solution of 358 g. (6.4 moles) of potassium hydroxide in 200 ml. of water. When the alkaline solution had cooled to 0°, a solution of 246 g. (1.6 moles) of II in 800 ml. of absolute ethanol was added slowly, and the temperature of the stirred mixture kept below 12°. A solution of 154 g. (1.6 moles) of monochloroacetic acid in 200 ml. of absolute ethanol then was added at such a rate that the temperature of the reaction mixture did not rise above 12°. The contents of the flask was allowed to warm slowly to room temperature as the ice melted, and stirring was continued for forty-eight hours. The reaction mixture then was made distinctly acid to congo red with hydrochloric acid and filtered to remove the potassium chloride that had separated from solution. The filtrate was taken to dryness under reduced pressure on the steam-bath, leaving a clear, light-brown, semi-solid material. This was dissolved in 500 ml. of absolute ethanol, and the solution was added to 1800 ml. of absolute ethanol that had been saturated with hydrogen chloride. The mixture was shaken vigorously and allowed to stand at room temperature for two days, after which it was refluxed on the steam-bath for *only* two hours, as it was found that a longer period of heating was unfavorable to the yield. After the reflux period, the alcohol and excess hydrogen chloride were removed under reduced pressure on the steam-bath until only a thick viscous mass remained in the flask. The flask and its contents then were cooled in an ice-bath and 200 ml. of ether added, after which a solution of liquid ammonia in ether was added slowly until a strong odor of ammonia persisted. Each addition of ammonia was accompanied by vigorous stirring and agitation in order to bring about intimate contact between the ether layer and the more dense lower layer. The liberation of IV was accompanied by the precipitation of ammonium chloride. After an excess of ammonia had been added, the liquid was decanted from the precipitated solid and the latter extracted with three 100-ml. portions of ether; it was necessary to centrifuge the ether–salt suspension to separate the ether in the last extraction. After removing the ether and residual alcohol, the product was distilled through a Vigreux column under reduced pressure. The forerun, principally 1-methyl-2-pyrrolidone (I), was collected up to 131° (10 mm.); it amounted to about 25% of the starting salt (II). The diester (IV) was collected at 133–137° (10 mm.); $n^{25}D$ 1.4380, and weighed 135 g. The residue in the flask was dissolved in ethanol and treated with excess hydrogen chloride. After separating a small amount of ammonium chloride, a white crystalline material was recovered from the ethanol solution. This material was found to be the hydrochloride of a half-ester of the dibasic acid of IV. Its melting point, 121–122°, was similar to that of II (120–121°), but a mixture of equal parts of these two salts melted at 92–103°.

*Anal.* Calcd. for $C_9H_{18}ClNO_4$: Cl, 14.8; N, 5.8. Found: Cl, 14.6; N, 5.2.

By re-esterifying this half-ester hydrochloride and processing the esterification mixture according to the procedure described above, an additional 35 g. of IV was obtained. The total amount, 170 g., represents a 46% yield.

The ethereal solution of ammonia was used to liberate IV from its hydrochloride, as it was found that aqueous solutions of alkali bases resulted in considerably lower yields of the product.

**1-Methyl-2- and 1-Methyl-4-benzylpiperidines.**—2-Benzylpiperidine and 4-benzylpiperidine were prepared by the hydrogenation[8] of the corresponding benzylpyridines.[9] These piperidines were N-methylated catalytically over copper–chromium oxide.[10] 4-Benzylpiperidine was also methylated with methyl iodide. The properties and analyses of these tertiary amines and their derivatives are listed in Table I.

**The Base-catalyzed Condensation of Benzaldehyde with 1-Methyl-3-piperidone (VI).**—To a solution of 10 g. (0.067 mole) of VI[2] in 70 ml. of 60% ethanol were added 7 g. (0.067 mole) of freshly purified benzaldehyde and 7.5 g. of solid potassium hydroxide. The mixture was shaken vigorously for fifteen minutes during which time a yellow, crystalline material separated. The reaction mixture then was allowed to stand in the dark at room temperature for four days. After separating the solid material by filtration, the filtrate was diluted with 100 ml. of water, causing a cloudiness to develop in the solution. As only a small amount of oil (0.1 g.) had separated after several days, it was discarded. The crude, yellow solid, m. p. 109–121° dec. was dissolved in ether to separate it from the potassium chloride which had crystallized from solution with it. After two recrystallizations from absolute ether, the yellow material attained a constant melting point range, 123–128° dec. and weighed 10.7 g.

*Anal.* Calcd. for $C_{13}H_{15}NO$ (VIII): C, 77.58; H, 7.51. Calcd. for $C_{13}H_{17}NO_2$ (VII): C, 71.20; H, 7.82. Found: C, 74.06; H, 7.65.

A solution of 9.2 g. of the product, m. p. 123–128°, from the preceding experiment in 300 ml. of absolute ether was treated with an excess of hydrogen chloride. This treatment caused the yellow color of the solution to disappear and a white solid separated, leaving a clear, colorless supernatant liquid. A solution of this hydrochloride in 25 ml. of water was treated with an excess of potassium carbonate and the liberated water-insoluble free base taken up in 50 ml. of ether. This solution was concentrated to the point where crystals began to separate from solution and then cooled for an hour in the refrigerator. The white, crystalline **1-methyl-4-benzal-3-piperidone (VIII)**, m. p. 112–113°, that separated weighed 4.0 g.

*Anal.* Calcd. for $C_{13}H_{15}NO$: C, 77.58; H. 7.51. Found: C, 77.68; H, 7.34.

The ether filtrate, from which VIII had been separated, was treated with hydrogen chloride. A white precipitate of 4.9 g. of **phenyl-4-(1-methyl-3-keto-piperidyl)-carbinol (VII) hydrochloride**, m. p. 192–202° dec., separated.

*Anal.* Calcd. for $C_{13}H_{18}ClNO_2$: C, 61.05; H, 7.06; Cl, 13.9. Found: C, 60.84; H, 6.88; Cl, 13.6.

This hydrochloride was also obtained from the monobenzal derivative (VIII). A solution of 100 mg. of VIII in 50 ml. of moist ether was treated with an excess of hydrogen chloride. A white solid, m. p. 176–197° dec., separated from solution. This product gave the following analysis: C, 61.21; H, 6.98.

**1-Methyl-4-benzal-3-piperidone (VIII) from VII.**—A solution of 0.8 g. of the hydrochloride of VII in 5 ml. of 60% ethanol was treated with 0.3 g. of solid potassium hydroxide. After shaking the mixture vigorously for fifteen minutes, it was allowed to stand in the dark for four days. From the reaction mixture 0.38 g. of the product, m. p. 124–128°, was obtained. The hydrochloride (0.4 g.) of this material, after conversion to the free base yielded 0.15 g. of VIII, m. p. 111–113°, by the procedure described above.

**Reduction of 1-Methyl-4-benzal-3-piperidone (VIII) to 1-Methyl-4-benzylpiperidine.**—A solution of 1.0 g. of VIII in 50 ml. of dixoane was hydrogenated over 0.5 g. of Raney nickel at room temperature and atmospheric pressure. The initial absorption of hydrogen was very rapid but became slower after the first five minutes. Addition of another portion (0.3 g.) of catalyst did not increase the rate of hydrogenation. At the end of thirty minutes, when 67% of the theoretical amount of hydrogen had been absorbed, the hydrogenation stopped. After removing the catalyst, the solution was taken to dryness under reduced pressure on the steam-bath. The residue was dissolved in 10 ml. of dilute hydrochloric acid and placed in a 50-ml. flask, which contained 2.0 g. of amalgamated zinc (prepared by shaking zinc with a solution of 0.1 g. of mercuric chloride in 10 ml. of water and 1 ml. of hydrochloric acid). The reaction mixture was refluxed for three hours during which time 8 ml. of hydrochloric acid was added in four 2-ml. portions. The solution then was decanted from the unreacted zinc amalgam and treated with excess solid potassium carbonate. The aqueous solution was shaken with ether and the supernatant liquids decanted from the inorganic salt. After shaking the suspension with 30 ml. of ether, the mixture was filtered and the precipitate washed several more times with ether. The aqueous solution was extracted twice more with ether and discarded. After drying the ether solution of the amine over anhydrous sodium sulfate, it was concentrated to 10 ml., a few drops of ethanol added, and then treated with methyl iodide. A solid, m. p. 158–208°, separated from solution. After four recrystallizations from ethanol, the product melted at 200–205°. A mixture of this material and an authentic sample of 1-methyl-4-benzylpiperidine methiodide (m. p. 206–207°) melted at 203–208°.

A solution of 4 g. of VIII in 35 ml. of dioxane absorbed two equivalents of hydrogen at 3000 p. s. i. of hydrogen at 250° over 1 g. of copper–chromium oxide. After separating the catalyst, the solvent was removed under reduced pressure on the steam-bath, leaving a light-brown, semi-solid material. A solution of 0.5 g. of this product in 15-ml. of colorless hydriodic acid was heated in a sealed tube at 250° from three hours. After cooling, the tube was opened and the reaction mixture was transferred to a 50-ml. flask. It was heated to about 50° and then treated with solid sodium sulfite until the solution became colorless and the water-insoluble material that had formed during the heating went into solution. The colorless solution then was treated with excess potassium hydroxide and extracted with two 25-ml. portions of ether. After drying the ether solution over anhydrous sodium sulfate, it was concentrated to 10 ml., a few drops of ethanol were added, and then it was treated with methyl iodide. An oil separated on standing; it was dissolved in a small amount of ethanol, and after adding a few drops of ether it was set aside. After several hours a solid, m. p. 185–197°, was deposited. After two crystallizations from an ethanol–ether mixture, it melted at 200–204°. A mixture of this product and the methiodide of 1-methyl-4-benzylpiperidine melted at 201–206°.

**Reduction of VII to 1-Methyl-4-benzylpiperidine.**—A solution of 0.5 g. of the carbinol (VII) hydrochloride in 20 ml. of ethanol and 16 ml. of hydrochloric acid was added to 2 g. of amalgamated tin. The mixture was refluxed gently for sixteen hours. After separating the unreacted metal, the alcohol and water were removed from the reaction mixture. The residue then was dissolved in 25 ml. of water and made basic to litmus paper with potassium hydroxide. The water-insoluble amine was extracted from the water with two 25-ml. portions of ether. After removing the ether, the amine was dissolved in 10 ml. of dilute hydrochloric acid and the solution was added to 2 g. of amalgamated zinc. The reaction mixture was refluxed for three hours during which time 10 ml. of hydrochloric acid was added in 2-ml. portions. After separating the unreacted metal, the reaction mixture was processed as described in the preceding procedure, yielding a crude methiodide, m. p. 192–203°. After two crystallizations from alcohol–ether, this product melted at 199–205°. A mixture of this material and the methiodide of 1-methyl-4-benzylpiperidine melted at 200–206°.

**The Acid-catalyzed Condensation of Benzaldehyde with 1-Methyl-3-piperidone (VI).**—A solution of 7.5 g. (0.05 mole) of VI and 10.6 g. (0.1 mole) of freshly distilled benzaldehyde in 30 ml. of absolute ethanol was saturated with hydrogen chloride and allowed to stand in the dark at room temperature. No sign of reaction was observed for several hours when a red color began to develop. The following day a crystalline deposit was noticed in the reaction mixture, and the supernatant liquid was a blood-red. The reaction mixture was allowed to stand for three weeks before the solid was filtered. This material, m. p. 162–166°, became colorless after three crystallizations from ethanol. The purified product, m. p. 163–166°, weighed 5.1 g., and represented a 43% yield of hydrochloride of a monobenzal derivative.

*Anal.* Calcd. for $C_{13}H_{16}ClNO$: C, 65.77; H, 6.73; Cl, 15.0. Found: C, 65.40; H, 6.79; Cl, 14.6.

The filtrate was distilled under reduced pressure in a water-bath kept below 35° to remove the ethanol. After dissolving the residue in 100 ml. of water, the solution was shaken with ether to remove the residual benzaldehyde. On making the red aqueous solution basic to litmus paper with potassium carbonate, a dark brown color developed and a dark oil separated. The oil was extracted from the water with benzene and, after drying over anhydrous sodium sulfate, it was treated with hydrogen chloride; 3.0 g. of a dark amorphous solid, m. p. 60–73° dec., separated and the blood-red color reappeared in the solution. All attempts to isolate a pure product from this solid material were unsuccessful.

To further characterize the reaction product, a solution of 2.4 g. of the salt, m. p. 165–166°, in 30 ml. of ethanol and 40 ml. of water was hydrogenated over a previously reduced 5% palladium chloride–charcoal catalyst. The absorption of hydrogen was slightly more rapid at the outset, but then proceeded at a uniform rate until the theoretical amount was absorbed in seven hours. After separating the catalyst, the solution was taken to dryness under reduced pressure on the steam-bath, leaving a light-brown, glassy material. This product was dissolved in 15 ml. of water and after the addition of 6.0 g. of amalgamated zinc and 15 ml. of hydrochloric acid, the mixture was refluxed gently for four hours during which time another 15 ml. of hydrochloric acid was added. After decanting the solution from the unreacted metal, it was made basic to litmus paper with excess potassium carbonate. The water-insoluble amine was then extracted from the aqueous suspension of inorganic salts with three 25-ml. portions of ether. The ether solution of the amine was dried over anhydrous sodium sulfate and concentrated to 40 ml.

A 15-ml. aliquot of this ether solution was evaporated to remove the solvent and the residue dissolved in 10 ml. of ethanol. This solution was treated with a saturated ethanolic solution of picric acid. The crude picrate, m. p. 137–145°, after two crystallizations from ethanol, melted at 149–150°. It gave analytical values corresponding to those of a 1-methylbenzylpiperidine picrate and is subsequently designated as mixture A.

*Anal.* Calcd. for $C_{19}H_{22}N_4O_7$: C, 54.54; H, 5.26. Found: C, 54.58; H, 5.20.

A mixture of equal parts of the authentic picrates of 1-methyl-2-benzylpiperidine (m. p. 180.5–181.5°) and 1-methyl-4-benzylpiperidine (m. p. 184–186°) melted at 156–161°. A mixture of A and this known synthetic mixture melted at 133–143°. A solution of equal amounts of the two authentic picrates in ethanol yielded a product, m. p. 154–163°, which melted at 155–165° and 158–165° after two recrystallizations from ethanol. A mixture of the product from the second recrystallization and A melted at 138–149°. From the filtrates of the recrystallizations of the known mixture, a sample melting at 179–181° was obtained. This product depressed the melting point of the authentic picrate of 1-methyl-2-benzylpiperidine to 157–173°, but when mixed with the picrate of 1-methyl-4-benzylpiperidine the mixture melted at 181–185°. Similarly, the melting point of A (149–150°) was not depressed by either the sample obtained from the filtrate or by the authentic picrate of 1-methyl-4-benzylpiperidine; the latter combination melted at 152–169° and the former at 148–158°. However, the melting point of A was depressed to 140–152° by the picrate of 1-methyl-2-benzylpiperidine.

To the remainder of the ether solution containing the reduction products of benzalpiperidones was added 3 ml. of ethanol and 2 ml. of methyl iodide. A solid product X, m. p. 181–186°, was separated by filtration; from the filtrate another product Y, m. p. 185–191°, was obtained after standing in the refrigerator for thirty minutes. Both X and Y gave analytical values for the methiodide of a 1-methylbenzylpiperidine.

*Anal.* Calcd. for $C_{14}H_{22}IN$: C, 50.75; H, 6.65. Found: X, C, 50.68; H, 6.43; Y, C, 50.97; H, 6.44.

A solution containing equal parts of authentic samples of the methiodides of 1-methyl-2-benzylpiperidine (m. p. 225–226°) and 1-methyl-4-benzylpiperidine (m. p. 206–207°) in ethanol yielded a product, m. p. 171–178°. From a succession of crystallizations of this product from ethanol, samples melting at 187–196°, 184–188°, 183–187°, 181–186° and 183–188° were obtained. A mixture of X and Y melted at 182–185°. A mixture comprised of the product (m. p. 183–188°) obtained from the last crystallization of the known mixture and the mixture of X and Y melted at 179–185°.

From the above observations on the melting behavior of these picrates and methiodides, it may be concluded that a mixture of 1-methyl-2-benzyl- and 1-methyl-4-benzylpiperidines were obtained from the reduction of the product isolated from the acid-catalyzed condensation of VI with benzaldehyde.

**1-Methyl-3-hydroxy-3-phenylpiperidine Methiodide.**—To a suspension of 7.0 g. (0.05 mole) of 1-methyl-3-piperidone hydrochloride (VI) in 75 ml. of thiophene-free benzene was added 15 ml. of a saturated solution of potassium carbonate. The mixture was stirred vigorously until the evolution of carbon dioxide ceased. The aqueous layer was separated and extracted with three 15-ml. portions of benzene. The combined benzene solution was distilled on the steam-bath until the volume was reduced to approximately 80 ml. in order to remove all water. The dry benzene solution of the piperidone then was added dropwise to a Grignard reagent, which had been prepared under nitrogen from 1.5 g. (0.06 atom) of magnesium and 9.6 g. (0.06 mole) of freshly distilled bromobenzene. The reaction mixture was stirred during the addition of the piperidone and then for two hours while refluxing gently on the steam-bath. The flask and its contents then were immersed in an ice-bath, and a solution of 15 ml. of hydrochloric acid in 35 ml. of water added slowly. The mixture was transferred to a separatory funnel and shaken thoroughly and after separation, the aqueous layer extracted with ether. It then was made basic with potassium hydroxide and the water-insoluble oil extracted with chloroform. After removing the chloroform, the product was distilled and 5.3 g. (60%) of **1-methyl-3-hydroxy-3-phenylpiperidine**, b. p. 106–108° (0.4 mm.), was collected.

This product darkened quite rapidly on exposure to air. Consequently, it was converted to the methiodide by treating an ether–ethanol solution of the compound with methyl iodide. This salt, after one crystallization from ethanol, melted at 239.5–240.5°.

*Anal.* Calcd. for $C_{13}H_{20}INO$: C, 46.85; H, 6.00; I, 38.1. Found: C, 47.02; H, 6.09; I, 37.7.

The hydrochloride of the carbinol was prepared by passing hydrogen chloride into an ethereal solution of the compound. The resultant solid was hygroscopic; m. p. 134–136° dec. All attempts to purify this product sufficiently for consistent analyses were unsuccessful.

**1-Methyl-3-phenyl-3-acetoxypiperidine Hydrochloride.**—To a solution of 3.0 g. of the hydrochloride, obtained in the above procedure, in 15 ml. of glacial acetic acid was added 15 g. of acetyl chloride and the mixture refluxed gently for two hours. After removing the acetic acid and excess acetyl chloride under reduced pressure on the steam-bath, a white solid material remained in the flask. The product was crystallized from an alcohol–ether mixture, yielding 1.9 g. of white crystals of **1-methyl-3-phenyl-3-acetoxypiperidine hydrochloride**, m. p. 188–189°. A second crop of crystals, m. p. 179–182°, weighing 0.5 g. was recovered from the filtrate.

*Anal.* Calcd. for $C_{14}H_{20}ClNO_2$: C, 62.34; H, 7.42; N, 5.19; Cl, 13.2. Found: C, 61.96; H, 7.70; N, 5.12; Cl, 13.2.

## Summary

An improved procedure for the preparation of ethyl γ-(N-methyl-N-carbethoxymethylamino)-butyrate (IV) from butyrolactone is described.

The condensation of 1-methyl-3-piperidone (VI) with benzaldehyde in basic medium yielded only the 4-substituted derivatives, 1-methyl-4-benzal-3-piperidone (VIII) and the corresponding carbinol VII. In acidic medium these reactants gave a mixture of VIII and its 2-benzal isomer (IX). None of the dibenzal derivative was obtained from either of these reactions.

The 3-piperidone (VI) reacts with phenylmagnesium bromide to yield 1-methyl-3-phenyl-3-hydroxypiperidine, which was isolated as the methiodide and as the 3-acetoxy derivative.

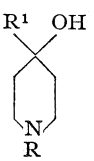
# Piperidine Derivatives. XXI. 4-Piperidone, 4-Piperidinol and Certain of their Derivatives

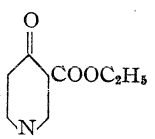
BY S. M. MCELVAIN AND ROBERT E. MCMAHON[1]



The preparation of 4-piperidinol (II) in 30% yield by the reduction of 4-hydroxypyridine with sodium in alcohol was reported[2] in 1915. A similar reduction of 4-methoxypyridine gave mainly piperidine together with a small amount of 4-methoxy-1,2,5,6-tetrahydropyridine, which was converted by hydrochloric acid to the hydrochloride of 4-piperidone (I).[2b] This piperidone could not be distilled, and on standing gradually underwent self-condensation to yield an odorless, amorphous solid.

Later a low yield of a crude hydrochloride of I was obtained by hydrolysis and decarboxylation of the reaction mixture resulting from the Dieckmann cyclization of di-($\beta$-carbethoxyethyl)-amine.[3] This hydrochloride was characterized as its 3,5-dibenzal derivative. Analyses of the self-condensation product of the free base (I) indicated that the condensation had involved a loss of water between amino hydrogen and the carbonyl oxygen, and the conclusion was drawn that the stability of such well known derivatives of I as nortropine (2,6-dimethylene), triacetoneamine (2,2,6,6-tetramethyl) and vinyldiacetoneamine (2,2,6-trimethyl) is the result of the steric inhibition of the reactivity of the secondary amino group by the 2,6-substituents.[3]

The Dieckmann cyclization of III with sodium ethoxide was later shown to yield only 10% of the 3-carbethoxy-4-piperidone (IV) and in view of the high yields of the 1-alkyl-3-carbethoxy-4-piperidones from IIIa, the low yield of IV was attributed to the high reactivity of the secondary amino group of III and/or its condensation product IV.[4]



I, R = H
Ia, R = $C_6H_5CO$

II, R = $R^1$ = H
IIa, R = $C_6H_5CO$
$R^1$ = H
IIb, R = H
$R^1$ = $C_6H_5$
IIc, R = $C_6H_5CO$
$R^1$ = $CH_2COOC_2H_5$

$RN(CH_2CH_2COOC_2H_5)_2$
III, R = H
IIIa, R = alkyl
IIIb, R = $C_6H_5CO$

IV, R = H
IVa, R = $C_6H_5CO$

The recently reported[5] preparation of IIIb in high yield and its cyclization to IVa, which in the present work was found to proceed with sodium hydride in 92% yield, offered readily available material for the preparation and study of I and II and their derivatives.

Hydrolysis and decarboxylation of IVa yields the hydrochloride of I, which was reported[4] to crystallize from an alcohol–ether mixture with 1.5 molecules of alcohol of crystallization; this conclusion was based on the chloride analyses of the salt. However, the hydrogenation behavior of this salt in the present work indicated it to be the hydrochloride of the diethylketal of I, which, incidentally, has a chlorine content comparable to that originally found.[4] Analyses for the other elements of this molecule confirmed the ketal structure.[6]

This ketal hydrochloride could not be hydrogenated in alcohol solution over a platinum catalyst, but in an aqueous solution containing a trace of hydrochloric acid it was readily hydrogenated to the hydrochloride of II. The latter salt also was obtained by the hydrolysis of 1-benzoyl-4-piperidinol (IIa) resulting from the hydrogenation of Ia.

The 4-piperidone (I) was readily N-acylated, *e. g.*, the benzoyl derivative (Ia) was obtained in 70% yield from IVa *via* I. All attempts to remove the 3-carbethoxy group of IVa without simultaneously removing the 1-benzoyl group were not very successful. Mild hydrolysis of IVa with 2% aqueous potassium hydroxide followed by decarboxylation gave only a 30% yield of Ia; heating IVa with benzoic acid and a trace of *p*-toluenesulfonic acid gave a quantitative yield of carbon dioxide, but only 23% of Ia could be isolated from the resulting mixture.

In view of the experience with the condensation of 1-methyl-4-piperidone and a variety of aromatic aldehydes,[7] it seemed of interest to determine the behavior of Ia in such reactions. In an alcoholic solution of hydrogen chloride Ia reacted with two equivalents of benzaldehyde to give a quantitative yield of the 3,5-dibenzal derivative (VI), as did the corresponding 1-methyl derivative.[7] Alcoholysis of VI with alcoholic hydrogen chloride gave the hydrochloride of the diben-

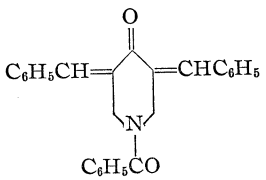
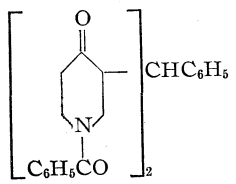
(5) McElvain and Stork, *ibid.*, **68**, 1049 (1946).

(6) It is of interest to note that the chlorine content reported for the hydrochloride of 1-phenylethyl-4-piperidone (Bolyard and McElvain, THIS JOURNAL, **51**, 922 (1929)) also corresponds to that of the hydrochloride of the diethylketal.



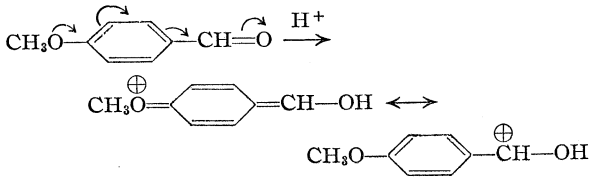
(7) McElvain and Rorig, *ibid.*, **70**, 1820 (1948).

zal derivative of I,[3,4] which on treatment with dilute alkali gave a stable free base. Apparently the 3,5-dibenzal substituents inhibit the reactivity of the carbonyl group of I as the previously noted[3] 2,6-substituents do for the amino group.

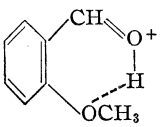


The course of the reaction of Ia with benzaldehyde in basic solution appeared even more complex than that of the 1-methyl analog.[7] A variety of conditions were tried and the procedure that produced the least complex mixture of reaction products is described in the experimental part. The products isolated from this condensation were: 16% of the monobenzal derivative (V), 29% of the phenyldipiperidylmethane (VII) and a trace of VI. The products V and VII precipitated from this reaction mixture as a complex that could not be separated by recrystallization from methanol. However, a solution of the complex in boiling ethyl acetate yielded the two components, *neither* of which would redissolve in this solvent.

V



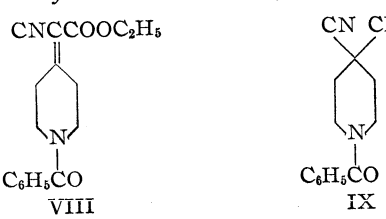
VI



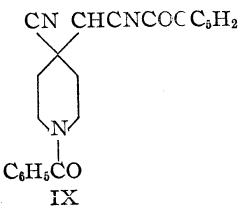
VII

To determine whether a weaker base would produce a less complex mixture of reaction products, sodium benzoate instead of potassium hydroxide was used to effect the condensation. The reaction was very slow: after a month, crystals of VI began to separate; they were removed periodically and after ten months a 65% yield of pure VI was obtained. A similar reaction mixture without the sodium benzoate gave no product.

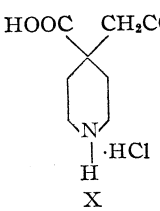
If the proposed mechanisms[7] for the condensation of aromatic aldehydes with 1-methyl-4-piperidone in acidic and basic medium are valid, substituents in the aldehyde would be expected to show a more pronounced effect on the rate of the acid-catalyzed condensation than on the base-catalyzed reaction. A series of condensations of a variety of substituted benzaldehydes with Ia confirmed this conclusion. In acidic medium a tremendous variation in reaction rate (see Table I) was noted: anisaldehyde and piperonal reacted more rapidly than benzaldehyde, which showed a greater reactivity than *p*-chlorobenzaldehyde and a very much greater reactivity than *m*- and *p*-nitrobenzaldehydes; *o*-chloro- and *o*-methoxybenzaldehydes gave no reaction whatsoever. In each case the dibenzylidene derivatives corresponding to VI were the sole reaction products. It appears, therefore, that a group, *e. g.*, *p*-methoxy, capable of increasing the electron density around the carbonyl oxygen facilitates the coördination of the proton at this point and the consequent formation of the reactive (and resonance-stabilized) carbonium ion



The failure of the *o*-substituted aldehydes, particularly the *o*-methoxy-benzaldehyde, to show any reaction is noteworthy and is probably related to the chelation (hydrogen bonding) between the oxonium hydroxyl and the adjacent methoxy group, which prevents formation of the carbonium ion necessary for the reaction



In contrast to their behavior in acidic medium, each of these aldehydes reacted quite rapidly with Ia in alkaline solution (see Table II). The small variations in the observed reaction rates indicate that those electron attracting substituents, *e. g.*, nitro and chloro, which have a retarding effect in acidic medium, definitely accelerate the reaction in basic solution. This behavior shows that the base-catalyzed condensation is relatively independent of the structure of the aldehyde, as the postulated mechanism[7] would indicate.



The condensation of the piperidone Ia with cyanoacetic ester[8] gave a 76% yield of the piperidylidene derivative VIII, the structure of which was shown by its reaction with aqueous potassium cyanide solution to form the dinitrile IX in 93% yield. The latter product was further characterized by hydrolysis to the dicarboxylic acid X.

VIII

IX

X

(8) Stork and McElvain, This Journal, **68**, 1053 (1946).

The $\alpha,\beta$-unsaturated cyanoester (VIII) reacted immediately with phenylmagnesium bromide to give a precipitate which appeared to be the magnesium enolate of VIII (with $\beta,\gamma$-unsaturation) as shown by the fact that 76% of the reaction product, after decomposition with acid, dissolved in cold, aqueous potassium cyanide; from another run 71% of VIII was recovered by adsorption on alumina. That portion of the reaction product which was insoluble in the cyanide solution could be evaporatively distilled, but the product so obtained did not give analytical data corresponding to those calculated for the product resulting from the 1,4-addition of the Grignard reagent to VIII. Methylmagnesium bromide gave even more of the enolate of VIII; 93% of this reaction product dissolved in aqueous potassium cyanide.[9]

Phenylmagnesium bromide reacted with the piperidone Ia to give the corresponding 4-phenyl-4-piperidinol, which was converted by alkaline hydrolysis to the piperidinol IIb.

The piperidone Ia and ethyl bromoacetate in the Reformatsky reaction gave a good yield of the piperidinol IIc, which proved to be remarkably resistant to dehydration: it was distilled without appreciable decomposition and also was recovered unchanged after heating in refluxing 90% formic acid.

## Experimental

**1-Benzoyl-3-carbethoxy-4-piperidone (IVa).**—A 3-liter three-neck flask was fitted with dropping funnel, a mercury-seal stirrer and a water-cooled condenser with a gas trap connected to the top. After filling the apparatus with nitrogen, the condenser was removed momentarily and 29.7 g. (1.24 mole) of sodium hydride added through a powder funnel; from the other neck of the flask 800 ml. of thiophene-free benzene was added through the dropping funnel.[10] After again flushing the system with nitrogen, stirring was started and 200 g. (0.62 mole) of N-benzoyl-di-($\beta$-carbethoxyethyl)-amine[5] (IIIb) was added. When 2 ml. of absolute alcohol was added, the reaction mixture became green in color and evolution of hydrogen started immediately. The rapidly stirred suspension was heated gently on a steam-bath for two and one-half hours, after which time it was cooled in an ice-bath and treated consecutively with 74.5 g. (1.24 moles) of glacial acetic acid and 67.0 g. (3.72 moles) of water. After the reaction mixture had stood for fifteen minutes, the crystalline sodium acetate trihydrate was removed by filtration and the filter cake washed with an additional 500 ml. of benzene.

The combined benzene filtrates were placed in a round-bottom flask and heated on a steam-bath at water-pump pressure until all of the solvent had been removed. The residue was 157 g. (92%) of IVa, a reddish oil, which crystallized after standing several days to give a solid melting at 56–59°.

(9) In contrast to these results, Kohler and collaborators (*Am. Chem. J.*, **33**, 21, 153 and 333 (1905); **35**, 386 (1906); **38**, 511 (1907)) reported the 1,4-addition of Grignard reagents to a variety of $\alpha,\beta$-unsaturated nitriles, aldehydes, ketones and esters. Birch and Robinson (*J. Chem. Soc.*, 501 (1943)) reported 1,4-addition of methylmagnesium bromide to ethyl cyclohexylidenecyanoacetate to the extent of 45%. More recently Widequist (*C. A.*, **41**, 1615 (1947)) reported good yields of the 1,4-addition products from isopropylidenemalonic ester and both methylmagnesium iodide and butylmagnesium bromide).

(10) These two materials were added from opposite necks of the flask to minimize the danger of fire, which once resulted from the sparking of a granule of sodium hydride when it and the benzene were added through the same neck.

**1-Benzoyl-4-piperidone (Ia).**—A mixture of 100 g. of IVa and 400 ml. of 6 *N* hydrochloric acid was refluxed for two hours. Extraction of the benzoic acid from the cooled reaction mixture with ether, followed by evaporation of the aqueous solution to dryness, gave the crude hydrochloride of I as a semi-solid mass. This material was dissolved in 30 ml. of water and to this stirred solution were added 50 g. of potassium carbonate, 500 ml. of chloroform, and then to this 51 g. of benzoyl chloride at a sufficient rate to maintain gentle reflux. The mixture was heated for four hours, after which time 30 ml. of alcohol was added and heating continued for an additional one-half hour. Then sufficient water to dissolve the precipitated salts was added to the cooled reaction mixture. The chloroform layer was separated and washed with 5% potassium carbonate solution, water, 5% hydrochloric acid, and with a saturated salt solution. After drying, the chloroform was removed by distillation and the residue distilled under reduced pressure to give 51 g. (70%) of Ia as a colorless liquid, b. p. 158–160° (0.2 mm.). Part of the product was allowed to stand in a closed flask and after several months it crystallized to a white solid, m. p. 49–52°. The succeeding batches of Ia could be crystallized readily by seeding with these crystals.

*Anal.* Calcd. for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45. Found: C, 71.17; H, 6.41.

The semicarbazone, which was prepared and crystallized from an ethyl acetate–ethyl alcohol mixture, melted at 193.5–195°,

*Anal.* Calcd. for $C_{13}H_{16}N_4O_2$: N, 21.55. Found: N, 21.77.

The 2,4-dinitrophenylhydrazone, after crystallization from methanol, melted at 196–198°.

*Anal.* Calcd. for $C_{18}H_{17}N_5O_5$: C, 56.39; H, 4.47. Found: C, 56.23; H, 4.48.

**1-Diphenylacetyl-4-piperidone.**—This compound was prepared by the procedure for Ia, except that diphenylacetyl chloride was substituted for benzoyl chloride. Recrystallization of the product from benzene gave fluffy white needles, m. p. 135–136°.

*Anal.* Calcd. for $C_{19}H_{19}NO_2$: C, 77.79; H, 6.53. Found: C, 77.80; H, 6.62.

The 2,4-dinitrophenylhydrazone melted at 185–187°.

*Anal.* Calcd. for $C_{25}H_{23}N_5O_5$: C, 63.42; H, 4.90. Found: C, 63.18; H, 4.89.

**1-Acetyl-4-piperidone.**—The crude hydrochloride of I from 75 g. of IVa was dissolved in 250 ml. of glacial acetic acid and a solution of 22.4 g. of sodium acetate in 150 ml. of glacial acetic acid added with stirring. Following this, 36 g. of acetic anhydride was added and the reaction mixture heated with stirring on a steam-bath for ninety minutes, after which time 10 ml. of methanol was added and heating continued for fifteen minutes. The precipitated salt was filtered off and the acetic acid removed by distillation. The residue was fractionally distilled under reduced pressure through a short (15 mm.) Vigreux column to give 18.6 g. (49%) of 1-acetyl-4-piperidone as a water-white liquid; b. p. 124–128° (0.2 mm.); $n^{25}D$ 1.5023; $d^{25}_4$ 1.144, and $M_D$ 36.4 (calcd. 36.3). This compound is completely miscible with water, but insoluble in ether.

*Anal.* Calcd. for $C_7H_{11}NO_2$: C, 59.55; H, 7.85. Found: C, 59.43; H, 7.99.

The 2,4-dinitrophenylhydrazone, after crystallization from ethanol, melted at 212–213°.

*Anal.* Calcd. for $C_{13}H_{15}N_5O_5$: C, 48.59; H, 4.71. Found: C, 48.40; H, 4.95.

**4,4-Diethoxypiperidine (4-Piperidone Diethylketal) Hydrochloride.**—The crude hydrochloride of I, obtained from 50 g. of IVa was recrystallized three times from an absolute alcohol–ether mixture to give 8.0 g. (21%) of 4,4-diethoxypiperidine hydrochloride; m. p. 138–140° (Kuettel and McElvain[4] reported 138–140° for the hydrochloride of $I \cdot 1.5C_2H_5OH$).

[a] After twelve hours the yield was 27%.

*Anal.* Calcd. for $C_9H_{20}ClNO_2$: C, 51.54; H, 9.61; Cl, 16.9; $OC_2H_5$, 43.0. Found: C, 51.37; H, 9.64; Cl, 16.9; $OC_2H_5$, 43.2.

A higher melting form of this ketal salt was obtained as follows: 2 g. of the above salt, m. p. 138–140°, was dissolved in 50 ml. of alcohol and the solution stirred for several hours in a hydrogenation apparatus with hydrogen over previously reduced platinum oxide catalyst (Adams). At the end of this time there had been no appreciable uptake of hydrogen. The catalyst was removed by filtration, the filtrate warmed and dry ether added. After standing overnight, 1.0 g. of white crystals melting at 150° separated. Upon cooling and remelting this salt, a melting point of 140–141° was obtained. A mixed melting point with the salt, m. p. 138–140°, was 147–148°. Upon cooling and remelting, this mixture melted at 140–141°.

*Anal.* Found: C, 51.25; H, 9.44; Cl, 16.9.

**1-Benzoyl-4-piperidinol (IIa).**—In the glass liner of the hydrogenation bomb was placed 20 g. of 1-benzoyl-4-piperidone (Ia), 2 g. of Raney nickel and 80 ml. of alcohol. The liner was placed in the bomb and the latter filled with hydrogen to a pressure of 2200 p. s. i. After hydrogenation at 75° for two hours, the bomb was opened, the catalyst removed by filtration and the filtrate evaporated to dryness to give a quantitative yield of IIa as a colorless oil, which crystallized to a solid, m. p. 70–73°.

*Anal.* Calcd. for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37. Found: C, 69.85; H, 7.42.

This compound also was prepared by reduction of Ia with Adams platinum-oxide catalyst.

**1-Benzoyl-4-piperidyl N-phenylcarbamate** was prepared by the action of phenyl isocyanate on IIa. After recrystallization from petroleum ether, it melted at 184–185°.

*Anal.* Calcd. for $C_{19}H_{20}N_2O_3$: C, 70.35; H, 6.22. Found: C, 70.26; H, 6.37.

**4-Piperidinol (II) Hydrochloride.**—Ten grams of 1-benzoyl-4-piperidinol (IIa) was refluxed with 100 ml. of 20% aqueous hydrochloric acid for one hour and the resulting solution cooled to room temperature. The benzoic acid, some of which had crystallized, was removed by extraction with benzene and the aqueous solution evaporated to dryness. The crude hydrochloride thus obtained was recrystallized from alcohol–ether to give 3.4 g. (50%) of 4-piperidinol hydrochloride; m. p. 151–153° (reported,[2b] 146–148°).

*Anal.* Calcd. for $C_5H_{12}ClNO$: C, 43.63; H, 8.79; Cl, 25.8. Found: C, 43.48; H, 8.43; Cl, 25.3.

This compound was also prepared by the hydrogenation of the hydrochloride of 4,4-diethoxypiperidine over Adams platinum oxide catalyst in an aqueous solution containing a few drops of hydrochloric acid; twenty-four hours were required to hydrolyze and reduce 1 g. of the ketal. The product was recovered by filtering off the catalyst, evaporating to dryness and recrystallizing the crude hydrochloride from an alcohol–ether mixture. The yield of II, m. p. 148–149°, was 0.4 g. (43%)

**The Acid-catalyzed Condensation of 1-Benzoyl-4-piperidone (Ia) with Aromatic Aldehydes.**—The procedure used in these condensations is illustrated by the following preparation of 1-benzoyl-3,5-dibenzal-4-piperidone (VI). A solution of 0.5 g. of Ia and 0.52 g. (2 equivalents) of benzaldehyde in 30 ml. of absolute alcohol was cooled in an ice-bath and saturated with hydrogen chloride. The solution soon became very dark in color and after six hours crystals began to form. After one day of standing, the bright-yellow crystals were filtered off and dried. The yield was 0.70 g. (75%) of large yellow crystals, m. p. 162–164°. After two more days, 0.2 g. of a second crop, m. p. 162–163°, was obtained, bringing the total yield to 0.90 g. (97%). The melting point of this product was raised to 165–167° by recrystallization from either methyl or ethyl alcohol. It, as well as the other diarylidene derivatives listed in Table I, has extremely low solubilities in methyl and ethyl alcohols, acetone, ether, petroleum ether and benzene.

The rates of formation, yields, melting points and analyses of the various 3,5-diarylidene derivatives of Ia are summarized in Table I.

The dibenzal derivative (VI) was also prepared in the following manner. In 15 ml. of 65% aqueous alcohol were dissolved 1.0 g. of Ia, 1.06 g. of benzaldehyde and 0.30 g. of sodium benzoate, and the solution was allowed to stand. Crystals started to form after one month. The product was filtered off at intervals to give, after ten months, 1.2 g. (65%) of VI, m. p. 164–166°.

**1-Benzoyl-3,5-dibenzyl-4-piperidone.**—In 100 ml. of ethanol was suspended 2.0 g. of VI and 150 mg. of Adams catalyst. This suspension was stirred with hydrogen until two moles had been absorbed (two hours). The catalyst was removed by filtration and the filtrate evaporated to dryness to give a viscous oil. This oil was dissolved in petroleum ether (b. p. 90–100°); from this solution 0.8 g. (40%) of a 1-benzoyl-3,5-dibenzyl-4-piperidone, m. p. 127–129° separated. Further recrystallization from the same solvent raised the melting point to 130–131°.

*Anal.* Calcd. for $C_{26}H_{25}NO_2$: C, 81.43; H, 6.57. Found: C, 81.33; H, 6.49.

The semicarbazone, after recrystallization from alcohol–water, was obtained as white needles, m. p. 162–165°.

*Anal.* Calcd. for $C_{27}H_{28}N_4O_2$: N, 12.72. Found: N, 12.96.

**1-Benzoyl-3,5-dibenzyl-4-piperidinol.**—In 100 ml. of ethyl alcohol was suspended 2.0 g. of VI and 150 mg. of Adams catalyst and the mixture was stirred in the hydrogenation apparatus until no more hydrogen was absorbed (three hours). After removing the catalyst the solution was evaporated to dryness to give a colorless, viscous oil. Three successive crystallizations of this material from

petroleum ether (90–100°) gave 0.7 g. (45%) of a product, m. p. 111–114°.

*Anal.* Calcd. for $C_{26}H_{27}NO_2$: C, 81.00; H, 7.06. Found: C, 80.98; H, 7.23.

**3,5-Dibenzal-4-piperidone Hydrochloride.**—A solution of 0.5 g. of VI in 40 ml. of absolute alcohol was saturated with hydrogen chloride and the mixture refluxed two hours. Upon cooling, 0.25 g. (62%) of fluffy yellow crystals, m. p. 270–273°, separated. Recrystallization from alcohol raised the melting point to 274–276° (reported, 276–277°[4]; 275–277°[3]).

**3,5-Dibenzal-4-piperidone.**—In 25 ml. of 5% potassium carbonate was suspended 0.5 g. of 3,5-dibenzal-4-piperidone hydrochloride and the mixture was stirred at room temperature for two hours to insure complete reaction. The free base (0.45 g.) was filtered off and dried, m. p. 183–185°; recrystallization from alcohol gave lustrous, pale yellow crystals, m. p. 183–184°.

*Anal.* Calcd. for $C_{19}H_{17}NO$: C, 82.88; H, 6.22. Found: C, 82.82; H, 6.49.

**3,5-Dibenzyl-4-piperidinol Hydrochloride.**—In 80 ml. of alcohol was suspended 1.5 g. of 3,5-dibenzal-4-piperidone hydrochloride and 100 mg. of Adams catalyst. This suspension was stirred with hydrogen until hydrogen absorption ceased (4 hours), during which time, 105% of the theoretical amount of hydrogen was taken up. The catalyst was removed by filtration and the product recovered by evaporating the solution to a volume of 40 ml. and adding ether to start crystallization; 1.1 g. (73%) of **3,5-dibenzyl-4-piperidinol hydrochloride**, m. p. 288–291°, was obtained.

*Anal.* Calcd. for $C_{19}H_{24}ClNO$: C, 71.83; H, 7.62; Cl, 11.2. Found: C, 71.94; H, 7.53; Cl, 11.1.

**The Base-catalyzed Reaction of 1-Benzoyl-4-piperidone (Ia) with Benzaldehyde.**—In 130 ml. of 95% ethyl alcohol were dissolved 10.0 g. of Ia, 5.3 g. (one equivalent) of freshly distilled benzaldehyde and 1.0 g. of potassium hydroxide pellets. After standing for several days, a crop of yellow crystals started to form. After two weeks, these were removed by filtration, found to weigh 3.6 g., and to melt at 165–175°. This material was recrystallized from methanol to give 2.8 g. of lustrous, white crystals, m. p. 205–210°. Further recrystallization from methanol did not raise the melting point above 210–214°.

This material gave a red color with concentrated sulfuric acid, decolorized dilute potassium permanganate solution, and was found to contain 77.58% carbon and 6.04% hydrogen. It was dissolved readily in hot ethyl acetate; upon cooling, a crop of white crystals separated. These were removed by filtration, dried and found to weigh 2.6 g., m. p. 205–207°. When treated with hot ethyl acetate as before, most of the material was insoluble. The insoluble material (2.3 g.) was **1-benzoyl-3-benzal-4-piperidone (V)**, m. p. 236–240°.

*Anal.* Calcd. for $C_{19}H_{17}NO_2$: C, 78.33; H, 5.88; N, 4.81. Found: C, 78.52; H, 5.92; N, 4.32.

From the ethyl acetate filtrates was obtained a second crop of crystals weighing 0.2 g. and melting at 228–240°. This material was recrystallized several times from ethanol to give **phenyl-bis-(1-benzoyl-4-keto-3-piperidyl)-methane (VII)** as a white powder, m. p. 272–274°. This compound gave no coloration with concentrated sulfuric acid and did not reduce dilute permanganate solution.

*Anal.* Calcd. for $C_{31}H_{30}N_2O_4$: C, 75.28; H, 6.11. Found: C, 75.07; H, 6.10.

After the original reaction mixture had stood an additional three weeks, a second crop of crystals, weighing 3.4 g., m. p. 215–230°, separated. Purification of this material showed it to be VII, bringing the total yield of this compound to 3.6 g. (29%).

From the mother liquors from the first recrystallization of both the first and the second crops of crystals from the original reaction mixture was obtained a trace (0.05 g.) of the dibenzal derivative (VI).

**The Rates of the Base-catalyzed Reaction of 1-Benzoyl-4-piperidone with Aromatic Aldehydes.**—In 6 ml. of 55% alcohol was dissolved 0.25 g. of Ia, two equivalents of the aldehyde and 0.05 g. of potassum hydroxide. The time required for the initial separation of a reaction product was noted; after two days the dry weight of this product was determined and expressed as the per cent. of the combined weight of the reactants. The results are summarized in Table II. No attempt was made to identify the reaction products.

TABLE II

BASE-CATALYZED CONDENSATIONS OF Ia AND AROMATIC ALDEHYDES, RCHO

| R | Time, (min.) for initial precipitation | Yield, % of combined wt. of reactants in 2 days | Nature of product |
|---|---|---|---|
| $C_6H_5$ | 11 | 28 | Oil |
| *o*-$ClC_6H_4$ | 0.25 | 83 | Oil |
| *p*-$ClC_6H_4$ | 2 | 92 | Oil |
| *m*-$NO_2C_6H_4$[a] | 0.25 | 89 | Oil |
| *p*-$NO_2C_6H_4$[b] | 1 | 97 | Yellow solid, m. p. 133–142° |

| *p*-$CH_3OC_6H_4$ | 40 | 77 | Yellow solid, m. p. 115–123° |

[a] Because of insolubility of aldehyde 65% alcohol was used. [b] Because of insolubility of aldehyde 75% alcohol was used.

**Ethyl (1-Benzoyl-4-piperidylidene)-cyanoacetate (VIII).**—In a 50-ml. round-bottom flask were placed 10.0 g. of 1-benzoyl-4-piperidone (Ia), 5.65 g. of cyanoacetic ester, 1 g. of anhydrous ammonium acetate, 3 ml. of glacial acetic acid, 20 ml. of dry benzene and a porcelain chip. The flask, after attachment to a Cope separator[11] filled with benzene, was heated in an oil-bath for one hour at 125°. Titration of the resultant water layer in the separator with standard base showed that it contained 0.4 g. of acetic acid; the yield of water amounted to 0.8 g. (calcd. 0.9 g.).

The reaction mixture was diluted with benzene, extracted with water and saturated sodium bicarbonate solution, and the benzene solution dried. The solvent was removed from the dried solution to give 14.0 g. of a dark-red oil. This oil was extracted with a total of 300 ml. of boiling ether to give, after evaporation of the solvent and drying the residue at 80° under 0.5 mm. pressure, 9.4 g. of **ethyl (1-benzoyl-4-piperidylidene)-cyanoacetate (VIII)** as a pale-yellow oil. A benzene solution of the ether-insoluble material was treated with ether until no further precipitate formed; the resultant suspension was filtered and the filtrate evaporated to dryness. The residual red oil was extracted with ether to give an additional 1.7 g. of VIII, bringing the total yield to 11.1 g. (76%). After standing overnight, the product crystallized to a white solid melting at 84–86°.

*Anal.* Calcd. for $C_{17}H_{18}N_2O_3$: C, 68.44; H, 6.08. Found: C, 68.49; H, 6.23.

**Ethyl (1-Benzoyl-4-cyano-4-piperidyl)-cyanoacetate (IX).**—The compound was made from VIII by the two following procedures.

(a)[12] A solution of 2.0 g. of VIII in 15 ml. of alcohol was treated with a solution of 0.87 g. of potassium cyanide in 5 ml. of water and the yellow solution cooled in an ice-bath. To this solution was added a mixture of 1.2 ml. of concentrated hydrochloric acid and 1 ml. of water and the reaction mixture allowed to stand twenty-five minutes at room temperature, before pouring into 50 ml. of cold 5% hydrochloric acid. The oily product that separated was taken up in benzene. After removal of the residual hydrogen cyanide by several extractions with water, the benzene was removed by distillation to give, after drying, 2.2 g. (96%) of IX as a colorless liquid, which crystallized

(11) Cope, *et al.*, THIS JOURNAL, **63**, 3452 (1941).

(12) *Cf.* Hope and Sheldon, *J. Chem. Soc.*, **121**, 2223 (1922).

to a solid melting at 110–113°. Recrystallization from benzene and petroleum ether (60–68°) gave white rosettes, m. p. 119–121°.

(b) A mixture of 10 ml. of 10% aqueous potassium cyanide solution and 0.2 g. of VIII was shaken for one-half hour and the resulting solution then carefully neutralized with 10% hydrochloric acid. Extraction with benzene gave 0.20 g. (93%) of IX after the benzene was removed and the residue dried.

*Anal.* Calcd. for $C_{18}H_{19}N_3O_3$: C, 66.45; H, 5.89. Found: C, 66.62; H, 6.02.

**4-(4-Carboxypiperidyl)-acetic Acid Hydrochloride (X).**—A solution of 1 g. of IX in 25 ml. of 25% hydrochloric acid was refluxed for twenty-four hours. After cooling, the benzoic acid was extracted with benzene. The aqueous solution was evaporated to dryness, the residue treated with an excess of 30% potassium hydroxide and the solution heated until the evolution of ammonia ceased. The alkaline solution was acidified with concentrated hydrochloric acid and evaporated to dryness.

The residue of sodium chloride and the salt (X) was treated with two 50-ml. portions of boiling absolute alcohol. The alcohol solutions were combined, filtered, evaporated to 40 ml. and treated with dry ether to the point of cloudiness. The flocculent precipitate which formed was removed by filtration and the filtrate placed in the refrigerator overnight. The product (X) that separated was removed by filtration, dried and found to weigh 0.51 g. (76%). Its melting point, 207–212°, was raised to 217–219° by two recrystallizations from alcohol–ether.

*Anal.* Calcd. for $C_8H_{14}ClNO_4$: C, 42.96; H, 6.31; Cl, 15.9. Found: C, 42.63; H, 6.54; Cl, 15.7.

**The Reaction of VIII with Phenylmagnesium Bromide.**—A solution of 4.5 g. (0.015 mole) of VIII in a mixture of 25 ml. of dry benzene and 75 ml. of dry ether was placed in a three-neck flask equipped with stirrer, condenser and dropping funnel. After filling the system with dry nitrogen 0.016 mole of phenylmagnesium bromide in 50 ml. of ether was added; an immediate precipitate formed. After refluxing for one-half hour, the reaction mixture was cooled, diluted with 100 ml. of ether and treated with cold 10% hydrochloric acid until the mixture cleared. The organic layer was removed, dried and evaporated to give 5.1 g. of a yellow gum. This gum was dissolved in 100 ml. of dry benzene and the resulting solution poured through a 20 cm. column of alumina. The column then was eluted with an additional 300 ml. of benzene and the combined eluates evaporated to dryness. The residue (3.3 g.) crystallized to a white solid, m. p. 78–80°; mixed m. p. with VIII 80–84°. By elution with chloroform 0.2 g. of a dark colored, saturated gum was obtained.

The yellow gum from another similar reaction was treated with 5 ml. of benzene and stirred overnight with 150 ml. of 10% aqueous potassium cyanide solution. The mixture then was extracted twice with 75-ml. portions of benzene to give, after evaporation of the solvent, 1.3 g. of a dark-colored gum which did not decolorize dilute permanganate solution. When this gum was evaporatively distilled, biphenyl first sublimed far up the tube and then, at 215–230° (0.4 mm.), a yellow oil was collected. A considerable quantity of carbonaceous material remained in the bottom of the tube. The yellow oil was separated from the rest of the material and again evaporatively distilled as a clear yellow oil at 215–225° (0.5 mm.). The analytical values (C, 75.57; H, 6.88; $OC_2H_5$, 8.1) obtained for this compound, however, did not check with those (C, 73.38; H, 6.43; $OC_2H_5$, 12.0) calculated for ethyl 1-benzoyl-4-phenyl-4-piperidylacetate.

**Ethyl (1-Benzoyl-4-hydroxy-4-piperidyl)-acetate (IIc).**—In a 500-ml. three-neck flask, equipped with condenser, stirrer and addition funnel were placed 5.0 g. of 1-benzoyl-4-piperidone (Ia), 5 g. of well-cleaned zinc foil, 20 ml. of dry ether and 20 ml. of dry benzene. After flushing the flask with a stream of nitrogen, 7.5 ml. of ethyl bromoacetate and a crystal of iodine were added. Stirring and heating caused the reaction to start immediately. The stirred reaction mixture was heated at gentle reflux for two and one-half hours, during which time an additional 5 g. of zinc was added.

After cooling the reaction mixture, 5 ml. of methyl alcohol and 5 ml. of acetic acid were added and the clear solution decanted into 50 ml. of water. The mixture was then acidified with acetic acid and extracted with 50 ml. of benzene. The organic layer was washed several times with dilute ammonia, dried and the solvent removed to give 6.6 g. (92%) of IIc as a dark-red oil. A small amount of this oil was subjected to evaporative distillation and it was found that practically all of the material distilled as a yellow oil at a jacket temperature of 205–215° (0.2 mm.).

*Anal.* Calcd. for $C_{16}H_{21}NO_4$: C, 65.96; H, 7.27. Found: C, 65.48; H, 7.34.

**4-Phenyl-4-hydroxypiperidine (IIb) Hydrochloride.**—A solution of 12.0 g. (0.059 mole) of Ia in a mixture of 30 ml. of dry benzene and 60 ml. of dry ether was treated with a solution of 0.067 mole of phenylmagnesium bromide in 100 ml. of ether. After the addition, the mixture was refluxed for one hour, with stirring. The cooled mixture then was treated with saturated ammonium chloride solution until it cleared. The organic layer was removed by decantation, the salt washed with ether and the combined ether solutions evaporated to dryness.

The yellow gum thus obtained was refluxed for three hours with a solution of 8 g. of potassium hydroxide in a mixture of 40 ml. of alcohol and 60 ml. of water. After removal of most of the alcohol by distillation, 100 ml. of water was added and the resulting mixture extracted with a total of 750 ml. of ether. After drying the ether extract with anhydrous potassium carbonate and Drierite, it was treated with hydrogen chloride. This gave 5.2 g. (41%) of a brown solid melting at 180–185°. Recrystallization from alcohol–ether gave 2.0 g. (16%) of the hydrochloride of IIb as a white solid, m. p. 202–204°.

*Anal.* Calcd. for $C_{11}H_{16}ClNO$: C, 61.82; H, 7.55; Cl, 16.6. Found: C, 61.73; H, 7.86; Cl, 16.4.

## Summary

A variety of derivatives of 4-piperidone and 4-piperidinol have been prepared from 1-benzoyl-4-piperidone and their properties reported.

The product obtained from the crystallization of 4-piperidone hydrochloride from alcohol is shown to be the ketal, 4,4-diethoxypiperidine hydrochloride.

The rates of the reactions of 1-benzoyl-4-piperidone with certain substituted benzaldehydes in acidic and basic media confirm the previously postulated mechanisms for such reactions.

The application of the Knoevenagel, Reformatsky and Grignard reactions to 1-benzoyl-4-piperidone are described. The product of the former reaction, ethyl (1-benzoyl-4-piperidylidene)-cyanoacetate, does not give significant amounts of 1,4-addition products with Grignard reagents, but reacts primarily as an acid to form a magnesium enolate.

# Electrophoretic Analysis of Ovalbumin

BY JOHN R. CANN

## Introduction

Longsworth, Cannan and MacInnes[1] found that within the *p*H range of 5 to 10 crystalline ovalbumin is resolved electrophoretically into two components, $A_1$ and $A_2$, $A_2$ being the slower moving component. The relative concentration of $A_2$ in freshly prepared material is reported to vary from 15 to 25%. A third component, $A_3$, has also been found to be present in small amounts.[2] $A_3$ is less mobile than $A_1$ and $A_2$ at *p*H 6.8.

In connection with the program of protein fractionation by electophoresis-convection being carried out in this Laboratory,[3] it has been necessary to analyze a large number of samples of ovalbumin electrophoretically using the moving boundary technique of Tiselius[4] as modified by Longsworth.[5]

The moving boundary theory recently extended by Dole[6] and Svensson[7] indicates that appreciable error may be made in the usual electrophoretic analyses of proteins due to the superposition of foreign protein and buffer gradients on the concentration gradient of a given electrophoretic component. In the case of protein mixtures in alkaline solution these superimposed gradients would cause the relative concentration of the fastest moving component, *e. g.*, albumin in serum, to appear greater than its real value. Since electrophoretic distributions appear to approach actual distributions at high ionic strengths and low protein concentrations, Longsworth[8] recommends that the true distribution of components be obtained either by extrapolating the apparent electrophoretic distributions to infinite ionic strength at constant protein concentration or zero protein concentration at constant ionic strength. Other workers[9] have suggested extrapolating to zero value of the ratio of protein concentration to ionic strength.

Since the electrophoretic analysis of ovalbumin is complicated by the change of relative mobilities of the components with ionic strength, it appeared desirable to report the findings of this Laboratory with respect to the variations in apparent distribution of the components of ovalbumin as a function of the conditions of electrophoresis.

## Experimental

**Method.**—The electrophoresis apparatus described by Longsworth[5] for use in the analysis of proteins by the Tiselius moving boundary method was used in this investigation. The time and field strength employed are noted under the appropriate pattern in Fig. 1. Photographic records of the refractive index gradients in the boundaries were made by the schlieren scanning method.

The apparent concentrations of the components of ovalbumin were determined by finding the ratio, in each case, of the component area to the total area, exclusive of the $\epsilon$-boundary. The areas were measured on projected tracings of the descending patterns with a planimeter, resolution into components being carried out by the method of Pedersen.[10]

**Material.**—Crystalline ovalbumin was prepared by the method of Sorensen and Høyrup.[11] Analysis of a 1% solution of a representative preparation in phosphate buffer, *p*H 6.81 and ionic strength 0.1, yielded 76.0% $A_1$ ($-5.93 \times 10^{-5}$ cm.$^2$ sec.$^{-1}$ volt$^{-1}$), 18.2% $A_2$ ($-5.05 \times 10^{-5}$) and 5.8% $A_3$ ($-4.4 \times 10^{-5}$).

## Experimental Results and Discussion

Electrophoretic experiments were carried out in phosphate buffers, *p*H 6.8 and ionic strength 0.05 and 0.1, and in phosphate–chloride buffer, *p*H 6.7 and ionic strength 0.3. In these runs the protein concentration was 0.74%. The resultant electrophoretic patterns are shown in Fig. 1. It will be noted that a marked decrease in resolution into components parallels an increase in ionic strength. Thus, at ionic strength 0.05 excellent resolution into three components was obtained, while at ionic strength 0.3 the pattern consisted of a single asymmetric peak ($-4.3 \times 10^{-5}$). The apparent distribution of components at ionic strength 0.05 was 78.6% $A_1$ ($-7.08 \times 10^{-5}$), 15.2% $A_2$ ($-5.93 \times 10^{-5}$) and 6.2% $A_3$ ($-5.2 \times 10^{-5}$), and at ionic strength 0.1, 77.9% $A_1$ ($-6.24 \times 10^{-5}$), 17.6% $A_2$ ($-5.37 \times 10^{-5}$) and 4.5% $A_3$ ($-4.8 \times 10^{-5}$). A similar behavior was observed in the case of electrophoresis in acetate buffers. Patterns obtained in phosphate buffer, *p*H 6.8 and ionic strength 0.3, revealed the presence of three components,

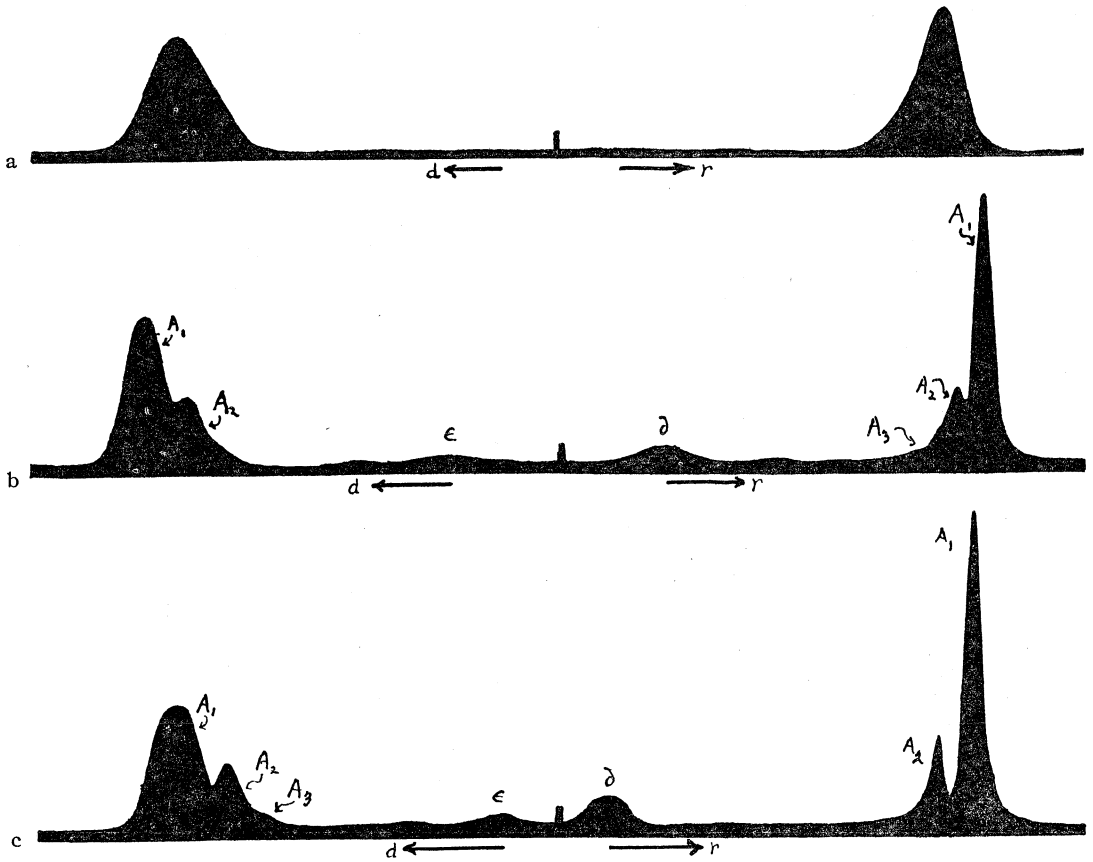

Fig. 1.—Electrophoretic patterns showing the effect of ionic strength on resolution of ovalbumin at a protein concentration of 0.74%; a, phosphate–chloride buffer of ionic strength 0.3, 28 hr. at a field strength of 1.1 volts cm.$^{-1}$; b, phosphate buffer of ionic strength 0.1, 4 hr. at a field strength of 5.0 volts cm.$^{-1}$; c, phosphate buffer of ionic strength 0.05, 2.2 hr. at a field strength of 8.9 volts cm.$^{-1}$.

although considerably less resolution was obtained than at ionic strength 0.1. In accordance with theory the $\epsilon$- and $\partial$-boundary anomalies were diminished and the enantiography of the patterns were increased as a result of increasing the ionic strength.

Because of the strong dependence of relative mobilities upon ionic strength, the "true"[12] electrophoretic distributions of components were determined by extrapolation of apparent distributions to zero protein concentration at constant ionic strength instead of to infinite ionic strength at constant protein concentration or to zero ratio of concentration to ionic strength. The apparent distributions were obtained by electrophoresis in phosphate buffer, *p*H 6.8 and ionic strength 0.1. A representative series of determinations is presented in Table I. The deviations of the apparent from extrapolated relative concentrations of component $A_1$ when plotted against the protein concentration fall on straight lines, arising from the origin. Theoretical deviations for ovalbumin samples containing 82.7 and 68.8% of $A_1$ were calculated by the equations of Dole, and are compared with experimental data in Fig. 2. The agreement between the computed and observed deviations is as good as can be expected considering the nature of the approximations made in the computations.[13] It would appear that Dole's the-

(12) It should be borne in mind that the extrapolated composition has not been shown to be the true value.

(13) The calculations were simplified by including the small contribution of component $A_3$ to the electrophoretic pattern with that of component $A_2$. Thus, the protein was considered as being composed of two components of mobilities $-6.45 \times 10^{-5}$ and $-5.88 \times 10^{-4}$, which correspond to the mobilities of $A_1$ and $A_2$, respectively, at zero protein concentration. These mobilities were obtained by extrapolation of the plot of the reciprocal of the mobility *vs.* the square root of the protein concentration, linear in the range of protein concentration 2 to 0.4%, to zero concentration. This method of extrapolation was suggested by Dr. A. Bueche, Baker Chemistry Laboratory, Cornell University.

In the calculations of the $V\sigma$ products for the boundaries (Dole,[6] equation 33) and of the component concentration ratios across them (Dole,[6] equation 31), (whose summations define the deviations of apparent from true electrophoretic distributions), the following relative mobilities were used: sodium + 1, monohydrogen phosphate −1.10, dihydrogen phosphate −0.66, component $A_1$ −0.322, component $A_2$ −0.293.

The equivalent concentration of component $A_1$ was arbitrarily taken from the net charge per g. of ovalbumin ($-2.7 \times 10^{-4}$ faraday equivalent per g. of protein) as given by the titration data of Cannan, Kibrick and Palmer (*Ann. N. Y. Acad. Sci.*, **41**, 243 (1941)). For component $A_2$ the net charge per gram was assigned the same ratio with that of $A_1$ as between its mobility and the mobility of $A_1$.

ory adequately accounts for the errors involved in ordinary electrophoretic analyses.

TABLE I

ELECTROPHORETIC ANALYSES OF OVALBUMIN

| Experiment | | Protein concentration, % by wt. | Apparent electrophoretic concentration of $A_1$, % | Deviation of apparent electrophoretic from extrapolated concentration of $A_1$, % |
|---|---|---|---|---|
| I | 1 | 1.41[a] | 88.4 | 5.7 |
| | 2 | 0.89[a] | 86.8 | 4.1 |
| | 3 | 0.72[a] | 85.5 | 2.8 |

| Extrapolation | | 0 | 68.8 | |

[a] From nitrogen determination. [b] From area of electrophoretic pattern. The relation between the protein concentration and the area of the electrophoretic pattern was determined empirically over the concentration range of 0.7 to 2%.

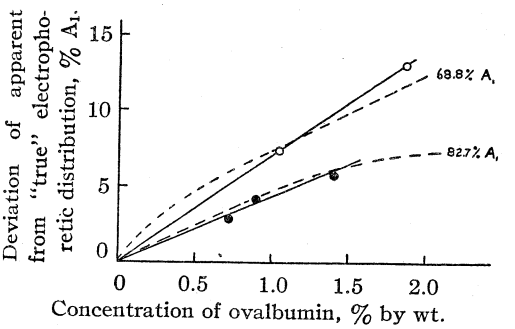

Fig. 2.—Deviations of apparent from "true" electrophoretic distributions: solid line, experimental deviations; broken curve, deviations calculated from the equations of Dole.

**Acknowledgment.**—The author is indebted to Dr. J. G. Kirkwood for his interest in this work and for his review of the manuscript.

## Summary

The electrophoretic analysis of ovalbumin is complicated by the fact that the change of relative mobilities of the components with ionic strength is such that, while resolution into components is obtained at *p*H 6.8 and ionic strength 0.1, only slight if any resolution is found at ionic strength 0.3. "True" electrophoretic distributions of components were obtained by extrapolation of apparent distributions to zero protein concentration at constant ionic strength of 0.1. The moving boundary theory of Dole adequately accounts for the deviations of apparent from "true" distributions.

# Spectrophotometric Studies of Complex Formation with Sulfosalicylic Acid. II. With Uranyl Ion

BY ROBERT T. FOLEY AND ROBBIN C. ANDERSON

As part of a series of studies on complex formation with sulfosalicyclic acid, it has been of interest to compare the reactions of uranium—as a member of another transition series of elements—with that of iron. Weil and Rozenblum[1] reported a solid compound of uranium and sulfosalicylate, $[C_6H_3(OH)(SO_3)(COO)]_2U$, but no observations in solution were made. Muller, Fernandes, Mai and Weinland and Hager[2] have reported complex formation between uranyl ion and salicylic acid or various salts.

In this particular investigation reactions of sulfosalicyclic acid in solutions containing uranium as uranyl ion have been studied.

(2) See R. Weinland and K. Hager, *Z. anorg. allgem. Chem.*, **160**, 193 (1927).

## Experimental

**Materials.**—Uranyl nitrate dihydrate was obtained by vacuum drying the hexahydrate (Eimer and Amend C. P grade) over sulfuric acid. A 0.005 *M* uranyl nitrate solution was prepared by dissolving the proper weight of the dihydrate in water at 25°.

Uranyl acetate dihydrate was also simply weighed and dissolved in water. The salt was Eimer and Amend C. P grade.

The sulfosalicylic acid was a special sample from Eastman Kodak Co. with melting point 112–120° (reported in literature, 108–113°.[3]) Analysis for sulfate gave 0.06%. Solutions of this acid were standarized by titration against a National Bureau of Standards sample of potassium acid phthalate.

**Apparatus.**—Measurements of optical density were made with a Beckmann Model DU Quartz Spectrophotometer, using a tungsten lamp and Corex cells of 10-mm. light path. The cells were held in a thermostatted cell

(3) Schulze, *Apoth. Ztg.*, **51**, 319 (1936).

compartment of design similar to that of Bell and Stryker.[4] Temperature measurements were made directly on the solution in the cells, and, unless otherwise specified, were at 25 ± 0.2° for all determinations.

*p*H measurements were made with a Beckmann *p*H meter, Model G. This was calibrated against a standard buffer.

**Procedure.**—After each solution was prepared, it was allowed to stand one hour in a thermostat at 25°. Preliminary experiments showed that the complex reached equilibrium within one hour and did not change appreciably in the next twenty-four hours. Each sample placed in the thermostatted absorption cells was allowed to stand at least fifteen minutes to reach thermal equilibrium before measurements were made.

## Results

**Absorption Spectra.**—In Fig. 1 are shown typical absorption curves for uranyl acetate solution and for a mixture of uranyl acetate and sulfosalicylic acid solutions.

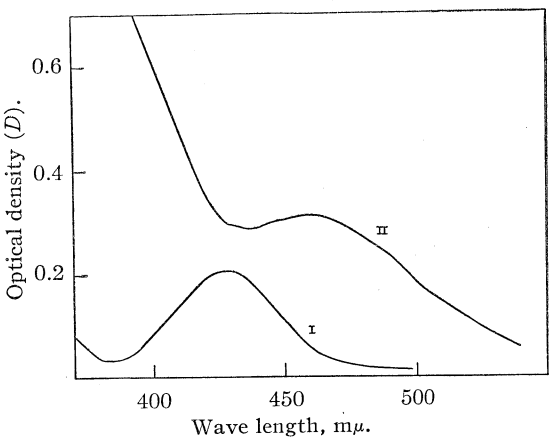

Fig. 1.

Curve I is for a solution 0.005 *M* in uranyl (II) acetate at a *p*H of 4.5. Curve II is for a solution 0.00075 *M* in uranyl acetate and 0.00425 *M* in sulfosalicyclic acid at a *p*H of 4.65. Sulfosalicyclic acid itself shows no appreciable absorption throughout this range. Since the concentration of uranyl salt is much less for curve II than for curve I, it is evident that a complex must be formed with sulfosalicyclic acid—a complex which absorbs much more strongly than uranyl acetate particularly in the region of 460 mμ and just below 400 mμ.

Uranyl nitrate solution showed essentially the same absorption curve as the uranyl acetate. (The peak at 430 mμ in absorption by these solutions possibly involves association with hydroxyl ions. Qualitative tests showed that increase in *p*H—*i. e.*, in hydroxyl ion concentration—causes an increase in intensity of the color in this wave length region. Although acetate also seems to form a complex, the complex does not absorb at this wave length).

**Composition of Complex.**—The composition of the complex was determined by Job's method of continuous variations.[5] In Fig. 2 are shown curves obtained when the quantity $\overline{D}$—the difference between the total optical density of the solution and that which would be shown by the uranyl salt alone if no reaction occurred—is plotted against the ratio

$$[UO_2^{++}]/[UO_2^{++}] + [C_6H_3OHCOOHSO_3H]$$

The curves in Fig. 2 are for mixtures of equimolar solutions of uranyl and sulfosalicylate at *p*H 4.65. The total molarity of uranyl plus sulfosalicylate is 0.005 throughout. Curve I is based on measurements at 400 mμ and Curve II at 460 mμ. Similar curves were obtained at 420 mμ and 440 mμ.

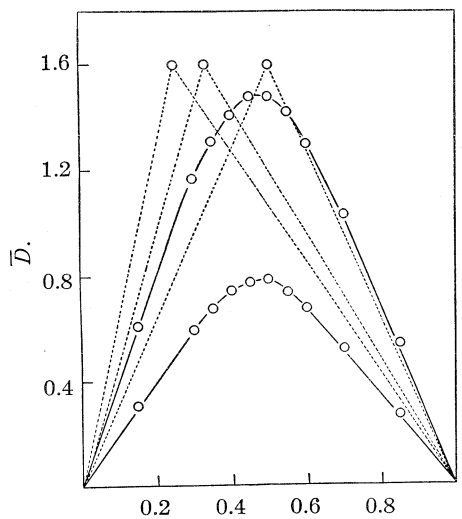

Fig. 2.

The dotted lines with peaks at ratios of 0.25, 0.33 and 0.5 represent theoretical curves which would be obtained for complexes having formulas $MR_3$, $MR_2$, and MR (where R might be sulfosalicylic acid or one of its ions), respectively—if the association reaction to form the complex were complete.

The experimental data clearly indicate that under these conditions a complex containing uranyl and sulfosalicylate in the ratio 1:1 is formed. The fact that the peak of the experimental curve is lower than that of the theoretical indicates that the association reaction is not complete, *i. e.*, that the complex is appreciably dissociated.

Measurements at *p*H 5.1 and 6.1, using acetate buffers, gave maxima at ratios between 0.45 and 0.5, thus indicating that the ratio of uranyl to sulfosalicylate is 1:1 in these regions also. However, measurements at higher *p*H values are more difficult because of the lower absorption.

**Effect of *p*H Change.**—The solution of the complex shows maximum absorption at a *p*H of about 4.5–4.7 and decreases markedly in absorption if the *p*H is increased or decreased, as shown in the curve of Fig. 3 (for $\lambda$ = 440 mμ).

(4) P. H. Bell and C. R. Stryker, *Science*, **105**, 415 (1947).

(5) P. Job, *Ann. chim.*, **9**, 113 (1928); **11**, 97 (1936); *cf.* also R. T. Foley and R. C. Anderson, THIS JOURNAL, **70**, 1195 (1948).

Since the $pK$ value for the second dissociation constant of sulfosalicylic acid is about 2.86 at 25°,[6] the effect of $p$H in the range 2 to 4.7 suggests complex formation must occur between $UO_2^{++}$ and $^-O_3SC_6H_4OHCOO^-$ ions. In this region increasing association to $^-O_3SC_6H_4OHCOOH$ might interfere with complex formation. The decreased complex formation at $p$H values above 4.67 may result from formation of a complex such as $UO_2OH^+$. The tendency of uranyl ion to form basic salts indicates this should be probable, but there is no conclusive evidence on this possibility at present.

**Effect of Acetate.**—It was noted in the experiments using acetate buffers that there was a marked decrease in color of the complex when the buffer was added. Such an effect might result from a change in the ionic strength or from a specific reaction of the acetate. Comparisons were made by adding acetate to one sample of a solution (0.002 $M$ in uranyl and sulfosalicylate) containing the complex and chloride to another so as to produce corresponding changes in ionic strength. These showed that the effect of the acetate is specific, being much greater than the effect of change in ionic strength as shown by the solutions containing chloride (see Table I).

TABLE I

ACETATE EFFECT

| Concn. added salt, moles/l. | Optical density at 460 mμ acetate added | chloride added |
|---|---|---|
| 0 | 0.643 | 0.643 |
| 0.18 | .242 | .620 |
| .36 | .103 | .607 |

Apparently the acetate ion competes with the sulfosalicylate in complex formation but forms a complex which does not absorb in this region of the spectrum. Ghosh and Mitter[7] have reported evidence from spectroscopic studies for the existence of such a complex.

**Dissociation Constant and Free Energy.**—Using optical densities for solutions containing a large excess (9:1 or more) of sulfosalicylic acid, so that as a first approximation the concentration of complex may be taken to be equal to that of uranyl added, one may determine values for the extinction coefficient of the complex.

Typical approximate values (for solutions 0.0005 $M$ in uranyl) are shown in Table II.

TABLE II

APPROXIMATE EXTINCTION COEFFICIENTS

| $T$, °C. | Coefficient, mμ 440 | 460 |
|---|---|---|
| 23.4 | 404 | 432 |
| 29.1 | 413 | 438 |
| 34.3 | 417 | 444 |

(6) Private communications, Dr. R. G. Bates, Nat. Bureau of Stds.

(7) J. C. Ghosh and B. N. Mitter, *J. Ind. Chem. Soc.*, **4**, 353 (1927).

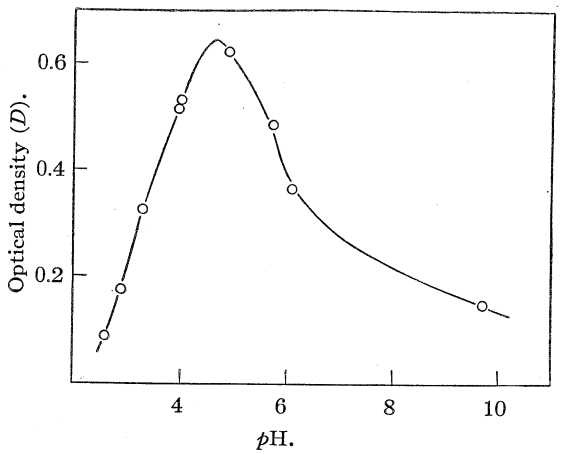

Fig. 3.

From these values one can calculate concentrations of the complex in various mixtures and thus calculate the dissociation constant. The concentration of uranyl ion is then calculated, and correction for its absorption gives a better value for the extinction coefficient of the complex. Successive approximations by this method from data for the various temperatures give for the extinction coefficient at 460 mμ, an average value of 451 (within ±2%). For 440 mμ the average value is 423. From determinations of the equilibrium constant calculated using equilibrium concentrations determined by this method an average value was obtained of

$$K = \frac{[UO_2^{++}][R]}{[UO_2^{++}R]} = 1.3 \times 10^{-4} \pm 0.8 \times 10^{-4}$$

The calculations above involve the initial assumption in each step that Beer's law may be applied for the color of the solution containing uranyl ion and the complex. This is an assumption which cannot be accurate except in very large excess of one of the reagents.[8] The variations in Table II show that it is not entirely accurate here.

A better method is to base calculations of equilibrium constants on comparisons made in solutions of equal or closely similar optical densities. A solution containing uranyl and sulfosalicylate in 1:1 ratio was diluted at constant ionic strength, until solutions were obtained having the same optical densities (after correction for $UO_2^{++}$ absorption by using the known approximate value of $K$ to determine $UO_2^{++}$ concentrations) as those at other ratios such as 2:8, 3:7, etc. In this manner pairs of solutions may be prepared which have the same optical density (from the complex) and thus contain equal concentrations of complex but different total concentrations of each reagent. Since the dissociation constant is the same for both members of a given pair, the concentration of

(8) *Cf.* for example, A. K. Babko, *Zavodskaya Lab.*, **23**, 9 (1947), or *Chem. Abs.*, **41**, 7175 (1947).

complex and thus the value of $K$ may be calculated from the relation

$$K = \frac{(a_1 - x)(b_1 - x)}{x} = \frac{(a_2 - x)(b_2 - x)}{x}$$

where the $a$'s and $b$'s denote initial concentration of uranyl and sulfosalicylate, respectively, and $x$ denotes the concentration of complex formed.

$K$ values calculated by this method are of the same order of magnitude as those obtained by the first method but show greater precision. The average $K$ from several determinations is

$$K = 1.93 \times 10^{-4} \pm 0.08 \times 10^{-4} \text{ (at } 25°)$$

The free energy of *formation* of the complex may be calculated readily from the relation $\Delta F = RT \ln K = -5060$ cal./mole (where $K$ denotes the *dissociation* constant as determined above).

**Temperature Effect and Heat of Reaction.**—From the data in Table II it may be seen that increased temperature tends to increase complex formation but that the effect is not pronounced. A determination of the dissociation constant at 33.2° gave an average value of $1.48 \times 10^{-4} \pm 0.6 \times 10^{-4}$.

It is apparent that the heat of reaction must be small. It can be calculated readily from standard relations, but since the difference in $K$ values is small the effect of experimental errors becomes very pronounced and can outweigh the temperature effect itself. Such a calculation is then of uncertain validity.

**Structure of Complex.**—None of the experiments using Job's method in the region of *p*H 4.6 indicate other than a 1:1 mole ratio in the complex. Since the color fades rapidly as the *p*H changes, there is no evidence for formation of more than one colored complex under the conditions of these experiments.

No attempt should be made to express a structural formula for this complex until more evidence is available, in particular concerning the presence or absence of hydrogen or hydroxide ions.

It may be noted, however, that the low free energy of formation indicates a weak association effect rather than a strong covalent bond. Extraction tests with various organic solvents such as benzene and carbon tetrachloride were unsuccessful, giving no positive evidence for the presence of any neutral, covalent grouping. The 1:1 ratio, the *p*H region in which the maximum effect occurs, and the rapid formation—without appreciable "aging" effect—indicate association of ions such as $UO_2^{++}$ and $^-O_3SC_6H_3OHCOO^-$. This would give an apparent charge of zero, but a "zwitterion" type of structure is possible. The *p*H effect and the apparently high reactivity of the complex with either increase or decrease in *p*H are suggestive of such a structure.

The authors wish to express their appreciation to the Pan American Refining Corporation for its generous support of this work by a fellowship grant (to R. T. F.).

## Summary

1. Spectrophotometric data for solutions with concentrations in the region of 0.005 $M$ and over a *p*H range of 2 to 10 indicate only one complex formed with uranyl ion and sulfosalicyclic acid. This involves a 1:1 mole ratio of uranyl and sulfosalicyclic acid.

2. The effects of changing *p*H, of temperature, and of acetate ion have been studied.

3. The dissociation constant and free energy of formation of the complex have been calculated.

# Spectrophotometric Studies on Complex Formation with Sulfosalicylic Acid. III. With Copper(II)

BY STANLEY E. TURNER AND ROBBIN C. ANDERSON

As part of a series of experiments on complex formation by sulfosalicylic acid with various metal ions in solution[1] a study of its reaction with copper (II) ions has been made.

Spacu and Macarovici[2] reported formation of a deep olive-green complex of composition $[Cu(OC_6H_3CO_2 \cdot SO_3)_2]H_4$ in connection with experiments on copper-cobalt complex sulfosalicylates. Babko[3] has studied the copper-salicylate system and reports a complex of the type CuR from *p*H 3-5 and $CuR_2$ from *p*H 7–9.

## Experimental

The apparatus used was the same as that described previously.[1] Preliminary absorption measurements were made with a General Electric Hardy Recording Spectrophotometer. Data for determination of composition of the complex, temperature effects, etc., were taken with a Beckmann Model DU Spectrophotometer equipped with a thermostat for temperature control in the absorption cells.

*p*H measurements were made with a Beckman model G *p*H meter.

To avoid any interference from iron, Merck Reagent Grade copper sulfate was precipitated and redissolved in ammonium hydroxide. The solution was acidified with nitric acid and evaporated almost to dryness to remove

ammonium nitrate. The resulting sludge was heated with sulfuric acid to drive off the nitric acid and water. In this manner crystals of copper sulfate with a small amount of residual sulfuric acid were obtained. Solutions were prepared by dissolving this material in distilled water and standardizing electrolytically with a Fisher Scientific Co. Electroanalyzer.

Sulfosalicylic acid and sodium hydroxide were prepared as described earlier.[1]

For comparisons of various mixtures at constant *p*H, the copper(II) sulfate and sulfosalicylic acid were mixed in proportion such as to give the desired final concentration. The mixture was then adjusted to the desired *p*H by adding sodium hydroxide and diluted to final volume with water containing a little sulfuric acid or sodium hydroxide as needed to bring it to the same *p*H.

## Results

**Effect of *p*H.**—Since Babko had reported different complexes in different *p*H ranges with copper(II) and salicylic acid, the effect of *p*H on color of the sulfosalicylate system was first tested. In Fig. 1 are shown three typical transmittance curves taken on the recording spectrophotometer using solutions containing 0.0055 *M* copper(II) sulfate and 0.0075 *M* sulfosalicyclic acid at different *p*H values (5.3 for curve I, 6.8 for II, and 10.9 for III). From a series of such curves at values from *p*H 3.6 to 11.7 it was found that curves for solutions above *p*H 8.5 were of the type of III, with an absorption peak at 660 mμ. Those for solutions of *p*H less than 5.5 were of the type such as I, with maximum absorption at 700 mμ or above. Between *p*H 5.5 and 8.5 there was apparently a transition from type I to III, as illustrated by curve II.

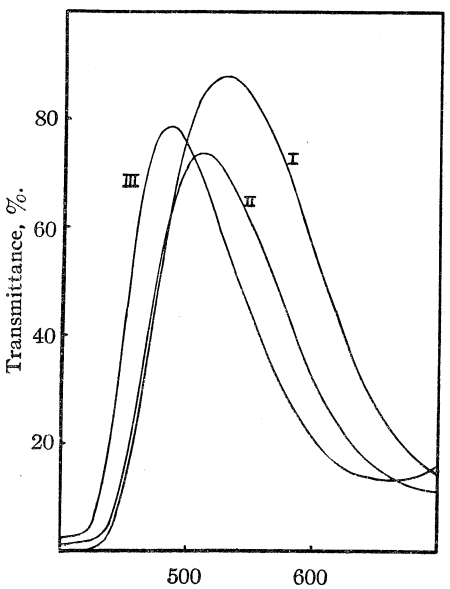

Fig. 1.

This suggested the existence of two different complexes, in this case also. Studies of composition were then made both at *p*H 5 and *p*H 9.

**Complex at *p*H 5.**—The ratio of copper(II) to sulfosalicylic acid in the complex was determined by Job's method of continuous variations.[4] A series of solutions was prepared with varying ratios of copper(II) and sulfosalicyclic acid, but with the total molarity of the two constant at 0.038 *M* and with the *p*H constant at 5. The difference ($\bar{D}$) between the observed optical density of each solution and that which would be given by the original reagents if no association occurred (in this case that of copper(II) since sulfosalicyclic acid is colorless) is plotted against the ratio $[Cu^{++}]/[Cu^{++}] + [HO_3SC_6H_3OHCOOH]$. This gives a curve which should rise to a maximum at a point corresponding to the ratio in which the reagents combine to form the complex.

The results are shown in Fig. 2, curves II and III. Curve II is for data taken at a wave length of 700 mμ and curve III at 630 mμ. The curves clearly indicate a complex of composition CuR (where R might be sulfosalicylic acid or one of its ions).

**Complex at *p*H 9.**—A similar determination by the Job method was made at *p*H 9. The result is shown in curve I of Fig. 2 (the total molarity of copper(II) plus sulfosalicylate being 0.038 *M*). The curve indicates that in this *p*H region the complex is of the type $CuR_2$.

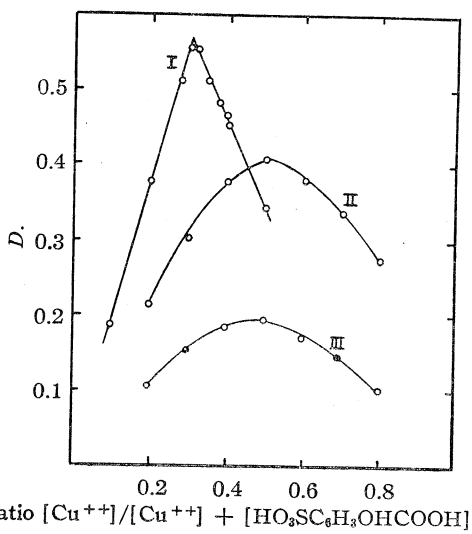

Fig. 2.—Method of continuous variations: I, *p*H 9, λ = 660 mμ; II, *p*H 5, λ = 700 mμ; III, *p*H 5, λ = 630 mμ.

**Effect of Temperature.**—Tests made over a range of 20 to 30°, showed only a small temperature effect practically within the range of experimental error. The tendency toward complex formation does show a slightly increasing trend with increase in temperature. Typical data are shown in Table I.

**Dissociation Constants.**—To determine the dissociation constant of the complex at *p*H 5 a mixture containing 0.019 *M* copper(II) and 0.019 *M* sulfosalicylate (corresponding to the

TABLE I

TEMPERATURE EFFECT, ($[Cu^{II}] = 0.019 = [HO_3SC_6H_3OHCOOH]$, $p$H = 5)

| Temp., °C. | Optical density 630 | Optical density 700 |
|---|---|---|
| 22 | 0.235 | 0.492 |
| 25 | .236 | .493 |
| 27 | .239 | .496 |
| 30 | .241 | .495 |

peak of curves II and III, Fig. 2) was diluted in successive stages—adding sodium sulfate as needed to keep the ionic strength constant. From this dilution curve and the data of Fig. 2 a series of pairs of solutions could be selected, having equal optical density (and thus essentially equal concentrations of complex) but different concentrations of reagents. From the equation

$$K = \frac{[Cu_1^{II} - X][R_1 - X]}{X} = \frac{[Cu_2^{II} - X][R_2 - X]}{X}$$

$X$ and $K$ could then be calculated since the values for $Cu^{II}$ and $R$ were known.

As a first approximation the effect of $Cu^{++}$ on the optical density was neglected, but, by using the value of $K$ so obtained, correction could be made for the optical density of unreacted $Cu^{++}$ and better values for $K$ determined. Results are shown in Table II for data at 630 mμ and 25°. A similar determination at 700 mμ gave a value in agreement with that at 630 mμ, but the variations are larger since much higher corrections have to be applied for absorption by copper(II) ions.

TABLE II

DISSOCIATION CONSTANT

| Total $[Cu^{++}$ | Total [R] | $K$ |
|---|---|---|
| 0.0076 | 0.0304 | $1.7 \times 10^{-3}$ |
| .0114 | .0266 | 2.3 |
| .0152 | .0228 | 2.0 |

Mean value = $2 \times 10^{-3}$

$K$ can also be determined by assuming that, in solutions containing large excess of sulfosalicyclic acid, association is complete. A value for the extinction coefficient can then be calculated and used to determine dissociation in other solutions. This method gives $K$ values showing wider variation than the data of Table II, but the average value is $1.8 \times 10^{-3}$—in agreement with the result above.

The approximate extinction coefficients as determined by this method were 16 at 630 mμ and 33 at 700 mμ.

The dissociation constant for the $CuR_2$ type complex cannot be determined so well because the data are not sufficiently accurate to permit correction for effects of precipitation, dissociation to the CuR type complex, and similar factors. However, the sharp peak at the maximum of curve I, Fig. 2 indicates that dissociation is small. Assumption that dissociation is negligible in the presence of fairly large excess of sulfosalicyclic acid (for example where the ratio $[Cu^{++}]/([Cu^{++}] + [R]$ is 0.1) should be reasonably well justified.

From the observed optical densities of such solutions, a value of 53 was obtained for the approximate extinction coefficient of the complex at 660 mμ. Using this extinction coefficient, the concentrations of complex in other solutions and the dissociation constant were determined. An average value of $8 \times 10^{-7}$ for $K$ at 25° was obtained. It should be noted that the results show some "drift," the $K$ value increasing somewhat as the proportion of sulfosalicyclic acid decreases. Such an effect must be expected since no correction could be made for the presence of the 1:1 complex.

From the dissociation constants above, one may calculate the free energies of formation: $\Delta F = RT \ln K$. This gives a value of −3700 cal./mole for the free energy of formation of the complex of type CuR and approximately −8000 cal./mole for the type $CuR_2$.

**Structure of the Complex.**—The close resemblance in reactions of copper(II) with salicylic and sulfosalicylic acids indicates that linkage occurs with the carboxyl and/or phenolic groups. Since at $p$H 5 the carboxyl group is largely dissociated, the 1:1 complex is probably a combination of $Cu^{++}$ and $^-O_3SC_6H_3OHCOO^-$ ions. At $p$H values in the region of 9, it seems likely that the phenolic group is also involved—the linkage with two carboxyl and two phenolic groups being in accord with the normal coördination number of 4 for the copper.

The authors wish to acknowledge the coöperation and assistance of Mr. L. L. Antes, Bureau of Engineering Research, in making the measurements with the recording spectrophotometer. This research was supported by a grant from the University of Texas Research Institute.

## Summary

Spectrophotometric measurements indicate copper(II) ions and sulfosalicylate ions react in a 1:1 ratio in the $p$H range 3–5.5 and a 1:2 ratio at $p$H values above 8.5, with mixtures of the two forming in the intermediate ranges.

Temperature changes within ordinary ranges were found to have little effect on the complexes.

Dissociation constants and approximate extinction coefficients for the two complexes have been determined.

# Kinetics of the Oxidation of Hypophosphorous Acid by Iodate Ion

BY PHILIP HAYWARD AND DON M. YOST

**Introduction.**—The rates of oxidation of hypophosphorous acid, $H_3PO_2$, to phosphorous acid, $H_3PO_3$, with various oxidizing agents have been the subject of a number of investigations.[1,2] An interesting feature was found to be common to all these reactions, namely, that the rate of reaction became independent of the concentration of oxidizing agent when this was made sufficiently large. To explain this phenomenon, the hypothesis has been made that hypophosphorous acid in aqueous solution exists in both a "normal" and an "active" form, the latter being much more reactive, and that the conversion of the normal to the active form occurs at a measurable rate. These suppositions lead to a rate law which agrees well with experiment; however, the nature of the postulated active form is unknown, although the present consensus is that it contains a univalent phosphorus atom. It seemed of interest, however, to extend the range of investigations on hypophosphorous acid in the hope of gaining a better understanding of its reactions.

## Experimental

The choice of iodate as the oxidizing agent leads to a rather complicated system, from the kinetics point of view. After the initial iodate–hypophosphorous acid reaction (1) has begun, there may also take place; (2) the iodate–iodide reaction; (3) the iodate–phosphorous acid reaction; (4) the iodine–hypophosphorous acid reaction; (5) the iodine–phosphorous acid reaction. Reaction (2), being very rapid in acid solution, is the chief trouble-maker, and any scheme for suppressing it would of course also dispose of (4) and (5). Reaction (3) seems to be unavoidable, but fortunately was found to be of minor importance. Our attention was therefore devoted mainly to minimizing the contribution of the iodate–iodide reaction. Successive approaches to this problem consisted of (1) measuring initial rates, abandoning a run as soon as a definite iodine color had appeared; (2) stirring the reaction mixture with finely divided silver chloride (several grams in 200–300 ml. of solution), a procedure which served to keep down the iodide ion concentration; (3) carrying out the reaction in the presence of small amounts of *n*-propanol, a substance which apparently inhibits the iodate–iodide reaction.[3]

C. P. chemicals were used throughout, and solutions were made up using ordinary distilled water. For about half of the experiments, stock solutions of hypophosphorous acid were prepared, either by treating phosphorus with barium hydroxide and obtaining the acid from barium hypophosphite, or as was suggested by Professor L. C. Pauling, by converting sodium hypophosphite to the acid by means of an Amberlite ion-exchange column. These solutions contained various amounts of phosphorous acid, the mole percentage being in no case higher than 4. For the rest of the experiments, stock solutions of sodium hypophosphite were used; these always contained negligible amounts of phosphite. Sulfuric acid was used when additional acid was needed. On occasion, the ionic strengths of the reaction mixtures were varied by adding potassium nitrate.

The reactions were usually carried out in glass-stoppered flasks placed in a water-bath, the temperature of which was kept constant within 0.02°. Samples of the reaction mixture were analyzed for iodate by running them into acidified potassium iodide solution and immediately titrating the iodine liberated with thiosulfate. Experiment showed that the error caused by the iodine–hypophosphorous acid reaction in this procedure is negligible.

**Calculations.**—The rate law upon which calculations were based is of the form given by Mitchell[1]

$$-\mathrm{d}(IO_3^-)/\mathrm{d}t = \frac{k_1(H^+)(H_3PO_2)}{1 + k_2(H^+)/k_3(IO_3^-)}$$

where the constants $k_1$, $k_2$, $k_3$ refer to the reactions

$$(H_3PO_2)_I \underset{k_2}{\overset{k_1}{\rightleftarrows}} (H_3PO_2)_{II} \xrightarrow{k_3} \text{products}$$

Here $(H_3PO_2)_I$ denotes the normal form of hypophosphorous acid, $(H_3PO_2)_{II}$ the active form. It should be observed that since the $k_1$ and $k_2$ reactions have been shown to be subject to general acid catalysis,[2] the above rate law is really a special case of a more inclusive expression, which may be written

$$-\mathrm{d}(IO_3^-)/\mathrm{d}t = \frac{(\Sigma k[HA])(H_3PO_2)}{1 + \Sigma k_2^a[HA]/k_3(IO_3^-)}$$

Here HA is any substance capable of furnishing a proton, such as water, bisulfate ion, undissociated hypophosphorous acid, etc., and $k^a$ is the corresponding catalytic coefficient. The simpler form of the rate law, however, was found to express the results sufficiently well for our purpose.

The reaction rates in this discussion are all given with respect to iodate ion, the units being moles per liter and hours. For purposes of calculation, the iodate concentrations were plotted against time on a large scale, and a smooth curve was drawn through the points. From these graphically smoothed data the rates of reaction at various times were found by numerical differentiation. These rates were also smoothed graphically, and the smoothed values used in the calculation of rate constants.

The stoichiometry of the iodate–hypophosphorous acid reaction was found experimentally to be expressed by the equation

$$IO_3^- + 3H_3PO_2 = I^- + 3H_3PO_3$$

The concentration of hypophosphorous acid at any time could therefore be obtained from the corresponding iodate concentration, provided the hydrogen ion concentration and the dissocia-

tion constant of hypophosphorous acid were known. It is here that the calculations are subject to considerable error. Dissociation constants of the acid at various ionic strengths were taken from the paper of Griffith, McKeown and Taylor.[2] Where sulfuric acid of sulfate–bisulfate buffer solutions were used, the data of Harned and Hamer[4] were used to calculate dissociation constants of bisulfate ion. The acidity at any time was assumed to be due solely to the hypophosphorous and sulfuric acids present, no correction being made either for the production of phosphorous acid during a run or for possible incomplete dissociation of iodic acid. Neglect of the first factor is justified both because hypophosphorous and phosphorous acids are of approximately equal strengths and because actual *p*H measurements during the course of the reaction showed (with an exception to be mentioned later) no significant change in acidity.

**Results and Discussion. 1. Determination of Initial Rates.**—In these experiments the attempt was made to determine the order of the reaction with respect to the various reactants. Figure 1 gives the results of a set of experiments designed to test simultaneously the dependence of the order on the hydrogen ion concentration and the concentration of (undissociated) hypophosphorous acid. In these experiments, the iodate concentration and the total concentration of hypophosphorous acid (undissociated acid plus hypophosphite ion) were kept constant, and the acidity varied by adding sulfuric acid. If the rate were proportional to the first power of both hydrogen ion and hypophosphorous acid concentrations, a straight line should result from plotting initial rate against $(H^+)^2/(K + (H^+))$, where $K$ is the ionization constant of hypophosphorous acid. It is seen that there is a linear relationship at lower acidities, but evidence of a falling off from this linear increase in rate at higher acidities. This, of course, is to be expected if the rate law derived by Mitchell is adhered to in this case, for when the ratio $(H^+)/(IO_3^-)$ becomes sufficiently large, the rate becomes independent of $(H^+)$.

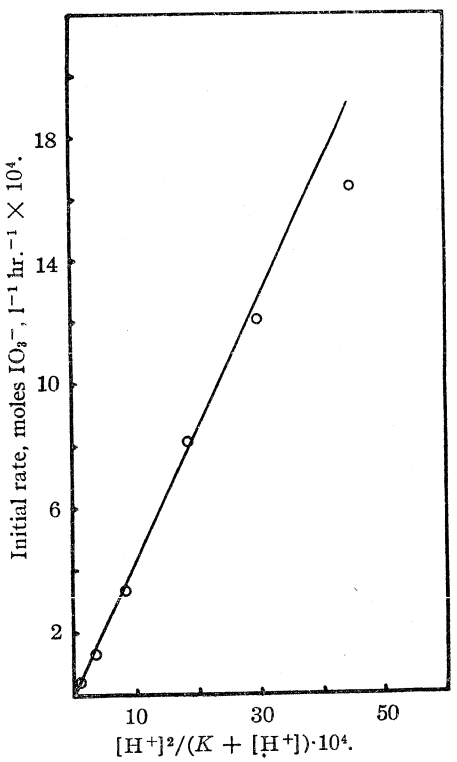

Fig. 1.—Dependence of initial rate on $[H^+][H_3PO_2]$ in the oxidation of hypophosphorous acid by iodate ion.

(4) Harned and Hamer, THIS JOURNAL, **57**, 27 (1935).

Another set of experiments, in which the iodate concentration was made small compared to the hypophosphorous acid concentration, was designed to test the dependence of rate on iodate concentration. Under such conditions, the assumed rate law can be written

$$\frac{1}{\text{initial rate}} = \frac{1}{k_1(H^+)(H_3PO_2)} + \frac{k_2}{k_3k_1(H_3PO_2)} \times \frac{1}{(IO_3^-)} = C + \frac{D}{(IO_3^-)}$$

where $C$ and $D$ are constants. Figure 2 shows the data plotted in conformity with this relation; the expected linearity is fairly apparent. However, it must be remarked that the subsequent evaluation of $k_1$ leads to a value of about $2.3 \times 10^3$ for the intercept $C$, instead of to a value of approximately zero, as shown in Fig. 2. In other words, the initial rates are higher than the rate law would predict. The major part of this discrepancy can probably be explained by the fact that the reaction mixtures were heavily buffered with phosphate, the catalytic effect of which in this case is considerably greater than that of hydrogen ion alone. Using the catalytic coefficients given by

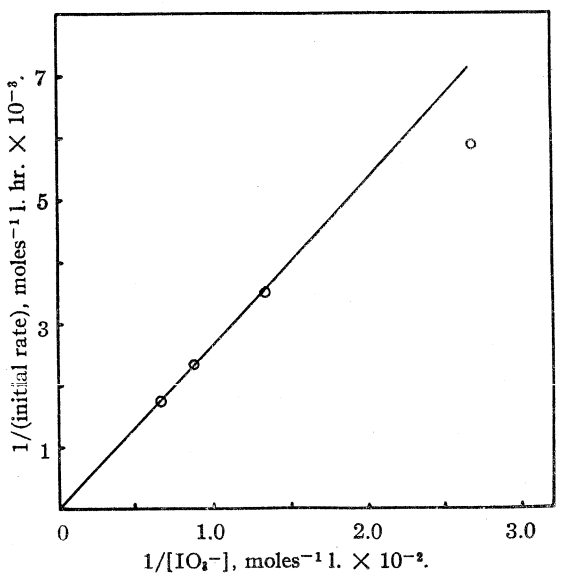

Fig. 2.—Dependence of initial rate on $[IO_3^-]$ in the rate of reduction of iodate ion by hypophosphorous acid.

Griffith, McKeown and Taylor,[2] we find the value of $C$ to be reduced to about $0.2 \times 10^3$, which, in view of the uncertainties in the initial rates, is now in reasonable agreement with the value found graphically. These phosphate buffers were not used in other experiments, which are therefore not subject to such a major correction.

The rate law can be written in the form

$$k_1 = \frac{\text{rate}}{(H^+)(H_3PO_2)} + \frac{\text{rate}}{(IO_3^-)(H_3PO_2)} \frac{k_2}{k_3} = A + B\frac{k_2}{k_3}$$

The experimentally determined quantities $A$ and $B$ determine the intercept and slope of a straight line, any point of which gives a pair of values of $k_1$ and $k_2/k_3$. Altering the experimental conditions should, by altering $A$ and $B$, give a family of straight lines which intersect in a point, the coördinates of which are the required values of $k_1$ and $k_2/k_3$. The results given by this procedure are presented in Table I.

TABLE I

"INTERACTION" VALUES OF $k_1$ AND $k_2/k_3$ AT 30°

| $k_1$, moles$^{-1}$ l. hr.$^{-1}$ | $k_2/k_3$ |
|---|---|
| 8.1 | 0.50 |
| 8.5 | .54 |
| 8.7 | .57 |
| 10.4 | .82 |
| 9.0 | .84 |
| 10.0 | .42 |
| 9.4 | .40 |
| 9.4 | .37 |
| 9.3 | .35 |
| 8.7 | .31 |
| 7.9 | .20 |
| Average 9.0 ± 0.7 | 0.48 ± 0.19 |

**2. The Reaction in the Presence of Silver Chloride.**—By stirring the reaction mixtures with silver chloride, it was found possible, if the acidity and iodate concentration were not too high, to prevent entirely the appearance of iodine. Blank experiments showed that oxidation of hypophosphorous acid by silver ion under these conditions was not appreciable, nor was there any evidence for precipitation of silver iodate. This procedure widened considerably the range of practicable initial conditions; also, since the reaction could now be followed through a greater portion of its course, $k_1$ and $k_2/k_3$ could be estimated from each experiment. From the rate law written in the form

$$(H_3PO_2)/\text{rate} = \frac{1}{k_1(H^+)} + \frac{k_2}{k_3k_1} \times \frac{1}{(IO_3^-)}$$

it can be seen that plotting the left-hand side against $1/(IO_3^-)$ should give a straight line from whose intercept and slope the values of $k_1$ and $k_2/k_3$ could be obtained.

This linearity was always found, at least during the first part of a run. Later on, the slopes of the curves often decreased markedly, an effect which is probably to be attributed to the iodate–phosphorous acid reaction, since the reaction mixtures usually began to give positive tests for phosphate at about the point where the curves began to drop off. It is possible that the phosphorous acid produced is responsible also because its catalytic effect is about twice that of hypophosphorous acid.[2] Table II and Fig. 3 give the results obtained from one of the best runs of this kind.

TABLE II

THE IODATE–HYPOPHOSPHITE REACTION AT 30.06° IN THE PRESENCE OF SILVER CHLORIDE

$[\Sigma H_3PO_2]_0 = 0.0525$, $K_{H_3PO_2} = 0.076$, $[H^+] = 0.037$, $\mu = 0.13$, temp., 30.06°

| Time, hours | $[IO_3^-]$, $\times 10^3$ | $[H_3PO_2]$, $\times 10^2$ | Rate, moles l$^{-1}$ hr.$^{-1}$, $\times 10^3$ |
|---|---|---|---|
| 0 | 11.59 | 1.73 | 3.38 |
| 0.25 | 10.72 | 1.64 | 3.12 |
| 0.50 | 9.95 | 1.56 | 2.85 |
| 0.75 | 9.23 | 1.49 | 2.60 |
| 1.0 | 8.51 | 1.42 | 2.37 |
| 1.25 | 7.90 | 1.36 | 2.15 |
| 1.50 | 7.35 | 1.31 | 1.96 |
| 1.75 | 6.83 | 1.26 | 1.79 |
| 2.0 | 6.35 | 1.21 | 1.65 |
| 2.25 | 5.93 | 1.17 | 1.53 |
| 2.50 | 5.55 | 1.13 | 1.43 |
| 2.75 | 5.17 | 1.09 | 1.32 |
| 3.0 | 4.86 | 1.06 | 1.23 |

The averages of thirty-nine determinations of $k_1$ and $k_2/k_3$, both by the method just indicated and by the "intersection" method previously described, are 12.2 ± 3.0 moles$^{-1}$ l. hr.$^{-1}$ and 0.48 ± 0.25, respectively.

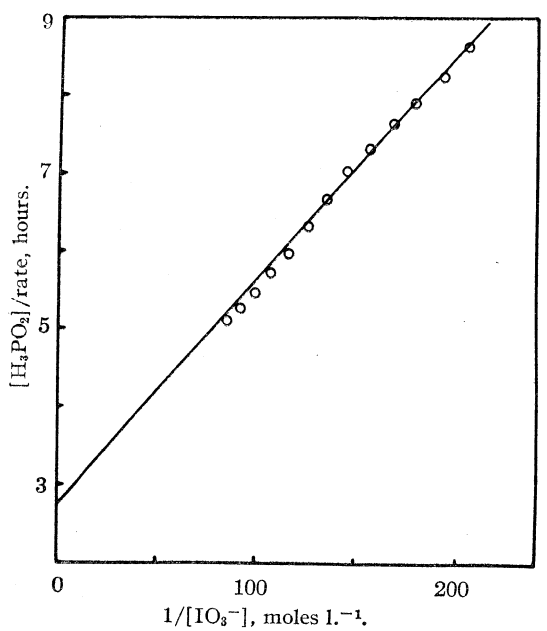

Fig. 3.—The rate of oxidation of hypophosphorous acid by iodate ion in the presence of solid AgCl.

**3. The Reaction in the Presence of *n*-Propanol.**—In these experiments small concentrations (never more than 7 volume per cent.) of

*n*-propanol were added to the reaction mixture. Tests showed that varying the concentration of alcohol in this range did not appear to have a significant influence on the rate, that there was no reaction between iodate and *n*-propanol, and that its presence did not interfere with the thiosulfate titrations. The dielectric constants of the solutions were lowered by as much as four per cent. by the addition of the alcohol,[5] but the error thus introduced into the calculations of hydrogen ion and hypophosphorous acid concentrations is hard to estimate quantitatively. At any rate, it was considered to be negligible, in view of the already considerable uncertainty in these quantities.

It was found that, while there was no apparent retardation of the reaction rate between iodate and hypophosphorous acid, the time of appearance of iodine was indeed delayed to an extent which, other things being equal, was quite accurately proportional to the amount of *n*-propanol added. It was noticed also that, while in previous experiments the acidity remained sensibly constant, in these experiments it dropped continuously, as shown by a *p*H meter. On this account, sodium sulfate–sodium bisulfate buffer solutions were used in some of the experiments designed to evaluate $k_2/k_3$; in other cases, when the acidity was not sufficiently well controlled, the calculated hydrogen ion concentrations were made proportional to their measured values.

It was now possible to work with such high iodate concentrations that a good first approximation to $k_1$ could be determined directly from the limiting form of the rate equation

$$k_1 = \text{rate}/(H^+)(H_3PO_2)$$

Using an average value of $k_1$ determined thus, values of $k_2/k_3$ could be found from experiments at lower iodate concentrations. These were used to correct the values of $k_1$, which in turn gave a final small correction in $k_2/k_3$. The values of the rate constants obtained using this technique agreed more closely among themselves than did those from the other experiments, and we therefore believe them to be the most reliable. Table III presents data from a representative experiment.

TABLE III

(5) Åkerlöf, THIS JOURNAL, **54**, 4125 (1932).

For $k_1$, the average value at 30.06° was found to be 9.7 ± 0.8 moles$^{-1}$ l. hr.$^{-1}$, and for $k_2/k_3$, 0.44 ± 0.03. These are to be compared with the values determined by Mitchell for the iodine reaction, which when adjusted to 30° and converted to these units amount to 9.0 and 0.012, respectively. The two values for $k_1$ are the same, within the limits of error, but $k_2/k_3$ is very different in the two cases. Recalling the interpretation of this constant, and assuming that $k_2$ has the same value in both reactions, we should conclude from this that the reaction of the active form of hypophosphorous acid with the halogens and mercuric ion is about thirty-five times faster than with iodate. It is interesting to point out in this connection that the iodate ion is unlike the other oxidizing agents studied in that it is not a simple neutral molecule or cation.

Increasing the ionic strength from 0.27 to 0.65 had no significant effect on the magnitude of $k_1$, and an increase from 0.66 to 1.29 cause $k_2/k_3$ to decrease from 0.47 to 0.42—a change which is also probably not significant, in view of the uncertain effects of changing ionic strength on the hydrogen ion and hypophosphorous acid concentrations. It is to be noted that the indifference of $k_2/k_3$ to changes in ionic strength is in accord with the postulated reaction-mechanism, in which both the $k_2$ and $k_3$ reactions involve a neutral molecule—*i. e.*, the active form of hypophosphorous acid.

The rate constants were also determined by means of similar experiments at 20.27°, the values being 3.66 for $k_1$ and 0.35 for $k_2/k_3$; these represent temperature coefficients of 2.7 and 1.3 per 10.4°, respectively. The corresponding activation energies are 17 and 4.5 kcal. The value for the temperature coefficient of the $k_1$ reaction is considerably below that of 3.14 per 10° found by Mitchell for the iodine reaction. Also, he states that the temperature coefficient of $k_2/k_3$ is "approximately unity"; lacking the data on which he based this statement, it may be that his value is compatible with the one found here.

**Acknowledgments.**—We wish to thank Professor E. H. Swift for help with analytical problems, Dr. Norman Davidson for general criticism, and Mr. Fred Ordway for the construction of a nomograph which materially shortened the labor of calculation. We also acknowledge the courtesy of the International Resin Corporation in supplying a sample of Amberlite IR-100 ion exchange resin for the preparation of hypophosphorous acid. The work was supported by a grant from The Research Corporation, and we are greatly indebted to them for this aid.

## Summary

The hypothesis that a normal and an active form of hypophosphorous acid coexist in aqueous

solution, and that the conversion of the normal to the active form can be a rate-determining step in its reactions with oxidizing agents, is supported by a study of the kinetics of its oxidation by iodate ion. The rate law

$$-d(IO_3^-)/dt = \frac{k_1(H^+)(H_3PO_2)}{(1 + k_2(H^+)/k_3(IO_3^-)}$$

is found to be in agreement with observation, the best values of the constants at 30° being 9.7 moles$^{-1}$ l. hr.$^{-1}$ for $k_1$ and 0.44 for $k_2/k_3$. The respective activation energies are 17 and 4.5 kcal.

It is probable that iodate ion reacts with the active form of hypophosphorus acid at a much slower rate than do other substances conforming to this rate law.

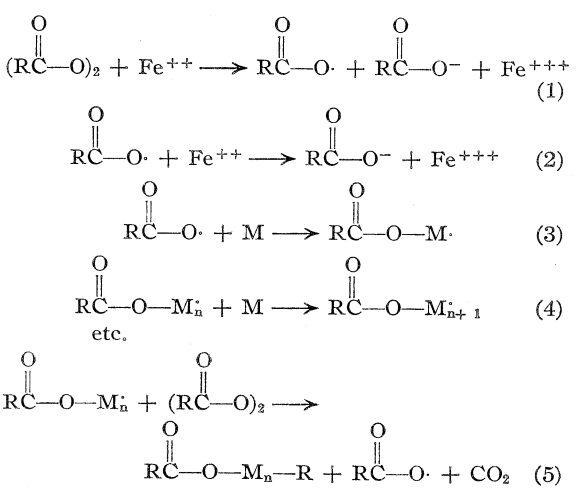
# An Oxidation-Reduction Cycle in Emulsion Polymerization Systems[1]



BY F. T. WALL AND T. J. SWOBODA[2]

## Introduction

The physical and chemical properties of synthetic polymers depend markedly upon the conditions under which they are made, particularly upon the temperature of polymerization.[3] In certain instances a superior product is obtained when the polymerization is carried out at low temperatures, but the rate of reaction may be so slow that the process is impractical. For this reason considerable effort has been directed toward activating polymerization catalyst systems to obtain substantial rates of polymerization at reduced temperatures.

For a polymerization taking place through a free radical mechanism, the over-all rate of reaction depends, among other things, upon the concentration of free radicals present. It would appear, therefore, that a high rate of polymerization might be attained at low temperatures if a sufficiently high concentration of free radicals could be realized. Unfortunately, the thermal decompositions of certain free radical producing compounds such as benzoyl peroxide are so slow[4] at reduced temperatures that they exhibit little or no catalytic effect under those conditions.[5] However, it is found that the formation of free radicals from benzoyl peroxide can be considerably hastened by the presence of ferrous iron. Since ferrous iron is a reducing agent and the peroxide an oxidizing agent, the combination is said to constitute a "Redox" system, and the increased catalytic effect of the peroxide is said to be the result of reduction activation.

The fundamental work of Haber and Weiss[6] on the reactions of iron with hydrogen peroxide forms the basis for the chemical aspects of reduction activation. Baxendale, Evans and Parks[7] made use of an iron–hydrogen peroxide system for the polymerization of acrylonitrile. If one employs an organic peroxide in place of hydrogen peroxide, the following reactions can be expected to occur in a polymerization system activated with ferrous iron

Reaction (1) involves the formation of one free radical and one acid ion, the latter being combined in some form of salt. (The use of the ionic nomenclature in this connection is for the purpose of designating the states of oxidation instead of the actual states of matter which are not necessarily in ionized form.) Reaction (2) represents the destruction of the initially formed free radicals by ferrous ions. It is clear that unless some other reaction intervenes to prevent (2) from occurring, the final result will simply be the complete reduction of the peroxide by the iron. If some polymerizable monomer is present, then reactions (3) and (4), which are precisely the polymer chain growth reactions, can occur. More-

(1) This investigation was carried out in part under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program, and was first reported on October 30, 1947. ADDED IN PROOF: Since the preparation of this manuscript, the authors have learned of some work by Werner Kern, "Die makromolekulare Chemie," **B1**, 199–268 (1948), dealing with topics closely related to those discussed in the present paper. Kern's findings are entirely compatible with those here indicated, although the cyclical aspect of the behavior was not emphasized.

over, once a monomer of the vinyl type has added to the initial free radical, the resulting free radical is no longer subject to the reaction represented by equation (2), since a stable salt can no longer be formed. However, a polymeric free radical can undergo reaction (5) which is equivalent to the induced free radical decomposition discussed by Nozaki and Bartlett.[5] Reaction (5) is also equivalent to chain transfer or modification so it is apparent that a peroxide can serve both as a catalyst and as a modifier[8] in a polymerization system.

If an appreciable amount of ferrous iron is brought into contact with an organic peroxide, reactions (1) and (2) take place so rapidly that the catalyst is soon spent. Accordingly, if reduction activation is to be of any use for promoting polymerization, some means must be found for controlling reaction (1) and for minimizing reaction (2) which does no good in a polymerization system. A solution to this problem can be found by keeping the iron concentration very low relative to the concentrations of the peroxide and of the monomer, since under these circumstances the rate of reaction (1) would be reduced to a reasonable value and reaction (3) would predominate over reaction (2). This pattern suggests that continuous addition of small amounts of ferrous iron to the polymerization recipe might give rise to the desired state of affairs. Although such addition by mechanical means is highly impractical, the same result can fortunately be accomplished in an emulsion system when appropriate auxiliary reagents are present. Thus certain highly effective "Redox recipes" for the preparation of a variety of polymers, such as the copolymer of butadiene and styrene, have actually been devised by polymerization technologists.[3] These recipes are complex reaction systems which involve a variety of substances in addition to the monomer, peroxide, and iron. The work reported here was undertaken to establish the role of each of the reagents in these recipes. It is our conclusion that a certain reaction cycle, to be called the "Redox Cycle," takes place, and that each of the reagents present in the simplest effective recipe serves a definite purpose in this cycle.

## The Emulsion "Redox" System

A typical recipe[9] for a "Redox" polymerization consisting only of those reagents which are necessary and sufficient is: 20 g. monomer, 40 g. water, 0.1 g. benzoyl peroxide, 0.1 g. ferric ammonium sulfate, 0.1 g. sorbose, 0.1 g. sodium pyrophosphate, 1.0 g. sodium stearate. In place of ferric ammonium sulfate, it is permissible to substitute ferrous ammonium sulfate for reasons which will be made clear presently. As we have already seen, if ferrous iron is present, such iron can react with benzoyl peroxide to form free radicals. Those free radicals then combine with monomer ultimately building up polymer molecules. It remains to be seen how the above recipe controls the decomposition of benzoyl peroxide to sustain a smooth and rapid polymerization at reduced temperature. As a result of this investigation, it appears that the following cycle properly describes the behavior of the system

The iron in the emulsion is originally present as ferric iron which is tied up for the most part as the pyrophosphate complex in the aqueous phase. But the ferric iron can be reduced by sorbose or some other reducing sugar to form ferrous iron, a large portion of which also remains as a pyrophosphate complex in the water layer. However, limited amounts of both ferrous and ferric iron will tend to pass into the oil phase, presumably as the stearate salts, since ferrous and ferric stearates are oil soluble compounds. The distribution between the phases will occur in accordance with the usual laws governing distribution of solutes between immiscible solvents. In the oil phase the ferrous iron can react with benzoyl peroxide to form free radicals and ferric iron. The free radicals start the polymerization going and the ferric iron ultimately passes back into the water layer to maintain distribution equilibrium. Since the iron finally returns to its original form, the net result of the whole process is the reduction and decomposition of benzoyl peroxide by sorbose.

Several factors contribute to the effectiveness of the cycle described above. First of all, the amount of iron present in a form capable of reacting with the peroxide is quite small. This means that reaction (1) will proceed at a moderate rate and will be followed almost exclusively by reaction (3), because of the large excess of monomer. Nevertheless, the total amount of iron in the system is appreciable, and hence can be readily controlled for reproducible results. The pyrophosphate serves to tie up most of the iron in complex form, thus providing a reservoir of iron to be drawn from as needed. If the pyrophosphate were not present, too much of the ferrous iron would be solubilized in the organic phase with the result that the peroxide would be decomposed too rapidly for sustained polymerization. Moreover, in the absence of pyrophosphate there would be little tendency for the ferric iron to be drawn into the water layer

where it can be reduced by the sorbose which is present for that purpose. If no sorbose is added, the system can still be made to function providing the original recipe contains a large amount of ferrous iron with sufficient pyrophosphate to handle it. The over-all operation under these conditions would lose its cyclical aspect, and the effective concentration of reducing iron would not be maintained at nearly as uniform a level.

The sodium stearate has a dual role in the "Redox" system, and it is largely because of this coincidence that the "Redox" system actually operates. Ordinarily sodium stearate would be added for emulsification purposes, and it does serve that function with the "Redox" recipe as well. Equally important, however, is the solubilization of the ferrous iron in the oil phase which is brought about by the formation of oil soluble ferrous stearate in the presence of soap. If the iron were not solubilized in the oil phase to a sufficient extent, then the entire cycle would break down. In fact, if certain cationic emulsifying agents such as the quaternary ammonium salts are substituted for sodium stearate without other changes in the recipe, the "Redox" system fails for the obvious reason that the iron is not brought into contact with the peroxide.

## Experimental

The validity of the cycle described above was established by a series of separate experiments which were designed to test every aspect of the cycle. To avoid the complications of actual polymerization, which would overshadow the reactions in the "Redox" cycle, chloroform was used in place of monomer. Thus there was obtained an emulsion system which simulated the polymerization system in all respects except that reaction (2) would take place instead of reactions (3), (4), and (5). Under these experimental circumstances, the stoichiometry of the cycle could be well established. Among the experiments carried out were the reaction of ferrous stearate with benzoyl peroxide, the reduction of ferric iron with sorbose, and the transfer of iron from one phase to the other. Other experiments involved the omission of one or more critical reagents. A description of the experiments which were performed is presented in Table I. Each experiment was carried out at room temperature in the absence of oxygen with vigorous agitation of the emulsion. The data for these experiments are given in Table II. The results of all the experiments were compatible with the cycle proposed, so the conclusions given above are considered correct.

Since the solubilization of ferrous iron in the oil phase of a reaction emulsion appears to be an important factor in the operation of the "Redox" system, several experiments were carried out to investigate this aspect of the system. The first experiments were of a qualitative nature designed to prepare ferrous stearate in chloroform or benzene solution and to observe its reaction with peroxide in such single phase oil systems. Solutions of ferrous stearate (0.01–0.02 molar) were simply prepared by adding, in the absence of oxygen, an aqueous solution of ferrous ammonium sulfate in slight excess to an agitated emulsion consisting of chloroform or benzene with water and sodium stearate. The phases were permitted to separate; then the water layer was discarded and the organic layer filtered. The experiments were continued by introducing benzoyl peroxide into these solutions of ferrous stearate. A very rapid decomposition of the peroxide with accompanying oxidation of the iron was observed.

After establishing the qualitative results described above, further quantitative experiments were carried out which involved the reaction of benzoyl peroxide with ferrous iron in an emulsion medium. For Experiment I an emulsion

[a] Total moles calculated per liter of chloroform; obtained by iodometric titration. [b] Total moles calculated per liter of water; obtained by dichromate titration. [c] Initial ferric iron concentration, 0.01069; subsequent concentrations, as plotted in Fig. 5, obtained by difference.

was prepared consisting of chloroform, water, benzoyl peroxide, ferrous ammonium sulfate, and sodium stearate with the latter three substances present in stoichiometrically equivalent amounts. In this experiment, the results of which are illustrated in Fig. 1, a rapid decomposition of peroxide occurred, accompanied by a rapid oxidation of ferrous iron to the ferric state.

Experiment II was identical to Experiment I except that only one half the equivalent amount of sodium stearate was included. The results of this experiment, also illustrated in Fig. 1, show the same rapid initial reaction observed for Experiment I. But when one half the reactants were consumed, the rate of reaction abruptly decreased to a very small value. These experiments demonstrate conclusively that the iron must actually get into the organic phase to be truly effective as a reduction activator and that the sodium stearate serves as the solubilizing agent.

Further evidence supporting the conclusion drawn above was obtained in Experiment III which involved a similar emulsion, except that no sodium stearate was initially included. In its place there was substituted an equivalent amount of benzyltrimethylammonium hydroxide, which is a cationic emulsifying agent incapable of solubilizing iron. The data as shown in Fig. 2 show that no significant amount of reaction occurred with this system. However, after 5.2 hours a 40% equivalent of sodium stearate was added, whereupon the rate of reaction immediately became very rapid but then slowly diminished due to the insufficiency of sodium stearate. A further addition of a large excess of sodium stearate at 11.4 hours caused another surge of reaction. Thus the dual role of sodium stearate as emulsifier and solubilizer is established.

The undesirably rapid reaction which ensues between benzoyl peroxide and ferrous iron, as in Experiment I, is effectively controlled by holding a large part of the ferrous iron in the water phase in the form of the stable water soluble pyrophosphate complex,[10] $Fe_2(P_2O_7)_3^{-8}$. The effect of the addition of sodium pyrophosphate on the reaction is to be seen by comparing the results of Experiment II with those of Experiment IV given in Fig. 1. The experiments were identical except that in Experiment IV there was added an amount of sodium pyrophosphate 50% in excess of that required to hold all the ferrous iron in the pyrophosphate complex. The data show that, although the total amounts of reaction in the experiments are comparable, for Experiment IV the reaction between the benzoyl peroxide and ferrous iron proceeded at a more moderate rate and continued over a longer period of time.

The behavior exhibited by the reaction mixture of Experiment IV suggests that it would be capable of satisfactory polymerization initiation, a fact which is borne out by experience. However, the characteristics of the reaction between benzoyl peroxide and ferrous iron can be further improved by including in the system a means for generating ferrous iron as it is needed during the course of the reaction, and thus eliminating the need for a large water phase reservoir of ferrous iron. The water phase reduction of ferric iron by sorbose accomplishes this task and makes up the remainder of the "Redox" cycle, which will now be considered. First it should be noted that the behavior of ferric iron is quite similar to that of ferrous iron with respect to its solubilization in the organic phase of the emulsion as ferric stearate and its ability to form the stable water soluble pyrophosphate complex,[10] $Fe_2(P_2O_7)_3^{-6}$. Two experiments were performed which indicate the characteristics of the reaction between sorbose and ferric iron. In Experiment V, equivalent amounts of ferric iron and sorbose were permitted to react in a single phase water system containing sodium stearate and so-

(10) Freed and Kasper, THIS JOURNAL, **52**, 2632 (1930); Pascal, *Ann. chim. phys.*, [8] **16**, 359 (1909).

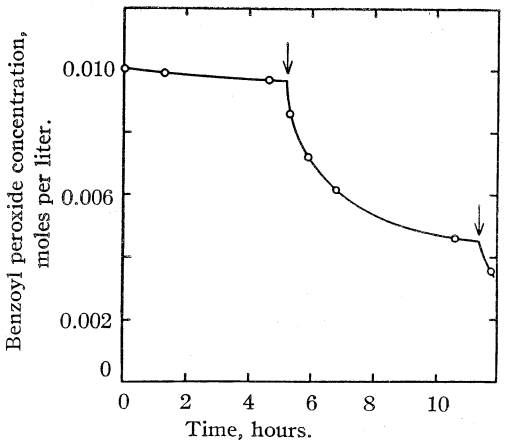

Fig. 2.—Peroxide–ferrous iron system with cationic emulsifier; soap added at times indicated by arrows.

dium pyrophosphate. (The composition of this reaction mixture is close to that of the water phase of a polymerization emulsion.) Experiment VI differed from Experiment V by the inclusion of a chloroform layer and the introduction of ferric iron as ferric stearate dissolved in the chloroform. The data for these experiments appear in Fig. 3. Both of these experiments show that the reaction between sorbose and ferric iron proceeds at a rate which is commensurate with the rate observed for the reaction between benzoyl peroxide and ferrous iron in the presence of pyrophosphate. The second of these two experiments demonstrates in particular the ability of the ferric iron to transfer from the organic to the water phase and to engage in the reaction with sorbose in an emulsion medium.

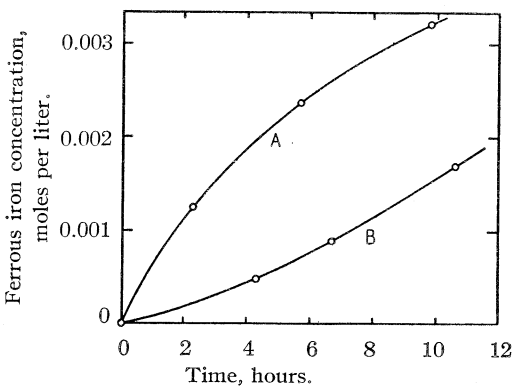

Fig. 3.—Sorbose–ferric iron systems: curve A, aqueous system; curve B, emulsion system.

With experimental verification of each step in the proposed "Redox" cycle completed, Experiment VII, involving the entire monomer free "Redox" system, was next considered. The reaction mixture of this experiment consisted of equal volumes of a chloroform phase, containing benzoyl peroxide and ferric stearate, and a water phase, containing sorbose, sodium stearate, and sodium pyrophosphate. The decomposition of benzoyl peroxide obtained in this experiment was moderate and uniform over an extended period, as shown by the data of Fig. 4. The desirability of this system is confirmed by its highly successful performance as a polymerization initiator.[9]

Two additional experiments involved interrupting certain steps in the "Redox" cycle to show that such interruptions result in almost complete breakdown of the mechanism leading to the decomposition of the benzoyl peroxide. Experiment VIII was equivalent to Experiment

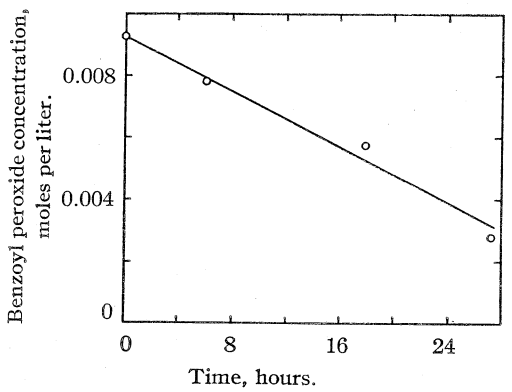

Fig. 4.—Peroxide decomposition for complete "Redox" system.

VII except that the pyrophosphate was eliminated. While this omission does not prevent the benzoyl peroxide–ferrous iron reaction from occurring, it renders difficult the transference of ferric iron from the organic to the water layer. The results of this experiment showed that, although some benzoyl peroxide did decompose, the rate of the decomposition was considerably reduced as compared with Experiment VII. Notwithstanding the small amount of benzoyl peroxide decomposition which occurred, the results are significant for the omission of the pyrophosphate does not positively assure the absence of small amounts of ferric iron in the water phase.

Experiment IX was also similar to Experiment VII, except that the reaction mixture initially contained a cationic emulsifying agent, benzyltrimethylammonium hydroxide, in place of sodium stearate. Here the only restriction placed on the system was to prevent the transfer of the ferrous iron from the water phase into the organic phase. The data for this experiment, appearing in Fig. 5, show that in the initial period no benzoyl peroxide decomposition occurred, even though the unrestricted sorbose–ferric iron reaction built up an appreciable ferrous iron concentration in the aqueous phase. At the end of 3.1 hours an amount of sodium stearate equivalent to 10% of the ferric iron originally present was added. Reaction immediately took place, giving rise to an abrupt drop in the benzoyl peroxide

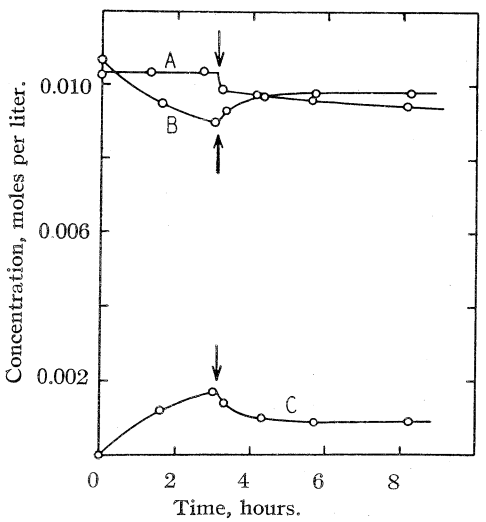

Fig. 5.—Peroxide–ferric iron–sorbose–pyrophosphate system with cationic emulsifier; soap added at time indicated by arrows: curve A, peroxide concn.; curve B, ferric iron concn.; curve C, ferrous iron concn.

concentration and an accompanying decrease in the ferrous iron concentration and increase in the ferric iron concentration. Following these adjustments the system approached a steady state in which the benzoyl peroxide concentration continued to decline at a slow rate while the ferrous and ferric iron concentrations became constant. This behavior can be readily interpreted in terms of the proposed "Redox" cycle. For given concentrations of benzoyl peroxide and sorbose, the rates of the various reactions will depend primarily upon the concentrations of the ferrous and ferric iron. But since the reaction which produces ferrous iron consumes ferric iron, and vice versa, it is obvious that the reaction system will approach a steady state in which the rates of the benzoyl peroxide–ferrous iron and the sorbose–ferric iron reactions become equal and the concentrations of the ferrous and ferric iron become constant.

## Summary

A mechanism is proposed for the reduction activation of polymerizations in emulsion systems. It is found that ferrous iron, solubilized in the oil phase as the stearate, promotes the decomposition of benzoyl peroxide into free radicals which are capable of initiating polymerization. In this process the ferrous iron is oxidized to the ferric form which is subsequently transferred to the aqueous phase where it exists as a pyrophosphate complex. The ferric iron is then reduced by an appropriate water soluble reducing agent such as sorbose. The reduced ferrous iron is ultimately transferred back to the oil phase to resume the cycle.

Sodium stearate is used as an emulsifying agent, but it does more than promote emulsification since it also renders the iron salts oil soluble. Omitting any of the reagents mentioned above or replacing the soap by a cationic emulsifying agent which is incapable of solubilizing the iron in oil, disrupts the smooth operation of the cycle. The net result of the entire cycle is the reduction of organic peroxides into free radicals and acid ions by a reducing sugar with iron serving as the effective intermediary.

# Absorption Spectra of Steroid–Antimony Trichloride Reaction Products[1]

BY ALEXANDER MUELLER

It has been reported by numerous workers that sterols give color reactions with various reagents.[2] The employment of antimony trichloride has been shown to give a greater specificity for quantitative determinations.[3] Examinations in this laboratory[4,5] have revealed that the spectra of the colors developed with the widely used antimony trichloride reagent are highly characteristic and have reasonably high extinction coefficients with magnitudes at specific wave length maxima directly related to the structure of the steroid molecule. Measurements on thirty-four steroids, mostly cholesterol derivatives, to confine the study to a homologous series, are reported in this communication. The interrelationships between molecular groupings and resulting spectra are summarized and the applicability of the measurements in characterization of molecular structure is indicated.

## Experimental

A 1-ml. aliquot of the steroid[6] solution in purified chloroform was pipetted into a 25-ml., glass-stoppered cylinder, 10 ml. of antimony trichloride reagent[7] added, and the reaction mixture thoroughly shaken. The solution is poured into one pair of matched 10-mm. corex cells while the second or reference cell is filled with 1 ml. of chloroform and 10 ml. of antimony trichloride reagent. The absorption spectra were determined with a Beckman spectrophotometer, Model DU, using an incandescent lamp as the source of illumination and varying the slit width to accord with the region of the spectrum examined.

Throughout the measurements, reaction periods were determined with a stopwatch and optimum concentrations of steroid solutions were ascertained as the result of adjustments in preliminary trials. For additional manipulative details see reference.[5] From the optical densities determined for the solutions at the respective time intervals and wave length maxima, corresponding extinction coefficients, $E(1\%, 1\text{ cm.})$, were calculated. The values are summarized in the accompanying table and graphs.

## Discussion

The compounds in Table I are arranged according to the following order: (1) saturated hydrocarbons with one or more substituents (excepting hydrogen) on Rings I and II; (2) one double bond with no substituents on Rings I and II; (3) one double bond with one substituent (such as hydroxy, keto, ester or halogen) on Rings I and II; (4) one double bond with two substituents on Ring I or II; (5) two double bonds with no substituents on Ring I or II; (6) two double bonds with one substituent on Ring I or II; (7) unclassified (calciferol and sex hormones).

Comparing the magnitude of absorption intensities of the various antimony trichloride reaction products, calciferol (Fig. 8), with an exo-

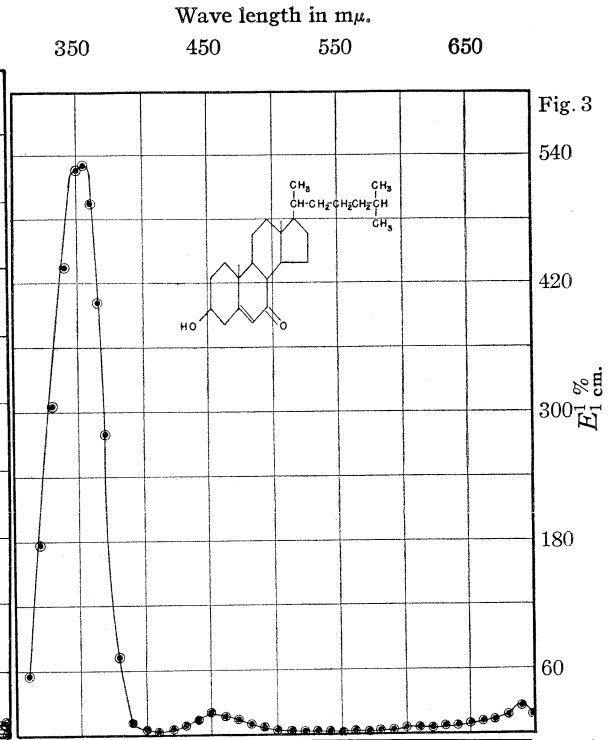
(6) The compounds examined were prepared in the Fine Chemicals Division of the R. P. Scherer Corp., and the purity verified by elemental analysis, melting point, optical rotation and ultraviolet absorption spectra.



(7) The solvent and reagent were prepared according to D. T. Ewing, G. V. Kingsley, R. A. Brown and A. D. Emmett, *Ind. Eng. Chem. Anal. Ed.*, **15**, 301 (1943).

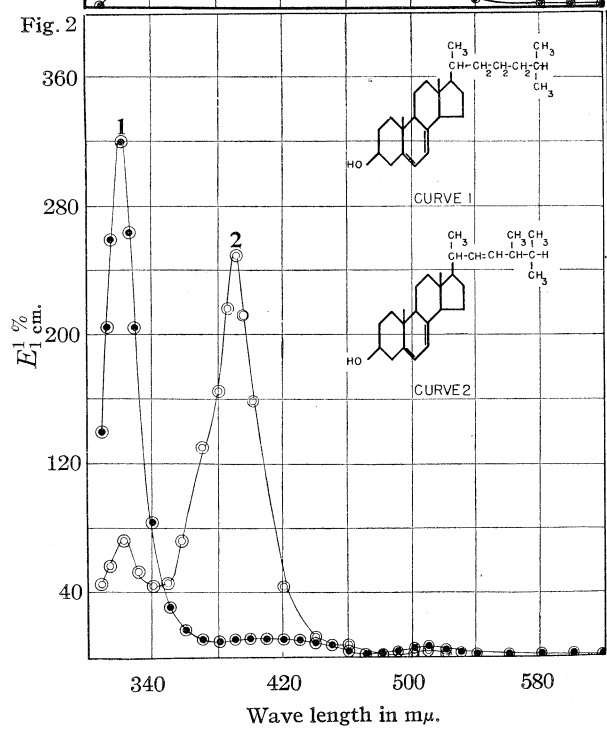


TABLE I

ABSORPTION PROPERTIES OF VARIOUS STEROID–ANTIMONY TRICHLORIDE REACTION PRODUCTS

| Compound | $\lambda_{max.}$, mμ | $E$ (1%, 1 cm.) | Time | Remarks |
|---|---|---|---|---|
| Cholestanone | 320 | 2.0 | 19 hr. | Slight maximum; continues to rise |
| Coprostanone | 320 | 24.3 | 44 hr. | Maxima develop very slowly, and are not sharp |
| | 415 | 6.0 | 20 hr. | |
| | 510 | 3.0 | 44 hr. | |
| 7-Keto-cholestanyl acetate | 355 | 11.4 | 1 hr. | Stable from 60 to 80 minutes |
| 6-Keto-cholestanyl acetate | 320 | 1.8 | 2 hr. | Very low absorption |
| | | 3.2 | 24 hr. | |
| 5,6-Dibromide cholestanyl acetate | 322 | 45.0 | 2 hr. | All maxima continue to rise |
| | 397 | 13.0 | 2 hr. | |
| | 490 | 6.0 | 2 hr. | Absorption similar to cholesteryl-α-oxide acetate (see Fig. 7) |
| $\Delta^4$-Cholestene | 320 | 5.0 | 30 min. | Absorption increases slowly |
| | 322 | 36.3 | 24 hr. | |
| | 424 | 19.5 | 30 min. | At 24 hr. 424 mμ max. has shifted to 450 mμ, and new max. is present at 525 mμ |
| | 450 | 15.0 | 24 hr. | |
| | 525 | 17.7 | 24 hr. | |
| $\Delta^5$-Cholestene | 322 | 7.0 | 30 min. | Absorption increases slowly |
| | 316 | 45.0 | 20 hr. | |
| | 420 | 24.0 | 30 min. | Both maxima are shifted at 20 hr. |
| | 430 | 33.0 | 20 hr. | |
| Cholesterol | 322 | 135.0 | 90 min. | Figure 1 (yellow color) |
| | 360 | 103.0 | 25 min. | |
| | 420 | 88.0 | 40 min. | |
| | 505 | 90.0 | 120 min. | |
| $\Delta^4$-Cholestenol-7 (pseudo-cholesterol) | 322 | 147.0 | 90 min. | Similar to cholesterol |
| | 360 | 106.0 | 25 min. | |
| | 420 | 45.0 | 40 min. | |
| | 505 | 36.0 | 120 min. | |
| Cholesteryl acetate | 322 | 107.0 | 90 min. | Similar to cholesterol |
| | 360 | 74.0 | 25 min. | |
| | 420 | 69.0 | 40 min. | |
| | 505 | 55.0 | 120 min. | |
| Cholesteryl benzoate | 322 | 95.0 | 90 min. | Similar to cholesterol |
| | 360 | 68.0 | 20 min. | |
| | 420 | 70.0 | 20 min. | |
| | 505 | 60.0 | 120 min. | |
| Cholesteryl chloride | 322 | 95.0 | 90 min. | Similar to cholesterol except reaction rate. $E$ (1%, 1 cm.) values continue to rise |
| | 360 | 49.0 | 35 min. | |
| | 420 | 35.0 | 35 min. | |
| | 505 | 87.0 | 90 min. | |
| Cholesteryl methyl ether | 322 | 114.6 | 90 min. | Similar to cholesterol except time reaction rate |
| | 360 | 69.4 | 40 min. | |
| | 420 | 63.6 | 60 min. | |
| | 505 | 82.2 | 120 min. | |
| *i*-Cholestanyl-6-methyl ether | 322 | 108.0 | 90 min. | Similar to cholesterol except time reaction rate |
| | 360 | 50.0 | 60 min. | |
| | 420 | 46.0 | 120 min. | |
| | 505 | 80.0 | 90 min. | |
| Cholesteryl-α-oxide acetate | 322 | 68.0 | 18 hr. | Figure 7. Maxima continue to rise |
| | 397 | 53.0 | 18 hr. | |
| | 480 | 28.0 | 18 hr. | |
| Cholestenone | 318 | 61.0 | 35 min. | Figure 4. Stable, then rises and shifts to 320 mμ, continues to rise |
| | 320 | 88.0 | 4 hr. | |
| | 320 | 116.0 | 24 hr. | |
| | 375 | 68.0 | 24 hr. | First observed at 24 hours |
| | 530 | 25.0 | 4 hr. | Maximum rises, then drops, then rises again |
| | 530 | 22.0 | 6 hr. | |
| | 530 | 40.0 | 24 hr. | Maximum shifts to 520 mμ at 24 hr. |
| | 650 | 7.0 | 4 hr. | |
| | | 12.0 | 6 hr. | Broad maximum, rises slowly shifts to 658, mμ |
| | | 15.0 | 24 hr. | |
| β-Sitosterol | 322 | 109.0 | 105 min. | Similar to cholesterol except time reaction rate |
| | 360 | 87.0 | 30 min. | |
| | 420 | 98.0 | 45 min. | |
| | 505 | 83.0 | 120 min. | |
| Stigmasteryl acetate | 322 | 48.0 | 30 min. | Similar to cholesterol except a marked change in time reaction rate and appearance of new maxima at 24 hours (green color) |
| | 360 | 72.0 | 20 min. | |
| | 420 | 114.0 | 50 min. | |
| | 505 | 67.0 | 120 min. | |
| | 640 | 30.0 | 24 hr. | |
| | 720 | 23.0 | 24 hr. | |
| 7-Keto-cholesterol | 355 | 533.0 | 50 min. | Figure 3 |
| | 460 | 22.0 | 2 hr. | |
| | 690 | 24.0 | 2 hr. | |
| 7-Keto-cholesteryl acetate | 355 | 593.0 | 50 min. | Similar to 7-keto-cholesterol |
| | 457 | 29.6 | 2 hr. | |
| | 695 | 25.6 | 2 hr. | |
| 7-Keto-cholesteryl benzoate | 355 | 450.0 | 50 min. | Similar to 7-keto-cholesterol except no 460 mμ maximum |
| | 685 | 36.0 | 90 min. | |
| 7-Hydroxy- | 590 | 159.0 | 1 min. | In usual $SbCl_3$ concentration |
| cholesteryl | 590 | 132.0 | 1 min. | In one-half usual $SbCl_3$ concentration |
| benzoate | 460 | 132.0 | 1 min. | In one-half usual $SbCl_3$ concentration |
| Cholesteryl dibenzoate | 590 | 138.0 | 1 min. | Figure 5. Similar to 7-hydroxycholesteryl benzoate (blue color) |
| | 460 | 125.0 | 1 min. | |
| | 590 | 181.0 | 5 min. | In one-half usual $SbCl_3$ concentration |
| $\Delta^3$, $\Delta^5$-Cholesterilene | 322 | 127.0 | 3 hr. | Figure 6 |
| | 360 | 141.0 | 5 min. | |
| | 420 | 268.0 | 3 min. | |
| | 500 | 100.0 | 3 hr. | |
| 7-Keto-cholesterilene | 355 | 655.0 | 1 min. | Stable from 1 to 25 minutes |
| | 450 | 11.0 | 2 hr. | Similar to 7-keto-cholesterol (see Fig. 3) |
| 6-Bromo-7-ketocholesterilene | 320 | 225.0 | 1 min. | Stable from 1 to 60 minutes (introduction of bromine changes entire character of absorption curve) |
| | 388 | 30.0 | 60 min. | |
| | 700 | 26.0 | 5 hr. | |
| | 700 | 68.0 | 22 hr. | |
| 7-Dehydro-cholesterol | 322 | 320.0 | 8 min. | Figure 2. The 322 mμ max. is stable from 4 to 10 min., then drops slowly |
| | 520 | 7.0 | 8 min. | |
| Ergosterol | 322 | 63.0 | 5 min. | Figure 2. The 393 mμ max. is stable from 5 to 10 min., then drops slowly |
| | 393 | 250.0 | 5 min. | |
| | 505 | 12.4 | 5 min. | |
| Androsterone | 320 | 110.0 | 48 hr. | Figure 9. Absorption rises very slowly |
| | 388 | 100.0 | 48 hr. | |

Fig. 12.—Absorption curves of testosterone– and $\Delta^5$-androstenediol-(3$\beta$,17$\alpha$)–antimony trichloride reaction products: 1, testosterone at one to five minutes; 2, testosterone at two to two and one-half hours; 3, $\Delta^5$-androstenediol-(3$\beta$,17$\alpha$) at fifty to sixty minutes.

cyclic, triply conjugated system, has the highest value. On the other hand, estrone (Fig. 11) with an endocyclic, triply conjugated system in Ring I has a contrastingly low absorption intensity. In general, the type of linkages which produces the highest absorption are the conjugated double bond, and the double bond in conjugation to a keto, hydroxy, or other polar grouping. Compounds having both endocyclic and exocyclic unsaturation produce high extinction coefficients (see 7-keto-cholesterilene, and 7-keto-cholesterol (Fig. 3)). The influence of exocyclic changes have little effect in the absence of endocyclic unsaturation, while endocyclic unsaturation in the absence of exocyclic groupings produces a spectrum of rather high intensity (see cholesterilene, Fig. 6). Generally, in a conjugated double bond system wherein there is one center of electronic interaction a single narrow absorption band is exhibited while a system having two or more locations of electron concentration exhibits more than one maximum. Comparing the antimony trichloride spectra of 7-dehydrocholesterol and ergosterol (Fig. 3) the difference apparently is due to the side chain double bond of ergosterol. 7-Dehydrocholesterol gives a single strong maximum, due to the single conjugated system in Ring II, while ergosterol with electronic interaction between the side chain and Ring II give two prominent bands. Conversely, calciferol (Fig. 8) with a double bond in the side chain gives a single absorption maximum. Possibly there is no interaction between the semicyclic, triply conjugated system in Ring II and the side chain double bond of calciferol. An interesting analogy exists in the comparison of the ultraviolet absorption of ergosterol and calciferol.[8]

(8) H. Dannenberg, *Abhandl. preuss. Acad. Wiss., Math. naturw. Klasse*, No. 21 (1939).

The nature of antimony trichloride reaction on a sterol was assumed (in the initial stages of this work) to be one of dehydration with subsequent shifting of double bonds, and possible introduction of an additional double bond. Preliminary experiments on the isolated reaction products of cholesterol, however, seem to indicate a cyclization product, probably forming a dicyclopentanoperhydrophenanthrene entity. A continuation of studies on this phase, as well as systematic investigations of a series are necessary before definite conclusions may be drawn.

**Acknowledgment.**—The writer wishes to express his appreciation to Sereck H. Fox for his criticism of this manuscript, and is very grateful to Gerard A. Fleisher for his interest and invaluable suggestions as well as for supplying most of the compounds investigated.

## Summary

The absorption spectra data of the antimony trichloride reaction products of thirty-four steroids are presented. Absorption curves are shown for fourteen representative compounds in the region from 310 to 700 mμ. The data indicate that the spectra are characteristic for specific molecular groupings or combination of groupings in the molecule. Generalizations of the influence of various groupings in the steroid molecule on the resulting spectra are summarized. The analysis of the data obtained from the spectra would indicate that the latter are particularly helpful in following the progress or change in a molecule during synthesis, degradation, or in its quantitative analysis for purity and concentration.

# The Microwave Spectra of $CH_3NCS$ and $CH_3SCN$[1]

BY C. I. BEARD[2] AND B. P. DAILEY[3]

## Introduction

The use of microwave absorption spectroscopy in determining the structure of linear and symmetric top molecules is now well established. The application to asymmetric molecules, although of much importance in broadening the scope of the techniques, has been very slow because of the complexity of the spectra which are observed. These complexities arise not only from the pattern (or lack of one) of rotational energy levels for the asymmetric rotor, but from nuclear quadrupole coupling, rotational-vibrational interaction, internal free or hindered rotation, and from experimental difficulties in observing spectra in the microwave region. All of these complications, except the last, are potential sources of useful information provided an analysis can be carried out. The natural procedure would seem to be to select molecules for study, to begin with, which would exhibit only one or two of these complications. As an example sulfur dioxide,[4] for whose spectrum a preliminary analysis has appeared, has no quad-

rupole interactions (except in molecules involving $S^{33}$), no internal rotation, and possesses a readily observable spectrum in the microwave region.

In this paper results of the investigation of the microwave spectra of the slightly asymmetric tops, methyl isothiocyanate ($CH_3NCS$) and methyl thiocyanate ($CH_3SCN$) will be presented. These are members of an interesting class of asymmetric molecules possessing internal rotating groups. Other members of this class whose microwave spectra have been studied are $CH_3NO_2$,[5] $CH_3NH_2$,[6] and $CH_3OH$.[6,7] $CH_3NCS$ would seem to be a favorable case for analysis since it has an easily observable spectrum in a convenient frequency range, has a negligible quadrupole coupling, and should be only slightly asymmetric. In addition the approximate dimensions of the NCS group are known from the microwave study of HNCS.[8]

## Experimental Details

The $CH_3NCS$ absorption spectrum has been studied in the frequency range from 20 to 30 kmc. using the Stark modulation spectrometer previously described.[9] The apparatus, shown in block diagram form in Fig. 1, used a waveguide absorption cell ten feet in length with a 100 kc./s. square wave Stark field. The $CH_3NCS$ was an Eastman Kodak Co. product used without further purification.

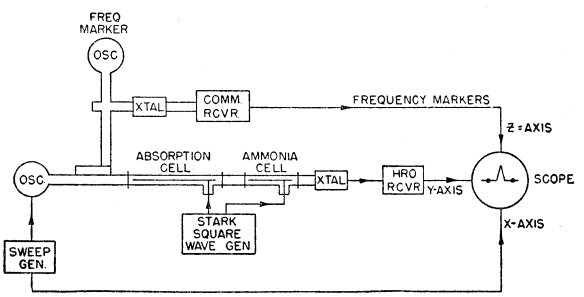

Fig. 1.—Arrangement of components in the microwave spectrometer.

With 100 v./cm. Stark field modulation and a vapor pressure ~0.05 mm. more than 29 $CH_3NCS$ absorption lines were found in the region from 19,440 to 29,800 mc./s. (Fig. 2 and Table I). Frequencies in most cases were determined using lines of the $N^{14}H_3$ and $N^{15}H_3$ inversion spectrum as secondary standards, measuring frequency differences by the method of Good and Coles.[10]

TABLE I

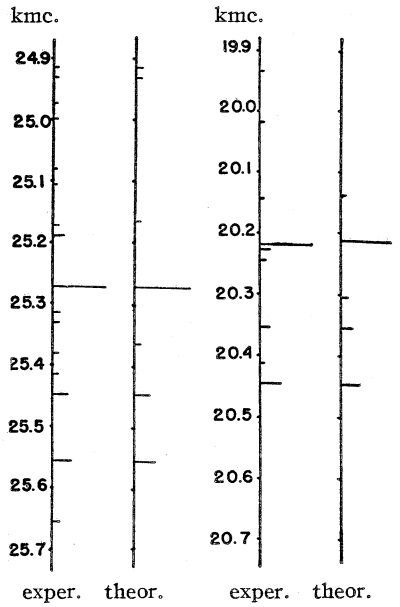
ASSIGNMENT OF LINES IN THE ROTATIONAL SPECTRUM OF $CH_3NCS$

| $\nu$ mc. | Relative intensity | Assignment |
|---|---|---|
| | | $J = 3 \rightarrow 4$ transition |
| 19700* | 5 | $CH_3NCS^{34}$; degenerate line, ground state |
| 19929* | 1 | $CH_3NCS^{34}$; degenerate line, J |
| 20020* | <1 | |
| 20140 | 10 | $CH_3NCS$: $+3_{1,3} \rightarrow 4_{1,4}$ ground state |
| 20216 | 100 | $CH_3NCS$; degenerate line, ground state |
| 20230 | <1 | |
| 20241 | 7 | $CH_3NCS$; degenerate line, E ? |
| 20350 | 20 | $CH_3NCS$; degenerate line, D |
| 20413 | <1 | |
| 20443 | 40 | $CH_3NCS$; degenerate line, J |
| | | $J = 4 \rightarrow 5$ transition |
| 24143* | <1 | $C^{13}H_3NCS$; degenerate line, ground state |
| 24609* | 5 | $CH_3NCS^{34}$; degenerate line, ground state |
| 24824 | 1 | |
| 24910 | 2 | $CH_3NCS^{34}$; degenerate line, J |
| 24930* | <1 | $CH_3NCS^{33}$; degenerate line, ground state |
| 24971* | 1 | |
| 25002* | <1 | $CH_3NC^{13}S$; degenerate line, ground state |
| 25077* | 1 | |
| 25100* | <1 | |
| 25161 | <1 | |
| 25195 | 10 | $CH_3NCS$; $4_{1,4} \rightarrow 5_{1,5}$, ground state |
| 25269 | 100 | $CH_3NCS$; degenerate line, ground state |
| 25306 | 7 | $CH_3NCS$; degenerate line, E ? |
| 25333 | 10 | $CH_3NCS$; $4_{1,3} \rightarrow 5_{1,4}$ ground state |
| 25390 | <1 | |
| 25409* | 1 | |
| 25442 | 25 | $CH_3NCS$; degenerate line, D |
| 25550 | 40 | $CH_3NCS$; degenerate line, J |
| 25653* | <1 | $CH_3NCS$; $4_{1,3} \rightarrow 5_{1,4}$, J |
| | | $J = 5 \rightarrow 6$ transition |
| 29700 | | $CH_3NCS^{34}$; degenerate line, ground state |

The frequencies of the lines marked by asterisks in Table I were determined only by cavity wavemeter readings. The approximate relative intensities reported represent observed signal strengths at the same power level incident on the terminal crystal detector. These relative intensities are comparable only within each group of lines and are not true relative intensities since they neglect the dependence upon the Stark effect of each line. Furthermore saturation effects tend to increase the apparent relative intensity of the weaker lines.

## Theoretical Spectrum

The analysis of the observed spectrum may be most conveniently discussed by setting up a probable structure for the molecule, calculating a theoretical spectrum and comparing with observed results. In view of the microwave data on HNCS, $CH_3NCS$ can with some confidence be pictured as being a resonance hybrid of the three structures shown in Fig. 3. If it is assumed that the structure of the NCS group suffers no major changes in



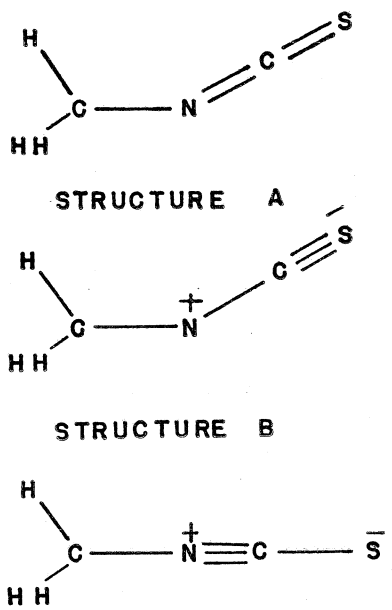


Fig. 2.—The experimental and calculated spectrum of $CH_3NCS$ in the microwave region.

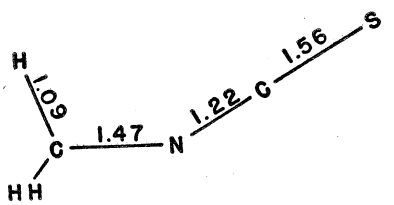
going from the acid to the ester, and the dimensions of the methyl group are taken from the recent accurate work on the methyl halides[11] only a value for the $CH_3$–N–C angle need be chosen for a complete molecular model. For a first approximation the H–N–C angle could be used although it has been determined only roughly. The N–C distance in HNCS indicates a predominance of the structure involving the N≡C bond and suggests



Structure C.

Fig. 3.—Resonating structures for $CH_3NCS$.

(11) J. W. Simmons, W. Gordy and A. G. Smith, *Phys. Rev.*, **74**, 243 (1948).

that an angle greater than the average for the resonating structures, 130°, may be the correct one. For the present purpose an angle of 142° has been chosen. The influence of hyperconjugation on the $CH_3$–$^+N{\equiv}C$–$S^-$ structure might lengthen the N–C bonds and shorten the $CH_3$–N bond but should leave the angle unchanged. The structure illustrated in Fig. 4 should roughly approximate the true molecular configuration and permit calculation of a theoretical spectrum correct in broad outline.

H–C–N angle 109°
C–N–C angle 142°

Fig. 4.—Approximate molecular configuration of $CH_3NCS$:

| | |
|---|---|
| $I_A$, $10.72 \times 10^{-40}$ g. cm.$^2$ | $A$, 2.61 cm.$^{-1}$ |
| $I_B$, 329.34 | $B$, 0.08498 |
| $I_C$, 334.85 | $C$, 0.08358 |

Using the formula given by Mecke[12] for the energy levels of a slightly asymmetric rotor (which, in view of the near degeneracy of the rotational constants $B$ and $C$, should apply in this case)

$$F(J,K)\ \text{cm.}^{-1} = \tfrac{1}{2}(B + C)J(J + 1) + [A - \tfrac{1}{2}(B + C)]K^2$$

where $A = h/8\pi^2cI_A$, $B = h/8\pi^2cI_B$, $C = h/8\pi^2cI_C$, the following formulas for observed frequencies may be obtained: For

$$\Delta J = +1,\ \Delta K = 0$$
$$\nu\text{cm.}^{-1} = (B + C)(J + 1)$$

For

$$\Delta J = 0,\ \Delta K = +1$$
$$\nu\text{cm.}^{-1} = [A - \tfrac{1}{2}(B + C)(2K + 1)$$

Using the calculated rotational constants based on the approximate molecular model, spectral lines would be predicted at the frequencies given in Table II. An inspection of this table permits the widely spaced groups of lines at 20,500 and 25,000

TABLE II

CALCULATED ROTATIONAL SPECTRUM FOR $CH_3NCS$ CONSIDERED AS A NEARLY SYMMETRIC ROTOR

| $J$ | $K$ | $J'$ | $K'$ | $\nu$, cm.$^{-1}$ | $\nu$, mc./s. |
|---|---|---|---|---|---|
| 0 | 0 | 1 | 0 | 0.16856 | 5,053 |
| 1 | 1 | 2 | 1 | .33712 | 10,106 |
| 2 | 2 | 3 | 2 | .50568 | 15,159 |

| 1 | 1 | 1 | 2 | 7.5772 | 227,148 |

(12) R. Mecke, *Z. Physik*, **81**, 313 (1933).

mc. to be identified as arising from the parallel type transitions $J = 3 \rightarrow 4$ and $J = 4 \rightarrow 5$. Detailed analysis to be presented later indicates that the lines at 29,800 are the beginning of the $J = 5 \rightarrow 6$ group. On the basis of these simple considerations, however, each of these transitions should consist of but a single line. Since there are more than 19 components in the $J = 4 \rightarrow 5$ group alone some explanation must be found for the extra lines.

### Removal of Degeneracies

Considering the various complicating factors in turn, the removal of degeneracies known to exist in the pattern of symmetric rotor energy levels by the asymmetry of the molecule and by the modulating field will be taken up first. Each $J$ level in the symmetric rotor is made up of $2J + 1$ degenerate levels corresponding to the individual values of $K$. In turn each $JK$ level is made up of $2J + 1$ levels, degenerate in the absence of an external field, corresponding to the individual values of the quantum number $M$. In the specific case of a molecule having the structure indicated in Fig. 4 the $K$ degeneracy is at least partially removed by the molecular asymmetry. The transition frequencies for such an asymmetric rotor have been calculated using third order perturbation theory and the coefficients tabulated by King, Hainer and Cross,[13] and are given in Table III. The single line predicted above for the $J = 4 \rightarrow 5$ transition, for example, has been replaced by a pattern of three lines. The lines corresponding to (in the KHC notation) the $4_{1,4;-3} \rightarrow 5_{1,5;-4}$ and $4_{1,3;-2} \rightarrow 5_{1,4;-3}$ transitions have split, not quite symmetrically, some 100 mc. away, on either side of the degenerate line.

TABLE III

CALCULATED ROTATIONAL SPECTRUM FOR $CH_3NCS$ CONSIDERED AS AN ASYMMETRIC ROTOR

| Transition | $\nu$, mc. |
|---|---|
| $3_{0,3;-3} \rightarrow 4_{0,4;-4}$ | 20,215 |
| $3_{1,3;-2} \rightarrow 4_{1,4;-3}$ | 20,131 |
| $3_{1,2;-1} \rightarrow 4_{1,3;-2}$ | 20,297 |
| $3_{2,2;0} \rightarrow 4_{2,3;-1}$ | 20,215 |
| $3_{2,1;+1} \rightarrow 4_{2,2;0}$ | 20,216 |
| $3_{3,1;+2} \rightarrow 4_{3,2;+1}$ | 20,215 |
| $3_{3,0;+3} \rightarrow 4_{3,1;+2}$ | 20,215 |
| $4_{0,4;-4} \rightarrow 5_{0,5;-5}$ | 25,262 |
| $4_{1,4;-3} \rightarrow 5_{1,5;-4}$ | 25,158 |
| $4_{1,3;-2} \rightarrow 5_{1,4;-3}$ | 25,364 |
| $4_{2,3;-1} \rightarrow 5_{2,4;-2}$ | 25,265 |
| $4_{2,2;0} \rightarrow 5_{2,3;-1}$ | 25,266 |
| $4_{3,2;+1} \rightarrow 5_{3,3;0}$ | 25,265 |
| $4_{3,1;+2} \rightarrow 5_{3,2;+1}$ | 25,265 |
| $4_{4,1;+3} \rightarrow 5_{4,2;+2}$ | 25,265 |
| $4_{4,0;+4} \rightarrow 5_{4,1;+3}$ | 25,265 |

Since the spectrometer employs an applied electric field for modulation, the spectrum actually observed is complicated by the presence of lines corresponding to the individual $M$ values. The experimental arrangement is such that the electric radiation vector and the applied electric field are parallel (except for negligible fringing effects near the edges of the waveguide absorption cell) and the selection rule $\Delta M = 0$ is obeyed. Analysis of this pattern of Stark components would allow calculation of the component of dipole moment along the approximate figure axis of the molecule but unfortunately the complexity of the not very intense spectrum was such that an analysis has not been carried out. In the reported spectrum Stark components have been omitted by eliminating all lines whose frequency varied with the electric field.

### Centrifugal Distortion

The foregoing calculations were based on the assumption that the molecule was rigid. The actual molecule is subject to centrifugal distortion which will have an effect on the pattern of rotational energy levels. Slawsky and Dennison[14] give an expression for the energy levels of a non-rigid symmetric rotor

$$F(J,K) = BJ(J+1) + (A-B)K^2 - D_J J^2(J+1)^2 - D_{JK}J(J+1)K^2 - D_K K^4$$

which leads to an expression

$$\nu = 2B(J+1) - D_J(J+1)^3 - D_{\bar{J}}(J+1) + D_{JK}K^2(J+1)$$

for the frequencies of the rotational transitions Slawsky and Dennison give the following calculated values of the constants for the case of $CH_3Cl$

$$D_J = 0.0036 \text{ mc/s.}$$
$$D_{\bar{J}} = 0.0414 \text{ mc/s.}$$
$$D_{JK} = 0.4020 \text{ mc/s.}$$

Gordy, Simmons, and Smith[9] report an experimental value of $D_{JK}$ for $CH_3Cl$ of 0.19 mc. The term involving $D_{JK}$ is much the largest and should lead to a separation between the $K = 0$ and $K = 4$ components of the degenerate transition of as much as 15 mc. In the experimental spectrum there is considerable evidence of fine structure on the high frequency side of the degenerate line but interference from the pattern of Stark components has prevented any accurate measurement of this centrifugal splitting. The term involving $D_J$ will cause deviations from the frequencies predicted using a linear relation between $\nu$ and $J(J+1)$. The example of $CH_3Cl$ makes it seem probable that this effect would be unobservable with the precision of frequency measurement available in this study.

### Excited Vibrational States

The interaction of vibration and rotation has so far been neglected. The rotational constant $B$ (and $A$ and $C$ as well) actually has different values in the different vibrational states. This de-

(13) G. W. King, R. M. Hainer and P. C. Cross, *J. Chem. Phys.*, **11**, 27 (1943).

(14) Z. I. Slawsky and D. M. Dennison, *J. Chem. Phys.*, **7**, 509 (1939).

pendence of $B$ on the vibrational quantum numbers is indicated by the following formula, taken from Herzberg[15] where the $\alpha_i$ are small compared

$$B_{[v]} = B_e - \sum_i \alpha_i^B (v_i + d_i/2)$$

to $B_e$, which is the rotational constant for the equilibrium position. $d_i$ is the degree of degeneracy of the vibration $v_i$. The summation extends over all vibrations. The constants $\alpha_i$ are usually positive for the non-degenerate vibrations of linear molecules, but may be positive or negative for the degenerate vibrations.

No complete vibrational study and resulting assignment of fundamentals has yet been published for $CH_3NCS$. However, Goubeau and Gott[16] have determined the stretching frequencies for the linear portion of the molecule and Eyster and Gillette[17] have made vibrational assignments for similar molecules including $CH_3NCO$. The approximate vibrational frequencies listed in Table IV should then be at least of the correct order of magnitude. The Boltzmann factors computed from these frequencies indicate roughly the expected ratio of relative intensities of spectral lines due to the same transition for molecules in the ground and excited vibrational states.

TABLE IV

APPROXIMATE VIBRATION FREQUENCIES FOR $CH_3NCS$

| Series | $CH_3NCO$ $\omega$ cm.$^{-1}$ | $CH_3NCS$ $\omega$ cm.$^{-1}$ | $CH_3NCS$ $e^{-h\nu/kT}$ |
|---|---|---|---|
| A | 870 | 850 | 0.0166 |
| B | 2232 | 2162 | < .0001 |
| C | 1412 | 1087 | .0052 |
| D | 353 | 300 | .2340 |
| E | 652 | 600 | .0550 |
| | 607 | 550 | .0699 |
| F | 2994 | 3000 | < .0001 |
| | 2951 | 2950 | < .0001 |
| G | 1453 | 1450 | .0009 |
| | | 1440 | .0009 |
| H | 1377 | 1375 | .0014 |
| I | 1181 | 1200 | .0030 |
| | 1107 | 1100 | .0049 |
| J | ? | 200 | .2982 |

The vibrations of series A correspond to $CH_3$–N stretching frequencies. Series B and C are stretching frequencies localized within the linear portion of the molecule. B is the N–C stretching and C the C–S stretching frequencies in $CH_3NCS$. The D vibration corresponds to the bending of the $CH_3$–N bond against the linear group. The E vibrations are the perpendicular bending vibrations of the linear group.

The vibrations F through H are the well known internal vibrations of the methyl group and the I vibrations correspond to the rocking frequencies of this group. The torsional oscillation frequency J requires further discussion.

## Internal Rotation

The features of the spectrum due to the internal rotation of the methyl group and isothiocyanate group independently about the molecular axis will depend upon the height of the barrier hindering the rotation. If the barrier is of a comparable (although probably somewhat smaller) magnitude to that in the roughly similar case of methanol[18] an appreciable number of molecules will occupy the first excited torsional vibration level. Indeed, if the figure 200 cm.$^{-1}$ for the height of this excited state above the ground level listed in Table IV is correct a line in the observed spectrum due to the second excited state might well appear. In methanol the ratio of populations for the ground state and first excited state of torsional vibration is 0.18; in the case of $CH_3NCS$ this ratio would probably be somewhat larger.

The torsional vibrational states, according to the analysis of the methyl alcohol problem presented by Koehler and Dennison,[18] are actually made up of a number of sublevels with a spread in energy which increases with the torsional vibration quantum number. In general there are three sublevels for each permitted $K$ value although certain degeneracies occur. For methyl alcohol the spread of the energy levels for the first excited state has been calculated to be 33 cm.$^{-1}$. Since this spread varies inversely with the barrier height an even wider separation of levels would be expected for $CH_3NCS$. It is difficult to predict whether the first excited torsional state will give rise to a single broad line in the pure rotation spectrum or will have a resolvable structure.

For low values of the barrier height, and in any case for torsional vibration states higher than the second or third, the internal rotation would be essentially free. If we apply the analysis of Koehler and Dennison[18] (which should fit only roughly because of the considerable asymmetry of the NCS group) the following expression for the frequencies of the lines in the $\Delta J = 0$ series may be used

$$\lambda = A_1 - B - 2BK + 2A_1K_1$$

$A_1$ is the rotational constant for the NCS group about the molecular axis (not the symmetry axis of the methyl group). Using the rotational constants given in Fig. 4 and a minimum value of $A_1$ of 3.0 cm.$^{-1}$ the frequencies for this series were calculated. All lie outside the experimental frequency range for this investigation.

A limit to the complexity introduced into the observed spectrum by excited vibrational states is set only by the available sensitivity of the spectrometer. If the observed spectrum is limited to those lines whose apparent intensity is at least

(15) G. Herzberg, "Infrared and Raman Spectra of Polyatomic Molecules," D. Van Nostrand Co., New York, N. Y., 1945, p. 370.

(16) J. Goubeau and O. Gott, *Ber.*, **73B**, 127 (1940).

(17) E. H. Eyster and R. H. Gillette, *J. Chem. Phys.*, **8**, 369 (1940).

(18) J. S. Koehler and D. M. Dennison, *Phys. Rev.*, **57**, 1006 (1940).

0.005 of that for the most intense line in the spectrum the Boltzmann factors listed in Table IV should permit selection of the vibrations whose first excited states might give rise to lines. On this basis the most intense of the excited vibration lines should be due to the torsional vibration J. Next most intense would be the line corresponding to the first excited state of the $CH_3$–N bending vibration, D. Following in order of intensity would be the second excited levels for these two vibrations and the first excited levels for the nearly degenerate bending modes of the NCS group, E. Finally a line due to the first excited level for the $CH_3$–N stretching vibration, A, might be seen. The $\alpha$'s for these vibrational states cannot be easily calculated so that the lines due to excited vibrational states must be identified from their intensities and from the change of intensity with temperature. The experimental measurement of temperature coefficients of intensity was made rather difficult by the small temperature range over which measurements could be made for this molecule and with the present equipment. The rough values obtained, however, definitely serve to establish several of the fairly intense lines as being due to excited vibrational states.

## Isotopic Spectra

There should be, of course, separate and easily resolvable microwave spectra for each of the different isotopic varieties of the $CH_3NCS$ molecule. The relative intensities of lines due to the more abundant naturally occurring $CH_3NCS$ molecules have been calculated and are given in Table V.

TABLE V

RELATIVE ABUNDANCE OF ISOTOPIC VARIETIES OF $CH_3NCS$

| Molecule | Relative abundance |
|---|---|
| $C^{12}H_3N^{14}C^{12}S^{32}$ | 100.00 |
| $C^{12}H_3N^{14}C^{12}S^{34}$ | 4.40 |
| $C^{12}H_3N^{14}C^{12}S^{33}$ | 0.76 |
| $C^{13}H_3N^{14}C^{12}S^{32}$ | 1.08 |
| $C^{12}H_3N^{14}C^{13}S^{32}$ | 1.08 |
| $C^{12}H_3N^{15}C^{12}S^{32}$ | 0.38 |

If the same range of relative intensities is used here as was proposed earlier in the discussion of excited vibrational states any or all of these molecules might give rise to observable spectra. It is even probable that for the molecule involving $S^{34}$ lines due to both the ground and excited vibrational states would be seen.

## Nuclear Quadrupie Coupling

Two of the nuclei which are concerned in the $CH_3NCS$ molecular species have nuclear quadrupole moments—$N^{14}$ and $S^{33}$. In the latter case the intensity of the main transition must be so low that the quadrupole fine structure would be unobservable. For $N^{14}$, intensities of the fine structure components might be sufficient but it is doubtful that the spectrometer was operated with sufficient resolving power to separate the individual lines. In the closely similar case of N in $CH_3NC$[5] the quadrupole splitting has been reported as less than 1 mc. Line widths in this study were considerably larger than this figure. Lines were, in fact, unusually broad although extra width seems to be a feature of the microwave rotational spectral lines of symmetric rotors possessing large dipole moments.

## Other Asymmetric Rotor Transitions

In considering the molecule as an asymmetric rotor certain transitions become possible other than the ones so far dealt with, which correspond to the parallel type $\Delta J = 1$, $\Delta K = 0$ transitions of the prolate symmetric rotor, and in the KHC notation[19] are described as $ae_{R_0,1}$ or $ao_{R_0,1}$. For the most part, however, the intensities of other types of "a" transitions may be shown to be too small to be detected with the present equipment for all reasonable values of the asymmetry parameter $\kappa$. The only other "$a$" transition which might be observable are the $ao_{Q_{0,1}}$-transitions between the split components of each K level. Very high J values would be required to bring the frequencies of such lines into the observed region so that the resulting Boltzmann factors would reduce their intensities to a rather small figure. Such transitions would be so widely spaced that at most they could account for only two or three lines in the entire experimental frequency range.

Since there is no component of the dipole moment along the $I_C$ axis (perpendicular to the C–N–C–S plane) "$c$" type transitions will have zero intensity. While a small component of the dipole moment does exist along the $I_B$ axis, the intensities of "$b$" type transitions would be quite small since the intensity is proportional to the square of the dipole moment component. There are a number of lines of low intensity in the observed spectrum which have not been accounted for (as well as some for whose assignment there is at least a reasonable doubt), so this possibility cannot be completely ruled out.

## Analysis of Observed Spectrum

An analysis of the observed spectrum has been made in the light of the discussion above and the results are presented in Table I. The theoretical spectrum, calculated using the molecular model described in Fig. 4, and compared to the experimental spectrum in Fig. 2, reproduces the general features of the experimental spectrum quite well. The features of this spectrum which are advanced with the most confidence are the following: The average rotational constants, $^1/_2(B + C)$, for $CH_2NCS$ in the ground vibrational state have the value indicated in Table VI. Certain of the lines in different transition groups reveal by the ratio of their frequencies that they correspond to the

(19) P. C. Cross, R. M. Hainer and G. W. King, *J. Chem. Phys.*, **12**, 210 (1944).

same average rotational constant, which is different from the value assigned the most abundant isotopic variety in the ground vibrational state.

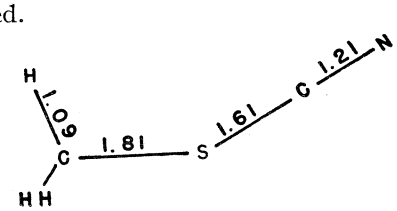
TABLE VI

| Molecule | $\nu$, mc. | $(B+C)^{1/2}$, cm.$^{-1}$ | Transition | Vib. state | $I_{av.}$, g. cm.$^2$ |
|---|---|---|---|---|---|
| $CH_3NCS$ | 20216 | 0.084295 | $J = 3 \rightarrow 4$ | Ground | $332.01 \times 10^{-40}$ |
| | 25269 | .084292 | $J = 4 \rightarrow 5$ | Ground | 332.02 |
| | 20443 | .085241 | $J = 3 \rightarrow 4$ | $J$ | 328.33 |
| | 25550 | .085223 | $J = 4 \rightarrow 5$ | $J$ | 328.40 |
| | 20350 | .084854 | $J = 3 \rightarrow 4$ | $D$ | 329.83 |
| | 25442 | .084869 | $J = 4 \rightarrow 5$ | $D$ | 329.77 |
| $CH_3NCS^{34}$ | 19700 | .082144 | $J = 3 \rightarrow 4$ | Ground | 340.71 |
| | 24609 | .082090 | $J = 4 \rightarrow 5$ | Ground | 340.93 |
| | 29540 | .082116 | $J = 5 \rightarrow 6$ | Ground | 340.82 |
| | 19929 | .083099 | $J = 3 \rightarrow 4$ | $J$ | 336.79 |
| | 24910 | .083094 | $J = 4 \rightarrow 5$ | $J$ | 336.81 |

The details of the assignment of these rotational constants to different isotopic varieties of the molecule in different vibrational states depends upon measurements of relative intensity and calculations of isotopic frequency shifts. The relative intensities are highly approximate because of difficulties encountered in their measurement. The calculated frequency shifts, of course, depend upon the assumed molecular model. However, in the case of the lines assigned to the first excited torsional vibration level the intensities are so large as to rule out most other possible assignments. For the lines assigned to $CH_3NCS^{34}$ both the frequency shifts and the intensities are of the right order of magnitude and their agreement tends to support the conclusion. The assignment of the next most intense set of lines to the first excited state of the $CH_3$–N bending mode seems reasonable since in the vibrational assignment for similar molecules this is much the lowest lying vibration exclusive of torsion. The assignment of lines to the nearly degenerate bending modes of the NCS group is much more doubtful but has been made simply on the basis of the relative intensities. Because of the complexity of the spectrum the interesting question of the effects of the near degeneracy and slight asymmetery on what would be $l$-type doubling in a linear molecule has not been pursued.

Because of the uncertainty in the degeneracy of the lines ascribed to the first excited torsional vibration level the assignment of the lines in the neighborhood of 25500 mc. is rather tentative. It is perhaps possible that this group of lines is made up of the resolved components of the degenerate line.

The designation of certain of the lines as components of the degenerate main transition split out by the molecular asymmetry is somewhat difficult because their spacing is quite sensitive to small changes in the rotational constants and their intensities are low enough to permit confusion with the excited vibrational lines. The spacing of the lines should be nearly symmetric about the degenerate line and should be greater for the $J = 4 \rightarrow 5$ transition than for $J = 3 \rightarrow 4$. The relative intensities should be in the calculated ratio. Most of these requirements are at least roughly met by the assignment given above.



## $CH_3SCN$ Spectrum

With the same Stark modulation apparatus, the region from 20,000 to 30,000 mc. was searched for lines of methyl thiocyanate. The observed spectrum was similar in many respects to that for the tautomeric ester although, of course, occurring at different frequencies. Again the spectrum consisted of complex groups of lines. However, for methyl thiocyanate the intensities were so low that only the strongest lines could be properly studied. The two strongest lines, which by analogy with the tautomeric ester would be assigned to the degenerate transition of the ordinary isotopic form of the molecule, were found to have the frequencies given in the table.

| Frequency, mc. | Transition | Average rotational constant, cm.$^{-1}$ |
|---|---|---|
| 22,680 | $J = 3 \rightarrow 4$ | 0.09457 |
| 28,380 | $J = 4 \rightarrow 5$ | .09467 |

The frequencies were determined using a cavity wavemeter and are accurate only to $\pm 10$ mc.

The frequency ratio of these lines enables them to be identified as $\Delta J = 1$, $\Delta K = 0$ transitions of a slightly asymmetric rotor involving the $J$ values listed above. This conclusion is supported by calculations based on various probable structures of the $CH_3SCN$ molecule. By assuming probable values of the interatomic distances, the C–S–C angle corresponding to moments of inertia resulting from the observed value of $\frac{1}{2}(B + C)$ could be calculated. The $CH_3SCN$ structure shown in Fig. 5 is the one consistent with the above considerations. In order to determine the structure completely from the spectrum, independent of the above assumptions, spectra for several different isotopic varieties of the molecule, probably synthesized from enriched material, would have to be observed.

H–C–S angle 109°
C–S–C angle 142°

Fig. 5.—Approximate molecular configuration of $CH_3SCN$.

## Summary

Measurements of the pure rotational spectra of $CH_3NCS$ and $CH_3SCN$ have been made in the frequency range from 20,000 to 30,000 mc. Experimental techniques used and the interpretation of the spectra of these molecules are discussed. A theoretical spectrum for $CH_3NCS$ has been set up and the complicating effects of the removal of de-

generacies by asymmetry and by an external electric field, of centrifugal distortion, of the presence of excited vibrational states, of internal rotation, of isotopic varieties of the molecule, of nuclear quadrupole coupling, and of other allowed asymmetric rotor transitions are calculated. There is good general agreement between the theoretical and observed spectra for $CH_3NCS$. The spectrum of $CH_3SCN$ was too weak for detailed analysis but values of the average rotational constant $^1/_2$ $(B + C)$ are presented.

# Steric Hindrance in the Stobbe Condensation[1]

BY MELVIN S. NEWMAN AND JACK LINSK[2]

The first step in the recently reported method for the synthesis of 1,2-benzanthracene[3] involves the Stobbe condensation (in 60% yield) of desoxybenzoin, I ($R_1 = R_2 = R_3 = H$), and methyl succinate. In order to apply this method to the synthesis of 1′,9-dimethyl-1,2-benzanthracene,

we prepared, *o*,α-dimethyldesoxybenzoin, II ($R_1 = R_3 = CH_3$, $R_2 = H$) and attempted to condense it with ethyl succinate. In spite of numerous attempts including the use of potassium *t*-butoxide[4] in place of sodium ethoxide and the substitution of methyl succinate, succinic anhydride, and *n*-methylsuccinimide for ethyl succinate, we were entirely unsuccessful. To test the suggestion that enolization of the ketone[5] might be responsible for this failure to condense, we prepared *o*,α,α-trimethyl-desoxybenzoin, III ($R_1 = R_2 = R_3 = CH_3$), and attempted the reaction, but without success. Hence it appeared that steric factors were involved.

Accordingly we prepared α-methyldesoxybenzoin, IV ($R_1 = R_3 = H$, $R_2 = CH_3$), α,α-dimethyldesoxybenzoin, V ($R_1 = R_2 = CH_3$, $R_3 = H$), and 2,5-dimethylphenyl benzyl ketone, VI (a compound analogous to *o*-methyldesoxybenzoin [$R_1 = R_2 = H$, $R_3 = CH_3$] but easier to prepare) and have tested these under similar conditions in the Stobbe reaction. All of these attempts failed except that with IV, which gave the expected product in about 60% yield. Thus, from a comparison of the reactions involving ketones IV and VI, it appears that the substitution of one methyl group in the ortho position of the phenyl group adjacent to the carbonyl is more effective in hindering reaction than the substitution of a methyl group in the methylene group. Substitution of a second methyl group in the methylene group (ketone V) effectively hinders reaction.

## Experimental[6]

**2-Phenyl-1-*o*-tolyl-1-propanol.**—A solution of 386 g. (2.87 mole) of hydratropaldehyde[7] in 600 cc. of dry ether was added dropwise during two hours to a well stirred solution containing the Grignard reagent prepared from 835 g. (3.83 mole) of *o*-iodotoluene in two liters of dry ether. After decomposition of the reaction mixture with iced hydrochloric acid, the alcohol was obtained as a colorless oil, b. p. 149–150° at 2 mm., in 65% yield. The *p*-nitrobenzoate melted at 112.1–113.4° after three recrystallizations from methanol.

*Anal.*[a] Calcd. for $C_{16}H_{18}O$: C, 84.9; H, 8.0. Found: C, 85.0; H, 8.1. Calcd. for $C_{23}H_{21}O_4N$: N, 4.0. Found: N, 4.2, 4.0.

**o,α-Dimethyldesoxybenzoin, II.**—In all attempts to oxidize the above alcohol using chromic oxide, potassium dichromate and sulfuric acid, or nitric acid, considerable cleavage into acetophenone and *o*-toluic acid occurred. In the best experiment 220 g. (0.98 mole) of the alcohol was added during ten minutes to a well-stirred two phase system composed of 100 cc. of benzene and a solution of 200 g. of potassium dichromate in 900 cc. of water and 90 cc. of concentrated sulfuric acid. The temperature slowly rose to 54° but did not go higher. After stirring for twelve hours, during which time the temperature fell to room, the reaction products were taken into ether. The acid was removed by an alkaline wash and the ketone was obtained in 65% yield as a colorless oil, b. p. 120–124° at 1 mm., which soon crystallized. A sample crystallized from methanol melted at 54.4–55.5°. The 2,4-dinitrophenylhydrazone formed small yellow needles, m. p. 136.0–137.0° after several crystallizations from ethyl acetate and from chloroform–alcohol. In all attempts to effect a Stobbe condensation, the ketone was recovered in high yield.

*Anal.* Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found[a]: C, 85.7; H, 7.3. Calcd. for $C_{22}H_{20}O_4N_4$: C, 65.3; H, 5.0; N, 13.9. Found[c]: C, 65.2; H, 4.7; N, 13.5.

**o,α,α-Trimethyldesoxybenzoin, III.**—Ketone II was methylated with potassium *t*-butoxide and methyl iodide[8] to yield III as a solid, m. p. 37–38°, in 92% yield. A sample recrystallized for analysis melted at 38.6–39.6°. We were unable to prepare a 2,4-dinitrophenylhydrazone, semicarbazone, or oxime of this ketone, or to secure any acidic material after attempted Stobbe condensations.[4]

*Anal.*[a] Calcd. for $C_{17}H_{18}O$: C, 85.6; H, 7.6. Found: C, 85.3; H, 7.4.

**α-Methyldesoxybenzoin, IV.**—To a solution of the Grignard reagent prepared from 157 g. (1 mole) of bromobenzene and 30 g. of magnesium in 400 cc. of ether was added dropwise during one hour a solution of 63 g. (0.48 mole) of hydratropanitrile[9] in 100 cc. of benzene. After replacing 200 cc. of ether, which was allowed to distil, with an equal volume of benzene, the mixture was refluxed for five hours. The complex was decomposed with dilute hydrochloric acid, 200 cc. of concentrated hydrochloric acid was added, and the mixture refluxed for two hours to hydrolyze the imine hydrochloride. The ketone, IV, was finally isolated in 57% yield as a colorless oil, b. p. 136–137° at 2 mm., which soon crystallized to a solid. On recrystallization this ketone was obtained as feathery needles, m. p. 52–53°.[10]

**3-Carboxy-4,5-diphenyl-4-hexenoic Acid.**[11]—A solution of 10.3 g. (0.05 mole) of IV and 15.5 g. (0.09 mole) of ethyl succinate in 30 cc. of *t*-butyl alcohol was added to a cooled stirred solution of 2.2 g. (0.055 mole) of potassium in 30 cc. of *t*-butyl alcohol maintained under nitrogen. After refluxing for one and three-quarters hours, the mixture was cooled and treated with 12 cc. of 6 *N* hydrochloric acid. Since the crude half ester did not crystallize, it was saponified and the acid obtained in 42% yield as colorless needles, m. p. 174–176°. More acid was present, but no attempt to isolate the maximum amount was made. The pure acid, obtained on recrystallization from aqueous methanol, melted at 174.6–175.7°. From the neutral reaction products, 19% of IV was recovered.

*Anal.*[c] Calcd. for $C_{19}H_{18}O_4$: C, 73.8; H, 6.0. Found: C, 74.0; H, 6.2.

**α,α-Dimethyldesoxybenzoin, V.**—On methylation[8] IV was converted into V in 84% yield. The product boiled at 137–138° at 2 mm. and crystallized on standing to give thin rods, m. p. 45–47°.[12] The attempted Stobbe condensation failed, 79% of V being recovered.

**2,5-Dimethylphenyl Benzyl Ketone, VI.**—To a stirred cooled solution of 77.3 g. (0.5 mole) of phenylacetyl chloride and 90 g. of pure *p*-xylene[1] in one pound of carbon disulfide was added 110 g. of aluminum chloride during one hour. After heating to reflux during one hour and stirring at room temperature for two more, the mixture was decomposed with ice and hydrochloric acid. The ketone, VI, obtained in 86% yield, boiled at 147–148° at 2 mm. and melted at 30.5–32.0°. The Stobbe reaction failed, an 82% yield of VI being recovered from the reaction mixture.

*Anal.*[c] Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found: C, 85.8; H, 7.4.

## Summary

Steric hindrance in the Stobbe condensation of several methylated desoxybenzoins has been observed. A methyl group ortho to the carbonyl effectively hinders the reaction as do two methyl groups in any positions adjacent to the carbonyl group.

# Local Anesthetics. Aminoalkoxyisoquinoline Derivatives

BY JAMES W. WILSON, III, NORMAN D. DAWSON,[1] WALTER BROOKS[2] AND GLENN E. ULLYOT

Aminoalkyl ethers of phenols have been reported to possess local anesthetic activity.[3,4]

As far as we can find, however, no one has investigated the pharmacological properties of aminoalkoxy derivatives of isoquinolines. Previous work in this Laboratory[5] provided an excellent method for preparing a group of isocarbostyrils (I) from which a series of aminoalkoxy derivatives (III) has been obtained according to the procedure outlined by formulas I–III.

In order to be able to study the effect of modifying the lipophylic and hydrophylic character of the terminal groups of the molecule (III) on the pharmacological properties, we have varied the nature of the R, $R_1$ and $R_2$ groups as shown in Table I. That such factors play a role is demonstrated by the effect of varying the R groups in the known local anesthetics of the quinoline type (IV),[6] and by gradations in the local anesthetic activity among our compounds, as indicated in the last column of Table I.

The 1-chloroisoquinolines which are intermediates in our syntheses are listed in Table II.

## Experimental

**Preparation of 1-Chloroisoquinolines.**—All of these compounds were prepared from the corresponding isocarbostyrils by the action of phosphorus oxychloride[7] using essentially the same procedure in each case.

**3-*n*-Butyl-1-chloroisoquinoline.**—A solution of 56 g. of 3-*n*-butylisocarbostyril in 86 g. of phosphorus oxychloride was refluxed for sixteen hours, cooled, and poured into 300 g. of cracked ice. The cold solution was carefully neutralized with 40% sodium hydroxide and the product extracted into ether. After drying over anhydrous sodium sulfate, the ether was removed, and the product distilled to yield 47 g. of colorless liquid.

**Preparation of Aminoalkyl Ethers.**—In each case a solution of the sodium derivative of the amino alcohol in toluene or xylene was condensed with the chloroisoquinoline. The ethers, with the exception of the 1-(β-benzylaminoethoxy)-3-ethylisoquinoline, were isolated by distillation.

**1-(β-Dimethylaminoethoxy)-3-propylisoquinoline.**—A mixture of 3.4 g. of finely divided sodium metal and 17.6 g. of β-dimethylaminoethanol in 100 ml. of dry xylene was heated at 60–80° with efficient stirring for three hours. While maintaining the resulting solution at 75–85°, 26 g. of 1-chloro-3-propylisoquinoline was added, with stirring, over a period of six hours. The heating was continued for an additional two hours, the sodium chloride was removed by filtration, the filtrate washed with water and the product extracted with 2 *N* hydrochloric acid. This acid solution was made alkaline and the product extracted with ether. After drying, the ether was removed and the product distilled to yield 29.4 g. of colorless oil, b. p. 150–152° (2 mm.).

**1-(β-Benzylaminoethoxy)-3-ethylisoquinoline Monohydrochloride.**—The initial condensation was carried out as described above, employing 2.3 g. of sodium, 18 g. of benzylaminoethanol, and 19.2 g. of 1-chloro-3-ethylisoquinoline. When this reaction mixture was extracted with acid, the hydrochloride of the product crystallized, yielding 28 g. (82%) of white solid. Crystallization from acetone–alcohol and vacuum drying gave 22 g., m. p. 154–155°.

**Pharmacological.**—We are indebted to Dr. Edwin J. Fellows of the Pharmacology Department of Temple University for the pharmacological results reported in Table I: the detailed results will be published elsewhere. Compounds (5), (6), and (9), were superior. Of these (9) appeared outstanding in that it exhibited local anesthetic activity in concentrations as low as 0.001%.

## Summary

The properties of five 1-chloroisoquinolines, including one not previously reported, are given.

Eight new 1-(β-dialkylaminoethoxy)-3-alkylisoquinolines and one secondary amine of the same type are described, and their local anesthetic activity is reported. The most effective agent in this series is the 3-butyl-1-(β-dimethylaminoethoxy)-isoquinoline.

# The Partial Methylation of Methyl β-D-Xylopyranoside with Methyl Sulfate

BY O. WINTERSTEINER AND ANNA KLINGSBERG

In connection with our study of O-tetramethylstreptamine[1] methyl trimethyl-β-D-xylopyranoside was needed. Instead of preparing this compound from β-methyl-D-xylopyranoside by the usual multiple treatment with methyl iodide and silver oxide,[2] we explored the use of the method of Holden and West[3] with dimethyl sulfate and sodium hydroxide which in other instances studied in our laboratory had given excellent yields of fully methylated sugars. However, the chloroform-extractable material obtained in a trial run amounted to only 20% of the starting product and consisted for the most part of a crystalline methyl dimethylxyloside m. p. 78°. The fully methylated product had evidently been lost by volatilization during the later stages (70–100°) of the reaction. By conducting the methylation under somewhat milder conditions in a closed vessel fitted with a reflux condenser there was obtained in good yield a mixture of methylated products the crystallizable part of which consisted again of the methyl dimethylxyloside m. p. 78°. The remainder could be conveniently and quantitatively separated into methyl 2,3,4-trimethyl-β-D-xyloside and dimethylated methyl xylosides by steam distillation.

The compound m. p. 78° was identified as methyl 2,4-dimethyl-β-D-xylopyranoside by the following reactions: On tosylation it yielded a monotosylate m. p. 76°, and on acid hydrolysis a crystalline dimethylxylose m. p. 118° which showed $[\alpha]_D$ −26° in chloroform and in water mutarotated to an equilibrium value of +24°, which is in the neighborhood of those reported for the sirupy 2,3- and 3,4-dimethyl-D-xyloses,[4,5] and the crystalline 2,4-dimethyl-β-D-xylopyranose[6] to be mentioned later. The phenylosazone (m. p. 158°) obtained from the dimethyl sugar contained only one methoxyl group, proving that the methyl group eliminated in its formation occupied position 2. The sugar was further characterized by the preparation of an anilide m. p. 157°, $[\alpha]_D$ −40° in ethyl acetate, which in ethyl acetate containing acetic acid attained an equilibrium rotation value of +85°. The sirupy dimethylxylonic lactone formed by bromine oxidation showed the characteristic fast mutarotation of a pyranolactone, and moreover on Purdie methylation yielded 2,3,-4-trimethylxylonic lactone. The dimethyl lactone was converted into two crystalline derivatives of the corresponding xylonic acid, namely, an amide m. p. 100° and a phenylhydrazide m. p. 144°. The amide was only very gradually attacked by periodic acid under conditions under which 2-tosyl-5-desoxyarabonamide[7] was readily cleaved. The phenylhydrazide consumed in rapid reaction 2 moles of periodic acid, but since a simple hydrazide, N-acetylphenylhydrazine, behaved in the same manner, it is clear that the xylose portion had remained unaffected. These findings, and the additional fact that the dimethylxylose itself proved to be inert toward periodate, show conclusively that the second methyl group in this compound occupies position 4.

It should be mentioned that a result seemingly inconsistent with the above conclusion was obtained in the periodate titration of the monomethylxylosazone derived from the dimethyl sugar. Since it is known that the phenylosazone grouping in glucosazone protects the linkage between carbon atoms 2 and 3 from cleavage by periodic acid,[7a] 4-methylxylosazone should not be attacked at all by this oxidant. Actually, a rapid uptake of periodate, which came to a standstill at between 1 and 2 molar equivalents, was observed. However, as it could be demonstrated that no formaldehyde is produced in this reaction, the 4-methyl structure is secure, and the observed uptake must be ascribed to an anomalous type of oxidation.

The methyl dimethylxyloside fraction remaining after steam distillation usually yielded additional small amounts of methyl 2,4-dimethyl-β-D-xyloside, and, on occasion, lower-melting crystalline products which were obviously mixtures containing the position-isomeric compounds. In one run the non-crystallizable part of the steam distillation residue was converted to a mixture of dimethylated xylonolactones. From the mutarotation characteristics of one of the lactone fractions it appeared that considerable amounts of the highly dextro rotatory 2,3-dimethyl-D-xylono-γ-lactone[4] were present. This was borne out by the fact that the sirupy amides prepared from the lactone mixtures rapidly consumed periodic acid equivalent to the presence of about 20% of the 2,3-dimethyl isomer.

In 1934 Robertson and Speedie[5] described a methyl dimethylxyloside (m. p. 61°, $[\alpha]_D$ −82°), to which they likewise attributed the methyl 2,4-dimethyl-β-D-xylopyranoside structure. They prepared this compound by a sequence of reactions involving first monotritylation of methyl β-

D-xylopyranoside, acetylation of the other two hydroxyl groups, replacement of the trityl by a nitrate group, deacetylation first with sodium methylate and then dimethylaniline, methylation according to Purdie, and finally reductive removal of the nitrate group with sodium amalgam. None of the intermediates except the diacetyl nitrate derivative were crystalline. The 2,4-position of the methylated hydroxyl groups in the final product was inferred from the fact that the monotosylate (m. p. 88°, $[\alpha]_D$ −58.9° in chloroform) was not identical with either the monotosylate of the crystalline β-methyl-3,4-dimethylxylopyranoside described by the same authors, or with that of the sirupy methyl 2,3-dimethylxylopyranoside of Hampton, Haworth and Hirst.[4] Though it would appear from the rotation characteristics that the compound m. p. 61° belongs to the β-xylopyranoside series, a more direct proof for the location of the methylated hydroxyl groups would be desirable. Since neither the free sugar nor the lactone were prepared, any basis for correlating this product with compounds of known structure is lacking, so that the marked discrepancies between the melting points and rotations reported by Robertson and Speedie and those found by us cannot be explained at present. The possibility that our compound m. p. 78° is a mixture of dimethylated methyl xylopyranosides seems to be excluded by the fact that the lactone obtained from it directly by hydrolysis and oxidation, that is without isolation of the intermediate dimethylxylose, gave no evidence of being contaminated by either 2,3-dimethylxylono-γ-lactone[4] or 3,4-dimethylxylonolactone,[8] both of which exhibit quite different mutarotation characteristics.

On the other hand, there is little doubt that our dimethylxylose m. p. 118° is essentially identical with the 2,4-dimethylxylose m. p. 108° (equilibrium rotation in water +22°) which Barker, Hirst and Jones[6] obtained by methylation of methyl α,β-D-xylopyranoside with methyl iodide and thallous hydroxide. The structure of this product was deduced from the non-identity with the position-isomeric dimethylxyloses, the mutarotation of the lactone, and the negative Weerman test of the (sirupy) amide. The only other derivative reported by Barker, *et al.*, is the anilide, which showed a somewhat higher melting point (170°) and levorotation (−80°, in dioxane) than the anilide prepared by us. These differences are probably to be ascribed to the presence of a greater proportion of the α-anomer in our product, and the lower melting point of their dimethylxylose preparation can be similarly explained. On the other hand, the mutarotation data obtained on the respective lactones are in excellent agreement.

The findings of the British authors parallel ours also in that the 2,4-dimethyl isomer preponderated in the dimethylxyloside fraction. To explain the preferential formation of this isomer they reason that "the hydrogen atoms on the hydroxyl groups at $C_2$ and $C_4$ are most likely to be substituted since they are the greatest distance apart, and the thallium atoms in these positions are therefore least likely to interfere with each other." However, this concept is applicable only when, as in the procedure with thallous hydroxide, the metal salt of the starting glycoside is isolated prior to this reaction with the anhydrous methylating agent. In our case, where the reaction proceeded in aqueous sodium hydroxide solution and the hydroxyl groups of the glycoside were presumably in the charged anionic form, it is difficult to see how steric factors could have played any role in preventing salt formation at the third hydroxyl group in position 3. This group, since it is situated *trans* to the neighboring, more reactive, hydroxyl groups, does not appear to be subject to steric hindrance of any kind in the model. It would be interesting to ascertain by a similar study on methyl arabinoside whether the *cis* relationship of two hydroxyl groups in the pyranoside ring *per se* predisposes them to preferential attack by methylating agents.

(8) S. P. James and F. Smith, *J. Chem. Soc.* 739 (1945).

## Experimental

**Methylation of Methyl β-D-Xyloside.**—A solution of methyl β-D-xyloside (m.p. 155°, $[\alpha]^{26}_D$ −64.7° in water, 13.6 g.) in water (10 cc.) was placed into a 500-cc. 3-neck reaction flask equipped with a mercury-sealed stirrer, reflux condenser, thermometer and two dropping funnels. After the addition of methyl sulfate (36.8 cc.) and carbon tetrachloride (50 cc.) the mixture was warmed to 55°. During the following dropwise addition, with stirring, of 60% sodium hydroxide solution (163 cc.) this temperature was maintained by outside cooling and regulation of the dropping rate. After about half of this volume had been added, cooling could be dispensed with, and the remainder of the solution was added at a rate of 3 drops per second. (Toward the end slight warming may be necessary to maintain the temperature at 55°.) Methyl sulfate (65 cc.) was then added dropwise in such a manner that the temperature remained around 55° during this period also (cooling). After all of the reagent had been added stirring was continued for thirty minutes at 55°. The mixture was allowed to come to room temperature, and after addition of sufficient water (*ca.* 90 cc.) to dissolve the sodium sulfate, was extracted with 900 cc. of chloroform in ten portions. The combined extracts were dried and concentrated *in vacuo* to a small volume (*ca.* 15 cc.). Ligroin (b.p. 90–100°) was added in small portions to faint turbidity (50 cc.). The crystalline product obtained on standing in the refrigerator (2.64 g.) yielded on recrystallization from warm ligroin substantially pure **methyl 2,4-dimethyl-β-D-xyloside**, m.p. 76–78°[9]; yield 2.31 g. or 14.5%. One more recrystallization raised the melting point to 77.5–78.5° (constant); $[\alpha]^{24}_D$ −70 ± 1° (*c*, 1.0 in chloroform).

*Anal.* Calcd. for $C_8H_{16}O_5$: C, 49.99; H, 8.39; $OCH_3$, 48.4. Found: C, 50.20; H, 8.60; $OCH_3$, 48.4.

The combined mother liquors were taken to dryness. The residue (*ca.* 12 g.) was dissolved in water (150 cc.) and subjected to steam distillation.[10] Exhaustive extraction of the steam distillate (320 cc.) with chloroform yielded a partly crystalline product (7.9 g.) which on recrystallization from ligroin melted at 47–49°. Further recrystallization yielded **methyl 2,3,4-trimethyl-β-D-xylo-**

(9) All melting points were taken in the capillary and are corrected for stem exposure.

(10) Fractional distillation *in vacuo* was not practicable because the products crystallized in the efferent parts of the distillation vessel.

pyranoside[2] m.p. 49–50°, $[\alpha]^{24}D$ −73° (*c*, 0.765 in chloroform).

*Anal.* Calcd. for $C_9H_{18}O_5$: C, 52.41; H, 8.79; $OCH_3$, 60.2. Found: C, 52.57; H, 8.93; $OCH_3$, 59.9.

The glycoside was converted to **2,3,4-trimethyl-D-xylose**[2], m.p. 88–91°, $[\alpha]^{27}D$ + 62.5° (*c*, 1.0 in chloroform), and further to 2,3,4-trimethylxylonolactone[11] m.p. 52–53°.

The products not volatile with steam (3.1 g.) were recovered by extraction with chloroform. The oily residue on seeding gave an additional small amount (520 mg.) of impure methyl 2,4-dimethylxyloside (m.p. 67–71°). The remainder was distilled *in vacuo* (100–110° (0.5 mm.)), and yielded 2.33 g. of a sirup consisting of mixed methyl dimethylxylosides ($[\alpha]^{26}D$ − 69°; $OCH_3$, found, 48.0; calcd., 48.4) which was hydrolyzed and oxidized to the mixture of lactones described further below.

In another methylation experiment carried out as described above, in which the yield of methyl 2,4-dimethylxyloside was 17.4%, the non-steam distillable fraction of the mother liquor material afforded a crystalline mixture of methyl dimethylxylosides (m.p. 55–58°, $[\alpha]D$ −65°; $OCH_3$, 49.2) accounting for an additional 22% of the starting material. Hydrolysis of this material gave a crystalline product, from which, however, only a small amount of impure 2,4-dimethylxylose (m.p. 108°) could be eventually obtained.

An attempt to increase the yield of pure 2,4-dimethyl isomer by conducting the methylation at 35–40° failed, as all the crystalline products isolated from the dimethylated fractions consisted of inseparable mixtures.

**Methyl 2,4-Dimethyl-3-tosyl-β-D-xyloside.**—To an ice-cold solution of methyl 2,4-dimethyl-β-D-xyloside (192 mg.) in pyridine (2.5 cc.) tosyl chloride (380 mg.) dissolved in chloroform (1 cc.) was slowly added. After standing at room temperature for forty-eight hours the product was recovered by chloroform extraction in the usual way. Crystallization of the oily residue (306 mg.) from ethyl acetate–hexane yielded plates (200 mg., m.p. 74–75°). The pure substance melted at 75–76°; $[\alpha]^{28}D$ + 28.8° (*c*, 1.06 in chloroform).

*Anal.* Calcd. for $C_{15}H_{22}O_7S$: C, 52.02; H, 6.40; S, 9.25. Found: C, 52.04; H, 6.59; S, 9.48.

**2,4-Dimethyl-D-xylose.**—A solution of methyl 2,4-dimethyl-β-D-xyloside (0.50 g.) in 0.6 *N* hydrochloric acid (13 cc.) was heated on the steam-bath till $[\alpha]^{26}D$ became constant at +23° (six hours). After removal of the chlorine ions with silver carbonate and of excess silver with hydrogen sulfide the solution was lyophilized. The partly crystalline residue (335 mg.), was recrystallized to constant melting point from ethyl acetate. 2,4-Dimethylxylose forms long fine needles melting at 116–118°; $[\alpha]^{25}D$ −26° (*c*, 0.95 in chloroform). A 3.0% solution in water showed $[\alpha]^{25}D$ +9.4° after five minutes and +24.7° after fifty minutes (constant).

*Anal.* Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92; $OCH_3$, 34.8. Found: C, 47.04; H, 7.82; $OCH_3$, 35.7.

An aqueous solution of the compound did not consume any periodate within a four-hour period. (Potassium paraperiodate was used in this and all other titrations.)

**The anilide** was prepared by refluxing a solution of the sugar (89 mg.) with aniline (623 mg.) in absolute ethanol (3 cc.) for two and one-half hours. The residue obtained after removal of the solvents was crystallized from ethyl acetate (0.7 cc.) and a few drops of pentane (23 mg., m. p. 144–145°). Two recrystallizations raised the melting point to 155–157°; $[\alpha]^{27}D$ −40° (*c*, 0.695 in ethyl acetate).

*Anal.* Calcd. for $C_{13}H_{19}O_4N$: C, 61.64; H, 7.56; N, 5.53. Found: C, 61.77; H, 7.61; N, 5.28.

A 0.74% solution in ethyl acetate containing 4% acetic acid showed rapid mutarotation from $[\alpha]^{27}D$ −7° (five minutes) to the equilibrium value +87° (two hours). The corresponding figures for another, independently prepared sample (m. p. 148–151°), $[\alpha]^{26}D$ −40° in ethyl acetate) were −56 and +85°, respectively.

**4-Methyl-D-xylosazone.**—2,4-Dimethyl-D-xylose (180 mg.) was dissolved in water (5 cc.), and acetic acid (0.25 cc.) and phenylhydrazine (0.5 cc.) were added. The solution was heated on a steam-bath for one and one-half hours while a slow stream of carbon dioxide was passed through it, and the water lost by evaporation was replaced from time to time. After cooling, the solution was extracted with benzene. The red oil obtained on evaporation of the dried benzene extract (454 mg.) could not be crystallized. It was dissolved in benzene and chromatographed on a column of acetic acid–washed alumina (1 × 20 cm.). After elution of pigmented amorphous material with benzene (300 cc.) and of some colorless crystalline material, probably acetylphenylhydrazine, with benzene–ether 3:1 (350 cc.), the crude osazone (153 mg.) was recovered by washing with benzene containing 3% of ethanol (250 cc.). Several recrystallizations from ethyl acetate–hexane 2:1 yielded small yellow needles melting at 158–158.5°; $[\alpha]^{25}D$ +25° → 0° (constant) in twenty-one hours (*c*, 0.91 in pyridine–ethanol 2:3).

*Anal.* Calcd. for $C_{18}H_{22}O_3N_4$: C, 63.14; H, 6.47; N, 16.4; $OCH_3$, 9.06. Found: C, 63.32; H, 6.56; N, 16.6; $OCH_3$, 10.24, 9.94.

For measuring the periodate consumption, weighed samples (*ca.* 4 mg.) of the osazone were dissolved in ethanol (5 cc.), and 0.0128 *M* aqueous potassium paraperiodate (5 cc.) was added. Aliquots (2 cc.) were withdrawn at intervals for the determination of the residual oxidizing capacity with 0.01 *N* thiosulfate. The total oxidizing capacity of the reagent in 50% ethanol was determined at the same intervals to eliminate possible errors due to the presence of the alcohol. The figures obtained in two different runs were not consistent. Molar equivalents consumed: (1) 0.67 (four min.); 0.86 (twenty-five min.); 1.05 (one and one-half hours, constant to nineteen hours); (2) 1.52 (four min.); 1.69 (forty-five min., constant to nineteen hours).

In order to ascertain whether or not formaldehyde was produced in the reaction the osazone (60 mg.) was treated with paraperiodic acid and the volatile products were tested with dimedon as described by Karrer and Pfaehler.[12] A reaction occurred, as evidenced by the formation of a yellow precipitate, but no formal-dimedon was obtained. Glucosazone (60 mg.) subjected to the same procedure gave 48% of formal-dimedone, m. p. 186–187°.

**2,4-Dimethyl-xylonolactone.**—The procedure of Haworth and Westgarth[11] for the oxidation of 2,3,4-trimethylxylose was employed, as 2,4-dimethylxylose proved to be rather resistant to bromine oxidation at room temperature. Methyl 2,4-dimethyl-β-D-xyloside (2.31 g.) was hydrolyzed with 3% hydrobromic acid (24 cc.) at 85° for one hour. Heating was continued for a total of ten hours at 75° while bromine (3.0 cc.) was added in small portions. The Fehling reaction at this point was only slightly positive. The reaction mixture was worked up in the usual manner by removal of the excess bromine by aeration and of the bromide ions with silver carbonate. The residue of the filtered solution was repeatedly extracted with dry ether. The extracted material (1.82 g.) was heated for two hours on the steam-bath to complete lactone formation, and then distilled at 105–125° (0.1 mm.), yielding 1.23 g. of a sirup ($n^{27}D$ 1.4652; $OCH_3$: Found, 35.1; calcd., 35.2). Mutarotation in water (*c*, 1.02): −13.2° (seven min.), −9.3° (fifty min.), −5.8° (three hours), +26.8° (twenty-four hours), +29.5° (forty-eight hours, constant), in good agreement with the data of Barker, Hirst and Jones[6] (−15° → +30°).

A portion (150 mg.) of the lactone was methylated with methyl iodide (10 cc.) and silver oxide (0.98 g.) in the usual way. Removal of the reagent and extraction of the residue with chloroform yielded a sirup (162 mg.) from which on crystallization from benzene–pentane 2,3,4-

(11) W. N. Haworth and G. C. Westgarth, *J. Chem. Soc.*, 880 (1926).

(12) P. Karrer and K. Pfaehler, *Helv. Chim. Acta*, **17**, 766 (1934).

trimethylxylonolactone (99 mg., m. p. 50–52°) was obtained. The purified product melted at 52–54° and did not depress the melting point of an authentic specimen.

**2,4-Dimethyl-D-xylonamide.**—The amide was prepared from the lactone (331 mg.) with methanol (5.0 cc.) saturated at 0° with ammonia. After standing for three days at room temperature the mixture was taken to dryness. Since the sirupy product could not be induced to crystallize, it was dissolved in water and treated with charcoal. The filtered solution was lyophilized, and the residue (309 mg.) extracted with warm ethyl acetate (10 cc.). The extract on cooling to room temperature deposited crystals (160 mg., m. p. 95–97°) which were purified by recrystallization from the same solvent; rods, m. p. 98–100°, $[\alpha]^{26}D$ + 51° (*c*, 1.00 in water).

*Anal.* Calcd. for $C_7H_{15}O_5N$: C, 43.51; H, 7.82; N, 7.25; $OCH_3$, 32.1. Found: C, 43.41; H, 7.56; N, 6.95; $OCH_3$, 32.2.

The amide consumed no periodate over a two-hour period, but after this time was attacked at a slow rate (0.14 and 0.33 molar equivalents after five and one-half and twenty-four hours, respectively).

**2,4-Dimethyl-D-xylonic Acid Phenylhydrazide.**—A mixture of the lactone (320 mg.) and phenylhydrazine (197 mg.) was heated on the steam-bath for one hour. Since the orange-colored, viscous product failed to crystallize, it was dissolved in ethylene chloride (5 cc.) and chromatographed on a small column of alumina (1 × 15 cm.). While washing with ethylene chloride (200 cc.) removed only pigmented impurities, the subsequent eluates with the same solvent containing 3% ethanol (150 cc.) and 10% ethanol (100 cc.) yielded the phenylhydrazide, which crystallized on addition of ethyl acetate. The combined crystalline material (363 mg., m. p. 142–144°) was recrystallized twice from the same solvent, blocks, m. p. 143.5–144.5°, $[\alpha]^{26}D$ + 47° (*c*, 0.98 in ethanol).

*Anal.* Calcd. for $C_{13}H_{20}O_5N_2$: C, 54.92; H, 7.09; N, 9.85; $OCH_3$, 21.8. Found: C, 54.73; H, 6.79; N, 10.14; $OCH_3$, 21.7.

The consumption of periodate was as follows (in molar equivalents): five min., 1.44; fifteen min., 1.80; four and one-half hours, 1.85; twenty-two hours, 1.99. Acetylphenylhydrazine behaved in a similar manner: five min., 1.62; twenty min., 1.78; three hours, 1.85; twenty hours, 2.17.

**Lactone and Amide Fractions from Methyl Dimethylxyloside Mixture.**—A portion (2.0 g.) of the mixture of methyl dimethylxylosides remaining after steam distillation (see above) was hydrolyzed and oxidized with bromine as described for the pure 2,4-dimethyl isomer, except that it was found necessary to employ larger amounts of bromine (6.5 cc.) and a longer heating period (twenty-six hours). The material finally recovered by ether extraction (1.3 g.) was heated at 75–80° at 12 mm. for one hour and then distilled fractionally *in vacuo*. Two main fractions were collected: I, 533 mg., b. p. 105–110° (0.05 mm.) and II, 469 mg., b. p. 125–130° (0.05 mm.). The mutarotation data were as follows: Fraction I (*c*, 1.14 in water): ten min., −5.3°; one hour, −4.2°; seven hours, −2.0°; twenty-four hours, +8.9°; thirty-four hours, +15.5°; fifty-four hours, +13.7. Fraction II (*c*, 0.99 in water): one hour, + 10.6°; four hours, +15.6; twenty-five hours, +34°; ninety-eight hours, +41° (constant).

The sirupy amides were prepared from both fractions in the usual fashion. Amide mixture II, but not I, gave on seeding with 2,4-dimethylxylonamide a small amount of crystalline material, which after purification melted at 93–95°. Both amide mixtures consumed periodate at a rapid rate:

| Time | | 5 min. | 3 hours | 20 hours |
|---|---|---|---|---|
| Molar equivalents of | I | 0.11 | 0.18 | 0.19 |
| periodate consumed | II | .23 | .22 | .27 |

Since 2,3-dimethylxylonamide is the only isomer which should be attacked by periodate, the above figures may be taken as indicating the presence of about 20% of the corresponding methyl xyloside in the original mixture. This is also borne out by the high positive equilibrium rotation value of lactone fraction II, since 2,3-dimethyl-D-xylono-γ-lactone[4] is strongly dextrorotatory and mutarotates very slowly (+97° → + 86° (forty-eight hours) → +69° (384 hours)). Apparently Fraction II consisted mainly of a mixture of the 2,3- and 2,4-isomers (isolation of the amide of the latter), while the mutarotation data of Fraction I and the failure of the corresponding amide mixture to yield 2,4-dimethyl-xylonamide are consistent with the properties to be expected of a mixture containing mainly the 2,3- and 3,4-dimethyl isomers (3,4-dimethyl-D-xylonolactone[5] mutarotates from −56° to −27° in sixty-five hours).

**Acknowledgment.**—The microanalyses were performed by Mr. J. F. Alicino and his assistants.

## Summary

Methyl-β-D-xyloside on methylation with methyl sulfate yields besides methyl 2,3,4-trimethyl-β-D-xyloside a mixture of methyl dimethylxylosides, which can be conveniently separated from the trimethyl derivative by virtue of the fact that only the latter is volatile with steam. Methyl 2,4-dimethyl-β-D-xyloside m. p. 78°, which can be obtained in 15–20% yield directly from the reaction mixture, preponderates among the dimethylated compounds. It was identified by conversion, *via* the free sugar, to a monomethyl-D-xylosazone, and by the behavior toward periodate of the crystalline amide and phenylhydrazide of the corresponding xylonic acid. Indirect evidence for the occurrence also of the 2,3-dimethyl isomer in the dimethylated fraction is presented.

# Catalytic Synthesis of Heterocycles.[1] III. Benzofuran

BY CORWIN HANSCH, WILLIAM SALTONSTALL[2] AND JAMES SETTLE[3]

The successful synthesis of thianaphthene from *o*-ethylbenzenethiol[1] suggested the possibility of accomplishing the same type of ring closure with the oxygen analog. This paper discusses the vapor phase catalytic dehydrocyclization of *o*-ethylphenol and *o*-allylphenol to benzofuran and 2-methylbenzofuran according to the equations

## Experimental

The apparatus and the technique used for the catalytic reactions have been described previously.[1]

**Catalyst Preparations.**—The method of preparation for the platinum catalyst has been described.[1] For the preparation of palladium on charcoal,[4] 10 g. of palladium chloride was dissolved in 40 ml. of hot concd. hydrochloric acid. This solution was diluted to 187 ml. with distilled water and 30 g. of activated charcoal added. The mixture was heated to boiling and the charcoal separated by decantation. The catalyst was dried at 115° for two hours. Before using, it was reduced *in situ* with a slow stream of

[a] This fraction consisted of benzofuran with some unidentified product. [b] The yield of pure benzofuran was somewhat higher than this would indicate because of about 1 to 2 g. holdback of material in the distilling column which contained considerable benzofuran. These fractions when mixed together had $n^{24}D$ 1.5631 and formed a picrate m. p. 102–103°. v. Auwers, *Ann.*, **408**, 271 (1915), reports $n^{22.7}D$ 1.565. Kramer and Spilker, *Ber.*, **23**, 79 (1890), report b. p. (758 mm.) 170–171° and *ibid.*, 3276, m. p. picrate 102–103°. [c] This fraction consisted of phenol along with some *o*-ethylphenol and probably some *o*-hydroxystyrene. [d] See Table I. [e] Fifteen ml. of catalyst used instead of usual 5 ml. [f] See Table I, *e*. [g] See Table I, *f* and *g*.

(4) The activated charcoal used in this work was Type B15P, 6–8 mesh, supplied through the courtesy of the Pittsburgh Coke and Chemical Company.

hydrogen saturated with formaldehyde by passing the hydrogen through aqueous 40% formalin. The reduction was carried out for forty-five minutes at 270° and then for forty-five minutes at temperatures slightly above those at which the dehydrogenation run was to be conducted.

**Catalytic Synthesis of 2-Methylbenzofuran.**—The following is an example of a typical dehydrogenation run for the preparation of 2-methylbenzofuran.

*o*-Allylphenol[5] (50.2 g.) was processed over 5 ml. of palladium catalyst at a temperature of 550 ± 4° over a period of one hundred thirty minutes. A total of 47.6 g. of condensate was collected and the catalyst tube gained 1.2 g. weight. About 0.3 g. of material remained in the seed system. A total of 3330 ml. of gas was given off during the course of the reaction as measured by a wet test meter. The rate of gas evolution was 40 ml./min. at the end of the first fifteen minutes at which time the catalyst reached a relatively steady activity. This rate gradually fell until it reached a constant value of 16 ml./min. at seventy minutes. This rate then held until the end of the reaction. On longer runs of four hours or more the rate sometimes fell as low as 12 ml./min.

The condensate was made alkaline with 20% sodium hydroxide and the 2-methylbenzofuran extracted with petroleum ether. After drying over sodium sulfate the extract was distilled through a 20-plate, 30″, "spinning band" distilling column. Distillation gave 14.6 g. of 2-methylbenzofuran, b. p. 190–196° (730 mm.), 3.3 g., 170–190° (730 mm.) which was mainly benzofuran, a residue and hold back of 1.7 g. remaining in the distilling flask.

The alkali-soluble portion of the condensate was acidified with hydrochloric acid, extracted with ether, the extract dried over calcium chloride and then distilled. Nine and four-tenths grams of material, mainly *o*-allylphenol, was collected between 200–216° (730 mm.). Three and seven-tenths grams was obtained, boiling at 175–200°, and consisting of a mixture of phenol, *o*-cresol and a trace of *o*-allylphenol.

Tables I and II summarize the results of the run with *o*-allylphenol and *o*-ethylphenol.[6] All of the runs were made and worked up as described above except where indicated.

(5) D. S. Tarbell, "Organic Reactions," John Wiley and Sons Inc., New York, N. Y., 1944, Vol. II, p. 26.

(6) The *o*-ethylphenol was supplied through the courtesy of Dale Robertson of this Laboratory. It was prepared by vapor-phase alkylation of phenol and had a b. p. of 203.1–205.1° (730 mm. cor.) after two distillations through a 20-plate distilling column.

## Discussion

In all of the catalytic runs made in this research using both *o*-ethylphenol and *o*-allylphenol, very little charring occurred on the catalyst or on the quartz chips used as preheater. The catalyst gained 0.6 g. to 1.2 g. depending on the size of the run and the temperature. The condensate was clear and light brown in color.

It should be noted that the catalyst activity as measured by the rate of gas evolution fell off after about the first hour to about 50% of the fifteen minute value. An attempt to use a chromium oxide on alumina catalyst was unsuccessful because of excessive decomposition of the phenols. At present work is in progress to find a more stable and more active catalyst. It was discovered that the activated charcoal[4] itself possessed considerable ability to bring about the dehydrocyclization. This may be due to the charcoal itself or possibly to impurities in it.

As noted in Table I, a considerable amount of benzofuran was formed in the preparation of 2-methylbenzofuran. This same phenomenon has been observed in the preliminary investigation of the preparation of other 2-methylbenzofurans and also with the corresponding sulfur analogs.

**Acknowledgment.**—The authors are indebted to the Research Corporation for a Frederick Gardner Cottrell grant-in-aid which supported this research.

## Summary

A vapor phase catalytic method for the dehydrogenation of *o*-ethylphenol to benzofuran and *o*-allylphenol to 2-methylbenzofuran is described.

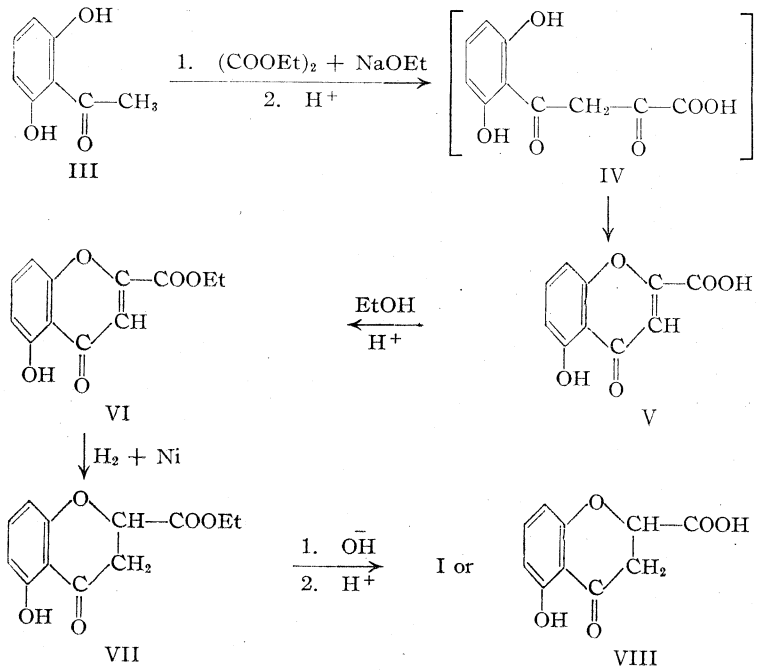
# Attempted Synthesis of β-2,6-Dihydroxybenzoyl- and β-2,4,6-Trihydroxybenzoyl-acrylic Acids

BY CHARLES I. JAROWSKI,[1a] WILLIAM J. MORAN[1b] AND BETTY JANE CRAMER[1c]

The most active bacteriostatic agent in a series of β-aroyl acrylic acids was β-2,4,6-triethylbenzoylacrylic acid.[2] The preparation of β-2,6-dihydroxy- (I) and β-2,4,6-trihydroxybenzoyl acrylic acid (II) was attempted to determine the effect of ortho hydroxyl groups. The formula chart shows the method used for I.

Condensation of III with diethyl oxalate in the presence of sodium ethoxide gave IV. The crude product was heated under reflux with a mixture of glacial acetic and concentrated hydrochloric acids to give V. This in turn was esterified and hydrogenated to VII.

It had been previously shown that 2-carbethoxy-γ-chromanone was easily converted to β-(*o*-hydroxybenzoyl)-acrylic acid by treatment with dilute alkali. Hence treatment of VII with alkali gave either I or VIII.



It was expected that the reaction between maleic anhydride and phloroglucinol would result in the formation of II and 2-carboxy-5,7-dihydroxy-γ-chromanone (IX), for a similar reaction using

cinnamoyl chloride led to the formation of a mixture of a chalcone and γ-chromanone derivative.[3] When the reaction mixture was worked up however only one acid was isolated.

The two acids are almost white in color whereas all the other β-aroylacrylic acids prepared were highly colored. They both failed to abolish the nitroprusside reaction of cysteine, a test designed for the detection of α,β-unsaturated ketones.[4] All the β-aroylacrylic acids previously prepared readily added cysteine.[2] The two compounds were ineffective as antibacterial agents. Treatment of the supposed β-2,6-dihydroxybenzoylacrylic acid with excess diazomethane in ether gave the methyl ester exclusively. The failure to methylate the phenolic group was not surprising for more drastic conditions are needed as a general rule to alkylate such a group ortho to a carbonyl.[5] The complete absence of any pyrazoline derivative was an argument against I. According to the work of Lutz and Scott[6] diazomethane reacts with β-aroylacrylic acids to give substituted pyrazolines.

From the above it was felt that the correct structures of the two acids prepared are most likely VIII and IX.

## Experimental[7]

**2-Carboxy-5-hydroxy-γ-chromone (V).**—Alcohol-free sodium ethoxide was prepared by adding 25 cc. of absolute ethanol to 8 g. (0.345 gram atom) of metallic sodium sanded in 350 cc. of dry xylene at 105–115° and distilling off the excess alcohol. The stirred suspension was cooled to 20° and a mixture of 16.1 g. (0.11 mole) ethyl oxalate and 15.2 g. (0.1 mole) of 2,6-dihydroxyacetophenone in 75 cc. of anhydrous ether was added during 15 minutes. The mixture was kept at 20–25° for 0.5 hr., heated under reflux for 1.5 hr., cooled and filtered. The sodium salt was dissolved in cold water and extracted twice with 200 cc. of ether. The aqueous solution was acidified to congo paper with 10% hydrochloric acid and extracted with 500 cc. of ether. The dried ethereal extract (sodium sulfate) was deprived of solvent and the residual red oil was dissolved in 90 cc. of 5 to 1 glacial acetic–concentrated hydrochloric acid and heated under reflux one hour. The reaction mixture was cooled and the insoluble solid (12 g.) was collected. Recrystallization from 75% acetic acid gave 10.3 g. (46%) of bright yellow crystals of V with a melting point of 264°.

*Anal.* Calcd. for $C_{10}H_6O_5$: C, 58.3; H, 2.9; neut. eq., 206. Found: C, 58.15; H, 2.97; neut. eq., 202.

**2-Carbethoxy-5-hydroxy-γ-chromone (VI).**—Concentrated sulfuric acid (5 cc.) was added to a suspension of 7.3 g. (0.035 mole) of V in 50 cc. of absolute ethanol and heated under reflux on a steam-bath. The insoluble chromone acid gradually went into solution. After one hour the reaction mixture was poured into 300 cc. of ice water with stirring. The solid was filtered off and washed free of acid with cold sodium bicarbonate solution. The ester was recrystallized from benzene to give 6.3 g. (76%) of yellow crystals melting at 148°.

*Anal.* Calcd. for $C_{12}H_{10}O_5$: C, 61.6; H, 4.3. Found: C, 61.88; H, 4.42.

**2-Carbethoxy-5-hydroxy-γ-chromanone (VII).**—A mixture of 4.7 g. (0.02 mole) of VI, 100 cc. of absolute ethanol and one-half teaspoonfull of a suspension of freshly prepared nickel catalyst[8] was heated to 80° under hydrogen at 30 lb. pressure. In ten minutes the pressure fell two pounds (theory, 1.6 lb.). The catalyst was filtered off and the filtrate was concentrated to 50 cc. and cooled. The less soluble VI was filtered off and identified by a mixture melting point. The filtrate was further concentrated and cooled. The yellow crystals obtained were recrystallized from absolute ethanol; m. p. 72–74°; 2.1 g. (44%).

*Anal.* Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.12. Found: C, 61.23; H, 5.18.

**Alkaline Hydrolysis of VII.**—Two grams (0.0084 mole) of VII was added to 25 cc. of 10% sodium hydroxide and heated to 75° for five minutes. The solution was acidified with 10% sulfuric acid and cooled. The tan product was recrystallized from 95% ethanol; m. p. of gray acid 191°; yield 0.95 g. (54%).

*Anal.* Calcd. for $C_{10}H_8O_5$: C, 57.7; H, 3.87; neut. eq., 208; mol. wt., 208. Found: C, 57.49; H, 4.03; neut. eq., 214; mol. wt., 240 (Rast method).

**2-Carbomethoxy-5-hydroxy-γ-chromanone.**—To an ethereal solution of 1.1 g. (0.0053 mole) of VIII was added a 5-fold (0.0265 mole) molar concentration of diazomethane in ether. The solution was allowed to stand overnight at room temperature. The excess diazomethane and solvent were distilled off and the sirupy residue was washed with sodium bicarbonate solution. The insoluble material was dissolved in ether and dried (sodium sulfate). Removal of the ether left a solid which was recrystallized from methanol; m. p. 78.5°; 0.74 g. (63%). The compound still gave a positive test for the phenolic group with ferric chloride solution.

**5,7-Dihydroxy-2-carboxy-γ-chromanone (IX).**—A mixture of 5.04 g. (0.022 mole) of phloroglucinol and 3.96 g. (0.04 mole) of maleic anhydride in 45 cc. of nitrobenzene was cooled to 10°. During the course of 15 minutes 17.42 g. (0.13 mole) of anhydrous aluminum chloride was introduced with mechanical stirring. External cooling was needed to keep the temperature at 30°. After 0.5 hr. the exothermic reaction subsided and the mixture was stirred at room temperature for 0.75 hr. The aluminum complex was decomposed in a mixture of ice and concentrated hydrochloric acid. The crude acid (4 g.) was recrystallized from water; m. p. of light colored acid 262.5° (dec.).

*Anal.* Calcd. for $C_{10}H_8O_6$: C, 53.56; H, 3.57; neut. eq., 224. Found: C, 53.14; H, 3.58; neut. eq., 230.

**Acknowledgments.**—The authors would like to express their thanks to Mr. Glenn B. Hess and Miss Celia Durham for their analytical results.

## Summary

An attempt was made to prepare β-(2,6-dihydroxybenzoyl)-acrylic acid and β-(2,4,6-trihydroxybenzoyl)-acrylic acid. The failure of these compounds to add cysteine and their almost white color indicate that cyclization has occurred to give the corresponding 2-carboxy-γ-chromanone.

# The Chemical Behavior of Hexachlorocyclopentadiene. I. Transformation to Octachloro-3a,4,7,7a-Tetrahydro-4,7-methanoindene-1,8-dione[1]

BY J. S. NEWCOMER[2] AND E. T. McBEE

During the course of extensive studies conducted in this Laboratory on the chlorination of organic compounds, it was discovered that the pentanes, with the exception of neopentane, can be readily converted to hexachlorocyclopentadiene. The results of preliminary investigations concerning the chemical behavior of this chlorocarbon are shown diagrammatically in Fig. 1.

In view of the recent publication of Prins,[3] the authors were prompted to report[4] the results of concurrent investigations on this versatile chemical intermediate. Since this report,[4] Krynitsky and Bost[5] have described the preparation of tetrachloro-5,5-diethoxycyclopentadiene by the reaction of hexachlorocyclopentadiene with sodium ethoxide.

Prins[3] reported the conversion of hexachlorocyclopentadiene to (a) nonachloromethylcyclopentene by the addition of chloroform, (b) a compound, $C_{10}Cl_{12}$, by the action of aluminum chloride, (c) 3,4,5-trichloro-3-cyclopentene-1,2-dione and 2,3,4,4,5-pentachloro-2-cyclopentenone by the action of sulfuric acid, and (d) octachlorocyclopentene by the addition of chlorine. Recently, Prill[6] described the use of hexachlorocyclopentadiene in the diene synthesis.

The ketals (II), tetrachloro-5,5-dimethoxy- and -diethoxycyclopentadiene, were prepared by the action of the appropriate sodium alkoxides or alcoholic potassium hydroxide on hexachlorocyclopentadiene (I). The ketals were shown to contain a diene system by effecting condensations with maleic anhydride. The adducts, 1,4,5,6-tetrachloro-7,7-dialkoxybicyclo(2.2.1)5-heptene-2,3-dicarboxylic acids (XIV), were converted to 4,5-dichlorobenzene-1,2,3-tricarboxylic acid (XV) upon treatment with sulfuric acid. The position of the two alkoxy groups on the same carbon atom was also established by hydrolysis of II with sulfuric acid to form tetrachlorocyclopentadienone, which immediately dimerized to form an indefinite hydrate of octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione. Recrystallization of the latter from aqueous acetic acid produced the tetrahydrate (III), which was identified by dehydration to the anhydrous form (IV) and by conversion to hexachloroindone (V) upon treatment with water. The anhydrous form (IV) was shown by the method of mixed melting points to be identical to that prepared as described by Zincke[7] and Meyer by the reduction of a hexachlorocyclopentenone (m. p. 28°) with stannous chloride. Although not reported by Zincke, the initial product isolated from the reaction mixture is an indefinite hydrate of IV. The hydrate is readily differentiated from the anhydrous form by the insolubility of the former in non-polar solvents at room temperature. However, if the hydrate is boiled with such solvents until solution is effected, the product obtained by cooling the solution is the anhydrous form. The reduction of an isomeric hexachlorocyclopentenone (m.p. 92°) with stannous chloride has been reported[5] to form a compound having the molecular formula $C_5H_2Cl_4O$. This material has now been found to be a hydrate of indefinite composition of IV, containing approximately two molecules of water.

Octachlorocyclopentene (VI) was prepared by the addition of chlorine to I at atmospheric pressure and in the presence of a catalytic amount of aluminum chloride. The rapid absorption of

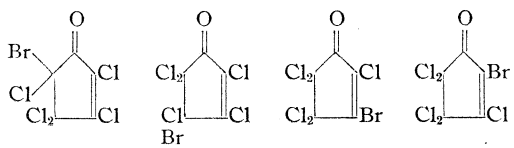
chlorine under these conditions provides a convenient method for preparing large quantities of VI in a short period of time.

Hexachlorocyclopentenone (m.p. 28°) used in this investigation was derived by the action of sulfuric acid on VI. The conversion of this ketone to (a) an isomeric hexachlorocyclopentenone (m.p. 92°) by the application of heat and (b) a pentachloropentadienoic acid (m.p. 124–125°) by treatment with alkali showed it to be identical to the ketone obtained from a hexachlorocyclohexenedione[8] through a series of reactions and also by the action of sulfuric acid on octachloropentadiene.[3] Considerable work has been performed[8,9,10] in attempts to determine the position of the ethylenic bond in the two isomeric hexachlorocyclopentenones (VIII) and (IX). van Brederode[11] states that "none of the reactions of the two ketones $C_5Cl_6O$ permits a definite choice between the two isomers." An attempt to identify the ketones by Raman spectra[11] was not decisive. The last attempt of Zincke[7] to establish the identity of the ketones was based upon the reduction of the isomer having a melting point of 28° to form a compound tentatively identified as 2,3,4,4,5-pentachloro-2-cyclopentenone, since it decomposed upon treatment with alkali. A more rigorous determination of the structure of the pentachlorocyclopentenone performed in this Laboratory has substantiated the proposed structure. It was assumed previously[7] that 2,3,4,4,5-pentachloro-2-cyclopentenone could be derived only from the conjugated hexachloroketone, apparently because (a) it was considered improbable that rearrangement might occur under similar treatment of the unconjugated hexachloroketone and (b) reduction of the hexachloroketone melting at 92° gave a compound $C_5H_2Cl_4O$ of unknown structure. Since this compound is now shown to be a hydrate of IV, rearrangement must have occurred upon reduction of the unconjugated ketone. Consequently, due to the lack of knowledge concerning the mechanisms of reduction and rearrangement of the unconjugated isomer, either hexachloroketone might have formed 2,3,4,4,5-pentachloro-2-cyclopentenone.

Based upon the data presented herein and further interpretation of published information, it seems probable that the ketone melting at 28° has the structure shown as compound VIII and that its isomer melting at 92° has the structure IX. It was known[12] that cleavage of the hexachloroketone melting at 28° produces a high yield of only one product, a pentachloropentadienoic acid (m.p. 124–125°), whereas cleavage of the isomeric ketone melting at 92° produces an isomeric acid (m.p. 96°) contaminated with a small quantity of the higher melting acid. Furthermore, separation of the two isomeric acids has been accomplished only by microscopic techniques. Investigations in this Laboratory show that pure pentachloropentadienoic acid (m.p. 124–125°) can be obtained in high yield by (a) treatment of octachlorocyclopentene with sodium methoxide to form a ketal of hexachlorocyclopentenone, (b) hydrolysis of the ketal to a hexachlorocyclopentenone, and (c) cleavage of the ketone with alkali to form the acid. The enhanced reactivity of chlorine atoms in a position allylic to a double bond is well known, and is used to establish the structure of the ketal as 1,2,4,4,5,5 - hexachloro - 3,3 - dimethoxycyclopentene. Hydrolysis of the ketal to form hexachloro-2-cyclopentenone may be readily explained. On the other hand, hexachloro-3-cyclopentenone could have been formed only through a rearrangement. Consideration of the equilibrium mixtures[10,11] of the two ketones at various temperatures shows that if a rearrangement had occurred upon hydrolysis of the ketal, the product would have been a mixture of the two ketones containing at least 5% of the isomer melting at 92°. Since the ketone melting at 28° was the only product, a rearrangement could not have taken place. Further evidence supporting structure VIII as that of the ketone melting at 28° is obtained by an interpretation of the results of Zincke and co-workers.[13,14,15,16] Whereas ammonia converted the higher melting ketone to an amide of a pentachloropentadienoic acid, the other ketone was converted to a pentachloro-3-iminocyclopentanone which was believed to be either 2,4,4,5,5-pentachloro-3-iminocyclopentanone or 2,2,4,5,5-pentachloro-3-iminocyclopentanone. The action of basic reagents on the lower melting ketone proceeds by two distinct modes of attack. Cleavage occurs by the action of aqueous potassium hydroxide to produce a pentachloropentadienoic acid. Addition to the conjugated system occurs by the action of both ammonia and aniline resulting in the ultimate formation of pentachloro-3-iminocyclopentanones. On the other hand, the higher melting ketone does not show the properties of a conjugated system, since both aqueous alkali and ammonia convert it to straight chain derivatives, while aniline reacts with it only on long standing to form an amorphous material.



Prins[3] reported the preparation of a pentachlorocyclopentenone (m.p. 82–83°) by the action of sulfuric acid on hexachlorocyclopentadiene at 100–105°, "the lowest temperature at which reaction occurs." Under these conditions, or at

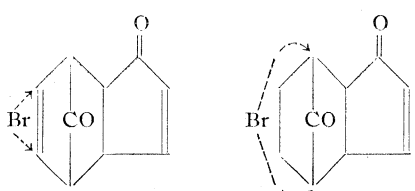
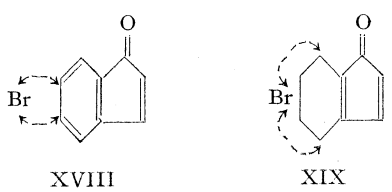
higher temperatures, the main product was 3,4,5-trichloro-3-cyclopentene-1,2-dione. It has been shown in this Laboratory that a compound $C_5HCl_5O$ (m.p. 82-83°) (X) can be obtained in 78% yield by performing the reaction at 80°. Both pentachlorocyclopentenones are identical to those obtained[7] by the reduction of VIII.

During the course of the identification of the pentachlorocyclopentenone, attempts were made to replace the hydrogen atom by a halogen atom. Although chlorination was not successful, bromination occurred readily to form a compound $C_5BrCl_5O$ (m.p. 3–4°). The identification of the bromo derivative as 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone (XI) and the reduction of the bromoketone to the original pentachloroketone provides evidence useful in establishing the structure of the pentachloroketone.

Of the six possible bromopentachlorocyclopentenones (XI-XIE), structures XIB and XIC



XI XIA XIB XIC



XID XIE

were readily eliminated, since treatment of the bromoketone with potassium iodide in acetone solution formed hexachloroindone (V). Structures XIB and XIC would have formed the intermediates XVI and XVII, in which a bromine atom is attached to either position 5 or 6 and 4 or 7, as indicated. The elimination of $COX_2$ from these intermediates would have formed bromoindone derivatives, represented by structures XVIII and XIX. The reduction of the bromo-

XVI XVII

XVIII XIX

ketone (XI) to form a stable pentachlorocyclopentenone eliminates structures XID and XIE. Structure XID would be expected to behave similarly to hexachloro-3-cyclopentenone, in which case an unstable intermediate, $C_5HCl_5O$, would immediately dehydrochlorinate and dimerize to form a hydrate of IV. Structure XIE is likewise improbable, since reduction with stannous chloride should form a bromocyclopentenone or the dimer of a tetrahalocyclopentadienone. Structure XIA, as well as XIB, XIC, and XIE was eliminated by cleavage of the bromoketone with aqueous alkali to form a bromotetrachloropentadienoic acid (XII), in which the bromine atom was shown to be on the terminal carbon atom. The salt solution obtained after removal of the acid was free of bromide ion. The bromo acid was identified by its synthesis from tetrachloro-5,5-dimethoxycyclopentadiene (II), involving (a) addition of bromine, (b) hydrolysis of the dibromoketal to a dibromotetrachlorocyclopentenone (XIIIA) or (XIIIB), and (c) cleavage of the dibromoketone with alkali. Irrespective of the structure of the dibromoketone, the resulting bromo acid, $C_4BrCl_4CO_2H$, must be 5-bromo-2,3,4,5-tetrachloropentadienoic acid. Since it is identical to the acid obtained by cleavage of the bromopentachlorocyclopentenone, only structure XI readily accounts for all the experimental results.

The reduction of hexachloro-2-cyclopentenone with stannous chloride to form a pentachlorocyclopentenone might be initiated at the carbonyl group, or at positions 4 or 5. Possible attack at the carbon to carbon double bond necessitates a consideration of allylic shifts involving carbon atoms 2, 3, and 4. On the other hand, the reduction of 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone to a pentachlorocyclopentenone could conceivably occur only at the carbonyl group or at position 5. The replacement of the bromine atom by a hydrogen atom is not concerned with the position allylic to the carbon to carbon double bond, and there is no reason to suspect an allylic shift involving carbon atoms 2, 3, and 4. Consequently, whether the reduction involves direct replacement of the bromine atom by a hydrogen atom, or conversion of the carbonyl group to an alcohol followed by dehydrobromination and ketolization, the only possible product is 2,3,4,4,5-pentachloro-2-cyclopentenone (X).

It is interesting to note that the reaction of hexachlorocyclopentadiene with sulfuric acid produces 2,3,4,4,5-pentachloro-2-cyclopentenone, whereas fluorosulfonic acid produces octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione, and chlorosulfonic acid produces a compound having the molecular formula $C_{10}H_2SCl_{12}O_3$, the identification of which is in progress.

## Experimental

**Materials.**—The hexachlorocyclopentadiene used in this investigation was supplied by the Hooker Electrochemical Company. Other reagents were obtained from the usual chemical supply houses.

**1,2,3,4-Tetrachloro-5,5-dimethoxycyclopentadiene.**—A solution containing 684 g. (12.2 moles) of potassium hydroxide dissolved in 3 liters of methanol was added to a

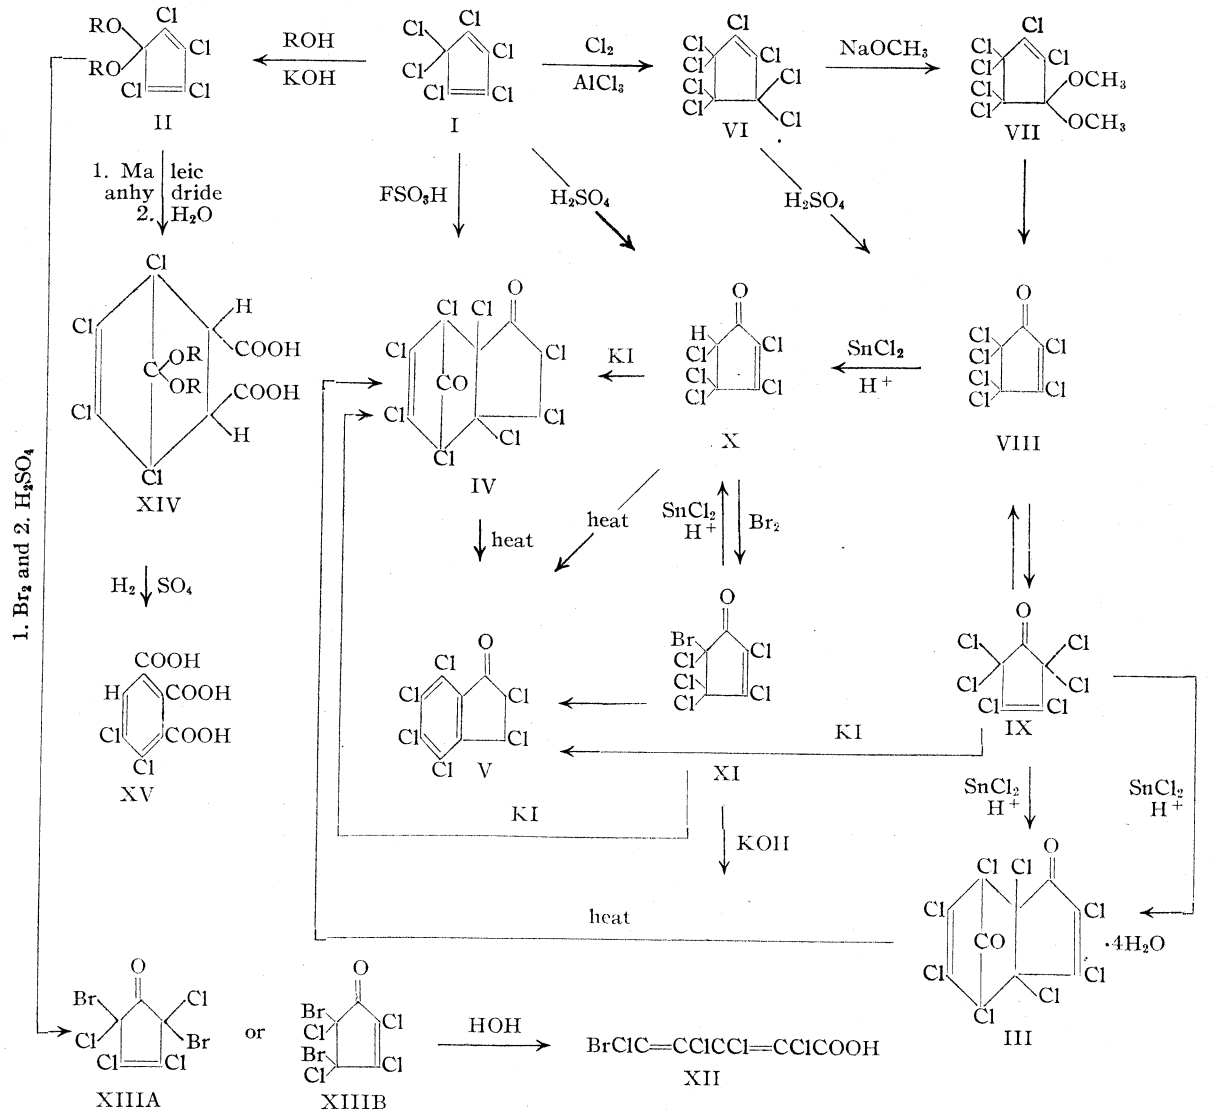


Fig. 1.

solution of 1270 g. (4.7 moles) of hexachlorocyclopentadiene in 4 liters of methanol during a period of four hours. The temperature increased from 48° at the beginning of the addition to 60° at the end. After dilution with water, the organic layer was separated, washed with water, dried, distilled, and rectified. There was obtained 841 g. (3.2 moles) of 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene, a yellow liquid having a sweet odor and the following physical properties: b. p. (11 mm.) 108–110°, $d^{20}_4$ 1.5010, $n^{20}D$ 1.5288.

*Anal.* Calcd. for $C_7H_6Cl_4O_2$: Cl, 53.8. Found: Cl, 53.8.

**1,2,3,4-Tetrachloro-5,5-diethoxycyclopentadiene.**—This acetal, b. p. (5 mm.) 101–103°, $d^{20}_4$ 1.3932, and $n^{20}D$ 1.5063, was prepared from hexachlorocyclopentadiene in a manner similar to that described for the dimethoxy derivative using ethanol as a solvent and reactant in place of methanol.

*Anal.* Calcd. for $C_9H_{10}Cl_4O_2$: Cl, 48.7; mol. wt., 292. Found: Cl, 49.2; mol. wt. (cryoscopic in benzene), 287.

**1,2,3,4,11,12,13,14-Octachloro-6,9,15,18-tetraoxadispiro(4.4.4.4)-1,3,11,13-octadecatetraene.**—Hexachlorocyclopentadiene (540 g., 2.0 moles) was added to a solution of potassium hydroxide (600 g., 10.7 moles) in ethylene glycol (750 g., 12.1 moles) at 50–60° during a period of two hours. After cooling, the reaction mixture was diluted with water and the organic layer separated and dissolved in petroleum ether. Upon cooling in a bath of Dry Ice and trichloroethylene, fine white needle-like crystals separated. Recrystallization of the solid from a mixture of acetone and benzene produced 63 g. of the octadecatetraene, m. p. 279–280°.

*Anal.* Calcd. for $C_{14}H_8Cl_8O_4$: Cl, 54.2; mol. wt., 524. Found: Cl, 54.1; mol. wt. (Rast), 511, 518.

**1,4,5,6-Tetrachloro-7,7-dimethoxybicyclo(2.2.1)-5-heptene-2,3-dicarboxylic Acid and Anhydride.**—A solution containing 53 g. of tetrachloro-5,5-dimethoxycyclopentadiene, 19 g. of maleic anhydride, and 300 ml. of xylene was refluxed for 1.25 hours. During this period, the pale yellow solution became orange and a solid crystallized. The solvent was removed by steam distillation. Upon cooling, tan crystals separated from the water and collected on the orange residue. After filtration, the solid product was washed repeatedly with petroleum ether (90–100°) at room temperature. The resulting white product (62 g.) was recrystallized from water to produce 1,4,5,6-tetrachloro-7,7-dimethoxybicyclo(2.2.1)-5-heptene-2,3-dicarboxylic acid, m. p. 196–197°.

*Anal.* Calcd. for $C_{11}H_{10}Cl_4O_6$: Cl, 37.4; neut. equiv., 190. Found: Cl, 38.0; neut. equiv., 192.

The dibasic acid (14 g.) was heated at 220–225° until the evolution of gases ceased. The product was cooled, extracted with hot benzene, filtered, and recrystallized from benzene to obtain the anhydride, m. p. 192°.

*Anal.* Calcd. for $C_{11}H_3Cl_4O_5$: Cl, 39.2; neut. equiv. (in methanol), 362. Found: Cl, 39.7; neut. equiv., 360.

**4,5-Dichlorobenzene-1,2,3-tricarboxylic acid.**—1,4,5,6-Tetrachloro-7,7-dimethoxybicyclo(2.2.1)-5-heptene-2,3-dicarboxylic acid (14 g.) was heated with concentrated sulfuric acid (150 g.) at 90° for twenty minutes. Upon cooling the resulting solution, crystals of 4,5-dichlorobenzene-1,2,3-tricarboxylic acid anhydride crystallized. The anhydride was filtered, dissolved in water, extracted with ether, and recrystallized from an ether–benzene mixture to produce 4 g. of 4,5-dichlorobenzene-1,2,3-tricarboxylic acid, m. p. 124–126°.

*Anal.* Calcd. for $C_9H_4Cl_2O_6$: Cl, 25.4; neut. equiv., 93. Found: Cl, 25.8; neut. equiv., 95.

**Octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione. Method A.**—1,2,3,4-Tetrachloro-5,5-diethoxycyclopentadiene (11 g.) was added slowly to 45 g. of concentrated sulfuric acid at 0–5°. Immediately upon the addition of each drop of the acetal, a red color formed which disappeared with the simultaneous precipitation of a white solid. The mixture was poured onto cracked ice and the solid was washed repeatedly with water and "dried" by exposure to the atmosphere. There was obtained 8.9 g. of a hydrate of octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione. This material melted with decomposition at 157–163°.

*Anal.* Calcd. for $C_{10}Cl_8O_2 \cdot 2H_2O$: Cl, 60.2; mol. wt., 462. Found: Cl, 59.2; mol. wt. (cryoscopic in nitrobenzene), 455.

A hydrate of octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione was also obtained by the reduction of hexachloro-3-cyclopentenone with stannous chloride as described by Zincke,[5] who reported the product to have the formula $C_5H_2Cl_4O_2$. The hydrate was converted to the tetrahydrate by recrystallizing from aqueous acetic acid. The tetrahydrate was converted to the anhydrous material by recrystallizing from petroleum ether as well as by heating to constant weight at 90–95° at 20 mm.

*Anal.* Calcd. for $C_{10}Cl_8O_2 \cdot 4H_2O$: Cl, 55.9; mol. wt., 508. Found: Cl, 55.9; mol. wt. (cryoscopic in glacial acetic acid), 509, 482, 508.

*Anal.* Calcd. for $C_{10}Cl_8O_2$: Cl, 65.2. Found: Cl, 65.2.

**Method B.**—A mixture containing 30 g. of potassium iodide, 27 g. (0.11 mole) of 2,3,4,4,5-pentachloro-2-cyclopentenone and 1 liter of acetone was refluxed for thirty minutes, cooled, and poured into water. There was an immediate precipitation of a red solid followed by the separation of a flocculent orange solid. Separation by decantation gave 4 g. of hexachloroindone, orange in color, and a red solid which was washed with aqueous potassium iodide and water to remove the color. Recrystallization from petroleum ether (90–100°) gave 19 g. of anhydrous octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione. The yields were 11 and 88%, respectively.

**Method C.**—Fluorosulfonic acid (200 g., 2.0 moles) was added to hexachlorocyclopentadiene (544 g., 2.0 moles) at 120° during a period of twenty-five minutes. After addition of the fluorosulfonic acid was completed, the mixture was heated at 80–100° with vigorous stirring for one and one-fourth hours. The orange-red reaction mixture was poured onto cracked ice and the organic layer separated and washed with water. The semi-solid product was filtered and the solid recrystallized from petroleum ether (90–100°). There was obtained 146 g. of octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione.

**Octachlorocyclopentene.**—Chlorine was bubbled rapidly into a stirred mixture of 2580 g. (9.49 moles) of hexachlorocyclopentadiene and 40 g. of anhydrous aluminum chloride. The temperature of the reaction mixture was maintained at 40–45° by absorbing the heat of the rapidly occurring exothermic reaction in an ice–water-bath. The mixture was washed with warm water and then purified by crystallization from ethanol. The purified product weighed 3245 g. (9.46 moles) and melted at 39°.

*Anal.* Calcd. for $C_5Cl_8$: Cl, 82.6. Found: Cl, 82.3.

**Hexachloro-2-cyclopentenone.**—A mixture containing 1832 g. (5.3 moles) of octachlorocyclopentene and 2600 g. of concentrated sulfuric acid was heated with vigorous stirring for seven hours at 105°. After cooling to 25°, the pale yellow upper layer was separated, washed with water and recrystallized twice from *n*-pentane. There was obtained 1138 g. (3.9 moles) of hexachloro-2-cyclopentenone, m. p. 28°. This product was converted to hexachloro-3-cyclopentenone (m. p. 92°) and to pentachloropentadienoic acid (m. p. 124.5–125° cor.).[8]

**Pentachloropentadienoic Acid.**—Sixty-seven grams of sodium (2.9 moles) was added to 1.5 liters of methanol. The solution was added to a suspension of 548 g. (1.6 moles) of octachlorocyclopentene in 2 liters of methanol at 45–50° during a three and one-half-hour period. Water was added to the reaction mixture and the solid which precipitated was separated and recrystallized from pentane. A 95-g. portion of a crude product was stirred with concentrated sulfuric acid at 45° for ten minutes. The sulfuric acid mixture was poured onto cracked ice, the resulting liquid was washed with water, and then it was added to a solution of 50 g. of potassium hydroxide in 400 g. of water at 25°. After stirring for ten minutes, the mixture was filtered to obtain 23 g. of unreacted octachlorocyclopentene. The filtrate was acidified with dilute hydrochloric acid. The pentachloropentadienoic acid, which precipitated, melted at 118–120°. This acid was readily purified by recrystallizing from a mixture of carbon tetrachloride and pentane. After two recrystallizations, the acid melted at 124.5–125° (cor.). This material was shown by a method of mixed melting points to be identical with pentachloropentadienoic acid obtained by cleavage of hexachloro-2-cyclopentenone.

**2,3,4,4,5-Pentachloro-2-cyclopentenone. Method A.**—A mixture of 814 g. (3.0 moles) of hexachlorocyclopentadiene and 1600 g. of concentrated sulfuric acid was heated with vigorous stirring at 80° until the solution was complete. This required eleven hours. A portion (790 ml.) of the homogeneous reaction mixture (total volume 1270 ml.) was poured onto cracked ice and the resulting solid was separated by filtration. The crude material was purified by recrystallization from petroleum ether (90–100°). There was obtained 372 g. (1.5 moles) of 2,3,4,4,5-pentachloro-2-cyclopentenone, m. p. 82–83°, yield 78%. This material did not depress the melting point of the compound $C_5HCl_5O$ prepared previously.[7]

*Anal.* Calcd. for $C_5HCl_5O$: Cl, 69.7; mol. wt., 254. Found: Cl, 69.6; mol. wt. (cryoscopic in benzene), 257.

**Method B.**—Thirty-one grams (0.14 mole) of stannous chloride dihydrate was dissolved in a mixture of 62 g. of glacial acetic acid and 150 g. of concentrated hydrochloric acid. The resulting solution was added to a mixture of 30 g. (0.9 mole) of 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone in 300 g. of glacial acetic acid at 10–15° during a period of twenty minutes. The reaction mixture was diluted with water and the solid material which separated was recrystallized from a pentane-carbon tetrachloride mixture. Eighteen grams (0.07 mole) of 2,3,4,4,5-pentachloro-2-cyclopentenone, m. p. 82–83°, was obtained in a yield of 78%. Attempts to convert this material to hexachlorocyclopentenone by reaction with liquid chlorine at 30° and by reaction with gaseous chlorine at 70° (carbon tetrachloride solution) were unsuccessful.

**5-Bromo-2,3,4,4,5-pentachloro-2-cyclopentenone.**—Two hundred and ten grams of bromine (1.3 moles) and 275 g. (1.08 moles) of 2,3,4,4,5-pentachloro-2-cyclo-

pentenone were added to 1.5 liters of carbon tetrachloride. The mixture was allowed to stand at 25° for twenty-two hours in the presence of light from two 40-w. 360 B. L. lamps. Carbon tetrachloride, bromine, and dissolved gases were removed by heating on a steam-bath under reduced pressure. The liquid product which remained was crystallized from petroleum ether (90–100°) to obtain 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone (221 g., 0.66 mole), m. p. 3–4°, and 102 g. of starting material. The conversion and yield were 62 and 98%, respectively.

*Anal.* Calcd. for $C_5BrCl_6O$: total halogen (calculated chloride, grav. anal.) 63.9. Found: total halogen, 62.8.

**Dibromotetrachlorocyclopentenone.**—A mixture containing 150 g. (0.94 mole) of bromine, 200 g. (0.73 mole) of 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene, and 500 g. of carbon tetrachloride was allowed to stand at room temperature for fifteen hours. The mixture was then heated on a steam-bath to remove excess bromine and carbon tetrachloride. The viscous liquid which remained was added slowly to 800 g. of concentrated sulfuric acid at 30°. The mixture was poured onto cracked ice and the organic product was crystallized from pentane. After repeated recrystallizations, a white solid melting at 156–157° was obtained. The odor of bromine was readily detected in the pure solid, and upon warming with water bromine vapors were evolved.

*Anal.* Calcd. for $C_5Br_2Cl_4O$: total halogen (calculated as chloride), 56.4. Found: total halogen, 56.4.

**5-Bromo-2,3,4,5-tetrachloropentadienoic Acid. Method A.**—Cleavage of 14 g. (0.042 mole) of 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone was accomplished by adding the ketone, with stirring, to 30 g. of potassium hydroxide in 270 ml. of water at 25°. The reaction mixture was diluted and filtered. A tan solid precipitated upon acidification of the filtrate with dilute hydrochloric acid. This solid was recrystallized from carbon tetrachloride to give 6 g. (0.02 mole) of 5 bromo 2,3,4,5-tetrachloropentadienoic acid: white solid, m. p. 118–119°.

*Anal.* Calcd. for $C_5HBrCl_4O_2$: total halogen (calculated as chloride), 56.4; neut. equiv., 315. Found: total halogen, 56.0; neut. equiv., 317.

**Method B.**—Excess bromine was added slowly to a few grams of 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene and the reaction mixture was allowed to stand until it cooled to room temperature. The mixture was dropped into concentrated sulfuric acid at room temperature, poured onto cracked ice, washed with water, and dissolved in 10% aqueous potassium hydroxide solution. After filtration and acidification, a white solid, m. p. 119°, was obtained. It did not depress the melting point of the acid obtained by Method A.

**Hexachloroindone.**—5-Bromo-2,3,4,4,5-pentachloro-2-cyclopentenone (60 g., 0.18 mole), potassium iodide (70 g., 0.42 mole) and acetone (1 liter) were mixed and refluxed for two and one-half hours. The reaction mixture was then cooled and diluted with water. The orange solid which precipitated was washed with aqueous potassium iodide and recrystallized from acetone to give 25 g. (0.074 mole) of hexachloroindone, m. p. 149°, yield 83%. This product is identical to that obtained by heating octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione with water.

*Anal.* Calcd. for $C_9Cl_6O$: Cl, 63.1. Found: Cl, 63.1.

**Reaction of Hexachlorocyclopentadiene with Chlorosulfonic Acid.**—A mixture of 1000 g. of hexachlorocyclopentadiene (3.68 moles) and 1000 g. (8.62 moles) of chlorosulfonic acid was stirred vigorously for two hours at 90°. Solid began to crystallize from the reaction mixture after one half hour. After cooling in an ice-bath, the thick slurry was filtered through a sintered glass funnel and the solid was washed with water, refiltered, and washed with petroleum ether (90–100°) saturated with the final product. The resulting product, 987 g., m. p. 143–147°, was a white, crystalline solid. Recrystallization from petroleum ether-benzene increased the melting point to 146–147°.

*Anal.* Calcd. for $C_{10}H_2Cl_{12}O_3S$: C, 19.11; H, 0.32; Cl, 67.8; S, 5.09; mol. wt., 627. Found: C, 19.02, 19.10; H, 0.26, 0.25; Cl, 67.6, 67.8, 67.8; S, 5.05, 5.12; mol. wt. (ebull. in benzene), 611, 639.

Distillation of the original filtrate produced 674 g. (5.81 moles) of chlorosulfonic acid and 130 g. of tar, whereas decomposition of the filtrate by dropping onto ice produced 97.5 g. of a mixture of hexachlorocyclopentadiene and the sulfur-containing product. The conversion and yield are 86 and 95%, respectively. The structure of the product is being investigated.

**Acknowledgment.**—The authors express their indebtedness to the Hooker Electrochemical Company for defraying the expenses of this investigation and for supplying the hexachlorocyclopentadiene used.

## Summary

Hexachlorocyclopentadiene reacts with alcoholic alkali to form the ketals, tetrachloro-5,5-dialkoxycyclopentadiene. The ketals react with dienophiles to form Diels–Alder adducts and undergo hydrolysis to give octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione. The tricyclic ketone was also prepared by treatment of 2,3,4,4,5-pentachloro-2-cyclopentenone and 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone with potassium iodide in acetone solution, as well as by the reaction of hexachlorocyclopentadiene with fluorosulfonic acid.

The reaction of hexachlorocyclopentadiene with sulfuric acid may be controlled to produce a 78% yield of 2,3,4,4,5-pentachloro-2-cyclopentenone, which was identified by bromination to 5-bromo-2,3,4,4,5-pentachloro-2-cyclopentenone, reduction of the bromoketone to the same pentachloroketone, and conversion of the pentachloroketone to octachlorotetrahydromethanoindenedione. Identification of the bromoketone was based primarily upon cleavage to form 5-bromo-2,3,4,5-tetrachloropentadienoic acid, the structure of which was demonstrated by synthesis involving (a) addition of bromine to tetrachloro-5,5-dimethoxycyclopentadiene, (b) hydrolysis of the acetal linkage to form a dibromotetrachlorocyclopentenone, and (c) cleavage of the dibromoketone with alkali.

Octachlorocyclopentene, prepared by the catalytic addition of chlorine to hexachlorocyclopentadiene, was found to produce hexachloro-2-cyclopentenone by reaction with sulfuric acid. Strong chemical evidence is presented in regard to the aged controversy as to the structure of the isomeric hexachlorocyclopentenones (m. p. 28° and 92°). The former is believed to be hexachloro-2-cyclopentenone; the latter, hexachloro-3-cyclopentenone.

# The Chemical Behavior of Hexachlorocyclopentadiene. II. Condensation with Trichloroethylene[1]

BY J. S. NEWCOMER[2] AND E. T. McBEE

The exceptional reactivity of hexachlorocyclopentadiene (I) in the presence of aluminum chloride may be attributed to the pentachlorocyclopentadienyl cation, $C_5Cl_5^+$. The resonance forms of this ion provide a theoretical basis for the susceptibility of I toward addition reactions, either as an addend or augend. The former is illustrated by the addition of chloroform to I to produce a nonachloromethylcyclopentene[3] and by the addition of chlorine in the presence of aluminum chloride to form octachlorocyclopentene.[4] The latter is illustrated by the addition of I to trichloroethylene to form 5-(1,2,2,2-tetrachloroethyl)-pentachlorocyclopentadiene (II). Both processes are illustrated by the dimerization of I to form a compound $C_{10}Cl_{12}$ (XVI). A summary of the reactions reported in this paper is shown diagrammatically in Fig. 1.

Since the presentation of this paper,[4,5] Krynitsky and Bost[6] reported the preparation of a compound $C_7HCl_9$ by the condensation of I with trichloroethylene in the presence of aluminum chloride. These investigators also reported the preparation of a chlorocarbon $C_7Cl_8$ by the dehydrochlorination of $C_7HCl_9$ with alcoholic alkali. No proof of the structure of these materials was presented. Investigations in this Laboratory have shown that the condensation of I with trichloroethylene may be controlled to produce high yields of either $C_7HCl_9$ (II) or $C_7Cl_8$(l), octachloro-1 or 2-vinylcyclopentadiene (IV), with a small quantity of a dimer of I as a by-product. Although I readily dimerizes in the presence of aluminum chloride, the rate of dimerization at 80° is not as rapid as the rate of condensation with trichloroethylene. By performing the condensation at 80°, and then increasing the temperature to 110–115°, the aluminum chloride effects rearrangement and dehydrochlorination of II to form IV. On the other hand, the dehydrochlorination of II with alcoholic alkali occurs without rearrangement to form an isomeric solid chlorocarbon $C_7Cl_8$(s), octachloro-5-ethylidenecyclopentadiene (III).

It is highly improbable that dehydrochlorination of $C_7HCl_9$ with alcoholic alkali involves a rearrangement. Consequently, the corresponding chlorocarbon $C_7Cl_8$(s) may be represented by structure III or IIIA, IVA, IVB, or IVC, depending upon whether it was derived from the structure II, IIA, IIB, or the bicyclic compound.

The isomeric chlorocarbons, $C_7Cl_8$(l) and $C_7Cl_8$(s) display entirely different chemical properties. The former undergoes reactions analogous to those of hexachlorocyclopentadiene, corresponding to structures IVA and IVB. The latter undergoes reactions typical of polychlorinated compounds which contain a trichloromethyl group attached to a carbon atom of an ethylenic bond, thus corresponding to structure III.

The bicyclic structure IVC can account in no apparent manner for either of these two types of reactions. In addition, IVC is not in accord with molecular refraction data, nor with the observed reactivity of both chlorocarbons toward alcoholic silver nitrate as well as toward alcoholic alkali. Furthermore, the liquid chlorocarbon, which was produced by the more drastic conditions, was converted to the unsaturated derivatives of ethylcyclopentane (XIII and XIV) by treatment with antimony pentafluoride. Fluorination of XIII with silver difluoride formed a chlorotridecafluoroethylcyclopentane. If the liquid chlorocarbon is assumed to have structure IVC, then cleavage must have occurred during the formation of the unsaturated compounds XIII and XIV. It is improbable that cleavage of the bicyclic compound would produce unsaturated derivatives of ethylcyclopentane, but more plausible to expect the cleavage

Chlorotridecafluoroethylcyclopentane. (*Position of trichlorovinyl group uncertain.)

to occur at a position allylic to the two ethylenic linkages to form unsaturated derivatives of methylcyclohexane, which might undergo further cleavage to form cyclohexene derivatives. However, no compound of these types of structures was obtained.

The fluorination of $C_7Cl_8$(l) (IV) with antimony pentafluoride to give high yields of the seven carbon atom compounds XIII and XIV may be contrasted with our previous investigations[7] in which it was shown that the fluorination of (tetrachlorophenyl) - pentachloroethane, (pentachlorophenyl)-dichlorotrifluoroethane, mixtures of polychloropolyfluoroethylbenzenes, pentachlorobenzotrifluoride, and hexachlorobenzene, under similar conditions, produced predominantly a six carbon atom compound, $C_6Cl_2F_8$.

The liquid chlorocarbon reacts rapidly with methanolic alkali to form an acetal, $C_7Cl_6(OCH_3)_2$ (IX), whereas the solid chlorocarbon reacts sluggishly to form a mixture of products. Structure III could form an acetal only by the elimination of a chloride ion to form an organic cation in which the charge could resonate from the terminal carbon atom of the side chain to one of the carbon atoms of the ring containing a chlorine atom. If this type of resonance were significant in the cation derived from structure III, then it should also be significant in the cations derived from structures IIIA, IVA, and IVB, since common resonance hybrids would be produced. Therefore, if III formed an acetal, IIIA, IVA, and IVB would also be expected to form acetals. The chlorocarbons $C_7Cl_8$(l) and $C_7Cl_8$(s) represent two of these four possible structures, but only the former forms an acetal. Hence, structure III cannot form an acetal and the structure of $C_7Cl_8$(l) is limited to IIIA, IVA, or IVB. Structure IIIA could form an acetal only by rearrangement, whereas IVA and IVB could form acetals with or without rearrangement. It seems highly improbable that IIIA would be converted to a completely conjugated system upon treatment with alcoholic alkali, but not in the presence of aluminum chloride for eleven hours at 110°, which are the conditions employed for the preparation of $C_7Cl_8$(l). The structure of this material is limited to octachloro-1 or 2-vinylcyclopentadiene (IVA or IVB). Further evidence supporting this contention is afforded by hydrolysis of the acetal with sulfuric acid at 5° to form a blood-red ketone, hexachloro-2 or 3-vinylcyclopentadienone (X) and its colorless Diels–Alder dimer (XI). In addition, reduction of $C_7Cl_8$(l) with zinc and acid resulted in the replacement of two chlorine atoms, and treatment with sulfuric acid formed a diketone $C_7HCl_5O_2$- (XII). This same diketone was obtained by hy-

(7) E. T. McBee, *et al.*, *Ind. Eng. Chem.*, **39**, 384 (1947).

drolysis of the acetal (IX) with sulfuric acid at 40°, thus illustrating the expected reaction of hexachloro-2 or 3-vinylcyclopentadienone (X) with sulfuric acid. These results are in accord with those expected of a simple derivative of hexachlorocyclopentadiene.[4]

There is no reason to expect structures IVA and IVB to behave differently toward alcoholic alkali. Therefore, the structure of $C_7Cl_8$(s) is limited to III or IIIA. Both of these compounds could have been derived only from structure II, thus establishing the compound $C_7HCl_9$ as 5-(1,2,-2,2-tetrachloroethyl)-pentachlorocyclopentadiene. The dehydrochlorination of II with alcoholic alkali to form IIIA would involve the removal of a primary chlorine atom which is not in an allylic position. Furthermore, the product of this type of dehydrochlorination results in the formation of an isolated double bond. On the other hand, it is more plausible to expect the dehydrochlorination of II to involve the removal of a tertiary chlorine atom which is also allylic to two double bonds. Furthermore, the product III contains a completely conjugated system of double bonds. In addition, III would be expected to react sluggishly with alcoholic alkali, as is the case, whereas IIIA should be exceedingly reactive. Contributing evidence that $C_7Cl_8$(s) has the structure III was obtained by its conversion to a white solid, pentachloro-2,4-cyclopentadienylideneacetyl chloride (V) by reaction with sulfuric acid. Although this material is an isomer of hexachloro-2 or 3-vinylcyclopentadienone (X), it has entirely different chemical and physical properties. It does not undergo Diels–Alder reactions, and can be distilled at atmospheric pressure with only slight decomposition. Also, it does not react with concentrated sulfuric acid at 100°, whereas X reacts readily at 40°. The acid chloride (V) is converted to methyl pentachloro-2,4-cyclopentadienylideneacetate (VIII) by refluxing with methanol or more rapidly by potassium hydroxide and methanol. Treatment of V with aqueous alkali forms the acid (VI). The amides (VII) were obtained by the action of the appropriate amines on both V and VIII.

Prill[8] has demonstrated the use of hexachlorocyclopentadiene in the diene synthesis. Derivatives of hexachlorocyclopentadiene in which the allylic chlorine atoms are replaced by methoxy and ethoxy groups have been found to react similarly.[4] The ease with which these highly chlorinated compounds undergo the diene synthesis may be attributed partially to the required *cis*-butadienoid configuration of the ring system. It is interesting to note, however, that III does not react with maleic anhydride under ordinary conditions. Another contrast is afforded by the dimerization of X at or below room temperature, as compared with the failure of IV to form an adduct with maleic anhydride in twenty hours at 135°.

## Experimental

**Materials.**—Hexachlorocyclopentadiene was obtained through the courtesy of the Hooker Electrochemical Company. Other reagents were obtained from the usual chemical supply concerns.

**Dimer of Hexachlorocyclopentadiene (XVI).**—A mixture of I (397 g.) and anhydrous aluminum chloride (40 g.) was stirred for one hour at 90–95°. In order to decrease the viscosity, carbon tetrachloride (300 ml.) was added and the mixture was heated for an additional three hours at 75–80°. The cooled reaction mixture was poured onto cracked ice, washed by decantation, and steam-distilled to remove the solvent. The resulting tan solid was recrystallized from benzene to give XVI (268 g.), a white solid which sublimes without melting at temperatures above 240°.

*Anal.* Calcd. for $C_{10}Cl_{12}$: Cl, 77.9, mol. wt., 544. Found: Cl, 77.9, mol. wt. (cryoscopic in benzene), 508, 529, 543.

The dimer was also prepared using tetrachloroethylene as the solvent. Although an 88% conversion to the dimer was obtained in the absence of a solvent, this method is not preferred because of the difficulty in controlling the highly exothermic dimerization.

**5-(1,2,2,2-Tetrachloroethyl)-pentachlorocyclopentadiene (II).**—One-fifth of 2.0 moles of trichloroethylene was added to a mixture of I (1.97 moles) and aluminum chloride (0.3 mole) during a period of twenty minutes as the temperature was increased to 80°. The remainder of the trichloroethylene was added during a period of forty minutes at 80°. After allowing the reaction to continue for an additional 1.5 hours, the purple mixture was cooled and poured onto ice. Recrystallization of the resulting tan solid from methanol gave II (1.80 moles), a white solid having a melting point of 80–81°.

*Anal.* Calcd. for $C_7HCl_9$: Cl, 78.9. Found: Cl, 78.6.

**Octachloro-5-ethylidenecyclopentadiene (III).**—A solution of potassium hydroxide (1.5 moles) in methanol (1 l.) was added to a stirred suspension of II (1.5 moles) in methanol (1.5 l.) during a period of twenty-five minutes at 42–45°. After dilution of the cooled reaction mixture with water, the resulting liquid was crystallized from pentane to obtain III (1.38 moles), a white solid of m. p. 53°, b. p. 146° at 7 mm.

*Anal.* Calcd. for $C_7Cl_8$: Cl, 77.2; mol. wt., 368. Found: Cl, 77.4; mol. wt. (cryoscopic in benzene), 370, 372.

It is important to avoid the use of an excess of alkali in the dehydrochlorination, for when 180% excess alkali was used, the yield of desired product was decreased to 27%.

**Octachloro-1- or 2-vinylcyclopentadiene (IV).**—During a period of thirty-five minutes, commercial trichloroethylene (17.0 moles) was added to a stirred mixture of I (16.3 moles) and aluminum chloride (60 g.) as the temperature was increased from 30 to 84°. External cooling was necessary for one hour to maintain the temperature at 75–87°. Heat was then applied to keep the temperature at 80–85° for three hours, 102–104° for fifteen hours, and 111–114° for eight hours. The cooled reaction mixture was poured onto ice, diluted with carbon tetrachloride, washed, dried, and subjected to distillation in a Claisen flask to obtain 5000 g. of liquid of boiling range 110–175° at 6–8 mm. Rectification of the distillate gave 38 g. of unreacted I and 3853 g. (10.46 moles) of IV; yellow liquid, b. p. 148–149° (13 mm.), 138° (5 mm.), $d^{20}_4$ 1.736, $n^{20}D$ 1.5852, MD 70.9.

*Anal.* Calcd. for $C_7Cl_8$: Cl, 77.2. Found: Cl, 77.6.

A by-product from this reaction is a viscous yellow liquid; b. p. 168–171° at 3 mm., 79.2% Cl, $d^{20}_4$ 1.8129, $n^{20}D$ 1.6011.

**Pentachlorocyclopentadienylideneacetyl Chloride (V).**—A mixture of III (100 g.) and concd. sulfuric acid (800 g.) was heated with vigorous stirring for two hours at 90–95°. White needles sublimed to cooler portions of

the reactor during the reaction period. Upon cooling, light yellow solid separated from the reaction mixture. The slurry was poured onto ice, and the resulting solid was washed with water and recrystallized rapidly from methanol to give V (65 g.); white needles of m. p. 85.0–85.5°, b. p. 266–267° at 750 mm.

*Anal.* Calcd. for $C_7Cl_6O$: Cl, 68.1. Found: Cl, 68.0.

**N,N-Diethylpentachloro-(cyclopentadienylideneacetamide) (VII).**—During a period of five minutes, diethylamine (6.3 g.) was added at room temperature to a solution of V (17 g.) in *n*-pentane (100 ml.). The yellow precipitate was washed thoroughly with water and recrystallized from a mixture of carbon tetrachloride and *n*-pentane to give VII (10 g.); yellow crystals m. p. 107°.

*Anal.* Calcd. for $C_{11}H_{10}Cl_5NO$: Cl, 50.7; N, 4.1; mol. wt., 349. Found: Cl, 50.7, 50.9; N, 4.0; mol. wt. (Rast), 343.

By employing a similar procedure, the diethylamide was also prepared by the action of diethylamine on the methyl (pentachlorocyclopentadienylidene)-acetate (VIII).

N-Phenylpentachloro-(cyclopentadienylideneacetamide) was prepared by the action of aniline on V in pentane solution. This amide is a white solid, m. p. 220°.

*Anal.* Calcd. for $C_{13}H_6Cl_5NO$: Cl, 47.9. Found: Cl, 47.9.

**Methyl Pentachlorocyclopentadienylidene)-acetate (VIII). Method A.**—A solution of potassium hydroxide (0.18 mole) in methanol (100 ml.) was added to a solution of V (0.17 mole) in methanol (200 ml.) during a period of twenty minutes at 45–47°. The reaction mixture was allowed to cool, diluted with water and filtered to obtain a white solid (39 g., m. p. 80–88°). The clear filtrate was acidified with dilute hydrochloric acid to obtain an additional quantity of white solid (11 g., m. p. 116°). Recrystallization of the former material from a mixture of hexane and carbon tetrachloride produced white crystals (25 g., m. p. 116°), which did not depress the melting point of that obtained upon acidification of the filtrate.

*Anal.* Calcd. for $C_8H_3Cl_5O_2$: Cl, 57.5. Found: Cl, 57.1.

**Method B.**—A solution of V (30 g.) in methanol (400 ml.) was refluxed for three hours. The solution was cooled, diluted with water, and the resulting solid was filtered. After two recrystallizations from a mixture of pentane and carbon tetrachloride, the solid melted at 84–97°; after three recrystallizations, 108–113°; and after four recrystallizations, pure VIII (7 g., m. p. 116°) was obtained. The product did not depress the melting point of that obtained by the action of alcoholic alkali on V.

**Dimer of Hexachlorovinylcyclopentadienone (XI). Step 1.**—A solution of potassium hydroxide (280 g.) in methanol (1000 ml.) was added to a stirred solution of IV (100 g.) in methanol (500 ml.) during a period of forty-five minutes at 40–45°. The cooled reaction mixture was diluted with water to dissolve potassium chloride and the resulting organic layer was washed with water to obtain a tan liquid (84 g.) having a sweet odor characteristic of the acetals of tetrachlorocyclopentadienone. Four recrystallizations of the product gave a pale yellow or white solid (60 g.), hexachloro-5,5-dimethoxy-1- or 2-vinylcyclopentadiene; m. p. 39°.

**Step 2.**—During a period of forty minutes, the acetal, prepared in step 1, (132 g.) was added to vigorously stirred concentrated sulfuric acid (800 ml.) at 0–5°. The blood-red solution was dropped onto cracked ice and the resulting red oil was washed with water. The addition of ethyl alcohol (90 ml.) at room temperature resulted in the crystallization of long red needles, which were recrystallized twice from acetone to give XI (2.8 g.); long white needles, m. p. 207°. The dimer evolves carbon monoxide at temperatures above 250°.

*Anal.* Calcd. for $C_{14}Cl_{12}O_2$: Cl, 68.0; mol. wt., 626. Found: Cl, 68.0, 68.1, 67.8; mol. wt. (ebullioscopic in benzene), 633, 639.

A blood red oil was obtained by evaporation of the alcohol from the filtrate. The oil is probably hexachloro-2 or 3-vinylcyclopentadienone (X).

**Hexachlorovinylcyclopentenedione (XII): Method A.**—A mixture of IV (1000 g.) and concentrated sulfuric acid (4000 g.) was stirred vigorously for seven hours at 120–125°. The reaction mixture gradually becomes black and resolves into a one-phase system. The cooled solution was extracted five times with a total of five liters of carbon tetrachloride. Evaporation of the solvent gave orange needles, which after two recrystallizations from carbon tetrachloride gave the diketone $C_7HCl_5O_2$ (XII) (315 g.); yellow needles, m. p. 96°.

*Anal.* Calcd. for $C_7HCl_5O_2$: Cl, 60.2. Found: Cl, 60.1, 60.1.

The diketone is decomposed by 5% aqueous potassium carbonate at room temperature.

**Method B.**—During a period of five minutes, hexachloro-5,5-dimethoxy-1 or 2-vinylcyclopentadiene (50 g.) was added to concentrated sulfuric acid (300 g.) at 40°. The blood-red mixture was dropped onto cracked ice and the red organic layer was washed with water and crystallized from petroleum ether (35–37°) to give an orange-red solid. Three additional recrystallizations produced the diketone XII (1.5 g.); yellow needles, m. p. 96°.

**Fluorination of Octachloro-1 or 2-vinylcyclopentadiene.**—A three-necked flask containing liquid $C_7Cl_8$ (440 g., 1.19 moles) was equipped with a thermometer, stirrer, distilling arm, and a dropping funnel containing antimony pentafluoride (2650 g., 12 moles). The distillation arm was connected to a water condenser, receiver, a second condenser, and finally a receiver cocled by ice water. The chlorocarbon was heated to 130° before the addition of antimony pentafluoride was begun. The heat was then discontinued and the temperature was regulated at 120–135° by the rate of addition of antimony pentafluoride. It was necessary to supply heat to maintain this temperature range after 1200 g. of the antimony fluoride had been added. At the conclusion of the addition, the temperature was increased gradually up to 170° to continue the gentle distillation of organic product. All of the product was collected in the first receiver. The colorless liquid distillate was washed with concd. hydrochloric acid, water, and dried to obtain 268 g. of clear, colorless, fluorinated product. Rectification of the crude product from a 52 in. column packed with small glass helices gave two clear-cut fractions; $C_7ClF_{11}$, 153.5 g., b. p. 90–92°, $d^{20}_4$ 1.7009, $n^{20}D$ 1.3210, and $C_7Cl_2F_{10}$, 62.5 g., b. p. 116°, $d^{20}_4$ 1.7174, $n^{20}D$ 1.3482.

*Anal.* Calcd. for $C_7ClF_{11}$: Cl, 10.7; F, 63.7; mol. wt., 328. Found: Cl, 10.9, 10.7; F, 63.8, 62.7; mol. wt. (vapor density), 328, 330.

*Anal.* Calcd. for $C_7Cl_2F_{10}$: Cl, 20.6; F, 55.1; mol. wt., 345. Found: Cl, 21.0; F, 55.6, 55.7; mol. wt. (vapor density), 346, 349.

Both fractions gave positive tests with permanganate indicating the presence of unsaturated linkages, as well as positive tests with alcoholic alkali establishing the presence of active halogen.

**Chlorotridecafluoroethylcyclopentane.**—The unsaturated derivative of ethylcyclopentane, $C_7ClF_{11}$ (118 g., 0.36 mole), was passed over silver difluoride (20 moles) during a period of two and one-half hours at 295–300°. At the conclusion of the addition, the reactor was swept out with nitrogen for three hours. The product was collected in an ice-water trap followed by a dry ice trap. The crude product (115 g.) was washed twice with water and dried over Drierite. Rectification gave only one fraction, chlorotridecafluoroethylcyclopentane, $C_7ClF_{13}$; 67 g., b. p. 102°, $d^{20}_4$ 1.7999, $n^{20}D$ 1.3073.

*Anal.* Calcd. for $C_7ClF_{13}$: Cl, 9.6; F, 67.5; mol. wt., 366. Found: Cl, 9.8, 10.2; F, 67.8, 68.3; mol. wt. (vapor density), 369, 370.

The physical constants of the product are in close agreement with those of a compound $C_7ClF_{13}$ obtained by Perkin[9] and believed to be a chlorotridecafluoroethyl-

(9) Private communication, M. Perkin, E. I. du Pont de Nemours and Co., Wilmington, Delaware.

cyclopentane, and differ appreciably from those of the four known chloroperfluoromethylcyclohexanes.[10]

**Acknowledgment.**—The authors express their indebtedness to the Hooker Electrochemical Company for defraying the expenses of this investigation and for supplying the hexachlorocyclopentadiene.

## Summary

The condensation of hexachlorocyclopentadiene with trichloroethylene in the presence of aluminum chloride produces 5-(1,2,2,2-tetrachloroethyl)-pentachlorocyclopentadiene, which undergoes dehydrohalogenation with aluminum chloride and alkali to form two isomeric chlorocarbons, $C_7Cl_8$, octachloro-1 or 2-vinylcyclopentadiene and octachloro-5-ethylidenecyclopentadiene, respectively. The former chlorocarbon was identified by its conversion to the unsaturated derivatives of ethylcyclopentane, $C_7ClF_{11}$ and $C_7Cl_2F_{10}$, chlorotridecafluoroethylcyclopentane, hexachloro-5,5-dimethoxy-1 or 2-vinylcyclopentadiene, hexachloro-2 or 3-vinylcyclopentadiene, hexachloro-2 or 3-vinylcyclopentadienone and its Diels–Alder dimer, and hexachlorovinylcyclopentenedione. The latter chlorocarbon was identified by its conversion to pentachlorocyclopentadienylideneacetyl chloride and functional derivatives thereof.

Whereas hexachlorocyclopentadiene readily undergoes the Diels–Alder reaction and also forms a dimer in the presence of aluminum chloride, the isomeric chlorocarbons $C_7Cl_8$ do not react with maleic anhydride under ordinary conditions. On the other hand, hexachloro-2 or 3-vinylcyclopentadienone dimerizes spontaneously via Diels–Alder.

# Interpretation of Lignin. III. The Synthesis and Polymerization of Stable Monomers[2]

BY ALFRED RUSSELL,[3] JOHN H. BAITY[4] AND HERBERT E. SMITH

There have already been described syntheses of three polymeric materials; one of these had many of the properties of spruce lignin[5] and the others were methoxyl-free analogs.[6] The polymers resulted by chain-like intermolecular aldolization of certain aryl methylketoaldehydes. The monomeric units were prepared by the Fries rearrangement of the monoacetates of monohydroxyarylaldehydes and could not be isolated due to their reactivity under the anhydrous conditions of the rearrangement reaction—polymerization proceeding at once to give polydihydrobenzopyrones.

It would be of interest to demonstrate the existence of similar stable monomeric units and their separate polymerization. Such methylketoaldehydes should be available by two general methods, either nuclear acylation of *suitably chosen* hydroxyarylaldehydes or nuclear formylation of *suitably chosen* hydroxyaryl ketones. Inactivation of the carbonyl group in the initial material by any conventional method would most likely be ineffective because the acylated or formylated reaction product would likely polymerize as soon as the inactivated carbonyl group was liberated if it did not do so even before liberation of the protected group.

A much more elegant procedure is to prepare a monomer which, because of its configuration, cannot polymerize easily. This may be accomplished by selecting the starting material so that the carbonyl group already present is chelated with an hydroxyl group and the second carbonyl group enters ortho to another hydroxyl group. A second chelate ring will form at once and, at least in some cases, the monomer should be stable.

Six such schemes may be tried rather easily since the starting materials are accessible: the nuclear acylation of β-resorcylaldehyde or of pyrogallic aldehyde; the nuclear formylation of resacetophenone, 2,6-dihydroxyacetophenone, gallacetophenone and 2,4,6-trihydroxyacetophenone (phloracetophenone).

No success was had in acylation attempts and the application of the Gattermann procedure to gallacetophenone was equally futile. However, the formylation of the other three hydroxy ketones by the Gattermann procedure, modified in one instance, was entirely successful and satisfactory yields were obtained of the three methylketoaldehydes — 2,4 - dihydroxy - 3 - formylacetophenone, 2,6-dihydroxy-3-formylacetophenone and 2,4,6-trihydroxy-3-formylacetophenone. All three monomers are stable, easily crystalline with sharp melting points. All three are unchanged by 40% aqueous alkali and by 50% sodium methoxide in methanol, but may be polymerized to red or brown amorphous materials by

sufficiently strong alcoholic sulfuric acid. The polymers are inert alkali-soluble materials and have similar solubility characteristics in organic solvents to those previously described. Some part of the polymer from the trihydroxy compound is slightly water-soluble.

Although each ketoaldehyde has a more or less reactive nuclear position, it does not seem likely that the polymers are phenol–aldehyde condensation products because of steric effects. They are not polybenzopyrrilium salts for they contain no halogen after reprecipitation from alkaline solution with hydrochloric acid. They may be formulated as in previous cases.

## Experimental

**Polymerization of 2,4-Dihydroxy-3-formylacetophenone[7] to Poly(2,8)-7-Hydroxydihydrobenzopyrone.**—2,4-Dihydroxy-3-formylacetophenone (1 g.) was dissolved in ethanol (20 cc.) and concentrated sulfuric acid (7.5 cc.) added. The whole was refluxed for thirty minutes, cooled and the deep red reaction mixture poured into water (250 cc.). The red amorphous precipitate was collected and washed free from acid. It was dissolved in dilute sodium hydroxide (100 cc., 5%) and reprecipitated with ice-cold hydrochloric acid. It was collected, washed free from acid and divided empirically into two fractions: (1) ether–dioxane insoluble, (2) dioxane–water insoluble.

*Anal.*[8] Calcd. for $C_9H_8O_4$: C, 60.44; H, 4.44. $C_9H_6O_3$: C, 68.66; H, 4.94. Found for $C_9H_8O_4$: C, 64.4, 64.7; H, 4.86, 4.80. $C_9H_6O_3$: C, 66.5, 66.3; H, 4.84, 4.83.

**Formylation of 2,6-Dihydroxyacetophenone.**—2,6-Dihydroxyacetophenone[9] (15 g. 1 mol) was dissolved in anhydrous ether (250 cc.) and dry, freshly prepared zinc cyanide (23 g., 2 mol) added. Anhydrous hydrogen chloride was passed into the ice-cold solution to saturation (six to seven hours). The reaction mixture was allowed to stand overnight (sixteen hours) and the supernatant ether poured away from the dark brown oil which was washed twice with 50-cc. portions of dry ether. The washed oil was treated with water (200 cc.) and traces of ether evaporated. Upon steam distillation, 2,6-dihydroxy-3-formylacetophenone was collected as a colorless solid. Recrystallized from dilute ethanol it forms colorless needles m. p. 101–102°; yield, 6.2 g.

*Anal.* Calcd. for $C_9H_8O_4$: C, 60.00; H, 4.44. Found: C, 60.1, 59.8; H, 4.19, 4.13.

**Polymerization of 2,6-Dihydroxy-3-formylacetophenone to Poly-(2,6)-5-Hydroxydihydrobenzopyrone.**—2,6-Dihydroxy-3-formylacetophenone (2 g.) was dissolved in ethanol (20 cc.) and alcoholic sulfuric acid (20 cc., 50%) added. The whole was refluxed for thirty minutes, cooled and poured into cold water. The precipitated amorphous brown solid was collected, dissolved in dilute sodium hydroxide (*ca.* 5%) and reprecipitated with ice-cold aqueous hydrochloric acid. The finely divided amorphous brown solid was collected, washed free from acid and dried.

*Anal.* Calcd. for $C_9H_8O_4$: C, 60.00; H, 4.44. $C_9H_6O_3$: C, 66.66; H, 3.70. Found: C, 64.1, 64.0; H, 4.29, 4.47.

**2,4,6-Trihydroxy-3-formylacetophenone.**—Phloracetophenone (8.4 g., 1 mol) was dissolved in anhydrous ether (125 cc.) and dry zinc cyanide (12 g., 2 mols) added, followed by anhydrous aluminum chloride (13 g., 1 mol) dissolved in anhydrous ether (50 cc.). The reaction mixture was cooled in Dry Ice and saturated with dry hydrogen chloride (seven hours). An orange-yellow colored solid started to separate after about two hours. Separation was completed by allowing to stand overnight. The supernatant ether was poured away and the residue washed twice with 50-cc. portions of dry ether. Water (125 cc.) was added to the solid residue and traces of ether evaporated. Upon raising the temperature the reaction product dissolved and a yellowish-colored crystalline precipitate separated. The whole was cooled, the solid product collected and recrystallized from dilute ethanol (charcoal). 2,4,6-Trihydroxy-3-formylacetophenone forms pale yellow microcrystalline needles m. p. 176°. The yield was 7.1 g. (73%).

*Anal.* Calcd. for $C_9H_8O_5 \cdot H_2O$: C, 50.5; H, 4.7. Found: C, 50.8, 51.0, 50.5; H, 4.97, 4.84, 4.42.

**Polymerization of 2,4,6-Trihydroxy-3-formylacetophenone.**—2,4,6-Trihydroxy-3-formylacetophenone (2 g.) was dissolved in ethanol (20 cc.) and alcoholic sulfuric acid (20 cc., 50%) added. The whole was refluxed for thirty minutes, cooled and poured into water (200 cc.). The bright red flocculent precipitate was collected, dissolved in aqueous sodium hydroxide (*ca.* 5%) and reprecipitated by dilute aqueous hydrochloric acid. The bright red amorphous precipitate was collected, washed until free from acid and dried.

*Anal.* Calcd. for $C_9H_8O_5$: C, 55.10; H, 4.08. $C_9H_6O_4$: C, 60.7; H, 3.37. Found: C, 63.7, 62.8; H, 4.42, 4.20.

## Summary

To investigate further the polymerization reaction used in the synthesis of lignin-like materials, three stabilized monomeric units—2,4-dihydroxy-3-formylacetophenone, 2,6-dihydroxy-3-formylacetophenone and 2,4,6-trihydroxy-3-formylacetophenone have been prepared, and separately polymerized.

# The Photochemistry of Cellulose. Effects of Water Vapor and Oxygen in the Far and Near Ultraviolet Regions

BY HERBERT F. LAUNER[1] AND WILLIAM K. WILSON

In a current study of the photochemistry of cellulose it was observed that water vapor strongly inhibits photochemical changes in cellulose in the far ultraviolet at 254 millimicrons. Very dry cotton or wood celluloses were found to undergo greater changes in color, cuprammonium degree of polymerization and alpha cellulose than the same celluloses with normal moisture content. This result indicates that at least some of the water molecules are held by cellulose in a fundamental chemical combination, as contrasted with physical phenomena, such as condensation.

It was also observed that gaseous oxygen has no effect upon the rate of change in the far ultraviolet. These results are in strong contrast with those observed by the writers[1a] for the near ultraviolet, and with those observed by Stillings and Van Nostrand[2] in heterogeneous ultraviolet, and permit some new theories regarding the photochemical processes of the cellulose chain molecule.

## Experimental

**Methods of Analysis.**—Values for alpha cellulose and cuprammonium degree of polymerization of the celluloses were determined before, and within one to four hours after, irradiation, using standard methods.[3]

The degree of polymerization was calculated from viscosity, using the expression derived by Battista,[4] DP = 2160 [log (relative viscosity +1) − 0.267]. The values for DP, plotted against log (time of flow), give an almost straight line from DP = 50 to DP = 3000. Cuprammonium dispersions, 0.50% by weight in cellulose, exclusive of other substances present, were used for measurement. The writers use the concept of cuprammonium DP as a convenient comparison of extent of cellulose change at various levels, rather than as fundamental constants capable of rigorous proof.

Diffuse reflectance of the sheets was measured using a Beckman UV spectrophotometer, standardized against freshly smoked magnesium oxide.

**Samples Studied.**—Widely differing types of cellulose, derived from cotton and wood, in the form of specially made papers, were studied. The use of cellulose in sheet form permitted adequate temperature control during irradiation, and allowed accurate measurement of reflectance.

The papers were made in the paper mill at the National Bureau of Standards, and are described in Table I, in terms of origins of the fibers, added materials, and chemical characteristics. Further details are given elsewhere,[5] the cellulose sample number corresponding to that of the original paper.

TABLE I

CHARACTERISTICS OF CELLULOSES STUDIED

| Cellulose | Fiber origin, and other sheet components | Alpha cellulose content, % | Cuprammonium degree of polymerization (DP) |
|---|---|---|---|
| 1372 | Unused, unbleached cotton from cloth. No alum, rosin or clay | 96.6 | 1660 |
| 1178 | Unused, bleached cotton from cloth. Alum and clay | 92.4 | 695 |
| 1193 | Used, bleached cotton from cloth. Alum and clay | 87.7 | 575 |
| 1380 | Purified sulfite wood pulp. No rosin, alum or clay. Known commercially as alpha pulp | 91.8 | 1195 |
| 885 | Ordinary sulfite wood pulp. No rosin, alum or clay. No connection with No. 1380 | 77.2 | 645 |

**Apparatus.**—The apparatus consisted of special equipment, some of which has been previously described,[1,6] in which celluloses in paper sheet form were irradiated, with several light sources, without heat effects, in atmospheres of air or nitrogen of various moisture contents. Air was passed over anhydrous magnesium perchlorate, or over saturated solutions of lithium chloride or sodium bromide, producing relative humidities of 0.01,[6] 11 and 56%,[7] respectively. Nitrogen was passed over hot copper at 500° to remove oxygen, and was either dried by anhydrous magnesium perchlorate or moistened by alkaline pyrogallol solution. The desired atmospheres were continuously circulated at 5 liters/min. through these systems one and one-half hours before, and during, the irradiation. An electrically heated copper mirror,[8] and a weighed amount of magnesium perchlorate, present in the gas stream during irradiation, served as checks on oxygen and moisture contents when desirable.

During irradiation in the near ultraviolet, usually 92 hours, the sheets were held within 1–2° of 30° by sucking them against a thermostated metal backing, and by elimi-

(8) This consisted of pure sheet copper folded around a nichrome heater, fed by a Variac (a variable transformer), and included a thermojunction in contact with the copper. Oxygen concentration in a gas stream was determined by measuring the temperature at which the interference bluishness of the oxide was observable in five minutes, the instrument being standardized against gases of known oxygen content. The device appeared useful down to concentrations of oxygen near 0.01%; below that, the hydrogen, used to regenerate the copper, was apparently dissolved by the latter in sufficient amounts to render oxide formation erratic. This and other complications, such as the rate being dependent upon the nature of the carrier gas, discouraged further development of the device.

nating the infrared from a Fadeometer carbon arc, used as the light source, with a liquid filter, which also limited the spectrum to the region 330 to 750 millimicrons,[6] with the principal maximum at 388 and a minor one at 359 millimicrons.

For irradiation in the far ultraviolet, usually one-half hour, a General Electric 15-watt Germicidal mercury vapor lamp, operated at regulated 115 volts, was used. This type of lamp is a very convenient source of almost monochromatic ultraviolet at 254 millimicrons, thus avoiding the uncertainties introduced by other wave lengths. The energy output (manufacturers' data) consists of 55% ultraviolet, 2% visible and 43% heat, and of the ultraviolet, 97% is at 254 millimicrons. Since this type of lamp has a very low intensity it was found convenient to wrap the sheets tightly on its glass surface for irradiation. The lamp, which is a tube 15″ × 1″, was then slipped into a glass tube of 2-mm. greater diameter, maintained at 30°, so that the gases passed between the two tubes. The rubber stopper carrying the four lamp leads out of the system was located at the gas-exit end, so that the apparatus, from the conditioning tubes to the paper, was all-glass. Because of the small space between the tubes, the gases previously brought to 30°, streamed past the sheets at high velocity, thus removing considerable heat. By measurement with a thermojunction imbedded in a sheet of paper by a technique previously described,[6] the temperature inside the sheet during irradiation was found to be 40°.

The change in intensity of the lamp with use, and the uniformity of intensity along the central 12-inch portion was studied with light-sensitive paper.[9] The variation in uniformity of four 3-in. portions was found to be less than 3%.

## Results

The effects of gases upon the rates of photochemical change in cellulose varied greatly with the spectral energy distribution of the sources used and are presented accordingly. The types of cellulose, test methods, apparatus, gases, and significance of the terms used to differentiate the ultraviolet regions are described in the preceding sections.

**Effects of Water Vapor and Oxygen in the Far Ultraviolet.**—The effects of water vapor and oxygen in the far ultraviolet, shown in Table II, differed radically from any reported heretofore.[1,2] The effect of water vapor appeared to be decisive whereas that of oxygen, negligible.

TABLE II

EFFECT OF WATER VAPOR AND OXYGEN DURING IRRADIATION IN THE *Far* ULTRAVIOLET[a]

Decrease[b] in alpha cellulose percentage and DP (in parentheses) during irradiation in various atmospheres.

| Cellulose no. and type | Moist air | Dry air | Moist $N_2$ | Dry $N_2$ |
|---|---|---|---|---|
| 1372 | 1.0 | 5.0 | 1.3 | 5.7 |
| Cotton | (325) | (415) | (325) | (440) |

[a] Irradiation for one-half hour at 254 millimicrons.
[b] Initial values of alpha cellulose and DP are given in Table I.

(9) Herbert F. Launer, *J. Research Natl. Bur. Standards*, **41**, 169 (1948), RP 1916.

For all types of celluloses studies, the drop in alpha cellulose was considerably greater in dry air and dry nitrogen, than in moist air and moist nitrogen, but practically the same in dry air and dry nitrogen or in moist air and moist nitrogen. These results are in agreement with those for DP when measured: for materials of low DP the test is insensitive and was not applied in all cases.

This effect of water vapor was not the result of absorption of ultraviolet by water vapor at this wave length. It can be calculated that even a 1-mm. thickness of liquid water will absorb only 0.1% at 254 millimicrons.[10]

The effect of water vapor was studied for intermediate values of relative humidity and for longer periods of irradiation, using cellulose 1372. The curves, given in Fig. 1, show that intermediate moisture content of the atmosphere during irradiation had an intermediate effect on the rate of decrease of alpha cellulose and DP. The curves in Fig. 1 also show that the effect of water vapor upon the rate persists until the cellulose has undergone considerable change (alpha cellulose = 85%, DP = 1150), after which the effect disappears, as seen from the fact that the curves tend to approach each other or become parallel, showing

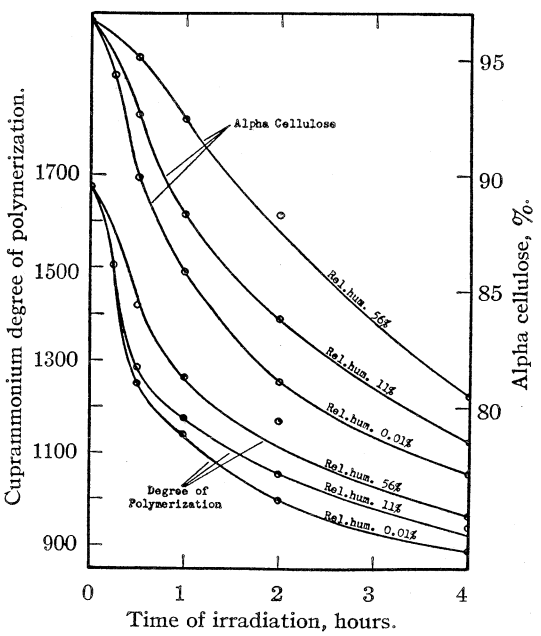

Fig. 1.—Effect of water vapor upon the rate of decrease of alpha cellulose percentage and degree of polymerization of cotton cellulose 1372 during irradiation in the far ultraviolet. The concentration of water vapor in each atmosphere is given in terms of per cent. relative humidity inscribed on each curve. Although the gases were at 30° the cellulose was at 40°. Using typical desorption isotherms, the calculated values for moisture content of the cellulose under the three conditions was 5.0, 2.0 and 0.002%.

(10) L. H. Dawson and E. O. Hulburt, *J. Optical Soc. Am.*, **24**, 175 (1934).

that the slopes and, therefore, the rates, reach common values.

The effect of oxygen was subjected to a similar detailed study for periods up to two hours of irradiation but no difference could be found between the rates in dry air and dry nitrogen. Experiments in pure, dry oxygen showed that DP, but not alpha cellulose values, were somewhat lower, by some 100 glucose units, after irradiation in pure oxygen than in air. Considering the small effect of the enormous differences in concentration, the role of oxygen, during irradiation in the far ultraviolet, can only be a minor one in the pure gas, and probably negligible in air.

The chemical results were borne out by reflectance measurements. The far ultraviolet was found to cause noticeable yellowing, the degree depending mainly upon water-vapor content. The yellowing was greater for dry air and dry nitrogen than for moist air and moist nitrogen. The reflectance curves over the region 360 to 500 millimicrons are shown in Fig. 2 for the typical example of cellulose 1380. The somewhat greater yellowing in dry and moist nitrogen than in dry and moist air is not believed to be due to an inhibitory effect of oxygen, but rather to a slight bleaching effect of ozone, the possibility of which must be considered when using lamps of this type in the presence of oxygen. Although the chemical results show no effect of ozone (with the possible exception of the results in pure oxygen, for which ozone might be held responsible), ozone being present only in the oxygen-containing atmospheres, it is not unreasonable to assume partial oxidation of the more readily oxidizable color bodies. Even so, such bleaching was not enough to reverse the curves for moist nitrogen and dry air.

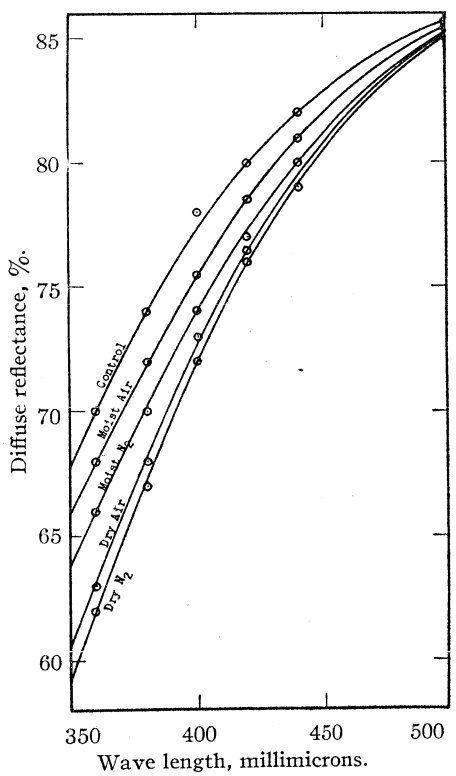

Fig. 2.—Effect of atmosphere upon the yellowing of wood cellulose no. 1380 during irradiation in the far ultraviolet for half an hour. The reflectances of sheets irradiated in the atmospheres as inscribed upon the curves are compared with the unexposed control.

The yellowing caused by far ultraviolet is of interest when compared to the effect of near ultraviolet, which the writers found bleaches cellulose.[1] It was shown that yellowing during irradiation in the near ultraviolet is the result of a thermal reaction which can be eliminated by control of cellulose temperatures.

It is not possible at present to state definitely that yellowing during irradiation in the far ultraviolet is a true photochemical reaction, although interior sheet temperatures during irradiation did not exceed 40°. Experiments were also conducted at 10, 20 and 30°, but no evidence of a temperature coefficient of yellowing was found. On the other hand, previously irradiated sheets yellowed extensively during storage in the dark, showing that yellowing does occur in the absence of light and must, therefore, be a thermal reaction. Such yellowing may, of course, be the result of another process. It is noteworthy that the yellowing during irradiation does not appear to be influenced by oxygen.

**Effects of Water Vapor and Oxygen in the *Near* Ultraviolet.**—The results for this region of the spectrum, given in Table III, confirm the writers' previous findings[1] for the effects of oxygen and water vapor, and those of others[2] for oxygen. The drop in alpha cellulose and in DP are considerably greater in the presence of oxygen than in its absence, for the various types of cellulose. In the presence of oxygen, water vapor promotes certain reactions and hinders others: the drop in DP of all of the celluloses is usually definitely greater in the presence of water vapor than in its

TABLE III

EFFECT OF OXYGEN AND WATER VAPOR DURING IRRADIATION IN THE *Near* ULTRAVIOLET[a]

Decreases in alpha cellulose percentage and DP (in parentheses) during irradiation in various atmospheres.

| Cellulose no. and type | Moist air | Dry air | Moist $N_2$ | Dry $N_2$ |
|---|---|---|---|---|
| 1372 | 0.4 | 1.1 | 0.0 | 0.2 |
| Cotton | (445) | (230) | (130) | (95) |
| 1380 | 4.0 | 2.8 | 0.8 | 1.1 |
| Wood | (385) | (250) | (115) | (120) |
| 885 | 5.9 | 4.5 | 1.5 | 1.4 |
| Wood | (110) | (55) | (50) | (40) |
| 1178 | 1.2 | 3.3 | 0.0 | 0.3 |
| Cotton | (65) | (20) | (0) | (0) |
| 1193 | 6.1 | 9.6 | 4.0 | 2.8 |
| Cotton | (75) | (75) | (0) | (0) |

[a] Irradiation for ninety-two hours with carbon arc.

absence, whereas the drop in alpha cellulose is greater in wood cellulose, and smaller in cotton cellulose, in the presence of water vapor, than in its absence. This confirms the previously found, more pronounced results[1] indicating a difference between wood and cotton celluloses. The results also illustrate that alpha cellulose and cuprammonium tests do not always coincide.

## Discussion

The lack of effect of oxygen and the inhibitory effect of water vapor show that oxidation and hydrolysis, the expected reactions, do not play a predominant part in the photochemical reactions of cellulose in the far ultraviolet. In the near ultraviolet, however, these reactions do play a dominant role.[1] When a light source including both of these regions is used, it is reasonable to expect a mixture of effects. This may explain why Stillings and Van Nostrand,[2] using a G.E. quartz Uviarc, model UA 26A2, which has about equal output in the near, middle and far ultraviolet regions,[11] did not observe the effects peculiar to each region. Upon decreasing the oxygen content in steps from 100 to 0.002% (the latter being the oxygen content of their purified nitrogen) they observed considerable decreases in the rate of change of cellulose. This apparently corresponded to the near ultraviolet portion of their spectrum, whereas some or all of the changes that persisted in purified nitrogen corresponded to the far ultraviolet, in which oxygen is without effect.

The differing mechanisms are explainable upon the basis of bond energies. Both the –C–C– and the –O–C– bonds, with dissociation energies near 80 kcal.,[12] are dissociable by a far-ultraviolet photon, corresponding to 112 kcal., without aid. However, the near-ultraviolet photons, in the cyanogen-band group at 388 to 385 millimicrons, corresponding to 73 to 74 kcal., lack the energy for such dissociation, and the deficit must be supplied by the exothermic reaction with oxygen, whose partial pressure thus becomes important in determining the rate in the near ultraviolet. The photons in the considerably weaker cyanogen band at 359 to 358 millimicrons, corresponding to 79 kcal., may barely have enough energy to cause disruption without the help of oxygen, in agreement with the writers' previous results[1] at low concentrations of oxygen, using the same carbon arc source.

The inhibitory effect of water vapor in the far ultraviolet indicates that some water molecules are in a fundamental chemical combination with cellulose. Such a combination is strongly indicated by the high heat of sorption and other departures from simple physical phenomena, as discussed by Valko[13] and is assumed to consist in bonds of –H–O–H– between proximate –OH groups along two or more molecular chains, producing a lateral, inter-chain "lacing," as discussed by Heuser.[14] These bonds are spontaneously formed, either at the expense of similar –H– bonds, than which they are more stable, as shown by the free energy decrease of water-bond formation, $-\Delta F = 3200$ cal./mole,[15] or they may be formed in addition to the existing –H– bonds with unsaturated –OH groups.[16] In either case it could be expected that the introduction of $H_2O$ molecules into the inter-chain spaces would result in decreased freedom of displacement for those C-atoms in the vicinity of a –H–O–H– bond. Thus, when a far-ultraviolet photon is absorbed, the deformation and disruption of a given glucose unit may be rendered less likely when such bonds exist nearby. The effect of deformability within the cellulose macro-molecule upon photochemical change has been indicated by the results of Mason and Rosevear.[17]

This explanation of the inhibition of the photochemical reaction by water vapor would indicate that the initial disruption occurs in the vicinity of C-atoms 2 or 3, rather than at the glycosidic linkage. This would in turn furnish a reasonable explanation for the instability of previously irradiated cellulose, observed by the writers[1] and confirmed by Heuser and his co-workers, Stillings, Van Nostrand and Chamberlin.[2,18] If, for example, the bond between C-atoms 1 and 2 were disrupted, this would not necessarily cause immediate rupture of the cellulose chain, but C-atom 1, attached now to three electronegative groups, would become sensitive to future thermal oxidation, thus disrupting the chain.

The –C–O– group is usually held responsible for the broad absorption band below 300 millimicrons, but such absorbed energy can migrate rapidly to another part of the molecule, as discussed by Frank and Teller.[19] Such transfer of absorbed energy to a more reactive group occurs even between discrete particles, as in photochemical sensitization.

It is of interest to note that the region of moisture content, 0 to 5%, for the results shown in Fig. 1, are essentially within the region found by Magne, Portas and Wakeham[20] to correspond to hydrogen-bonded water in cotton fibers.

Referring again to Fig. 1, it is of further interest to note that the first addition of water vapor to the dry cellulose has a smaller inhibitory effect upon

the chemical changes than the second addition of water vapor. This does not coincide with the known energy changes of hydration,[15] but a consideration of the molecular processes involved shows that no correlation is to be expected. When a photon is captured by dry, *i. e.*, 0.002%-moisture, cellulose, corresponding to one water-molecule per three cellulose chains of some 1700 glucose units each, the probability that the capture and C–C-bond rupture will occur near a water-bridge is very small. Even if the moisture content were increased 100-fold to 0.2%, corresponding to 30 water-molecules per chain of 1700 glucose units, the probability of a photon rupturing an adjacent C–C-bond is still very small. Thus, the first increments of water cannot be expected to exert much inhibitory effect, and proportionality of effect cannot obtain until a sizable fraction of the glucose units are water-bonded.

The depolymerizing action of water vapor observed during the ninety-two hours of irradiation in the near ultraviolet is a slow reaction which probably occurs to a slight extent in the one-half hour of irradiation in the far-ultraviolet, and which would probably manifest itself upon extensive irradiation in the latter region. This may partially explain the fact that the curves in Fig. 1 approach each other for longer periods. Such an approach would, furthermore, be a result of progressive depolymerization, inasmuch as water bonding probably decreases as the chains shorten and start to lose their high-polymeric character.

The differing effects of water vapor during irradiation in the near ultraviolet upon the alpha cellulose values of wood and cotton celluloses, as seen from Table III, appear to arise from unknown differences between these two types of cellulose.

Finally, it is of interest to attempt a calculation of the quantum efficiency, that is, the frequency with which cellulose chains are ruptured by captured photons at 254 millimicrons.

At this wave length the lamp radiates 2.9 watts (manufacturers' data) or $3.7 \times 10^{18}$ quanta/sec., over its arc length, 14 in. During one-half hour, one piece of paper, no. 1372, 3 in. wide, wrapped completely around the lamp, absorbs $1.4 \times 10^{21}$ quanta, assuming practically no loss by transmission through the paper (0.08 mm. thickness). This amount of paper corresponds to 0.5 g. cellulose or $1.9 \times 10^{21}$ glucose units. Since there are 1660 glucose units in an average chain (*i. e.*, DP = 1660) of this cellulose, there are $1.1 \times 10^{18}$ chains before irradiation. From the expression derived by Sakurada and Okamura[21] relating change in DP to the number of scissions, $s$, per chain

$$\frac{\text{DP final}}{\text{DP initial}} = \frac{2}{s^2}(s - 1 + e^{-s})$$

and from the final DP = 1245, after irradiation, in dry air, it may be calculated that, on the average, 0.93 scission per chain molecule, or $1.0 \times 10^{18}$ scissions occurred. Thus $1.4 \times 10^3$ quanta or photons were required per scission, or roughly every thousandth photon encountered conditions favorable for a rupture of a cellulose chain molecule. Actually, the number of successful encounters was probably larger than this, inasmuch as a disproportionately large number of scissions may have occurred in the leading layers of cellulose chains, without greatly affecting the cuprammonium DP values.

**Acknowledgment.**—The authors acknowledge with thanks the assistance and coöperation of Alice J. Padgett and Frances Dodge Gagliardi.

## Summary

1. Water vapor was found to retard, and oxygen was found to be without effect upon, the decrease in alpha cellulose and the depolymerization, of cotton and wood celluloses, during irradiation in the far ultraviolet. The reverse of both of these effects was confirmed for the near ultraviolet.

2. The contrasting behavior of cellulose in the two spectral regions is ascribed to bond energies in the molecular chain, in relation to the photon energies involved. Far ultraviolet photons have sufficient energy to disrupt the bond, whereas most near ultraviolet photons do not, and require participation of oxygen.

3. The retarding action of water vapor in the far ultraviolet is ascribed to inter-chain water bridging with the hydroxyl group on carbon atoms 2 or 3, thus interfering with the freedom of displacement of the carbon atom. This supports the theory that a part of the moisture in cellulose is in a fundamental chemical combination.

4. It was found that only one photon out of $10^3$, at 254 millimicrons, encounters conditions favorable for a rupture of the cellulose molecular chain.

# Polydimethylsilanes

BY CHARLES A. BURKHARD

Many publications dealing with the alkyl-substituted polysiloxanes have appeared in recent years,[1] but only very little interest has been shown in the alkyl-substituted polysilanes. An investigation of this latter type of compound has now been made. These new materials are the first alkyl-substituted polysilanes reported in which more than two silicon atoms are directly united. Hexamethyldisilane,[2] hexaethyldisilane,[2c,3] and hexa-*n*-propyldisilane[3e] have been prepared previously.

A similar investigation has been reported by Kipping[4] and co-workers in which the preparation and properties of aryl-substituted polysilanes are given. From diphenyldichlorosilane and molten sodium, Kipping was able to prepare several polydiphenylsilanes, which included a "*saturated*" $Si_4(C_6H_5)_8$ compound and a second $Si_4(C_6H_5)_8$ compound, which was reported to be an "*unsaturated*" compound. This apparent "*unsaturation*" was thought to be due to the presence of two tervalent silicon atoms in the $Si_4(C_6H_5)_8$ molecule. In addition to these materials, Kipping also isolated several $[Si(C_6H_5)_2]_n$ compounds in which $n$ varied from approximately six to eight as determined from chemical evidence. The extreme insolubility of these compounds made it impossible to obtain molecular weights. The majority of the product obtained from the reaction of sodium with diphenyldichlorosilane was soluble in the inert hydrocarbon solvent, and on evaporation of the solvent was found to be a glue-like or resinous mass.

In contrast to these results, it has now been found that dimethyldichlorosilane reacts with molten sodium to give a major quantity of hydrocarbon-insoluble material together with a minor quantity of hydrocarbon-soluble material. Analysis of the hydrocarbon-insoluble product (I) shows it to be a polymer of $[(CH_3)_2Si]$. Its extreme insolubility has made it difficult to make accurate molecular weight determinations. However, a molecular weight was obtained ebullioscopically in biphenyl and the results indicate an average degree of polymerization of approximately 55. X-Ray powder data indicate that this material is somewhat crystalline. It is unstable thermally; in fact, if heated in air at 200° for sixteen hours, a gel-like material is produced.

Isolation of hydrocarbon-soluble products by distillation at reduced pressure was difficult as evidenced by erratic heat-temperature readings in the column. However, it was possible to isolate a crystalline material, which when recrystallized from methanol and water, was shown by analytical and molecular weight data to be the cyclic hexamer, dodecamethylcyclohexasilane (II), $[(CH_3)_2Si]_6$.

After II was recovered, a high boiling residue (III) remained which is a grease-like solid at room temperature. Analytical data indicate that III is a copolymer of $[(CH_3)_2Si]$ and $[(CH_3)_2SiO]$ units. A small amount of chlorine is also present in this product. Analytical data indicate that on an average approximately three silicon atoms are directly united for each siloxane linkage present.

Martin[5] has reported hydrocarbon-insoluble polymers which contain both Si–Si and Si–O–Si linkages. These materials were prepared by the reaction of the methyl Grignard reagent with hexachlorodisilane followed by hydrolysis of the remaining silicon–halogen bonds. From a consideration of the method of preparation and the reported analytical data, it is seen that the polymers obtained by Martin have no more than two silicon atoms directly united and that the methyl to silicon ratio is less than two.

The blue color[4a] that develops when the arylchlorosilanes react with molten sodium is observed also when dimethyldihalogenosilanes are allowed to react with molten sodium. In both cases, the blue color is discharged by water. The development of this blue color recalls the reaction in which ketones, that are incapable of forming enols, form colored metal ketyls. For example, benzophenone reacts with sodium to form a blue derivative, which dimerizes to form a new carbon–carbon bond.[6] The blue color of the metallic ketyls is discharged by water.

$$(C_6H_5)_2CO + Na \longrightarrow (C_6H_5)_2C{-}O{-}Na \quad (1)$$

ketyls, it is reasonable to believe that a radical of the type $R_2Si-O-Na$ is formed which would be capable of forming Si–Si bonds by subsequent dimerization. The presence of oxygen can be explained by contact with air during the reaction or from the oxide film on the surface of the sodium.

$$R_2SiCl_2 \xrightarrow{Na + O_2} R_2Si(-O-Na)_2 \quad (3)$$

$$2R_2SiONa \longrightarrow \begin{matrix} R_2Si-O-Na \\ | \\ R_2Si-O-Na \end{matrix} \quad (4)$$

Further evidence in support of the structure for this intermediate radical is given by the fact that dimethyldibromo- and dimethyldichlorosilane both react with molten sodium to give this blue color. If sodium is to be expected to form a radical with the dimethylsiloxane unit which is similar to the radical that was formed with benzophenone, it is required that the "*enol*" form of the siloxane be incapable of existence.

The formation of the "*enol*" form of the siloxane requires the simultaneous formation of a carbon–silicon double bond; however, attempts to synthesize carbon–silicon double bonds have met with failure in spite of many diligent trials.[7] Thus it is reasonable to assume that the dimethylsiloxane unit differs from its carbon analog, acetone, in that it is incapable of existing in an enolic form. Therefore, the formation of the radical $R_2Si-O-Na$ in which R is methyl or phenyl is not considered unreasonable.

Kipping[8] experienced considerable difficulty in hydrolyzing the Si–Si bonds in the polydiphenylsilanes with aqueous and alcoholic alkali. Kipping found, however, that moist piperidine would hydrolyze these materials quantitatively. In contrast I is not hydrolyzed by aqueous caustic or by moist piperidine. In order to hydrolyze this compound, it was found necessary to heat it with alkali in hexanol.

## Experimental

**Reaction of Dimethyldihalogenosilanes with Sodium.**—As no reaction is obtained until the sodium is molten, it is necessary to use either a halogenosilane whose boiling point is greater than 98° or carry out the reaction in a sealed autoclave under elevated temperature and pressure. The products in either case appear to be the same. Dimethyldibromosilane, b. p. 112°, can be used when the reaction vessel is at atmospheric pressure; however, it was more advantageous to use dimethyldichlorosilane in a sealed autoclave.

Two preparations were made using the following charge of 1 lb. of sodium metal, from which most of the oxide film had been removed, 700 g. dimethyldichlorosilane (54.9% $Cl_2$) and 1 l. of dry benzene in each run. These materials were sealed in a 3 l. steel autoclave. The autoclave was heated and shaken. An exothermic reaction developed after the temperature had exceeded that of the melting point of the sodium. The pressure rose rapidly to 220 p. s. i. and the temperature to 200°. After cooling, the reaction vessel was again heated at 115° for approximately ten hours with continuous shaking. The extent of reaction as measured by titration of hydrolyzable halogen in the benzene solution was shown to vary between 95 and 99.6%.

The products were removed from the autoclave and filtered. A blue-colored residue and excess sodium were retained by the filter. The blue residue and excess sodium was added to a mixture (*ca.* 50–50) of glacial acetic acid and 95% ethanol to decompose the excess sodium. When the decomposition of the sodium had been completed, the entire mixture was added to water. By this time, the blue color had been discharged completely. The white powder, I, that formed was washed with water until free of acid and chloride ion. The resulting product was then dried at 75° *in vacuo*.

The benzene was removed from the combined filtrates leaving a solid product which yielded II on distillation. No definite boiling point of the fraction could be obtained as crystals of II formed, and the temperature was erratic. When the head temperature reached 170° at 2 mm., the distillation was stopped. A residue, III, remained which is grease-like. Products I and II are shown to be $[(CH_3)_2Si]_x$ polymers, and molecular weight determinations indicate that $x$ is approximately 55 for I and 6 for II. Compound II was recrystallized from methanol and water. Using a melting point block fitted with Nicol prisms, it was observed that II shows a change of its crystal form at 74°. This change is reversible if II is not heated to a temperature which is much greater than 74°, and at 100° II appears to sublime.

*Anal.* Calcd. for I, $C_2H_6Si$: C, 41.32; H, 10.41; Si, 48.72. Found: C, 40.1, 40.4; H, 10.1, 10.2; Si, 48.0; mol. wt.,[9] *ca.* 3200.

*Anal.* Calcd. for II, $C_{12}H_{36}Si_6$: C, 41.32; H, 10.41; Si, 48.72; mol. wt., 348. Found: C, 40.9, 41.2, 40.7; H, 10.6, 10.4, 10.2; Si, 47.2; mol. wt.,[10] 318.

*Anal.* Found for III: C, 38.6, 38.1; H, 9.4, 9.2; Si, 42.8, 42.2; Cl, 2.9, 2.8; mol. wt.,[11] 1700.

The yield of I from the two runs is 412 g. The yield of II and III is 237 g.

**Acknowledgment.**—The author wishes to acknowledge the aid given by Dr. R. H. Krieble in consultation, and wishes to thank Dr. E. W. Balis, Mr. L. B. Bronk and Miss M. Caldwell for analytical data, and Dr. W. L. Roth for X-ray data.

## Summary

1. The reaction of molten sodium with dimethyldichlorosilane has been shown to give polydimethylsilanes as the major product.

2. Dodecamethylcyclohexasilane has been isolated and characterized.

3. A colored radical of the type $R_2Si-O-Na$, which appears to be similar to the metallic ketyls, is postulated as a by-product of the reaction of diorganodihalogenosilanes and sodium.

# Organosilicon Chemistry: The Mechanisms of Hydrolysis of Triphenylsilyl Fluoride and Triphenylmethyl Fluoride in 50% Water–50% Acetone Solution[1]

BY C. GARDNER SWAIN, RAMON M. ESTEVE, JR., AND RICHARD H. JONES

Certain of the reactions of organosilicon compounds have been written by Whitmore and coworkers as proceeding through siliconium ion intermediates, analogous to the carbonium ion intermediates well established for similar reactions of carbon compounds. For example, the fission (cleavage) of trimethyl-$\beta$-hydroxypropylsilane by dilute acids or of trimethylsilylacetone even in neutral water have been represented with siliconium ion intermediates.[2] Siliconium ions have been used by these investigators primarily as *formal* ways of explaining the products obtained, since evidence was really not available to permit evaluation of their importance or stability as reaction intermediates. It is therefore of interest to determine how stable and how common are siliconium ion intermediates relative to analogous carbonium ions.

These intermediates with a positive charge on silicon might seem particularly likely, *a priori*, in view of the fact that silicon is a more electropositive element than carbon, and even has some of the properties of the metals.[3] Therefore, one might expect silicon to form a positive ion even more readily than carbon.

The carbonium ion intermediate in the hydrolysis of triphenylmethyl (trityl) halides is one of the stablest known carbonium ions.[4] The *formally analogous* hydrolysis of triphenylsilyl (hereafter referred to as "trisyl") halides was therefore studied to see whether the same mechanism (here involving a siliconium ion intermediate) really held. The results indicate that this is not the case. Parallel kinetic experiments have been carried out with trisyl fluoride and trityl fluoride to test the effect on the rate of hydrolysis caused by variations in *p*H, *p*-substituents, concentration of inert salt, and composition of the solvent.

**Data.**—The results of typical runs are summarized in Table I and detailed data are given for three runs with trisyl fluoride in Table II and Fig. 3 and for one run with trityl fluoride in Table III and Fig. 4.

Trisyl fluoride reacts more than a million times as rapidly with hydroxide ion (calculated for 1 *M*) as with water in 50% water–50% acetone solution (see experimental section on procedure), whereas trityl fluoride reacts at the same rate regardless of *p*H. Fluorosilanes have been reported[5] to react only slowly with strong alkali even when heated. We observed the same results with trisyl fluoride when working in a pure water solvent, but this was due to the existence of a heterogeneous system. In solution, reaction occurs very rapidly.

Substitution of three *p*-methyl groups in trisyl fluoride *decreases* the rate of reaction with water about five-fold, whereas *p*-alkyl substitution *increases* the rate of solvolysis of trityl halides.[6]

The salt and solvent effects are positive, *i. e.*, the rate increases with concentration of inert salt or increasing polarity of the solvent, for both trisyl fluoride and trityl fluoride, although the effects are much stronger with trityl fluoride.

The activation energy for hydrolysis of trisyl

(3) Rochow, "Chemistry of the Silicones," Wiley and Sons, Inc., New York, N. Y., 1946, pp. 3–4. From the heats of formation of Si–Si, C–C, Si–C, Si–H, C–H, and H–H single bonds, it appears that the electronegativity of silicon is 1.8 compared to 2.1 for hydrogen and 2.5 for carbon (Pauling, "Nature of the Chemical Bond," Cornell Univ. Press, Ithaca, N. Y., 1945, pp. 58–70).

(4) From conductivity of halides in liquid sulfur dioxide it is clear that triphenylcarbonium ion is enormously stabler than trimethylcarbonium ion (Hantzsch, *Ber.*, **54**, 2573 (1921); Walden, *Z. physik. Chem.*, **43**, 454 (1903)), yet even the latter is stable enough to exist as a relatively free intermediate, as indicated by the noncorrelation of product composition with rate in the solvolysis of *t*-butyl halides in water-alcohol mixtures [Bateman, Hughes and Ingold, *J. Chem. Soc.*, 881 (1938); Cooper, Hughes and Ingold, *ibid.*, 1280 (1937)].

(5) Pearlson, Brice and Simons, THIS JOURNAL, **67**, 1769 (1945).

(6) Three *p*-*t*-butyl substituents increase the rate of methanolysis of trityl chloride in benzene solution at 25° thirty fold (Swain, THIS JOURNAL, **70**, 1119 (1948)). One *p*-methyl substituent increases the rate of ethanolysis of trityl chloride four-fold in 40% ethanol-60% ether at 25° (Nixon and Branch, *ibid.*, **58**, 496 (1936)).

fluoride is 13.6 ± 0.5 kcal. in 50% water–50% acetone, 15.5 ± 0.5 kcal. in 40% water–60% acetone. For solvolysis of trityl fluoride the figures are 13.0 ± 0.6 kcal. in 50% water–50% acetone and 14.9 ± 0.5 kcal. in 95% methanol–5% acetone.

**Discussion.**—The mechanism of hydrolysis of trisyl fluoride is evidently quite different from that of trityl fluoride. The above experimental facts can be used to disprove all but one out of the following limited group of mechanisms[7] for

(7) This group includes the mechanisms commonly written. Other mechanisms can easily be written, but seem less probable, more complicated, or not really physically different from one of the five given. In these mechanisms all ions are understood to be hydrated and two (or more) solvent molecules are understood to play the role of reactants in solvating both anion and cation forming in each ionization step; these solvent molecules are omitted only to save space. The conjugate acid of silanol is the primary product of all these mechanisms. It will, of course, come into rapid equilibrium with silanol, water and oxonium ion, after its formation.

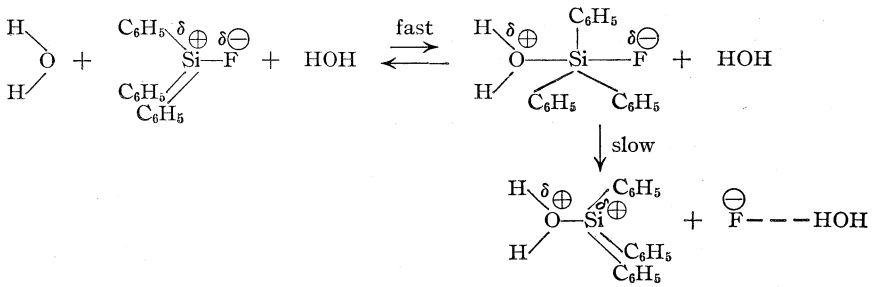
the hydrolysis of trisyl fluoride under our acid conditions.

$$(C_6H_5)_3SiF \xrightarrow{\text{slow}} (C_6H_5)_3Si^{\oplus} + F^{\ominus} \quad (1a)$$

$$(C_6H_5)_3Si^{\oplus} + H_2O \xrightarrow{\text{fast}} (C_6H_5)_3SiOH_2^{\oplus}$$

$$(C_6H_5)_3SiF \xrightleftharpoons{\text{fast}} (C_6H_5)_3Si^{\oplus} + F^{\ominus} \quad (1b)$$

$$(C_6H_5)_3Si^{\oplus} + H_2O \xrightarrow{\text{slow}} (C_6H_5)_3SiOH_2^{\oplus}$$



$$H_2O + (C_6H_5)_3SiF \xrightarrow{\text{slow}} H_2\overset{\oplus}{O}Si(C_6H_5)_3 + F^{\ominus} \quad (2)$$

$$H_2O + (C_6H_5)_3SiF \xrightarrow{\text{slow}} H_2OSi(C_6H_5)_3F \quad (3a)$$

$$H_2OSi(C_6H_5)_3F \xrightarrow{\text{fast}} H_2\overset{\oplus}{O}Si(C_6H_5)_3 + F^{\ominus}$$

$$H_2O + (C_6H_5)_3SiF \xrightleftharpoons{\text{fast}} H_2OSi(C_6H_5)_3F \quad (3b)$$

$$H_2OSi(C_6H_5)_3F \xrightarrow{\text{slow}} H_2\overset{\oplus}{O}Si(C_6H_5)_3 + F^{\ominus}$$

There are three general possibilities for the mechanism of hydrolysis of trisyl fluoride under our acid conditions.

(1) The old bond to fluorine may break *before* the new bond to oxygen forms. This would be a two-step mechanism involving a siliconium ion intermediate. (We have subdivided this possibility into mechanisms 1a and 1b, depending on which step is rate determining.)

(2) Breaking the old bond and making the new bond may be exactly *simultaneous*. This would be a one-step displacement (Mechanism 2).

(3) The old bond may break *after* the new bond forms. This would be a two-step mechanism involving a pentacovalent silicon compound as an intermediate. (We have subdivided this possibility into mechanisms 3a and 3b, depending on which step is rate determining.)

The retarding effect of *p*-methyl substituents in trisyl fluoride shows that the charge on the silicon atom in the transition state is less positive than in the ground state. This eliminates mechanisms 1a, 1b and 2. The silicon atom should be increasingly positive in the series trisyl fluoride (I), triphenylsilanol conjugate acid (II), triphenyl siliconium ion (III). Hence the silicon in the transition state would be more positive than in (I) regardless of whether the transition state were half way from I to III (mechanism 1a), III to II (mechanism 1b) or I to II (mechanism 2). Only mechanisms 3a and 3b predict a less positive silicon atom in the transition state.

By mechanism 3a one would expect trisyl fluoride to be more reactive than trisyl chloride, since fluorine is a stronger electron attractor than chlorine and should give a more positive or electrophilic silicon atom. Actually, the converse appears to hold,[8] leaving mechanism 3b as the only possibility out of this group of mechanisms.

The positive salt and solvent effects show that there is greater charge or charge separation in the transition state than in the ground state. This is also consistent with mechanism 3b, where the transition state would be half way from intermediate to product.

One cannot be sure from our experiments whether the charge on silicon in the transition state, and in the pentacovalent silicon intermediate, is slightly positive or slightly negative in an absolute sense, only that it is less positive in both states than in the starting material.

These observations permit one to draw the free energy diagram of Fig. 1 to represent qualitatively the free energy of the intermediate and

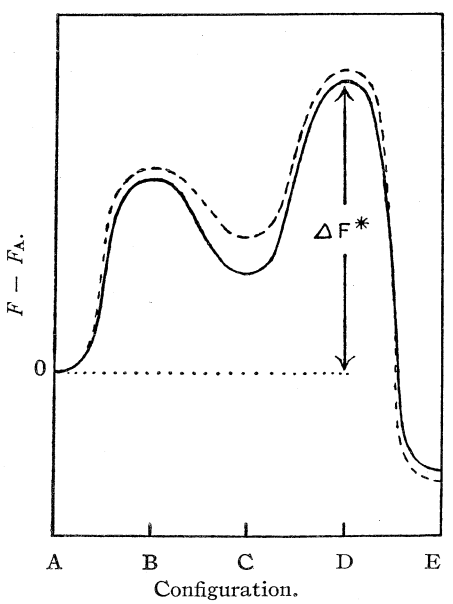


Fig. 1.—Free energy changes in the hydrolysis of triphenylsilyl fluoride: A, ground state of reactants; B, first activated state; C, pentacovalent silicon intermediate; D, second activated state; E, ground state of products.

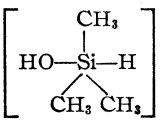
(8) Burkhardt, Rochow, Booth and Hartt, *Chem. Rev.*, **41**, 121 (1947); Medoks and Kotelkov, *J. Gen. Chem.* (*USSR*), **7**, 2007 (1937); Gierut, Sowa and Nieuwland, THIS JOURNAL, **58**, 897 (1936).

activated states. The solid curve represents trisyl fluoride, the dashed curve the tri-*p*-methyl substituted compound. The spread between the two curves is at all points proportional to the magnitude of the increase or decrease of the charge on silicon relative to that in the ground state (A).

The plot for trityl fluoride would differ in the following ways. The intermediate (C) would have a more positive charge on the atom undergoing displacement than the ground state (A), rather than less positive. The first hill would represent chiefly bond breaking, the second bond making, rather than the reverse shown in Fig. 1. The first hill would be higher, not lower, than the second. The dashed curve would be everywhere below, not chiefly above, the solid curve. The separation between the curves would again be less for the activated states (B and D) than for the intermediate (C), but the separation at E would be comparable with that at C, rather than of reversed sign as in Fig. 1.

Mechanism 3 (a or b) has long been recognized as a possibility for the reaction of silicon compounds.[9] Not only are pentacovalent silicon intermediates possible and probable in view of the existence of the very stable fluosilicate ion, $SiF_6^=$, but $(C_6H_5)_3Si^{\oplus}$ or $(CH_3)_3Si^{\oplus}$ ions are improbable[10] relative to their carbon analogs because their resonance stabilization would require double bonds to silicon for which there is no stable example known. Mechanism 3 has also been advanced[9] as an attractive explanation for the remarkable ease of displacements on silicon, which are often much faster than analogous displacements on carbon, as in these examples[11]

$$HO:^{\ominus} + R_3SiH + H_2O \longrightarrow HO{-}SiR_3 + H_2 + :OH^{\ominus}$$



$$4HO:^{\ominus} + Cl_3SiCH_2CH_2Cl \xrightarrow[\text{dil. aq. NaOH}]{\text{titrate with}} (SiO_2)_n + CH_2{=}CH_2 + 4:Cl^{\ominus}$$

$$4CH_3MgBr + Cl_3SiCH_2CH_2Cl \xrightarrow{\text{ether}} (CH_3)_4Si + CH_2{=}CH_2 + 4MgBrCl$$

$$2(CH_3)_3SiOH \xrightarrow[\text{anhyd. } K_2CO_3]{\text{stand over}} CH_3{-}\underset{CH_3}{\overset{CH_3}{Si}}{-}O{-}\underset{CH_3}{\overset{CH_3}{Si}}{-}CH_3$$

$$(CH_3)_3SiNHCi(CH_3)_3 \xrightarrow[\text{dilute aq. HCl}]{\text{titrate with}} 2(CH_3)_3SiOH + NH_4Cl$$

Were a displacement like the first one above to occur on carbon, it would probably be through an unstable transition state with hydroxyl and hydrogen both only partly bonded. With silicon the following is a relatively much more stable structure due to the ability of silicon to expand its

valence shell to include more than eight electrons, and this should correspondingly lower the energy of the transition state separating this intermediate from the products.

## Experimental

**Reagents.**—Triphenylsilyl (trisyl) fluoride was prepared according to the procedure of Medoks and Kotelkov[8] by passing gaseous silicon tetrafluoride through 250 cc. of 2.8 *M*, phenylmagnesium bromide in ether for four hours at 25°. The silicon tetrafluoride was generated according to Nieuwland and Sowa[12] by adding 100 cc. of concd. sulfuric acid slowly to a mixture of 30 g. (0.16 mole) of sodium fluosilicate and 10 g. (0.17 mole) of silica (pumice) in a round-bottom glass flask while heating with a bunsen burner. After standing for a week at 25° the reaction mixture was hydrolyzed with acidified ice water and worked up as usual. The yield was 24 g. (0.086 mole, 36% based on sodium fluosilicate), b. p. 160–170° at 0.5 mm. (reported[8] 205° at 10 mm.) The distillate was crystallized twice from ether, once from acetone and again from ether, each time cooling finally with Dry Ice, to obtain a constant m. p., 61.4–61.6° (reported[8] 64°).

Tri-*p*-tolylsilyl fluoride (previously unreported) was similarly prepared starting with 29 g. (0.17 mole, b. p. 183–184°) of *p*-bromotoluene, 4.6 g. (0.19 atoms) of magnesium turnings, 200 cc. of dry ether, 7.5 g. (0.04 mole) of sodium fluosilicate, and 20 cc. of concd. sulfuric acid. The silicon tetrafluoride was passed through the Grignard solution for three hours, then the solution was allowed to stand for one hour at 25° before hydrolysis. The ether extracts were dried over sodium sulfate, evaporated on a water-bath and the residue cooled in a Dry Ice–acetone-bath to induce crystallization. The yield of crystals was 5.5 g. (0.017 mole, 28% based on sodium fluosilicate), m. p. 69–83°. This material was recrystallized from acetone by cooling with Dry Ice, then twice from petroleum ether, till a constant m. p. of 108–109° was obtained. The sample used for kinetic studies had the following analysis.

*Anal.* Calcd. for $C_{21}H_{21}SiF$, C, 78.71; H, 6.61. Found: 78.11; 6.69.

Triphenylmethyl (trityl) fluoride was prepared from acetyl fluoride and triphenylcarbinol (tritanol) by the procedure of Blicke.[13] The acetyl fluoride was prepared from zinc fluoride and acetyl chloride.[14] Zinc fluoride (technical grade) was heated at 150° for ten hours under oil-pump vacuum to remove all traces of water. Acetyl chloride (150 g., 2.1 moles) was added dropwise through a dropping funnel to 100 g. (0.96 mole) of the dried zinc fluoride in a well-cooled flask protected from moisture by calcium chloride tubes. After completing the addition, the water-bath around the reaction flask was warmed to 30°. All liquid boiling up to 30° was distilled through a Vigreux column and collected in a well cooled receiver. The distillate was poured into a flask containing a small amount of zinc fluoride and redistilled through the column, collecting 76 g. (1.2 moles, 63% yield), of b. p. 20–28°. In a subsequent preparation of acetyl fluoride, constant

(10) It is, however, possible that siliconium ions may exist as intermediates in reactions with exceptionally electrophilic reagents such as aluminum chloride. To decide this, the effect of substituents on the rate of the reactions in question could be determined.

mechanical stirring was found to increase the speed of reaction and ease of operation. To prepare the trityl fluoride 81 cc. (1.3 moles) of acetyl fluoride was added to a cold mixture of 80 g. (0.31 mole) of tritanol, m. p. 161–162°, and 400 cc. of benzene in a round-bottom flask, stoppered securely with a rubber stopper (wired in), and allowed to stand for four days at 25° with occasional shaking. The benzene was then distilled to reduce the volume to 100 cc., petroleum ether (100 cc.) was added and the solution was cooled. The crystals were collected and recrystallized from ligroin, yielding 48 g. (0.18 mole, 59%), of m. p. 99.5–101°. Five recrystallizations from ligroin, petroleum ether, carbon tetrachloride–ligroin and petroleum ether–ligroin and drying of the crystals *in vacuo* over soda lime and paraffin raised the m. p. to 102–103° (reported m. p., 102–104).[13] Kinetics showed that about 70% of this product was trityl fluoride and 30% tritanol. It appears to be very difficult to separate trityl fluoride from tritanol by recrystallization. Acetyl fluoride was badly occluded when the material was recrystallized in its presence. Further recrystallizations from thoroughly dried solvents, or crystallizations of the mother liquor, or preparations under slightly different conditions all gave less pure products. Therefore this material was used in the kinetic studies, since the presence of tritanol should not interfere with the analytical methods nor affect the rate of reaction of trityl fluoride.

The acetone was Merck reagent grade. Stock solutions (usually 0.02 *M*) were made by weighing out the fluorides and volumetrically dissolving them in Merck reagent acetone.

**Procedure.**—The approximate solubility of the fluorides in water–acetone mixtures is given in Table IV. This was determined by adding water from a buret to acetone solutions until turbidity appeared.

TABLE IV

SOLUBILITIES OF TRIPHENYLSILYL AND TRIPHENYLMETHYL FLUORIDES IN WATER–ACETONE MIXTURES

| Fluoride | Water, % | Solubility (*M*) at 25° | 45° | 100° |
|---|---|---|---|---|
| $(C_6H_5)_3Si$ | 40 | 0.01 | | |
| $(C_6H_5)_3Si$ | 50 | .002 | 0.02 | |
| $(C_6H_5)_3Si$ | 60 | .0005 | .01 | |
| $(C_6H_5)_3Si$ | 65 | .0002 | | |
| $(p\text{-}CH_3C_6H_4)_3Si$ | 30 | | .01 | |
| $(p\text{-}CH_3C_6H_4)_3Si$ | 40 | | | 0.01 |
| $(p\text{-}CH_3C_6H_4)_3Si$ | 50 | | .001 | |
| $(C_6H_5)_3C$ | 45 | .005 | | |
| $(C_6H_5)_3C$ | 60 | .002 | | |
| $(C_6H_5)_3C$ | 80 | .0005 | | |

Temperature control was ±0.02° at 25°, ±0.1° at 45° and ±0.5° at 100°. A steam-vapor-bath at atmospheric pressure was used at 100°.

Preliminary experiments demonstrated that the reaction of trisyl fluoride with hydroxide ion is so fast that one cannot titrate aliquot samples of 0.001 *M* solutions with dilute sodium hydroxide at 25° to determine the per cent. hydrolysis without hydrolyzing the remaining trisyl fluoride. The end-points were vague and indefinite. The reaction appears to have a half life of ten seconds or less at *p*H 11, corresponding to a rate constant for reaction with hydroxide ion of over $10^{+3}$ liters mole$^{-1}$ min.$^{-1}$, or ten million times that for reaction with water. This meant that the reaction with water had to be studied below *p*H 7 using analytical procedures in which aliquots were kept always below this *p*H. Methods A, B, and C served this function. The fact that good straight lines on a semi-log plot were obtained below *p*H 7 in spite of increasing acidity during the run shows that the reaction under these conditions was with water rather than with hydroxide ion.

Method A involved periodically titrating aliquot portions of the kinetic solution for fluoride ion with 0.0385 *N* thorium nitrate in acid solution using sodium alizarin sulfonate as indicator.[15] To 25 cc. of distilled water in a flask are added three drops of a saturated water solution of sodium alizarin sulfonate, two drops of 0.02 *M* nitric acid (which gives a yellow color), then 10 cc. of the solution to be titrated. The end-point is the change to a pink color. The method is accurate to ±2%. Time was counted from the moment of removal of the first aliquot, and the titer for this was used as a blank for all later aliquots. The final titer at ten times the half life was used as 100%. The thorium nitrate solution was standardized against a weighed sample of Merck reagent potassium fluoride. The blank in the standardization was 0.02 cc.

Method B used a separate sealed tube for each point, and was used for the runs at 100°. Into soft glass testtubes previously pulled out for easy sealing, 10-cc. aliquots of a water–acetone solution of fluoride were pipetted. The sealed tubes were placed in the 100° steam-bath simultaneously. On removal each was immediately placed in ice water and the time it was in the steam-bath was recorded. Each tube was opened, emptied into a flask and titrated as in method A. The first tube was used as a zero time point and blank for all the rest.

Method C involved following the increase in acidity by using a concentration cell.[16,17] Two 150 cc. extraction flasks fitted with rubber stoppers were used. In each stopper was fitted one arm of the salt bridge, a sleeve for the glass stirrer, and a shiny platinum wire electrode. In the stopper of the titrating (dummy) cell a 5-cc. buret was also inserted. The stirrers were fitted with rubber sleeves and lubricated with glycerol to cut down evaporation and keep the solutions carbon dioxide free. They were driven by one-inch pulleys on the same belt. The salt bridge was filled with 3% agar gel saturated with potassium chloride. The galvanometer was a Leeds and Northrup No. 2420-D enclosed scale type with a sensitivity of $3 \times 10^{-8}$ amp. mm.$^{-1}$ on a ground glass scale.

Initially 125 cc. of solution was placed in each cell. Quinhydrone (0.01 g.) was added to make the electrodes sensitive to *p*H. At zero time 5 cc. of the stock solution of fluoride was introduced into the reaction cell and 5 cc. of pure acetone into the dummy cell. To follow the reaction the cell was balanced by adding standard hydrofluoric acid to the dummy cell. The buret readings and times when the galvanometer swung through zero were recorded. The first titer was used as 0% and the final titer (at ten times the half life) as 100%.

This method is not as satisfactory for high concentrations because the platinum electrodes are gradually poisoned or desensitized by the organosilicon compounds after continued use (possibly due to coating over, although they remain bright and shiny in appearance). However, it will work with lower concentrations than the other methods.

Method D involved intermittent direct titration with sodium hydroxide of the acid liberated by the whole reacting solution.[18] This method is applicable to trityl halides since the rate of their hydrolysis is independent of the hydroxide ion concentration. Brom thymol blue was used as an indicator. The cell (Fig. 2) consisted of a 4.6 × 21 cm. test-tube, with a capillary side arm entering near the bottom for degassing with a stream of nitrogen. The shaft of a small glass stirrer rested in a depression blown in the bottom of the cell and passed through a glass sleeve in the rubber stopper in the top of the cell. It was driven at high speed by an electric motor. Small vanes, 4 cm. from the bottom, caught the gas bubbles issuing from the capillary tube, causing them to break and fill the whole solution. A thermometer graduated in 0.1° passed through a hole in the rubber stopper.

Standard sodium hydroxide solution (0.0480 *M*) was prepared from a 50% solution with freshly boiled distilled

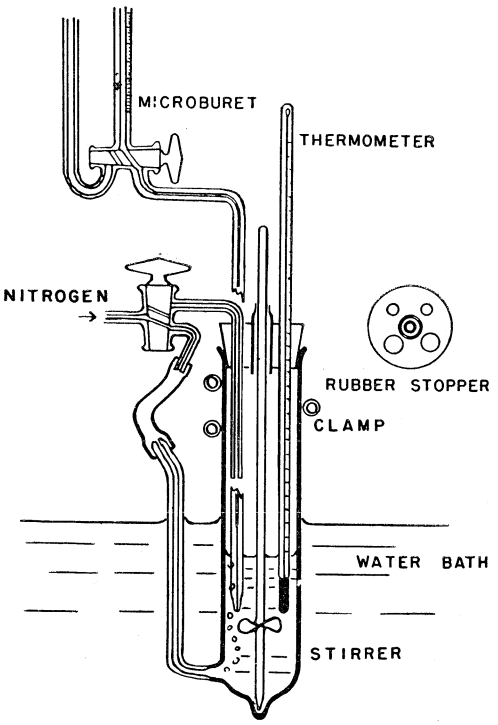

Fig. 2.—Cell used for intermittent titration in methods D and E.

water and protected from atsmospheric carbon dioxide. It was standardized against potassium acid phthalate. It was added from a 2-cc. microburet with a long fine capillary tip below the surface of the solution. For the runs in 95% methanol–5% acetone the methanol was dried over Drierite and distilled before use; in these a sodium methoxide (0.0546 *M*) solution in methanol (prepared by dissolving sodium) was used for titrating.

A cell containing the green shade of brom thymol blue to be matched was clamped in the thermostat bath next to the titration cell. A white porcelain plate was placed behind the two cells and good illumination was provided. The titration apparatus was mounted on a sliding assembly so that it could be easily raised out of the bath. By turning a stopcock the nitrogen stream could be introduced either through the solution or over the surface. Before entering the cell the nitrogen was passed through drying towers containing potassium hydroxide pellets to remove carbon dioxide and then saturated with the solvent by bubbling through two wash bottles each containing 100 cc. of 50% water–50% acetone mixture to prevent the evaporation of acetone from the reaction mixture. Before starting a run 50 cc. of water, 45 cc. of acetone, and 6 drops of 0.1% brom thymol blue were added to the cell. Nitrogen was bubbled through the solution with good motor stirring to remove carbon dioxide until the color of the kinetic cell matched the neutral green of the standard cell. Then the nitrogen stream was diverted over the surface of the liquid and 5 cc. of the stock solution of trityl fluoride was injected with a syringe pipet. The stopwatch was started when the pipet was half empty. It emptied within two seconds. The solution immediately turned yellow but excess base was added to make it blue. Each time when the solution reached a neutral green the time and buret reading were recorded and the solution immediately made basic again by adding excess base. Infinite or total hydrolysis was taken as the volume of base required at ten times the half life (99.9% hydrolysis). Dividing each volume by the total volume gave uncorrected per cent. reaction at a given time. Extrapolation back to zero time gave the initial per cent. reaction due to hydrogen fluoride

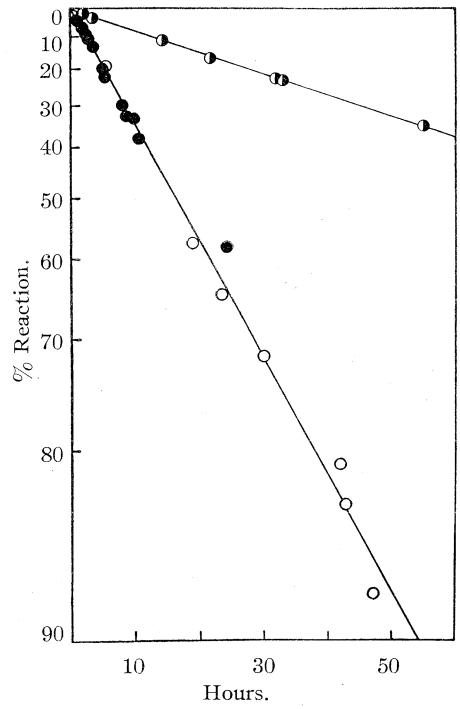

Fig. 3.—Hydrolysis of triarylsilyl fluorides in 50% water–50% acetone solution at 45°. ⊙, 0.0093 *M* triphenylsilyl fluoride, method A; ●, 0.00085 *M* triphenylsilyl fluoride, method C; ◑, 0.00091 *M* tri-*p*-tolylsilyl fluoride, method C.

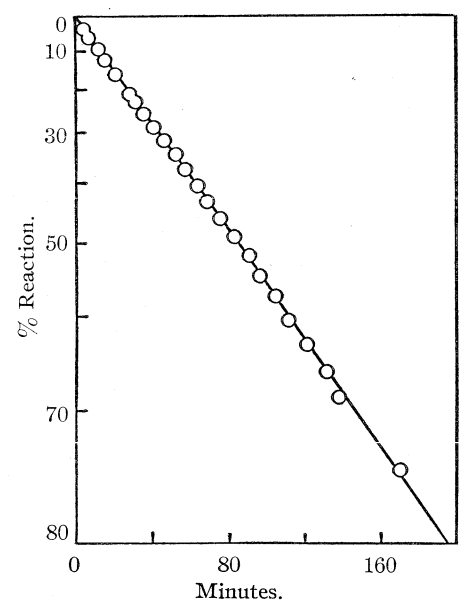
impurity. This was subtracted out in obtaining corrected per cent. reaction, such as given in Table III or Fig. 4.

Method E was the same as Method D except that the solution was kept acid, rather than basic, except when taking end-points. The fact that methods D and E give



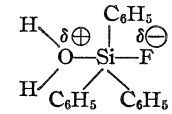


Fig. 4.—Methanolysis of 0.00100 *M* triphenylmethyl fluoride in 95% methanol–5% acetone solution at 25° by method E.

results which are identical within experimental error demonstrates that the rate of reaction of trityl fluoride is independent of *p*H.

## Summary

The hydrolysis of triphenylmethyl fluoride in 50% water–50% acetone is insensitive to *p*H, is aided by *p*-alkyl substituents, and is strongly accelerated by increasing the per cent. of water. This indicates an intermediate with a more positive charge on the central carbon atom than the starting material and only three groups attached to it by predominantly covalent bonds.

The hydrolysis of triphenylsilyl fluoride in 50% water–50% acetone is more than a million times faster with hydroxide ion than with water, is retarded by *p*-alkyl substituents, and is weakly accelerated by increasing concentration of inert salt or per cent. of water. These observations are not consistent with the idea of a siliconium ion intermediate with a positive charge on silicon analogous to the "carbonium ion" intermediate in the hydrolysis of triphenylmethyl fluoride above. They indicate instead that the intermediate in the reaction with water has a less positive charge on the silicon atom than the starting material and is more closely represented by the following structure with pentacovalent silicon.

It appears that many reactions of organosilicon compounds may proceed through similar pentacovalent silicon intermediates. This constitutes an easy reaction path for displacements on silicon which is not available to displacements on carbon, since carbon lacks the ability to expand its valence shell to include more than eight electrons.

# Methyldichlorosilane and its Fluorination Products[1]

BY HAROLD SIMMONS BOOTH AND ROGER LUCIEN JARRY

This investigation is a continuation of the work done in this Laboratory on the alkyl chloro silanes.[2–7] To the best of our knowledge no mention of the fluorination products, methylchlorofluorosilane and methyldifluorosilane, is made in the literature.

## Experimental

**Fluorination of Methyldichlorosilane.**—Purification of the methyldichlorosilane[7a] prior to fluorination was accomplished by fractional distillation in a column having a total condensation head, and take-off of the design used by Whitmore and Lux. The fluorination was carried out by the Swarts reaction using antimony trifluoride as the fluorination agent, but without the use of a catalyst. The decision not to use a catalyst was made after preliminary tests indicated the possibility of chlorination of the methyldichlorosilane by antimony pentachloride; the yields of the two products without the usual catalyst were in sufficient quantity for purification and study. The apparatus and procedure for the fluorination were essentially the same as those described in previous papers from this Laboratory[8,9] with the modification of the direct condensation described by Booth and Spessard.[2] This modification entailed direct condensation in liquid-nitrogen-cooled ampules instead of the previous procedure of passing the fluorination products through a stripping column and refluxing. Since the problem of producing the intermediate fluorination product in this case was not considered difficult, as subsequent fluorinations proved, the fluorination was carried out at room temperature and atmospheric pressure. The average yields were about fifty per cent. fluorinated products, of which methyldifluorosilane comprised 70% and methyl chlorofluorosilane comprised 30%. The unfluorinated methyl dichlorosilane was repurified and refluorinated. The threshold fluorination temperature is below 20°.

**Purification of the Fluorination Products.**—The products of fluorination, methylchlorofluorosilane and methyldifluorosilane, were fractionally distilled in a low temperature distillation column of the type previously described[8] with the exception that the packing was a single Podbielniak Heligrid. The pressure control was a modification of the anticipator previously described[10] and will be given in a future publication. The cooling agent used in the column head was acetone cooled by a Dry Ice–acetone-bath. The methylchlorofluorosilane was distilled at pressures of 740 mm. and 300 mm. approximately; the methyl difluorosilane at 740 mm. and 250 mm. approximately.

**Analysis.**—Samples for analysis were taken in small sealed-glass bulbs.[11] Chlorine was determined by the Volhard method and fluorine by hydrolysis with standard base and back-titrating with standard acid with correction for the hydrochloric acid produced in the hydrolysis. The analysis of the methyldichlorosilane by the Volhard method, after hydrolysis with sodium hydroxide, gave consistently low results. To avoid this a modified Chablay method[12] was used. The results are shown in Table I.

**Determination of Physical Constants.**—Molecular weights of methylchlorofluorosilane and methyldifluorosilane were determined, during the course of distillation, by means of a gas density balance.[8]

The freezing points were determined as described by Booth and Martin.[13] Methyldichlorosilane supercooled about 3.6° the other two compounds showing no supercooling.

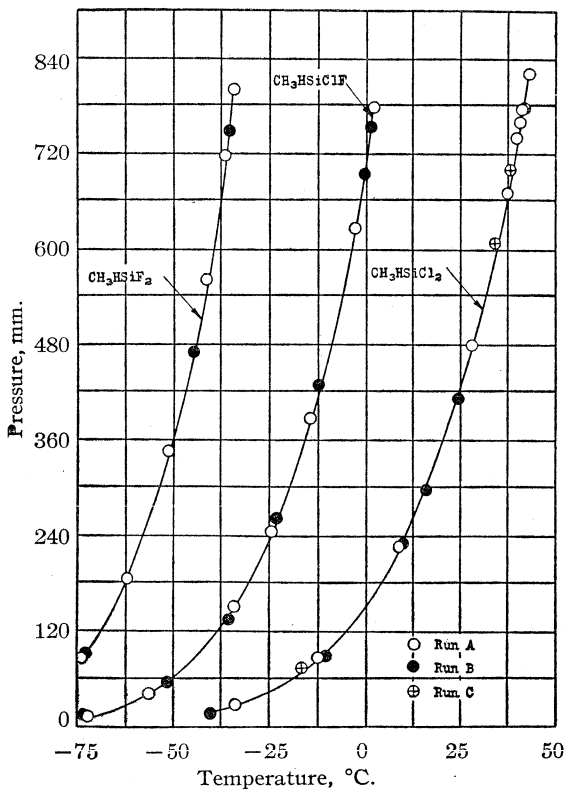

Fig. 1.—Plot of temperature *vs.* pressure for monomethyldichlorosilane and its fluorination products.

(13) H. S. Booth and D. R. Martin, *Chem. Rev.*, **33**, 2 (1943).

Liquid density of methyldichlorosilane and methylchlorofluorosilane were determined in a special type of pycnometer previously described.[14] The pycnometer was calibrated with freshly distilled mercury at 0° and the densities determined at the same temperature, allowance being made in the calculations for the free vapor space above the liquid.

Vapor pressures were determined as described by Booth, Elsey and Burchfield.[15]

The above determined physical properties are summarized in Table I. The vapor pressure data are given in the form of equations in Table I, and in Fig. 1 as a graph of the original data.[15a]

**Physical and Chemical Properties.**—These compounds fume in air and have sharp, irritating odors due to the hydrogen halides formed. They are readily hydrolyzed and dissolved by strong alkaline hydroxides with the evolution of hydrogen. They all smutted mercury, at room temperature, in time.

The lowering of the boiling point by the substitution of fluorine for chlorine followed the Swarts rule fairly closely; the substitution of the first fluorine lowered the boiling point by 39.3° while the substitution of the second fluorine lowered it 36.8°.

Trouton's constant showed an increase with increasing fluorine content which is to be expected with the more polar character of the fluorine.

## Summary

Methyldichlorosilane has been fluorinated with antimony fluoride at room temperature and atmospheric pressure to yield the new compounds methyl chlorofluorosilane and methyldifluorosilane. Certain of the physical constants and chemical properties have been determined.

# Polarography of the Various Oxidation States of Tungsten

BY JAMES J. LINGANE AND LYNDON A. SMALL

The polarography of +6 tungsten in weakly acid solution and of the heteropoly acids, such as the phospho- and silico-tungstates has been studied by Souchay.[1] Stackelberg, *et al.*,[2] studied the polarography of tungsten(VI) in concentrated hydrochloric acid and they reported only a single reduction wave. No polarographic studies of tungsten in oxidation states lower than +6 have previously been reported.

No polarographic waves are found for tungsten (VI) in basic or neutral solution. Tungsten(VI) is insoluble in dilute strong acids, but is soluble in concentrated halogen acids. This paper presents the results of an investigation of the polarography of the various oxidation states of tungsten in hydrochloric acid, together with application of controlled potential electrolysis to the interpretation of the polarograms and the preparation of the lower oxidation states.

## Experimental

Standard solutions of tungsten(VI) were prepared from reagent quality sodium tungstate and standardized gravimetrically by the conventional tungstic acid precipitation with the aid of cinchonine.[3]

Polarographic measurements were made both by the resistance–potentiometer method,[4] and by use of a Heyrovsky–Shikata type photographic recording polarograph constructed in this Laboratory. An H-type cell[5] was used in most cases, with a saturated calomel electrode. Nitrogen, hydrogen or carbon dioxide purified by passage over copper gauze at 400°, or by passage through a solution of a chromous salt, was used for removal of dissolved oxygen and protection of air-sensitive solutions. All polarographic measurements were made at 25.0°; and all potentials are referred to the saturated calomel electrode at 25°. Appropriate corrections for residual current were made in calculating diffusion current constants. Electrolytic reductions at controlled potential were carried out according to the technique of Lingane, Swain and Fields,[6] with a cell of the same design as that used by those authors but with the rubber stopper replaced by a ground-glass joint and cap. The cell was constructed from a 250-ml. wide-mouth Erlenmeyer flask, with a 30-mm. medium porosity Pyrex sintered-glass disk as diaphragm. A mercury cathode and carbon anode were used. The potential of the mercury electrode was automatically controlled by a potentiostat[7] with respect to a saturated calomel reference electrode. Reduced solutions in the cell were protected by nitrogen or hydrogen, which was passed over rather than through the solution. Polarographic measurements on the cell contents were made by inserting the dropping electrode into the cell and using the mercury pool as anode.

Oxidation states were determined both by measurement with an oxygen–hydrogen coulometer of the current passed during reduction[8] and by an iodate titration. The latter was based on the Andrews iodine monochloride procedure.[9] According to Lang[10] iodate ion directly oxidizes tungsten (III) to tungsten(VI) only slowly, but reacts rapidly if catalyzed by ferric iron. Accordingly, an aliquot of the reduced solution was added to an air-free solution of excess of ferric iron in 4 to 6 *M* hydrochloric acid, and the ferrous iron produced was titrated potentiometrically with standard 0.01 *N* potassium iodate solution. The validity of this method was established by titration of samples of tungsten(III) prepared by reduction of tungsten(VI) in 12 *M* hydrochloric acid by saturated lead amalgam by the method of Someya.[11] Accuracy of about ±0.5% was obtained with 0.1 *N* iodate solutions. Deduction of a small blank (*ca.* 0.10 ml.) was found necessary in titrating with 0.01 *N* iodate.

Absorption spectra were recorded by use of the Beckman Model DU Photoelectric Quartz Spectrophotometer, with 1-cm. quartz cells. Some measure of protection of the solutions from air and of protection of the instrument from acid fumes was obtained by sealing the loose fitting glass cell covers with vaseline, and by providing the cell compartment with a cover fitted with tubulatures through which air was passed to provide ventilation. Slit widths of 0.02 to 0.2 mm. were used, corresponding to nominal band widths smaller than 5 millimicrons.

## Results and Discussion

**Tungsten(VI).**—It was found that tungsten (VI) in 12 *M* hydrochloric acid produces a double polarographic wave as shown in Fig. 1, one wave starting from zero applied e. m. f. and the second having a half-wave potential of −0.56 v. *vs.* S.C.E. In less concentrated acid, the half-

wave potential of the second wave is shifted somewhat in the negative direction. In both 10 *M* and 8 *M* hydrochloric acid, the half-wave potential was −0.62 v.; in 6 *M* acid −0.64 v.; in 4 *M* acid −0.66 v. *vs.* S.C.E. The solubility of tungsten (VI) in hydrochloric acid much less concentrated than 4 *M* is too small to allow the wave to be distinguished. Diffusion current constant data are given in Table I.

TABLE I

DIFFUSION CURRENT CONSTANTS OF TUNGSTEN(VI) IN HYDROCHLORIC ACID AT 25.0°

(a) 12 *M* Hydrochloric Acid. $m^{2/3}t^{1/6}$ = 1.61 mg.$^{2/3}$ sec.$^{-1/2}$ at −0.40 v. and 1.63 mg.$^{2/3}$ sec.$^{-1/2}$ at −0.67 v. *vs.* S. C. E.

|---|---|---|
| 1.00 | 1.49 | 4.78 |
| 1.97 | 1.45 | 4.62 |

Since the ratio of the diffusion current constants is 1:3, reduction apparently proceeds to the +5 and +3 states, respectively. The alternative would be deposition of tungsten metal, which has never been achieved from such strongly acid solutions. Direct proof of the above interpretation is given below.

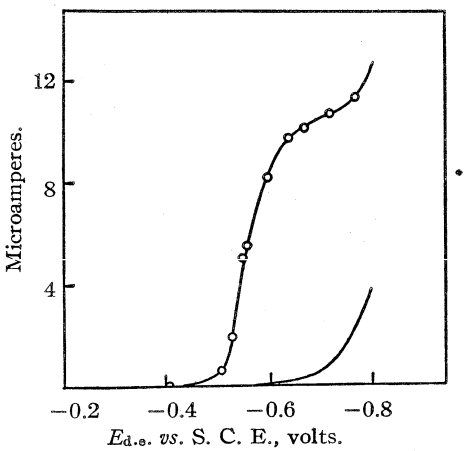

Fig. 2.—Polarogram of 2.61 millimolar tungsten(V) in 12 *M* hydrochloric acid.

**Tungsten(V).**—Reduction of solutions of tungsten(VI) in 12 *M* hydrochloric acid on the mercury cathode at −0.40 v. *vs.* S.C.E., *i. e.*, corresponding to the plateau of the first wave of the tungsten(VI) polarogram, produced blue solutions of tungsten(V). The identity of the product was established both by titration with iodate, which indicated an oxidation state of 5.00 in a typical case, and coulometric measurements during the controlled potential electrolysis, which indicated an oxidation state of 4.97. The +5 state has been obtained previously by Collenberg and Backer[12] by reduction of tungsten(VI) in concentrated hydrochloric acid on a platinum cathode without potential control.

As shown in a previous paper[13] the current in a controlled potential electrolysis in which diffusion is the controlling factor obeys the relation $i = i_0 \cdot 10^{-kt}$, where $k = 0.43\ DA/\delta V$, where $D$ is the diffusion coefficient, $A$ the electrode area, $V$ the solution volume, $\delta$ the diffusion layer thickness and $t$ is time. In reductions of 2, 4 and 8 millimolar tungsten(VI) in 12 *M* hydrochloric acid at −0.40 v. *vs.* S.C.E., the plots of log $i$ *vs.* time gave straight lines as required by the above equation, and the values of $k$ obtained were 0.049, 0.052 and 0.052 min.$^{-1}$, respectively. Under these conditions reduction to the +5 state was 99% complete in 2/0.051 or thirty-nine minutes.

The polarogram for the reduction of tungsten(V) to the +3 state is shown in Fig. 2. The slope of the wave corresponds to a reversible 2-electron reduction. The half-wave potential (0.56 v.) is identical with that of the second wave of the tungsten(VI) polarogram, and the diffusion current constant as shown in Table II agrees very well with the value 2.51 found for the difference between the two constants for the tungsten(VI) waves. No anodic wave is observed, showing that the potential of the tungsten(VI)–tungsten(V) couple has a value more positive than the oxidation potential of mercury.

TABLE II

DIFFUSION CURRENT CONSTANT OF TUNGSTEN(V) IN 12 *M* HYDROCHLORIC ACID AT 25°

| Tungsten(V) millimolar | $m^{2/3}t^{1/6}$ mg.$^{2/3}$ sec.$^{-1/2}$ | $i_d/Cm^{2/3}t^{1/6}$ at −0.67 v. *vs.* S. C. E. |
|---|---|---|
| 0.79 | 1.57 | 2.53 |
| 1.59 | 1.59 | 2.55 |
| 1.78 | 2.09 | 2.53 |
| 2.37 | 1.57 | 2.49 |
| | | Av. 2.53 ± 2 |

On dilution of a hydrochloric acid solution of tungsten(V) the blue color remains and the polarogram is qualitatively unchanged until the acid concentration is somewhat less than 6 *M*, but on further dilution the solution turns progressively more yellow, and the polarographic wave disappears.

(12) O. Collenberg and J. Backer, *Z. Elektrochem.*, **30**, 230 (1924).
(13) J. J. Lingane, *Anal. Chim. Acta*, **2**, in press (1948).

**Coulometric Reduction of Tungsten(V).**—The formation of tungsten(IV) in the reduction of tungsten in hydrochloric acid has previously been somewhat uncertain. The solid $K_2W(OH)Cl_5$ was isolated by Collenberg and Backer[12] from solutions of tungsten in concentrated hydrochloric acid after reduction on lead or mercury cathodes to below the +5 state, but these authors voiced the suspicion that the apparent tungsten(IV) might be only a compound between tungsten(V) and tungsten(III). The tungsten(VI) and tungsten(V) polarograms that we have studied indicate that reduction of tungsten(V) to tungsten(III) takes place directly, and that tungsten(IV) is unstable with respect to disproportionation into the higher and lower states.

Collenberg and Backer[12] isolated red $Rb_2WCl_5 \cdot H_2O$ containing tungsten(III) from solutions reduced on a mercury or lead cathode at temperatures below 18°; the red form was converted to the familiar green $Rb_3W_2Cl_9$ at higher temperatures.

In order to carry out the reaction corresponding to the tungsten(V) polarogram in Fig. 2, a solution of tungsten(VI) in 12 *M* hydrochloric acid was first reduced to tungsten(V) at −0.40 v. and then reduced further at −0.67 v. *vs.* S.C.E., a potential on the plateau of the tungsten(V) wave. The blue tungsten(V) solution first became purple, then red and finally yellow. After passing the +5 state and while the solution remained red the current consumption indicated by the coulometer was in close agreement with that indicated by iodate titration, *i. e.*, the current efficiency was 100%. The indicated oxidation state at one such point in the reduction of 0.01 *M* tungsten at 18° was 3.08 coulometrically and 3.09 by iodate titration. Since the solution was still red at this point, and turned yellow rather rapidly after the current had dropped to a nearly negligible value, it is clear that the red solution contained tungsten(III) rather than tungsten(IV). Immediately after completion of the electrolysis, iodate titration of the yellow solution indicated an oxidation state of 2.89, while the coulometer indicated 2.76. The latter value was lower due to a visible simultaneous reduction of a small amount of hydrogen ion near the end of the electrolysis. About fifteen minutes after completion, iodate titration indicated an oxidation state of 3.01. It thus appears possible that some lower state is formed, but is rapidly oxidized by hydrogen ion to the +3 state. All attempts to obtain reduction to a lower state failed. It is seen, therefore, that the reduction of tungsten(V) proceeds to red tungsten(III), which is spontaneously converted to the green or yellow form. The red form is presumably the reduction product involved in the polarographic wave.

We have obtained some evidence that either tungsten(IV) or a compound of tungsten(V) and tungsten(III) is produced transiently during the coulometric reduction of hydrochloric acid solutions of tungsten(V) when the concentration of the latter is relatively large. When 8 and 2 millimolar solutions of tungsten(V) were reduced, the red color produced after the quantity of electricity passed corresponded to the +4 state was much more intense with the larger concentration than could be accounted for by the ratio of the concentrations. Such intensification of color is commonly associated with compounds containing an element in two oxidation states. Further indication of an apparent +4 state was obtained by measurement of the oxidation potential at various stages during the reduction of a 2 millimolar and an 8 millimolar solution of tungsten(V). The potentials were measured against the saturated calomel electrode by interrupting the electrolysis and employing the large mercury cathode as indicator electrode. The data obtained are shown in Table III.

TABLE III

POTENTIAL CHANGES DURING REDUCTION OF TUNGSTEN (V) TO RED TUNGSTEN(III) IN 12 *M* HYDROCHLORIC ACID

The potentials are referred to the saturated calomel electrode.

(a) Total tungsten, 2.00 milimolar; 1 electron = 8.40 ml. hydrogen-oxygen at S. T. P.

| Coulometer reading, S.T.P., ml. | Apparent oxidation state | $E_{obs.}$ | $E^0$ |

| 35.8 | 3.92 | − .516 | − .514 |
| 44.4 | 3.68 | − .533 | − .524 |

The values of $E^0$ listed in the last column of Table III were computed by the equation $E_{obs.} = E^0 - (0.059/2) \log C_{III}/C_V$, where $C_{III}/C_V$ is the ratio of the concentrations of +3 and +5 tungsten calculated from the coulometer readings. With the 2 millimolar solution a very constant value of $E^0$ is obtained over the entire range of values of $C_{III}/C_V$, showing that the couple behaves reversibly at this concentration. Furthermore the $E^0$ value agrees with the half-wave po-

tential observed with tungsten(V) solutions (−0.56 v.), showing that the reduction of tungsten(V) to red tungsten(III) proceeds reversibly at the dropping electrode. With the 8 millimolar solution, on the other hand, the $E^0$ values are much too positive, and are not constant with varying values of $C_{III}/C_V$ but show a steady decrease down to an apparent oxidation state of +4, and then an increase with larger values of the $C_{III}/C_V$ ratio. Furthermore the observed potentials with the 8 millimolar solution were not steady but showed a continuous positive drift. Slow combination of tungsten(V) and tungsten(III) to produce a compound of the two states, or actual reaction to produce tungsten(IV), could account for this behavior.

**Red Tungsten(III).**—Solutions of the red form of tungsten(III) in 12 *M* hydrochloric acid were prepared by partial electrolytic reduction of tungsten(V) as described above. The reductions were not carried to completion because transformation of the red tungsten(III) to the yellow form occurs when this is done. The typical polarogram of such a mixture shown in Fig. 3 displays a well developed anodic diffusion current due to the oxidation of tungsten(III), as well as the cathodic wave of the remaining tungsten(V).

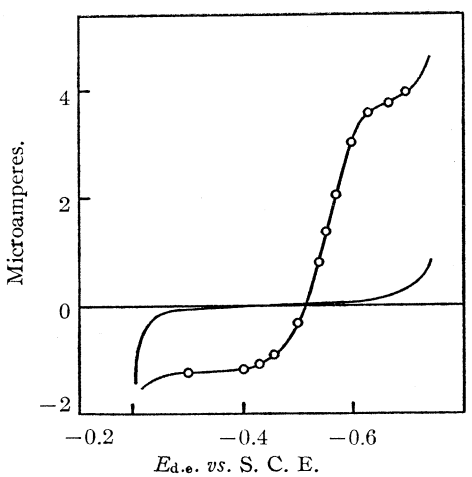

Fig. 3.—Polarogram of a mixture of 0.91 millimolar tungsten(V) and 0.67 millimolar red tungsten(III) in 12 *M* hydrochloric acid.

The fact that the composite cathodic–anodic wave shows no inflection at zero current is a commonly accepted criterion for reversibility of the electrode reactions but is misleading in this case because the anodic reaction is not the reverse of the cathodic reaction.

The anodic wave of red tungsten(III) actually corresponds to oxidation to the +4 state and not to the +5 state. With concentrations of red tungsten(III) between 0.3 and 0.7 millimolar the anodic diffusion current was directly proportional to concentration, and the average value of the diffusion current constant $i_d/Cm^{2/3}t^{1/6}$ was 1.10 ± 0.01 at 25° in 12 *M* hydrochloric acid. This is somewhat less than one-half the diffusion current constant (2.53) observed in the 2-electron reduction of tungsten(V), and slightly smaller than the diffusion current constant (1.31) observed in the 1-electron reduction of tungsten(VI) in 12 *M* hydrochloric acid. It is evident that the red tungsten(III) undergoes only a 1-electron oxidation to the +4 state. The alternative conclusion (oxidation to the +5 state) would require that the diffusion coefficient of tungsten(III) be about five times smaller than the diffusion coefficients of tungsten(V) and tungsten(VI), and this is very improbable.

This interesting result indicates that the rate of disproportionation of tungsten(IV) must be so small that no appreciable disproportionation occurs during the life of each mercury drop at the dropping electrode.

The absorption spectrum of red tungsten(III), which has not previously been reported, is shown as curve 1 in Fig. 4. This was obtained with a mixture of tungsten(III) and tungsten(V) and correction was applied for the small contribution of tungsten(V) to the measured optical density in calculating the extinction coefficient of the tungsten(III).

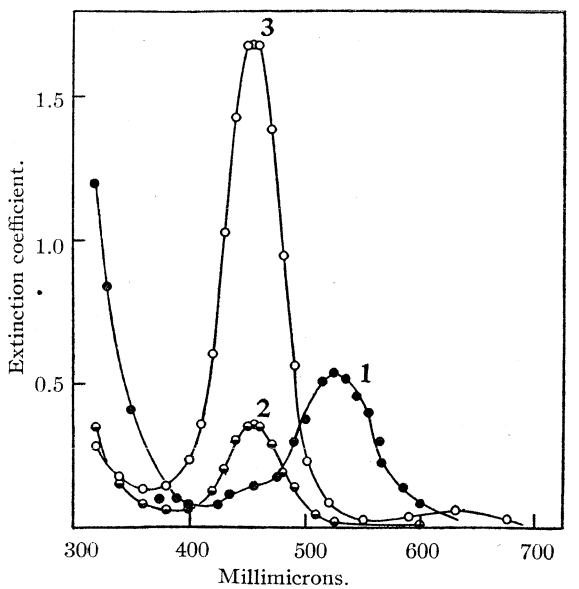

Fig. 4.—Absorption spectra of tungsten(III): (1), red form; (2), yellow form; (3), green form. Measured with Beckman UV Spectrophotometer with slit widths adjusted so that nominal band width was smaller than 4 millimicrons at all wave lengths.

**Yellow and Green Tungsten(III).**—Solutions of the red tungsten(III) turn yellow on standing, continued electrolysis or heating. A typical polarogram of the previously unreported yellow tungsten(III) is shown in Fig. 5. The well developed anodic wave has a half-wave potential of −0.53 v. *vs.* S.C.E., and thus nearly the same

as that of the red form. The anodic diffusion current is directly proportional to the concentration of yellow tungsten(III) only below about 4 millimolar, and with larger concentrations the diffusion current "constant" decreases significantly. The average value of $i_d/Cm^{2/3}t^{1/6}$ with 1 to 4 millimolar yellow tungsten(III) in 12 *M* hydrochloric acid was found to be 1.38 ± 0.06 at 25°. This is so nearly the same as that observed with red tungsten(III) that it is clear that the yellow form, like the red form, is oxidized only to the +4 state at the dropping electrode.

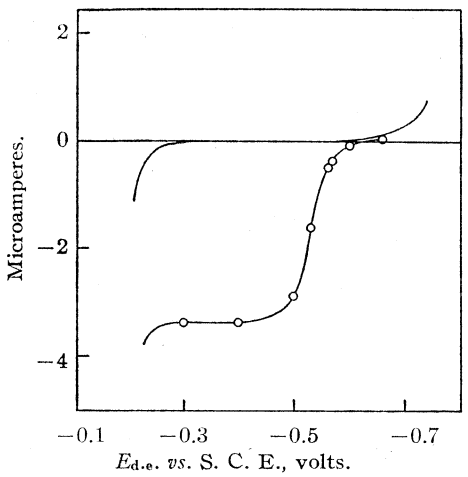

Fig. 5.—Polarogram of 1.59 millimolar yellow tungsten (III) in 12 *M* hydrochloric acid.

That the "yellow" form of tungsten(III) is actually distinct from the familiar "green" modification is demonstrated by the fact that solutions of the green $K_3W_2Cl_9$, prepared by the method of Olsson,[14] showed no anodic wave in either concentrated or dilute hydrochloric acid.

Absorption spectra of the "yellow" and "green" forms of tungsten(III) are shown in Fig. 4. The extinction of the green form at 455 millimicrons was found to obey Beer's law over a tenfold range of concentrations. The spectrum of the "yellow" form shows the same band at 455 millimicrons as the green form, but its extinction coefficient is very much smaller. Furthermore, solutions of the "yellow" form do not obey Beer's law; the extinction coefficient at 455 millimicrons was found to increase from 0.058 to 0.71 when the concentration was increased from 1 to 16 millimolar. The extinction coefficient of the green form is 1.64 at 455 millimicrons.

It seems very likely from these experiments that the "yellow" form may actually be a colorless modification of tungsten(III), and the apparent yellow color probably is caused by a small amount of the "green" form in the solutions used. This yellow or colorless form transforms to the "green" form, the rate and relative proportion of the "green" form increasing with increasing concentration.

(14) O. Olsson, *Z. anorg. allgem. Chem.*, **88**, 50 (1914).

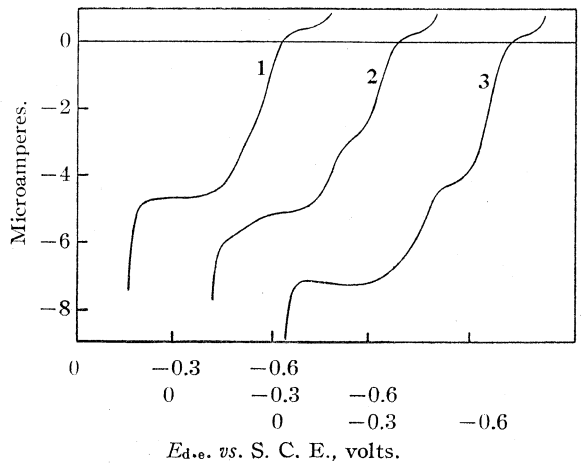

Fig. 6.—Polarogram of 1.33 millimolar yellow tungsten (III) in: (1) 9 *M*, (2) 6 *M*, and (3) 3 *M* hydrochloric acid.

Figure 6 shows polarograms of the same concentration of the "yellow" tungsten(III) in 9, 6 and 3 *M* hydrochloric acid. With decreasing concentration of hydrochloric acid the anodic wave divides into two parts and the total diffusion current increases markedly. The magnitude of the total diffusion current in 3 *M* hydrochloric acid, coupled with the fact that the two parts of the wave are of nearly equal height, indicates stepwise oxidation of the tungsten(III) to the +4 and +5 states. The other alternative is that the doublet wave results from the separate oxidation to the +4 state of two different molecular species of +3 tungsten in sluggish equilibrium, and the increase in the total diffusion current would then be attributed to an increased diffusion coefficient in 3 *M* hydrochloric acid. We believe, however, that this is unlikely.

**Controlled Potential Oxidation of "Yellow" Tungsten(III).**—Electrolytic oxidation of yellow solutions of tungsten(III) in 12 *M* hydrochloric acid was performed with the potential of the mercury electrode at −0.40 v. *vs.* S C.E., corresponding to the plateau of the anodic polarographic wave (compare Fig. 5). The oxidation was followed coulometrically. The results obtained with various concentrations of tungsten (III) at different temperatures are summarized in Table IV.

In all cases the current decreased to virtually zero at the end of the electrolysis, and the values of the average final oxidation state computed from the coulometer reading are listed in Table IV.

During the initial stages of the electrolysis the solutions tended to bleach slightly. For example, during the oxidation of a 4 millimolar solution the optical density at 455 millimicrons decreased from 0.197 to 0.186, and no other absorption band appeared, up to an apparent oxidation state of 3.50. On continued electrolysis

| 8.00 | 12 | 4.08 |
| 8.00 | 20 | 4.37 |
| 8.00 | 20 | 4.38 |
| 8.00 | 25 | 4.35 |
| 8.00 | 25 | 4.33 |
| 8.00 | 33 | 4.12 |
| 16.0 | 25 | 3.86 |

the solution became red and the absorption band at 525 millimicrons of red tungsten(III) appeared. This band then faded out and the solution finally acquired a pale brownish-yellow color with a weak band at 455 millimicrons.

With the larger concentrations of tungsten (III) the final oxidation state is very close to +4, especially at the lower temperatures, but with small concentrations the final apparent oxidation state is consistently in the neighborhood of 4.5 and independent of the temperature between 10 and 30°.

These results furnish a clear indication that a fairly stable molecular species containing tungsten (IV) and tungsten(V) in a 1:1 ratio is formed in the more dilute solutions. Apparently the "yellow" tungsten(III) is first oxidized to a colorless species of tungsten(IV), which then slowly disproportionates to red tungsten(III) and tungsten(V). On continued electrolysis the red tungsten(III) is oxidized to tungsten (IV), and finally the tungsten(IV) and tungsten (V) combine to form a stable species with an apparent oxidation state of +4.5. The fact that with the larger concentrations the final oxidation state was closer to +4 than +4.5 was simply caused by the original presence in these solutions of a considerable proportion of the green tungsten(III) which, as the polarographic experiments demonstrate, is not easily oxidized at the mercury electrode. This interpretation is substantiated by the fact that the absorption spectra of the final solutions obtained with the larger concentrations showed the characteristic band of green tungsten(III) at 455 millimicrons. No other band is observed with the final solutions.

The final solutions containing the tungsten in an apparent oxidation state of +4.5 produce a polarogram which comprises a single cathodic wave with a half-wave potential of −0.56 v. *vs.* S.C.E., and is thus very similar to the wave of tungsten(V). The average diffusion current constant, measured with several solutions in which the apparent oxidation state of the tungsten was between 4.49 and 4.56, was 2.28 ± 0.04, which is consistent with reduction to the +3 state. This was confirmed by controlled potential reductions of the final solutions which yielded the "yellow" form of tungsten(III).

## Summary

The polarogram of tungsten(VI) in 12 *M* hydrochloric acid consists of two waves: one, reduction to tungsten(V), starting from the anodic dissolution potential of mercury, and the second, reduction to red tungsten(III), having a half-wave potential of −0.56 v. *vs.* S.C.E. Using these waves as guides, tungsten(VI) was reduced by controlled potential electrolysis with a large mercury cathode at −0.40 v. *vs.* S.C.E. to tungsten(V), the polarogram of which is identical with the second wave of the tungsten(VI) polarogram.

On reducing tungsten(V) at −0.67 v. *vs.* S.C.E. red tungsten(III) was found to be the primary product, with a deep red tungsten(IV) formed during reduction of 4 and 8 millimolar solutions but not of 2 millimolar. A mixture of tungsten(V) and red tungsten(III) gives a continuous anodic–cathodic polarographic wave at −0.55 v., with the anodic oxidation being to tungsten(IV) rather than to tungsten(V).

The standard reduction potential of the tungsten(V), red tungsten(III) couple in 12 *M* hydrochloric acid at 25° was found to be −0.555 ±5 v. *vs.* S.C.E.

Red tungsten(III) is spontaneously converted to a "yellow" tungsten (III) which displays an anodic polarographic wave at −0.53 v. *vs.* S.C.E. It was shown that in more concentrated solution, the familiar green tungsten (III), which gives no polarographic wave, is formed.

Electrolytic oxidation of yellow tungsten(III) at −0.40 v. *vs.* S.C.E. produced tungsten(IV) which disproportionates to red tungsten(III) and tungsten(V); tungsten(V) and tungsten (IV) then combine in dilute solution in a 1:1 ratio to form a species with an apparent oxidation state of +4.5. The polarogram of this species shows a cathodic wave at −0.56 v. *vs.* S.C.E., corresponding to reduction to the +3 state.

Absorption spectra of the red, yellow and green species of tungsten(III) are presented.

# Synthesis of Chlorofluoropropanes

BY DONALD D. COFFMAN, RICHARD CRAMER AND G. W. RIGBY

Chloroform or carbon tetrachloride reacts with chloroethylenes in the presence of aluminum chloride to yield chloropropanes.[1] In seeking to extend this addition reaction to fluorinated methanes, Henne and co-workers[2] were deterred by the replacement of organic fluorine by chlorine from the aluminum chloride catalyst; to prepare the desired chlorofluoropropanes, they treated various chloropropanes with antimony fluoride.[2b,3]

We have now successfully brought about the aluminum chloride-catalyzed addition of chloromethanes and chlorofluoromethanes to tetrafluoroethylene as shown in Table I. In addition reactions with chlorotrifluoroethylene (see Table II), the yields were smaller and halogen exchange occurred with replacement of organic fluorine by chlorine.

[a] The authors are indebted to Dr. T. A. Ford for this experiment.

Formation of the primary adducts without halogen exchange appears dependent on the use of a monofluoromethane. Thus dichlorofluoromethane and trichlorofluoromethane gave only the primary products in reactions with tetrafluoroethylene, chlorotrifluoroethylene or tetrachloroethylene. In a single instance, the replacement of chlorine by fluorine was observed. The product from carbon tetrachloride and chlorotrifluoroethylene contained a fraction $C_3Cl_4F_4$ which can be accounted for in this way.

The structures assigned in Table III to five of the chlorofluoropropanes are identical with structures previously proposed by Henne and coworkers for chlorofluoropropanes synthesized in a different way and of somewhat different properties. The structures designated in Table III can be inferred from the following facts. The product from carbon tetrachloride and tetrafluoroethylene corresponds in composition to the chlorofluoropropane formed by addition of one chlorine atom and one trichloromethyl group across the ethylenic bond. In reactions involving a chloromethane containing hydrogen or fluorine, the fragments which add must also be chlorine and its complementary halomethyl group, since neither carbon tetrafluoride nor trifluoromethane combines with tetrafluoroethylene and since the carbon–hydrogen bond of chloroform is not broken in Prins type reactions.[1b]

The synthesis of chlorofluoropropanes from chlorotrifluoroethylene apparently proceeds by a similar mechanism. The chlorine evidently attaches itself to chlorotrifluoroethylene at the carbon atom already bonded to chlorine, since none of the products could be dechlorinated by refluxing with zinc and alcohol. This indicates that adjacent carbon atoms are not chlorinated and therefore the central carbon atom of the propane must be completely fluorinated. This mechanism is similar to that established by Prins[1b] for the addition of chloromethanes to chloroethylenes.

In selected instances in which fluorine was replaced by chlorine, the halogen exchange *must* have taken place after formation of the chlorofluoropropane, while in other instances the exchange *may* have occurred before the Prins type reaction.

## Experimental

Most of the chlorofluoropropanes were synthesized in a silver-lined autoclave under their own pressures at 50–125° with aluminum chloride catalyst present in amounts ranging from 0.5 to 10.0% by weight of combined reactants. The reaction times varied from two to twenty-four hours. The reactants used and the yields and properties of the products are listed in Table III. The aluminum chloride, and halomethane if liquid at room temperature, were placed in the

[a] Henne, *et al.*,[4c] have assigned this structure to a compound boiling at 91.7–91.9°; $n^{20}D$ 1.3750; $d^{20}_4$ 1.5877. [b] Henne, *et al.*,[4c] have described a compound of this structure, b. p. 112–112.5°; $n^{20}D$ 1.3961; $d^{20}_4$ 1.6992. [c] Henne, *et al.*,[4a] have described a compound of this structure, b. p. 174°; $n^{20}D$ 1.46410; $d^{20}_4$ 1.7557. [d] Melts at 55–56°. Henne, *et al.*,[4a] attribute this structure to a compound melting < −80°; b. p. 152–154°; $n^{20}D$ 1.43887; $d^{20}_4$ 1.7607. [e] Melts at −5°. Henne, *et al.*,[4a] have described a compound of this structure, b. p. 194–194.4°; m. p. −15.8°; $n^{20}D$ 1.48064; $d^{20}_4$ 1.8136. [f] When carbon tetrachloride or chloroform was one of the reactants the mole ratio of methane to olefin was about 2:1. In all other cases the mole ratio was 1:1. [g] Based on olefin used.

autoclave which was closed and chilled in Dry Ice–acetone. The halomethane if gaseous at room temperature and the haloethylene were forced in under pressure. The autoclave was clamped in a reciprocating shaker and heated. Following reaction, the gaseous compounds were bled off and liquified in a trap cooled with Dry Ice–acetone. The condensate was fractionally distilled. The liquid and solid remaining in the autoclave were removed by slurrying with ether. The slurry was shaken with hydrochloric acid containing crushed ice, and the ethereal extract was washed with water, dried over Drierite and fractionally distilled.

The reaction of dichlorofluoromethane with tetrachloroethylene was carried out at atmospheric pressure. A glass flask fitted with a reflux condenser and an efficient stirrer was charged with tetrachloroethylene and aluminum chloride at room temperature, and dichlorofluoromethane was distilled in slowly. The reaction was accompanied by the evolution of heat. When the reaction mixture had cooled to room temperature, the product was removed and washed with hydrochloric acid containing ice. After washing with water, the product was dried over calcium chloride and fractionated.

**Acknowledgment.**—The authors desire to express their appreciation to Dr. Paul R. Austin and to Dr. R. M. Joyce for helpful suggestions relating to this investigation.

## Summary

Chlorofluoropropanes, including several new ones, have been prepared by the reaction of halogenated methanes with haloethylenes in the presence of aluminum chloride.

Reactions of chloroform or carbon tetrachloride with tetrafluoroethylene, of dichlorofluoromethane or trichlorofluoromethane with tetrafluoroethylene or chlorotrifluoroethylene, and of dichlorofluoromethane with tetrachloroethylene, proceeded normally without appreciable replacement of fluorine by chlorine. Halogen replacement occurred in reactions involving chlorodifluoromethane.

# Diamides from Carboxylic Acids and their Nitriles

BY RICHARD H. WILEY AND W. B. GUERRANT

The formation of diamides on heating together an acid and its nitrile was first observed by Gau-

$$RCO_2H + RCN \longrightarrow (RCO)_2NH$$

tier[1a] and subsequently extended[1b-h] to a variety of acid–nitrile combinations. These studies, although not defining optimum reaction conditions, established that yields of diamide are increased by the presence of negative substituents on the $\alpha$-carbon atom. Trichloroacetic acid and nitrile gave a nearly quantitative yield and phenylacetic acid and its nitrile gave "good" yields of diamide. In the present study it has been shown that the phenylacetic acid–nitrile reaction is an equilibrium and that the yield is dependent upon reaction temperature and reaches a maximum of 45%. Also, it has been shown that the reaction of *p*-nitrophenylacetic acid with its nitrile to form the corresponding diamide, a new compound, takes place more rapidly than does the reaction of the unsubstituted phenylacetic type. Considerable decomposition accompanies the reaction of the nitro compounds.

## Experimental

Phenylacetic acid (Eastman Kodak Co.) was recrystallized from petroleum ether and vacuum dried over phosphorus pentoxide. Phenylacetonitrile (E. K. Co.) was redistilled from phosphorus pentoxide and a fraction b. p. 109–111° (4–6 mm.) collected. *p*-Nitrophenylacetic acid (E. K. Co.) was used and *p*-nitrophenylacetonitrile was prepared by nitration of phenylacetonitrile.[2]

The reaction between nitrile and acid was carried out by heating together equimolar amounts of acid and nitrile at the desired temperature. Since slightest exposure of the hot reaction mixture to air caused an immediate discoloration, all operations were conducted under oxygen-free nitrogen. The reaction mixture was sampled at time intervals and the composition of the phenylacetic acid–nitrile samples determined by one of the following methods.

A. The cooled, solidified sample (4–20 g.) was pulverized and thoroughly washed twice with 100 ml. of ether. The residue was dried and weighed as $\alpha,\alpha'$-diphenyldiacetamide, m. p. 189–191°, reported[1b] m. p. 192°. A typical sample gave the following analysis.

*Anal.* Calcd. for $C_{16}H_{15}NO_2$: N, 5.53. Found: N, 5.88.

The ether solution was titrated with standard potassium hydroxide to a phenolphthalein end-point and the acidity expressed as yield of phenylacetic acid. With three samples the aqueous alkaline extract of the ether solution was acidified to precipitate phenylacetic acid. A typical sample of acid gave the following analysis.

*Anal.* Calcd. for $C_8H_9O_2$: neut. equiv., 142. Found: neut. equiv., 136.

The yield of acid isolated in this way was 90% of the amount calculated from the titration. The ether extracts after washing with aqueous alkali were evaporated to dryness and the residue weighed as phenylacetonitrile. A typical sample of nitrile gave the following analysis.

*Anal.* Calcd. for $C_8H_7N$: sapon. equiv., 117. Found: sapon. equiv., 119.

The total yield of isolated products in the three fractions accounted for 86–89% of the starting materials. A prepared mixture of the three products was separated by this technique with 95.2% accuracy.

B. This procedure, similar to that used by Colby and Dodge,[1b] was considered less reliable because of possible alcoholysis or hydrolysis of the diamides noted by Konig[1c] with phthalonitrile. A sample of $\alpha,\alpha'$-diphenyldiacetamide, subjected to this separation procedure, was recovered in 87% yield. The sample was washed with 5% aqueous sodium carbonate, then with 95% ethanol at 0°, and finally recrystallized from 95% ethanol. Prolonged heating in dissolving the diamide was avoided. The yield of diamide was taken as the amount of dried, recrystallized solid.

The composition of the reaction mixture using *p*-nitrophenylacetic acid and its nitrile was determined by the following procedure.

C. The sample was extracted with ether in an Underwriter's extraction apparatus. The extracted residue was $\alpha,\alpha'$-di-(*p*-nitrophenyl)-diacetamide, m. p. 215–219° dec. Recrystallization from nitrobenzene gave a product m. p. 219–221° dec. in 95% recovery.

*Anal.* Cacld. for $C_{16}H_{13}N_3O_6$: C, 55.86; H, 3.82; N, 12.24. Found: C, 55.75; H, 3.81; N, 12.38.

The weight of extracted residue was taken as yield of diamide. The extracts were titrated for acidity, which, calculated as *p*-nitrophenylacetic acid, was taken as unreacted acid. The acid isolated was found to be essentially that calculated by titration. The unreacted nitrile was not separated from nitrobenzene solvent left in the neutral residue. The ether insoluble residue obtained in runs made for periods of time much beyond those reported in Fig. 3 was contaminated with a brown impurity which made the estimation of yield of diamide unreliable. Trituration with ether gave similar amounts of extract and was used in most separations in place of the extraction.

The reaction temperature, at first supposed to be of secondary importance, was controlled manually within ±5° for the series reported in Fig. 1. When it became apparent that narrow temperature limits were required, the reaction was carried out in a thermostatically controlled bath at ±2°. The series reported in Figs. 2 and 3 were made thus.

The conversion of $\alpha,\alpha'$-diphenyldiacetamide to an equilibrium mixture was demonstrated by heating 10 g. of diamide at 200°, for one hour to melt, and then at 190° for eight hours. Separation of the reaction mixture by procedure A gave 35.9% yield of recovered diamide, 29.4% of acid by titration, and 29.9% of nitrile as neutral residue. Both $\alpha,\alpha'$-diphenyldiacetamide and $\alpha,\alpha'$-di-(*p*-nitrophenyl)-diacetamide were converted to tars, from which no acid or nitrile was isolated, when heated at 180° for eight to fifteen hours in nitrobenzene.

## Discussion

**Phenylacetic Acid–Nitrile Reaction.**—The data for two series of runs are given in Figs. 1 and 2. The data obtained at 225 and 250° (Fig. 1) show that the reaction produces about 25% of diamide within one to three hours and then on

prolonged heating the yield of diamide drops off presumably due to decomposition since there is considerable discoloration and tar formation. At 200°, the yield of diamide levels off at about 30% and there is no extensive discoloration and tar formation. At 175° (Fig. 1) and at 180 and 190° (Fig. 2) a constant yield of diamide is established at 35–46%. These data indicate the existence of an equilibrium reaction which was established by converting the melted diamide by heating at 190° for nine hours to a mixture similar in composition to that obtained from the nitrile–acid reaction at this temperature.

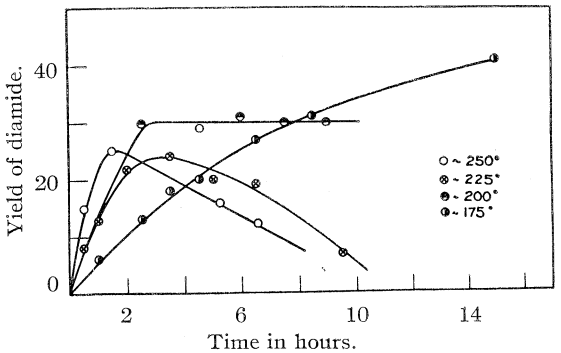

Fig. 1.—Yield of $\alpha,\alpha'$-diphenyldiacetamide at different temperatures; separation by procedure B.

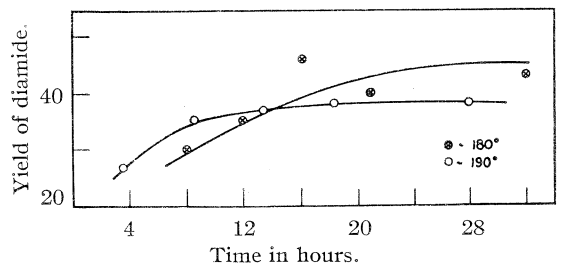

Fig. 2.—Yield of $\alpha,\alpha'$-diphenyldiacetamide at 180–190°; separation by procedure A.

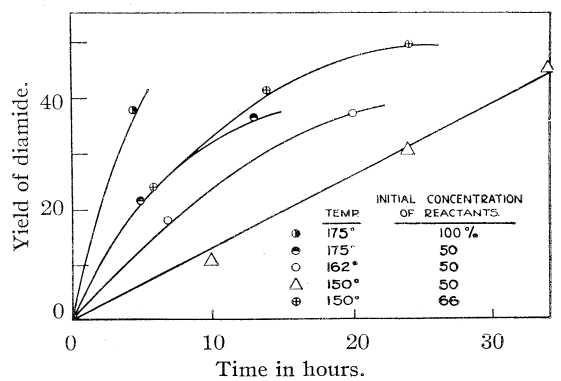

Fig. 3.—Yield of $\alpha,\alpha'$-di-($p$-nitrophenyl)-diacetamide at different temperatures and concentrations.

**$p$-Nitrophenylacetic Acid–Nitrile Reaction.**—The data for this series of runs are given in Fig. 3. Extensive decomposition takes place when the reaction is run at 160° or over. At 175° the reaction mixture solidifies after four hours with formation of 38% yield of diamide. A weight of nitrobenzene equal to or one-half that of the combined weight of nitrile and acid was added to the reaction mixture to give 50 and 66% concentration of total reactants and to keep the reaction mixture liquid in the other run. At the 50% concentration, the reaction rate increases as the temperature is raised from 150 to 175° but decomposition becomes extensive. At 66% concentration yields of 50 and 45% diamide are obtained at twenty-four and thirty-six hours, respectively. Under the conditions tried the maximum yield of diamide was 50% obtained at 66% concentration and 150° for twenty-four hours. The presence of an $\alpha$-$p$-nitrophenyl group increases the rate of reaction. High yields are not formed presumably because of side reactions caused by the oxidizing action of the nitro groups.

## Summary

The reaction between phenylacetic acid and phenylacetonitrile gives an equilibrium mixture containing 35–46% $\alpha,\alpha'$-diphenyldiacetamide at 180–190°.

The reaction between $p$-nitrophenylacetic acid and $p$-nitrophenylacetonitrile gives a 38% yield of $\alpha,\alpha'$-di-($p$-nitrophenyl)-diacetamide in four hours at 175°. With nitrobenzene as a solvent 50% of the diamide is formed at 150° in twenty-four hours.

# Investigation of Pyrazole Compounds. VIII.[1] Synthesis and Acylation of Pyrazolones Derived from Hydrazine and Methylhydrazine

BY BRUCE GRAHAM, H. D. PORTER AND A. WEISSBERGER

Aromatic hydrazines and ethyl β-amino-β-ethoxyacrylate, I,[2] form the respective ethyl β-imino-β-(β-R-hydrazino)-propionates, II,[2] and/or 1-R-3-amino-5-pyrazolones, III.[3] The isolation of the intermediate, II, in high yields (80–90%) proves (1) that the $=C(NH_2)OC_2H_5$ group of I reacts in preference to the $-CO_2C_2H_5$ group, and (2) that the β-nitrogen atom of the aromatic hydrazines is much more reactive (basic) than the α-nitrogen atom. The latter observation agrees with the fact that aromatic hydrazines are acylated in the β-position exclusively.[4] However, aliphatic hydrazines are acylated[5] primarily at the more basic[6] α-nitrogen atom, although some acylation takes place in the β-position.[7] In a similar twofold reaction, *methylhydrazine* reacted with I to give two isomers: a compound melting at 180–182° in a yield of 47%, and another compound melting at 192–194° in a 6% yield. Both isomers analyze for the cyclized products, IV or V, and form soluble dyes in the oxidation film-strip test[8] and by condensation with *p*-nitrosodimethylaniline.[9] The formation of dye with both isomers in this latter test is unusual, because 1-aryl or 1-heterocyclic substituted 3-hydroxy-5-pyrazolone imides, *i. e.*, the isomers corresponding to V, give no dye in this test.[9] The fact that the higher-melting isomer obtained from methylhydrazine gives more dye with nitrosodimethylaniline than the lower-melting isomer, suggests[9] the structure *1-methyl-3-amino-5-pyrazolone*, IV, for the compound melting at 192–194°, and the structure *1-methyl-3-hydroxy-5-pyrazolone imide*, V, for the compound melting at 180–182°.

I II

III IV V

An attempt was made to prove the structure of the higher-melting compound to be IV by an unequivocal synthesis similar to that described in the first paper of this series.[10] 1-Methyl-3-carbethoxy-5-pyrazolone, VI, was prepared from methylhydrazine and ethyl oxalacetate. No intermediate methylhydrazone could be isolated in the reaction. However, the product couples in the film-strip test[8] which proves it to be VI and excludes the remotely possible structure, VII. Next, VI was converted to the hydrazide, VIII, and many attempts were made to obtain the azide, IX, from the latter. However, at best only a trace of the azide was isolated because nitrous acid reacted at the 4-position of the pyrazolone ring under the conditions of the experiments. Kufferath[11] got similar results when he treated 5-pyrazolone-3-acethydrazide with nitrous acid. The difference in reactivity between VIII and 1-phenyl-5-pyrazolone-3-carboxhydrazide[10] toward nitrous acid is noteworthy, since the 4-position of the latter is unaffected during the formation of the azide. Excess nitrous acid produced X in good yield. The compound gave uninviting products when subjected to the Curtius degradation.

In order to avoid nitrosation at the 4-position, VI was treated with *p*-methoxybenzenediazonium chloride to give XI. This was converted to the hydrazide, XII, which readily formed the azide, XIII. This azide was subjected to the Curtius degradation, producing 1-methyl-3-amino-4-(*p*-methoxyphenylazo)-5-pyrazolone, XVI, by way of the intermediates, XIV and XV. XVI is a red dye, melting at 172–174°.

The two products from the reaction of methylhydrazine with I were treated with *p*-methoxybenzenediazonium chloride to produce dyes for comparison with XVI. The higher-melting (192–194°) compound formed a red dye, melting at 172–174°, identical in every respect with XVI. The parent compound is, therefore, 1-methyl-3-amino-5-pyrazolone, IV. The lower-melting (180–182°) product formed a bright yellow dye, melting at 240–242°, XVII.

Upon benzoylation with two moles of benzoyl chloride in pyridine, IV and V yielded the dibenzoyl derivatives, XVIII, melting at 146–148°,

(1) Weissberger, Porter and Gregory, VII, THIS JOURNAL, **66**, 1851 (1944).

(2) This compound, previously[1] formulated as ethyl malonate monoimidoester, $C_2H_5OCCH_2CO_2C_2H_5$ (NH), was shown by Glickman and Cope [*ibid.*, **67**, 1017 (1945)] to be the tautomer, I. We continue to formulate the *hydrazine* derivative, II, as an imino compound without wishing to imply that this structure is more probable than other tautomeric forms.

(3) All derivatives of pyrazole, which, by prototropic shifts, could form pyrazolones are named pyrazolones [see Weissberger and Porter, *ibid.*, **64**, 2133 (1942)].

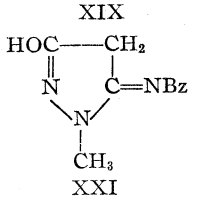
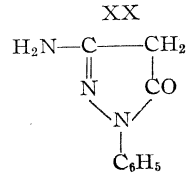
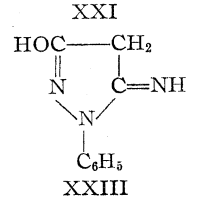
XIV



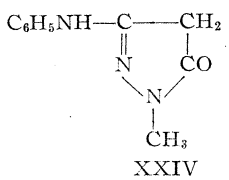
XV



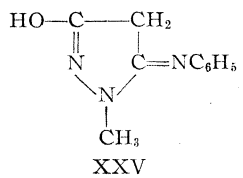
and XIX, melting at 150–153°, respectively. Both are insoluble in dilute sodium carbonate solution, but with alcoholic potassium hydroxide at room temperature, one benzoyl group was hydrolyzed from each of these compounds. The monobenzoyl derivative, XX, of IV formed in the film-strip test a magenta dye typical of 1-aryl-3-benzamido-5-pyrazolones. The corresponding derivative, XXI, of V formed no dye on the film strip but did form a very soluble blue dye in the test solution. It is noteworthy that the difference in the color test, which is pronounced[9] with the 1-phenyl derivatives, XXII and XXIII, and which is smaller with the 1-methyl derivatives, IV and V, becomes strong again if the 1-methyl pyrazolones bear a phenyl group on the 3-amino, XXIV, or the 5-imino nitrogen, XXV.[9] The relative yields of IV and V are those to be expected if the $=C(NH_2)OC_2H_5$ group of I reacts first and predominantly with that nitrogen which is more reactive in common acylations.[5,7]



XVIII



XIX



XX

XXI

XXII

XXIII

XXIV

XXV

Two isomers were also formed in the condensation of α-carbethoxyacetothioacetanilide with methylhydrazine,[9] *viz.*, 1-methyl-3-anilino-5-pyrazolone, XXIV, in 11% yield and 1-methyl-3-hydroxy-5-pyrazolone anil, XXV,[9] in 2% yield. If, as we assumed,[1] the $-CO_2C_2H_5$ group reacts first in this case, the relative yields agree with the higher reactivity of the α-nitrogen in methylhydrazine because XXIV is the result of primary reaction with the α-nitrogen atom, while XXV is the result of primary reaction at the β-nitrogen. However, the low total yield renders these observations rather inconclusive.

*Methylhydrazine* reacts with ethyl cyanoacetate under very mild conditions and *without alkali* to produce a mixture of IV and V. The yields are 29 and 26%, respectively. The high yield of *cyclized* products is rather surprising in view of the results obtained with hydrazine and with phenylhydrazine. When reacted with ethyl cyanoacetate *in the absence of alkali, hydrazine* produces only cyanoacethydrazide (quantitative),[12] and *phenylhydrazine* produces only cyanoacetphenylhydrazide[13] (10%, see Experimental). The cyanoacethydrazide and the cyanoacetphenylhydrazide can be cyclized in the presence of alkali to 3-amino-5-pyrazolone, XXVI,[14] and 1-phenyl-3-hydroxy-5-pyrazolone imide, XXIII,[13] respectively.

The same three hydrazines reacted with ethyl cyanoacetate *in the presence of two moles of sodium*

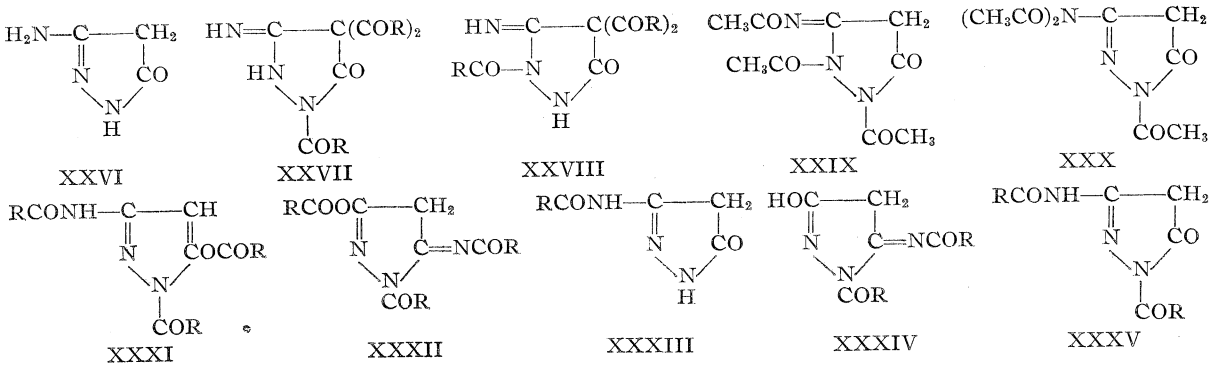
*methylate. Methylhydrazine* and *hydrazine* gave no color-forming products so this reaction was not explored further. Phenylhydrazine formed 1-phenyl-3-amino-5-pyrazolone, XXII,[3] in 43% yield.

The different behavior of the three hydrazines in the absence of caustic alkali can be explained by the high basicity of the methylhydrazine. It appears that the latter takes over the role which, in the reaction of phenylhydrazine, is played by sodium methylate, and that methylhydrazine acts as its own condensing and cyclizing agent. The nitrile group probably reacts with the more reactive $\alpha$-nitrogen of methylhydrazine to produce the intermediate, $CH_3N(NH_2)C(NH)CH_2COOC_2H_5$, which immediately cyclizes, forming V. IV is probably produced by an initial reaction of the carbethoxy group at the $\alpha$-nitrogen of the methylhydrazine to form the intermediate, $CH_3N(NH_2)COCH_2CN$, which cyclizes to IV.

The formation of the two isomers, IV and V, might also be explained by a primary reaction of the nitrile group at the $\beta$-nitrogen and at the $\alpha$-nitrogen of the methylhydrazine, respectively. However, we are inclined to believe that the relative yields would then probably show a larger difference and would be in the opposite direction.

Hepner and Fajersztejn[14] prepared several acyl derivatives of 3-amino-5-pyrazolone. Acetylation with boiling acetic anhydride gave two isomeric triacetyl derivatives, melting at 190° and 130°. They considered them to be 1,4,4-triacetyl-3-imino-5-ketopyrazolidine, XXVII (R = $CH_3$), and 2,4,4-triacetyl-3-imino-5-ketopyrazolidine, XXVIII (R = $CH_3$), respectively, because neither compound reacted with nitrous acid, and boiling water hydrolyzed both to the parent compound. The same authors obtained a tribenzoyl derivative, melting at 183°, by a Schotten–Baumann reaction of XXVI with benzoyl chloride. They formulate this, by analogy, as 1,4,4-tribenzoyl-3-imino-5-ketopyrazolidine, XXVII (R = $C_6H_5$).

In our work, by using sodium methylate for the cyclization of cyanoacethydrazide we raised the melting point of XXVI by 10°. XXVI was also obtained by the reaction of I with hydrazine. On heating with acetic anhydride on the steam-bath and fractional crystallization, XXVI gave two triacetyl derivatives, melting at 202° and 130°. Not only the latter but probably also the higher-melting compound are identical with the products obtained by Hepner and Fajersztejn.



Both *triacetyl compounds* are insoluble in dilute sodium carbonate and do not couple with *p*-nitrosodimethylaniline.[9] On mild hydrolysis with dilute sodium hydroxide, both give the same *monoacetyl derivative*, melting at 227°, which is soluble in 3% sodium carbonate and couples with *p*-nitrosodimethylaniline. When the high-melting triacetyl compound is treated with one equivalent of piperidine, a *diacetyl* derivative, melting at 195°, is formed, which is soluble in 3% sodium carbonate and couples with *p*-nitrosodimethylaniline.[9] The lower-melting isomer gave the *monoacetyl* derivative, m. p. 227°, even under very mild conditions, *e. g.*, when the piperidine was added slowly at room temperature. Similar difficulties in selective deacylations have been noted before.[8]

The structures, XXVII and XXVIII (R = $CH_3$), which were given by Hepner and Fajersztejn to the triacetyl derivatives, are untenable because the ready hydrolysis of *all three acetyl* groups[14] excludes any 4-acetyl groups.[8] Moreover, the coupling action of the monoacetyl derivative, m. p. 227°, and the diacetyl derivative, m. p. 195°, excludes a 4-acetyl group in either of these compounds.[15] The structures, XXIX and XXX, are excluded because these compounds should be soluble in dilute carbonate and couple with *p*-nitrosodimethylaniline. This leaves for the two isomeric triacetyl compounds only structures XXXI and XXXII (R = $CH_3$). Inasmuch as both isomers hydrolyze to the same monoacetyl derivative, the latter compound, melting at 227°, is assigned the structure *3-acetamido-5-pyrazolone*, XXXIII (R = $CH_3$), because the other acetyl group which is common in XXXI and XXXII would be hydrolyzed[8,15] under the conditions for the preparation of XXXIII. The diacetyl compound, melting at 195°, is considered to be *1-acetyl-3-acetamido-5-pyrazolone*, XXXV (R = $CH_3$), because the isomeric compound, XXXIV, would not couple in the *p*-nitrosodimethylaniline test.[16] The triacetyl compound, melting at 202°, is therefore *1-acetyl-3-acetamido-5-acetoxypyrazole*, XXXI (R = $CH_3$), which leaves for the triacetyl compound, melting at 130°, the structure of *1-acetyl-3-acetoxy-5-pyrazolone acetylimide*, XXXII (R = $CH_3$).

By analogy with the determination of the structures of the acetyl derivatives, the structure of the tribenzoyl derivative (m. p. 185°), prepared as given in the literature was readily determined. It gives, on hydrolysis in dilute sodium hydroxide, a monobenzoyl derivative, melting at 205°. This is carbonate-soluble and couples in the *p*-nitrosodimethylaniline test and is, therefore, assigned the structure of *3-benzamido-5-pyrazolone*, XXXIII (R = $C_6H_5$). Reaction of the tribenzoyl compound with one equivalent of piperidine gives a dibenzoyl derivative, melting at 175°. Since this is soluble in carbonate and does not couple to form a dye even in the film-strip test,[15] it is assigned the structure *1-benzoyl-3-hydroxy-5-pyrazolone benzoylimide*, XXXIV (R = $C_6H_5$). This leaves only the structure *1-benzoyl-3-benzoyloxy-5-pyrazolone benzoylimide*, XXXII (R = $C_6H_5$), for the tribenzoyl compound (m. p. 185°) because of its insolubility in alkali.

If 3-amino-5-pyrazolone is benzoylated in pyridine solution, a different tribenzoyl derivative,

(15) Weissberger and Porter, THIS JOURNAL, **65**, 2180 (1943).
(16) *Cf.* XVII in ref. 8.

XXVI XXVII XXVIII XXIX XXX

XXXI XXXII XXXIII XXXIV XXXV

melting at 161°, is obtained. On hydrolysis with dilute sodium hydroxide, this also gives 3-benzamido-5-pyrazolone, XXXIII (R = $C_6H_5$). When the tribenzoyl derivative (m. p. 161°) is treated with one equivalent of piperidine, a dibenzoyl derivative, melting at 171°, is obtained. Since this is soluble in carbonate and couples in the film-strip test,[8] it is assigned the structure *1-benzoyl-3-benzamido-5-pyrazolone*, XXXV (R = $C_6H_5$). It follows that the tribenzoyl compound, melting at 161°, is *1-benzoyl-3-benzamido-5-benzoyloxypyrazole*, XXXI (R = $C_6H_5$).

## Experimental

**1-Methyl-3-amino-5-pyrazolone, IV, and 1-Methyl-3-hydroxy-5-pyrazolone Imide. V.**—(a) A solution of 21 g. (0.46 mole) of methylhydrazine in 75 ml. of absolute alcohol was added to a solution of 72.5 g. (0.46 mole) of ethyl β-amino-β-ethoxyacrylate I, in 75 ml. of absolute alcohol. The mixture warmed spontaneously to 60°. The solution was allowed to stand for twenty hours. Two easily distinguishable types of crystals separated. The crystals were large enough to be separated mechanically.

There were 24.3 g. (47%) of large prisms, 3.1 g. (6%) of needles, and 5 g. (10%) of mixed material. These fractions were carefully recrystallized to produce 14 g. of prisms, melting at 180–182°, and 1 g. of needles, melting at 192–194° in a sealed tube (190° if heated very slowly in an open tube). The needles were proved (by compound XVI) to be 1-methyl-3-amino-5-pyrazolone while the prisms were the 1-methyl-3-hydroxy-5-pyrazolone imide.

(b) Methylhydrazine (5 g., 0.11 mole) was dissolved in 10 ml. of water and the resulting solution was cooled. To this was added 12.3 g. (0.11 mole) of ethyl cyanoacetate. After a few minutes the ester dissolved, and the solution was placed in a vacuum desiccator for three days. Large prisms (some an inch long) formed but no needles were present. The prisms were collected and washed with 50 ml. of absolute alcohol; 3.2 g. (26%) melting at 180°. The mother liquor and washings were evaporated on a steam-bath. The residue was dissolved in 25 ml. of boiling absolute alcohol and cooled slowly. The needles were collected and washed with alcohol; 3.5 g. (29%), m. p. 190°. Recrystallization raised the melting point to 192–194° (in a sealed tube).

*Anal.* Calcd. for $C_4H_7N_3O$: C, 42.5; H, 6.2; N, 37.1. Found, for isomer melting at 180–182°: C, 42.4; H, 6.2; N, 36.9. Found, for isomer melting at 192–194°: C, 42.3; H, 6.2; N, 37.1.

**1-Methyl-3-carbethoxy-5-pyrazolone, VI.**—Freshly prepared methylhydrazine (2.3 g.) in 20 ml. of dry benzene was added to a solution of freshly prepared ethyl oxalacetate (9.4 g.) in 80 ml. of dry benzene. The temperature of the solution rose from 28° to 41°. After standing one hour at room temperature, the solution was refluxed for five minutes and cooled. The precipitate of sirupy crystals was collected and recrystallized from 50 ml. of water. The resulting white needles weighed 3.5 g. (41%) and melted at 148–150°.

The compound can also be prepared from the salts of the two starting materials. A solution of 14.4 g. of methylhydrazine sulfate in 20 ml. of water was diluted with 300 ml. of hot ethanol. To this was added a hot solution of 21.0 g. of sodium ethyl oxalacetate in 700 ml. of ethanol. Sufficient alcoholic potassium hydroxide was added to neutralize the solution. The inorganic salts were removed by filtration, and the alcoholic solution was concentrated under reduced pressure to near dryness. The residue was recrystallized from 200 ml. of water. The yield using this procedure was 11.5 g. (68%), m. p. 148–150°.

*Anal.* Calcd for $C_7H_{10}N_2O_3$: N, 16.5. Found: N, 16.6.

**1-Methyl-5-pyrazolone-3-carboxyhydrazide Hydrochloride, VIII.**—1-Methyl-3-carbethoxy-5-pyrazolone, VI, (6.9 g.) was suspended in 18 ml. of 42% hydrazine hydrate solution. After sixteen hours, the solution was acidified with 14 ml. of concentrated hydrochloric acid under cooling. The product was collected and washed with 30 ml. of water in three portions. It was recrystallized from 25 ml. of water. The product weighed 3.6 g. (46%) and melted at 253–255°.

*Anal.* Calcd. for $C_5H_8N_4O_2 \cdot HCl$: C, 31.3; H, 4.5; N, 28.3. Found: C, 31.2; H, 4.7; N, 29.1.

**1-Methyl-5-pyrazolone-3-carbazide, IX.**—1-Methyl-5-pyrazolone-3-carboxyhydrazide hydrochloride, VIII (0.90 g.) was suspended in 10 ml. of water. The slurry was layered with 20 ml. of ether and cooled to 0°. To this was added a solution of 0.33 g. of sodium nitrite in 5 ml. of water. The mixture was strongly agitated for ten minutes before the ether layer was removed. This ether layer yielded 0.05 g. of light yellow crystals after standing at 0° for one hour. The compound deflagrates at 113°.

*Anal.* Calcd. for $C_5H_5N_5O_2$: C, 35.9; H, 3.0. Found: C, 36.5; H, 2.9.

**1-Methyl-4-isonitroso-5-pyrazolone-3-carbazide, X.**—1-Methyl-5-pyrazolone-3-carboxyhydrazide hydrochloride, VIII (4.0 g., 0.021 mole), was suspended in 50 ml. of water, and the mixture was cooled in a salt–ice-bath.

A solution of 1.47 g. (0.021 mole) of sodium nitrite in 10 ml. of water was added to the slurry at such a rate that the temperature did not exceed 0°. The mixture was stirred for one hour. The yellow precipitate was collected, washed with water, and dried at room temperature. The yield was 2.1 g. The material explodes at 112° (slightly higher if heated rapidly).

*Anal.* Calcd. for $C_5H_4N_6O_3$: C, 30.6; H, 2.1; N, 42.6. Found: C, 30.1; H, 2.3; N, 42.6.

**1-Methyl-3-carbethoxy-4-(*p*-methoxyphenylazo)-5-pyrazolone, XI.**—1-Methyl-3-carbethoxy-5-pyrazolone, VI (5.0 g., 0.029 mole), was dissolved in 50 ml. of pyridine. The solution was cooled to 0° and treated with a cold solution of 0.029 mole of *p*-methoxybenzenediazonium chloride in 60 ml. of water. After ten minutes, 50 ml. of water was added to the mixture. The dye was

collected, washed with water, and recrystallized from 100 ml. of ethanol. There resulted 6.8 g. of orange dye, melting at 125–127°.

*Anal.* Calcd. for $C_{14}H_{16}N_4O_4$: C, 55.3; H, 5.3; N, 18.4. Found: C, 55.7; H, 5.6; N, 18.7.

**1-Methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-carboxyhydrazide, XII.**—1-Methyl-3-carbethoxy-4-(*p*-methoxyphenylazo)-5-pyrazolone, XI (6.5 g.), was stirred into 80 ml. of 42% hydrazine hydrate solution. The stirring was continued for four hours. All the dye changed from orange to yellow. Water (100 ml.) was added, and the solution was filtered to remove a small amount of insoluble material. The clear solution was acidified with 50 ml. of acetic acid. The red dye was collected and washed with 100 ml. of boiling alcohol. The material weighed 3.8 g. (60%) and melted at 212–214°.

*Anal.* Calcd. for $C_{12}H_{14}N_6O_3$: C, 49.7; H, 4.9; N, 29.0. Found: C, 50.1, 49.9; H, 4.8, 4.9; N, 29.6.

**1-Methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-carbazide, XIII.**—1-Methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-carboxyhydrazide, XII (2.9 g.), was dissolved in a solution of 100 ml. of water, 100 ml. of dioxane, and 5 ml. of concentrated hydrochloric acid. The solution was cooled to 0°, and 0.70 g. of sodium nitrite in 30 ml. of water was added. The azide precipitated immediately. It was washed with water and ethanol. This process yielded 2.5 g. of the azide which explodes at 120°.

*Anal.* Calcd. for $C_{12}H_{11}N_7O_3$: N, 33.2. Found: N, 32.6.

**1-Methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-isocyanate, XIV.**—A suspension of 2.5 g. of 1-methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-carbazide, XIII, in 150 ml. of absolute alcohol was refluxed on a steam-bath for two hours. When all evolution of nitrogen had ceased, the insoluble product was collected and washed with ethanol. The product, 1.5 g., melted at 245–249°. A sample recrystallized from dioxane melted at 253–255°. Analysis proved it to be the isocyanate rather than the expected urethan.

*Anal.* Calcd. for $C_{12}H_{11}N_5O_3$: C, 52.8; H, 4.2; N, 25.7. Found: C, 52.5; H, 4.2; N, 24.9.

**1-Methyl-3-carbethoxyamino-4-(*p*-methoxyphenylazo)-5-pyrazolone, XV.**—A suspension of 0.35 g. of 1-methyl-4-(*p*-methoxyphenylazo)-5-pyrazolone-3-isocyanate, XIV, in 50 ml. of absolute alcohol was refluxed for twenty hours. The resulting solution was filtered and cooled. The precipitate was collected, washed with alcohol, and recrystallized from alcohol. The product was 0.20 g. of bright orange dye, melting at 181–182°.

*Anal.* Calcd. for $C_{14}H_{17}N_5O_4$: C, 52.7; H, 5.4; N, 21.9. Found: C, 52.4; H, 5.4; N, 22.1.

**1-Methyl-3-amino-4-(*p*-methoxyphenylazo)-5-pyrazolone, XVI.**—(a) A solution of 0.10 g. of 1-methyl-3-carbethoxyamino-4-(*p*-methoxyphenylazo)-5-pyrazolone, XV, in 4 ml. of 10% sodium hydroxide was warmed for two hours on a steam-bath. The solution was filtered, and acidified with 0.60 ml. of acetic acid. The precipitate was recrystallized from ethanol. It was a dull red dye, melting at 172–174°.

(b) A solution of 1.13 g. (0.01 mole) 1-methyl-3-amino-5-pyrazolone, IV, in 20 ml. of 5% sodium hydroxide solution at 0° was treated with (0.01 mole) of benzene diazonium chloride in 20 ml. of cold water. After fifteen minutes, the solution was acidified with acetic acid, and the dye was collected. It was washed with water and recrystallized from 20 ml. of ethanol. This procedure produced 1.0 g. of dull red dye, melting at 172–174°. The mixed melting point of (a) and (b) was 172–174°.

*Anal.* Calcd. for $C_{11}H_{13}N_5O_2$: C, 53.5; H, 5.3; N, 28.4. Found: C, 53.4; H, 5.2; N, 28.3.

**1-Methyl-3-hydroxy-4-(*p*-methoxyphenylazo)-5-pyrazolone Imide, XVII.**—A solution of 1.13 g. (0.01 mole) of 1-methyl-3-hydroxy-5-pyrazolone imide, V, in 25 ml. of pyridine and 5 ml. of water was cooled to 0° and treated with a cold solution of 0.01 mole of benzenediazonium chloride in 15 ml. of water. After a few minutes, a yellow dye separated. It was collected, washed with water, and recrystallized from 50 ml. of ethanol. There resulted 0.9 g. of bright yellow dye, melting at 240–242°. A mixture of this material with XXIa melted at 167°.

*Anal.* Calcd. for $C_{11}H_{13}N_5O_2$: C, 53.5; H, 5.3; N, 28.4. Found: C, 53.5; H, 5.7; N, 27.9.

**1-Methyl-3-benzamido-5-benzoyloxypyrazole, XVIII.**—Benzoyl chloride (3 g., 0.021 mole) was added dropwise to a solution of 1-methyl-3-amino-5-pyrazolone, IV (1.13 g., 0.010 mole) in 20 ml. of pyridine at room temperature. The mixture was warmed for one-half hour on a steam-bath, cooled, and drowned out with 20 ml. of water. The solid was collected, washed, dried, and recrystallized from 25 ml. of ethanol. This process yielded 1.9 g. (60%) of white powder, m. p. 146–148°.

*Anal.* Calcd. for $C_{18}H_{15}N_3O_3$: C, 67.5, H, 4.9; N, 13.1. Found: C, 67.4; H, 4.6; N, 13.3.

**1-Methyl-3-benzoyloxy-5-pyrazolone Benzoylimide. XIX.**—1-Methyl-3-hydroxy-5-pyrazolone imide, V, was acylated, and the product was purified by the same procedure used in making XVIII. The yield was 1.9 g. (60%) of white powder, m. p. 150–153°. A mixture of XVIII and XIX melted above 130°.

*Anal.* Calcd. for $C_{18}H_{15}N_3O_3$: C, 67.5; H, 4.9; N, 13.1. Found: C, 67.0; H, 4.8; N, 12.6.

**1-Methyl-3-benzamido-5-pyrazolone, XX.**—To a solution of 5 ml. of alcohol and 10 ml. of 5% sodium hydroxide was added 1.6 g. of 1-methyl-3-benzamido-5-benzoyloxypyrazole, XVIII. The solution was stirred for one hour, filtered, and acidified with acetic acid. The precipitate was collected, washed with alcohol, dried, and recrystallized from 40 ml. of ethanol; 0.7 g. (65%) of white crystals, which slowly melted, with decomposition, at 215°.

*Anal.* Calcd. for $C_{11}H_{11}N_3O_2$: C, 60.9; H, 5.1; N, 19.3. Found: C, 61.1; H, 5.1; N, 19.7.

**1-Methyl-3-hydroxy-5-pyrazolone Benzoylimide, XXI.**—1-Methyl-3-benzoyloxy-5-pyrazolone benzoylimide, XIX (3.2 g.) was added to a solution of 10 ml. of ethanol and 20 ml. of 5% sodium hydroxide. The solution was stirred for one hour, filtered, and acidified with acetic acid; 2.1 g. (96%), m. p. 243–249°. The material melted over the same range after recrystallization from ethanol.

*Anal.* Calcd. for $C_{11}H_{11}N_3O_2$: C, 60.9; H, 5.1; N, 19.3. Found: C, 60.5; H, 4.6; N, 19.2.

**Reaction of Phenylhydrazine with Methyl Cyanoacetate.**—A mixture of 10.8 g. of phenylhydrazine and 9.9 g. of methyl cyanoacetate in 20 ml. of dioxane was heated on the steam-bath for eighteen hours, cooled, drowned out with 100 ml. of water, and the solution decanted from the precipitated oil. The latter was triturated with ether, cooled, filtered, and the gummy product extracted with 100 ml. of benzene in four portions. The combined extracts, on cooling, gave 1.8 g. (10%)[17] of β-cyanoacetphenylhydrazide.

**3-Amino-5-pyrazolone, XXVI.**—Cyanoacethydrazide[8] (10 g.), in sodium methylate solution (4.6 g. of sodium in 50 ml. of methanol) was refluxed for one hour, cooled, and the sodium salt filtered off. The latter was dissolved in 35 ml. of water, acidified with 6 ml. of acetic acid, and the precipitated product was recrystallized from water; 7 g. (71%) of short, ivory needles, m. p. 214–215° dec. The compound deteriorates considerably on standing for more than a week at room temperature.

Ethyl β-amino-β-ethoxyacrylate, I (15.9 g.), and 5.9 g. of hydrazine hydrate (85%) in 25 ml. of absolute ethanol were brought to boiling on the steam-bath and the heat supply removed. Heat was evolved and crystals sepa-

(17) The low yield in the case of the phenylhydrazine is in agreement with low yields in the reaction of phenylhydrazine with other esters because of numerous side reactions. *Cf.* Baidowski and Slepak, *Chem. Zentr.*, **74**, I, 829 (1903).

rated. After standing at room temperature for one hour, the product was collected and washed with alcohol and ether; 7.0 g. (71%), m. p. 213–215° dec. When recrystallized from water, it formed short, ivory needles, m. p. 214–215° dec.

*Anal.* Calcd. for $C_3H_5N_3O$: C, 36.36; H, 5.09; N, 42.41. Found: C, 36.50; H, 5.12; N, 42.39.

**1-Acetyl-3-acetamido-5-acetoxypyrazole, XXXI** (R = $CH_3$).—A mixture of 2.3 g. of 3-amino-5-pyrazolone, XXVI, and 11 ml. of acetic anhydride was stirred on the steam-bath for twenty minutes. The resulting solution was cooled under the tap and filtered; 1.8 g. (36%), m. p. 192–196°. The product was recrystallized twice from *n*-propanol; it gave white, pearly flakes; m. p. 202–203°.

*Anal.* Calcd. for $C_9H_{11}N_3O_4$: C, 48.01; H, 4.92; N, 18.66. Found: C, 47.99; H, 5.02; N, 18.76.

Under the conditions for the hydrolysis of XXXII (R = $CH_3$) to XXXIII (R = $CH_3$), XXXI (R = $CH_3$) also gave XXXIII (R = $CH_3$) (60%) identified by melting point and mixed melting point. There was no evidence of rearrangement of XXXI into XXXII on heating in glacial acetic acid.

**1-Acetyl-3-acetoxy-5-pyrazolone Acetylimide, XXXII** (R = $CH_3$).—The filtrate from XXXI (above) was cooled in an ice–salt-bath, the mixture (m. p. 125–135°) which crystallized was filtered out, and the filtrate stirred with ice water and filtered; 0.45 g. (9%), m. p. 130–132°. Recrystallization from a 1:1 mixture of benzene and cyclohexane produced white needles, m. p. 131–132°.

*Anal.* Calcd. for $C_9H_{11}N_3O_4$: C, 48.01; H, 4.92; N, 18.66. Found: C, 48.25; H, 5.02; N, 18.64.

Under the conditions for the preparation of XXXV, XXXII gave XXXIII (81%).

**3-Acetamido-5-pyrazolone, XXXIII** (R = $CH_3$).—To a suspension of 1.8 g. of 1-acetyl-3-acetoxy-5-pyrazolone acetylimide, XXXII (R = $CH_3$), in 9 ml. of water was added dropwise 1.7 ml. of 40% sodium hydroxide diluted with 3 ml. of water, while stirring vigorously in an ice-bath. Ten minutes after addition was complete (five minutes), the solution was filtered from a slight insoluble portion, acidified with glacial acetic acid, and filtered; 0.85 g. (75%); m. p. 225–227°. Recrystallization from methanol produced short, white needles, m. p. 227–228° dec.

*Anal.* Calcd. for $C_5H_7N_3O_2$: C, 42.55; H, 5.00; N, 29.79. Found: C, 42.64; H, 5.15; N, 29.58.

**1-Acetyl-3-acetamido-5-pyrazolone, XXXV** (R = $CH_3$). —To a solution of 0.7 g. of 1-acetyl-3-acetamido-5-acetoxypyrazole, XXXI (R = $CH_3$), in 25 ml. of 1-1 isopropyl alcohol–dioxane was added 0.3 ml. of piperidine in 5 ml. of isopropyl alcohol dropwise (twenty-five minutes) while stirring at room temperature. The solution was allowed to evaporate to dryness, the residue was triturated with *n*-propanol, and filtered; 0.5 g. (86%), m. p. 193–195°. Recrystallization from dioxane produced fine, white granules, m. p. 195–196°.

*Anal.* Calcd. for $C_7H_9N_3O_3$: C, 45.90; H, 4.95, N, 22.93. Found: C, 46.02; H, 5.13; N, 22.57.

**1-Benzoyl-3-benzoyloxy-5-pyrazolone Benzoylimide, XXXII** (R = $C_6H_5$).—The directions in the literature[14] were followed, and the product was recrystallized from isopropyl alcohol. The yield was 25% of fine, white needles, m. p. 185–186°.

Hydrolysis of XXXII (R = $C_6H_5$) as of XXXI (R = $C_6H_5$) gave XXXIII (R = $C_6H_5$).

**1-Benzoyl-3-hydroxy-5-pyrazolone Benzoylimide, XXXIV** (R = $C_6H_5$).—To a solution of 0.6 g. of 1-benzoyl-3-benzoyloxy-5-pyrazolone benzoylimide XXXII (R = $C_6H_5$) in 6 ml. of dioxane, heated on the steam-bath, was added dropwise, with stirring, a solution of 0.15 ml. of piperidine in 1 ml. of dioxane. After heating for fifteen minutes, the solution was cooled to room temperature, diluted with 5 ml. water, cooled under the tap, and filtered; 0.3 g. (65%), sinters at 170°, m. p. 172–175°. Recrystallization from *n*-propanol gave fine, white, feathery crystals, m. p. 175–176°.

*Anal.* Calcd. for $C_{17}H_{13}N_3O_3$: C, 66.44; H, 4.23; N, 13.68. Found: C, 66.39; H, 4.44; N, 13.81.

**1-Benzoyl-3-benzamido-5-benzoyloxypyrazole, XXXI** (R = $C_6H_5$).—To a mixture of 2.5 g. of 3-amino-5-pyrazolone, XXVI (3 ml.), in 25 ml. of pyridine was added 10.5 g. of benzoyl chloride. The solution was heated one-half hour on the steam-bath. When cool, it was diluted with 5 ml. of water, cooled under the tap, filtered, rinsed with 50% ethanol, and recrystallized from 150 ml. of isopropyl alcohol; 5.9 g. (57%) of fine, white crystals, m. p. 161–163°.

*Anal.* Calcd. for $C_{24}H_{17}N_3O_4$: N, 10.21. Found: N, 9.92.

**3-Benzamido-5-pyrazolone, XXXIII** (R = $C_6H_5$).—A mixture of 3 g. of 1-benzoyl-3-benzamido-5-benzoyloxypyrazole, XXXI (R = $C_6H_5$), in 50 ml. of 2% sodium hydroxide and 20 ml. of 95% ethanol was stirred for one and one-half hours, filtered from a small amount of insoluble material, acidified with acetic acid, and concentrated *in vacuo* until the solution clouded. It was cooled and filtered. The product was digested with 8 ml. of methanol, cooled, and filtered; 1.2 g. (80%), m. p. 203–205°. Recrystallization from methanol gave a white powder, m. p. 205–206°.

*Anal.* Calcd. for $C_{19}H_9N_3O_2$: N, 20.68. Found: N, 20.84.

**1-Benzoyl-3-benzamido-5-pyrazolone, XXXV** (R = $C_6H_5$).—To a solution of 0.6 g. of 1-benzoyl-3-benzamido-5-benzoyloxypyrazole, XXXI (R = $C_6H_5$), in 12 ml. of boiling isopropyl alcohol was added dropwise 0.15 ml. of piperidine in 1 ml. of isopropyl alcohol. The solution was refluxed fifteen minutes, cooled, filtered, and the product was recrystallized from 95% ethanol; 0.2 g. (43%), white microcrystals, m. p. 171–172°.

*Anal.* Calcd. for $C_{17}H_{13}N_3O_3$: N, 13.68. Found: N, 13.26.

**1-Methyl-5-pyrazolone-3-carboxamide.**—1-Methyl-3-carbethoxy-5-pyrazolone, VI (10 g.), was dissolved in 100 ml. of 28% ammonium hydroxide. After three days, the solution was neutralized with acetic acid, the precipitate was collected, washed with water, and recrystallized from water. The yield was 5 g. of fine, white needles that sinter above 230°.

*Anal.* Calcd. for $C_5H_7N_3O_2$: C, 42.5; H, 5.0. Found: C, 42.7; H, 5.1.

This compound brominates readily so that no attempts were made to use it in a Hofmann degradation.

## Summary

1. Methylhydrazine, when reacting with either ethyl cyanoacetate or ethyl β-amino-β-ethoxyacrylate, yields two pyrazolones, namely, 1-methyl-3-hydroxy-5-pyrazolone imide and 1-methyl-3-amino-5-pyrazolone. The structure of the latter was proved unequivocally.

2. Acetylation of 3-amino-5-pyrazolone with boiling acetic anhydride produces 1-acetyl-3-acetamido-5-acetoxypyrazole and 1-acetyl-3-acetoxy-5-pyrazolone acetylimide rather than 1,4,4-triacetyl-3-imino-5-ketopyrazolidine and 2,4,4-triacetyl-3-imino-5-ketopyrazolidine suggested by Hepner and Fajersztejn.[12]

3. 1-Benzoyl-3-benzoyloxy-5-pyrazolone benzoylimide was obtained using benzoyl chloride in a Schotten–Baumann reaction on 3-amino-5-pyrazolone. 1-Benzoyl-3-benzamido-5-benzoyloxypyrazole was produced when the benzoylation was done in pyridine.

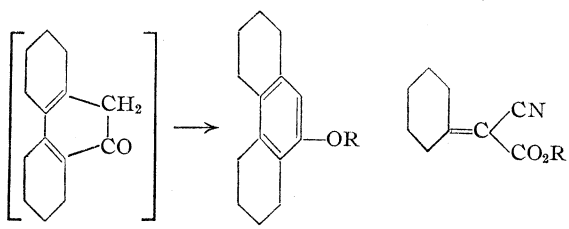
# A New Synthesis of 9-Hydroxy-*sym*-octahydrophenanthrene



BY PHANINDRANATH BAGCHI,[1] FELIX BERGMANN[1a] AND D. K. BANNERJEE[2]

A common method for the synthesis of polycyclic ring systems consists in the cyclization of a saturated side-chain bearing a carboxyl group. This method has been applied to γ-aryl[3]- and γ-cyclohexenyl-butyric acids.[4] However, an old observation of Fittig[5] shows that unsaturated side chains may also be useful. β-Styrylacetic acid is converted thermally to α-naphthol, and a similar observation has been reported by Linstead[6] for 2-phenylcyclohexylidenecyanoacetic acid. It was, therefore, of interest to determine whether this type of reaction would apply also to dienic acids.

As a suitable system we intended to prepare 1,1′-dicyclohexenyl-2-acetic acid (IIIb),[6a] which we expected to cyclize to 9-hydroxy-*sym*-octahydrophenanthrene (IVa) according to the scheme

(I) (II) (a, R = $C_2H_5$; b, R = H) (III) (a, R = $C_2H_5$; b, R = H)

(IV) (a, R = H; b, R = $CH_3$) (V) (a, R = $C_2H_5$; b, R = H)

Reformatsky's method, when applied to the system cyclohexenylcyclohexanone (I) and ethyl bromoacetate, gave an 83% yield of the hydroxy ester (IIa). The latter could be dehydrated either by phosphorus pentoxide in benzene or by thionyl chloride in a pyridine-ether mixture (yield 76 and 78%, respectively). The dienic acid (IIIb) was cyclized by phosphorus pentoxide in benzene, after a number of other methods proved to be inferior. It was essential to sustain vigorous stirring throughout the cyclization and to add the dehydrating agent in small portions over an extended period. The phenol (IVa)[7,6] was obtained in 44% yield. The method was considerably simplified by saponifying the hydroxy ester (IIa) and treating the crude hydroxy-acid (IIb) directly with phosphorus pentoxide. The over-all yield (IIa → IVa) was 35% as compared to 30% in the more elaborate process described before.

The phenol (IVa), its acetate and its 10-bromo derivative (VIIIa) all showed properties identical with the corresponding compounds described in the literature, and the methyl ether (IVb) was found to be identical with the corresponding derivative of Bachmann[8] by direct comparison.

A second compound suitable for cyclization, was obtained by condensation of (I) with ethyl cyanoacetate. Three products were isolated from the reaction mixture: (i) ethyl cyclohexylidenecyanoacetate (Va)(26%); (ii) ethyl 2-(Δ¹-cyclohexenyl) - cyclohexylidene - cyanoacetate (VI) (44%); (iii) 9-hydroxy-10-cyano-1,2,3,4,5,6,7,8-octahydrophenanthrene (VIIa) (~1%). The first product (V) was obtained in each run, even when the starting material (I) was purified scrupulously and a constant boiling middle fraction was used for the reaction. It is thus beyond doubt that (V) originates from a reversed aldol condensation, occurring either before or after condensation with ethyl cyanoacetate.

The ratio of the yields of products varied according to the conditions employed during distillation. The higher the distillation temperature, the higher the proportion of (VIIa) formed. This could also be confirmed by direct conversion of (VI) into (VIIa) under the influence of heat (yield 50%) or in boiling acetamide as solvent (yield 72%). This type of cyclization is similar to the one observed by McRae,[9] Cope[10] and Linstead.[6]

The structure of (VII) was established in two ways: The nitrile (VII) was "denitrilated" to (IVa) by a mixture of zinc, zinc chloride and sodium chloride at 300°.[10] 9-Methoxy-10-bromo-octahydrophenanthrene (VIIIb) was converted into (VIIa) by cuprous cyanide. It is remarkable that this reaction was accompanied by demethylation. An analogous observation was made during "denitrilation" of (VIIb) by zinc dust.

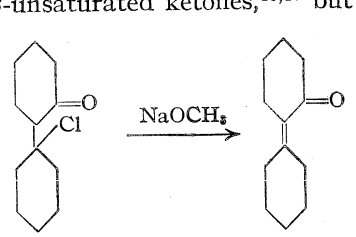
VIII (a, R = H; b, R = $CH_3$)

IX

X

(XI)



Acid hydrolysis of (VI) gave the lactone (IX), which was insoluble in sodium bicarbonate solution, but dissolved in warm sodium hydroxide solution, from which only the lactone could be recovered upon acidification. The lactonic structure was confirmed by decarboxylation to 1,1′-dicyclohexenyl-2-acetonitrile (X).

Ethyl cyclohexylidene-cyanoacetate, as shown by Kon and Nutland,[11] possesses the structure (Va) in view of its oxidative degradation to cyclohexanone and the exaltation shown by its molecular refraction. Decarboxylation of (Vb), however, gives a $\beta,\gamma$-unsaturated nitrile. In the case of compound (VI), it is possible that one or both of the double bonds are conjugated with the cyano-ester grouping. This problem was investigated by means of absorption spectra.

Although in $\alpha,\beta$-unsaturated acids and esters absorption bands are not as sharply defined as in $\alpha,\beta$-unsaturated ketones, it is possible, within a closely related group of compounds, to define the exact position of double bonds, *e. g.*, $\alpha$-cyanocrotonate shows a maximum at 2200 Å., the corresponding $\beta$-methyl derivative at 2300 Å. (log $\epsilon$ = 4.0). $\alpha$-Cyanosorbate and its $\delta$-methyl derivative have maxima at 2820 and 3020 Å., respectively.[12] Inspection of Fig. 1 demonstrates the close relationship between (Va), (Vb), (VI) and (IX) ($\lambda_{max.}$ at 2350 Å., log $\epsilon$ = 4.0–4.1). Furthermore, as all the three compounds are $\beta,\beta$-disubstituted carboxyl derivatives, their absorption maximum corresponds approximately to that of $\beta$-methyl-$\alpha$-cyanocrotonate. It is thus clear, that in (VI) only one double bond is conjugated with the ester group, the other being located inside the second ring.

The spectra of the acetic acids and acetonitriles are represented in Fig. 2. Cyclohexenylacetonitrile, acid (IIIb) and its ester again form a close group with absorption maxima < 2200 Å. In view of the fact that dicyclohexenyl itself has a maximum at 2360 Å. (log $\epsilon$ = 4.25)[13] and that acids of the abietic type, in which the butadienic structure is not conjugated with the carboxyl group, possess maxima at 2400–2500 Å.,[14] it is quite certain that the acid (IIIb) does not possess the expected 1,1′-dicyclohexenyl ring structure, but is to be represented rather as (XI). However, the nitrile(X), showing an appreciable absorption over the entire range of 2200–2700 Å. (log $\epsilon$ = 3.8–3.3), may contain partially conjugated structures.

In this connection, it is also of interest to discuss the structure of cyclohexenylcyclohexanone. Kon[11] assumed for this ketone the non-conjugated structure (I), in equilibrium with a small amount of cyclohexylidenecyclohexanone (XIII). Evans and Gillam[15] concluded from the fact that (I) shows an absorption of $\epsilon$ = 800 at $\lambda$ = 2540 Å. "This low intensity of absorption suggests the predominance of an unconjugated isomer." Recently Reese[16] prepared (XIII) in crystalline form by dehydrochlorination of (XII) by means of sodium methoxide in methanol. Therefore he ascribed to the "liquid isomer" the $\beta,\gamma$-unsaturated structure (I). The absorption spectrum of our preparation, obtained by dehydrochlorination of (XII) by means of methanolic potassium hydroxide, is given in Fig. 3. The liquid shows two absorption maxima, $\lambda_1$ < 2200 Å., $\lambda_2$ = 2450 Å. The value of $\lambda_2$ is near to that of $\alpha,\beta,\beta$-trisubstituted $\alpha,\beta$-unsaturated ketones,[15,17] but $\epsilon_2$ is only

## Experimental[18]

Cyclohexenylcyclohexanone (I) was prepared in 80% yield following essentially the procedure of Wallach,[19] methanolic caustic potash being used for dehydrochlorination of the intermediate chloroketone.

**Condensation of (I) with Ethyl Bromoacetate.**—Strips of zinc foil were activated by washing consecutively with

(18) All melting points are uncorrected.

(19) Wallach, *Ber.*, **40**, 70 (1907).

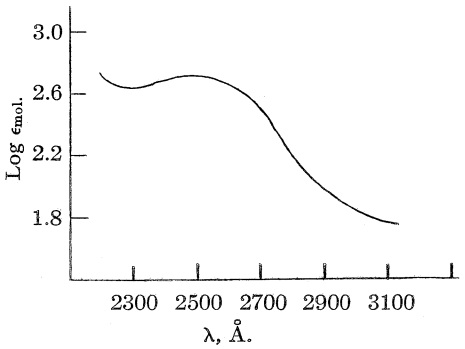

Fig. 3.—Ultraviolet absorption spectrum of cyclohexenylcyclohexanone (I).

5% sodium hydroxide, water, 2% hydrochloric acid, water, ethanol and finally with ether. When cyclohexenylcyclohexanone (22 g.), ethyl bromoacetate (30 g.) and zinc (11.5 g.) in benzene (90 cc.) were heated on a water-bath, a vigorous reaction set in. Thereafter the mixture was refluxed for one hour, the dark brown liquid decanted from the unreacted zinc and treated with cold dilute hydrochloric acid. The benzene solution was washed with water, dried over calcium chloride and fractionated. The yield of (IIa) was 83%; b. p. 144–146° (1.5 mm.); $n^{23.5}D$ 1.4960.

*Anal.* Calcd. for $C_{16}H_{26}O_2$: C, 72.2; H, 9.8. Found: C, 72.1; H, 9.6.

**Dehydration to Ethyl 1,1′-Dicyclohexenyl-2-acetate (IIIa): (a) Pyridine–Thionyl Chloride Method.**—To a stirred solution of the hydroxy ester (24.5 g.) in pyridine (18 cc.) and anhydrous ether (100 cc.), cooled to 0°, was added dropwise thionyl chloride (9 cc.). The mixture was left overnight and then decomposed with cold water containing a small amount of hydrochloric acid. The ether layer was washed with water and dried over calcium chloride. Distillation gave (IIIa) as a colorless oil of b. p. 114–115° (1.5 mm.) in 78% yield; $n^{23}D$ 1.5006.

*Anal.* Calcd. for $C_{16}H_{24}O_2$: C, 77.4; H, 9.7. Found: C, 77.3; H, 9.6.

(b) **Phosphorus Pentoxide Method.**—The hydroxy ester (24 g.) and phosphorus pentoxide (16 g.) in dry benzene (100 cc.) were refluxed for three and a half hours. The benzene layer was decanted, the sirupy pentoxide decomposed with water and extracted with benzene. The combined benzene layers were washed, dried and fractionated. The product (IIIa) obtained in 76% yield was identical with the one described before.

**Saponification to 1,1′-Dicyclohexenyl-2-acetic Acid (IIIb).**—The dienic ester (10 g.) and potassium hydroxide (4 g.) in methanol (20 cc.) were heated on a water-bath for three hours. After evaporation of the methanol, the residue was dissolved in water. After extracting any unsaponified matter with ether, the aqueous layer was acidified at 0°. A sticky, light brown precipitate was obtained, which crystallized on scratching. Two crystallizations from dilute methanol yielded the acid (IIIb) in the form of colorless prismatic blocks, m. p. 97°, yield 85%.

*Anal.* Calcd. for $C_{14}H_{20}O_2$: C, 76.4; H, 9.1. Found: C, 75.9; H, 9.1.

**9-Hydroxy-1,2,3,4,5,6,7,8-octahydrophenanthrene (IVa): (a) From Acid (IIIb).**—To a boiling solution of the dienic acid (10 g.) in dry benzene (150 cc.), thoroughly stirred, was added phosphorus pentoxide (15 g.) in several portions during one and one-half hours. Thereafter the mixture was refluxed for one-half hour and worked up as usual. Distillation at 150–160° (3 mm.) gave a viscous, semi-solid mass, which was dissolved in petroleum ether (90–100°). The solution deposited crystals of m. p. 130–132°, yield 44%. Two crystallizations from the same solvent gave (IVa) as prismatic columns of m. p. 134–135°.

*Anal.* Calcd. for $C_{14}H_{18}O$: C, 83.2; H, 8.9. Found: C, 83.2; H, 8.9.

From the mother liquor of the first crystallization some impure starting material was recovered.

The phenol (IVa) was obtained in only 8% yield, when (IIIb) was first converted into its acid chloride, treated with stannic chloride in dry carbon disulfide solution and the product dehydrochlorinated with dimethylaniline.[4]

(b) **From the Hydroxy Ester (IIa).**—The hydroxy ester (15 g.) and potassium hydroxide (5 g.) in water–methanol (1:2, 45 cc.) were heated on a water-bath for three hours. After removal of methanol and extraction of any unsaponified matter with ether, the solution was acidified with cold dilute hydrochloric acid. The precipitated oily acid was taken up in ether. After washing and drying, the ether was evaporated, the sirupy residue dried *in vacuo* and dissolved in dry benzene (100 cc.). To the boiling benzene solution phosphorus pentoxide (20 g.) was added portionwise during two hours, under vigorous stirring. After heating for one more hour, the mixture was worked up as before and yielded 35% of the phenol (IVa), m. p. and mixed m. p. 134–135°.

**9-Methoxyoctahydrophenanthrene (IVb).**—(a) The hydroxy compound (IVa) (2 g.) was warmed with 10% potassium hydroxide (20 cc.), when an insoluble potassium salt separated. It was dissolved by addition of methanol and warming. To the stirred solution dimethyl sulfate (2 cc.) was added. Upon heating an oil separated. Three more portions of potassium hydroxide (10 cc.) and dimethyl sulfate (1 cc.) were added. Upon cooling, the methyl ether (IVb) separated. Two crystallizations gave (IVb) in the form of prismatic columns, m. p. 92–93°; yield 70%.

This product did not depress the m. p. of the compound of Bachmann and Ness.[8]

(b) The phenol (IVa) (2 g.) was added to a solution of sodium (0.6 g.) in methanol (15 cc.) and methylated with methyl iodide (5 cc.) by refluxing for two hours; yield 65%.

**9-Methoxy-10-bromo-*sym*-octahydrophenanthrene (VIIIb).**—(a) 9-Hydroxy-*sym*-octahydrophenanthrene was brominated according to v. Braun and Bayer[7] and the 9-hydroxy-10-bromo derivative methylated by dimethyl sulfate as described above. (VIIIb) forms minute colorless prismatic plates from methanol, m. p. 99–100°; yield 70%.

*Anal.* Calcd. for $C_{15}H_{19}OBr$: C, 61.0; H, 6.5. Found: C, 61.2; H, 6.6.

(b) The same compound was obtained by bromination of the methyl ether (IVb) in glacial acetic acid; yield 66%.

**Condensation of (I) with Ethyl Cyanoacetate.**—A mixture of cyclohexenylcyclohexanone (17.8 g.), ethyl cyanoacetate (11.3 g.), ammonium acetate (1.5 g.), glacial acetic acid (10 cc.) and benzene (40 cc.) was refluxed for eight hours, and the water formed during the reaction was separated with the help of a separator. The light brown solution was washed with water, dried and fractionated at 1.5 mm.

Fraction 1. B. p. 112–114°; $n^{22}D$ 1.4970; yield, 5 g. of colorless oil (Va).

*Anal.* Calcd. for $C_{11}H_{15}O_2N$: C, 68.4; H, 7.8. Found: C, 68.1; H, 7.9.

Fraction 2: b. p. 146–148°; $n^{23}D$ 1.5180; yield 12 g. of a faintly yellow viscous liquid (VI).

*Anal.* Calcd. for $C_{17}H_{23}O_2N$: C, 74.7; H, 8.2. Found: C, 74.8; H, 8.5.

Fraction 3: residue; it was dissolved in benzene and left overnight, yielding 0.2 g. of crystals (VIIa). After repeated crystallizations from benzene or methanol, (VIIa) was obtained as colorless prismatic columns of m. p. 215–216°.

*Anal.* Calcd. for $C_{15}H_{17}NO$: C, 79.3; H, 7.5. Found: C, 79.2; H, 7.4.

Like (IVa), this compound gave no color reaction with ferric chloride.

When fractionation was carried out at 7 mm. pressure, the yield of (VIIa) was 0.6 g. It was also obtained in 50% yield upon heating the ester (VI) to 210–215° for three hours and in 72% yield when (VI) was heated with an equal weight of acetamide to 200° for two hours.

The phenol (VIIa) was methylated as described above for (IVa) to give a 52% yield of (VIIb). On recrystallization from methanol prismatic columns were obtained, m. p. 105–106°.

*Anal.* Calcd. for $C_{16}H_{19}ON$: C, 79.7; H, 7.9. Found: C, 79.4; H, 7.9.

**Denitrilation.**—The hydroxy cyano compound (VIIa) (1 g.), zinc chloride (5 g.), zinc dust (1 g.) and sodium chloride (1 g.) were thoroughly mixed by grinding and the mixture heated to 215–225° for fifteen minutes. The mass was treated with dilute hydrochloric acid, and the residue recrystallized from methanol. The product had m. p. 212–224°, representing unchanged starting material. From the mother liquor a second crop of crystals was obtained which after repeated recrystallization from petroleum ether showed a m. p. of 133–134° and was identical with (IVa).

When the methoxy derivative (VIIb) was subjected to the same treatment, denitrilation was accompanied by demethylation to (IVa).

When 9-methoxy-10-bromo-*sym*-octahydrophenanthrene (VIIIb) (1.7 g.) was mixed with powdered cuprous cyanide (0.75 g.) and heated in pyridine (1 cc.) for ten hours to 215–225°, and the product directly sublimed in a high vacuum, 0.5 g. of a yellowish solid was obtained, which after repeated recrystallization from methanol showed a m. p. of 213–215°, not depressed by admixture of (VIIa).

**Lactonization of (VI).**—Ethyl cyclohexenylcyclohexylidene cyanoacetate (VI) (6 g.) in ethanol (60 cc.) was refluxed with concentrated hydrochloric acid (20 cc.) for four hours. Upon cooling crystals separated, which were recrystallized from methanol; prismatic plates of m. p. 171–172° (IX); yield 2 g.

*Anal.* Calcd. for $C_{15}H_{19}O_2N$: C, 73.5; H, 7.8; N, 5.7. Found: C, 73.4; H, 7.7; N, 5.8.

The lactone is insoluble in warm sodium carbonate solution, but dissolves in warm caustic soda or potash. Acidification reprecipitates the lactone.

When the lactone was heated to 200°, decarboxylation took place. The yellowish oil obtained in 90% yield, distilled at 114–117° (1.5 mm.) (X).

*Anal.* Calcd. for $C_{14}H_{19}N$: N, 7.0. Found: N, 7.4.

**Absorption Measurements.**—All absorption spectra were measured in 95% alcohol, using a Beckman quartz spectrophotometer.

## Summary

1,1′-Dicyclohexenyl-2-acetic acid is cyclized by phosphorus pentoxide to 9-hydroxy-*sym*-octahydrophenanthrene. Ethyl cyclohexenylcyclohexylidenecyanoacetate is cyclized thermally to 9-hydroxy-10-cyano-*sym*-octahydrophenanthrene. Spectrographical analysis shows that in the dicylohexenyl derivatives investigated usually the two double bonds are not conjugated.

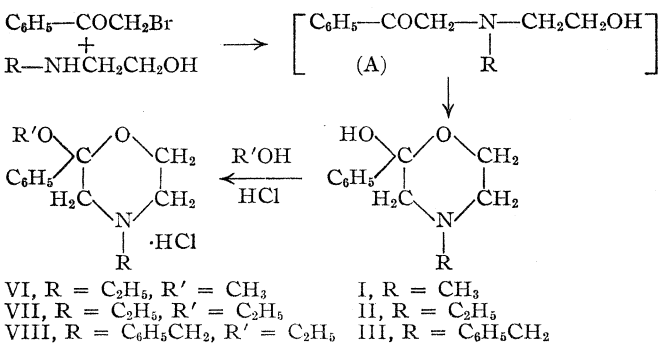
# Keto-Hemiacetal Tautomerism of Some N-Phenacyl-N-substituted Ethanolamines

BY NORMAN H. CROMWELL AND KWAN-CHUNG TSOU

In a previous communication[1] the syntheses of some N-benzohydryl-N-substituted ethanolamines and derivatives were reported. The present investigation was begun with the idea of extending the preparation of such compounds to the phenacyl series. The presence of the keto group in the latter series was expected to provide for further wide variation in the structures of the various derivative types.



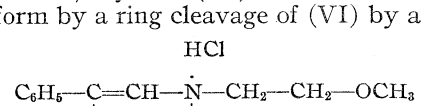
The reactions of the N-methyl, N-ethyl and N-benzyl ethanolamines with phenacyl bromide were investigated and the solid free bases, (I), (II) and (III) were isolated in fair yields. The behavior of the hydrochlorides of these bases upon attempted recrystallization from ethanol or methanol showed reaction with these solvents in such a manner as to indicate acetal formation. An inspection of the structure of an N-phenacyl-N-substituted ethanolamine (A) suggests the possibility of the formation of a six-membered ring, hemiacetal, which would, of course, be expected to form an acetal with reactive alcohols in the presence of hydrogen chloride. This phenomenon was not found for the previously investigated N-benzohydryl-N-substituted ethanolamine hydrochlorides.[1]

This problem then resolved itself into a study of the structures of the free bases (I), (II) and (III), their hydrochlorides, and their reaction products with ethanol and methanol. Helferich has made an extensive study of the analogous $\gamma$-hydroxy- and $\delta$-hydroxy aldehydes and ketones and has reported that they undergo such cyclization to give hemiacetals which react with methyl alcohol to form acetals.[2]

Recently, Hill and Powell[3] have reported a cyclization and dehydration of N-(3,4-dihydroxyphenacyl)-N-benzoylethanolamine hydrochloride to 2-(3′,4′-dihydroxyphenyl)-4-benzoyl-5,6-dihydro-1,4-oxazine. The former compound may actually exist in the hemiacetal form.[4]

The free bases (I), (II) and (III) did not readily form either phenylhydrazones or oximes. This was the first indication that they might not contain a keto group. All three of them gave an immediate Tollens test, which is not observed with either $\omega$-morpholinoacetophenone nor N-benzohydryl-N-benzylethanolamine.[1]

The hydrochlorides (IV) and (V) of (II) and (III), respectively, were obtained only when recrystallizations of the products were carried out very rapidly from cold methyl alcohol and dry ether, or from *t*-butyl alcohol and ether. When these hydrochlorides were dissolved in the hot alcohols the alkoxy derivatives, such as (VI), (VII) and (VIII) resulted. These latter compounds reduced Tollens solution only after warming.



VI, R = $C_2H_5$, R′ = $CH_3$
VII, R = $C_2H_5$, R′ = $C_2H_5$
VIII, R = $C_6H_5CH_2$, R′ = $C_2H_5$

I, R = $CH_3$
II, R = $C_2H_5$
III, R = $C_6H_5CH_2$

Considerable difficulty was often experienced in repeating the preparation of (VI), (VII) and (VIII), in our numerous runs of these reactions. Further reaction with the alcohol often occurred, and compounds which analysis indicated might be of the nature of (IX), discussed below, resulted. Analyses of (VI), (VII) and (VIII), as well as for (IV) and (V) were difficult to obtain because the compounds often decomposed if the usual drying techniques were used. Such difficulties prevented us from obtaining analytically pure samples of the 2-phenyl-2-alkoxy-4-methylmorpholine hydrochlorides. Although acceptable chlorine and nitrogen analysis were not difficult to obtain in these various series, it was obvious that carbon and hydrogen analyses would be required here to establish definitely the identity of these compounds.

When a sample of the alkoxy compound (VI) was allowed to stand for some time in methanol before recovering a product, a further change took place to give a dialkoxy compound which possibly is $\alpha$-methoxy-$\beta$-(N-ethyl-N-($\beta'$-methoxyethyl)-amino)-styrene (IX). Such a compound could form by a ring cleavage of (VI) by a second

(3) Hill and Powell, THIS JOURNAL, **67**, 1462 (1945).

(4) An interesting paper by Lutz, Freek and Murphey, *ibid.*, **70**, 2015 (1948), has recently appeared which reports that ring-chain tautomerism does result with various $\alpha$-(N-substituted-N-ethanolamino)-desoxybenzoins. The evidence cited was the non-reducibility of the carbonyl group in such compounds. These authors further indicated that they were studying such tautomerism in the related acetophenone series.

molecule of methanol, followed by the loss of water. This product (IX) did not react with Tollens solution until the reaction mixture was heated to boiling. After standing for several weeks (IX) underwent decomposition.

The absorption spectra studies (Table II and Fig. 1) of the free bases (I), (II) and (III), when compared with that of ω-dibenzylaminoacetophenone, offer convincing evidence that they exist almost wholly in the cyclic hemiacetal forms, as given by the 2-hydroxymorpholine structures. Acetophenone itself shows an absorption maximum of 2415–2430 Å. with a molar extinction coefficient of 12,600–16,200.[5] Thus it seems certain that if these compounds actually contained a benzoyl group ($C_6H_5$–CO–) they would show a strong absorption band near 2400 Å. with a molar extinction coefficient of at least 12,000.

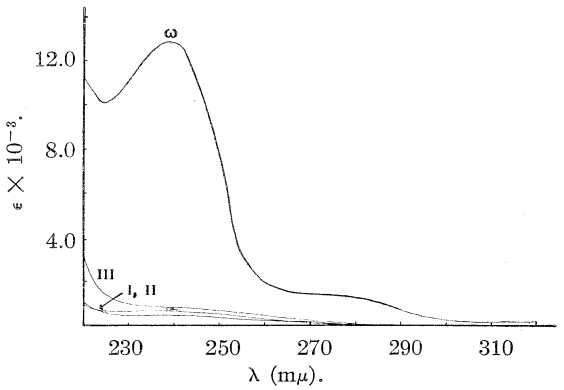

Fig. 1.—Absorption spectra of ω-dibenzyl-aminoacetophenone; of (I); of (II); and of (III) in heptane solution.

The fact that dilution had little effect on the absorption spectra (Table II, Fig. 2), indicated little tendency for (I) or (III) to exist in equilibrium with the open chain keto compounds (A) in heptane solution.

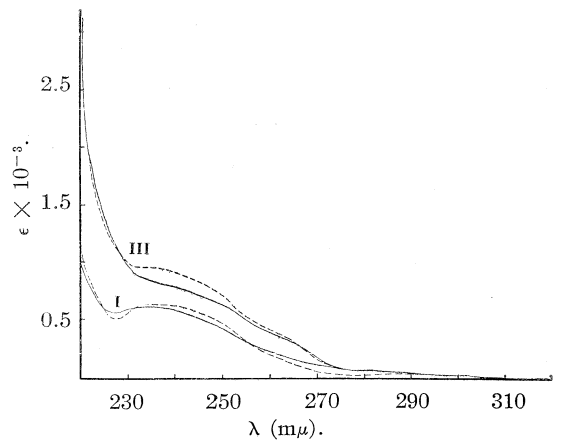

Fig. 2.—Absorption spectra dilution studies of (I) and (III): .... more dilute; — more concentrated; in heptane solution.

(5) Bielecki and Henri, *Ber.*, **47**, 1709 (1914); Morton and Sawires, *J. Chem. Soc.*, 1054 (1940).

The comparisons of the spectra of ω-morpholino- and ω-dibenzylaminoacetophenone hydrochlorides with those of the 2-hydroxymorpholine hydrochloride (V) and the 2-alkoxymorpholine hydrochlorides (VII) and (VIII), are equally convincing that these latter compounds do not contain a keto group (see Table III and Fig. 3).

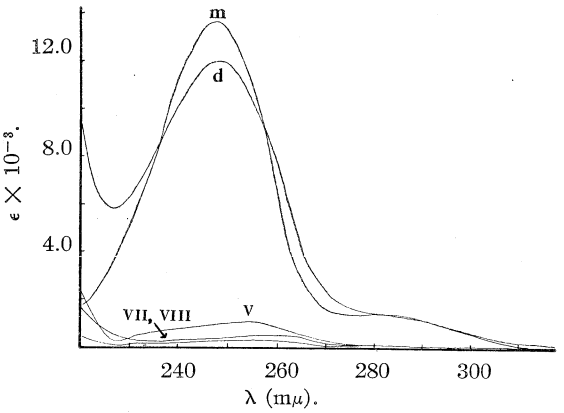

Fig. 3.—Absorption spectra in abs. ethanol: (m), ω-morpholinoacetophenone hydrochloride; (d), ω-dibenzylaminoacetophenone hydrochloride; (V); (VII); and (VIII).

The curves in Fig. 4 for the morpholine hydrochlorides (IV) and (VI) have been plotted on such a scale as to show more clearly the actual presence of weak bands for these compounds in the area expected for the keto structures. The magnitude of the molar extinction coefficients for these maxima are so low, however, that if the keto form actually exists in such solutions, it is present in very low concentrations (less than 10%). The absorption curve for the dialkoxy compound (IX) is given here, without comment, since no strictly analogous compounds were available for comparison. Styrene is known to have a maximum absorption band at 2450 A. with a molar extinction coefficient of 10,720.[6]

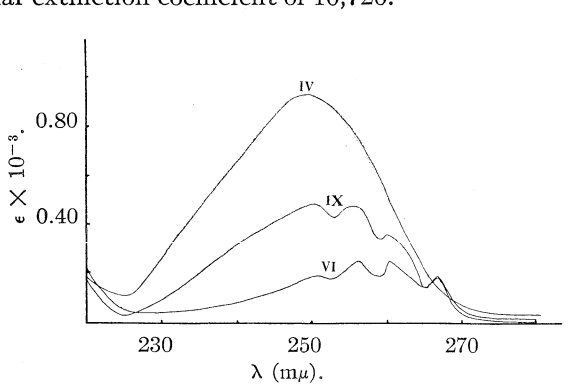

Fig. 4.—Absorption spectra in absolute methanol of (IV); (VI); and (IX).

[a] Micro analyses for carbon, hydrogen and nitrogen were carried out by the Clark Microanalytical Laboratory, Urbana, Illinois.

Herold has studied the ultraviolet absorption spectra of γ-hydroxybutyraldehyde in various solvents and has concluded that only about 10% of the free aldehyde is present.[7]

It seems evident that all of these compounds, (I) through (VIII), are essentially substituted morpholines.

## Experimental

**2-Hydroxy-2-phenyl-4-substituted Morpholines.**—Pure phenacyl bromide (0.20 mole) was dissolved in 400 ml. of dry ether and added dropwise with stirring to 0.40 mole of the corresponding N-substituted ethanolamine dissolved in 300 ml. of dry ether. The mixture was kept at near room temperature during the addition and then allowed to stand at this temperature for twenty-four hours. The supernatant liquid was decanted or filtered from the precipitated N-substituted ethanolamine hydrobromide and washed several times with saturated salt water, dried over anhydrous calcium sulfate and evaporated. The crude solid products were recrystallized from ether–petroleum ether mixtures to give almost colorless crystalline products.

In this way (I), (II) and (III) were obtained using, respectively, N-methylethanolamine,[8] N-ethylethanolamine,[9] and N-benzylethanolamine.[1]

These morpholines (I), (II) and (III) gave only slight tests with phenylhydrazine and no solid derivatives could be isolated. All three gave an immediate silver mirror formation with Tollens solution at room temperature. They did not give isolable products from reaction mixtures of hydroxylamine. An attempted hydrogenation of (III) in absolute alcohol at room temperature using platinum oxide catalyst and 50 lb. per square inch used up no hydrogen in three hours.[4] It was not possible to obtain a benzoate of (II) employing the usual methods with benzoyl chloride.

The compounds (I), (II) and (III) were each dissolved in dry ether and treated with one equivalent of dry hydrogen chloride gas in dry ether to give almost quantitative yields of the very hygroscopic hydrochlorides.

The hydrochloride of (I) could not be handled. The crude hydrochloride of (II) melted at 112–115° but rapid recrystallization, by dissolving in cold methyl alcohol followed by the immediate addition of dry ether, or solution in warm 85% *t*-butyl alcohol, followed by the addition of ether, gave the higher melting, pure hydrochloride (IV). The crude hydrochloride of (III) melted at 131–134° but recrystallization from 90% *t*-butyl alcohol and ether gave a higher-melting, pure product (V). These hydrochlorides, like the pure bases, gave an immediate, positive Tollens test at room temperature.

**2-Alkoxy-2-phenyl-4-substituted Morpholine Hydrochlorides.**—Dry ether solutions of the morpholines (II) and (III) were treated with dry hydrogen chloride by cooling the solutions in an ice-bath and bubbling in the dry gas. The flocculent precipitates were filtered off, washed with dry ether and dissolved in the corresponding hot absolute alcohols, methyl and ethyl. Dry ether was added and the solutions cooled to precipitate the alkoxy compounds which were again recrystallized from the corresponding alcohols and ether mixtures to give the pure alkoxy compounds (VI), (VII) and (VIII); see Table I. Samples of these compounds for analyses were dried under vacuum at room temperature for eight hours. An excess of ether was avoided in precipitating these products since it often carried down the dialkoxy compounds of type (IX) discussed below.

These compounds gave a positive test with Tollens reagent only after the solution was warmed.

**Reaction of (VI) with Methyl Alcohol.**—A 10-g. sample of (VI) was dissolved in 60 ml. of dry methyl alcohol at 50° and the solution allowed to stand at room temperature for twelve hours and in the ice-chest for three days. Dry ether was added to precipitate the product which was recrystallized again from methyl alcohol and dry ether; m.p. 142°, wt., 5.4 g. A fresh sample of (IX) did not react with warm Tollens solution, but upon boiling the mixture, reaction took place.

*Anal.* Calcd. for $C_{14}H_{22}NO_2Cl$: C, 61.88; H, 8.16; N, 5.15; Cl, 13.05. Found: C, 61.27; H, 7.86; N, 5.07; Cl, 13.07.

**Absorption Spectra Studies.**—These measurements were made with a Beckman Model DU Photoelectric Quartz Spectrophotometer. At the sensitivity used, the maximum band width was one millimicron with an accuracy of 0.1% for the density measurements. The solvents used were laboratory grade absolute ethanol, methanol, and heptane-from-petroleum, purified by the procedure recommended by Weissberger.[10]

The ultraviolet absorption spectra of (I), (II), (III) and ω-dibenzylaminoacetophenone[11] were observed using heptane as the solvent. These studies were made within two hours of the time

## Summary

1. The reactions of phenacyl bromide with N-substituted ethanolamines have been studied and the desired N-phenacyl-N-substituted ethanolamines have been found to have tautomerized to their respective hemiacetal forms, the 2-phenyl-2-hydroxymorpholines.

2. Some acetal derivatives, or 2-phenyl-2-alkoxymorpholines, have been obtained from these hemiacetals.

3. Absorption spectra studies have aided in the elucidation of these structures.

4. These results confirm for the N-phenacyl-N-substituted ethanolamines the conclusions reached by Lutz, *et al.*, with the related α-(N-substituted-N-ethanolamino)-desoxybenzoins.[4]

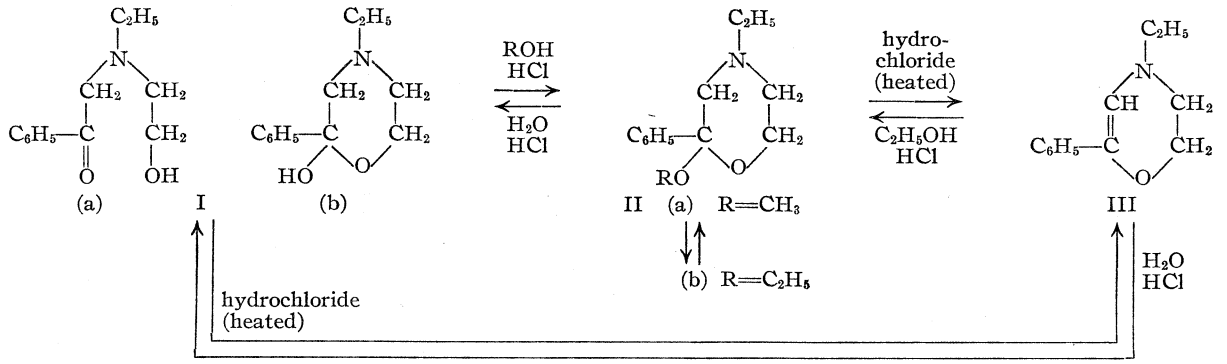
# Ring-Chain Tautomerism of α-(Ethylethanolamino)-acetophenone[1]

BY ROBERT E. LUTZ AND ROBERT H. JORDAN[2]

Because of the ring-chain tautomerism involved in the α-(ethylethanolamino)-desoxybenzoins,[3] and because of the interest in these compounds as possible tumor-necrotizing agents,[3,4] it seemed important to explore other series, especially simpler ones such as that based on acetophenone.[5] The present paper deals with preliminary work in this field.

α-(Ethylethanolamino)-acetophenone (I) (m. p. 52–53°) was made by condensing ethylethanolamine with phenacyl bromide.[6] It was readily con-

(1) This is the second paper dealing with ring-chain tautomerism of hydroxyalkylamino ketones. This work, except for the ultraviolet absorptions, was included in a doctorate dissertation by R. H. Jordan, University of Virginia, May, 1948. Some financial support for measurements and analyses, from a grant-in-aid by the National Cancer Institute, is acknowledged.

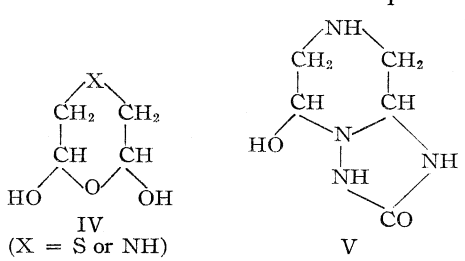


(2) Holder of Tennessee Eastman Company Fellowship, 1947–1948.

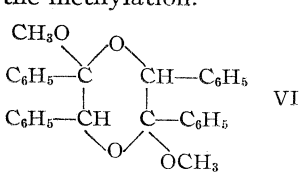
(3) (a) Lutz, Freek and Murphey, THIS JOURNAL, **70**, 2015 (1948) [an error appears in Table I, page 2016, where $NR_2$ for compound 612 should read $NHC_6H_4N(C_2H_5)_2$-*p*. Another typographical error appears in the last sentence of the first column of page 2020, where "δ-hydroxyl" should read α-hydroxyl]. (b) Lutz and Murphey, *ibid.*, **71**, 478 (1949); (c) Lutz, Freek and Murphey, a paper presented at the Chicago meeting of the American Chemical Society, April 20, 1948.

(4) Unpublished work of Shear, Downing, MacCardle, Hartwell, *et al.*, at the National Cancer Institute.

(5) Prior work had already been under way on the 2,4-dichloro, 3,4,5- and 2,3,5-trichloro analogs (Lutz, Jordan and Ford; results to be published shortly; *cf.* also ref. 3c).



(6) (a) The hydrochloride of this compound (I) has recently been prepared by this method and converted into the *p*-ethoxybenzoyl derivative [Christiansen and Harris, U. S. Patent, 2,404,691 (July 1946); *C. A.*, **41**, 157*f* (1947)]; (b) *cf.* Brighton and Reid, THIS JOURNAL, **65**, 479 (1943).



verted into the methyl and ethyl derivatives (IIa and b) by acid catalyzed alcoholysis. The conversion of the methoxy compound (IIa) into the ethoxy (IIb) was accomplished by means of ethanolic hydrogen chloride; and hydrolysis of both alkoxy compounds with dilute aqueous hydrochloric acid regenerated the original compound (I). Isopropyl alcohol did not react under these conditions.

It is noteworthy that the methoxy compound (IIa), which has not been obtained in crystalline form, was distillable under reduced pressure without loss of methanol. However, heating of either the methoxy or ethoxy compounds (II) or the parent compound itself (I), in the form of the hydrochloride or with a small amount of added hydrochloric acid, brought about elimination of the alcohol or water and gave the dehydromorpholine (the dihydro-1,4-oxazine, III). This compound was converted back into the original compound (I) by the action of hot dilute aqueous hydrochloric acid, and into the cyclic acetal (IIb) by ethanolic hydrogen chloride.[7] The reactivity of the dehydro compound in this series (III) is to be contrasted with the stability of the one obtained from α-(N-ethylethanolamino)-desoxybenzoin. The latter compound, with its stilbene double bond, seems to be stable under these conditions, is not readily hydrated to the cyclic hemiacetal nor does it react with alcohols to give the cyclic acetals.[7c]

The best known compounds showing this type of ring-chain tautomerism, of course, are the sugars and γ- and δ-hydroxyaldehydes and ketones; but special reference should be made to less well known analogs where the chain between the carbonyl group and the reacting hydroxyl is broken by an intervening hetero-element, nitrogen, oxygen or sulfur. The compounds of the type $R_2C(OH)CH_2–X–CH_2CHO$[8] and $HOCH_2CH_2–X–CH_2CHO$[9,8b] (where X = oxygen or sulfur), which doubtless involve ring-chain tautomerism, have not yet been studied adequately from this viewpoint. Related to these compounds is the dialdehydo thioethyl ether, $S(CH_2CHO)_2$, which apparently exists as the cyclic monohydrate, 2,6-dihydroxythioxane,[10] and forms the cyclic acetal, 2,6-diethoxythioxane (*cf.* IV).[11] The nitrogen analog, $NH(CH_2CHO)_2$, which appears to exist also as the cyclic monohydrate, 2,6-dihydroxymorpholine (IV),[12] is of particular interest because of the condensation with semicarbazide; the compound obtained, in view of its behavior,[13] is probably V, a possibility considered but not favored by the original authors.[12] The dimolecular product obtained from benzoin by the action of methanolic hydrogen chloride also is of interest here because it seems to be the cyclic diacetal (VI),[14] formed presumably through a benzoin hemiacetal or benzoin-methyl acetal of benzoin, cyclization and completion of the methylation.

In order to decide whether the ethylethanolamino ketones are cyclic or open-chain in simple solution [apart, for example, from possible stabilization as a complex with aluminum isopropoxide],

(c) In this connection a correction must be made to ref. 3(a and c); the supposed hydration of 3,4-dihydro-1,2-diphenyl-4-ethyl-1,4-oxazine, reported in the earlier paper, appears to be an experimental error; numerous attempts since then to repeat this experiment under a variety of conditions have failed and will be described in a later paper (Lutz and Truett).

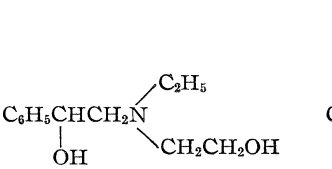
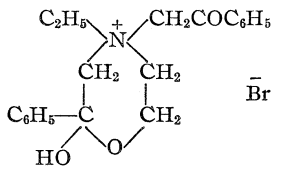
ultraviolet absorptions were carried out on the α-(ethylethanolamino) derivatives of acetophenone (I),[15a] desoxybenzoin[15b] and 5-chloro-2-methoxyacetophenone.[16] These compounds absorbed only very slightly in the region 240–250 mμ where ketones such as acetophenone,[17a] desoxybenzoin,[15,17b] and α-diethylaminodesoxybenzoin,[17c] show characteristic maxima. The ethyl derivative of I (the acetal IIb) and the amino-dialcohol corresponding to α-(ethylethanolamino)-desoxybenzoin (namely, VII),[15] neither of which possess a carbonyl group, show no significant absorption maxima in this range. From these facts it is to be concluded that the ethylethanolamino ketones under discussion are largely cyclic, and that the open-chain forms, if present in appreciable amounts in solution (in isoöctane), are there in concentrations probably below 3–5%.



VII

It is of interest to contrast these results with those observed in the systems, —CHCH$_2$CH$_2$CH$_2$C—; the δ-hydroxyketone appears, on the basis of molar refraction, to be largely open-chain,[18a] and the δ-hydroxyaldehyde appears, on the basis of both molar refraction and ultraviolet absorption, to be largely cyclic.[7b,18b] As mentioned before[3a] the enhanced activity of the keto group in the present case (Ia) must be attributed to the heteroelement in the chain, amino nitrogen, which is at the same time alpha to the carbonyl group and comparable to the alpha hydroxyls in the ketone sugars.



That the ethylethanolamino ketones studied so far,[3] including I, exist largely in the cyclic hemiacetal forms, is indicated[3] also by the fact that they are not reduced readily by the carbonyl-specific reagent, aluminum isopropoxide, under the usually effective conditions. If the open-chain form were present in small amounts, as is perhaps indicated by the ultraviolet absorption experiments, it is possible that the cyclization is actually promoted to some extent by combination with the reagent, because of the greater acidity of the hemiacetal hydroxyl (*cf.* Ib) as compared with the alcoholic hydroxyl of the open-chain form (Ia).

It is pertinent to note in this connection that in a preliminary experiment catalytic reduction of α-(ethylethanolamino)-desoxybenzoin[19] proceeds with far greater difficulty than it does with α-(piperidyl)-desoxybenzoin[3] which is necessarily open-chain.

The amino-dialcohol (VIII) which was desired for tests and for comparison with the corresponding ketone (I), was subsequently made by standard procedure through condensation of styrene bromohydrin with ethylethanolamine. It was not obtained in a crystalline form and was characterized as the picrate.

VIII

IX

As a minor by-product of the condensation of ethylethanolamine with phenacyl bromide, there was obtained the quaternary compound (IX), which is obtainable in good yield by the use of an excess of phenacyl bromide. It doubtless exists as the cyclic hemiacetal as formulated; it is easily converted by means of alcoholic hydrogen bromide into a monoethoxy derivative (the cyclic acetal). The compound (IX) is of interest in connection with the study of tumor-necrotizing agents in view of the known activity of certain phenacylpyridinium salts.[4]

The compounds I, IIb, III, VIII and IX, are being screened for pharmacological activity, and especially for tumor-necrotizing action.[4]

Further studies are in progress in the field of hydroxyalkylamino ketones and their reactions and derivatives, especially with respect to various aspects of the problem of ring-chain tautomerism. These include absorption spectral, reduction and polarographic studies.

**Acknowledgment.**—The ultraviolet absorption studies reported in this paper were carried out by Spencer M. King. Microanalyses were carried out by Mrs. Joyce Blume Caliga.

## Experimental[20a,b]

**α-(Ethylethanolamino)-acetophenone (I) [4-Ethyl-2-hydroxy-2-phenylmorpholine].**[6]—A solution of 60 g. (0.3 mole) of phenacyl bromide in 200 ml. of commercial absolute ether was slowly added under stirring to 60 g. (0.82 mole) of ethylethanolamine in 100 ml. of ether. After standing for two hours, filtering, washing, drying over sodium sulfate and evaporating, the residual oil was dissolved in 80 ml. of isoöctane, filtered from a small amount of the quaternary compound (IX) (see below), and was induced to crystallize by cooling in an ice–salt-bath; 43 g. (64%); m. p. 50–51°; m. p. after recrystallization from isoöctane, 52–53°. The compound was very sensitive, especially in contact with metals; on standing overnight the melting point dropped to 48–51°.

*Anal.* Calcd. for $C_{12}H_{17}NO_2$: C, 69.43; H, 8.26. Found: C, 69.41; H, 8.19. Ultraviolet abs. max. in isoöctane: λ 238–242 mμ ($\epsilon \times 10^3 = 0.28$; $c = 0.001$)[14].

(15) These determinations of ultraviolet absorption were carried out in this Laboratory by Spencer M. King. (a) λ (in isoöctane) 238–242 mμ ($\epsilon \times 10^{-3} = 0.28$; $c = 10^{-3}$). (b) λ (in isoöctane) 250–258 mμ ($\epsilon \times 10^{-3} = 0.44$; $c = 10^{-3}$).

(16) The work on this series was done in this Laboratory by Gilbert Ashburn (to be published shortly).

(17) (a) λ 246–249 mμ [Scheibe, *Ber.*, **59**, 2621 (1926)]; (b) λ (in isoöctane) 239–241 mμ ($\epsilon \times 10^{-4} = 1.2$; $c = 10^{-4}$). (c) λ (in isoöctane) 241–243 mμ ($\epsilon \times 10^{-4} = 1.2$; $c = 10^{-3}$).

(18) (a) Bergmann and Miekeley, *Ber.*, **55**, 1394 (1922); (b) Schniepp and Geller, THIS JOURNAL, **68**, 1646 (1946).

(19) Lutz and Truett, reduction studies in progress.

(20) (a) Melting points are corrected. (b) The ultraviolet absorptions reported were taken with a Beckman DU quartz spectrophotometer. The solvent used was isoöctane (2,2,4-trimethylpentane) (Phillips Petroleum Co.).

**The hydrochloride**[6] was precipitated from ether; m. p. 125–125.5°.

*Anal.* Calcd. for $C_{12}H_{17}NO_2 \cdot HCl$: C, 59.12; H, 7.44. Found: C, 59.18; H, 7.42.

Recrystallization from ethanol caused partial conversion to the ethoxy compound (IIb) (demonstrated by pyrolysis of the product and identification of the ethanol generated, by micro-boiling point).

Isopropyl alcohol was found not to react with I under the various conditions which were effective with ethanol and methanol.

**Treatment with aluminum isopropoxide** under the usual conditions,[3a] using a large excess of reagent, in isopropyl, alcohol refluxing for six hours, gave no test for evolved acetone; the recovery (crude, 80%) of pure material of melting point 51.5–52.5° was 40%.

**2-Ethoxy-4-ethyl-2-phenylmorpholine (IIb).**—Either of two procedures was effective. (A) A solution of I in 25:10 absolute ethanol–saturated ethereal hydrogen chloride was allowed to stand at room temperature for twelve days. The base was liberated and converted to the hydrochloride (yield 64%). (B) A solution of 24 g. of I-hydrochloride in 100 ml. of absolute ethanol with an added 5 ml. of saturated ethanolic hydrogen chloride, was refluxed for one and one-half hours. The volume was reduced to 50 ml. by distillation under reduced pressure and the hydrochloride was precipitated by ether; yield 22 g. (82.5%).

**The base** (liberated by alkali) crystallized on seeding. After recrystallization from petroleum ether it melted at 49–50°.

*Anal.* Calcd. for $C_{14}H_{21}NO_2$: C, 71.52; H, 9.00. Found: C, 71.25; H, 8.74.

The **hydrochloride** had to be handled under non-aqueous conditions to avoid the facile hydrolysis to I. It crystallized as rhombic plates from ethanol–ether mixtures; m. p. 144.5°.

*Anal.* Calcd. for $C_{14}H_{21}NO_2 \cdot HCl$: C, 61.86; H, 8.16. Found: C, 61.82; H, 8.01.

**Hydrolysis** to I was effected by 6 *N* hydrochloric acid (warmed, thirty min.); identified by mixture m. p.; yield 65%.

**4-Ethyl-2-methoxy-2-phenylmorpholine** (IIa) was prepared by (A) and (B) under IIb, using methanol. **The hydrochloride** was crystallized from isopropyl alcohol–ether mixture; it was hygroscopic; m. p. (dried *in vacuo*) 148–149°.

*Anal.* Calcd. for $C_{13}H_{19}NO_2 \cdot HCl$: N, 5.44. Found: N, 5.33.

**The base** did not crystallize, and was fractionated. The yield of the principal cuts was 42%; b. p. 112° (1.8 mm.); $n^{25}D$ 1.5151; $d^{25}_4$ 1.051; $(R)D$ 62.91.

*Anal.* Calcd. for $C_{13}H_{19}NO_2$: C, 70.55; H, 8.65. Found: C, 70.47; H, 8.61.

**Hydrolysis** (warm 6 *N* hydrochloric acid) gave I (yield 75%). **Ethanolysis** by method (B) under IIb, gave IIb (yield 64%).

**4-Ethyl-2-phenyl-5,6-dihydro-1,4-paroxazin (III).**—Micropyrolyses of less than 40-mg. samples of I and IIb hydrochlorides gave water and ethanol, respectively (identified by micro-boiling points[21]).

A mixture of 5 g. of I and 5 drops of concd. hydrochloric acid was heated at 175–180° until evolution of water ceased (*ca.* five minutes). The base could be distilled under reduced pressure, but a cloudy distillate was always obtained. There was evidence of change in the oil, even upon standing overnight. The hydrochloride was precipitated from an isoöctane solution of the base by ethereal hydrogen chloride; 3 g. (65%). After washing with a small quantity of acetone to remove some resinous material, it was recrystallized from acetone–ether mixture; m. p. 163.5–165.5° (dec.).

*Anal.* Calcd. for $C_{12}H_{15}NO \cdot HCl$; C, 63.85; H, 7.14. Found: C, 63.61; H, 7.24.

Pyrolysis of IIb under the above conditions gave III in similar yields.

**Hydrolysis** (hydration) by 6 *N* hydrochloric acid (warmed) gave I (60%). **Ethanolysis** (alcoholation) by (B) under IIb gave IIb (98%).

**4-Ethyl-2-hydroxy-4-phenacyl-2-phenylmorpholinium Bromide (IX).**—A mixture of 5 g. of I and 5 g. of phenacyl bromide was heated at 40–60° until the melt solidified (forty-five minutes); trituration and washing with ether gave 9.2 g. (94%); m. p. 183.5–184.5°. It crystallized from ethanol as short prisms; m. p. 189.5–190° (initial bath temperature 170°, heating rate 3° per minute).

*Anal.* Calcd. for $C_{20}H_{24}BrNO_3$: C, 59.11; N, 5.95. Found: C, 58.81; H, 5.84.

**2-Ethoxy-4-ethyl-4-phenacyl-2-phenylmorpholinium Bromide** was made from IX by the action of refluxing ethanolic hydrogen bromide (forty-five minutes) and precipitation by ether; yield 36% (on a 3-g. run). After recrystallization from absolute ethanol it melted at 181.5–182° (taken as above). A mixture melting point with IX showed a 5° depression below this point.

*Anal.* Calcd. for $C_{22}H_{28}BrNO_3$: C, 60.82; H, 6.49. Found: C, 61.05; H, 6.19.

**2-Ethylethanolamino-1-phenylethanol (VII).**—A solution of 24 g. (0.118 mole) of 2-bromo-1-phenylethanol (obtained in 65% yield by aluminum isopropoxide reduction of phenacyl bromide)[22] in 32 g. (0.35 mole) of ethylethanolamine, was heated at 100° for fifteen hours. The product was taken up in ether, washed, dried over sodium sulfate and obtained as an oil upon evaporation of the solvent.

**The hydrochloride** did not crystallize. The base was fractionated; the principal cuts of nearly constant refractive index totaled 15 g. (61%); b. p. 152–155° (1.8 mm.). Vacuum evaporation of the middle cut onto a cold-finger drip-condenser gave a pure fraction; $n^{25}D$ 1.5279.

*Anal.* Calcd. for $C_{12}H_{19}NO_2$: C, 68.86; H, 9.15. Found: C, 68.69; H, 9.18.

**The picrate,** obtained from ethanol, was crystallized from ethanol–isoöctane mixture; m. p. 100.5–102°.

*Anal.* Calcd. for $C_{18}H_{22}N_4O_4$: C, 49.31; H, 5.06; N, 12.77. Found: C, 48.96; H, 5.38; N, 12.60.

## Summary

α-(Ethylethanolamino)-acetophenone shows typical ring-chain tautomerism. It is not reduced by aluminum isopropoxide. It is easily mono-alkylated under acid catalysis by methanol and ethanol but not by isopropyl alcohol. Pyrolysis of these compounds gives the dihydroparoxazine. The compounds are interconvertible.

The absence of significant ultraviolet absorption maxima in the region of 240–250° mμ shows this and other ethylethanolamino ketones to exist in the cyclic or hydroxymorpholine forms.

The corresponding amino-dialcohol, 2-ethylethanolamino-1-phenylethanol, was made through styrene bromohydrin.

The quaternary phenacyl derivative of α-(ethylethanolamino)-acetophenone was obtained; it gave a mono-ethyl derivative upon treatment with ethanol–hydrobromic acid.

# The Ultraviolet Absorption Spectra of Steroidal Dinitrophenylhydrazones

BY CARL DJERASSI AND ELIZABETH RYAN

2,4-Dinitrophenylhydrazones are employed widely as carbonyl derivatives in view of their comparatively high melting points and easy crystallizability; furthermore, they are particularly useful in the chromatographic separation of a variety[1,2] of ketones including those of the steroid series.[3,4] Correlations between the ultraviolet absorption spectra of dinitrophenylhydrazones and the structure of the carbonyl compounds from which they are derived are therefore of obvious significance. Important contributions on this subject have been published recently by Braude and Jones,[5] and Roberts and Green,[6] who investigated the spectra of a considerable number of dinitrophenylhydrazones of representative saturated and unsaturated carbonyl compounds in both the aliphatic and aromatic series.

In connection with a study of the reaction of dinitrophenylhydrazine with steroidal bromo ketones,[7] it was necessary for comparison purposes to prepare authentic samples of a number of dinitrophenylhydrazones of steroid ketones with varying degrees of unsaturation and to determine their ultraviolet absorption curves. The present series of compounds is structurally more closely related than the hydrazones studied previously[5,6] and it was thus possible to examine the influence of relatively minor changes in the ketone moiety upon the absorption of the dinitrophenylhydrazone. Furthermore, precise absorption data for steroidal dinitrophenylhydrazones are lacking and in conjunction with the spectra of the carbonyl compounds should prove useful in the characterization of unknown steroid ketones or in the chromatographic separation of ketone mixtures *via* their dinitrophenylhydrazones.

## Experimental

In the present investigation all determinations were carried out in chloroform because of solubility considerations, although ethanol, employed by Roberts and Green,[6] has the considerable advantage that the effect of alkali on the spectrum can also be determined. The spectrum of each com-

| $\Delta^4$-Unsaturated | $C_8H_{17}$, (12-hydroxy)-cholenate | 390[d] | 240–242 |
| $\Delta^{1,4}$-Unsaturated | $C_8H_{17}$, $COOCH_3$, $OCO_6H_{11}$ | 400–402 | 243–244 |
| $\Delta^{4,6}$-Unsaturated | $C_8H_{17}$, $COOCH_3$, $OCOC_6H_5$ | 402–404 | 282–284 |

[a] The data refer to chloroform solutions and the typical log $E$ values can be obtained from Figs. 1 and 2. [b] In ethanol solution. [c] Sitostanone dinitrophenylhydrazone is reported (ref. 5) with max. at 368 mμ. [d] As in all other cases, all values refer only to data obtained by us on our compounds on a standardized Beckman spectrophotometer. Jones, *et al.*, ref. 4, give a max. at 391 mμ for $\Delta^4$-cholestenone and 392 mμ for the hydrazones of three other $\Delta^4$-3-ketosteroids. For the same ketones Braude and Jones, ref. 5, report maxima ranging from 393–395 mμ. We consider the values of Jones, *et al.*, more reliable.

pound was examined in a Beckman quartz spectrophotometer in the region 252 mμ to 415 mμ at 2.5 mμ intervals, except around maxima and minima where 1 mμ intervals were used; $E_m = 1/c \log I_0/I$, where $c$ is the concentration in moles per liter. All samples were of analytical purity and in most instances were prepared by two different methods as described elsewhere.[7]

## Discussion

It is apparent from an inspection of Table I and Figs. 1 and 2 that the main maxima of the dinitrophenylhydrazones of the various types of ketones in the steroid series do not overlap and differ sufficiently so that they may be correlated with the structure of the ketone from which the hydrazone is prepared. The various factors contributing to the absorption spectra of dinitrophenylhydrazones have already been discussed by earlier workers,[5,6] but it will be necessary to revise, or at least amplify somewhat, the position of the maxima as given by them for the various types of carbonyl derivatives. In the case of the wave length limits given by Roberts and Green,[6] a slight expansion is necessary to accommodate certain unsaturated ketones and to apply the data to chloroform solutions. It is suggested that this solvent should be used in preference to ethanol, since many dinitrophenylhydrazones are insoluble in the latter and no definite correction can be made for shifts in the two solvents.[8] The values of Braude and Jones[5] for compounds which we have checked, occasionally needed corrections ranging from 2–5 mμ,[9] either reflecting differences in the purity of the samples or in the spectrophotometers. These experimental differences as well as the fact that our narrow wave length limits given in Table I refer only to steroid ketones (cyclic six-membered), while those of the English workers include predominantly open-chain derivatives, account for the differences in our respective wave length ranges for unsaturated ketones.

While saturated 3-ketosteroids possess a low

(8) It should be noted that although no correction appears necessary in changing from ethanol to chloroform in the case of unsaturated ketones [Woodward, THIS JOURNAL, **63**, 1123 (1941)], erratic shifts are obtained in the case of dinitrophenylhydrazones as shown below (*cf.* ref. 5), thus making it desirable to employ only one solvent. The unpublished results of Roberts and Trimble were kindly supplied by Dr. John D. Roberts of M. I. T.

| | λmax (EtOH) (ref. 5) | λmax ($CHCl_3$) (ref. 5) | λmax (EtOH) (ref. 6) | λmax ($CHCl_3$) (Roberts and Trimble) |
|---|---|---|---|---|
| 2,4-Dinitrophenylhydrazine | 350 | 343.5 | 352 | 341 |
| Formaldehyde DNPH | 348 | 348 | 349 | 345 |
| Acetaldehyde DNPH | 360 | 360 | 356 | 356 |
| Crotonaldehyde DNPH | 373 | 372 | 377 | 374 |
| Chalcone DNPH | ... | ... | 395 | 398 |

We have confirmed Roberts' results for dinitrophenylhydrazine and the shift in the case of chalcone DNPH is quite similar to that observed in the case of benzalacetone DNPH (Table II).

(9) In that connection, see Jones, *et al.*, ref. 4, Barton and Jones, *J. Chem. Soc.*, 599 (1943), and the comparison with Roberts' results (footnote 8, this paper).

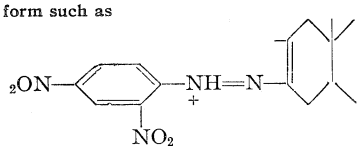
maximum at *ca.* 280–286 mμ (log *E ca.* 1.5),[10] the corresponding dinitrophenylhydrazones show a pronounced maximum (log *E* 4.4) at 367–369 mμ,[11] thus constituting a good diagnostic test for this type of carbonyl compound The introduction of one double bond results in a bathochromic shift of about 15–20 mμ, thus again permitting ready differentiation from the corresponding saturated derivatives. The dinitrophenylhydrazones of such singly unsaturated ketones can be separated into two classes on the basis of the absorption spectra although the difference (6–8 mμ) between the maxima of the hydrazones of the $\Delta^1$-ketones (one β-substituent and no exocyclic double bond) and the $\Delta^4$-ketones (two β-substituents and one exocyclic bond) is not as pronounced as in the corresponding ketones (10–15 mμ).[12] This is understandable since it has been noted already[5,6] that relatively minor changes in the carbonyl part of the molecule are not too readily transmitted over the =N–NH–bond. Of considerable interest is the fact that the introduction of an additional α,β-conjugated double bond next to the keto group exerts a pronounced bathochromic shift. Thus while $\Delta^4$-3-ketosteroids and the corresponding $\Delta^{1,4}$-dien-3-ones show practically the same selective absorption (*ca.* 242 mμ), the maxima of their dinitrophenylhydrazones differ markedly (390 mμ as compared to 404 mμ) and this should prove quite useful for purposes of differentiation between those two types of compounds (see Table I). It is also interesting to note that in the case of the hydrazones, both the cross-conjugated $\Delta^{1,4}$-dienone and the linear conjugated $\Delta^{4,6}$-dienone derivatives possess nearly the same maximum (around 404 mμ), whereas the spectra of the parent dienones differ very considerably (by about 40 mμ, see Table I). The hydrazones of those two types of dienones can be differentiated, however, by their spectra in the region 280–330 mμ,[13] since the dinitrophenylhydrazones of the $\Delta^{4,6}$-dienones exhibit a new and characteristic maximum at 309 mμ (Fig. 2).

It is of interest to note that the maximum of the $\Delta^1$-2-bromo-3-keto*allo*steroid dinitrophenylhydrazones occurs at an appreciably lower wave length (*cf.* Table I) than that of the $\Delta^1$- and $\Delta^4$-unsaturated hydrazones,[14] which is in contrast to the absorption spectra of the corresponding ketones, where the $\Delta^1$-2-bromo-3-ketones absorb at a higher wave length.[15]

The spectra of some miscellaneous dinitrophenylhydrazones are recorded in Table II. Through the kind coöperation of Drs. H. Sobotka and J. D. Chanley of the Mt. Sinai Hospital, New York City, we obtained authentic samples[16] of the dinitrophenylhydrazones of α- and β-ionone (compounds 5 and 6, Table II). Their spectra are reproduced in Fig. 2 and corroborate the previous report[5] that β-ionone dinitrophenylhydrazone lacks a definite maximum at 309 mμ in contrast to the hydrazones of ψ-ionone or the $\Delta^{4,6}$-3-ketosteroids discussed above, even though all three possess the same conjugated system. We did observe, however, that the β-isomer showed a slightly higher absorption maximum (392 mμ) than the α-isomer (387 mμ).[16a] It is probably not necessary to assume that some isomerization of the β-isomer had occurred during the preparation of its dinitrophenylhydrazone in glacial acetic acid, in order to explain the lowered maximum (392 as compared to *ca.* 404 mμ) and the absence of the maximum at 309 mμ, since β-ionone appears to be stable in acid solution.[17] It is simply a further instance of the anomalous spectral behavior of β-ionone, as exemplified by the ionone semicarbazones[17,18] and ionylideneacetones,[19] which has been ascribed[18] in part to a steric effect of the methyl group.

Qualitatively, a benzene ring adjacent to a carbonyl group can be considered equivalent (as a chromophore) to a double bond[20] and on that basis the two naphthalene derivatives 3 and 4 (Table II) represent a single unsaturated ketone and a cross-conjugated dienone, respectively. The spectra of their dinitrophenylhydrazones differ in the same manner as the comparable steroid derivatives discussed above.

The light absorption of the dinitrophenylhydra-



(10) *E. g.*, cholestanone, max. at 286 mμ (log *E ca.* 1.3) [Klotz, THIS JOURNAL, **66**, 90 (1944)] and dihydrotestosterone hexahydrobenzoate, max. at 280.5 mμ (log *E* 1.49) [Wilds and Djerassi, *ibid.*, **68**, 2128 (1946)].

(11) The maxima for the dinitrophenylhydrazones of cyclohexanone (366 mμ) and sitostanone (368 mμ) (ref. 5) are in agreement with this classification.

(12) *Cf.* Woodward, THIS JOURNAL, **63**, 1123 (1941); **64**, 76 (1942); and Gillam, *et al.*, *J. Chem. Soc.*, 815 (1941); 486 (1942), for correlation of absorption spectra and structure of ketones.

(13) This region cannot be employed for the characterization of the other hydrazones, since their spectra coincide almost completely with that of dinitrophenylhydrazine. This region of the spectrum of dinitrophenylhydrazine is discussed in detail by Braude and Jones (ref. 5).

(14) The influence of substituents in the carbonyl moiety of dinitrophenylhydrazones on the relative importance of contributing forms to the resonance hybrid has been discussed by Roberts and Green (ref. 6). It seems likely that the effect of the bromine atom is to favor a form such as

at the expense of quinoid structures with longer conjugated systems.

(15) It has been pointed out [Djerassi and Scholz, THIS JOURNAL, **69**, 2405 footnote 5 (1947)] that the $\Delta^1$-2-bromo-3-ketones do not follow Woodward's rules (ref. 12) with respect to their absorption maxima.

(16) Sobotka, Bloch and Glick, THIS JOURNAL, **65**, 1961 (1943).

(16a) NOTE ADDED IN PROOF: Since the submission of this manuscript, a paper by Naves and Ardizio [*Helv. Chim. Acta*, **31**, 1926 (1948)] appeared in which the ultraviolet absorption spectra of the dinitrophenylhydrazones of α-ionone (max. at 376 mμ) and β-ionone (max. at 385 mμ) were determined in ethanol solution. This serves as a furthes illustration of the irregular shifts observed in changing from ethanol to chloroform (*cf.* footnote 8).

(17) *Cf.* Young, Cristol, Andrews and Lindenbaum, *ibid.*, **66**, 855 (1944).

(19) Young and Linden, THIS JOURNAL, **69**, 2042 (1947) and references cited therein.

(20) See for instance Wilds, Beck, Close, Djerassi, Johnston, Johnson and Shunk, *ibid.*, **69**, 1991 (1947).

zones of benzalacetone (no. 7) and of the cyclopentenonaphthalene derivative 8 resembles that of linear conjugated dienones by exhibiting the characteristic maximum between 305–312 mμ in addition to the one at 396–404 mμ. The introduction of a *p*-methoxy group into such a system (no. 9) results in an expected bathochromic shift.[21] A considerable number of compounds would be required, however, to establish definite figures on the effect of a five-membered ring or ring substituents on the absorption of such aromatic dinitrophenylhydrazones.

In Table II are also listed the spectra of three α-(2,4-dinitrophenyl)-α-methylhydrazones of the steroid series. Although a slight bathochromic shift with respect to the corresponding dinitrophenylhydrazones was to be expected by analogy to the behavior of the methylsemicarbazones,[22] the pronounced shift (10–20 mμ) which was observed was not anticipated. These derivatives crystallize only poorly in the steroid series and thus do not lend themselves readily to the characterization of unknown carbonyl derivatives.

(21) A shift of the same magnitude was observed in the hydroxybenzaldehyde series (ref. 6).

## Summary

As an additional tool for the characterization of steroid ketones, the ultraviolet absorption spectra of a number of representative saturated and unsaturated steroid 2,4-dinitrophenylhydrazones have been determined. The position of their maxima is discussed on the basis of earlier work on the light absorption of such carbonyl derivatives.

The spectra of certain other dinitrophenylhydrazones are also recorded, including those of α- and β-ionone.

# The Scope and Mechanism of the Reaction of Dinitrophenylhydrazine with Steroidal Bromo Ketones[1]

BY CARL DJERASSI

Most of the physiologically potent steroids in the androgenic, progestational and cortical hormone series possess a $\Delta^4$-3-keto grouping (IIa). Unless prepared from a steroid already possessing unsaturation in the 4-5 or 5-6 positions, the double bond is usually introduced by brominating the saturated 3-ketosteroid and dehydrobrominating the resulting bromo ketone, a method which is particularly important in the synthesis of the cortical hormones. Since 3-keto*allo*steroids (A:B ring juncture as in *trans* decalin) on monobromination give the 2-bromo derivative III,[2] in general only the ketones of the "normal" series (A:B juncture *cis*) have been employed for this purpose since they lead to 4-bromo-3- ketones I.[2,3] The dehydrobromination of the latter is usually accomplished by refluxing with pyridine for several hours[3,4] and it is believed[4] that frequently one of the factors responsible for the relatively poor yield is the formation of two diastereoisomeric 4-bromo derivatives, only one of which can undergo facile *trans*-elimination of hydrogen bromide. Recently, the mono- and dibromination products of the *allo* series have gained increased importance, since the 2,4-dibromo-3-ketosteroids (VII) on dehydrobromination yield the 1,4-dienones VIIIa, which represent the key intermediates in the partial synthesis of the estrogens.[5,6] Furthermore, partial dehydrobromination of the dibromo ketones (VII) leads to the 2-bromo-$\Delta^4$-3-ketosteroids (IX)[7,8] which can be converted to $\Delta^4$-3-ketosteroids (IIa). Even the 2-bromo-3-keto*allo*steroids (III) can be transformed partially to the $\Delta^4$-ketones[8,9] although the main product is the $\Delta^1$-isomer (IVa). Although Butenandt and co-workers[10] have shown that collidine is much more effective in the dehydrobromination of brominated derivatives of the *allo* series than is pyridine, the latter is still the base of choice for normal ketones. In spite of the importance of dehydrobrominations in steroid chemistry, even in the most thoroughly studied cases (both *allo* and normal series) using either collidine or pyridine, the yield in that step has never surpassed 60% which in turn has been a serious drawback in a number of syntheses.

A few months ago, Mattox and Kendall[11] in a preliminary communication recorded the interesting observation that when certain cortical hormone intermediates containing the 3-keto-4-bromo grouping (I) were treated in acetic acid solution with 1.2 moles of dinitrophenylhydrazine

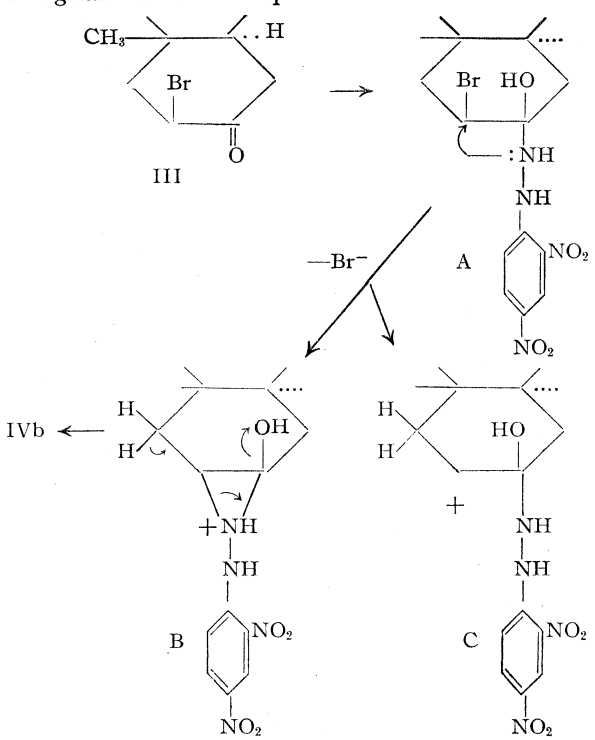
with or without the addition of sodium acetate, the dinitrophenylhydrazone IIb of the corresponding $\Delta^4$-3-ketosteroid was obtained in excellent yield. Furthermore, on cleavage with pyruvic acid in the presence of hydrogen bromide, the unsaturated ketone could be regenerated almost quantitatively. Aside from the statement that "the reactivity of the bromine at $C_4$ is greatly increased through formation of a hydrazone at $C_3$," no mechanism was advanced, and no exact experimental details as to time or temperature were given. The purpose of the present paper is to record the results of an investigation of the scope of this reaction, particularly as applied to 3-keto*allo*steroids, and to suggest a reaction mechanism.



In the present investigation it was found that the reaction of the steroidal bromo ketone with 1.0–1.1 moles of dinitrophenylhydrazine was completed after heating for three to five minutes. Sodium acetate was not used so as not to introduce complications in a discussion of the reaction mechanism and those conditions were adhered to for all of the compounds described below.

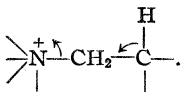
Since 4-bromo-3-ketosteroids of the normal series (I) have already been studied by Mattox and Kendall,[11] only one additional example (methyl 3-keto-4-bromo-12-hydroxycholanate) was tested which gave nearly 90% of the dinitrophenylhydrazone IIb.

Three examples of 2-bromo-3-keto*allo*steroids (III) were investigated (R = $C_8H_{17}$, $COOCH_3$, $OCOC_6H_{11}$), all of which gave 80–90% of the dinitrophenylhydrazone IVb of the $\Delta^1$-3-ketone. Just as with collidine,[7,8] 2,2-dibromoketones V (R = $C_8H_{17}$, $OCOC_6H_{11}$) led to the $\Delta^1$-2-bromo derivatives VIb in 60% yield. In each case, the identity of the product was confirmed by analysis and direct comparison with authentic samples of the dinitrophenylhydrazones prepared from the known unsaturated ketones (Table I). Furthermore, cleavage of the ketone derivatives with pyruvic acid–hydrogen bromide by a slight modification of the Mattox-Kendall procedure[11] led to the unsaturated ketones. As described in detail in the experimental section the water content of the pyruvic acid apparently plays an important role in this cleavage. The regeneration of the carbonyl compound was nearly complete in the case of the $\Delta^4$- and $\Delta^1$-3-ketones (IIa and IVa), but only partial with $\Delta^1$-2-bromo compounds VIa (up to 30% of ketone, the remainder being recovered as hydrazone).

The remarkable fact about the dehydrobromination is that it is complete in a matter of minutes in acid solution in the presence of one mole of the very weak base[12] dinitrophenylhydrazine, while refluxing for fifteen minutes to four hours is required with a large excess of comparatively strong bases such as collidine or pyridine. Initial attack on the bromine by dinitrophenylhydrazine is quite unlikely, since under the same conditions (1.0–1.2 moles of base in glacial acetic acid) no comparable reaction is observed with benzylamine, aniline, ethylaniline or collidine. On the other hand, phenylhydrazine, $\alpha$-(2,4-dinitrophenyl)-$\alpha$-methylhydrazine, hydroxylamine and semicarbazide[13] produced essentially the same results as dinitrophenylhydrazine. Initial formation of a hydrazone of the bromo ketone as intimated by Mattox and Kendall[11] leaves no reasonable path for the elimination of hydrogen bromide, unless it is assumed that the bromine atom is so labilized by hydrazone formation as to be lost on warming for a few minutes in acetic acid.

It is suggested that the results are compatible with a reaction mechanism employing the concept of participation of neighboring groups in nucleophilic displacement reactions as developed by Winstein and co-workers in a brilliant series of papers,[14] and the reaction is depicted as proceeding as follows, a 2-bromo-3-keto*allo*steroid (III) being taken as an example

The initial attack of dinitrophenylhydrazine on the ketone III proceeds in the usual manner[15] to



(12) See Davies, *J. Chem. Soc.*, 715 (1922) and Sidgwick, "Organic Chemistry of Nitrogen," Oxford, 1937, p. 395.

(13) All of the reagents (both successful and unsuccessful) were tried with 2-bromocholestanone. Phenylhydrazine and hydroxylamine hydrochloride did result in loss of hydrogen bromide but the product crystallized very poorly. Examples with the other two reagents are given in the experimental section. It should be noted however, that dinitrophenylhydrazine surpasses all reagents because of the ease with which the dinitrophenylhydrazones crystallize in the steroid series.

(14) See for instance Winstein, Grunwald, Buckles and Hanson, THIS JOURNAL, **70**, 816 (1948).

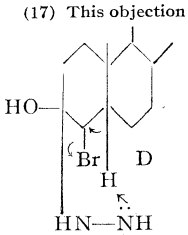
yield intermediate A, in which the nitrogen atom with its available electron pair represents a powerful neighboring group, thus leading to expulsion of a bromide ion and the formation of a cyclic imonium compound such as B, in which the carbonium ion C represents one of the extreme ionic forms contributing to the resonance hybrid. The hydroxy–imonium compound B is formally identical with quaternary ammonium salts in the Hofmann reaction where elimination of the β-hydrogen occurs as well as rupture of the N–C bond:

The mechanism of the Hofmann elimination is only incompletely understood[16] and the reaction is therefore written in the non-committal form B, even though it may proceed through the carbonium ion C. The strain of the positively charged three-membered ring and the tendency toward dehydration constitute a strong driving force in the expulsion of the proton and fission of the N–C bond with the resulting formation of the final product IVb. Furthermore it is necessary to ascribe an important function (possibly due to momentary formation of a second positive charge) to the adjoining second nitrogen atom in the Hofmann-type elimination which proceeds under such mild conditions in an acid medium, in contrast to the usual basic thermal treatment. This last assumption is a necessary corollary to the imonium ring mechanism, since otherwise primary and secondary amines, *e. g.*, ethylaniline or benzylamine, should also be effective in the dehydrobromination.[17]



At this point it is necessary to consider the stereochemistry of the bromo compounds. As mentioned in the first paragraph, there exists some evidence[4] that 3-ketosteroids of the "normal" series on bromination often yield both stereoisomeric 4-bromo compounds, since only one form can be dehydrobrominated with ease. In the case of 2-bromo-3-keto*allo*steroids (III) such evidence is not available since *trans* elimination of hydrogen bromide is possible with either isomer. However, recent work[18] based on molecular rotation differences points toward the presence of both isomers in this series. On that basis the two bromo compounds (III, R = $C_8H_{17}$, and R = $COOCH_3$) represent different isomers at C-2 and yet both reacted equally fast with dinitrophenylhydrazine. Since the formation of the cyclic imonium compound B would require a *trans* relationship between the bromine atom and the dinitrophenylhydrazyl radical as in A in order to allow for rearward attack, it is necessary to postulate that in the case of the 4-bromo-normal (I) and 2-bromo-*allo* compounds (III) either the entrance of the dinitrophenylhydrazine molecule is always directed by steric factors of the steroid molecule in such a manner that a *trans* relation (A) is present, or more likely that a rapid equilibrium exists in which only one form (*trans*) reacts.

In the case of the 2,4-dibromo-3-keto*allo*steroids (VII), it is known that the 4-bromine atom has the (β)-configuration, since it can be eliminated with collidine[7,8] in less than one minute with the formation of the unsaturated bromo ketone IX. The configuration of the 2-bromine atom in VII is not known, but it is likely, again on the basis of rotation measurements,[18] that it has one and the same configuration in all of the *allo* compounds studied so far. It is conceivable that if a cyclic imonium ring mechanism operates, both bromines could be removed by one mole of dinitrophenylhydrazine, since a second ring could be formed after elimination of the first bromine atom, unless (a) dehydration to the hydrazone is an essential factor in that step, (b) both bromine atoms do not possess the same stereochemical configuration and (c) the hydroxyl group introduces steric hindrance. When the reaction was applied to 2,4-dibromo ketones (VII, R = $C_8H_{17}$, $COOCH_3$, $OCOC_6H_{11}$), a mixture was obtained, which by analysis still contained one mole of bromine, but which seemed to contain at least some of the $\Delta^{1,4}$-dien-3-one hydrazone VIIIb on the basis of the ultraviolet absorption spectra (Fig. 1). The hydrazone mixture could not be cleaved with pyruvic acid which was in agreement with experiments carried out on the hydrazones prepared from authentic dienones, and the results, therefore, are not conclusive.[19]

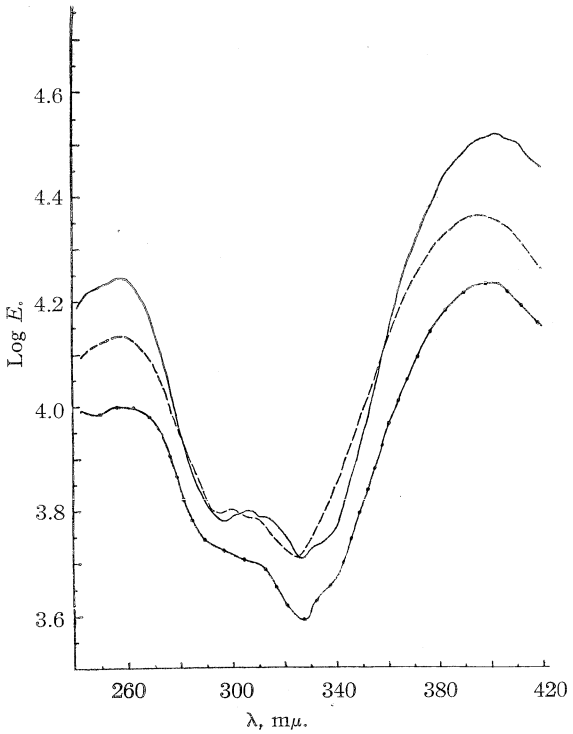
In order to elucidate further the action of dinitrophenylhydrazine on the 2,4-dibromo ketones VII, the 2-bromo-$\Delta^4$-3-ketones (IX) were investigated since they might be intermediates in the reaction of VII. The surprising observation was made that those ketones reacted with dinitro-

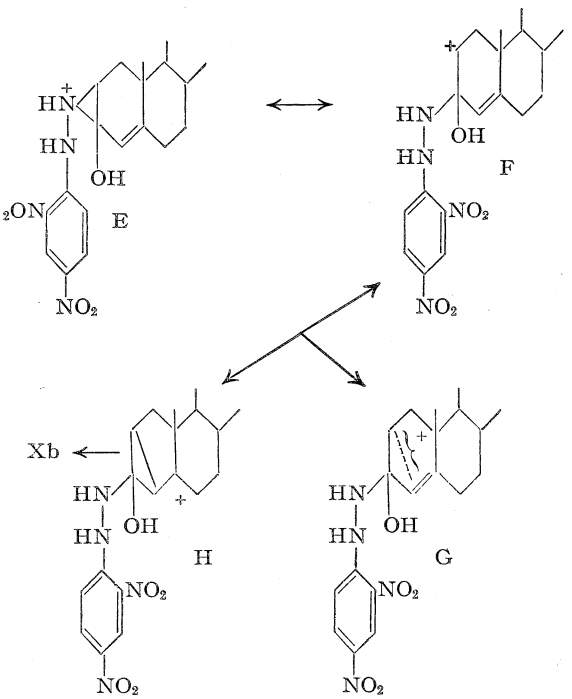
(16) *Cf.* Hughes and Ingold, *Trans. Faraday Soc.*, **37**, 657 (1941).

(17) This objection has been brought up during a discussion at the University of California at Los Angeles. Drs. C. F. Koelsch and S. Winstein suggested as a possible alternative a mechanism, D, in which the α-nitrogen atom (which appears to be essential from our observations) assumes the dominant role by removing the proton on the β-carbon atom, the remaining steps being unexceptional. Such a suggestion, however, involves certain difficulties in the reaction of the $\Delta^4$-2-bromoketones (IX) leading to Xb, which incidentally could also be accomplished with semicarbazide hydrochloride.

(18) Djerassi, *J. Org. Chem.*, **12**, 823 (1947).

(19) Recently, an article appeared [Klein, Weiner and Gordon, *Anal. Chem.*, **20**, 174 (1948)] in which it was postulated that α,β-unsaturated steroid ketones such as progesterone reacted with dinitrophenylhydrazine to form a pyrazoline derivative, since the product could not be split with acid. It has since been shown [Djerassi, *Anal. Chem.*, **20**, 880 (1948)] that the product is in fact the bis-dinitrophenylhydrazone since it led to progesterone in 60% yield on cleavage with pyruvic acid. In view of the resistance of $\Delta^{1,4}$-dien-3-one hydrazones (VIIIb) even toward pyruvic acid, it might be suggested that they represent pyrazoline derivatives (according to ref. 26, pyrazolines are not affected by pyruvic acid), but the absorption spectra speak against such a supposition. By analogy to the ultraviolet absorption spectra of other steroid hydrazones (ref. 20), such pyrazolines would be expected to have maxima below 390 mμ, rather than at 402 mμ as observed for the reaction product.





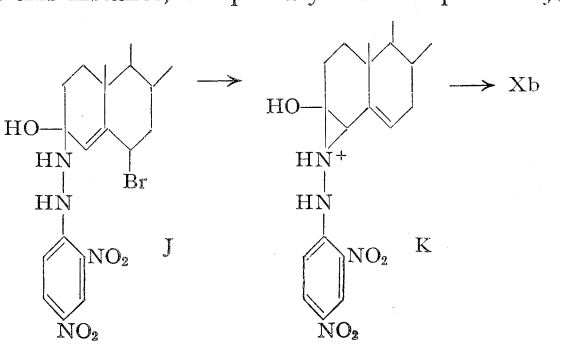


Fig. 1.—Ultraviolet absorption spectra in chloroform solution: — 1,4-androstadien-17-ol-3-one 17-hexahydrobenzoate dinitrophenylhydrazone; – – – – – product from reaction of 2,4-dibromoandrostan-17-ol-3-one 17-hexahydrobenzoate and 2,4-dinitrophenylhydrazine; —·—·— product from reaction of methyl 2,4-dibromo-3-keto*allo*etiocholanate and 2,4-dinitrophenylhydrazine.

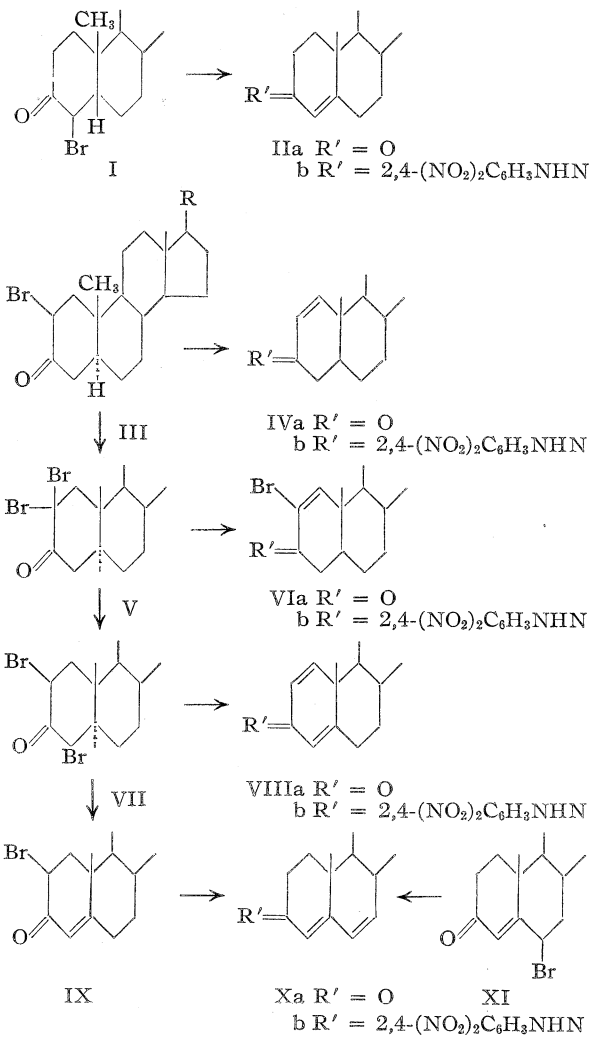
phenylhydrazine to afford in about 45% yield the hydrazones of the corresponding $\Delta^{4,6}$-dien-3-one (Xb, R = $C_8H_{17}$, $COOCH_3$). The structure of the products was established by direct comparison with authentic samples (Table I) prepared from the known $\Delta^{4,6}$-dien-3-ones (Xa) as well as by their characteristic ultraviolet absorption spectra.[20] As was to be expected, the dinitrophenylhydrazones Xb were cleaved very incompletely with pyruvic acid but enough of the ketone was isolated to permit identification as the dienone Xa (m. p. and characteristic u. v. maximum at 282.5 mu). On applying the imonium-ring mechanism to this reaction, it is suggested that the primary intermediate is again a cyclic compound such as E. In this instance, the contributing carbonium ion form F, in contrast to C which lacks the double bond, is further stabilized by forms such as the hybrid carbonium ion G or the rearranged carbonium ion H. Forms F, G and H are somewhat comparable to the intermediates postulated in the *i*-steroid rearrangement.[21] It is realized that in this instance it is necessary to postulate a shift of hydrogen to C-2 in order to accommodate for structure Xb and the sequence of reactions from H leading to Xb is not depicted. Various explanations are possible for providing this shift, particularly since a proton donor is available in the solvent. It should be noted that if an alternate mechanism is considered in which the α-nitrogen atom is the essential factor,[17] it would be necessary to assume first that the bromine atom rearranged either to position 4 or 6, which could not be demonstrated (see experimental section), although it is conceivable that a very small amount of rearrangement product at any one time would be sufficient to drive the reaction to completion.

In view of the formation of the $\Delta^{4,6}$-derivative Xb from the $\Delta^4$-2-bromoketone IX it was of considerable interest to investigate the behavior of the $\Delta^4$-6-bromo-3-ketones XI (R = $COOCH_3$, $OCOC_6H_5$), where the bromine atom is not adjacent to the carbonyl group. As with the 2-bromo derivatives IX, the 6-bromo isomers XI also yielded the dinitrophenylhydrazones Xb although in appreciably higher yield. It is quite likely that in this instance, the primary reaction product J,



(20) Djerassi and Ryan, THIS JOURNAL, **71**, 1000 (1949).

(21) Winstein and Adams, *ibid.*, **70**, 838 (1948); Dodson and Riegel *J. Org. Chem.*, **13**, 424 (1948).

representing a particularly labile allylic system, undergoes simultaneous attack on position 4 by the nitrogen atom and shift of the double bond,[22] thus leading directly to the imonium compound K.

In conclusion, it can be stated that the Mattox–Kendall reaction[11] is useful for the dehydrobromination of 2-bromo-3-keto*allo*steroids and for 4-bromo-3-ketones of the normal series, particularly when employed on a small scale. The reaction has no practical applications in the other cases cited, unless a procedure is discovered for cleaving the dinitrophenylhydrazones of such poly-unsaturated ketones as the $\Delta^{4,6}$-dienones. It should be of interest to investigate this dehydrobromination procedure in simpler ketones other than steroids, where complicated steric factors do not enter and which may thus shed more light on the reaction mechanism.

**Acknowledgment.**—The author would like to express his gratitude to Dr. Gilbert Stork of Harvard University for the numerous stimulating discussions on the subject of this paper; furthermore, he is indebted to Dr. W. E. Doering of Columbia University for comments and to the Misses Helen Dudek and Jean Rogers for technical assistance. Since the completion of this work, the author has had the benefit of a critical discussion regarding the reaction mechanism with members of the summer staff of the University of California at Los Angeles, and he is thankful to Dr. S. Winstein for providing that opportunity.

## Experimental[23]

**General Procedure for Reaction of Steroid Ketones with 2,4-Dinitrophenylhydrazine.**—The following method was used for both the dehydrobromination of steroidal bromo ketones as well as for the preparation of comparison samples of dinitrophenylhydrazones from authentic saturated and unsaturated 3-ketosteroids.

Approximately 200 mg. of steroid was dissolved in 5–10 cc. of warm glacial acetic acid (depending on the solubility of the ketone) in an open Erlenmeyer flask while passing a slow current of nitrogen over the surface of the solution, 1.1 moles of dinitrophenylhydrazine was added, and the solution was heated on the hot-plate for five minutes in the open flask without condenser. In those instances where the hydrazone precipitated immediately, the heating time was reduced to three minutes. In practically all cases the hydrazone crystallized on cooling. Recrystallization was best effected from a mixture of ethanol and chloroform (all of the hydrazones were very soluble in chloroform) and all reactions involving solutions of hydrazone were carried out in an atmosphere of nitrogen. Experiments ranging from 25 mg. to 1.2 g. of steroid gave equally good results and required no modification except for variations in the amount of acetic acid. Remarks as to the applicability of this procedure to the dehydrobromination of the various classes of steroidal bromo ketones are given below in appropriate sections together with the physical constants of the products. In Table I are summarized the constants of some previously undescribed dinitrophenylhydrazones of both saturated and unsaturated steroid ketones which were prepared for one or more of the following purposes: Determination of the ultraviolet absorption spectra which are reported elsewhere,[20] preparation of authentic samples for comparison with the products arising from the dehydrobromination, and as model substances for determining conditions for the regeneration of the carbonyl compound from the hydrazone.

**General Procedure for the Cleavage of Steroidal Dinitrophenylhydrazones.**—The dehydrobromination procedure of Mattox and Kendall[11] is useful only if the unsaturated carbonyl compound can be regenerated from its dinitrophenylhydrazone. These workers indicated that the cleavage of the dinitrophenylhydrazones of $\Delta^4$-3-ketosteroids could be accomplished in nearly quantitative yield by warming for two and one-half hours at 45° in 20 cc. of chloroform, 30 cc. of pyruvic acid and 2.2 cc. of 2.3 *N* hydrogen bromide solution (in acetic acid), but they neglected to state the quantity of hydrazone which could thus be cleaved. Using the dinitrophenylhydrazones of $\Delta^1$- and $\Delta^4$-cholesten-3-one our initial experiments to confirm those results failed completely. The following variations also resulted in partial or complete recovery of the hydrazone: Refluxing the reaction mixture (containing hydrazone, pyruvic acid and chloroform) with either 4 *N* hydrogen bromide–acetic acid or hydrogen bromide–acetic acid–

(23) All melting points are uncorrected. The microanalyses were carried out by Mr. Joseph F. Alicino, Metuchen, N. J., and Mr. George L. Stragand, Microchemical Laboratory, University of Pittsburgh.

TABLE I

AUTHENTIC SAMPLES OF DINITROPHENYLHYDRAZONES OF SOME STEROID KETONES[a]

| Dinitrophenylhydrazone of | M. p., °C., (dec.) | Formula | Analyses, % Calcd. C | Calcd. H | Calcd. N | Found C | Found H | Found N |
|---|---|---|---|---|---|---|---|---|
| Cholestan-3-one | 228–230 | $C_{33}H_{50}O_4N_4$ | 69.93 | 8.89 | 9.89 | 69.74 | 8.99 | 9.70 |
| 2-Acetoxycholestan-3-one[b] | 173–175 | $C_{35}H_{52}O_6N_4$ | | | 8.97 | | | 8.60 |
| Dihydrotestosterone hexahydrobenzoate | 206–208 | $C_{32}H_{44}O_6N_4$ | 66.17 | 7.64 | 9.65 | 66.61 | 7.77 | 9.25 |

| $\Delta^{1,4}$-Cholestadien-3-one | 183–184 | $C_{33}H_{46}O_4N_4$ | 70.43 | 8.24 | 9.96 | 70.50 | 8.60 | 10.12 |
| $\Delta^{1,4}$-Androstadien-17-ol-3-one 17-hexahydrobenzoate | 263–264 | $C_{32}H_{40}O_6N_4$ | 66.64 | 6.99 | 9.72 | 66.80 | 6.92 | 9.56 |

[a] With one exception (preparation given in this paper) all of the ketones have been described in the literature. [b] Acetyl, calcd.: 6.89; found: 7.29. [c] Methoxyl, calcd.: 6.08; found: 5.85. [d] Bromine, calcd.: 12.42; found: 12.45. [e] Bromine, calcd.: 12.15; found: 11.92.

water,[24] using Hershberg's[25] pyruvic acid cleavage for semicarbazones, or that of Anchel and Schoenheimer[26] for splitting *p*-carboxyphenylhydrazones. Similarly, refluxing with pyruvic acid or biacetyl[27] alone resulted in recovery of the hydrazone. Finally, it was noted that the water content of the pyruvic acid greatly influenced the extent of cleavage and this unquestionably was the reason why Mattox and Kendall's procedure[11] could not be repeated originally. The following method gave fairly reproducible results:

A solution of 100 mg. of steroid dinitrophenylhydrazone in 5 cc. of chloroform is treated in a stoppered flask (air displaced by nitrogen) at 50–60° with 7.5 cc. of commercial pyruvic acid (83–85%) and 0.6 cc. of approximately 4 *N* anhydrous hydrogen bromide in acetic acid for three hours. It appears that pyruvic acid of neutral equivalent 105 or higher yields two layers under the conditions specified and hence continuous shaking is essential for cleavage. Pyruvic acid of neutral equivalent 102 or less gives a homogeneous solution, thus not requiring any shaking, and the yield of ketone seems to be higher. The completion of the reaction is usually indicated by appreciable lightening of the color of the solution. After dilution with chloroform and extraction with carbonate solution, the organic layer is dried and if the residue is still colored, it is recrystallized preferably from ethanol (using Norit), since any unchanged hydrazone is practically insoluble in that solvent.

This procedure has given satisfactory results in the cleavage of hydrazones of saturated as well as $\Delta^1$- and $\Delta^4$-unsaturated 3-ketosteroids,[28] where 60–70% of the pure ketone could be isolated. Losses in the purification of the ketone on such a small scale may be responsible for the lower yield as compared to that reported by Mattox and Kendall.[11] With $\Delta^1$-2-bromo-3-keto derivatives, the reaction proceeded to the extent of 20–30%, while in the case of the hydrazones of $\Delta^{4,6}$-dien-3-ones only about 5–10% of the ketone could be isolated, the rest being recovered as unchanged hydrazone. The derivatives of $\Delta^{1,4}$-dien-3-ones could not be split at all.[19] The $\alpha$-(dinitrophenyl)-$\alpha$-methylhydrazone of even a singly unsaturated ketone (such as $\Delta^1$-cholestenone) also were unaffected under those conditions.

**Preparation of Bromo Ketones.**—With a few exceptions the synthesis of the bromo ketones used below for the dehydrobrominations has been described in papers from this or other laboratories.[2,6,8,29,30] The following either are new compounds or require comment.

**$\Delta^4$-2-Bromocholesten-3-one (IX, R = $C_8H_{17}$).**—By analogy to related 2,4-dibromo ketones[7,8] 4 g. of 2,4-dibromocholestan-3-one[29] was refluxed for forty seconds with 18 cc. of redistilled collidine, which resulted in the loss of 1.2 moles of hydrogen bromide on the basis of collidine hydrobromide isolated. After working up as usual and recrystallizing from ethanol, there was obtained 1.17 g. (34%) of colorless, long needles melting at 117–119°, $[\alpha]^{29}D$ + 81° (chloroform), maximum at 243 mu, log *E* 4.15 (ethanol).

*Anal.* Calcd. for $C_{27}H_{44}OBr$: C, 69.80; H, 9.55; Br, 17.21. Found: C, 69.81; H, 9.22; Br, 17.05.

The structure of the compound was confirmed by further dehydrobromination to $\Delta^{1,4}$-cholestadien-3-one and dienone-phenol rearrangement of the latter to the corresponding 1-methylphenol.[29]

**Methyl $\Delta^4$-6-Bromo-3-ketoetiocholenate (XI, R = $COOCH_3$).**—The method of Ruzicka and Bosshard[30] for 6-bromotestosterone benzoate was applied to methyl $\Delta^5$-3-hydroxyetiocholenate by adding one mole of bromine, oxidizing with chromic anhydride and dehydrobrominating the crude 5,6-dibromo-3-ketone with anhydrous sodium acetate in ethanol. After recrystallization from hexane–acetone, there was obtained 59% of the desired unsaturated bromo ketone with m. p. 136–137°, $[\alpha]^{26}D$ + 30° (chloroform). Reich and Lardon[31] prepared the compound by the action of N-bromoacetamide on the enol acetate of the corresponding $\Delta^4$-3-ketone and reported m. p. 139–140°. The structure of the bromo ketone was proved by collidine dehydrobromination to methyl $\Delta^{4,6}$-3-ketoetiocholadienate with its characteristic maximum at 282.5 m$\mu$, and which gave no depression in m. p. on admixture with a sample prepared by the following method.

(24) Johnson, Petersen and Schneider, THIS JOURNAL, **69**, 75 (1947), described a mixture of acetic acid, 48% hydrobromic acid and water from which the hydrogen bromide was not lost on heating which was initially believed to be the reason why cleavage was unsuccessful on refluxing with anhydrous hydrogen bromide–acetic acid.

(26) Anchel and Schoenheimer, *J. Biol. Chem.*, **114**, 539 (1936).

(27) Strain, THIS JOURNAL, **57**, 758 (1935).

(28) Even a 3,20-bis-dinitrophenylhydrazone (see ref. 19 for cleavage of progesterone bis-dinitrophenylhydrazone) can be split under those conditions.

(29) Wilds and Djerassi, THIS JOURNAL, **68**, 1712 (1946).

(30) Ruzicka and Bosshard, *Helv. Chim. Acta*, **20**, 328 (1937).

(31) Reich and Lardon, *ibid.*, **29**, 671 (1946).

**Methyl $\Delta^{4,6}$-3-Ketoetiocholadienate** (Xa, R = $COOCH_3$).—This previously unknown dienone was needed for comparison with the above sample prepared by dehydrobromination of the $\Delta^4$-6-bromo-3-ketone as well as for conversion to an authentic sample of dinitrophenylhydrazone. Wettstein's modification[32] of the Oppenauer oxidation presented a convenient one-step synthesis. Two grams of methyl $\Delta^5$-3-hydroxyetiocholenate was oxidized with quinone exactly as described for cholesterol[29] except that commercial aluminum isopropylate was substituted for the *t*-butoxide.[33] After chromatographing the crude, crystalline residue and recrystallizing from methanol, there was obtained 0.81 g. (41%) of colorless rosettes of prismatic needles with m. p. 165–165.5°, $[\alpha]^{26}D$ + 125° (chloroform), max. at 282.5 mμ (log *E* 4.49), and min. at 235 mμ., (log *E* 3.46 in ethanol).

*Anal.* Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59; methoxyl, 9.45. Found: C, 76.75; H, 8.48; methoxyl, 9.67.

**Dehydrobrominations with 2,4-Dinitrophenylhydrazine**

(a) **2-Bromo-3-keto*allo*steroids** (III).—The dehydrobromination of 2-bromocholestanone and methyl 2-bromo-3-ketoetio*allo*cholanate led in 80–90% yield to the hydrazones of the corresponding $\Delta^1$-3-ketones. These were found to be identical (m. p., u. v. spectrum, analysis) with authentic samples described in Table I and were further identified by pyruvic acid cleavage to the known[8] unsaturated ketones. 2-Bromoandrostan-17-ol-3-one 17-hexahydrobenzoate gave 83% of the corresponding $\Delta^1$-unsaturated dinitrophenylhydrazone, m. p. 237–239° (dec.), the analysis of which is reported since an authentic sample was not available.

*Anal.* Calcd. for $C_{32}H_{42}O_6N_4$: C, 66.41; H, 7.32; N, 9.68. Found: C, 66.69; H, 7.68; N, 9.93.

It is interesting to note that the last mentioned two 2-bromo compounds are believed[18] to possess a different configuration of the bromine atom as compared to 2-bromocholestanone, but that no difference in the rate of dehydrobromination was observed.

(b) **2,2-Dibromo-3-keto*allo*steroids** (V).—The general procedure for dehydrobromination was varied slightly in that the dinitrophenylhydrazine was dissolved in hot glacial acetic acid first and the dibromo ketones were then added, since it has been shown previously[8] that those ketones rearrange in a few minutes on heating in acetic acid to the 2,4-isomers. When applied to 2,2-dibromocholestan-3-one and 2,2-dibromoandrostan-17-ol-3-one 17-hexahydrobenzoate, 58–62% of the corresponding $\Delta^1$-2-bromo hydrazones was isolated on cooling. These products were identical with samples prepared from the known $\Delta^1$-2-bromo-ketones (*cf.* Table I).

(c) **4-Bromo-3-ketosteroids** (I).—These have already been investigated by Mattox and Kendall[11] and only one additional example was examined in order to demonstrate the applicability of our reaction conditions to such ketones. Methyl 3-keto-4-bromo-12-hydroxycholanate afforded 87% of methyl $\Delta^1$-3-keto-12-hydroxycholenate dinitrophenylhydrazone melting at 240–242° (dec.) after recrystallization from ethanol–chloroform. The ultraviolet absorption spectrum has already been reported.[20]

*Anal.* Calcd. for $C_{31}H_{42}O_7N_4$: C, 63.90; H, 7.27; N, 9.58. Found: C, 63.54; H, 7.35; N, 9.39.

Pyruvic acid cleavage of 70 mg. of this dinitrophenylhydrazone gave 35 mg. (72%) of methyl $\Delta^4$-3-keto-12-hydroxycholenate with m. p. 147–149°, $[\alpha]^{27}D$ + 78° (acetone), identical with a sample prepared by another method.[34]

(d) **2-Bromo-$\Delta^4$-3-ketosteroids** (IX).—Bromo ketones of this type have been reported[7] to be rearranged in the presence of hydrogen bromide to presumably the isomeric 6-bromo isomers. Since in the present dehydrobromination procedure, the ketone is heated first in acetic acid before dinitrophenylhydrazine is added, it was necessary to show that no rearrangement occurred during the initial heating period. This was tested in the case of methyl $\Delta^4$-2-bromo-3-ketoetiocholenate[35] which was recovered unchanged (melting point, bromine analysis, rotation) on heating for five minutes in glacial acetic acid. When this bromo ketone or 2-bromo-$\Delta^4$-cholesten-3-one was heated with dinitrophenylhydrazine in the usual manner, 44–46% of the dinitrophenylhydrazone (Xb) of the corresponding $\Delta^{4,6}$-dien-3-one was obtained. These compounds exhibited a shiny-red color and showed typical maxima at 309 mμ and 404 mμ as discussed elsewhere.[20] Furthermore, they were identical with samples prepared from authentic dienones (Table I) and on cleavage with pyruvic acid, 100 mg. of $\Delta^{4,6}$-cholestadien-3-one dinitrophenylhydrazone afforded 5 mg. of the ketone,[29] characterized by its selective absorption at 282.5 mμ and melting point. It is interesting to note that in the dehydrobomination of these compounds or the isomeric 6-bromo derivatives described below, occasionally on cooling the acetic acid solution yellowish-orange colored crystals appeared instead of bright red ones which, however, turned reddish on filtering and assumed the usual color on subsequent recrystallization. No obvious explanation seems evident for this behavior.

(e) **$\Delta^4$-6-Bromo-3-ketosteroids** (XI).—Methyl $\Delta^4$-6-bromo-3-ketoetiocholenate and 6-bromotestosterone benzoate[30] on dehydrobromination with dinitrophenylhydrazine behaved exactly as the above mentioned 4-bromo isomers, except that the yield of $\Delta^{4,6}$-dienone hydrazone (Xb) was appreciably higher (69–71%). 6-Dehydrotestosterone benzoate dinitrophenylhydrazone melted at 252–254° and showed ultraviolet absorption maxima at 309 mμ (log *E* 4.10) and 404 mμ (log *E* 4.49 in chloroform), typical of this type of conjugated system.[20]

*Anal.* Calcd. for $C_{32}H_{34}O_6N_4$: C, 67.35; H, 6.01; N, 9.82. Found: C, 66.94; H, 5.88; N, 9.88.

(f) **2,4-Dibromo-3-ketoallosteroids** (VII).—The behavior of 2,4-dibromocholestanone, methyl 2,4-dibromo-3-ketoetio*allo*cholanate and 2,4-dibromoandrostan-17-ol-3-one 17-hexahydrobenzoate with one mole of dinitrophenylhydrazine in glacial acetic acid was investigated and in each case it was necessary to add water to the reaction mixture in order to precipitate the products. They evidently consisted of a mixture which was not amenable to effective separation by recrystallization and which could not be cleaved with pyruvic acid, but which by analysis still contained approximately one bromine atom. On the basis of the ultraviolet absorption spectra (Fig. 1), it seems likely that some of the desired $\Delta^{1,4}$-dien-3-one dinitrophenylhydrazone was formed.

**Reaction of Steroid Ketones with α-(2,4-Dinitrophenyl)-α-methylhydrazine.**[36]—The reactions with this reagent were carried out in glacial acetic acid as described for dinitrophenylhydrazine. Unfortunately, the resulting hydrazones crystallized very poorly in nearly all cases (gelatinous solutions) and with the exception of cholestanone, no sharp melting points were obtained. No definite product could be isolated from the reaction of this reagent with $\Delta^4$-cholesten-3-one or methyl $\Delta^4$-2-bromo-3-ketoetiocholenate. It has been pointed out[20] that those derivatives exhibit an interesting shift in the ultraviolet absorption maxima.

**Cholestanone α-(2,4-dinitrophenyl)-α-methylhydrazone** was obtained as a yellow solid with m. p. 203–205° which crystallized directly from the reaction mixture.

*Anal.* Calcd. for $C_{34}H_{52}O_4N_4$: C, 70.31; H, 9.03; N, 9.65. Found: C, 69.99; H, 8.90; N, 9.58.

**$\Delta^1$-Cholestenone α-(2,4-dinitrophenyl)-α-methylhydrazone** was isolated in 66% yield as a greenish-yellow solid on diluting the reaction mixture from the dehydrobromina-

(32) Wettstein, *Helv. Chim. Acta*, **23**, 388 (1940).

(33) A trial run with cholesterol using the earlier conditions (ref. 29), but employing the more readily available aluminum isopropylate gave the same yield of $\Delta^{4,6}$-cholestadien-3-one.

(34) Djerassi and Scholz, *Experientia*, **3**, 107 (1947).

(35) The melting point of this compound was previously reported (ref. 8) as 162.5–163.5°. On repeating the synthesis, it was possible to raise the melting point to 167–167.5°, without, however, changing the rotation.

(36) Blanksma and Wackers, *Rec. trav. chim.*, **55**, 655 (1936).

tion of 2-bromocholestanone with this reagent, and recrystallizing from ethanol–chloroform (gelatinous solution); m. p. 166–177° (dec.).

*Anal.* Calcd. for $C_{34}H_{50}O_4N_4$: C, 70.55; H, 8.71; N, 9.68. Found: C, 70.23; H, 8.55; N, 9.57.

Methyl 2-bromo-3-ketoetio*allo*cholanate as well as 2,2-dibromocholestanone could be dehydrobrominated in a similar manner, but the products gave analytical figures which were always 2% too low in carbon content.

**Reaction of 2-Bromocholestanone with Semicarbazide Hydrochloride.**—A solution of 230 mg. of 2-bromocholestanone in 5 cc. of glacial acetic acid was heated with 60 mg. of finely crushed semicarbazide hydrochloride for six minutes. After dilution with water and recrystallization from ethanol–chloroform, there was obtained 170 mg. (78%) of $\Delta^1$-cholestenone semicarbazone with m. p. 233–235°, undepressed on admixture with an authentic specimen; the derivative showed the typical maximum at 266 mμ, log $E$ 4.41 (chloroform). The product gave a negative Beilstein test and was cleaved almost instantaneously with dioxane–43% sulfuric acid to yield 86% of $\Delta^1$-cholestenone. It should be noted that while dinitrophenylhydrazones are usually isolated and purified more readily than the corresponding semicarbazones, the latter are very easily split into their components.[25]

## Summary

The dehydrobromination of steroidal bromo ketones with dinitrophenylhydrazine, first discovered by Mattox and Kendall[11] in the case of 4-bromo-3-ketosteroids, has been examined critically. In addition to the 4-bromo ketones, the method is applicable to the dehydrobromination of 2-bromo- and 2,2-dibromo-3-keto*allo*steroids as well as 2-bromo- and 6-bromo-$\Delta^4$-3-ketosteroids. The last two compounds both yield the hydrazone of the $\Delta^{4,6}$-dien-3-one. A mechanism for the reaction is suggested which employs a cyclic imonium compound as the key intermediate.

The regeneration of the unsaturated carbonyl compounds from the dinitrophenylhydrazones was examined and was found to be feasible from a preparative standpoint only in the case of the $\Delta^1$- and $\Delta^4$-3-ketones, thus imposing somewhat of a limitation on the Mattox–Kendall reaction.

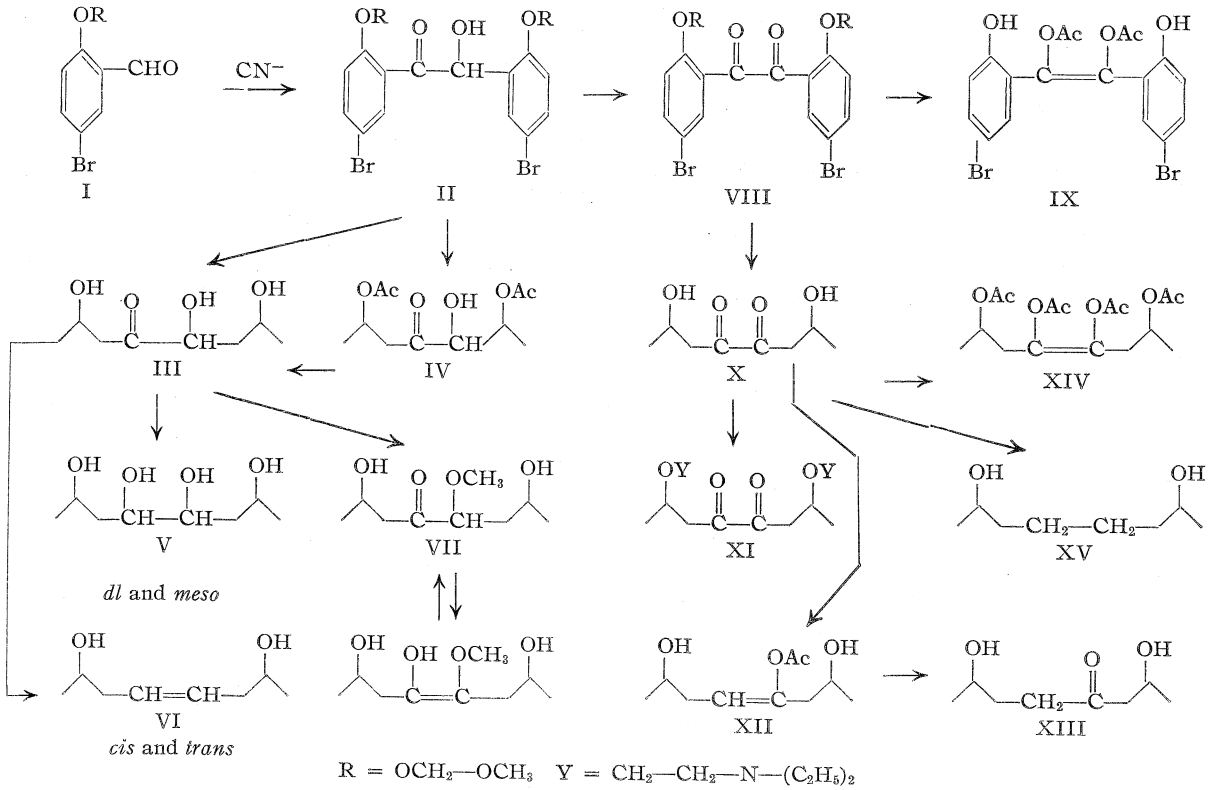
# Synthesis of 5,5′-Dibromosalicil and Related Compounds

BY JACOB FINKELSTEIN AND SEYMOUR M. LINDER

In reports distributed by the Office of The Publication Board, No. 20,466 (Bios Final Report No. 219) it was revealed that Kuhn, in 1943, at Heidelberg had prepared 2,2′-dihydroxy-5,5′-dibromobenzil (3065) and claimed it to be the first compound found to be effective against Rickettsia and Influenza virus strain A employing mice as test animals. The I.G. Laboratories at Elberfeld found this substance to be tolerated by man in ten-gram doses. However, they were disappointed in its action in bacterial infections when compared to the sulfa drugs of choice. The substance is extremely insoluble. Therefore, the solubilized form prepared in borax and soda was tested and showed a fatal dose in the mouse of 30 mg./kg. Nevertheless, the claim by another I.G. Laboratory of its activity against virus organisms served as a stimulus to prepare the substance for testing in our chemotherapeutic laboratories. Although we were unable to confirm Kuhn's chemotherapeutic findings for the compound, we continued the investigation by synthesizing closely related substances. However, none of the compounds prepared was active *in vivo*, but the chemistry involved is interesting and forms the subject of this paper.



The methods of synthesizing the dibromosalicil are rather straight-forward. Kuhn, *et al.*[1] employed two closely related procedures. In one they started with 1,1′-dimethoxybenzil which was previously reported by Schonberger and Kraemer[2] and Irvine.[3] The compound was smoothly demethylated by aluminum chloride and then brominated in acetic acid. The other method by Perkin[4] starts with 2-methoxy-5-bromobenzaldehyde undergoing the benzoin condensation to produce the bromomethoxybenzoin. Another synthesis was outlined in the Department of Commerce Publication paralleling the latter method starting with 2-methoxymethoxy-5-bromobenzaldehyde (I). This methoxymethoxy substituent is ultimately removed by extremely mild conditions to produce the dibromosalicil.

For our investigation, the last method discussed was selected and the compound at each intermediate stage isolated and chemotherapeutically tested. In extending the problem to the preparation of closely related compounds, different compounds from those expected were isolated in several instances.

The first compound in the series capable of variation, 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin (II), was subjected to hydrolysis for two minutes to produce the 2,2′-dihydroxy derivative (III). However, under identical conditions and with the reaction time increased to thirty minutes, the expected phenolic compound was readily acetylated to form 2,2′-diacetoxy-5,5′-dibromobenzoin (IV). The structure of this compound was proven by a negative color reaction with ferric chloride and conversion to III by hydrolysis with 10% sodium hydroxide.

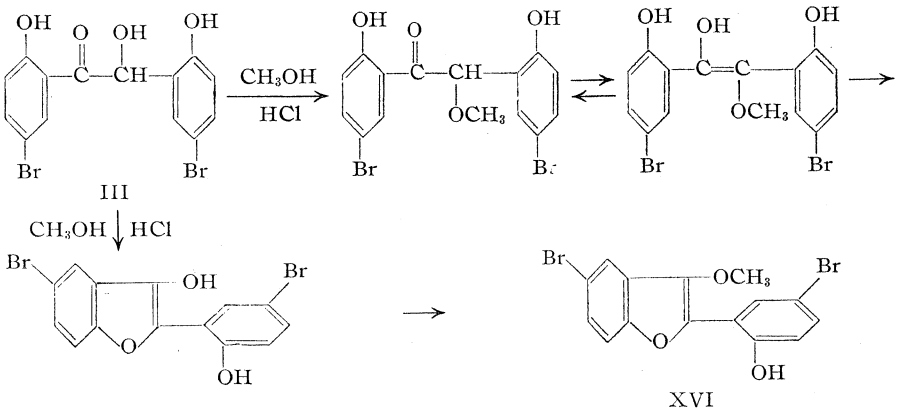
FLOW SHEET

R = $OCH_2—OCH_3$ Y = $CH_2—CH_2—N—(C_2H_5)_2$

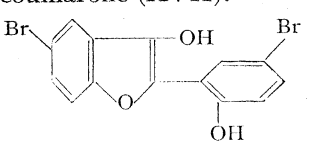
From the dihydroxybenzoin (III), five additional compounds were prepared. By reduction with sodium amalgam in wet ether in the manner of Irvine and Weir[5] as applied to benzoin, we were able to isolate the two possible hydrobenzoins (V), the *dl* and *meso* forms.



The stilbene derivative, 2,2′-dihydroxy-5,5′-dibromostilbene (VI) was prepared from the benzoin analog following the method of Ballard and Dehn[6] for the conversion of benzoin into stilbene. The two possible isomers were obtained.

Clemmensen[7] was able to convert benzoin or benzil to α,β-diphenylethane by reduction with zinc amalgam in dilute hydrochloric acid. Upon attempting to prepare 2,2′-dihydroxy-5,5′-dibromo-α,β-diphenylethane (XV), from the corresponding benzoin (III), a substance was obtained which is believed to be 2,2′-dihydroxy-5,5-dibromomethoxybenzoin monohydrate (VII). To account for such a substance, it would not be unreasonable to postulate the replacement of the alcoholic hydroxy group by a chlorine atom which when treated with methanol, as worked up, would produce the methyl ether. The location of the methoxy group was established by the negative reaction of the compound to Fehling solution.

To prove that the compound obtained is 2,2′-dihydroxy-5,5′-dibromomethoxybenzoin, an attempt was made to prepare it by another method for comparison purposes. Irvine[8] prepared methoxybenzoin by passing dry hydrogen chloride into a methanol solution of benzoin without controlling the temperature. When this was done with the benzoin (III), the compound isolated was alkali soluble and did not reduce Fehling solution. Thus phenolic methylation did not occur. The empirical formula, $C_{15}H_{10}O_3Br_2$, is that of the expected compound $C_{15}H_{12}O_4Br_2$, less the elements of water indicating the formation of a cyclic compound which could be 2-(2′-hydroxy - 5′ - bromophenyl) - 3 - methoxy - 5 - bromocoumarone (XVI). The possible courses of reaction may be graphically indicated as follows.



To obtain further information as to the course of reaction, 2,2′-dihydroxy-5,5′-dibromomethoxybenzoin monohydrate (VII) was treated with dry hydrogen chloride in methanol without any cooling. Under these conditions, the coumarone was not formed but a substance melting at 119–121° was obtained as compared to 173–175° for the starting compound. It gave an analysis which indicated no change in chemical formula and no reaction with Fehling solution. It is probable, therefore, that the compound VII was the *cis* form and the halogen acid catalyzed its conversion to the *trans* form. This conversion undoubtedly takes place more readily than ring closure. The melting point relationship is reversed from the usual and since the 119–121° iso-

(5) Irvine and Weir, *J. Chem. Soc.*, **91**, 1385 (1907).
(6) Ballard and Dehn, THIS JOURNAL, **54**, 3970 (1932).
(7) Clemmensen, *Ber.*, **47**, 683 (1914).
(8) Irvine, *J. Chem. Soc.*, 670 (1901).

mer did not undergo ring closure to form a coumarone it is therefore *trans*.

Pursuing the original objective to prepare the methoxybenzoin from the benzoin compound, the above experiment was repeated keeping the reaction temperature between −15 and 10°. The compound thus obtained gave a positive Fehling reaction and was alkali soluble. The analysis also indicated the elimination of a molecule of water and analogously must be the unmethylated coumarone (XVII).

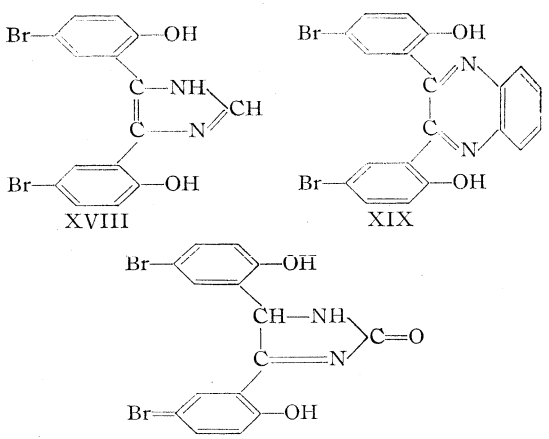
XVII

The positive Fehling test is not surprising especially since it was shown by Friedländer and Neudörfer[9] that 3-hydroxycoumarone displays such a reaction. It was also found that the hydroxycoumarone could be obtained from the methoxymethoxybenzoin II when its methanol solution was saturated at 0° with dry hydrogen chloride. In this case, the methoxymethoxy ethers are readily cleaved and ring closure follows. The compounds obtained from each source are identical.

From all these observations, compound XVI is probably prepared *via* the hydroxycoumarone intermediate rather than through the methoxybenzoin since the latter did not undergo cyclization.

However, the desired diphenylethane derivative (XV) was obtained when 2,2′-dihydroxy-5,5′-dibromobenzil was reduced by zinc and concentrated hydrochloric acid in alcohol. The compound was extremely difficult to purify. Although its melting point indicated that it may have been the lower melting stilbene isomer VI, a mixed melting point gave a depression.

For another series of compounds, 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin II was first oxidized by Fehling solution to 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzil (VIII).



(9) Friedländer and Neudörfer, *Ber.*, **30**, 1081 (1897).

When VIII was subjected to reductive–acetylation below 40°, there was obtained 2,2′-dihydroxy-5,5′-dibromo-α,α′-diacetoxystilbene (IX).

Thus, during the reaction, the phenolic ethers were cleaved. However, when the ethers of VIII were removed by hydrolysis, 2,2′-dihydroxy-5,5′-dibromobenzil (5,5′-dibromosalicil) (X) was obtained. It agreed in all respects with the compound obtained by Kuhn. In an extension of the work several closely related compounds were synthesized. It was thought to be interesting to synthesize a derivative containing a basic water-soluble group. Therefore, 2,2′-bis-(β-diethylaminoethoxy)-5,5′-dibromobenzil (XI), was obtained as the free base and hydrochloride.

When Thiele's[10] procedure for reductive–acetylation was applied to dibromosalicil, 2,2′-dihydroxy-5,5′-dibromo-α-acetoxystilbene (XII) was produced. The formation of this substance probably involved the dehydration of the intermediate di-hydroxy compound to the mono-hydroxy stilbene which was then acetylated. This compound, when hydrolyzed by 10% sodium hydroxide, yielded 2,2′-dihydroxy-5,5′-dibromodesoxybenzoin (XIII). Only by modification of the procedure for reductive-acetylation of dibromosalicil (X) could 2,2′,α,α′-tetraacetoxy-5,5′-dibromostilbene (XIV) be prepared.

Three cyclic derivatives of possible chemotherapeutic interest were also synthesized. These were 4,5-bis-(2-hydroxy-5-bromophenyl)-imidazole (XVIII), 2,3-bis-(2-hydroxy-5-bromophenyl)-quinoxaline (XIX) and 4,5-bis-(2-hydroxy-5-bromophenyl)-glyoxalone (XX). The imidazole was prepared from 2,2′-dihydroxy-5,5′-dibromobenzil

(10) Thiele, *Ann.*, **306**, 142 (1899).

(X) by the improved procedure of Davidson, *et al.*[11] The quinoxaline (XIX) was obtained from X and *o*-phenylenediamine. The glyoxalone (XX) was formed from 2,2′-dihydroxy-5,5′-dibromobenzoin (III) as in "Organic Syntheses."[12]

**Chemotherapeutic Results.**[13]—5,5′-Dibromosalicil, its water-soluble borate complex and the thirteen dibromo derivatives which constitute chemical variations of dibromosalicil were tested as to their toxicity for mice and their possible therapeutic effect in selected experimental infections.

**Toxicity.**—Since the majority of compounds were insoluble in water, they were administered by the oral route. Their LD50 was found to be higher than 5.0 g./kg., *i.e.*, that a 10% suspension given by gavage did not produce toxic symptoms. Compound VIII was injected by the subcutaneous route dissolved in peanut oil. A 5% solution was tolerated, corresponding to LD50 of more than 2.5 g./kg. The LD50 of 5,5′-dibromosalicil borate complex was 0.095 g./kg. for the subcutaneous injection.

**Chemotherapeutic Activity** *in vivo*.—All compounds were tested in experimental infections with a hemolytic streptococcus (group A, type 3), or a type 1 pneumococcus, but none of them exerted any therapeutic effect. Furthermore all compounds were tried in the infection with poliomyelitis virus (SK strain). Up to ten treatments were given during the incubation period, but no protective effect was noted. There was also no evidence of the alleged activity of dibromosalicil in experimental influenza infections of mice (intranasal infection with type A strain PR 8). Neither dibromosalicil nor its borate complex and none of the other compounds had any significant activity toward this viral infection.

Two compounds, VI, IX, were also tried in mice infected with *Trypanosoma equiperdum*. No trypanocidal effect was observed.

**Anti-bacterial Activity** *in vitro*.—The lack of solubility in water of most of the compounds did not allow determinations of the bacteriostatic activity *in vitro* at least not with the usual methods of the dilution test. Two compounds, the borate complex and III, were sufficiently soluble to permit *in vitro* testing. The results are shown in the Table I which gives the reciprocal figures of the minimal bacteriostatic concentrations after forty-eight hours of contact.

TABLE I

| Compound | Strepto-cocci | Pneumo-cocci | *Staph. aureus* | *E. coli* | *E. typhosa* |
|---|---|---|---|---|---|
| 5,5′-Dibromosalicil borate complex | 25,600 | 25,600 | 1,024,000 | 51,200 | 6400 |
| 2,2′-Bis-β-diethyl-aminoethoxy-5,5′-dibromo-benzil dihydro-chloride | 128,000 | 64,000 | 16,000 | 8,000 | 1000 |

The findings, as far as the soluble borate complex of 5,5′-dibromosalicil is concerned, confirm the figures recently given by Schales and Suthon[14] particularly the specific effect on *Staphylococcus aureus*. The substituted dibromobenzil derivative XI had a more marked limitation of activity to the group of gram-positive organisms.

## Experimental

**Chloromethyl Ether.**—This compound was prepared according to the method of Clarke, Cox and Mack.[15]

**5-Bromo-2-hydroxybenzaldehyde.**—This compound was prepared as per Avwers and Burger[16] by bromination of salicylaldehyde.

**2-(Methoxymethoxy)-5-bromobenzaldehyde (I).**—To a solution of 63.5 g. of sodium in methanol, 555 g. of 5-bromo-2-hydroxybenzaldehyde and 2.5 liters of dry toluene were added. The excess methanol was removed by distillation. After cooling to 0°, 220 g. of pure chloromethyl ether was added dropwise with stirring during one hour keeping the temperature between 0–10°. After the reaction was stirred and refluxed for one hour, the mixture was slightly acid. After cooling to room temperature, water was added to dissolve the sodium chloride and separated. The toluene layer was extracted with dilute sodium hydroxide until a test portion of the washings did not produce a precipitate upon acidification. Then, the toluene solution was washed with water until neutral and concentrated *in vacuo* from a water-bath to remove the solvent leaving a yellow oil, which was fractionated *in vacuo*. At 5 mm. the desired product was collected between 152–154°. The yield was 82%. *Anal.* Calcd. for $C_9H_9O_3Br$: C, 44.21; H, 3.70. Found: C, 43.55; H, 3.76.

**2,2′-Di-(methoxymethoxy)-5,5′-dibromobenzoin (II).**—A solution of 296 g. of 2-methoxymethoxy-5-bromobenzaldehyde in 320 cc. of alcohol was mixed with a solution of 31 g. of potassium cyanide in 100 cc. of water and refluxed for two hours. As much alcohol as possible was distilled off from the steam-bath and the heavy residual oil was poured into cold water. The organic product was extracted with ether which was washed with water. The small amount of solid interface was discarded. The ether solution was dried and concentrated *in vacuo*. The remaining oil was dissolved in 170 cc. of warm methanol. Upon cooling, the benzoin compound crystallized. After recrystallization it melted at 89–91°. *Anal.* Calcd. for $C_{18}H_{18}O_6Br_2$: C, 44.11; H, 3.70. Found: C, 43.87; H, 3.68.

**2,2′-Dihydroxy-5,5′-dibromobenzoin (III).**—To a solution of 100 g. of 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin in 500 cc. of warm acetic acid, 40 cc. of 15% sulfuric acid was added, and the mixture then heated on the steam-bath for two minutes. It was poured into cold water and the resulting oil taken up into ether. The ethereal solution was washed with water, then with a sodium bicarbonate solution until the washings were alkaline and finally with water. After drying over sodium sulfate, the ether was distilled off. The residual oil was dissolved in benzene and the product induced to crystallize by scratching and seeding; m. p. 133–135°. This was sufficiently pure for the following reactions. Further purification when necessary was effected by several recrystallizations from benzene; m. p. 146–146.5°. *Anal.* Calcd. for $C_{14}H_{10}O_4Br_2$: C, 41.81; H, 2.51; Br, 39.74. Found: C, 41.72; H, 2.58; Br, 39.64.

**2,2′-Dihydroxy-5,5′-dibromodihydrobenzoin (V).**—A 5-g. solution of 2,2′-dihydroxy-5,5′-dibromobenzoin (III) was prepared in 100 cc. of wet ether. While a stream of carbon dioxide was passed through the solution, 18 g.

(16) Avwers and Burger, *Ber.*, **37**, 3934 (1904).

of 3.3% sodium amalgam was added in small portions. The *p*H of the mixture was thus kept at 8 (or below). It was necessary to replace the ether lost by evaporation. Small amounts of water were added from time to time to replace that used in the reaction and to dissolve some of the salts formed. After two hours, the addition was completed. When hydrogen was no longer evolved, water was added to dissolve the sodium bicarbonate. The ether layer was separated, washed with water and dried. When the ether was removed, crystals were obtained which melted between 136–138°. When recrystallized from acetone–Skellysolve B mixture, m. p. 149–152°. This proved to be a mixture of the *dl*- and *meso*. Upon repeated crystallization, one product m. p. 225–229° was obtained and probably is the *dl* (racemic) mixture. *Anal.* Calcd. for $C_{14}H_{12}O_4Br_2$: C, 41.61; H, 2.99; Br, 39.59. Found: C, 41.60; H, 3.06; Br, 39.56.

To obtain the *meso* form, the above mother liquors were combined and concentrated to obtain a solid. Upon recrystallization from benzene, the *meso* form was obtained pure; m. p. 155–156°. *Anal.* Calcd. for $C_{14}H_{12}O_4Br_2$: C, 41.61; H, 2.99; Br, 39.59. Found: C, 41.73; H, 2.87; Br, 39.37.

**2,2′-Dihydroxy-5,5′-dibromostilbene (VI).**—To zinc amalgam prepared from 5 g. of mercuric chloride and 20 g. of zinc dust, a solution of 9 g. of 2,2′-dihydroxy-5,5′-dibromobenzoin (III) dissolved in 50 cc. of alcohol was added. While stirring and maintaining a reaction temperature of 15°, 40 cc. of concentrated hydrochloric acid was added dropwise over a period of two hours. After stirring for an additional hour, the mixture was diluted with a large volume of water and filtered. After washing with water, the residue was treated with ether to dissolve away the product from metal. The ether solution was dried and concentrated. The oil which was obtained soon crystallized. After three recrystallizations from xylene, the product was pure; m. p. 201–202°. This is the *trans* isomer. *Anal.* Calcd. for $C_{14}H_{10}O_2Br_2$: C, 45.41; H, 2.73; Br, 43.20. Found: C, 45.50; H, 2.64; Br, 43.03. The *cis* isomer was isolated from the xylene mother liquors and purified by recrystallization from benzene; m. p. 169–173°. *Anal.* Found: C, 45.18; H, 3.07.

**2,2′-Dihydroxy-5,5′-dibromomethoxybenzoin (VII).**—Zinc amalgam was prepared from 10 g. of mossy zinc, 1 g. of mercuric chloride, 0.5 cc. of concentrated hydrochloric acid and 15 cc. of water. To the amalgam, were added 5 g. of 2,2′-dihydroxy-5,5′-dibromobenzoin, 20 cc. of water and 20 cc. of concentrated hydrochloric acid. Upon refluxing, a vigorous reaction took place and, to prevent the solids from coating the flask, 5 cc. of alcohol was added. The reaction mixture was refluxed for five hours and at each hour 2 cc. of concentrated hydrochloric acid was added. After cooling, filtering and washing with water, the product was taken up in ether to separate it from the metal, and dried. Upon removal of the ether, a greenish glassy substance was obtained. It was then triturated with methanol whereupon some crystals appeared. Another crop was obtained by concentrating the methanol. The second crop was recrystallized twice from xylene; m. p. 173–175°. *Anal.* Calcd. for $C_{14}H_{12}O_2Br_2$: C, 45.20; H, 3.25; Br, 42.95. Calcd. for $C_{15}H_{13}O_4Br_2 \cdot H_2O$: C, 41.54; H, 3.22; Br, 36.86. Found: C, 41.54; H, 2.23; Br, 36.89.

**2,2′-Diacetoxy-5,5′-dibromobenzoin (IV).**—Eighty grams of 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin was dissolved in 300 cc. of glacial acetic acid with warming, and 32 cc. of 15% sulfuric acid was added. The solution was heated on the steam-bath for thirty minutes and worked up as for III above. The benzene solution did not produce any crystals and so was concentrated on the steam-bath to a smaller volume. After keeping in the refrigerator, a small amount of crystals appeared. These were collected and washed with benzene; m. p. 183–187°. For Compound III the m.p. 146–146.5°. By recrystallization from methanol, the pure compound was obtained; m. p. 199–201°; no color with ferric chloride. *Anal.* Calcd. for $C_{14}H_{10}O_4Br_2$ (free phenol): C, 41.81; H, 2.51. Calcd. for $C_{16}H_{12}O_5Br_2$ (mono-acetoxy): C, 43.28; H, 2.73. Calcd. for $C_{18}H_{14}O_6Br_2$ (di-acetoxy): C, 44.46; H, 2.90. Found: C, 44.77, 44.58; H, 2.65, 2.57.

**Conversion of IV to III.**—One-half gram of IV and 5 cc. of 10% sodium hydroxide were mixed. The solid turned yellow and, upon heating on the steam-bath, went into solution. Upon cooling, the yellow sodium salt precipitated out. The mixture was acidified with dilute hydrochloric acid and a colorless product was obtained. It was filtered, washed and purified; m. p. 143–145°; for III crystallized several times from benzene, m. p. 146–146.5°.

**2,2′-Di-(methoxymethoxy)-5,5′-dibromobenzil (VIII).**—To 64.5 g. of crude 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin in 75 cc. of alcohol, the following were added: A, 151 g. of $CuSO_4 \cdot 5H_2O$ in 600 cc. of water; B, 225 g. of $KNaC_4H_4O_6 4H_2O$ and 162 g. of potassium hydroxide dissolved in water to a volume of 860 cc. The reaction mixture was stirred at 75–80° for two hours. After cooling, the product was collected and freed from copper oxide by dissolving in hot alcohol and decolorized with Nuchar. The filtrate yielded practically colorless crystals. When recrystallized from alcohol, the compound was pure; m. p. 115–116°. A second crop can be obtained from the mother liquors. *Anal.* Calcd. for $C_{18}H_{16}O_6Br_2$: C, 44.28; H, 3.30. Found: C, 44.10; H, 3.43.

**2,2′-Dihydroxy-5,5′-dibromo-α,α-diacetoxystilbene (IX).**—Six grams of 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzil VIII was added to 10 cc. of acetic acid previously saturated with dry hydrogen chloride. Then, 60 cc. of acetic anhydride was added, and while stirring at 30°, zinc dust was added over one-half hour in several portions until 6 g. was added. The mixture was then stirred for an additional hour and a half and poured into 500 cc. of cold water. After standing overnight, the oil was extracted with ether, washed, first with water and then sodium bicarbonate and then water again. After drying over sodium sulfate, the ether was removed and the residual oil soon crystallized. It was purified by crystallization from butanol; m. p. 121–124°. *Anal.* Calcd. for $C_{18}H_{14}O_6Br_2$: C, 44.48; H, 2.90; Br, 32.88. Found: C, 44.27; H, 3.13; Br, 32.52.

**2,2′-Dihydroxy-5,5′-dibromobenzil (X).**—Fifty grams of 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzil (VIII) was dissolved in 250 cc. of glacial acetic acid. To the hot solution, 17 cc. of 15% sulfuric acid was added. Then, at once, 25 cc. of hot water was added and immediately crystals began to form. The heating was continued for one minute and the mixture cooled. The product was filtered, washed with methanol and dried at 90; m. p. 204–206°. Recrystallized from alcohol, the product was obtained pure; yield 95%; m. p. 209–210°; lit. m. p. 210°. *Anal.* Calcd. for $C_{14}H_8O_4Br_2$: C, 42.04; H, 2.03. Found: C, 42.44; H, 2.12.

**2,2′-Dihydroxy-5,5′-dibromodiphenylethane (XV).**—To a refluxing mixture of 2 g. of 2,2′-dihydroxy-5,5′-dibromobenzil (X) dissolved in 60 cc. of alcohol, 3.5 g. of 30-mesh zinc and 5 cc. of concentrated hydrochloric acid was added. A vigorous reaction took place. At half-hour intervals, 5-cc. portions of acid were added. After one-half hour, the yellow color was discharged and after one and one-half hours, the refluxing ceased. After cooling, the solution was poured into water yielding an oil which soon crystallized. The product was filtered and dried at 100°; m. p. 153–160°. After recrystallization from benzene, the product melted at 172–173°. *Anal.* Calcd. for $C_{14}H_{12}O_2Br_2$: C, 45.20; H, 3.25; Br, 42.95. Found: C, 45.64; H, 2.54; Br, 43.22.

**2,2′-Di-(β-diethylaminoethoxy)-5,5′-dibromobenzil (XI).**—The disodium salt of 2,2′-dihydroxy-5,5′-dibromobenzil was prepared from 6.5 g. of the compound and 2 equivalents of sodium ethylate in alcohol and obtained dry by continuous concentration with benzene. It was then treated with excess β-diethylaminoethyl chloride in 100 cc. of dry toluene and refluxed for ten hours with continuous stirring. The sodium chloride was filtered off and the toluene solution was washed with alkali and then with water. The solution was dried over sodium sulfate and concentrated *in vacuo*. The oil soon crystallized. The free base so obtained melted at 82–84°. When recrystal-

lized from Skellysolve B, yellow crystals were obtained; m. p. 84–86°. *Anal.* Calcd. for $C_{26}H_{34}O_4Br_2N_2$: C, 52.18; H, 5.72; N, 4.68. Found: C, 52.18; H, 5.44; N, 4.72. The base was converted into the di-hydrochloride and recrystallized from isopropyl alcohol; m. p. 195–196°. *Anal.* Calcd. for $C_{26}H_{34}O_4Br_2N_2 \cdot 2HCl$: C, 46.53; H, 5.40; N, 4.17. Found: C, 46.67; H, 5.18; N, 4.36.

**5,5′-Dibromo-2,2′-α,α′-tetraacetoxystilbene (XIV).**—To 5 g. of 2,2′-dihydroxy-5,5′-dibromobenzil (X) dissolved in 60 cc. of acetic anhydride, 10 cc. of acetic acid previously saturated with hydrogen chloride at 15° was added with stirring and cooling. Then, at 30–40°, 6 g. of zinc dust was gradually added. The reaction mixture turned green and then black. After one hour, the reaction mixture was poured into 500 cc. of cold water. The sticky solid thus produced was filtered and dissolved in ether. The ethereal solution was first washed with water then with sodium bicarbonate and water. When dried, the solution was concentrated leaving an oil. When treated with butanol, the product crystallized. It was then recrystallized from butanol several times to constant melting point; m. p. 155–157°. *Anal.* Calcd. for $C_{22}H_{18}O_8Br_2$: C, 46.31; H, 3.18; Br, 28.02. Found: C, 45.87; H, 3.27; Br, 28.22.

**2,2′-Dihydroxy-5,5′-dibromo-α-acetoxystilbene (XII).**—To a suspension of 4.5 g. of 2,2′-dihydroxy-5,5′-dibromobenzil (X) in 60 cc. of acetic anhydride, with cooling, a solution of 5 cc. of concentrated sulfuric acid in 10 cc. of acetic acid was slowly added to avoid undue rise in temperature. Then, at 30–40°, 6 g. of zinc dust was gradually added with good stirring. After one hour, white crystals appeared. The reaction mixture was diluted with water and filtered. To separate the zinc, the compound was extracted in a Soxhlet extractor with ether. The ether removed, the solid was recrystallized from butanol until pure; m. p. 145–147°. *Anal.* Calcd. for $C_{16}H_{12}O_4Br_2$: C, 44.85; H, 2.80; Br, 37.40; acetyl, 10.1. Found: C, 44.74; H, 2.61; Br, 37.25; acetyl, 10.9.

**2,2′-Dihydroxy-5,5′-dibromodesoxybenzoin (XIII).**—A solution of 1.8 g. of 2,2′-dihydroxy-5,5′-dibromo-α-acetoxystilbene (XII) in 18 cc. of 10% sodium hydroxide was warmed for fifteen minutes on the steam-bath. After neutralization with dilute hydrochloric acid, the product crystallized. It was filtered, washed and recrystallized from benzene until it melted at 209–211°. *Anal.* Calcd. for $C_{14}H_{10}O_3Br_2 \cdot {}^1/_2H_2O$: C, 42.55; H, 2.78; Br, 40.51. Found: C, 42.24; H, 2.64; Br, 40.59.

**2-(2′-Hydroxy-5′-bromophenyl)-3-methoxy-5-bromocoumarone (XVI).**—A solution of 3.5 g. of 2,2′-dihydroxy-5,5′-dibromobenzoin (III) in 50 cc. of methanol was saturated with dry hydrogen chloride without any cooling. The temperature rose sufficiently to cause refluxing. After saturation and cooling, the product crystallized out. It was recrystallized from methanol, m. p. 103–104°. The Fehling test is negative. *Anal.* Calcd. for the coumarone $C_{15}H_{10}O_3Br_2$: C, 45.25; H, 2.53; Br, 40.12. Found: C, 45.78; H, 2.69; Br, 40.15.

**2-(2′-Hydroxy-5′-bromophenyl)-3-hydroxy-5-bromocoumarone (XVII).**—A. A solution of 3 g. of 2,2′-dihydroxy-5,5′-dibromobenzoin (III) in 100 cc. of methanol was cooled to −15° and saturated with dry hydrogen chloride. During the reaction, the temperature rose to 10°, before it could be checked, and then kept at 0°. The saturated solution was poured into 500 cc. of ice-water and the resultant precipitate filtered, washed with water and dissolved in ether. The ether solution was extracted with dilute sodium hydroxide and the combined alkali extracts were acidified. The solid was collected and recrystallized from toluene, m. p. 155–156°. The Fehling test was positive. *Anal.* Calcd. for the coumarone $C_{14}H_8O_3Br_2$: C, 43.80; H, 2.10. Found: C, 44.06; H, 1.94. B. A solution of 4 g. of 2,2′-di-(methoxymethoxy)-5,5′-dibromobenzoin (II) in 100 cc. of methanol at −25° was saturated with dry hydrogen chloride keeping the temperature below 0°. The yellow precipitate obtained when the reaction mixture was poured into ice-water was collected and recrystallized from toluene; m. p. 158–159°. When mixed with the compound obtained in A, there was no depression. It also gave a positive Fehling test. *Anal.* Calcd. for $C_{14}H_8O_3Br_2$: C, 43.80; H, 2.10; Br, 41.61. Found: C, 43.96; H, 2.17; Br, 41.33.

**Conversion of *cis*-2,2′-Dihydroxy-5,5′-dibromo-α-methoxybenzoin to *trans* Form.**—Ninety mg. of *cis*-2,2′-dihydroxy-5,5′-dibromo-α-methoxybenzoin was dissolved in 5 cc. of methanol and saturated with dry hydrogen chloride without cooling. Then, after refluxing for fifteen minutes, it was cooled and crystals separated. After filtering and recrystallizing from methanol, it melted at 119–121°. *Anal.* Calcd. for $C_{15}H_{10}O_3Br_2$ (coumarone): C, 45.28; H, 2.53; Br, 40.12. Calcd. for $C_{15}H_{12}O_4Br_2 \cdot H_2O$ (starting compound): C, 41.50; H, 3.22; Br, 36.86. Found: C, 42.22; H, 2.79; Br, 36.83.

**4,5-bis-(2-Hydroxy-5-bromophenyl)-imidazole (XVIII).**—A mixture of 3.0 g. of 5,5′-dibromosalicil (X), 0.2 g. of hexamethylenetetramine, 4.5 g. of ammonium acetate and 95 cc. of glacial acetic acid was refluxed for one hour. After *dilution* with 900 cc. of water and clarification by filtration, the solution was made alkaline with ammonia. The precipitate was collected and recrystallized from dilute alcohol twice and dried at 100°; m. p. 235–237°. *Anal.* Calcd. for $C_{15}H_{10}N_2O_2Br_2$: N, 6.83. Found: N, 7.05.

**2,3-bis-(2-Hydroxy-5-bromophenyl)-quinoxaline (XIX).**—A solution of 4 g. of 5,5′-dibromosalicil (X), 1 g. of *o*-phenylenediamine in 125 cc. of acetic acid was refluxed for three hours and poured into ice. The crystallized product was dried by distillation of a benzene solution and recrystallized from small amounts of benzene; m. p. 216–219°. With 5,5′-dibromosalicil, the melting point was depressed. This compound does not form a hydrochloride. *Anal.* Calcd. for $C_{20}H_{12}O_2N_2Br_2$: C, 50.85; H, 2.56; N, 5.94. Found: C, 50.68; H, 2.67; N, 5.85.

**4,5-bis-(2-Hydroxy-5-bromophenyl)-glyoxalone (XX).**—A solution of 3 g. of 2,2′-dihydroxy-5,5′-dibromobenzoin (III), 0.81 g. of urea in 20 cc. of glacial acetic acid was refluxed for seven hours, during which time crystallization started. After standing, the product was filtered and washed with ether to remove starting material. The compound was purified by recrystallization from aqueous pyridine; m. p. 272–273°. *Anal.* Calcd. for $C_{15}H_{10}N_2O_3Br_2$: C, 42.30; H, 2.37; N, 6.58. Found: C, 42.50; H, 2.75; N, 6.41.

**Acknowledgment.**—The authors wish to thank Dr. John Lee for his interest, advice and helpful discussions during the course of this research and also Dr. Al Steyermark and his associates for the microanalyses.

## Summary

The 2,2′-dihydroxy-5,5′-dibromosalicil (5,5′-dibromosalicil) compound of Kuhn was synthesized and his claims for its activity toward virus infections could not be substantiated.

Many closely related compounds were synthesized and tested *in vitro* against hemolytic streptococcus, pneumococcus, poliomyelitis, trypanosoma, and gram-positive organisms without revealing any marked activity.

It was shown that benzoins substituted on the adjacent carbon atom with a hydroxy group can be converted into a coumarone upon treatment with dry hydrogen chloride.

The keto-alcohol part of the substituted benzoin molecule is capable of reaction to produce a cyclic compound as a glyoxalone.

The di-keto part of the substituted benzil molecule is capable of reaction to produce cyclic derivatives as the imidazole and quinoxaline.

# Reactions of Dehydroperillic Acid

BY CHARLES D. HURD AND O. E. EDWARDS[1]

A crystalline acid, m.p. 88°, obtainable from the heartwood of Western Red Cedar was studied by Anderson and Sherrard.[2] It was named dehydroperillic acid and was assigned structure I.

I

Some of this compound was prepared for the present study through the courtesy of W. G. Van Beckum of Weyerhaeuser Timber Company.

It was found that the acyl chloride could be prepared by use of thionyl chloride and pyridine but not by thionyl chloride alone, since alkaline hydrolysis of the latter product gave rise to a mixture of carboxylic acids melting over a wide range. Anderson and Sherrard noted that dehydroperillic acid underwent isomerization into cuminic (*p*-isopropylbenzoic) acid when heated with mineral acids. The dehydroperillyl chloride formed in the presence of a little pyridine, however, was readily hydrolyzed to dehydroperillic acid of reasonable purity. Treatment of the acyl halide with ethanol, ammonia or aniline caused conversion to the ethyl ester, amide and anilide, respectively.

The isoprene-like structure of dehydroperillic acid made it seem reasonable to expect ease of polymerization but any such tendency was found to be slight. Attempts to polymerize the ester or the acid by heating with benzoyl peroxide were negative. The butyl-rubber type of polymerization procedure was also unsatisfactory. For these tests we are indebted to P. J. Frolich and W. J. Sparks of Esso Laboratories, Linden, New Jersey. They tested the acid, ester and anilide and found that although resinous products or oils could be obtained both at −23 or −97°, the degree of polymerization was low. Copolymerization experiments with isobutylene were unsuccessful also, since small quantities of dehydroperillic acid or its derivatives inhibited the reaction to such an extent that the only polymers formed were much too low in molecular weight for adequate vulcanizability. If the two double bonds in the ring of structure I were changed so as not to be conjugated with the double bond of the side chain, the present data would then become more understandable. The unconjugated, terminal methylene group seems necessary, however, to explain formaldehyde on ozonolysis[2] of I.

(1) Weyerhaeuser Timber Company Fellow, 1943.

(2) Anderson and Sherrard, THIS JOURNAL, **55**, 3813 (1933). In a private communication Dr. Anderson advises that Dr. H. Erdtman and associates of the Royal Institute of Technology, Stockholm, are investigating this acid with a view toward more complete elucidation of its structure.

## Experimental

Crude dehydroperillic acid was purified by crystallization from alcohol. Colorless needles were obtained melting at 85–86.5°.

**Dehydroperillyl Chloride.**—Five grams of the acid was added gradually into a mixture of 8 g. of thionyl chloride and five drops of pyridine. The temperature dropped rapidly to 10–15° as sulfur dioxide and hydrogen chloride were evolved. The reaction mixture was left at room temperature for twenty minutes after the acid was all added. Gas evolution had ceased at this time. The product was used directly for the preparation of the anilide.

**Dehydroperillanilide.**—The above crude acyl chloride was added slowly into a mixture of aniline (10 g., an excess) and benzene (60 cc.). A vigorous reaction ensued. The aniline hydrochloride was separated and any excess of aniline in the benzene layer was removed by washing with dilute hydrochloric acid, then with dilute alkali. The crude anilide (6.5 g.) remaining on evaporation of the solvent was crystallized from 75% alcohol; m.p. 97–98°.

*Anal.* (by T. S. Ma). Calcd. for $C_{16}H_{17}NO$: N, 5.86. Found: N, 5.68.

**Dehydroperillamide.**—Five grams of the acid was converted to the acyl chloride as before, and to the latter, dissolved in ether, was added powdered ammonium carbonate until gas was no longer evolved. Water was then added and the ether layer was separated, washed with concentrated ammonium hydroxide, then processed for the amide. Crystallization from 50% alcohol yielded colorless plates of m.p. 95–96°; yield 2 g.

*Anal.* (by M. Hines). Calcd. for $C_{10}H_{13}NO$: C, 73.58; H, 8.03. Found: C, 73.43; H, 8.03.

**Ethyl Dehydroperillate.**—The acid chloride, prepared from 16 g. of acid, was poured slowly into a mixture of 24 g. of absolute alcohol and 14 g. of dry pyridine. After warming the solution for ten minutes on the steam-bath, it was poured into water and the ester was taken up in ether. As finally purified, the ester was collected at 88° (4 mm.); yield, 13 g. or 70%; $d^{25}_{25}$ 0.999. On alkaline hydrolysis, it gave a 95% yield of pure dehydroperillic acid.

*Anal.* (by T. S. Ma). Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39. Found: C, 73.77; H, 8.26.

**Heating with Benzoyl Peroxide.**—No polymeric material resulted on heating a mixture of 0.05 g. of benzoyl peroxide and 1.5 g. of dehydroperillic acid at 95° for one day. Similarly, 1.5 g. of the ethyl ester was not changed by heating at 70° with 0.07 g. of the peroxide.

It is of interest to note that when the acid was heated alone at 110° for half an hour, no pyrolysis was evident. The melt crystallized on cooling, m.p. 85–88°.

## Summary

Derivatives of dehydroperillic acid are reported. The conjugate unsaturation in the structure of these compounds suggests ready polymerizability which was not experienced in practice.

# *p*-Toluenesulfonyl and Iodo Derivatives of the Three Lower Polyethylene Glycol Monoethyl Ethers[1]

BY CLINTON W. TASKER AND C. B. PURVES[2]

As a prelude to a study of the hydroxyethyl ethers of cellulose,[3] it seemed advisable to check the physical properties of the *p*-toluenesulfonyl (tosyl) esters of simple monoethyl ethers in the polyethylene glycol series, and to examine the reactivities of the tosyloxy group during solvolysis and toward sodium iodide. The general formula of the compounds studied was $C_2H_5(OCH_2CH_2)_xR$, where $x$ was 1, 2 or 3, and R was OH, OTs or I. The marked tendency of some of the derivatives to undergo autoxidation during brief storage was noted, and the products formed in the thermal decomposition of the two higher tosylates were identified. A knowledge of these peculiarities made it possible to prepare the hitherto missing members of the above series.

Wurtz[4] noticed in 1859 that ethylene oxide slowly condensed with hydroxylic substances, and the employment of metallic catalysts by later investigators[5,6,7] to hasten such condensations resulted in a general method of preparing the monoalkyl ethers of polyethylene glycols. Another general method depended on the condensation of an appropriate sodium alcoholate with an appropriate alkyl halide.[8,9,10,11] The physical constants of lower members of the series, collected by Davidson,[12] revealed the interesting fact that the boiling points of the monoethyl ethers were very close to those of the next lower, unsubstituted polyethylene glycol. Unfortunately, this fact was overlooked until 1941, when Seikel[13] found that the monoethyl ether of diethylene glycol (x, 2; R, OH) could not be satisfactorily freed from ethylene glycol by fractional distillation. The observation that commercial samples of the monoether contained up to 28% of glycol explained in some degree the variable values quoted in the literature for the physical constants of this substance, and the many failures encountered in attempts to obtain crystalline derivatives.[14,15,16,17,18] The use of a sample adequately purified from glycol enabled Shupe[19] to crystallize the xanthate of diethylene glycol monoethyl ether, and recent workers[20] isolated crystalline tri-iodobenzoates of various monoethers of ethylene glycol and diethylene glycol without undue difficulty.

Cretcher and his collaborators[21,22] prepared the tosyl esters of a large number of the monoalkyl ethers of ethylene glycol, including that of the monoethyl ether (x, 1; R, OTs). The side reactions liable to occur during such tosylations were carefully investigated by Tipson,[23] who was able to improve the method of preparation. Although some of these esters were oils that decomposed on distillation,[22,24] the tosyl group was sufficiently resistant to hydrolysis to permit of their purification by thorough washing in cold water. The higher members of the series (x, 2 and 3; R, OTs) do not seem to have been accurately characterized, although presumably they were included in a patent by Adams,[24] which described the series in general terms as heavy, viscous oils, insoluble in water but soluble in organic liquids.

The action of sodium iodide in a ketone solvent would be expected to substitute an iodine atom for the tosyloxy group in the above esters, since all of the latter are derived from primary alcohol units.[25] β-Iodoethyl ether (x, 1; R, I), the product from the lowest member of the series, was first encountered in a preparation of ethylene di-iodide from ethylene and an alcoholic solution of iodine.[26] Later syntheses, which established the correct structure, involved the action of phosphorus tri-iodide on ethylene glycol monoethyl ether,[27,28] and of sodium iodide on β-chloroethyl ether.[29] Although decomposed by sodium ethylate at 150°[26,27] and by alcoholic silver nitrate,[30]

β-iodoethyl ether was stable to solid potassium hydroxide at 150°,[26,27] to tripropylamine at 100° for one hour,[30] and was affected neither by sodium amalgam,[26,27] nor by distillation (b.p. 155°) from pulverized silver[28] or metallic sodium.[30] The halogen atom in β-iodoethyl ether therefore has the low reactivity that is a general characteristic of β-, as opposed to α-halogen substituted ethers.[29] No reference has been found to the higher members of the iodinated ethers under consideration (x, 2 or 3; R, I).

## Experimental

**Materials and Reagents.**—Technical ethylene glycol monoethyl ether was thoroughly dried over anhydrous calcium sulfate and fractionally distilled through a Vigreux column. The fraction, free from aldehydes and peroxide, boiling correctly at 134.5° and with the correct refractive index of $n^{20}D$ 1.4073, was collected.[31] A benzene solution of technical diethylene glycol monoethyl ether was selectively extracted with water, by Seikel's[13] procedure, to remove ethylene glycol. It was not found necessary to remove any residual traces of the glycol from the dried benzene solution by a subsequent selective oxidation with lead tetraacetate,[32] a reagent which, indeed, slowly oxidized the monoether. Care was taken to fractionate repeatedly until all traces of peroxide oxygen and aldehydes were absent from the product, which had the correct b. p. of 196° (760 mm.) and $n^{20}D$ 1.4273.

Technical ethylene chlorohydrin was dried over anhydrous sodium sulfate and vacuum distilled. To avoid thermal decomposition,[33] a stream of dry carbon dioxide was passed through the still to prevent bumping. The fraction collected boiled constantly at 38.5–39.0° (10 mm.) and samples had the recorded constants b. p. 128.7° (760 mm.), and $n^{15}D$ 1.4438.[34]

Ethyl *p*-toluenesulfonate, prepared by Tipson's[23] method in a crude yield of 73%, gave 49% of recrystallized material melting correctly at 33 to 34°. A similar preparation[23] gave an 83% yield of analytically pure ethylene glycol monoethyl ether *p*-toluenesulfonate, melting correctly at 18.5°. The tosyl chloride used in such preparations, together with all organic solvents, was carefully purified by standard procedures.

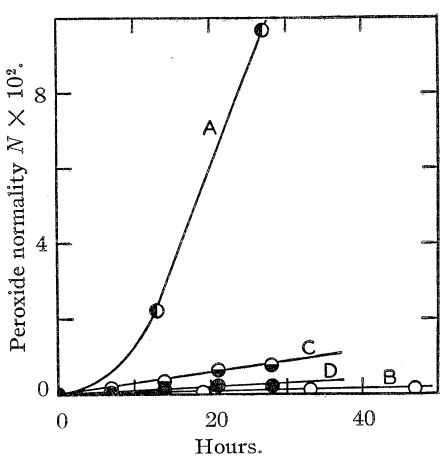

Fig. 1.—Peroxide formation: plot A, diethylene glycol monoethyl ether stored in light and air; plot B, the same in dark and nitrogen; plot C, ethylene glycol monoethyl ether in light and air; plot D, the same in dark and nitrogen.

**Analytical Methods.**—Combustion and other analyses were on the semimicro scale. Attempts were made to determine sulfur by a sodium peroxide fusion followed by a barium chloride titration with tetrahydroquinone as an internal indicator.[35] These attempts were discontinued because of difficulties with the end-point, and all sulfur analyses reported were by a standard Carius method employing barium chloride instead of silver nitrate.[36] Decomposition of the β-iodoethers by alcoholic caustic soda was quite inadequate to serve as a basis for rapid iodine estimations[37] and so the gravimetric Carius method[36] was used.

The fact that ethoxy estimations with hydriodic acid gave erratic and high results in the polyethylene oxide series[38,39,40,41] was thoroughly confirmed, but Morgan's[42] estimation for the ethylene as well as the ethyl iodide evolved from these substances was published too late for adoption in the present work.

**Peroxides and Autoxidation.**—Peroxides were detected by adding 1 cc. of the sample to 1 cc. of a 50% solution of aldehyde-free acetic acid. After shaking, a few mg. of potassium iodide was added and the mixture, together with a blank, was kept in the dark for five minutes. Even small traces of peroxide were sufficient to develop the deep color of free iodine. Quantitative estimations (Fig. 1) required a solution of potassium iodide in a glacial acetic acid–sodium bicarbonate mixture.[43] After discharging the slight yellow color of the mixture with 0.01 *N* sodium thiosulfate, better to a visual than to a starch end-point, the iodine liberated by the addition of the sample was titrated with the thiosulfate. This titration had to be carried out in stages at ten-second intervals, since the reaction was not instantaneous. With 5-cc. samples, the volume in cc. of peroxide oxygen per liter was 11.2 times the consumption of 0.01 *N* thiosulfate in cc.[44] The data were corrected for a blank which was usually 0.1 cc., and the limit of error of about 0.1 cc. corresponded to $2 \times 10^{-4}$ *N* peroxide.

Aldehydes were detected by Brady's 2,4-dinitrophenylhydrazine reagent[45] and were identified by Allen's[46] modification of the method. A red-orange 2,4-dinitrophenylhydrazone was obtained as small needles from samples of ethylene and diethylene glycol monoethyl ethers which contained peroxides. After recrystallization from glacial acetic acid or nitrobenzene, the hydrazone melted at 332° (cor.) and a mixed m. p., with authentic glyoxal-bis-2,4-dinitrophenylhydrazone (m. p. 330°[47]) was not depressed. Wieland and Wingler's work[48] was adapted for estimations of acidity caused by peroxide formation.

**Density and Molecular Refraction.**—Standard directions[49] were followed, densities being determined in 1.0 cc. and 0.1 cc. pycnometers and refractive indices with an Abbé refractometer kept to ±0.1° of the desired temperature and re-calibrated frequently. The Lorenz and Lorentz function was used to calculate molecular refractions from observed densities and refractive indices. Molecular refractions were also calculated from a table of atomic refractivities.[49] The results are collected in Table I.

**Triethylene Glycol Monoethyl Ether (x, 3; R, OH).**—A three-necked, round-bottomed, glass-jointed flask was equipped with a capillary bubbling tube, a mechanical stirrer with mercury seal and a reflux condenser closed by a calcium chloride drying tube. After adding 175 cc. of anhydrous methanol, the air in the system was thoroughly displaced by a stream of dry, oxygen-free nitrogen introduced through the capillary below the level of the methanol. Clean sodium (16.2 g., 0.704 mole) was then added piece by piece through the condenser and, when all had dissolved, 105 g. (0.784 mole) of pure diethylene glycol monoethyl ether was introduced. Keeping a large flow of nitrogen passing through the system, the stirrer was replaced by a plug, and the reflux condenser was turned downward for distillation. The methanol was then removed by gradually increasing the bath temperature to 100° and decreasing the pressure to 20 mm. The viscous, deep red-brown residue of the sodium alcoholate of the monoether was diluted with enough of the pure monoether to bring the molar excess over the sodium to 45%, and traces of methanol were eliminated by two to three days' heating at 100° (15 mm.).

A dropping funnel was attached while nitrogen perfused the system and 63 g. (0.774 mole or 10% excess) of pure ethylene chlorohydrin was slowly added, with vigorous stirring and heating under reflux at 70 to 80° for twelve hours. No volatile matter passed through the water-cooled condenser. The contents of the reaction flask were diluted with dry ether and filtered to recover 39.7 g. (95.6%) of sodium chloride. Evaporation of the ether and fractional distillation up to 95° at 15 mm. recovered some chlorohydrin and 33.3 g. of diethylene glycol monoethyl ether; refractionation of a higher-boiling fraction gave 48 g. of the same monoethyl ether and 38 g. of a fraction of b. p. 85–90° (0.5 mm.). Careful refractionation of the latter from a 50-cc. Widmer flask left 36 g. of pure triethylene glycol monoethyl ether having b. p. 86–91° (0.5 mm.).

*Anal.* Calcd. for $C_8H_{18}O_4$: C, 53.9; H, 10.2. Found: C, 53.7; H, 10.5.

The yield was 29% based on the sodium and 48% on the unrecovered monoethyl ether. An earlier run gave a 15% yield on the sodium, and another, using a larger excess of chlorohydrin, gave none of the desired product.

**Tosylate of Diethyleneglycol Monoethyl Ether (x, 2; R, OTs).**—A freshly purified, peroxide- and aldehyde-free sample of the monoethyl ether (30 g., 0.224 mole) was tosylated in anhydrous pyridine according to Tipson's procedure.[23] Four 100-cc. volumes of chloroform were used to extract the product from the final aqueous pyridine solution, and pyridine was removed from the extract by successive washing with ice-water, dilute sulfuric acid, ice-water and sodium bicarbonate solution. The chloroform was removed from the dried extract, using a capillary bubbler and pure dry nitrogen, by warming for ten hours at 42° (23 mm.), and finally for seven hours at 42–45° (0.1 mm.). The 51.1 g. (79.2%) of slightly yellow, viscous oil was analyzed without being fractionally distilled, since distillation caused decomposition.

*Anal.* Calcd. for $C_{13}H_{20}O_5S$: C, 54.2; H, 7.0; S, 11.1. Found: C, 53.8; H, 7.1; S, 11.1.

The substance was difficult to burn, for its sudden decomposition sent a rush of gas through the train. Other preparations resulted in yields of 84, 84 and 74%.

(49) Shriner and Fuson, "The Systematic Identification of Organic Compounds," 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1940.

**Tosylate of Triethylene Glycol Monoethyl Ether (x, 3; R, OTs).**—Tipson's procedure,[23] employing 0.056 mole (10g.) of the pure ether, 0.067 mole of tosyl chloride and 100 cc. of dry pyridine, gave 13.1 g. or 71% of a slightly yellow viscous oil. This oil was decolorized in hot benzene solution with adsorbent charcoal and, after recovery, was somewhat low in sulfur content but was halogen-free. Chilling caused the product to separate into two oily layers, but the fraction deposited from a hot, concentrated solution of petroleum ether (b. p. 30 to 60°) remained homogeneous when cooled, and was accepted as pure.

*Anal.* Calcd. for $C_{15}H_{24}O_6S$: C, 54.2; H, 7.3; S, 9.6. Found: C, 53.8; H, 7.4; S, 9.6.

Combustion difficulties were as encountered with the lower homolog. Other preparations gave 77% yields.

**β-Iodoethyl Ethyl Ether (x, 1; R, I).**—A solution of 0.0205 mole of pure ethylene glycol monoethyl ether tosylate and 0.05 mole of dry C. P. sodium iodide in 75 cc. of pure acetone was heated at 115° for two hours in a stainless steel bomb.[25] Filtration removed the crystalline deposit of sodium *p*-toluenesulfonate, and, after recovery, the residual slightly yellow oil was repeatedly distilled from solid sodium hydroxide.[30] The pure product, b. p. 154° (754 mm.), was isolated in 81% yield.

*Anal.* Calcd. for $C_4H_9OI$: I, 63.5. Found: I, 63.5.

**β-Iodo-β′-ethoxy Diethyl Ether (x, 2; R, I).**—A solution of 0.0626 mole of pure tosylated diethylene glycol monoethyl ether and 0.187 mole of sodium iodide in 625 cc. of dry acetone was kept for sixty hours at 22 to 23°. The filtrate from the precipitated sodium *p*-toluenesulfonate was concentrated *in vacuo* at 30° to a volume of 100 cc., and 200 cc. of dry ethyl ether was then added to precipitate residual sodium iodide. The ethereal solution and washings were extracted with 100 cc. of aqueous sodium thiosulfate to remove some free iodine, and after two extractions with ice-water were dried over anhydrous potassium carbonate. Removal of the ether, finally at 30° (0.06 mm.), and fractional distillation of the residue resulted in an 88% yield of a colorless oil, b. p. 42° (0.4 mm.).

*Anal.* Calcd. for $C_6H_{12}O_2I$: C, 29.5; H, 5.4; I, 52.0. Found: C, 29.8; H, 5.6; I, 51.5.

The pure substance was stable enough to undergo no change beyond slight discoloration when stored in a cool dark place for five months.

**β-Iodo-β′-ethoxyethoxy Diethyl Ether (x, 3; R, I).**—A solution of the corresponding pure tosylate, 0.042 mole, and sodium iodide, 0.141 mole, in 625 cc. of acetone was kept for five days at 20 to 25°. After recovering 96.7% of the theoretical amount of sodium *p*-toluenesulfonate, the product was isolated from the mother liquors as just described for the lower homolog. Distillation of the crude red oil gave a 73% yield of a clear, very slightly yellow oil, b.p. 97 to 98° (0.15 mm.).

*Anal.* Calcd. for $C_8H_{17}O_3I$: C, 33.3; H, 6.0; I, 44.1. Found: C, 33.4; H, 6.0; I, 44.0.

**Thermal Decomposition of Higher Tosylates.**—(a) Tosylated Diethylene Glycol Monoethyl Ether: The pure ester (22.6 g., 0.0786 mole) was slowly heated up to 160° in a 50-cc. distilling flask filled with glass wool and evacuated to 0.13 mm. pressure. The side arm of the flask was connected to another, which served as an air-cooled receiver, and then to a trap cooled in chloroform–Dry Ice. Slow, even distillation took place at 125° (0.13 mm.) with no increase in pressure, and some of the distillate kept solidifying at the entrance to the Dry Ice trap. The air-cooled receiver eventually contained 15.33 g. (97.4%) of a slightly yellow, slightly acid oil whose m. p. of 30 to 33° was increased to m. p. 34 to 35° by recrystallization from petroleum ether. The elementary composition, the refractive index of $n^{40}D$ 1.5050, and the m. p. were those of ethyl *p*-toluenesulfonate and a mixed m. p. with an authentic sample was not depressed.

A clear colorless solid, 6.65 g. (97%), b. p. 100°, m. p. 6 to 9°, $n^{25}D$, 1.4190, collected in the Dry Ice trap, was

slightly impure 1,4-dioxane, which when pure has the constants $n^{25}D$ 1.4198 and m. p. 11.8°.[50a] This conclusion was confirmed by the preparation of the crystalline bromine addition compound with the proper m. p. 65 to 66°, undepressed by admixture with an authentic specimen.

(b) Tosylated Triethylene Glycol Monoethyl Ether: The pure ester (3.6 g., 0.011 mole) was heated at 0.03 mm. pressure in equipment as described in (a), but made from 10-cc. flasks. Even, smooth distillation occurred at 133 to 135° with no increase in pressure. The air-cooled receiver contained 2.03 g. (76.6%) of a slightly yellow, slightly acidic oil, $n^{25}D$ 1.5010, which after recrystallization melted at 18 to 19° and had $n^{25}D$ 1.5030. These were the constants of pure tosylated ethylene glycol monoethyl ether and a mixed m. p. was not depressed.

The Dry Ice trap contained 0.94 g. of a slightly unsaturated liquid that on distillation yielded 0.6 g. (62.8%) of nearly pure 1,4-dioxane with the constants b. p. 100°, $n^{25}D$ 1.4190, m. p. 8 to 10°. The identity was confirmed by preparing the orange-yellow bromine addition compound, m. p. 65 to 66°.

**Rate of Solvolysis of the Tosylates.**—In all cases 0.0015 mole of the tosylate was washed with anhydrous methanol into a 250-cc. volumetric flask to which 25 cc. of water was added. After being made up to the mark with anhydrous methanol at 25°, the solution was transferred to a 500-cc. flask equipped with a water-cooled reflux condenser and drying tube. Samples removed after various periods of heating at 65 ± 1° were rapidly cooled to 25° and 10-cc. aliquots were titrated with 0.1 *N* sodium hydroxide, using a microburet. Since the molar ratio of water to tosylate was 1.557 to 0.0015, the amount of water remained practically constant and the solvolysis was assumed to follow a first order rate course given by $kt = 2.303 \log a/(a - x)$, where $a$ was the initial concentration of tosyl ester and $(a - x)$ the concentration remaining after any time $t$. The quantity $(a - x)$ was readily calculated from the titrations. Table II and Fig. 2 summarize the results.

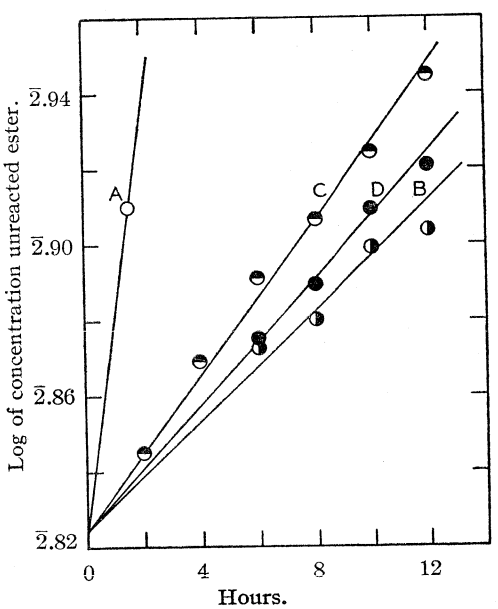

Fig. 2.—First order solvolyses of various *p*-toluenesulfonates in excess 90% aqueous methanol at 65°: plot A, ethyl; plot B, β-ethoxy ethyl; plot C, 2-(β-ethoxyethoxy)-ethyl; plot D, 2-(β-ethoxyethoxyethoxy)-ethyl *p*-toluenesulfonate.

(50) Huntress and Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1st ed., 1941 (a) p. 457; (b) p. 428.

**Rate of Iodination of the Tosylates.**—The tosyl ester, 0.0025 mole, and 0.0075 mole of dry, C. P. sodium iodide were completely dissolved in exactly 25 cc. of pure acetonylacetone by shaking the mixture for about five minutes in a 50-cc. glass-stoppered flask. The refractive index of the solution was promptly noted on an Abbe refractometer. The solution was then kept in the dark at 22 ± 0.5° and at intervals of two hours samples were removed by a capillary pipet and transferred directly into the refractometer for measurement. This technique was possible because the sodium *p*-toluenesulfonate separated as large crystals that settled readily. When the change in refractive index became slow, the solution was kept at 100° under a reflux condenser for two hours in order to complete the iodination. After making the final measurement at 22°, the sodium salt was recovered, washed, dried and weighed as a check on the completeness of the reaction. The recovery was 95.4 to 99.4%.

In order to calculate rate of iodination constants, the assumption was made that the refractive index varied linearly with the replacement of tosyloxy groups by iodine atoms. The moles of tosylate, $x$, converted at any time $t$ was then given by the change in refractive index at that time divided by the over-all change observed after the iodination was complete. This over-all decrease varied from $n^{22}D$ 0.0033 to $n^{22}D$ 0.0040 with different tosylates. If $a$ was the initial concentration of tosyl ester, 0.1 mole per liter, and $b$ that of sodium iodide, 0.3 mole per liter, the rate of iodination was given by the second order relation

$$k_2t = \frac{2.303}{(a - b)} \log \frac{b}{a} \frac{(a - x)}{(b - x)}$$

The results are summarized in Table II and Fig. 3, the former of which includes runs with tosylated ethanol and ethylene glycol monoethyl ether in which $a = b = 0.15$ mole per liter. In these cases the rate equation reduced to $k_2t = x/a(a - x)$.

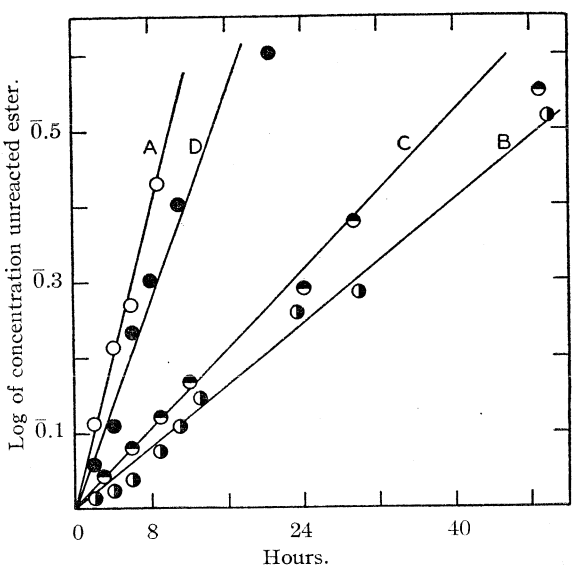

Fig. 3.—Second order iodination of various *p*-toluenesulfonates with sodium iodide in acetonylacetone at 22°: plot A, ethyl; plot B, β-ethoxy ethyl; plot C, 2-(β-ethoxyethoxy)-ethyl; plot D, 2-(β-ethoxyethoxyethoxy)-ethyl *p*-toluenesulfonate.

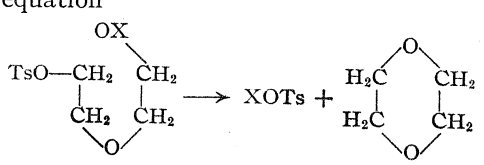

## Results and Discussion

The monoethyl ethers of both ethylene glycol and diethylene glycol readily formed peroxides and acidic products, the peroxide oxygen or acidic normalities sometimes exceeding 0.2 *N*

after storage in diffuse daylight and over a drying agent for prolonged periods. Storage even for one or two weeks was quite capable of producing peroxide oxygen normalities of the order of 0.04 *N* without causing a significant change in refractive index, a correct value of which was in consequence no decisive test of purity. Since both monoethyl ethers were practically odorless when quite pure,[12] the "fruity" odor they usually possess was tentatively attributed to aldehydes and other contaminants resulting from autoxidation.

The experiment summarized in Fig. 1, plots A and C, showed that very carefully purified diethylene glycol monoethyl ether greatly exceeded its lower homolog in ability to accumulate peroxide when kept in Erlenmeyer flasks exposed to diffuse daylight. Plots D and B record the great decrease in peroxide formation observed when aliquots of the same pure samples were stored under nitrogen in dark, glass-stoppered bottles. This result was to be expected, but for unknown reasons the monoethyl ether of triethylene glycol in all conditions tried gave negative tests for peroxide. Peroxide-containing ethylene glycol monoethyl ether yielded the crystalline bis-2,4-dinitrophenylhydrazone of glyoxal, which no doubt arose from glycolic aldehyde. Aldehydes are known to be primary decomposition products of peroxides[48,51] and, indeed, Milas[52] clearly showed that glycolic aldehyde was formed in the autoxidation of 1,4-dioxane. The same dinitrophenylhydrazone was isolated from peroxide-containing diethylene glycol monoethyl ether but failure to detect ethoxyacetaldehyde or hydroxyethoxyacetaldehyde, $HO-CH_2-CH_2-O-CH_2-CHO$, either as such or as dinitrophenylhydrazones, suggested that in this monoether both ether oxygen atoms acted as centers for peroxide formation. Ethoxy groups presumably produced acetic acid, since no acetaldehyde could be detected.

It was observed that tosylated diethylene glycol monoethyl ether appeared to distil smoothly at 125° (0.13 mm.), but the distillate consisted of 1,4-dioxane and ethyl *p*-toluenesulfonate, each recovered in 97% yield. The tosyl ester of triethylene glycol monoethyl ether decomposed similarly at 134° (0.03 mm.) to 1,4-dioxane (63%) and the crystalline tosylated monoether of ethylene glycol (76%), together with a somewhat unsaturated, acidic mixture that was not further examined. In both cases, therefore, the dominant reaction was a thermal cleavage represented by the equation

Structure I

in which X is $C_2H_5$ or $C_2H_5O-CH_2-CH_2-$. Ethyl *p*-toluenesulfonate and tosylated ethylene glycol monoethyl ether were stable to the cracking temperature, in accord with Tipson's observation that both could be purified by distillation under diminished pressure.[23] The thermal breakdown of the higher tosylates to 1,4-dioxane was not inconsistent with the fact that β,β'-dichloroethyl ether, when heated with aqueous caustic soda at 200°, yielded principally 1,4-dioxane and β-chloroethyl vinyl ether, rather than the divinyl derivative expected.[53] Cretcher and his coworkers[22] found that decomposition occurred during the high vacuum distillation of the tosylated monochlorohydrin of diethylene glycol; corresponding diethers yielded low-boiling fractions on distillation,[54] and only 30 to 40% of the original diether. Gallaugher and Hibbert[55c] noted that polyethylene glycols and their derivatives gave volatile, sweet-smelling distillates, sometimes at very low temperatures, and that the monochlorohydrin of tetraethylene glycol decomposed at 140°.

Such observations suggested that the OTs and X groups in Structure I might be replaceable in certain cases by hydroxyl, alkoxyl, halogen or similar units without abolishing the tendency of the polyethylene oxide chain to yield dioxane when heated. Anomalous physical properties, indeed, led to the inference[55b] that an intramolecular attraction existing between the hydroxyl groups of diethylene glycol maintained the molecule in a conformation approximating that of 1,4-dioxane. A more usual mode of decomposition was revealed in a recent careful study,[56] which showed that monoethers of ethylene and diethylene glycols were partially interconvertible when heated at 105 to 130° in presence of 1.5% sulfuric acid.

Although diethylene glycol readily yielded a white, crystalline monosodium salt when treated with metallic sodium or sodium methylate,[11] the monoethyl ether of the same glycol decomposed in part to very dark red-brown viscous materials under similar circumstances. Condensation of the resulting crude mixture with ethylene chlorohydrin gave the monoethyl ether of triethylene glycol in a yield whose small amount might possibly be attributed in part to thermal decomposition during the fractional distillation. The preparation of the corresponding tosylate was uneventful, but the thermal instability of this compound, and also of tosylated diethylene glycol monoethyl ether, made it prudent to conduct the double decompositions with sodium iodide near 23°,[57] instead of at the more usual temperature of

[a] Densities at 25–25° unless otherwise mentioned. [b] From tables of atomic refractivity, ref. 49. [c] Ref. 50 b. [d] At 20°/20°. [e] Ref. 31. [f] Ref. 13. [g] Davidson's value of $n^{26}D$ 1.4389 (ref. 12) was high, probably because of contamination with diethylene glycol, $n^{20}D$ 1.4475. [h] At 40°/40°. [i] Contribution of $-O-SO_2$ group omitted. [k] Contribution of $-O-SO_2$ group. [l] Tipson (ref. 23) found $n^{25}D$ 1.5026. [m] At 18.5°/4°. Quoted from Beilstein. [n] Ref. 30. [o] At 15°/4°.

Table I, column 5, records the molar refractions of compounds rigorously purified for the first time during this research, together with relevant data from the literature. The fact that values in the ethylene glycol monoethyl ether and in the β-iodoether series agreed closely with those calculated from a table of atomic refractivities (column 6) argued for the purity of the samples examined. In the first and second of these series the average increments occasioned by addition of an ethylene oxide unit were 10.95 and 10.88, respectively, in good agreement with the theoretical value of 10.88.[59] Since the observed increments in the tosylates, $10.98 \pm 0.21$, were also in good agreement, it followed that the tosylates were probably pure and that the presence of the sulfonic group occasioned no marked change in the molecular refraction of the remaining atoms. Column 7, giving the difference between the calculated molecular refraction of these atoms and that observed for the tosylate, therefore represents the molecular refraction of the $O-SO_2$ group. The result, $10.53 \pm 0.35$, was somewhat higher than the molecular refraction of $9.7 \pm 0.2$ found for the $O-SO_2$ group in several esters of ethylene sulfonic acid,[60] perhaps because of different amounts of optical exaltation.

Inspection of column 2, Table I, reveals that specific refractive indices in the series R–OH increased with $x$ but that the increment decreased. This tendency was true of the polyethylene glycol series[55a] and was included in a generalization about specific refraction by Smiles.[61] The values for tosylated and iodinated derivatives in Table I, however, decreased as each series was ascended and were in opposition to the generalization. Conn and his co-workers,[14] on the other hand, found no regular trend in refractive index in passing from the benzoates and *p*-nitrobenzoates of a number of ethylene glycol monoethers to the corresponding diethylene glycol derivatives. It is probable that in this and in much other work in the polyoxyethylene series,[14,18,62] the accuracy of the recorded physical constants was often impaired by the presence of impurities originating in autoxidation, incomplete fractional distillation or in thermal cracking.

Figures 2 and 3 record the relative rates of solvolysis of the tosylates in a large excess of aqueous methanol (1:9) at 65°, and their relative reactivities toward sodium iodide. The solvolyses followed a first order course and all the observations fell, within the experimental error, on the lines shown in Fig. 2. This error reflected the uncertainty of ±0.05 cc. in the titrations of acidity, and corresponded to 14 to 8% in the log $(a-x)$ values for solvolysis up to 10% completion. Between 10 and 20% completion the errors in log $(a-x)$ were 8 to 4%, being least for the fastest reaction. Iodinations (Fig. 3) were carried out with sodium iodide in acetonylacetone and the progress of the reaction was followed by the change in refractive index of the solution. Since the error in the refractometer readings was about $\pm 10^{-4}$, the extent of iodination was in serious doubt in the initial stages, and by 5 to 7.5% in the later stages of the reactions. Within these limits all observations fell upon straight lines passing through the origin, when second order kinetics were assumed,[63] but did not define the slope of the lines within 15%. Second order kinetics also applied to the reaction of ethyl *p*-toluenesulfonate, and other substituted benzene sulfonates, with sodium ethylate in absolute ethanol.[64]

The rate constants (Table II) refer only to the over-all kinetics of solvolysis and iodination since actual reaction mechanisms and possible side-reactions were not determined. Ethyl *p*-

TABLE II

APPROXIMATE RATE CONSTANTS FOR SOLVOLYSIS AND IODINATION OF THE TOSYLATES

| Tolsylate $C_2H_5(OCH_2CH_2)_xOTs$ | Solvolysis $k_1$[a] | Iodination $k_2$[b] | Iodination $k_2$[c] |
|---|---|---|---|
| x = 0 | 0.124 | 0.56 | 0.66 |
| 1 | .017 | .12 | .06 |
| 2 | .023 | .15 | |
| 3 | .019 | .36 | |

[a] In aqueous methanol (1:9) at 65 ± 1°; first order; unit, hours$^{-1}$. [b] With 0.1 mole of tosylate and 0.3 mole of iodide per liter at 22 ± 0.5°; second order; units, liters, moles$^{-1}$, hours$^{-1}$. [c] With 0.15 mole per liter both of tosylate and of iodide.

toluenesulfonate ($x = 0$) obviously was most reactive, as might have been expected from the known depressing effect of a β-ether group on the reactivity of organic halides, and from the similarity between halides and sulfonates.[57] Tosylated ethylene glycol, for example, hydrolyzed twelve times more slowly than tosylated ethanol.[65] The differences between the solvolysis rate constants for the higher tosylates ($x = 1$, 2 and 3, Table II) probably fell within the experimental error, and the same remark was true of the iodination rate constants for the tosylates with $x = 1$ and 2. The results in general suggest that the tosylation–iodination reaction as applied to cellulose acetates and ethers is valid for research on hydroxyethylcelluloses.

**Acknowledgment.**—The authors greatly appreciate the interest that Dr. R. T. K. Cornwell, of the Sylvania Division, American Viscose Corporation (formerly Sylvania Industrial Corporation), showed in the research. One of us (C. W. T.) also wishes to thank the same organization for the Fellowship, and the Canadian Pulp and Paper Association for the summer stipend, awarded to him for the period of the work (1945–1946).

## Summary

1. The following compounds were obtained pure: triethylene glycol monoethyl ether, its *p*-toluenesulfonate, the *p*-toluenesulfonate of diethylene glycol monoethyl ether, β-ethoxyethoxy-β′-iododiethyl ether and β-ethoxy-β′-iododiethyl ether. A new preparation of β-iodoethyl ether was described.

2. Diethylene glycol monoethyl ether was particularly liable to peroxide formation, was partly decomposed by sodium methylate, and yielded a tosylate decomposing at 125° (0.13 mm.) to equimolar amounts of 1,4-dioxane and ethyl *p*-toluenesulfonate. The latter product was replaced by tosylated ethylene glycol monoethyl ether when tosylated triethylene glycol monoethyl ether was thermally decomposed at 134° (0.03 mm.). Ethyl *p*-toluenesulfonate was more reactive toward solvolysis in 90% methanol, and toward iodination with sodium iodide in acetonylacetone, than the higher tosylates.

3. Data for the molar refractivities of the above series of compounds were completed, and the molar refraction of the O–$SO_2$ group in *p*-toluenesulfonates was found to be 10.5 ± 0.35.

# *p*-Toluenesulfonyl Chloro and Iodo Derivatives of an Alkali-Soluble Hydroxyethylcellulose[1]

BY CLINTON W. TASKER AND C. B. PURVES[2]

Hydroxyethyl ethers of cellulose were first described by Hubert[3] in 1920, but excited no general interest until 1933, when the publications of Shorygin and Rymaschewskaja[4] commenced. These articles, together with those of Sönnerskog,[5] and Schorger and Shoemaker,[6] and also the relevant patents[7–19] showed that hydroxyethyl-

celluloses were obtained by condensing cellulose, either aged or pretreated or not, with ethylene chlorohydrin in the presence of alkali,[6,7,13b,18,19a] or with ethylene oxide, usually in the presence of caustic soda or a wide variety of other inorganic bases and salts.[7,10,15,19b] Control over the experimental conditions and the relative amounts of the reactants made it possible to prepare substantially similar products either by the chlorohydrin or the ethylene oxide route.[7] Hydroxyethylcelluloses thought to average substantially less than one hydroxyethyl group per glucose unit[7] were usually soluble in cold 10% caustic soda, while solubility in weaker alkali and in water increased as the substitution increased from more than unity to three. Acetates,[4a] benzoates,[6,7,20] stearates, xanthates[6] and mixed methyl and ethyl ethers[5,6] were prepared, but Sönnerskog[5] could not correlate their properties accurately with the degree or the uniformity of substitution.

The existence of hydroxyethylcelluloses averaging four,[21] or even six[22] substituent groups per glucose residue made it clear that some of the substitution occurred at previously formed hydroxyethyl groups rather than at the free hydroxyl groups of the cellulose itself. It followed that such products contained structures of type I in which $n$ was an integer greater than unity, although simpler structures with $n$ equal to unity

I, $n$ an integer

were not excluded. With the possible exception of preparations made from cellulose dissolved in a quaternary ammonium base,[23] hydroxyethylcelluloses resulted from condensations between cellulose and ethylene oxide carried out in heterogeneous, or at best in quasihomogeneous, systems. Even samples of low average hydroxyethyl content might therefore contain local substitutions so high that units of type I, $n > 1$ might be present. Type I, $n > 1$ would also result, even in a homogeneous system, if ethylene oxide condensed preferentially with hydroxyethyl units. Consideration of structure I also shows that substitution in the sixth position of a glucose residue in cellulose failed to alter the number of primary alcohol groups from the original value of unity. Substitution in the second or third positions, however, replaced a secondary alcohol by the primary hydroxyethyl unit. If the total number of primary hydroxyl groups was $1 + x$ per glucose residue, it followed that the number of hydroxyethyl groups attached to secondary positions was $x$, or an integral multiple thereof. One of the objects of the present research was to determine the value of $x$.

The preceding article[24] showed that the primary hydroxyl groups in the series $C_2H_5[OCH_2CH_2]_nOH$ were esterified at the normal rapid rate by excess *p*-toluenesulfonyl chloride (tosyl chloride) in pyridine. Although the resulting tosylates hydrolyzed with some rapidity and the higher members ($n$, 2 and 3) underwent quantitative decomposition during distillation *in vacuo*, all reacted normally with sodium iodide in acetonylacetone and yielded the corresponding β-halogen ethers. These experiments have now been extended to a commercial, alkali-soluble hydroxyethyl ether of cellulose of average substitution 0.44 and the molar amount of halogen in the final products has been assumed to be a measure of the moles of primary alcohol in the starting material. Although this method sharply differentiated unsubstituted primary from secondary hydroxyl groups in certain partly substituted glucose[25] and cellulose[26,27] derivatives, Malm and his collaborators[28] lately showed that with drastic conditions of halogenation, or with highly tosylated celluloses, the replacement extended to some secondary alcohol positions. The method has therefore to be used with discretion.

The hydroxyethyl content of hydroxyethylcelluloses has in the past been estimated from the gain in weight caused by the addition of ethylene oxide, and from the increase in carbon content,[20,22] but both methods are insensitive to appreciable changes in the substitution. Use was also made of the standard alkoxy estimation[20] because the hydroxyethyl group evolved ethyl iodide when heated with hydriodic acid. The recognition in 1946 by Morgan,[21] that ethylene was also evolved in this reaction and had to be included in the estimation, made it possible for him to devise the first reliable determination for the hydroxyethyl group. This valuable advance rendered the present work feasible.

## Experimental

**Materials and Analytical Methods.**—The commercial hydroxyethylcellulose (Ceglin E. S. type H,[29] moisture 5.9%; ash 0.12%; substitution 0.443) consisted of white flocks that were freely soluble in cold caustic soda, that swelled in water, but were only incompletely gelatinized by prolonged steeping in pyridine.

After being ground in a Wiley mill to pass a 60-mesh

sieve, the material was carefully tested for peroxide oxygen by the ferrous–cyanate,[30] the benzidine–copper sulfate[31] and the acetic acid–potassium iodide[32] procedures, with uniformly negative results. Indeed, in the latter method the samples often failed to liberate the minute amount of iodine found in the blanks. Oxidations with 0.03 *M* iodine in a borate buffer at *p*H 9.2 and 25°, as recommended for the estimation of aldehyde groups in celluloses[33] revealed consumptions equivalent to 0.66, 1.31, 1.97 and 2.46 cc. of 0.1 *N* iodine per gram sample (iodine no.) after six, twelve, eighteen and twenty-four hours. The hydroxyethyl ether group was intrinsically unstable to hypoiodite because an iodine number greater than 4 was recorded for highly purified ethylene glycol monoethyl ether after twenty-four hours.

The sulfur and halogen analyses were by the semi-micro Carius method, with 20 to 30 mg. samples and 0.5 cc. of nitric acid. Over ninety consecutive analyses were made in this way without incident, but when the stated amount of nitric acid was exceeded, explosion of the glass Carius tube almost always resulted. Morgan's modified alkoxyl method[21] was used for all estimations of the ethylene oxide (hydroxyethyl) group, using 20 cc. of freshly distilled hydriodic acid for each 0.2 to 0.4 g. sample. If the sample contained a, b, c, and d moles of hydroxyethyl, tosyl, chlorine and iodine, respectively, per glucose unit, the base molecular weight, *Z*, was $162.14 + 44.04a + 154b + 18.5c + 110d$. The individual substitutions were found by solving the simultaneous equations, % $OCH_2CH_2$ = $4404\ a/Z$; % S = $3206\ b/Z$, % Cl = $3550\ c/Z$; and % I = $1274\ d/Z$. Either *b*, *c*, or *d*, of course, was often known to be zero. All percentages used in these calculations were the average of closely concordant duplicate or triplicate analyses.

All reagents and solvents were carefully purified as previously described,[24] and all equipment was connected through ground glass joints.

**Tosylation of the Hydroxyethylcellulose.**—The sample, 14.88 g. air dry or 14.0 g. oven dry, corresponded to 0.077 mole containing 0.231 mole of free hydroxyl groups. After being dissolved in 350 g. of 5% sodium hydroxide by stirring under nitrogen at −10°, the hydroxyethylcellulose was reprecipitated in ribbons and pellets of highly swollen gel by pouring the solution into 1.5 liters of gently stirred 50% aqueous acetic acid. After complete coagulation had taken place it was possible to stir the mixture vigorously for twenty minutes without producing a system so dispersed that easy separation was impossible. The gel was recovered and washed in a well-laundered muslin bag until the effluent had the same *p*H (5.7) as the water used. The weight of the dry bag before and after use showed no significant change. The gel was then transferred to a tared 2-liter flask and the water it contained was eliminated by the continous addition and evaporation of dry pyridine into a vacuum so regulated that the bath temperature never exceeded 60°. Distillation was stopped when the distillate had regained the refractive index, $n^{20}D$, 1.5090, of pure dry pyridine and was miscible without turbidity with petroleum ether. The resulting transparent hydroxyethylcellulose–pyridine gel was cooled to 5°, and 274.1 g. (1.44 moles) of tosyl chloride, dissolved in enough cold pyridine to give a total weight of 1540 g. (19.46 moles) of pyridine, was added. Thereafter the tightly stoppered flask was kept at 25 ± 0.1° and was periodically shaken vigorously by hand. All gel particles disappeared after about twelve hours and for a few hours subsequently the system appeared homogeneous, but after fifteen to twenty-one hours separated into a highly swollen gel and a slightly yellow supernatant liquid phase.

In contrast to the earlier state, it was possible, from twenty-one hours onward, to disperse the gel uniformly by shaking and to withdraw representative aliquots of 100 to 150 cc. at various times. Each of these aliquots was slowly poured into 1.5 liters of chilled, rapidly stirred water, and the fibrous tosylate that precipitated was washed by decantation with 500 cc. of water, recovered quantitatively on a sintered glass funnel, and washed thoroughly until free from chlorine ions and pyridine. The fibers from the earlier aliquots were white, but those isolated from the later red-brown aliquots were tan in color. They were dried through methanol and ether and finally *in vacuo* over phosphorus pentoxide for at least two days at room temperature prior to analysis. Since reliable aliquots could not be obtained from the tosylation mixture prior to about twenty-one hours, separate 2-g. samples (dry weight) of the original hydroxyethylcellulose were precipitated from caustic soda, exchanged into pyridine and tosylated for varying brief times exactly as described, but using one-seventh quantities of reagents. Precipitation of each entire tosylation mixture into 2.5 liters of cold water yielded hard white pellets gradually giving place to white fibers as the time of tosylation increased. The percentage analyses of these products, isolated exactly as described, are included in Table I, the corresponding substitutions being in Figs. 1 and 2.

TABLE I

ANALYSES OF HYDROXYETHYLCELLULOSE TOSYLATED FOR INCREASING TIMES

| Tosylation,[a] hours[b] | S, % | Cl, % | $CH_2CH_2O$, % | Yield,[d] % |

[a] With excess tosyl chloride in pyridine at 25°. [b] Individual runs. [c] Aliquots from one large run. [d] Corrected for substitutions.

**Partial Replacement of Tosyloxy Group by Chlorine.**—A 1.2 g. (0.003 mole) sample of the product from twenty days of tosylation, dissolved in 20 cc. of dry pyridine, was mixed with 1.5 g. (0.041 mole) of dry hydrogen chloride gas dissolved in 30 cc. of the same solvent. After being heated under reflux at 85° for four hours, the mixture was cooled and poured into 200 cc. of dry, redistilled petroleum ether (b. p. 30 to 50°). The granular, light-tan precipitate together with pyridine salts was recovered as a filter cake which was macerated and thoroughly washed with water until free from chloride ion and pyridine. This product, 0.985 g. after drying as described above, did not swell or dissolve in water or in common organic liquids, even when the latter contained some water. *Anal.* Found: S, 9.30, 9.40; Cl, 8.51, 8.65; $OCH_2CH_2$, 1.99, 1.74, 1.68. The composition corresponded to cellulose substituted with 0.819 chlorine atom, 0.982 tosyl and 0.132 ethylene oxide groups per glucose unit, and the yield to 100%.

The tosylates obtained after seven hours and two days were submitted to the above reaction, but the chlorinated products were soluble, or so highly dispersed in water, aqueous pyridine and common organic liquids that they

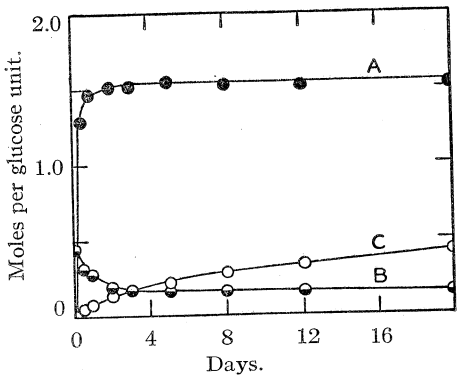

Fig. 1.—Changes in substitution of a hydroxyethyl cellulose during tosylation at 25°: plot A, tosyl; plot B, hydroxyethyl; plot C, chlorine substitution.

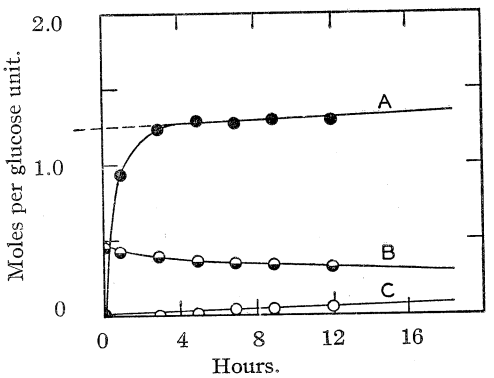

Fig. 2.—Initial changes in substitution of a hydroxyethyl cellulose during tosylation at 25°: plot A, tosyl; plot B, hydroxyethyl; plot C, chlorine substitution.

could not be isolated in good yield or adequately purified. A sample of the original hydroxyethylcelluose, when heated with a similar pyridine hydrochloride solution at 85° for four hours, was recovered chlorine-free and with the original hydroxyethyl content. Found: $CH_2CH_2O$, 10.69, 10.77; substitution, 0.44.

**Partial Replacement of Tosyloxy Group by Iodine.**—A 250-cc. flask containing 200 cc. of pure, dry acetonylacetone, 4 g. (0.027 mole) of sodium iodide and 2.42 g. (0.007 mole) of the three-hour tosylated hydroxyethylcellulose was heated under reflux for twelve hours at 115 to 120°. The ester was not completely soluble in the mixture, which developed a deep red color. Precipitation of the entire mixture into 1.8 liters of rapidly stirred ice-water yielded a granular, slightly yellow product that was repeatedly washed with water, then with 0.1 *N* sodium thiosulfate and again with water until all traces of iodide ion, free iodine and acetonylacetone had been removed. The iodinated product, 1.84 g., was dried *in vacuo* over phosphorus pentoxide for two days at room temperature. *Anal.* Found: S, 1.19, 1.15; I, 41.3, 41.4; $CH_2CH_2O$, 5.43, 5.44, 5.29. When the original trace of chlorine (0.14%) was neglected, these data corresponded to iodine, tosyl and ethylene oxide substitutions of 0.996, 0.114 and 0.373, respectively, and to a yield of 92%.

## Results and Discussion

Although the pure monoethyl ethers of diethylene and triethylene glycol readily formed peroxides,[24] three different tests for peroxides were negative with the commercial hydroxyethylcellulose, of unknown age, that was used. The observation that the latter, like the simpler analogs, slowly reduced alkaline hypoiodite discredited the use of the iodine number as a measure of average molecular weight[7,19b,22] in the hydroxyethylcellulose series.

Experiment showed that precipitation from alkali followed by careful solvent-exchange from water to dry pyridine converted the hydroxyethylcellulose to a uniform, highly swollen, completely translucent gel that seemed physically suitable for the tosylation with excess tosyl chloride and pyridine at 25°. This reaction was followed by the analyses of intermediate products (Table I) and from these data it was easy to calculate the corresponding changes in the tosyl, chlorine and ethylene oxide substitutions recorded in Figs. 1 and 2. The smooth nature of the plots, the high yields of the intermediate products, and the proved reliability of the analytical methods with simple analogs,[24] made it likely that these calculations were accurate to within ±0.02 mole per glucose unit. Figure 1, plot B shows that about half of the original 0.44 hydroxyethyl groups were eliminated during the first two days of tosylation but that the subsequent decrease was very slow, about one third remaining after twenty and also after forty days. Although pyridine hydrochloride was formed as a by-product of the tosylation and was used by Prey,[34] as an ether-cleaving agent, the original material was stable when heated at 85° with this substance in pyridine solution. It followed that the loss of hydroxyethyl groups occurred after, and not before, their tosylation and that these groups consisted of two distinct kinds, about one-third yielding stable, and the other two-thirds unstable, tosylates. When it was recalled that ethyl and β-ethoxyethyl *p*-toluenesulfonates were stable to vacuum distillation[35] but that the tosylates of higher homologs were nearly quantitatively cleaved to 1,4-dioxane and a stable lower tosylate,[24] it seemed likely that in the hydroxyethylcellulose one-third of the substituent was united as individual groups to the cellulose (structure I, $n = 1$) whereas the remaining two-thirds was present as polyethylene oxide chains (structure I, $n > 1$). The decomposition of an even-membered chain in the way suggested would transfer the tosyl group to the cellulose skeleton and would alter its nature from primary to secondary if the original chain was attached to a secondary alcohol position. An odd-membered chain, on the other hand, would yield a stable, tosylated, monomeric substituent and the ratio of primary to secondary tosyl groups would not be altered. Nothing in this mechanism would necessarily involve the permanent loss of tosyl units.

Plot C records a rather rapid chlorination, which probably resulted in the conventional way by the interaction of primary tosyl groups with by-product pyridine hydrochloride. The difference in reaction rates in plots B and C suggested

(34) Prey, *Ber.*, **75**, 350, 445 (1942).
(35) Tipson, *J. Org. Chem.*, **9**, 235 (1944).

that the loss of hydroxyethyl units and the gain in chlorine were independent side-reactions, and this inference was supported by the fact that the sum of the tosyl (plot A) and chlorine substituents increased steadily as hydroxyethyl groups decreased. Since both side reactions were insignificant during the early hours of the tosylation (Fig. 2, plots B and C), it seemed legitimate to determine the extent of the initial rapid tosylation by extrapolating the latter portion of plot A to zero time. The result, 1.22 moles, was taken as equal to the number of primary alcohol groups in the original hydroxyethylcellulose because their rate of reaction was comparable to that displayed by primary alcohol groups in cellulose ethers[27] and cellulose acetate[26] tosylated in closely similar circumstances. It then followed from the argument in the Introduction that 0.22 mole represented hydroxyethyl units substituted in the secondary alcohol positions of the cellulose, the actual number of such units being greater if they included polymers.

The fact that hydroxyethylcellulose tosylated for only three hours contained a negligible substitution (0.01 mole) of chlorine (Table II, line 2) made it possible to check the content of primary tosyl groups by the iodination method. Although the sample was heated with excess sodium iodide in acetonylacetone for twelve, instead of the usual two or four,[26] hours at 115 to 120°, and the replacement proceeded in over 90% yield, the product contained only 1.00 instead of the expected 1.22 moles of iodine (line 3), and the over-all substitution (tosyl plus halogen) decreased from 1.24 to 1.11 moles. According to Malm and his collaborators[28] the iodination method sometimes overestimated, but never underestimated, the content of primary tosyl groups. The replacement of primary tosyl by chlorine in the sample tosylated for twenty days (line 4) was completed by heating with pyridine hydrochloride in pyridine, the yield of the granular light tan product being nearly quantitative. A decrease in tosyl plus chlorine substitution from 1.93 to 1.80 moles, or of 0.13 mole, corresponded exactly to the similar decrease occasioned by iodination but the final chlorine content was only 0.82 mole. Halogenation, therefore, revealed only 1.00 and 0.82 mole of primary hydroxyl groups, whereas the minimum number possible was 1.0 for cellulose, or any hydroxyethylcellulose, and the number probable in the present case was 1.22. This large discrepancy, which could not be attributed to inadequate conditions of halogenation, suggested that another side-reaction occurred. No significant loss of the hydroxyethyl group was involved (Table II, lines 2 and 3, 4 and 5) but the reaction occasioned a decrease of 0.13 mole in the tosyl plus halogen substitution and another of at least 0.18 mole in primary tosyl. Although no direct evidence was obtained, this side-reaction was perhaps connected with the well-known ability of alkyl *p*-toluenesulfonates to act as alkylating agents in basic media.[36] Let it be assumed that the 0.15 mole of hydroxyethyl group stable throughout the tosylation quickly became esterified and then slowly alkylated unsubstituted hydroxyl groups of the cellulose at some stage in the reactions. As structures II and III show, such an alkylation might involve either the tosyl or halogen group and would result in the formation of a cyclic ether of ethylene glycol, the ethylene oxide unit being retained while 0.15 mole of primary alcohol group was eliminated. Although structures II and III are quite arbitrary as to detail, the iodinated and halogenated derivatives were soluble in some organic liquids and therefore were not likely to contain glycol ether cross-links between different glucose residues.

TABLE II

CHANGES IN SUBSTITUTIONS CAUSED BY HALOGENATION OF TOSYLATED HYDROXYETHYLCELLULOSES

| Sample | Moles per glucose residue $-OCH_2-CH_2$ | Tosyl | Halogen | Primary hydroxyl | Secondary tosyl |
|---|---|---|---|---|---|
| Original | 0.44 | 1.22[a] | 0.0 | 1.22[a] | 0.0 |
| Three-hour ester | .39 | 1.23 | 0.01 Cl | | |
| Iodinated | .37 | 0.11 | 1.00 I | 1.00 | .11 |
| Twenty-day ester | .15 | 1.51 | 0.42 Cl | | |
| Chlorinated | .13 | 0.98 | 0.82 Cl | 0.82 | .98 |

[a] Later tosylation rate plot extrapolated to zero time.

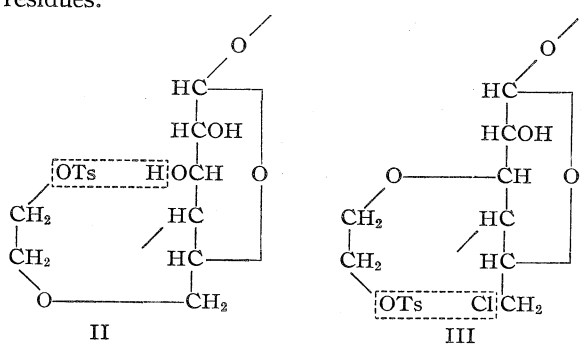

Table III contains an arbitrary distribution of monomeric and dimeric substituents in the primary and secondary positions of the hydroxyethylcellulose. The distribution was found by trial and error and its only merit is to summarize the experimental data and the series of unproved *ad hoc* assumptions outlined above.

The original material was assumed to have 0.05 primary plus 0.10 secondary position substituted by the dimeric unit, $-O-CH_2CH_2-O-CH_2-CH_2OH$, which during tosylation was gradually eliminated. This elimination reduced the ethylene oxide substitution from 0.44 to 0.38 and finally to 0.14 mole, and involved the transfer first of 0.02 and then of 0.10 mole of primary tosyl group to secondary positions on the cellulose. The monomeric hydroxyethyl substituents (0.02 plus 0.12 mole) were retained by the cellulose but the alkylating action of their tosylates converted them to cyclic

(36) Morgan and Cretcher, THIS JOURNAL, **70**, 375 (1948).

ether units. The same action caused the loss of at least 0.16 mole of primary tosyl or hydroxyl positions (structures II and III).

TABLE III

ARBITRARY DISTRIBUTION OF SUBSTITUENT IN AN ALKALI-SOLUBLE HYDROXYETHYLCELLULOSE

| Sample | Moles $CH_2CH_2O$ per glucose unit: Primary position, Monomer | Primary position, Dimer | Secondary position, Monomer | Secondary position, Dimer | Total | Primary OH |
|---|---|---|---|---|---|---|
| Original | 0.02 | 0.05 | 0.12 | 0.10 | 0.44 | 1.22 |
| | | | Found | | .44 | 1.22[a] |
| Three-hour tosylate | .02 | .04 | .12 | .08 | .38 | 1.06[b] |
| | | | Found | | .39 | 1.00 |
| Twenty-day tosylate | .02 | .0 | .12 | .0 | .14 | 0.86[b] |
| | | | Found | | .15 | 0.82 |

[a] By extrapolation of tosylation rate plot. [b] All tosylated monomers (0.02 + 0.12 mole) assumed to have become alkylated at primary hydroxyl positions, with elimination of the tosyl group.

**Acknowledgments.**—The authors are greatly indebted to Dr. R. T. K. Cornwell, of the Sylvania Division, American Viscose Corporation (formerly the Sylvania Industrial Corporation) for literature references, for several valuable suggestions, and for his sustained interest in the work. One of us (C. W. T.) also wishes to thank the same organization for the Fellowship, and the Canadian Pulp and Paper Association for the summer stipend, awarded to him for the period of the research (1946–1947).

## Summary

1. A commercial alkali-soluble hydroxyethylcellulose of substitution 0.44 was esterified at 25° with excess *p*-toluenesulfonyl chloride in pyridine. The rapid initial reaction was attributed to a primary hydroxyl content of 1.22 moles per glucose residue and in consequence at least 0.22 mole of the hydroxyethyl substituent was tentatively assigned to secondary positions in the cellulose.

2. When the tosylation was prolonged for twenty to forty days, only 0.14 mole of hydroxyethyl group remained in the product. The elimination of 0.30 mole might be a measure of the polyethylene oxide units originally present as even-membered chains. The residual 0.14 mole might be attached to the cellulose directly, either as a monomer or as the initial unit of an odd-membered polyethylene oxide chain.

3. Partial replacement of tosyloxy groups by halogen, using sodium iodide or pyridine hydrochloride, had little effect on the hydroxyethyl substitution, but decreased the combined tosyl plus halogen substitution by 0.13 mole. Iodine, 1.0 mole per glucose unit, was introduced into one sample and 0.82 mole of chlorine into another, the substitution in both cases presumably occurring in the primary alcohol positions remaining in the two samples. Possible causes for the apparent decrease from the original 1.22 moles of primary alcohol units were suggested.

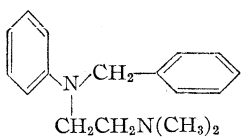
# Histamine Antagonists. IV. Indole and Carbazole Derivatives



BY JOHN B. WRIGHT

In conjunction with a broad study of histamine antagonists under way in this Laboratory a number of 1-(dialkylaminoethyl)-indole and 9-(dialkylaminoethyl)-carbazole derivatives have been prepared and tested for antihistaminic activity.

A degree of similarity of structure exists between certain of these derivatives, such as 1-dimethylaminoethyl-2-phenylindoline (I), and N,-N - dimethyl - N′ - benzyl - N′ - phenylethylenediamine ("Antergan") (II). Because of this resemblance and the comparative ease with

I

II

which indole and carbazole derivatives may be prepared by means of the Fischer synthesis it seemed of interest to investigate compounds of this type. In this work β-(1-pyrrolidyl)-ethyl and β-dimethylaminoethyl were chosen as substituting groups in the indole or carbazole nucleus. The former grouping was chosen because of the promise that it has shown with other nuclei.[1,2]

The preparation of these compounds was carried out by forming the sodium salt of the indole or carbazole derivative by heating with either sodium or sodium amide in toluene or xylene solution, followed by heating of the resulting mixture under reflux with the dialkylaminoethyl chloride, either as the free base or as the hydrochloride salt. The yields ranged from 34–96%. The method of preparation outlined is essentially that of Eisleb[3] who prepared 9-(β-diethylaminoethyl)-carbazole and 1-(β-diethylaminoethyl)-2-methylindole by this method.

The indole and carbazole nuclei that were used in this work were indole, indoline, 2-phenylindole,

(3) Eisleb, *Ber.*, **74B**, 1433 (1941).

2-phenylindoline, carbazole,[4] 1,2,3,4-tetrahydrocarbazole and 1,2,3,4,10,11-hexahydrocarbazole.

Preliminary pharmacological tests[5] indicate that these compounds possess weak to moderate antihistaminic activity. The results of these tests are indicated in Table I.

TABLE I

ANTIHISTAMINE ACTIVITY

| Name of compound[a] | Activity[b] |
|---|---|
| 1-[β-(1-Pyrrolidyl)-ethyl]-indole | [c] |
| 1-[β-(1-Pyrrolidyl)-ethyl]-indoline | 1/100–1/10 |
| 1-[β-(1-Pyrrolidyl)-ethyl]-2-phenylindole | 1/100–1/10 |
| 1-[β-(1-Pyrrolidyl)-ethyl]-2-phenylindoline | *ca.* 1/2 |
| 1-(β-Dimethylaminoethyl)-2-phenylindoline | 1/8–1/2 |
| 9-[β-(1-Pyrrolidyl)-ethyl]-carbazole | 1/100–1/10 |
| 9-[β-(1-Pyrrolidyl)-ethyl]-1,2,3,4-tetrahydrocarbazole | 1/100–1/10 |
| 9-[β-(1-Pyrrolidyl)-ethyl]-1,2,3,4,10,11-hexahydrocarbazole | 1/6–1/3 |

[a] The pharmacological tests in all cases were carried out on aqueous solutions of the hydrochloride salts. [b] Activity is expressed in terms of β-dimethylaminoethyl benzhydryl ether hydrochloride as the unit of activity. These tests were carried out on isolated guinea pig small intestine. [c] Pharmacological results not yet available.

## Experimental[6,7]

**1-[β-(1-Pyrrolidyl)-ethyl]-indole.**—A mixture of 29.3 g. (0.25 mole) of indole and 5.76 g. (0.25 mole) of sodium was heated for two hours, with stirring, in an oil-bath at 180–200°. The mixture was allowed to cool somewhat, 100 cc. of dry xylene was added to the very viscous dark material and the mixture stirred and heated under reflux for fifteen minutes. The mixture was allowed to cool and 33.4 g. (0.25 mole) of β-(1-pyrrolidyl)-ethyl chloride[1] was added all at once. The mixture was stirred and heated under reflux for six hours. After the mixture had cooled to room temperature, the sodium chloride was filtered and washed with a small amount of xylene. The salt was dissolved in water and the aqueous solution extracted with about 250 cc. of xylene. The combined xylene solutions were extracted with a 3% hydrochloric acid solution, the acid extracts basified by the addition of solid potassium carbonate and the resulting mixture extracted with ether. The ether extracts were dried over anhydrous magnesium sulfate, the solvent removed and the residue distilled *in vacuo* through a Vigreux column. There was obtained 29.9 g. (56%) of a colorless liquid, boiling at 128–129° (0.25 mm.), which darkened on standing.

**The picrate**, after two recrystallizations from ethyl acetate, consisted of reddish-orange flat needles melting at 142–142.5°.

*Anal.* Calcd. for $C_{14}H_{18}N_2 \cdot C_6H_3N_3O_7$: C, 54.17; H, 4.77; N, 15.80. Found: C, 54.34; H, 4.51; N, 15.62.

**1-[β-(1-Pyrrolidyl)-ethyl]-indoline.**—Sodamide was prepared from 1.9 g. (0.083 mole) of sodium according to the method of Vaughn, Vogt and Nieuwland.[8] To a mixture of the sodamide in 75 cc. of dry toluene was added, dropwise, 8.93 g. (0.075 mole) of indoline.[9] The mixture was stirred and heated under reflux for two and one-half hours. After cooling somewhat, 10.0 g. (0.075 mole) of β-(1-pyrrolidyl)-ethyl chloride was added and the mixture stirred and heated under reflux for fifteen hours. The mixture was filtered and the precipitate dissolved in 100 cc. of water and the aqueous phase extracted with toluene. The toluene extracts were combined with the toluene filtrate and the solution dried over anhydrous magnesium sulfate. The toluene was removed at atmospheric pressure and the residue distilled *in vacuo* through a Vigreux column. After a small amount of forerun, the main fraction boiled at 102–105° (0.2 mm.); yield, 11.3 g. (70%). The free base when freshly distilled is colorless but turns yellow slowly on standing.

*Anal.* Calcd. for $C_{14}H_{20}N_2$: C, 77.73; H, 9.32; N, 12.95. Found: C, 78.03; H, 9.05; N, 12.89.

**1-[β-(1-Pyrrolidyl)-ethyl]-2-phenylindole.**—The procedure given above for 1-[β-(1-pyrrolidyl)-ethyl]-indoline was followed using 5.06 g. (0.22 mole) of sodium, 19.3 g. (0.1 mole) of 2-phenylindole[10] and 17.0 g. (0.1 mole) of β-(1-pyrrolidyl)-ethyl chloride hydrochloride.[1] Xylene was used as the solvent in place of toluene. The reaction mixture was filtered, the precipitate dissolved in water and the resulting solution extracted with xylene. The combined xylene extracts and filtrate were extracted with a 3% hydrochloric acid solution. The acid extract was basified with potassium carbonate and the resulting mixture extracted with ether. The ethereal extract was dried over anhydrous magnesium sulfate, the solvent removed and the residue distilled *in vacuo* through a short Vigreux column. There was obtained 19.1 g. (66%) of a light-yellow viscous oil boiling at 187–189° (0.9 mm.). Upon standing the distillate solidified. Two recrystallizations of the crude product from methanol gave colorless needles melting at 78–78.5°.

*Anal.* Calcd. for $C_{20}H_{22}N_2$: C, 82.71; H, 7.64; N, 9.65. Found: C, 83.04; H, 7.36; N, 9.71.

**2-Phenylindoline** was prepared by the reduction of 2-phenylindole[10] with zinc dust and hydrochloric acid, according to the method of Fischer and Schmitt.[11] From 17.1 g. (0.087 mole) of 2-phenylindole there was obtained 14.4 g. (83%) of 2-phenylindoline boiling at 148–149° (1.4 mm.) and melting at 46–47.5°.

**1-[β-(1-Pyrrolidyl)-ethyl]-2-phenylindoline Hydrochloride.**—The procedure given for 1-[β-(1-pyrrolidyl)-ethyl]-2-phenylindole was followed with the exception that the crude undistilled product of the reaction was heated on a steam-bath for one hour with an excess of acetic anhydride. The solution, when cool, was poured into water. When the excess acetic anhydride had hydrolyzed completely the solution was neutralized with potassium carbonate and extracted with ether. The ethereal solution was extracted with dilute (3%) hydrochloric acid solution, the aqueous phase basified by the addition of solid potassium carbonate and the resulting mixture extracted with ether. The ether extracts were dried over anhydrous magnesium sulfate, the ether removed and the residue distilled *in vacuo* through a short Vigreux column. The product was obtained as a light-yellow viscous liquid boiling at 162–165° (0.2 mm.); yield, 34%.

**The hydrochloride** was prepared by adding the theoretical amount of a 2.96 *N* alcoholic hydrogen chloride solution to a solution of the free base in anhydrous ethanol and then adding an excess of anhydrous ether to precipitate the hydrochloride salt. Four recrystallizations of the crude material from an isopropyl alcohol–ethyl acetate mixture (1:1) gave clusters of small needles melting at 189.5–191.5°.

*Anal.* Calcd. for $C_{20}H_{24}N_2 \cdot HCl$: C, 73.04; H, 7.66; N, 8.52; Cl, 10.78. Found: C, 72.99; H, 7.48; N, 8.56; Cl, 10.88.

(4) 9-(β-Dimethylaminoethyl)-carbazole has recently been tested for antihistaminic activity by Freese, Hambourger and Michiels [*Federation Proc.*, **7**, 219 (1948)]. This compound has been reported also by Viaud [*Technologie Produits Pharmaceutiques*, **2**, 53 (1947)].

(5) For these results grateful acknowledgment is made to Dr. Milton J. VanderBrook of the Division of Pharmacology and Endocrinology of these laboratories.

(6) All melting points are corrected.

(7) For the analyses reported in this paper we are indebted to Mr. Harold C. Emerson and his staff of our Microchemical Division.

(10) "Organic Syntheses," **22**, 98 (1942).

(11) Fischer and Schmitt, *Ber.*, **21**, 1075 (1888).

**1-(β-Dimethylaminoethyl)-2-phenylindoline Hydrochloride.**—The procedure described above was employed, using an equivalent amount of β-dimethylaminoethyl chloride hydrochloride. From 12.9 g. (0.66 mole) of 2-phenylindoline there was obtained 12.6 g. (71.5%) of the free base. The free base is a colorless liquid boiling at 183–184° at 3.8 mm. The hydrochloride, prepared as described above, after four recrystallizations from absolute ethanol consisted of fine colorless needles melting at 210.5–212.5°.

*Anal.* Calcd. for $C_{18}H_{22}N_2$·HCl: C, 71.38; H, 7.65; N, 9.25. Found: C, 71.38; H, 7.50; N, 9.00.

**9-[β-(1-Pyrrolidyl)-ethyl]-carbazole.**—Sodamide[8] was prepared from 3.8 g. (0.17 mole) of sodium. A mixture of sodamide, 150 cc. of dry xylene and 25.1 g. (0.15 mole) of carbazole was stirred and heated in an oil-bath at 130° for three hours. To the mixture was added 20.0 g. (0.15 mole) of β-(1-pyrrolidyl)-ethyl chloride and the mixture stirred and heated under reflux for eight hours. The mixture was filtered and the precipitate washed with about 200 cc. of xylene. The xylene filtrate was extracted with dilute hydrochloric acid, the acid extracts made basic by the addition of a cold solution of sodium hydroxide, whereupon a light brown precipitate formed. This was filtered and dried in air. The weight of crude product was 38.4 g. (96%); m. p. 80–81°. Two recrystallizations from petroleum ether (Skelly B) after treatment with charcoal gave light yellow needles melting at 80.5–81.0°.

*Anal.* Calcd. for $C_{18}H_{20}N_2$: C, 81.77; H, 7.63; N, 10.60. Found: C, 81.80; H, 7.47; N, 10.51.

**9-[β-(1-Pyrrolidyl)-ethyl]-1,2,3,4-tetrahydrocarbazole Hydrochloride.**—The procedure given above for 9-[β-(1-pyrrolidyl)-ethyl]-carbazole was followed using 25.6 g. (0.15 mole) of 1,2,3,4-tetrahydrocarbazole.[12] The product, which separated as an oil, was taken up in ether and the ethereal solution dried over anhydrous magnesium sulfate. The drying agent was filtered off and the hydrochloride precipitated by bubbling dry hydrogen chloride through the solution. The yield of crude product, melting at 211–220°, was 38.1 g. (83%). Three recrystallizations from an ethyl acetate–absolute ethanol mixture (3:1) using decolorizing carbon gave light yellow needles melting at 232.5–233.0°.

*Anal.* Calcd. for $C_{18}H_{24}N_2$·HCl: C, 70.91; H, 8.27; N, 9.19. Found: C, 70.74; H, 8.01; N, 9.42.

**9-[β-(1-Pyrrolidyl)-ethyl]-1,2,3,4,10,11-hexahydrocarbazole Hydrochloride.**—The procedure given above for 1-[β-(1-pyrrolidyl)-ethyl]-2-phenylindoline was followed using the appropriate quantity of 1,2,3,4,10,11-hexahydrocarbazole.[13] The free base was obtained as a light yellow, slightly fluorescent liquid boiling at 147–149° (0.5 mm.); yield 62%.

**The hydrochloride** was prepared as described in the same procedure. The crude product, upon five recrystallizations from ethyl acetate, in the presence of decolorizing charcoal, gave light yellow needles melting at 135–137.5°. The hydrochloride darkens upon standing.

*Anal.* Calcd. for $C_{18}H_{26}N_2$·HCl: C, 70.45; H, 8.87; N, 9.13; Cl, 11.55. Found: C, 70.40; H, 8.67; N, 9.07; Cl, 11.55.

## Summary

1. Four new 1-[β-(1-pyrrolidyl-ethyl]-indole derivatives, three new 9-[β-(1-pyrrolidyl)-ethyl]-carbazole derivatives, and 1-β-(dimethylaminoethyl)-2-phenylindoline hydrochloride have been prepared.

2. The results of preliminary pharmacological tests on these compounds for antihistaminic activity is reported.

# Characterization of Certain Alkaloids from *Fagara coco*

BY C. ERNST REDEMANN, BURNETT B. WISEGARVER AND GORDON A. ALLES

Stuckert[1] and co-workers in 1925 began the isolation and separation of the alkaloids of *Fagara coco* (Gill.) Engl. Six alkaloids were listed, only four of which, α-, β-, γ-, and δ-fagarine, were sufficiently well characterized to be considered discrete compounds. Merck and Company of Darmstadt subsequently carried out the isolation of the fagara alkaloids on a large scale and reported only two alkaloids, designated fagarine I, m.p. 163°, and fagarine II, m.p. 202°. Fagarine I is to be identified with α-fagarine, but fagarine II appears to be a new alkaloid. Later Deulofeu[2] and co-workers isolated α-, β-, and γ-fagarine from a sample of *Fagara coco* supplied by Stuckert. β-Fagarine has been identified[2] as skimmianine[3,4] and γ-fagarine as 8-methoxydictamnine.[5]

The structure of α-fagarine has been of interest since the report of Stuckert and Sartori[6] that it exerts a depressant action upon cardiac function, and the subsequent finding of Moisset de Espanés[7] that it raises the threshold for both auricular and ventricular fibrillation arising from faradic stimulation. It has more recently been reported as a superior substitute[8] for quinidine for controlling cardiac arrythmias. Stuckert[1] arrived at the empirical formula $C_{19}H_{22}NO_4$ for α-fagarine, while Merck[1] gave $C_{19}H_{23}NO_5$. Deulofeu[2,8,9] and co-workers concluded that the empirical formula is $C_{19}H_{23}NO_4$ and suggest a provisional structure.

Dried ground leaves and twigs of *Fagara coco* were extracted by the method of Deulofeu.[2]

(9) Deulofeu, Labriola and Berinzaghi, *J. Org. Chem.*, **12**, 217 (1947).

The α-fagarine thus obtained melted at 159–160° instead of either 163° or 169–170°, both values having been reported by Deulofeu. Analyses and molecular weight determination of our α-fagarine[10] indicated an empirical formula $C_{21}H_{23}NO_5$. The failure of Deulofeu and co-workers to determine neutral equivalent weights of the base and halogen analyses of the halogen acid salts of α-fagarine is probably responsible for the erroneous empirical formula they reported, for had they determined these quantities it would have been apparent that some of their analytical values were in error. Treatment of α-fagarine with phosphorus oxychloride gave an anhydromethochloride which is impossible with a compound having the provisional structure given by Deulofeu. In addition a careful repetition of Deulofeu's oxidative degradation in acid medium confirmed the presence of methanal, but failed to show any *m*-methoxybenzaldehyde. The identity of our α-fagarine with that described by Deulofeu is based upon the fact that five derivatives of our α-fagarine had melting points in agreement with the corresponding derivatives reported by Deulofeu.

α-Fagarine and α-allocryptopine[11] were found to be identical. Schmidt and co-workers[12] have shown that allocryptopine exists in two isomeric modifications, the α-melting at 160°, and the β-melting at 169–170°, which they were able to interconvert,[13] thus suggesting that these two modifications may arise from dimorphism. The melting points of α-allocryptopine and the α-fagarine we isolated are the same, while the higher melting point of β-allocryptopine is the same as that recently reported by Deulofeu[9] and co-workers for their α-fagarine. Deulofeu in an earlier paper[2] reported the m.p. of α-fagarine as 163°, which he subsequently attributed to a solvate. Jowett and Pyman[14] have isolated β-allocryptopine (γ-homochelidonine) from a closely related species of Fagara, *Xanthoxylum brachyacanthum*, F. Muell., more recently classified as *Fagara brachyacanthum* (F. Muell.) Engl.

α-Fagarine hydrochloride melted at 190–192° dec. which is in agreement with the dec. temperature of 190° reported by Haworth and Perkin[15] for α-allocryptopine hydrochloride. α-Fagarine aurichloride melted at 187° dec. in agreement with that given by Schmidt and Wintgen[12b] for α-allocryptopine aurichloride. When treated with phosphorus oxychloride α-fagarine gave an anhydromethochloride, m.p. 205°, which is close to the m.p. 200–201° reported by Gadamer[16] for the anhydromethochloride produced from α-allocryptopine by similar treatment.

An authentic sample of α-allocryptopine isolated from another plant source was kindly supplied by Dr. R. H. F. Manske. After recrystallizing both his α-allocryptopine sample and our α-fagarine from the same solvent a determination of the mixed melting point showed no depression. A comparison of crystal forms showed the two substances to be identical in crystal habit. The ultraviolet absorption spectra of α-fagarine and α-allocryptopine (Fig. 1) are identical, the two curves falling upon each other so exactly as to be indistinguishable. Our α-fagarine was shown to be identical with the α-fagarine commercially available in Argentina by direct comparison with an authentic sample purchased from the Laboratories Apotarg, Cordoba, Argentina. Both samples melted at 159–160° and in admixture showed no depression in m.p.

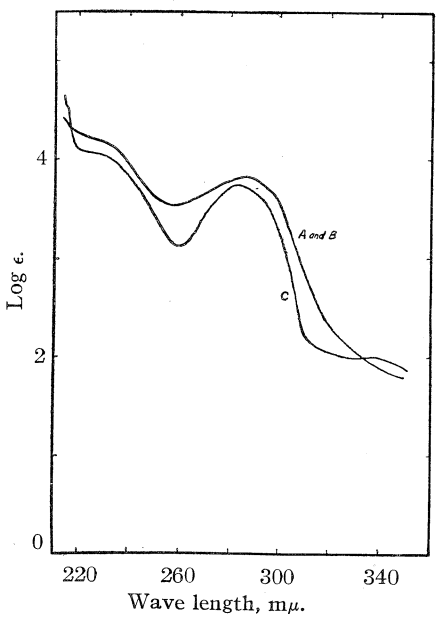

Fig. 1.—A, α-Allocryptopine; B, α-fagarine; C, α-fagarine hydrochloride.

It was found that a small quantity of hydrochlorides crystallized upon cooling a hot aqueous solution of the crude fagarine in dilute hydrochloric acid. The bases obtained from the crystalline hydrochlorides were separated into two fractions, one melting at 181–183° and the other at 198–199°. The base melting at 198–199° is to be identified with Merck fagarine II, while that melting at 181–183° appears to be new and will be referred to as fagarine III in this paper.

(10) Much difficulty was experienced in obtaining correct analyses of α-fagarine. Analyses were run by three commercial microanalytical laboratories and in our own laboratory before it was possible to get consistent analytical values.

(11) Stuckert annotated on p. 199 of his later report[1] that Merck suggested that α-fagarine was similar to α-allocryptopine, but this suggestion does not seem to have been followed. α-Allocryptopine is also called β-homochelidonine.

(12) (a) Schmidt and Fischer, *Arch. Pharm.*, **239**, 409 (1901); (b) Schmidt and Wintgen, *ibid.*, **239**, 438 (1901).

(13) We attempted the innerconversion following their directions, but all attempts were unsuccessful, probably because we had no seed crystals of the β-allocryptopine. The same difficulty is encountered with many polymorphic organic compounds.

(14) Jowett and Pyman, *J. Chem. Soc.*, **103**, 290 (1913).

(15) Haworth and Perkin, *ibid.*, 445 (1926).

(16) Gadamer, *Arch. Pharm.*, **258**, 148 (1919).

Analyses of fagarine II, its hydrochloride, hydrobromide, aurichloride and methiodide indicate an empirical formula of $C_{21}H_{23}NO_5$ for the base, with a methylimide, a methylenedioxy and two methoxy groups present. The lack of optical activity would indicate either the absence of an asymmetric carbon atom, or easy isomerization. Treatment with phosphorus oxychloride gave an anhydromethochloride. The ultraviolet absorption spectra of fagarine II and its hydrochloride (Fig. 2) are very similar to those of α-fagarine. The two molecules probably differ only in the positions occupied by the methylenedioxy and methoxy groups.

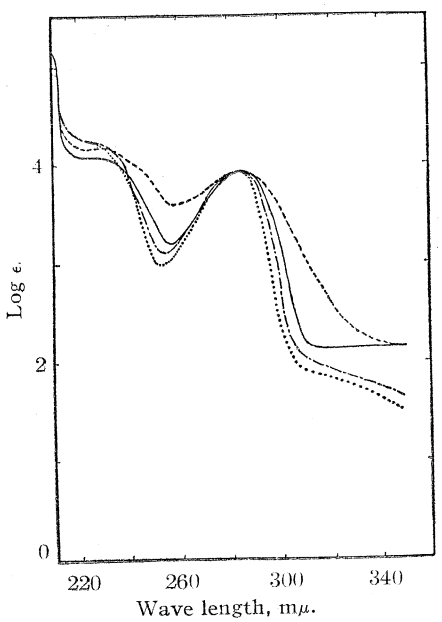

Fig. 2.— – – – –, Fagarine II; ——, fagarine II hydrochloride; – – – –, fagarine III; . . . . . , fagarine III hydrochloride.

The amount of fagarine III obtained has been too small for an extensive study of its properties and derivatives. This alkaloid gives no color with concentrated sulfuric acid, a negative Labat test for a methylenedioxy group, and is strongly levo-rotatory. Its ultraviolet absorption spectrum (Fig. 2) is similar to that of α-fagarine and fagarine II.

## Experimental[17,18]

**Purification of Crude α-Fagarine.**—Crude α-fagarine, extracted from ground *Fagara coco* by the method of Deulofeu,[2] was reprecipitated from its hydrochloride solution and then crystallized from ethanol giving pure α-fagarine, m. p. 159–160°. Samples of purified α-fagarine were crystallized from ethyl acetate, acetone, benzene and chloroform–petroleum ether, with no change in m. p. A sample of α-fagarine crystallized from ethyl acetate and dried at 100° *in vacuo* over phosphorus pentoxide at 2 mm. for nine hours was analyzed.

*Anal.* Calcd. for $C_{21}H_{23}NO_5$: C, 68.27, H, 6.27; N, 3.79; $CH_3O$, 16.80; mol. wt., 369.4; neut. eq., 369.4. Found: C, 68.47, 68.37; H, 6.18, 6.20; N, 3.37, 3.71; $CH_3O$, 16.93, 16.96; mol. wt., 362, 368, 370 (ebullioscopic in benzene); neut. eq., 368.5, 368.5, 369.5.

**α-Fagarine Hydrochloride.**—The hydrochloride was obtained from absolute ethanol solution in nearly the theoretical yield as a crystalline powder, m. p. 190–192° dec.; Deulofeu[9] gave the m. p. 192–193°. A sample of this hydrochloride was dried at 100° over phosphorus pentoxide at 2 mm. for six hours before analysis.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot C_2H_5OH \cdot HCl$: C, 61.1; H, 6.64; Cl, 7.87, $CH_3O$, 20.33. Found: C, 60.76, 60.78; H, 6.56, 6.60; Cl, 7.85, 7.89; $CH_3O$, 18.96, 19.17. (The ethyl alcohol of crystallization would be estimated as a methoxyl group, thus giving the equivalent of three methoxyl groups.)

The presence of ethanol in the analytical sample of α-fagarine hydrochloride was shown by distilling 5 g. with 20 ml. of 2 *N* hydrochloric acid and then redistilling the first 5 ml. of distillate. The first 0.5 ml. from the second distillation (b. p. 78°) was treated with 3 ml. of pyridine and 0.5 g. of 3,5-dinitrobenzoyl chloride, giving a 3,5-dinitrobenzoate, m. p. 92.5°, which is the melting point of ethyl 3,5-dinitrobenzoate. Concentration of the aqueous boiler residue from the first distillation gave a white crystalline product which turned slightly yellow when dried at 130° over phosphorus pentoxide at 2 mm. for two hours.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot HCl \cdot 0.5H_2O$: Cl, 8.54. Found: Cl, 8.54, 8.56.

The ionization constant of α-fagarine was estimated from the hydrolysis of its hydrochloride in aqueous solution. A 0.022 *M* solution of the hydrochloride in doubly distilled water had a *p*H of 5.38 at 25° from which the basic ionization constant, $K_b$, was calculated to be $1.3 \times 10^{-5}$.

**α-Fagarine Hydrobromide.**—This was prepared in ethanol by the procedure of Deulofeu.[9] The crystals were collected and dried at 100° over phosphorus pentoxide at 2 mm. for two hours; m. p. 185–188° dec.; Deulofeu gave 186–188° dec.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot HBr \cdot 0.5C_2H_5OH$: C; 55.7; H, 5.75; Br, 17.05. Found: C, 55.55; H, 5.77, Br, 16.95.

**α-Fagarine Hydroiodide.**—A solution of 300 mg. of α-fagarine in 5 ml. of ethanol and 0.5 ml. of freshly distilled hydroiodic acid (d. 1.57) was prepared by warming. Two crystal forms were observed after standing overnight. These were thought to be different solvates, since after drying they showed identical melting points, m. p. 192–194° dec. Deulofeu[9] gave 190–192° dec.

*Anal.* (A) Sample dried at 50° in air. Calcd. for $C_{21}H_{23}NO_5 \cdot HI \cdot C_2H_5OH$: I, 23.4. Found: I, 23.4. (B) Sample dried at 100° *in vacuo* over phosphorus pentoxide for three hours. Calcd. for $C_{21}H_{23}NO_5 \cdot HI$: C, 50.7; H, 5.52; I, 25.5. Found: C, 50.6; H, 5.52; I, 24.84, 24.95.

**α-Fagarine Methiodide.**—This was obtained by a slight variation of Deulofeu's procedure as a fine crystalline powder, m. p. 205–206°. Deulofeu gave 205°.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot CH_3I$: C, 51.6; H, 5.08; I, 24.84. Found: C, 51.77; H, 5.27; I, 24.82.

**α-Fagarine Picrate.**—This was prepared by the procedure of Deulofeu[9]; observed m. p. 207–208°; Deulofeu gave 208–209°.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot C_6H_3N_3O_7$: C, 54.1; H, 4.34. Found: C, 53.9; H, 4.45.

**α-Fagarine Aurichloride.**—A solution of 74 mg. of α-fagarine, 80 mg. of gold chloride, a few drops of diluted hydrochloric acid and 3 ml. of ethanol was prepared by warming slightly. Water was added to the warm solution, a few drops at a time, until just turbid. Garnet-red, warty, crystal masses gradually formed; m. p. 187° dec.

*Anal.* (A) Sample dried at 50° in air. Calcd. for $C_{21}H_{23}NO_5 \cdot HAuCl_4 \cdot H_2O$: Au, 27.0. Found: Au, 27.0.

(17) All melting points are uncorrected.

(18) The methoxy and methylimide determinations were made by the Elek Micro Analytical Laboratories, Los Angeles.

(B) Sample dried at 100° over phosphorus pentoxide *in vacuo* for three hours. Calcd. for $C_{21}H_{23}NO_5 \cdot HAuCl_4$: Au, 27.80. Found: Au, 27.82.

**Oxidation of α-Fagarine with Acid Permanganate.**—One gram of α-fagarine was oxidized by the procedure of Deulofeu.[9] An excess of a solution of 2,4-dinitrophenylhydrazine in 6 *N* hydrochloric acid was added to the steam distillate and the solution allowed to stand until precipitation was complete, in place of the ether extraction used by Deulofeu. The precipitate was collected and recrystallized from ethanol, giving yellow crystals, m.p. 165°, whose m.p. was not lowered in admixture with an authentic sample of formaldehyde 2,4-dinitrophenylhydrazone. The alcoholic mother liquor was evaporated to dryness leaving 30 mg. of a dinitrophenylhydrazone, m.p. 160–164°, whose m.p. was not depressed in admixture with formaldehyde 2,4-dinitrophenylhydrazone. In addition, Deulofeu[9] reported isolating *m*-methoxybenzaldehyde 2,4-dinitrophenylhydrazone, m.p. 220°, but we were not able to find any trace of such a substance.

The adequacy of our isolation procedure was demonstrated by a model experiment with 20 mg. of *m*-methoxybenzaldehyde which gave a copious yield of its 2,4-dinitrophenylhydrazone, m.p. 220°.

**Treatment of α-Fagarine with Phosphorus Oxychloride.**—A mixture of 2 g. of α-fagarine and 2 ml. of phosphorus oxychloride was allowed to stand without external heating for ten minutes, after which the mixture was heated in an 110° oil-bath for forty-five minutes. The excess phosphorus oxychloride was removed *in vacuo* and the residue was dissolved in hot water from which it crystallized upon cooling as very small needle crystals. Recrystallization from 2% hydrochloric acid gave crystals, m.p. 205° with previous browning and dec. A sample dried *in vacuo* at 130° decomposed.

*Anal.* (A) Dried at 50° in the air. Calcd. for $C_{21}H_{22}NO_4 \cdot HCl \cdot 3H_2O$: Cl, 8.01. Found: Cl, 8.04. (B) Dried at 65° for eight hours *in vacuo* over phosphorus pentoxide. Calcd. for $C_{21}H_{22}NO_4 \cdot HCl \cdot H_2O$: Cl, 8.71. Found: Cl, 8.63.

**Mixed Melting Point of α-Allocryptopine and α-Fagarine.**—A sample of authentic α-allocryptopine was kindly furnished by Dr. Manske. Both his sample and our α-fagarine were recrystallized from ethyl acetate. Each sample melted at 159–160° and no depression was shown in the melting point of their mixture.

**Isolation of Fagarines II and III.**—While working up a composite lot of 200 g. of crude α-fagarine from the first precipitation at *p*H 12–13, the dark-brown granular mass was dissolved in 2 l. of hot 1 *N* hydrochloric acid and the filtered solution was allowed to stand overnight at room temperature. The 43 g. of sparingly soluble hydrochloride which separated was dissolved in 2 l. of boiling water and the base liberated with sodium hydroxide. The crude base (26.5 g.) which separated was crystallized from "Cellosolve" and then from ethanol, giving 13.8 g. of fine white needles, m.p. 198–199°, of crude fagarine II. From the mother liquors 1.6 g. of another base, fagarine III, was obtained by taking advantage of its much smaller rate of crystallization. Fagarine III separated as large, pale yellow octahedral prisms, m.p. 181–183°.

**Fagarine II.**—Pure fagarine II was obtained by repeated crystallization of the crude fagarine II from "Cellosolve," ethanol, ethyl acetate and benzene. The melting point of the long fine white needles remained constant at 198–199°. This base showed no optical activity in chloroform solution, had a bitter taste and gave a red-violet color with concd. sulfuric acid which slowly changed to a purple color. The Labat test[19] for the methylenedioxy group was strongly positive.

*Anal.* Calcd. for $C_{21}H_{23}NO_5$: C, 68.27: H, 6.27; N, 3.79; 2 $CH_3O$, 16.80; mol. wt., 369.4; neut. eq., 369.4: 1 $CH_3N$, 7.8. Found: C, 68.4, 68.2; H, 6.31, 6.38; N, 3.61, 3.71; $CH_3O$, 15.29; mol. wt., 374 (ebullioscopic in benzene); neut. eq., 373, 374; $CH_3N$, 5.6.

(19) Labat, *Bull. soc. chim.*, [4] **5**, 745 (1909).

**Fagarine II Aurichloride.**—A solution of 160 mg. of fagarine II, 160 mg. of gold chloride trihydrate, 5 ml. of water and a few drops of hydrochloric acid was prepared by heating moderately. The aurichloride separated as a granular orange-colored solid, m.p. 218–219°. After boiling with ethanol and drying *in vacuo* at 130° this solid was analyzed.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot HAuCl_4$: Au, 27.80. Found: Au, 27.97, 27.49, 27.80.

**Fagarine II Methiodide.**—A suspension of 1.0 g. of fagarine II in 10 ml. of absolute ethyl acetate and 2 ml. of methyl iodide was heated in a sealed tube at 80° for four hours. The fine crystalline powder was collected and dried at 60°; weight 1.37 g. (99% yield); m.p. 234° dec.; sparingly soluble in hot water and hot ethanol.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot CH_3I$: C, 51.66; H, 5.13; I, 24.82. Found: C, 51.5; H, 5.18; I, 24.91, 24.78.

**Fagarine II Anhydromethochloride.**—A mixture of 1.0 g. of fagarine II and 2 ml. of phosphorus oxychloride was allowed to stand for ten minutes at room temp. During this time the solid dissolved with slight evolution of heat. After heating in an oil-bath at 110° for forty-five minutes the excess phosphorus oxychloride was distilled under reduced pressure and the residue was dissolved in 60 ml. of boiling water. The crystals which separated were recrystallized from 200 ml. of boiling 2% hydrochloric acid, giving pale yellow scales which turned red upon exposure to light. These crystals were dried in the dark at 50° and then in a brown glass vial at 65° for four hours *in vacuo* over phosphous pentoxide, weight 0.8 g.; m.p. 210–215° with previous sintering and browning.

*Anal.* Calcd. for $C_{21}H_{22}ClNO_4$: C, 65.01; H, 5.72; Cl, 9.14. Found: C, 64.5, 64.5; H, 6.05, 6.08; Cl, 8.57.

There may have been a slight contamination of unreacted fagarine II hydrochloride present in this material since the hydrochloride is much less soluble than the anhydromethochloride.

**Fagarine II Hydrochloride.**—A solution of 2.3 g. of fagarine II dissolved in a slight excess of hot dilute hydrochloric acid was evaporated to dryness. The residue was crystallized from ethanol–ether, giving 1.9 g. of microscopic needle crystals, m.p. 200–202° dec., but on rapid heating a m.p. as high as 215° dec. was observed. The sample for analysis was dried for four hours at 100° *in vacuo* over phosphorus pentoxide.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot HCl \cdot 0.5H_2O$: C, 60.79; H, 6.07; Cl, 8.54. Found: C, 60.5, 60.8; H, 6.29, 6.33; Cl, 8.47, 8.52.

**Fagarine II Hydrobromide.**—A suspension of 1.0 g. of fagarine II in 15 ml. of warm ethanol was treated dropwise with 48% aqueous hydrobromic acid until the solid dissolved and the solution was acidic. Ether was added to incipient turbidity and after standing for some time the crystalline hydrobromide was collected and dried four hours at 130° *in vacuo* over phosphorus pentoxide; weight 0.8 g.; m.p. 208–210° dec.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot HBr \cdot 0.5H_2O$: C, 54.91; H, 5.49; Br, 17.40. Found: C, 54.55, 54.30; H, 5.66, 5.73; Br, 17.60, 17.67.

**Fagarine II Picrate.**—A solution of 37 mg. of fagarine II in 25 ml. of hot ethanol was treated with 25 mg. of picric acid in 10 ml. of ethanol. Upon cooling, the bright yellow picrate crystallized as microscopic needles, m.p. 214°.

*Anal.* Calcd. for $C_{21}H_{23}NO_5 \cdot C_6H_3N_3O_7$: C, 54.2; H, 4.38. Found: C, 54.4; H, 4.65.

**Fagarine III.**—After recrystallizing from ethanol, pure fagarine III was obtained as almost colorless large octahedral prisms, m.p. 181–183°. This melting range could not be reduced by repeated crystallization from ethanol. $[\alpha]^{27}D$ −300° (112.4 mg. made up to 10.00 ml. with chloroform, $[\alpha]^{27}D$ −3.37°, *l*, 1 dm.). Fagarine III is tasteless, gives a colorless solution with concd. sulfuric acid, even when heated, and a negative Labat test[18] for a methylenedioxy group.

*Anal.* Calcd. for $C_{22}H_{26}NO_4$: C, 71.7; H, 7.07; N, 3.80. Found: C, 71.5, 71.6; H, 7.11, 7.17; N, 2.98, 3.03.

**Fagarine III Hydrochloride.**—Upon dissolving 1.6 g. of fagarine III in 200 ml. of dilute hydrochloric acid and cooling, very fine needle crystals of the hydrochloride separated. These were collected and dried at 130° *in vacuo* over phosphorus pentoxide; m.p. 232–234° dec.

*Anal.* Calcd. for $C_{22}H_{26}NO_4 \cdot HCl$: C, 65.2; H, 6.68; Cl, 8.77. Found: C, 64.4, 64.6; H, 6.87, 6.93; Cl, 9.15.

**Ultraviolet Absorption Spectra.**—The ultraviolet absorption spectra were determined using a Beckman model DU quartz spectrophotometer. The solvent was 99% ethanol for the bases, and 0.1 *N* aqueous hydrochloric acid for the hydrochlorides. Minimum slit widths were used with a 1.00 cm. quartz cell. All measurements were made against a blank of an identical sample of the pure solvent to eliminate its absorption.

**Acknowledgment.**—The authors wish to express their gratitude to Dr. R. H. F. Manske for supplying us with an authentic sample of α-allocryptopine.

## Summary

1. A re-investigation of α-fagarine and its derivatives has shown it to be identical with α-allocryptopine.

2. A second alkaloid, fagarine II, has been isolated and several derivatives have been prepared and analyzed. These data would suggest that fagarine II is isomeric with α-fagarine, differing only in the positions of the substituents.

3. Fagarine III has been isolated in very small amount. The ultraviolet absorption spectra of this alkaloid and its hydrochloride would suggest that it, also, belongs to the cryptopine group of alkaloids.

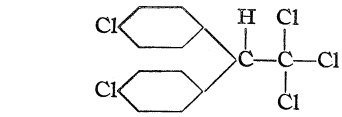
# The Action of Ultraviolet Light on DDT

BY ELMER E. FLECK

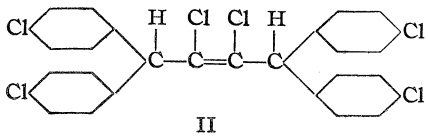
The prolonged residual action of DDT (I) is due to its low vapor pressure[1] and to its stability toward oxidation.[2] Recently evidence has been accumulating to show that DDT is not so stable when exposed to direct sunlight in solution as when it is exposed in the solid state.[3]

Attempts have been made to explain this phenomenon by isolating the decomposition products of DDT produced by ultraviolet light. The isolation of 4,4′-dichlorobenzophenone (IV) was accomplished during 1945 in this laboratory by irradiating DDT dissolved in γ-valerolactone in an open Petri dish with ultraviolet light from a 100-watt mercury-vapor lamp. Since that time Wichmann, *et al.*,[4] have confirmed the formation of this compound by isolating the 2,4-dinitrophenylhydrazone of 4,4′-dichlorobenzophenone from the products obtained by irradiation of a benzene solution of DDT in an open Petri dish with ultraviolet light.



The formation of 4,4′-dichlorobenzophenone from DDT has been assumed to proceed first by elimination of hydrogen chloride from the trichloroethane group and then by oxidation of the resulting double bond. This mechanism of reaction was tested by irradiation of solutions of DDT in completely filled quartz cells. A wide variety of solvents were tried, and in every case hydrogen chloride was evolved but dehydrochlorinated DDT could not be isolated.

When a solution of DDT in ethyl alcohol was irradiated with a 360-watt mercury-vapor lamp for sixteen hours, about 1 mole of hydrogen chloride was evolved. A strong odor of acetaldehyde was present, and cooling the solution yielded about 10% of a crystalline compound which melted at 230–231°. This was shown to be 2,3-dichloro-1,1,4,4-tetrakis-(*p*-chlorophenyl)-2-butene (II) by analysis and by mixed melting point determinations with authentic material made by the method of Brand and Bausch.[5] These authors prepared II by hydrogenation of DDT in the presence of Pd–$CaCO_3$ catalyst. The identity of the two compounds was further substantiated by conversion of the irradiation product into 1,1,4,4-tetrakis-(*p*-chlorophenyl)-1,-2,3-butatriene (III) by refluxing with alcoholic sodium hydroxide. This procedure eliminated 2 moles of hydrogen chloride from II and resulted in a yellow crystalline product which melted with decomposition at 286°. Brand and Bausch give 288° with decomposition for this same compound. Mixed melting points of the two preparations showed no depression.



The butatriene (III), obtained by irradiation and reaction with alkali, was oxidized with chromic anhydride to form IV. This is in accordance with the oxidation of III prepared by the method of Brand and Bausch.[5]

In order to eliminate the possibility of an unknown impurity being present in the *p,p′*-DDT, the irradiation was repeated with a second preparation of *p,p′*-DDT made from DDT produced by a different manufacturer. The same yield of II was obtained.

I

II

III

IV

Irradiation of dehydrochlorinated DDT and also of 1,1-dichloro-2,2-bis-(*p*-chlorophenyl)-ethane (TDE) in alcohol solution in quartz cells, under the same conditions that were used for DDT, resulted in recovery of the unchanged starting material.

The conversion of DDT into II by ultraviolet light provides a second and perhaps more probable mechanism by which sunlight may decompose DDT. The presence of another compound that can serve as a reactor with chlorine would tend to increase the speed of the reaction. In the case where alcohol is used as a solvent the chlorine oxidizes it to form acetaldehyde. When hydrocarbons are present the chlorine may react to form substitution products, or unsaturated groups in the molecule may serve as acceptors of chlorine to form addition compounds. These and other similar reactions may account for the more rapid decomposition of DDT in solution than in the solid state.

Although a large proportion of II would probably not exist at any one time in a DDT spray deposit, its presence can be detected by the yellow color of III formed by heating with alcoholic alkali. By contrast, the dehydrochlorinated DDT is colorless. When II is subjected to the colorimetric test of Schechter and Haller,[6] a wine-red color is produced. This is in contrast to the blue color produced by *p,p'*-DDT.

## Experimental

**Description of Apparatus.**—The quartz cell used was cylindrical in shape. The diameter was 40 mm. and the height 40 mm. A four × fifty mm. side tube was sealed on halfway up the side of the cylinder. This side tube was connected with a small rubber tube to a glass tube which was drawn down to a capillary. The rubber tube was shielded with a small piece of aluminum foil. The cell and side tubes were completely filled with liquid at the start of the experiment. As the solution warmed under the ultraviolet light, the excess liquid escaped through the capillary. The capacity of the cell was 42 ml.

In the early experiments a 100-watt Mazda mercury-vapor lamp was used. The light source was 25 cm. above the surface of the irradiated liquid. In the experiments with the quartz cell a 360-watt Uviarc lamp was used. It was fitted with an aluminum reflector and mounted so that the source of light was 25 cm. above the surface of the quartz cell. The cell was placed on a filter paper and was cooled by a strong current of air from an 8-inch fan. The temperature of the solution was between 35 and 40° during the experiments.

**Irradiation of DDT in Presence of Air.**—A solution of 1 g. of *p,p'*-DDT (m. p. 108–109°) in 10 ml. of γ-valerolactone was placed in a 100-mm. Petri dish. The irradiation was carried out for forty hours with the 100-watt mercury-vapor lamp. At the end of this period the solution had acquired a yellowish cast, and some of the DDT had crystallized on the side of the Petri dish. The liquid was pipetted out of the dish into water. The oil that separated crystallized when stirred. The mixture was extracted with ether and the ether solution washed with water until the wash was neutral to congo red. The ether was evaporated on the steam-bath, and the residue was taken up in 20 ml. of alcohol. When this solution was held at 0°, crystals separated which proved to be DDT (m. p. 107–108°, yield 0.4 g.).

The mother liquor from this separation was held at −30° for several days. The crystals that separated were recrystallized from alcohol to a constant melting point of 144–145°, yield 0.1 g. No depression of melting point could be observed when the sample was mixed with authentic 4,4'-dichlorobenzophenone.

**Irradiation of DDT in Absence of Air.**—A solution of 1 g. of *p,p'*-DDT (m. p. 108–109°) in 30 ml. of boiling alcohol was washed into the quartz cell with alcohol. The cell was cooled to room temperature and completely filled with alcohol. The capillary side tube was filled with alcohol and attached to the cell. The cell was placed with a flat surface up and irradiated for four hours with a 360-watt mercury-vapor lamp. The cell was then reversed and irradiated for four hours through the other window. This was followed by four hours of irradiation on each side of the cell with the side tube as a pivot. This change of surface is necessary, as small amounts of decomposition products deposit on the inside of the window and thereby reduce the yield. Between runs it was necessary to clean the cell with boiling ethyl acetate and also with boiling acetone.

The alcoholic solution irradiated in this manner acquired a yellowish cast. It sometimes contained a small amount of crystalline material. The product of irradiation was removed from the cell and cooled to −30° for several days. Four such runs were combined and filtered. A yield of 0.4 g. of crystalline material of melting point around 200° was obtained. Recrystallization from benzene gave prisms which melted at 230–231°. No yellow color was developed when a carbon tetrachloride solution was treated with tetranitromethane.

*Anal.* Calcd. for $C_{28}H_{18}Cl_6$: C, 59.29; H, 3.20; Cl, 37.51. Found: C, 59.59, 59.81; H, 3.38, 3.36[7]; Cl, 37.56.

No depression of melting point could be observed when this material was mixed with II prepared by the catalytic reduction of *p,p'*-DDT.[5]

II is insoluble in water, but very slightly soluble in methanol and ethanol. It is slightly soluble in ethyl acetate and acetic acid, and soluble in hot benzene, toluene, and chloroform.

**Hydrogen Chloride Produced by Irradiation of DDT.**—Alcoholic solutions of 1 g. of *p,p'*-DDT were irradiated as above for four-, eight- and sixteen-hour periods. Each alcoholic solution was poured into 200 ml. of water to which 3 ml. of concentrated nitric acid had been added. When precipitation was complete, the mixture was filtered

(6) M. S. Schechter, S. B. Soloway, R. A. Hayes and H. L. Haller, *Ind. Eng. Chem., Anal. Ed.*, **17**, 704 (1945).

(7) Analysis by N. Green.

by gravity and the filter paper washed with water. The filtrate was titrated with silver nitrate by means of an electrometric titrimeter.

*Anal.* Calcd. as moles of hydrochloric acid per mole of DDT: 4-hour irradiation, 0.39; 8-hour irradiation, 0.67; 16-hour irradiation, 0.88.

**1,1,4,4-Tetrakis-(*p*-chlorophenyl)-1,2,3-butatriene (III).**—A suspension of 100 mg. of II (from irradiated DDT) in 50 ml. of 2 *N* alcoholic potassium hydroxide was refluxed for two hours. The mixture was poured into 150 ml. of water and filtered by gravity when precipitation was completed. The yellow reaction product was washed with water, and the washings were added to the filtrate. The reaction product was dissolved in 50 ml. of benzene and shaken with water. The aqueous extracts were added to the filtrate.

The benzene solution was concentrated to 5 ml. on the steam-bath, and the yellow-orange needles that separated were recrystallized and dried in vacuum at room temperature. The product melted at 288° with decomposition, and no lowering of melting point could be observed when it was mixed with III prepared in accordance with Brand and Bausch.[5]

The filtrate from the original precipitation together with the washings was neutralized with concentrated nitric acid, and then a 3-ml. excess was added. The solution was titrated with 0.1 *N* silver nitrate with an electrometric titrimeter.

*Anal.* Calcd. for $C_{28}H_{18}Cl_6$: 2 moles Cl, 13.40 mg. Cl. Found: 13.65 mg. Cl.

**4,4′-Dichlorobenzophenone (IV).**—A solution of 45 mg. of III (from irradiated DDT) and 50 mg. of chromic anhydride in 5 ml. of acetic acid was refluxed for two hours. The solution was poured into 50 ml. of water and the reaction product filtered and recrystallized from alcohol. The product weighed 27 mg. and melted at 145–146°. No depression of melting point was observed when the product was mixed with authentic 4,4′-dichlorobenzophenone.

The ketone yielded an oxime of melting point 134–135°. Dittrich[8] gives the melting point as 135°.

## Summary

It has been shown that ultraviolet light catalyzes the decomposition of DDT.

One of the decomposition products is 4,4′-dichlorobenzophenone when air is present. In the absence of air 2,3-dichloro-1,1,4,4-tetrakis-(*p*-chlorophenyl)-2-butene is formed. This compound, through loss of hydrogen chloride and subsequent oxidation, may be converted into 4,4′-dichlorobenzophenone.

# Catalytic Reduction of Aromatic Ketones

BY E. C. HORNING AND D. B. REISNER[1]

The problem of reducing β-aroylpropionic acids to the corresponding γ-arylbutyric acids in convenient fashion and in good yield has led to continued investigation of classical chemical methods for the reduction of an aryl keto group to a methylene group. This work has led to the development of greatly improved procedures in the form of the Clemmensen–Martin–Sherman procedure[2] and the Wolff–Kishner–Huang method.[3] Modifications of these procedures can be applied to the reduction of aliphatic and alicyclic carbonyl groups as well, and these methods are of particular value because of this degree of generality.

The reduction of a carbonyl group adjacent to an aromatic nucleus does not present a difficult problem in terms of reactivity; the conversion of keto groups of this kind to the corresponding alcohols has been observed under a variety of mild catalytic hydrogenation conditions, and it is known that compounds of the benzyl alcohol type will undergo catalytic hydrogenolysis with ease to yield a fully reduced system. The fact that catalytic methods are not widely used for the reduction of such carbonyl groups to methylene groups is apparently due to the circumstance that appropriate catalytic conditions have not been established in many instances. We have found that certain types of carbonyl compounds can be reduced easily and in good yield by catalytic means, but that it is not always possible to predict in advance what effect structural changes will have upon the reduction. For example, 6-acetoxycoumaran-3-one can be reduced easily to 6-acetoxycoumaran, but under the same conditions the reduction of 6-hydroxycoumaran-3-one proceeds very slowly to give a mixture which includes products resulting from reduction of the aromatic ring.[4]

In the case of ketoacids, catalytic reduction with a palladium–carbon catalyst appears to proceed with particular ease in acetic acid at 65°. Two examples of the reduction of β-aroylpropionic acids are described; on a scale of about 0.1 mole the reduction was completed in about thirty or forty minutes, and the product was isolated easily in good yield. There was no apparent change in the rate of reduction during this period, and no attempt was made to isolate an intermediate reduction stage. For acids of this kind, this method may be superior to the procedures now in general use.

The reduction of *o*-benzoylbenzoic acid proceeded smoothly and rapidly to give *o*-benzylbenzoic aid in 95% yield.

The reduction of benzoin, under the same conditions, occurred very much less readily. The rate of reduction was rapid at first, but the time required for completion was much longer (about eight hours) and slightly less than the theoretical

(4) Horning and Reisner, *ibid.*, **70**, 3619 (1948).

amount of hydrogen was taken up. The product, 1,2-diphenylethane, was isolated easily in crystalline form by dilution of the solvent with water. In this case, both oxygenated functional groups were converted to methylene groups.

**Acknowledgment.**—We are indebted to the Research Corporation for a grant-in-aid of this work.

## Experimental

All melting points are corrected.

**Palladium–Carbon Catalyst.**—A 5% palladium–carbon catalyst was prepared according to the general method of Hartung.[5] The palladium was obtained from J. Bishop and Company, in a 10% solution, and was deposited on Norit.

**γ-(*p*-Tolyl)-butyric Acid.**—A mixture of 20.0 g. of β-(*p*-toluyl)-propionic acid,[6] 3.0 g. of 5% palladium–carbon catalyst, and 40 ml. of acetic acid was shaken with hydrogen (initial pressure, 40 lb.) in a Parr hydrogenation apparatus at approximately 65°. The reduction (100% absorption) was completed in about twenty-five minutes. No further absorption occurred on continued shaking. The catalyst was removed by filtration and washed with acetic acid. The solvent was removed by distillation at atmospheric pressure; the distillation was continued under reduced pressure to yield 14.7 g. (79%) of γ-(*p*-tolyl)-butyric acid, b. p. 124–134° (0.3–0.5 mm.), m. p. 54–56° (reported, m. p. 61–62°, 92%, Clemmensen–Martin method).[7]

**γ-(*p*-Anisyl)-butyric Acid.**—The reduction of 20.8 g. of β-(*p*-anisoyl)-propionic acid[8] was carried out in 125 ml. of acetic acid with 3.0 g. of 5% palladium–carbon catalyst at approximately 65°. About forty minutes was required for the reduction (100% absorption). After removal of the catalyst, the solution was added to 200 ml. of water. The mixture was chilled and filtered to provide 14.5 g. (75%) of colorless γ-(*p*-anisyl)-butyric acid, m. p. 61–62° (reported, Clemmensen–Martin method, m. p. 59–60°, 65%[9]; m. p. 60–61°, 85%[7]; Wolff–Kishner–Huang method, 75%.[10]

***o*-Benzylbenzoic Acid.**—The reduction of 27.6 g. of *o*-benzoylbenzoic acid was carried out in 40 ml. of acetic acid with 3.0 g. of palladium–carbon catalyst at approximately 65°. About seventy-five minutes was required for completion of the reaction. After removal of the catalyst, the solution was poured into 200 ml. of water, and the mixture chilled for twelve hours. Filtration and drying *in vacuo* yielded 24.5 g. (95%) of colorless *o*-benzylbenzoic acid, m. p. 111–113° (reported, m. p. 113–114.2°, 75%, Clemmensen method).[11] The product was completely soluble in warm sodium bicarbonate solution.

**1,2-Diphenylethane.**—The reduction of 21.2 g. of benzoin was carried out in 200 ml. of acetic acid with 3.0 g. of 5% palladium–carbon catalyst at 65°; the rate of hydrogen absorption slowed gradually and stopped after about eight hours at 92% of completion. The catalyst was removed and the solution was poured into 300 ml. of water. The product crystallized immediately; after chilling, filtration yielded 13.5 g. (74%) of 1,2-diphenylethane, m. p. 49–50° (reported,[12] 51.5–52.5°).

## Summary

A method for the catalytic reduction of certain aryl ketones is described. The keto group is reduced to a methylene group in acetic acid solution at 65° with a palladium–carbon catalyst.

# Allylic Chlorides. V. Relative Reactivities with Sodium Ethoxide in Ethanol

BY LEWIS F. HATCH AND HAROLD E. ALEXANDER

The relative reactivities of various allylic chlorides with potassium iodide in acetone have been reported[1,2] which indicate that both position isomerism and geometrical configuration have an effect on the rate of reaction. Although the reaction between sodium ethoxide and several allylic chlorides has been reported,[1,3] no effort had been made to ascertain if this reaction is influenced by geometrical configuration until the recent work of Andrews and Kepner.[4] Young and Andrews[3] had, however, suggested that this might be the case.

The present study was made to extend previously reported investigations on the sodium ethoxide reaction to determine the effects of substituents on the rate of reaction, and also to confirm the observation of Andrews and Kepner pertaining to the lack of influence of geometrical isomerism.

## Materials

**1-Chloro-1-propene.**—A mixture of *cis* and *trans* 1-chloro-1-propene (Research Chemicals, San Jose, California) was distilled to obtain a fraction with a boiling range of 34–35°. This fraction, being intermediate in boiling range between the two isomers (*cis* 32.0–32.2°; *trans* 36.7°), was assumed to contain both isomers.

**Allyl chloride**[5] boiling at 44.3° was used without further purification; $n^{25}D$ 1.4109.

**Methallyl chloride**[5] was redistilled and a fraction boiling at 70.9–71.0° was used.

**2-Bromo-3-chloro-1-propene** obtained from Halogen Chemicals of Columbia, S. C., was distilled at 150 mm. pressure. The fraction used boiled at 61.5°; $n^{25}D$ 1.4967.

**2,3-Dichloro-1-propene**[5] was distilled at 150 mm. pressure and a fraction boiling at 48° was used: $n^{25}D$ 1.4578; $d^{25}_4$ 1.2004; *MR* (calcd.) 25.32, (obsd.) 25.16.

**1,3-Dichloropropene.**—A mixture of the two isomers of 1,3-dichloropropene[5] was fractionated. The low boiling

(5) Furnished by Shell Chemical Co., San Francisco, California.

isomer boiled at 103.3°: $n^{25}D$ 1.4653. The high boiling isomer boiled at 111.5–111.9°: $n^{20}D$ 1.4742.

**1,3-Dichloro-2-methyl-1-propene.**—The isomeric 1,3-dichloro-2-methyl-1-propenes were prepared from methallyl chloride.[6] The methallyl chloride was chlorinated to 1,2,3-trichloro-2-methylpropane using sulfuryl chloride. The trichloride was dehydrochlorinated and hydrolyzed to a mixture of the 3-chloro-2-methyl-2-propen-1-ols from which the two alcohols were separated by means of a Podbielniak Hypercal distillation column. The chloroalcohols were converted to the corresponding dichlorides using concentrated hydrochloric acid. The low boiling isomer boiled at 130°: $n^{25}D$ 1.4702. The high boiling isomer boiled at 132°: $n^{25}D$ 1.4745.

**1,1,3-Trichloro-2-methyl-1-propene** was obtained from Halogen and Perfume Chemicals, Columbia, S. C., and was distilled at 150 mm. The fraction used boiled at 101°: $n^{25}D$ 1.4932.

## Experimental

The rates of reaction were obtained at 50.0 ± 0.1° using the procedure described by Tamele, *et al.*[1] The molar concentration of the chloride was 0.0998 ± 0.0018 and of the sodium ethoxide 0.0984. The data obtained are given in Table I. For each chloride at least four measurements were made covering the range of about 25 to 60% conversion. The individual values showed little or no drift and were constant as indicated in column 3 of Table I wherein the mean values of $k$ are given along with the average deviation of the individual measurements from them.

## Discussion

Table I lists the various allylic chlorides studied in the increasing order of their relative reactivity. The rate constant of allyl chloride was taken as unity, because all the other allylic chlorides may be considered as derivatives of allyl chloride, and also for a comparison between this reaction and that with potassium iodide.[2] A mixture of *cis* and *trans* 1-chloro-1-propene was tested to determine if a vinyl chlorine would react under the conditions of the rate determinations. There was no measurable reaction in twenty-four hours at 50°.

TABLE I

RELATIVE REACTIVITIES OF ALLYLIC CHLORIDES

| Compound | $k$ for $NaOC_2H_5$ 50° | Rel. reactivity $NaOC_2H_5$ 50° | Rel. reactivity KI 20°[a] |

[a] Hatch, Gordon and Russ, THIS JOURNAL, **70**, 1093 (1948). [b] A mixture of *cis* and *trans* isomers. [c] Tamele, Ott, Marple and Hearne, *Ind. Eng. Chem.*, **33**, 115 (1941). This may be the *trans* isomer. [d] Low boiling. [e] High boiling.

The influence of the relative electronegativity of the atom or group on the number 2 carbon apparently is not as pronounced nor as consistent as it is for the reaction with potassium iodide. The effect of replacing the number 2 hydrogen with chlorine is more pronounced than in the potassium iodide reaction, but the bromine compound has essentially the same relative reactivity. Replacing the hydrogen with a methyl group increases the reactivity very slightly in contrast to a definite increase in reactivity toward potassium iodide. There is a slight inhibiting effect of the methyl group noted between the 1,3-dichloropropenes and the 1,3-dichloro-2-methyl-1-propenes.

A chlorine atom on the number 1 carbon causes a definite increase in the reaction rate, while a second chlorine atom in the same position (1,1,3-trichloro-2-methyl-1-propene) more than doubles the relative reactivity. Tamele, *et al.*, found that crotyl chloride (probably either *trans* or predominantly *trans*) had a relative reactivity of 3.71 at 35° compared to allyl chloride at the same temperature. This would indicate that a methyl group on the number 1 carbon has a greater activating effect than chlorine in the same position. Previous work[1,2] has indicated that with potassium iodide, chlorine has a greater activating effect than a methyl group.

The effect of geometrical configuration is much less pronounced and in the opposite direction from that shown in the reaction with potassium iodide. It is of interest to note that the high boiling isomer of 1,3-dichloropropene has nearly the same relative reactivity for both reactions. The relative reactivities of both isomers of 1,3-dichloro-2-methyl-1-propene, however, are much less than with potassium iodide. This reduced reactivity with sodium ethoxide may be caused by the lack of the activating effect of a methyl group in the number 2 position, an activation which is present with the potassium iodide reaction.

From these observations it is suggested that the reactions of allylic chlorides with sodium ethoxide and with potassium iodide may go by different mechanisms. It has been postulated[2] that the reaction with potassium iodide takes place through a negative iodide ion attack on the carbon atom holding the allylic chlorine. It may be that the reaction with sodium ethoxide is through an electrophilic attack on the allylic chlorine by the sodium ethoxide molecule. A reaction of this type should not be influenced appreciably by geometrical configuration, but should respond to inductive effects.

**Acknowledgment.**—This investigation was supported by a Grant-in-Aid from the Research Corporation for "Research on Allylic Chlorides." The authors wish to express their appreciation.

## Summary

A study has been made of the effect of both substituents and geometrical configuration on the relative reactivity of allylic chlorides with sodium ethoxide in ethanol at 50°.

(6) Hatch, Russ and Gordon, THIS JOURNAL, **69**, 2614 (1947).

The replacement of the hydrogen on the number 2 carbon by chlorine or bromine decreases the reactivity of the allylic chlorine. The effect of a methyl group in this position is very slight.

The replacement of the hydrogen on the number 1 carbon by chlorine causes a marked increase in reactivity.

It has been confirmed that geometrical configuration has only a slight effect on this reaction. It is suggested that the reaction mechanism for the reaction with sodium ethoxide is different from that in the reaction between allylic chlorides and potassium iodide.

# Allylic Chlorides. VI. Preparation of the 1,3-Dichloro-2-butenes

BY LEWIS F. HATCH AND STUART G. BALLIN

Several investigators have reported the preparation of 1,3-dichloro-2-butene from either vinylacetylene[1,2] or methyl vinyl ketone,[3] but no attempt was reported of the isolation and characterization of its two geometrical isomers. This is understandable, because the two isomers boil within 2 degrees of one another, and the higher boiling isomer rearranges to the lower boiling isomer rather readily.

Recently, 1,3-dichloro-2-butene has become available commercially and is called DCB.[4] It was possible, however, to obtain only the lower boiling isomer from this material probably because previous heating had rearranged the higher boiling isomer to the lower.

The two isomers of 1,3-dichloro-2-butene have now been prepared by the addition of hydrogen chloride to chloroprene. The isomers have been separated and various physical constants obtained. The same constants were also obtained for the corresponding isomeric chloro-alcohols (3-chloro-2-buten-1-ol). These data, together with available data from the literature, are given in Table I.

The 3,5-dinitrobenzoates were prepared from the dichlorides by use of silver 3,5-dinitrobenzoate and from the chloro-alcohols using 3,5-dinitrobenzoyl chloride. The high boiling chloro-alcohol gave a derivative of each isomer, probably because the hydrogen chloride (produced in the reaction) brought about interconversion.[5] This interconversion was also observed in the regeneration of the dichlorides from the corresponding chloro-alcohols. These interconversions of the high boiling isomer to the low boiling isomer would indicate that the high boiling isomer had the *cis* configuration. The geometrical configuration of the two isomers as indicated by their relative reactivities with potassium iodide,[6] cuprous chloride catalyzed hydrolysis[7] and sodium ethoxide[8] is discussed in the following paper.[9]

## Experimental

**Attempt to Obtain the Geometrical Isomers of 1,3-Dichloro-2-butene from Commercial Sources.**—Only the low boiling isomer of 1,3-dichloro-2-butenes ($n^{25}D$ 1.4695) was isolated from DCB[4] by distillation at various pressures down to 20 mm.

**Hydrochlorination of Chloroprene.**—Two moles of chloroprene distilled from a chloroprene solution[10] containing 50% xylene and 0.1% catechol by weight was shaken for twelve hours in a pressure bottle at room temperature with 37% hydrochloric acid (4 moles), 50 g. of cuprous chloride, and 20 g. of ammonium chloride. The reaction mixture was then cooled and the organic layer was separated and distilled at 20 mm. pressure through a 40-cm. vacuum-jacketed column without packing. A 58% yield of relatively pure high boiling 1,3-dichloro-2-butene ($n^{25}D$ 1.4708 to 1.4712) was obtained together with some unreacted chloroprene and polymers. Repeated distillations of the center cut at 20 mm. pressure caused no change in the refractive index of $n^{25}D$ 1.4711 if the kettle temperatures were no higher than 35–40°.

Attempts to cause hydrogen chloride to add to chloroprene at room temperature without the use of cuprous chloride or under anhydrous conditions were unsuccessful.

**Separation of the Isomeric 1,3-Dichloro-2-butenes.**—When the products from the hydrochlorination of chloroprene were distilled through a 4-ft. glass-helices packed column at atmospheric pressure with kettle temperatures in the range of 130–135° a 30–40% yield of relatively pure low boiling 1,3-dichloro-2-butene ($n^{25}D$ 1.4692–1.4699) was obtained. Further distillations at pressures of 1 atmosphere or less caused no further change in the refractive index of $n^{25}D$ 1.4695. Moreover, when the higher boiling isomer was distilled at atmospheric pressure, or even at pressures of 150 and 100 mm., only the lower boiling isomer could be obtained in appreciable quantities.

Apparently the high boiling isomer is the labile form and can readily be converted to the stable isomer by heat. Attempts to demonstrate this by maintaining the two isomers at 100° were unsuccessful primarily because polymerization occurred with both isomers, and the resulting products could not be identified. The rate of polymerization of the high boiling isomer exceeded that of the low boiling isomer, as indicated by changes in index of refraction.

Small quantities of each isomer were stored in dark bottles at 0° and at 27° for five months; no change of the index of refraction was observed, but a discoloration developed in each case.

R.*), **7**, 658 (1937). Maybe this should have been 1.1592. [f] Determined by using a semimicro ebulliometer. [g] Apparently interconversion—both derivatives were isolated.

Various physical data for these dichlorides are given in Table I.

**3,5-Dinitrobenzoxy Derivative of the 1,3-Dichloro-2-butenes.**—The silver salt of 3,5-dinitrobenzoic acid was prepared by dissolving 4 g. of the acid in 80 ml. of 5% sodium hydrogen carbonate at room temperature. After filtration the solution was acidified with 10% nitric acid until the first permanent cloudiness of the free acid appeared. A 10% silver nitrate solution was added dropwise until no further silver salt precipitated. The product was filtered with suction, washed successively with hot water, ethanol, and ethyl ether, and dried in a vacuum desiccator. A 2-g. yield of a very light, flaky, white solid melting at 315° was obtained. Silver 3,5-dinitrobenzoate is very insoluble in water and all common organic solvents, but it dissolves readily in pyridine. It burns with a flame leaving a silver residue.

One gram of silver 3,5-dinitrobenzoate (0.0031 mole) was refluxed in 3 ml. of 95% ethanol with 0.3 ml. (0.0028 mole) of 1,3-dichloro-2-butene for one hour. The solid product was extracted with three 3-ml. portions of boiling ether, filtered and evaporated to dryness. The resulting yellowish solid was triturated with 5 ml. of 5% sodium carbonate solution and filtered with suction. More sodium carbonate solution followed by distilled water was used to wash the derivative.

Recrystallization of the benzoates from an ethanol–water solution produced nearly white crystals, melting at 75–76° for the low boiling dichloride, and 58–59° for the high boiling isomer. Further purification by this procedure produced no change in the melting points.

**Basic Hydrolysis of the 1,3-Dichloro-2-butenes.**—One hundred and twenty-five grams of the dichloride (1.0 mole) was treated with 106 g. of sodium carbonate (1.0 mole) in 2500 g. of water (4% sodium carbonate) in a 3-l. three-necked flask equipped with a stirrer. After three hours at 80° the two phases became homogeneous. The chloro-alcohol was distilled off as an azeotrope (98.1° for the low boiling isomer and 98.8° for the high boiling isomer). The aqueous layer in the distillate was further concentrated by distilling through a 3-ft column packed with glass helices; an additional quantity of the chloro-alcohol separated when the solution was saturated with sodium chloride. Yield of the crude 3-chloro-2-buten-1-ol was 75%.

**Catalytic Hydrolysis of the 1,3-Dichloro-2-butenes.**—The hydrolysis procedure used was similar to that for the basic hydrolysis except that the hydrolyzing solution contained 1.5% hydrochloric acid and enough copper (I) oxide to have 0.1 mole of cuprous chloride for each mole of allylic chloride and hydrogen chloride. The reaction was completed in less than a third of the time required for the basic hydrolysis, but the yield of the 3-chloro-2-buten-1-ol was not as high, because of a side reaction producing methylvinyl ketone.[9]

The isomeric chloro-alcohols were obtained by distillation through a 40-cm. column at 20 mm. pressure. As in the case of the corresponding dichloride, the high boiling isomer was readily converted to the low boiling, stable isomer by heat. Atmospheric boiling points were obtained on a semi-micro scale. The physical data obtained for these compounds are given in Table I.

**3,5-Dinitrobenzoate of the 3-Chloro-2-buten-1-ols.**—One ml. of each isomer of the chloro-alcohol was heated for ten minutes near its boiling point in a small test-tube with 0.5 g. of 3,5-dinitrobenzoyl chloride. The products were recrystallized from hot ethanol–water solution and identified by their melting points. The 3,5-dinitrobenzoxy derivative of the low-boiling 3-chloro-2-buten-1-ol melted at the same point as the 3,5-dinitrobenzoxy derivative of

the low boiling 1,3-dichloro-2-butene (75–6°). A mixture of the two dinitrobenzoxy derivatives also melted at 75–6°. The high boiling 3-chloro-2-buten-1-ol apparently gave a mixture of both isomers of 1-(3,5-dinitrobenzoxy)-3-chloro-2-butene.

**Regeneration of the 1,3-Dichloro-2-butenes from the 3-Chloro-2-buten-1-ols.**—Hydrogen chloride was passed for fifteen hours at room temperature into a 20-ml. sample of the chloro-alcohol contained in a small flask fitted with a reflux condenser. Heat developed at first, and there was an aqueous layer toward the end of the reaction. The product was washed twice with 25-ml. portions of water and dried over calcium chloride. Analysis by distillation at 20 mm. showed that while the corresponding dichloride was obtained from the low boiling chloro-alcohol, the high boiling isomer gave both isomeric 1,3-dichloro-2-butenes.

## Summary

The two geometrical isomers of 1,3-dichloro-2-butene have been prepared and the index of refraction, density, boiling point and the melting point of the 3,5-dinitrobenzoxy derivative of each isomer have been obtained.

The higher boiling isomer was converted into the lower boiling isomer at its boiling point, but it was stable at room temperature.

The index of refraction, density, freezing point, and boiling point of each isomer of 3-chloro-2-buten-1-ol have also been determined.

The low boiling 3-chloro-2-buten-1-ol gave the same 3,5-dinitrobenzoxy derivative as the low boiling dichloride but the high boiling chloro-alcohol gave a mixture of the two isomeric benzoates.

The high boiling 3-chloro-2-buten-1-ol is converted to the low boiling isomer by heat, and when treated with hydrogen chloride, a mixture of the isomeric 1,3-dichloro-2-butenes is formed.

# Allylic Chlorides. VII. Relative Reactivities of the 1,3-Dichloro-2-butenes

BY LEWIS F. HATCH AND STUART G. BALLIN

Current work on allylic chlorides has shown that geometrical isomerism plays an important part in determining the reactivity of the allylic chlorine with potassium iodide in acetone,[1] sodium ethoxide in ethanol,[2] and in the cuprous chloride catalyzed hydrolysis reaction.[3] These studies have been made using dichlorides with the basic structure

where X and Y are either both hydrogens, or where X is hydrogen and Y is a methyl group.

The recent availability of the two isomers of 1,3-dichloro-2-butene[4] has made possible an extension of this investigation to include a compound where X is a methyl group and Y is hydrogen. A compound of this type should be especially useful in evaluating the influence of steric hindrance of groups on the number 3 carbon for an $S_N2$ type reaction involving the number 1 carbon. A study of the influence of the relative position of the vinyl chlorine has been made by Tishchenko[5] for hydrolysis using calcium carbonate and water. He made no effort to separate the two isomers of 1,3-dichloro-2-butene.

## Experimental

**1,3-Dichloro-2-butenes.**—The isomeric 1,3-dichloro-2-butenes were prepared by the addition of hydrogen chloride to chloroprene.[4] They had the following physical properties: low boiling (alpha) isomer: b. p. (20 mm.) 33.3°; $n^{25}D$ 1.4695; $d^{25}_4$ 1.1528; high boiling (beta) isomer: b. p. (20 mm.) 34.0°; $n^{25}D$ 1.4711; $d^{25}_4$ 1.1542.

**Catalytic Hydrolysis with Cuprous Chloride in Hydrochloric Acid.**—The procedure previously reported[3] was modified to permit the use of the more stable cuprous oxide (Baker C. P. Analyzed, 98.8%) instead of cuprous chloride. One-fourth gram (0.0017 mole) of cuprous oxide was placed in a 200-ml. 3-necked flask fitted with a stirrer, condenser, and combination thermometer-well and carbon dioxide delivery tube. One hundred milliliters of 1.5% hydrochloric acid (0.041 mole) was added to the reaction flask and the cuprous oxide dissolved in about fifteen minutes at 75–85°. Carbon dioxide was slowly passed over the surface of the solution from the time the hydrochloric acid was added to the flask until the run was completed.

A five gram sample of the 1,3-dichloro-2-butene was weighed to the nearest milligram into 4 gelatin capsules (size 000). These capsules were added to the flask by removing the condenser, and dissolved within ten seconds under vigorous stirring. The reaction was carried out at a temperature of 40 ± 0.5°. At the end of the desired time the reaction mixture was cooled to 20° in about three minutes and a 1-ml. sample of the aqueous layer was pipetted into 50 ml. of distilled water containing 2 ml. of 10% sodium hydrogen carbonate solution. The extent of reaction was determined from the increase in chloride ion in a manner similar to that previously reported.[3]

Data for the hydrolysis of both isomers are given in Table I and Fig. 1. Both isomers gave chloride ion concentrations indicating that both chlorine atoms were hydrolyzable under the conditions of the reaction. The lower boiling isomer (alpha) gave the following data in addition to those in Table I: 6.25 hours, 122.0%; 9.00 hours, 131.5%.

The reaction mixtures apparently contained in addition to 3-chloro-2-buten-1-ol, a relatively large amount of methyl vinyl ketone. Tishchenko has reported[5] the formation of about 2% methyl vinyl ketone when 1,3-dichloro-2-butene was hydrolyzed with calcium carbonate.

**Attempted Catalytic Hydrolysis of 3-Chloro-2-buten-1-ol.**—Attempts were made to hydrolyze the vinyl chlorine of the lower boiling isomer of 3-chloro-2-buten-1-ol using the same conditions as used for the dichloride. There was no appreciable hydrolysis in half an hour at 40°, 60°, 80° or in 4.5 hours at 60°.

**Reaction with Potassium Iodide in Acetone.**—The same procedure was used as previously described.[1] Reaction rates and other data are given in Table I.

**Reaction with Sodium Ethoxide in Ethanol.**—These rates were also determined using a previously described procedure.[2] The concentration of the 1,3-dichloro-2-butenes was 0.1000 molar and the sodium ethoxide solution in ethanol was 0.0905 molar. The rate constants and other data are also given in Table I.

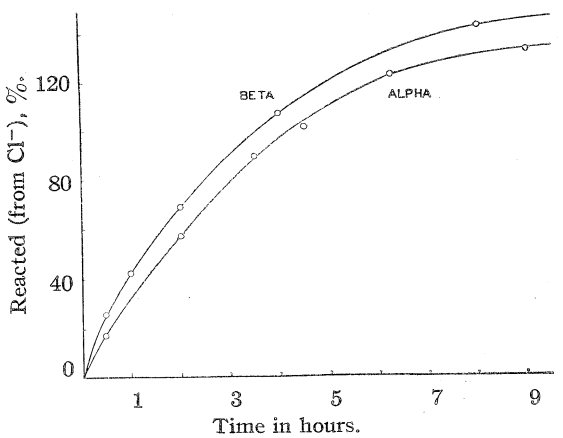

Fig. 1.—Catalytic hydrolysis of 1,3-dichloro-2-butene with cuprous chloride in hydrochloric acid.

## Discussion

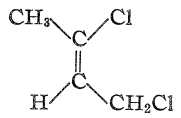
Previous work on the influence of geometrical isomerism on the reactivity of allylic chlorides has been with isomers of the types Cab–Cad and Cab–Cdc. The *cis* configuration for the latter type has been assigned to the isomer with the vinyl chlorine and the chloromethyl group on the same side of the molecule. The same convention is used with 1,3-dichloro-2-butene.

Neither of the isomers of either 1,3-dichloropropene or 1,3-dichloro-2-methyl-1-propene undergoes interconversion to the more stable form at its boiling point. With 1,3-dichloro-2-butene, however, the higher boiling isomer is readily converted at its boiling point to the lower boiling isomer.[4] Usually the *cis* form of geometrical isomers is the labile form and the *trans* form the stable one. The higher boiling (beta) isomer of 1,3-dichloro-2-butene is therefore tentatively assigned the *cis* configuration and the lower boiling (alpha) isomer the *trans* configuration.

It has previously been proposed from chemical evidence that the higher boiling isomers of both 1,3-dichloropropene and 1,3-dichloro-2-methyl-1-propene have the *cis* configuration. Chemical evidence of the type obtained in these studies, however, may be amenable to several interpretations. Andrews and Kepner[6] have interpreted some of these results in such a way as to indicate that the higher boiling isomers have the *trans* configuration.

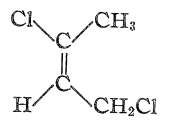
**Catalytic Hydrolysis.**—From the nature of the reaction and the errors inherent in following its course it has not been considered desirable to calculate a rate constant for the cuprous chloride catalyzed hydrolysis of 1,3-dichloro-2-butene. Figure 1 gives a graphic indication of the differences in rate of reaction between the two isomers.

As with 1,3-dichloropropene[3,7] the high boiling isomer of 1,3-dichloro-2-butene is the more reactive, but the difference in reactivity between the two isomers is not as great as it is between the isomers of 1,3-dichloropropene. This would indicate that a methyl group on the number 3 carbon of the *cis* isomer offers some interference to this reaction, although the over-all effect of a methyl group on this carbon is one of activation.



The fact that both chlorines of 1,3-dichloro-2-butene are hydrolyzable by cuprous chloride in hydrochloric acid while the vinyl chlorine in 3-chloro-2-buten-1-ol is not hydrolyzed under the same conditions is being studied further. Because both chlorines are removed from the dichloride, it was not possible to compare the rate of reaction of this compound with 1,3-dichloropropene to evaluate the effect of replacing a hydrogen on the number 3 carbon with a methyl group.

**Potassium Iodide.**—An interpretation of the results of the $S_N2$ reaction of potassium iodide with 1,3-dichloro-2-butene is based on the assumption that the reaction involves a nucleophilic attack on the carbon atom holding the allylic chlorine. A reaction of this type would be inhibited by the group in the *cis* position on the number 3 carbon with the size of the group governing the degree of inhibition. With 1,3-dichloropropene and 1,3-dichloro-2-methyl-1-propene the two substit-



(6) Andrews and Kepner, THIS JOURNAL, **69**, 2230 (1947).

(7) Data for the 1,3-dichloro-2-methyl-1-propenes will be given in a forthcoming paper.

uents are chlorine and hydrogen with a consequent wide difference in the relative reactivity of the geometrical isomers. When the two substituents are chlorine and a methyl group as with 1,3-dichloro-2-butene the difference in reactivity is only slight with the *cis* form being the most reactive.

*cis*, more reactive

*trans*, less reactive

The larger methyl group would be expected to cause the *trans* isomer to be less reactive.

A methyl group increases the reactivity of the allylic chlorine for this reaction when it is not in the *cis* position, where its activating effect is counteracted by its steric hindrance. This activation of the allylic chlorine by a methyl group on the number 3 carbon has been noted by Tamele, *et al.*,[8] and in these laboratories with 1-chloro-3-methyl-2-butene.[9]

**Sodium Ethoxide.**—The two isomers of 1,3-dichloro-2-butene show a relatively small difference in reactivity with the higher boiling isomer being the more reactive. This is similar to the results obtained with 1,3-dichloropropene and 1,3-dichloro-2-methyl-1-propene[2] and provides further evidence that this reaction is of a type different from that with potassium iodide and is only slightly affected by geometrical isomerism. As with the reaction with potassium iodide, substituting a methyl group for a hydrogen on the number 3 carbon increases the reactivity of the allylic chlorine. This observation has also been made by Tamele, *et al.*[8]

(8) Tamele, Ott, Marple and Hearne, *Ind. Eng. Chem.*, **33**, 115 (1941).

(9) Unpublished work of Louis S. Gerhardt.

## Summary

The relative reactivity of the geometrical isomers of 1,3-dichloro-2-butene has been determined for their reaction with potassium iodide, sodium ethoxide, and the cuprous chloride catalyzed hydrolysis reaction.

The high boiling (beta) isomer was the most reactive with each reagent.

The high boiling (beta) isomer is converted at its boiling point into the low boiling (alpha) isomer.

For these reasons the low boiling (stable) isomer of 1,3-dichloro-2-butene has tentatively been assigned the *trans* structure.

A methyl group on the number 3 carbon increases the reactivity of the allylic chlorine of 1,3-dichloro-2-butene.

# Preparation and Properties of Certain Alkyl Azamalonates[1]

BY CHESTER E. SLIMOWICZ AND ED. F. DEGERING

Although urethan, or ethyl carbamate, and many of its derivatives have been investigated as physiologically active agents,[2,3] no record has been found of a similar study of the unsubstituted alkyl azamalonates. The preparation of a few of these compounds has been reported, namely, ethyl methyl,[6] dimethyl,[7] diethyl,[4] and the ethyl phenyl[5] azamalonates.

Recently, Tompkins and Degering[10] have described a series of N-substituted diethyl azamalonates. In connection with this work, it was deemed desirable to prepare a series of N-unsubstituted azamalonates of the general formula ROOCNHCOOEt. These compounds were prepared by a modification of the procedure employed by Kraft.[8] The reaction may be represented by the equations

$$H_2NCOOEt + Na \longrightarrow H(Na)NCOOEt + {}^1/_2H_2, \text{ then}$$
$$H(Na)NCOOEt + ClCOOR \longrightarrow ROOCNHCOOEt + NaCl$$

It was found, however, that besides the expected mixed alkyl ethyl ester there were obtained the symmetrical diethyl and dialkyl di-esters. It is significant to note that the yield of the dialkyl di-ester, in general, was higher than that for the expected mixed ester. This result may be interpreted by assuming that a redistribution reaction occurred.

The compounds were either white crystalline solids having fairly low melting points, or colorless liquids having high boiling points. In all cases the di-esters were solids and the mixed esters were liquids. All of the compounds were generally soluble in the common organic solvents and insoluble in water. Their identification was based

on the characterization of the saponification products of each and on nitrogen determinations.

The compounds prepared, together with the evaluation of their fungicidal activity and their physical properties are summarized in Table I.

## Experimental[11]

The alkyl chloroformates used in this investigation were prepared by a method developed in this Laboratory by Engelman and Degering[12] in which yields of 85 to 95% were obtained.[13] Other investigators have reported yields approximately half these values.[14] The reactions were carried out in an efficiently ventilated hood.

The following examples may be considered as typical.

**Butyl Chloroformate.**—One mole (74 g.) of butyl alcohol was added dropwise (or in small amounts, if the alcohol is a solid), with stirring, to a half-molar excess (85 g.) of liquid phosgene contained in a large $1^1/_2'' \times 12''$ test-tube immersed in a salt–ice, or Dry Ice–trichloroethylene bath. (The latter was found a little more convenient to handle.) The reaction temperature during the addition of the alcohol was maintained at 0°, or slightly lower, otherwise the formation of the carbonate is favored. When all of the alcohol had been added, the bath temperature was allowed to rise very slowly to room temperature. (During this period the stopcock of the dropping funnel, which was protected by a drying tube filled with calcium chloride, was left open to permit the escape of excess phosgene. In case the phosgene boiled off too rapidly, it was necessary to cool the bath.) Then the reaction mixture was stirred ten to fifteen hours. The stirrer and dropping funnel arrangement was replaced by a stopper containing an inlet tube extending to the bottom of the reaction vessel and an outlet tube. The inlet tube was connected to a source of air and the reaction mixture aerated to expel the excess phosgene. As a precautionary measure the outlet tube was extended well into the hood vent by means of a rubber tubing connection.

After all of the phosgene had been expelled, the butyl chloroformate was purified[15] by distillation at reduced pressure. The fraction, b. p. 35–36° (13 mm.), weighed 117 g. (85% of the theoretical yield).

**Butyl Ethyl and Dibutyl Azamalonates.**—One mole (89 g.) of urethan was dissolved in 1.2 l. of xylene (purified grade) contained in a 3-l., three-necked flask equipped with a mercury-sealed stirrer, dropping funnel and water-cooled reflux condenser protected by a drying tube filled with anhydrous calcium chloride. One gram atom (23 g.) of metallic sodium was added and the mixture stirred and heated cautiously until all of the sodium had reacted. When the mixture had cooled to approximately 60°, one mole (136 g.) of butyl chloroformate was added dropwise. An exothermic reaction accompanied the addition of the chloroformate. The mixture was stirred at room temperature for approximately thirty hours, after which time it was filtered through a fritted glass filter. Three to five grams of filter-cel was stirred in with the mixture prior to filtration in order to facilitate the separation of the finely precipitated sodium chloride.

A red-brown colored oil was obtained from the filtrate after the solvent had been distilled at reduced pressure. On distillation, 116 g. of colorless liquid, b. p. 138–150° (13 mm.), was collected. This distillate was fractionated to give 20 g. of solid, b. p. 90–104° (3–4 mm.); 52 g. of liquid, b. p. 104–115° (3–4 mm.); and 42 g. of a solid pot residue.

The 20 g. fraction was recrystallized twice from petroleum ether (60–70°) to yield 14 g. of fine white needles, m. p. 48–50°. A mixture of this product with an authentic specimen of diethyl azamalonate, m. p. 49–50°, did not depress the melting point.

The 52 g. fraction was rectified in a 24-in. Podbielniak type column and yielded 25 g. of colorless liquid, b. p. 104–106° (4 mm.). Five grams of this product was refluxed for thirty hours with 40 ml. of 40% aqueous sodium hydroxide. The distillate from the alkaline solution was saturated with anhydrous potassium carbonate. The resulting alcoholic phase was pipetted into a 10-ml. Vigreux type distilling flask and fractionated to give one fraction distilling up to 85°, and the other, 85–115°. The lower boiling fraction gave positive iodoform and ceric nitrate tests; the higher boiling one gave a negative iodoform test and a positive ceric nitrate test. Each of these fractions was treated with 0.5 g. of 3,5-dinitrobenzoyl chloride to yield an ester, m. p.'s 90–91° and 62–63°, respectively, for the lower and higher boiling fractions. The

(15) Tetradecyl chloroformate was not distillable.

reported melting point for the ethyl ester is 93°; for butyl 64°.[16]

*Anal.* Calcd. for $C_8H_{15}O_4N$: N, 7.41. Found: N, 7.24, 7.44.

The 42-g. pot residue was recrystallized three times from ether–petroleum ether mixture to yield 38 g. of fine white needles, m. p. 42–43°. Four grams of this solid was saponified in the manner previously described. The saponification distillate gave a positive ceric nitrate test and a negative iodoform test. Treatment of the alcoholic phase of the distillate with 3,5-dinitrobenzoyl chloride resulted in an ester, m. p. 63–64°. The reported melting point for butyl 3,5-dinitrobenzoate is 64°.[16]

*Anal.* Calcd. for $C_{10}H_{19}O_4N$: N, 6.45. Found: N, 6.34, 6.28.

**Acknowledgment.**—The authors wish to express their appreciation to the Hooker Electrochemical Company for the generous supply of allyl chloroformate.

## Summary

The synthesis of a number of new alkyl azamalonate has been described and a redistribution reaction has been postulated for the formation of the symmetrical di-esters. These compounds are to be tested for their pharmacological activity.

Fungicidal data are presented.

# A Synthesis of Adrenaline-like Compounds

BY GÁBOR FODOR AND ÖDÖN KOVÁCS

According to a recent review[1] on the subject, the best method of obtaining aryl methylaminoethanols, *e. g.*, synephrine, is the condensation of ω-chloro-*p*-benzoyloxyacetophenone with methylbenzylamine, followed by hydrolysis and subsequent hydrogenation.[2] Another useful method[3] consists of the condensation of hydroxy derivatives of benzaldehyde bisulfite with a salt of nitromethane, followed by the reductive condensation of the nitro ethanol with formaldehyde[3] to the corresponding aryl aminoethanol.

An excellent synthesis of ephedrine is described by Manske and Johnson[4] from phenyl methyl methyl diketone with methylamine. In this process the authors applied, for the first time, ketonic aldehydes and diketones as starting materials[5]; no similar reactions have been reported previously in the literature.

However, the use of methoxy and hydroxy derivatives, even in the case of diketones, offered some difficulties. It was thought, therefore, to be of interest to work out a synthesis of hydroxy aryl ethanolamines, starting from hydroxy arylglyoxals, similar to that of phenyl-methylaminopropanol.[4]

4-Hydroxyphenylglyoxal[6] (II) has been obtained from phenol through 4-hydroxyphenyltrichloromethyl-carbinol.[7] We have synthesized it in another manner: first, 4-hydroxyacetophenone (I) was prepared according to Meerwein.[8] This was then oxidized with selenium dioxide, without protecting the phenolic group, to 4-hydroxyphenylglyoxal; this latter was isolated as a crystalline hydrate and further identified by its well defined quinoxaline derivative (V). Several attempts were made for the condensation of this ketonic aldehyde with methylamine, with subsequent or simultaneous reduction of the azomethine formed (III). However, when this amorphous compound or an equimolecular mixture of the glyoxal and of methylamine was reduced catalytically, a sudden initial reaction occurred, but the hydrogen consumption stopped with an absorption of only 0.5 to 0.8 mole of hydrogen against the calculated 2 moles. The expected 1-(4-hydroxyphenyl)-2-methylamine ethanol (IV) could not be obtained from the reaction mixture. We supposed that our failure to obtain the desired compound was due to the fact that the 4-hydroxyphenylglyoxal reacted with methylamine in much the same manner as phenylglyoxal, which gives heterocyclic condensation products with hydroxylamine,[9] ammonia[10] and methylamine.[11] In order to prevent these undesired reactions, we carried out experiments in which the azomethine was reduced instantaneously after its formation: the alcoholic solution of 4-hydroxy-phenylglyoxal was added under vigorous mechanical stirring drop by drop to a suspension of palladium on charcoal in an alcoholic solution of methylamine in a hydrogen atmosphere. Two moles of hydrogen were consumed for each mole of 4-hydroxy phenylglyoxal hydrate and a colorless solution resulted giving 1-(4′-hydroxyphenyl)-2-methylaminoethanol with good yield and high degree of purity. It seems, there-

fore, that the methylamine did not react with the ketonic group of the arylglyoxal (II).

Phenylglyoxal reacts with aminoguanidine in alkaline medium similarly as an aldehyde, whereas in acid medium a selective condensation of the ketonic group occurs.[12]

2-Hydroxyacetophenone[13] (Type I) was converted in a similar manner into the 2-hydroxy phenylglyoxal (Type II), characterized by its crystalline condensation product (VI) with *o*-phenylenediamine. Two moles of this *o*-hydroxy ketonic aldehyde reacted only with their aldehyde groups with one mole of diamine, as the ketonic group could be chelated by the *o*-standing hydroxy group, a hydrogen bridge being formed. Hydrogenation of 2-hydroxyphenylglyoxal by the method described above led to *o*-synephrine[14] (Type IV). 3-Hydroxyphenylglyoxal was obtained in the same way from 3-hydroxyacetophenone[15] and converted into the crystalline quinoxaline derivative.

4-Methoxyacetophenone[16] gave on oxidation with selenium dioxide the crystalline 4-methoxyphenylglyoxal hydrate (Type II). On reducing the latter together with methylamine, the expected amino alcohol could not be obtained; however, 1-(4′-methoxyphenyl)-ethanediol-1,2 was isolated with a good yield. Phenylglyoxal was converted similarly into 1-phenyl-ethanediol-1,2. In these cases the hydrogenation reaction of the ketonic aldehydes has a greater velocity than their condensation reaction with methylamine.

In order to employ the method for the synthesis of adrenaline derivatives, *e. g.*, N-isopropyl-nor-adrenaline,[17] it was necessary to prepare 3,4-dihydroxyphenylglyoxal as an intermediate. This was obtained by the oxidation of 3,4-diacetoxyacetophenone[18] to the corresponding 3,4-diacetoxyphenylglyoxal and subsequent hydrolysis with boiling water. It could not be obtained by the direct oxidation of 3,4-dihydroxyacetophenone with selenium dioxide as the *o*-hydroxy groups are oxidized prior to the methyl group.

When 3,4-dihydroxy phenylglyoxal was reduced catalytically together with isopropylamine, N-isopropylamino-nor-adrenaline[17] was obtained, as sulfate. We synthesized the same compound also from 3,4-dibenzyloxy phenylglyoxal, prepared from 3,4-dibenzyloxyacetophenone[19] with selenium dioxide, by reductive condensation with isopropylamine with a simultaneous hydrogenolysis of the benzyl ether linkage.

It is surprising that under our experimental conditions reductive condensation occurs smoothly only in the presence of free phenolic hydroxyl.

This 3-step synthesis of synephrine is far simpler than those discussed by Priestley and Moness,[1] or by Kamlet.[3] The new synthesis of N-isopropyl-nor-adrenaline, from catechol, via diacetoxyacetophenone and dihydroxyphenylglyoxal is also useful, as only these two intermediates must be isolated. The method is consequently of general value for the preparation of hydroxyaryl ethanolamines.[20]

## Experimental

**Phenylglyoxal hydrate**[21] was converted in a concentrated aqueous solution into 2-phenylquinoxaline,[22] m. p. 78°.

**4-Hydroxyphenylglyoxal Hydrate.**—Twenty-two and two-tenths grams (0.2 mole) of selenium dioxide was dissolved in 120 ml. of dioxane and 4 ml. of water at 60°, then 27.2 g. (0.2 mole) of 4-hydroxyacetophenone[8] was added and the reaction mixture boiled for four hours in a steam-bath. The separated selenium was filtered off, the yellow solution was evaporated in vacuum at 40°. The residue was treated with 150 ml. of water on the steam-bath for three hours under stirring, the resulting solution decolorized with charcoal, filtered and concentrated to a small volume. The yellowish colored hydrate crystallized. Yield was 31.4 g. (87%). Recrystallized from the fourth amount of water, 27 g. of greenish white prisms was obtained, m. p. 111°.[6] Oxidation in alcoholic solution gave a similar

(85%) yield; whereas in aqueous solution only 42% 4-hydroxyphenylglyoxal could be obtained.

**2-(4'-Hydroxyphenyl)-quinoxaline** was recrystallized from methanol as white plates, m. p. 204°.

*Anal.* Calcd. for $C_{14}H_{10}ON_2$: C, 75.66; H, 4.54. Found: C, 75.85; H, 4.68.

**4-Methoxyphenylglyoxal Hydrate.**—A mixture of 50 ml. of dioxane, 2 ml. of water, 11.1 g. (0.1 mole) of selenium dioxide and 15 g. (0.1 mole) of 4-methoxyacetophenone[16] was refluxed for forty-eight hours. After removal of selenium and of the solvent, the oily residue was treated with 500 ml. of water at 100° for four hours with stirring, the solution was clarified with charcoal, the hydrate crystallized on cooling. A second crop of crystals was obtained by concentrating the solution: yield was 15 g. (82%), m. p. 84°.

**2-(4'-Methoxyphenyl)-quinoxaline.**—Long colorless needles, from ethanol, m. p. 102°.

*Anal.* Calcd. for $C_{15}H_{12}ON_2$: C, 75.76; H, 5.12. Found: C, 75.99; H, 4.88.

**3-Hydroxyphenylglyoxal.**—A mixture of 10 g. of selenium dioxide (0.09 mole), 60 ml. of dioxane, 2 ml. of water and 13.6 g. (0.1 mole) of 3-hydroxyacetophenone[15] was refluxed for twenty hours, then worked up as described above. The hydrate, 14.3 g., could not be crystallized. It was identified by its crystalline quinoxaline derivative.

**2-(3'-Hydroxyphenyl)-quinoxaline.**—Yellow needles from ethanol, m. p. 169°.

*Anal.* Calcd. for $C_{14}H_{10}ON_2$: C, 75.66; H, 4.54. Found, C, 75.64; H, 4.65.

**2-Hydroxyphenylglyoxal.**—Thirteen and six-tenths grams (0.1 mole) of 2-hydroxyacetophenone[13] was oxidized in the same manner as described before. The oily glyoxal derivative, 12.1 g., could not be crystallized for identification; it was condensed with *o*-phenylenediamine.

**1,2-*bis*-(2'-Hydroxyphenyl-glyoxalylidene)-phenylenediamine.**—One and forty-three hundredths grams of the oily product was dissolved in 5 ml. of water, a hot solution of 1 g. *o*-phenylenediamine was added and the separated yellowish crystals filtered off. Recrystallization from ethanol produced delicate needles, 1.72 g., m. p. 295°.

*Anal.* Calcd. for $C_{22}H_{16}O_4N_2$: C, 70.79; H, 4.33; N, 7.54. Found: C, 70.69; H, 4.19; N, 7.20.

**3,4-Dibenzyloxyphenylglyoxal.**—From 10 g. (0.09 mole) of selenium dioxide in 150 ml. of ethanol (96%) and 33.2 g. (0.1 mole) of 3,4-dibenzyloxyacetophenone[19] 28.3 g. of recrystallized dibenzyloxyphenylglyoxal was obtained, m. p. 98–100°, white needles from ethanol.

**2-(3',4'-Dibenzyloxyphenyl)-quinoxaline.**—2-(3',4'-Dibenzyoxyphenyl)-quinoxaline was prepared in methanolic solution, since the glyoxal is insoluble in water; wadding-like needles from methanol, m. p. 118°.

*Anal.* Calcd. for $C_{28}H_{22}O_2N_2$: C, 80.36; H, 5.29. Found: C, 80.07; H, 5.30.

**3,4-Dihydroxyphenylglyoxal.**—A mixture of 11.1 g. (0.1 mole) of selenium dioxide and 26 g. (0.11 mole) of 3,4-diacetoxyacetophenone,[18] 65 ml. of dioxane and 2 ml. of water was refluxed for thirty hours. Selenium and the solvent were removed in the usual manner and the brownish oily residue hydrolyzed by treatment with 120 ml. of water and heating in a nitrogen atmosphere for six to ten hours in a steam-bath. The endpoint of the reaction is indicated by the formation in a sample taken from the solution of a crystalline precipitate with *o*-phenylenediamine. The decolorized solution yielded in the usual manner 18.1 g. of a solid foam.

**2-(3',4'-Dihydroxyphenyl)-quinoxaline,** yellow colored needles from diluted ethanol (50%), m. p. 254–256°.

*Anal.* Calcd. for $C_{14}H_{10}O_2N_2$: C, 70.58; H, 4.23. Found: C, 70.41; H, 4.42.

***dl*-1-(4'-Hydroxyphenyl)-2-methylaminoethanol.**—All reductions were carried out in a three-necked, round-bottomed flask, equipped with a ground glass mechanical stirrer (1000 to 1200 r. p. m.), a dropping funnel and a gas introducing tube.

One and six-tenths grams of Pd-charcoal (containing 12% PdO) in 100 ml. of ethanol was saturated with hydrogen, then 1.12 g. (0.03 mole or 20% excess) of methylamine in 60 ml. of ethanol was introduced. A solution of 5.31 g. (0.03 mole) 4-hydroxyphenylglyoxal hydrate in 80 ml. of alcohol was added slowly through the dropping funnel (10–12 drops per minute), followed by 40 ml. of alcohol. The mixture absorbed 1420 normal ml. of hydrogen in 110 minutes (calcd. 1344 ml. for 2 moles). The pale yellow colored solution was filtered from the catalyst and both the solvent and the excess methylamine were removed under reduced pressure at 50°. When the solution had been concentrated to one third of its volume, the product began to crystallize. The residue was cooled, filtered and washed with 5 ml. of ice-cold ethanol; yield was 4.05 g. (81%) of synephrine, m. p. 180°; after recrystallization from alcohol, the m. p. rose to 184°.[2]

*Anal.* Calcd. for $C_9H_{13}O_2N$: C, 64.65; H, 7.84. Found: C, 64.61; H, 7.69. Similar yields were obtained by using an Adams catalyst, or a Raney-nickel catalyst instead of palladium–charcoal.

**1-(2'-Hydroxyphenyl)-2-methylaminoethanol.**—Five and a half grams of the crude 2-hydroxyphenylglyoxal was condensed in the same manner as above with 1.39 g. of methylamine in the presence of 1.2 g. of the catalyst in 280 ml. of ethanol; 1080 ml. of hydrogen (calcd. for 2 moles 1344 ml.) was absorbed in 230 minutes. Evaporation in a vacuum furnished a crop (2.8 g.) of white crystals of the amino alcohol; recrystallized from ethanol (87%), m. p. 211°.

*Anal.* Calcd. for $C_9H_{13}O_2N \cdot H_2O$: C, 58.35; H, 6.42; N, 7.56. Found: C, 58.17; H, 6.11; N, 7.31.

**1-(3',4'-Dihydroxyphenyl)-2-isopropylaminoethanol (N-Isopropylnoradrenaline). A. From 3,4-Dihydroxyphenylglyoxal Hydrate.**—To a suspension of 1.6 g. of Pd-charcoal in 160 ml. of ethanol containing 1.92 g. (0.033 mole) of isopropylamine, 5 g. (0.03 mole) of the amorphous 3,4-dihydroxyphenylglyoxal in 120 ml. of ethanol was added drop by drop (5–8 drops per minute) at 50° in a hydrogen atmosphere under mechanical stirring. During 370 minutes 980 ml. (standard) of hydrogen was taken up (calcd. 1090 ml.). The solution was neutralized with 2 *N* sulfuric acid (calcd. for isopropylamine) and evaporated to a small volume. The sulfate of N-isopropyl-nor-adrenaline crystallized in white prisms, yield 3.75 g. (47%), m. p. 180°. It may be recrystallized from alcohol (90%). This compound was assayed by Prof. B. Issekutz, Jr., on guinea pigs for bronchospasmolytic activity and found as effective as aleudrine.[17]

*Anal.* Calcd. for $C_{11}H_{17}O_3N \cdot 0.5H_2SO_4$: N, 5.3. Found: N, 5.1.

**B. From 3,4-Dibenzyloxyphenylglyoxal.**—Ten grams (0.03 mole) of 3,4-dibenzyloxyphenylglyoxal, 2 g. (0.034 mole) of isopropylamine in 280 ml. of alcohol in the presence of 1.6 g. Pd-charcoal absorbed at 50° 2580 N ml. of hydrogen (calcd. for 4 moles 2690 N ml.) in 330 minutes. Yield was 4.9 g. (61%) of the same amino alcohol sulfate.

**1-Phenylethanediol-1,2.**—A solution of 4.56 g. (0.03 mole) of phenylglyoxal hydrate was added in ninety minutes to a suspension of 0.8 g. of Pd-charcoal in 160 ml. of ethanol, containing 1.4 g. (0.045 mole) of methylamine by the above-described method. During 120 minutes 1370 N ml. of hydrogen was absorbed (calcd. for 2 moles 1344 ml.). The solution was evaporated, the residue recrystallized from 10 ml. of benzene, furnishing 2.95 g. (71%) of white needles, m. p. 67°.[23] It does not contain nitrogen.

*Anal.* Calcd. for $C_8H_{10}O_2$: C, 69.51; H, 7.22. Found: C, 69.49; H, 7.21.

**1-(4'-Methoxyphenyl)-ethanediol-1,2.**—Starting with 5.46 g. of 4-methoxyphenylglyoxal hydrate, hydrogenation occurs under the same conditions as described for phenylglyoxal. The addition of the glyoxal required 110 minutes, the uptake of hydrogen stopped after 190 minutes and was 1350 N ml. (instead of 1344 ml. calcd.).

(23) Zincke, *Ann.*, **216**, 293 (1883).

Recrystallization produced 4.45 g. (68%) of 4-methoxyphenylethanediol, m. p. 82°. It is free of nitrogen.

*Anal.* Calcd. for $C_9H_{12}O_3$: C, 64.32; H, 7.17. Found: C, 64.50; H, 7.17.

**Acknowledgment.**—The authors are indebted to Mrs. Bruckner-Hatz and to Miss Kovács Oskolás for the microanalyses and to Prof. B. Issekutz, Jr., for the pharmacological assay of some compounds.

## Summary

A new synthesis of hydroxyaryl N-alkylamino ethanols is described. Hydroxyaryl methyl ketones, respectively, their esters or ethers were oxidized by means of selenium dioxide with very good yields to the corresponding aryl glyoxals. Some hydroxyaryl, respectively, benzyloxyaryl glyoxals were reduced together with methyl amine, respectively, isopropylamine to the adrenalinelike aryl ethanolamines. Synephrine and N-isopropyl-nor-adrenaline were prepared with good yields. Phenylglyoxal and 4-methoxy phenylglyoxal gave under the same conditions only the corresponding glycols as in these cases condensation before reduction of the glyoxals did not take place.

# Alkaloids of *Dichroa febrifuga*. I. Isolation and Degradative Studies[1]

BY J. B. KOEPFLI, J. F. MEAD[2] AND JOHN A. BROCKMAN, JR.

A part of the war-born government sponsored research on malaria[3] was directed to a search for new antimalarials from plant sources. In papers by Liu[4] there is incidental mention of an antimalarial drug indigenous to Yunnan, and samples of this drug (SN 6355),[5] supplied by Liu, when tested in this country were found to be quite active against avian malaria. The samples were labeled "Chunine Leaf Powder" and further identified only as "from Saxifragaceae." The significance of the Saxifragaceae as a source of new antimalarials was further indicated when the Chinese drug Ch'ang Shan (SN 10767), reputed to be the roots of the Saxifrage, *Dichroa febrifuga*, Lour., also proved active in avian malaria. The availability of an adequate supply of Ch'ang Shan plant material led to this investigation the results of which have been briefly communicated by us.[6]

In 1943 when we began our work, the available information on Ch'ang Shan was meager and often contradictory.[7] Furthermore, we were particularly concerned as to the botanical identity of our plant material since the Ch'ang Shan supplied us had been obtained from Chinese herb stores either in this country or abroad. Comparison of some of our root material with herbarium specimens and information[8,9] later available indicate that the type of Ch'ang Shan used in this investigation is derived from the roots of *D. febrifuga*. Supporting evidence of a chemical nature was obtained when we were able to isolate from *D. febrifuga* (SN 6521), botanically identified at the time of collection in India, the same alkaloids isolated from our supply of Ch'ang Shan.

Since *D. febrifuga* has long been used in the treatment of "intermittent fevers" in southeastern Asia it is surprising that except for one reference to a possible glucoside, "dichroin(?),"[10] no chemical examination of the plant has been reported until lately. References to investigations which have appeared recently will be cited below.

## Isolation and Characterization[11]

**Isolation from Ethanol Extracts.**—From crude basic fractions of *D. febrifuga* we have isolated two alkaloids for which we have proposed[6] the names febrifugine (DR 15381)[12] and isofebrifugine (SN 14821). Reports that this plant does not contain alkaloids[13,14] are probably explained by the fact that the alkaloidal content of the root material is small, 0.05 to 0.1%, and by the fact that Meyer's reagent which is commonly used as a test for alkaloids is remarkably insensitive for these bases.

**Crude Basic Fractions.**—The ground root material was extracted exhaustively with hot 96% ethanol, and the extract evaporated to a thick paste. The paste was extracted with 0.1 *N* hydrochloric acid, the acid solution was extracted with chloroform, and the chloroform was discarded. The aqueous phase was then made basic with sodium carbonate and extracted with chloroform. Evaporation of the chloroform at room temperature left a crude basic residue, A.

The alkaline aqueous phase was next extracted with butanol, the butanol was extracted with *N* hydrochloric acid, and the acid solution was made basic and extracted with chloroform. Evaporation of the chloroform gave a crude basic residue, B.

**Isofebrifugine.**—A sample of the crude basic fraction, A, was triturated and washed with acetone until no more color was extracted. The light buff-colored solid remaining melted at 125 to 127°. This was crystallized from methanol or from chloroform–ethanol mixture by slow evaporation at room temperature. If prolonged heating is avoided, it will crystallize from hot methanol in colorless chunky prisms, m.p. 129–130°, $[\alpha]^{25}D$ +131° (*c* 0.35, chloroform). At room temperature it is approximately 0.5% soluble in water, 3 to 4% in methanol, 7% in chloroform, very soluble in methanol–chloroform mixtures, almost insoluble in acetone, and very insoluble in ether, benzene and petroleum ether. It is easily extracted from basic solution by chloroform (distribution coefficient, $K = 10$) and by butanol ($K = 6$).

*Anal.* Isofebrifugine. Calcd. for $C_{16}H_{19}O_3N_3$: C, 63.8; H, 6.4; N, 14.0. Found: C, 63.3, 63.5; H, 6.4, 6.0; N, 14.0, 14.1.

A comparison of the antimalarial activity of isofebrifugine with that of its mother liquors indicated that the latter still contained most of the activity. The properties of the compound responsible for this activity necessitated an extensive chromatographic study which ultimately led to the isolation of febrifugine and to the establishment of its homogeneity.

Several adsorbents were tried and found to be unsatisfactory, but new alumina gave a single, reproducible zone which yielded pure, crystalline febrifugine. When this chromatographic zone was divided into three equal parts and each section was eluted and worked up separately, three crops of crystalline material with identical properties were obtained. Such behavior is strongly indicative of a pure substance.

Some samples of reclaimed alumina, as well as samples of calcium carbonate, gave the curious "double zone" effect described by Schroeder[15] for silicic acid.

**Febrifugine.**—Pure febrifugine was isolated from the crude basic fraction, B, by chromatographing the material from chloroform solution on to ALORCO, Grade F, minus 80 mesh alumina, reground to pass 200 mesh, and mixed with one-half part of Celite. As a developer 2% methanol in chloroform was used. The columns were post-washed with chloroform so that the developer would not interfere with the streak. The zone of febrifugine was located by streaking the column with an aqueous solution containing 0.1% potassium permanganate and 1% sodium hydroxide. The zone was evidenced by an immediate green streak which soon bleached. Elution of the febrifugine was accomplished with methanol.

Under the proper conditions, isofebrifugine appears in the filtrate of the chromatogram and can be recovered and purified as indicated above.

To obtain pure febrifugine from the eluate it was evaporated to dryness at room temperature under vacuum. The residue was taken up in dilute hydrochloric acid, extraneous oil (extracted from the alumina) was removed by extracting with ligroin and chloroform, the solution was made basic and extracted with butanol, and the butanol extract was evaporated to dryness at room temperature under vacuum. The febrifugine left as a residue crystallized from ethanol in colorless needles, m.p. 139–140°, $[\alpha]^{25}D$ + 6° (*c* 0.5, chloroform) and + 28° (*c* 0.5, ethanol).

At room temperature febrifugine is approximately 1 to 3% soluble in water, ethanol, acetone and chloroform, very soluble in methanol–chloroform mixtures and in water–ethanol mixtures, and very insoluble in ether, benzene and petroleum ether. From basic solution it is easily extracted by butanol ($K = 31$) and by 1:4 butanol–chloroform mixture ($K = 11$) but not very well by chloroform ($K = 0.7$).

*Anal.* Febrifugine. Calcd. for $C_{16}H_{19}O_3N_3$: C, 63.8; H, 6.4; N, 14.0. Found: C, 63.5, 63.5; H, 6.1; 6.3; N, 13.9, 14.0.

Febrifugine dihydrochloride was prepared by adding a 10% excess of 12 *N* hydrochloric acid to febrifugine dissolved in sufficient absolute ethanol so that the final solvent was 90 to 95% ethanol. It was recrystallized from 90% ethanol, m.p. 220–222° (dec.).

*Anal.* Febrifugine dihydrochloride. Calcd. for $C_{16}H_{21}O_3N_3Cl_2$: C, 51.3; H, 5.7; N, 11.2; Cl, 18.9. Found: C, 51.2, 51.3; H, 5.6, 5.8; N, 11.2, 11.2; Cl (Carius) 18.6, (ionic) 18.9.

**Dimorphism of Febrifugine.**—A crude base melting at *ca.* 150° was occasionally encountered during our early isolation studies, and at one time was thought to be a third alkaloid, isomeric with febrifugine and isofebrifugine. Subsequently the base has been obtained from water by the addition of the theoretical amount of 2.5 *N* sodium hydroxide to a saturated solution of febrifugine dihydrochloride and from spontaneous crystallization of melted isofebrifugine. The highest melting point obtained for this base is 154–156°, $[\alpha]^{25}D$ + 28° (*c* 0.5, ethanol).

A comparison with febrifugine revealed that both bases, in addition to having the same optical rotation, give the same zone when chromatographed on alumina under standard conditions and give the same dihydrochloride. Furthermore, a chloroform solution of febrifugine at room temperature, seeded with a crystal of the high melting base, deposits crystals of that base on slow evaporation, and conversely a chloroform solution of the high melting base gives febrifugine when appropriately seeded. This would appear to be conclusive evidence that the base of m.p. 154–156° is not an isomer of febrifugine but merely a higher melting modification and that febrifugine is dimorphic.

**Interconversion of Isofebrifugine and Febrifugine.**—In the early stages of this investigation attempts to characterize these alkaloids were greatly complicated by apparent anomalies in physical behavior. These difficulties were resolved when febrifugine was found to be dimorphic (see above) and when the bases were found to be readily interconvertible.

A 51-mg. sample of isofebrifugine was refluxed for one-half hr. in 10 ml. of absolute ethanol. The solution was

(15) W. A. Schroeder, "Annals N. Y. Acad. Sci.," Vol. XLIX, Art. 2, p. 211 (1948).

evaporated to a small volume and seeded with febrifugine to give a yield of 13.3 mg. of febrifugine, m.p. 138–139°. The mother liquors after further refluxing with alcohol for two hours, yielded an additional 12.5 mg. of febrifugine, and, on addition of hydrochloric acid, 7.7 mg. of febrifugine dihydrochloride. Isofebrifugine (74 mg.) was heated for a few minutes at 135° until crystallization took place (in some cases seeding was necessary). The solid was washed with acetone and dried to give 53 mg. of the higher melting form (154–156°) of febrifugine.

A 52-mg. sample of febrifugine was refluxed in 25 ml. of chloroform for three hours. The solution was chromatographed on alumina. The yield of crude isofebrifugine was 22.3 mg., which on recrystallization gave 16.0 mg. of pure isofebrifugine, m.p. 129–130°.

**Isolation from Acid Extracts.**—With a few centigrams of the pure alkaloids available it was possible to determine some of their properties and devise a far more satisfactory extraction and isolation procedure.

**Isolation of Febrifugine and Isofebrifugine by Adsorption on Fuller's Earth.**—The plant material was ground to 8 to 10 mesh and extracted with portions of 0.1 *N* hydrochloric acid until it was essentially free of alkaloids as indicated by a test of the extract with Dragendorff's reagent. The concentration of alkaloids in the combined extracts was then at least 75 μg./ml. Dragendorff's reagent is a sensitive test for the alkaloids, three drops of the reagent giving an immediate cloudiness with 1 ml. of 0.1 *N* hydrochloric acid containing 12 μg. of alkaloids, a barely perceptible cloudiness in one-half to one minute with 6 μg., and a clear solution with 3 μg. The test is not critically dependent on the acid concentration, but the sensitivity is somewhat less, and the precipitate forms more slowly at higher concentrations of acid.

The combined extracts were stirred for a few hours with fuller's earth and sufficient 12 *N* hydrochloric acid to keep the mixture acidic to congo red. A crude adsorption isotherm indicated that 150 g. of fuller's earth under these conditions is sufficient to adsorb more than 99% of 1 g. of the alkaloids. An amount of Celite equal to one-third the weight of fuller's earth was added, and the mixture was filtered through a pad of Celite weighing about one-sixth the weight of fuller's earth.

The filter cake was mixed with enough sodium carbonate solution (6 g. per 100 ml.) to make a thin paste, three volumes of butanol were added, and the mixture was vigorously agitated for about two hours. The butanol layer was separated and a second and third extraction made.

The combined wet butanol extracts were diluted with one-half volume of ligroin (60–70°) and extracted with dilute hydrochloric acid. The acid extracts were made basic with sodium carbonate and extracted with 1:4 butanol–chloroform mixture, and the extraction into acid and back into butanol–chloroform mixture from basic solution was repeated. The butanol–chloroform solution was then dried with sodium sulfate and evaporated almost to dryness at reduced pressure and room temperature. A light-colored solid separated, and it was mixed with a little ether and filtered off. Evaporation of the filtrate gave a second crop.

The crude alkaloids were taken up in sufficient hot absolute ethanol so that after a 10% excess of 12 *N* hydrochloric acid was added to convert the material to dihydrochlorides the final solvent was 90 to 95% ethanol. The mixture was seeded with febrifugine dihydrochloride and allowed to crystallize overnight in the cold. The febrifugine dihydrochloride obtained can be recrystallized by dissolving it in a minimum of hot 1:1 water–ethanol mixture, and adding sufficient absolute ethanol to make the final concentration of ethanol 90%.

The mother liquors from the febrifugine dihydrochloride were taken almost to dryness at room temperature, the residue taken up in a small amount of water, sufficient sodium carbonate added to make the solution basic, and the mixture extracted with chloroform. Evaporation of the chloroform at room temperature gave crude isofebrifugine which was purified by recrystallization from hot methanol.

Mother liquors from the above crystallizations are best worked up for additional material by chromatographing them from chloroform on alumina as previously described.

**Results with *D. febrifuga*.**—The fuller's earth adsorption method has given higher and more consistent yields of the alkaloids than could be obtained from ethanol extracts. The results of applying the method to the various plant materials available to us indicated that the root material of Chinese origin had a crude base content of 0.08–0.1% and that 55% of this consisted of febrifugine and isofebrifugine. The ratio of febrifugine to isofebrifugine varied from 6:1 to 1:1 which is not surprising in view of their interconvertibility. The root material from India had a crude base content of 0.05% of which 63% was febrifugine and only 2% isofebrifugine. Although botanically identified leaf material from China was not available to us, that from India had a crude base content of only 0.01–0.02% of which 50% was febrifugine (the presence or absence of isofebrifugine was not confirmed).

**Results with "Chunine Leaf Powder."**—Liu[4] in mentioning the leaves of a plant called by him "Chunine tree" stated that the antimalarial activity was due to an alkaloid "chunine," but he gave no experimental evidence whatsoever for the presence of alkaloids.

Since our interest in antimalarials of Chinese origin was first occasioned by Liu's report, we made numerous unsuccessful attempts to learn something of the nature of his "chunine leaf powder" from the small supply available. In this connection the effectiveness of the fuller's earth adsorption method was demonstrated in that we have now been able to isolate from a 25-g. sample of Liu's material (SN 6355), 8 mg. of febrifugine, identified by melting point, dihydrochloride, and absorption spectrum. This supplies experimental evidence for the presence of an alkaloid in Liu's material and suggests that the material was derived in whole or in part from *D. febrifuga* or a related plant.

**Pharmacology.**[16]—Isofebrifugine when given intravenously three times a day to ducks infected with *P. lophurae* was found to have a *Q* of 1 (tests G-5 and I-2), whereas it was found to be inactive at the maximum tolerated dose in test D-1 when given intravenously two times a day.

Febrifugine has a *Q* of 100 when tested against *P. lophurae* in ducks (tests G-5 and I-2) and a *Q* of 64 against *P. gallinaceum* in chicks (test A-1). When tested against the trophozoites of *P. cynomolgi* in the monkey it is at least 100 times as active as quinine.[17]

Studies of the acute oral toxicity of febrifugine[17]

(16) Description of the avian tests, A-1, D-1, G-5 and I-1, together with a definition of *Q*, the quinine equivalent, will be found in ref. 3.

(17) Private communication from Dr. L. H. Schmidt, Christ Hospital, Cincinnati, Ohio.

indicate that the $LD_{50}$ for the white mouse is *ca.* 2.5 to 3.0 mg. per kg. This is somewhat more than 100 times that of quinine but the toxic symptoms are quite different. Febrifugine is slower in its action, giving rise to symptoms some two to four hours after administration. These symptoms include effects on respiration, urinary incontinence, sweating and a corrosive effect on the gastric mucosa.

Experiments on subacute toxicity were carried out with rhesus monkeys.[17] An animal receiving 0.3 mg. per kg. daily (administered in three doses, one every eight hours) survived sixteen days of treatment with no untoward reactions. An animal receiving 0.75 mg. per kg. daily succumbed on the ninth day of treatment, and marked hyperemia of the gastric mucosa (but no frank ulceration) was the only finding of note on autopsy. Febrifugine did not affect the formed elements of peripheral blood or bone marrow and did not produce methemoglobinemia or cyanosis.

Preliminary results[18] of a clinical trial of febrifugine indicate that while the drug reduces the parasite count when given in four oral doses totaling 2.5 mg. per day it is at the same time such a powerful emetic as to probably preclude its clinical use in malaria.[19]

## Structural Studies[11]

A potentiometric titration of isofebrifugine indicated two basic groups of $pK_{B_1}$ 5.7 and $pK_{B_2}$ 12. A comparative value of $pK_{B_1}$ 6.3 for febrifugine was calculated from distribution coefficient values around *p*H 7.

Zeisel determinations for methoxyl groups were negative for both alkaloids. The Herzig and Meyer determination for N-methyl gave varying results of *ca.* 1% with either alkaloid whereas the theoretical value for one such group is 5%.

Both alkaloids reduce Tollens reagent at room temperature, but a number of color tests for aldehydes or methyl ketones (Schiff reagent, sodium nitroprusside, *o*-dianisidine in glacial acetic, and sodium bisulfite) were negative.

Acetylation and benzoylation of the alkaloids gave oily products which could not be crystallized.

TABLE I

MELTING POINTS

| Compound | Febrifugine | Isofebrifugine |
|---|---|---|
| Free base | 139–140° | 129–130° |
| | 154–156° | |
| Dihydrochloride | 220–222° (dec.) | Hygroscopic |
| Dibenzenesulfonyl | 148.0–148.5° | 182.5–183.5° |
| Semicarbazone | 187–188° (dec.) | ..... |
| Oxime | 224–225° (dec.) | ..... |
| N-Nitroso | 171.5–172.5° | 185–186.5° |
| Dihydro | 192–193° | 156.5–157.5° |

(18) Private communication from Dr. G. Robert Coatney, National Institute of Health, Bethesda, Maryland.

(19) For recent reports of the clinical use of extracts of Ch'ang Shan in the treatment of malaria see ref. 8 and C. F. Tsu, *J. Trop. Med. and Hyg.*, **50**, 75 (1947).

Several crystalline derivatives of the alkaloids have been prepared and analyzed, and their melting points and those of the free bases may be compared in Table I.

**Benzenesulfonyl Derivatives.**—The alkaloids were treated overnight with excess benzenesulfonyl chloride in pyridine. Addition of water and dilute acid caused the derivatives to precipitate. The derivative of isofebrifugine was recrystallized from chloroform–ethanol mixture and from aqueous ethanol, and that of febrifugine from aqueous ethanol. Both derivatives were insoluble in dilute sodium hydroxide and dilute hydrochloric acid.

*Anal.* Calcd. for $C_{28}H_{27}O_7S_2N_3$: C, 57.9; H, 4.7; N, 7.2. Found for isofebrifugine: C, 57.9; H, 4.6; N, 7.3. Found for febrifugine: C, 57.8; H, 5.0; N, 7.3.

**Febrifugine Semicarbazone and Oxime.**—Febrifugine dihydrochloride was treated overnight with sodium acetate and either semicarbazide hydrochloride or hydroxylamine hydrochloride in aqueous solution. The derivative separated when the solutions were made just basic with sodium hydroxide. The semicarbazone was recrystallized from ethyl acetate or absolute ethanol and the oxime from aqueous ethanol.

*Anal.* for semicarbazone: Calcd. for $C_{17}H_{23}O_3N_6$: C, 56.9; H, 6.4; N, 23.4. Found: C, 57.1; H, 6.5; N, 23.1.

*Anal.* for oxime: Calcd. for $C_{16}H_{20}O_3N_4$: C, 60.8; H, 6.3; N, 17.7. Found: C, 60.9; H, 6.2; N, 17.5.

Under similar conditions isofebrifugine did not give an oxime or semicarbazone.

**Nitroso Derivatives.**—The alkaloids were treated in dilute hydrochloric acid with excess sodium nitrite for one-half hour at 0°. The nitroso compounds separated when the solutions were made basic. N-Nitrosofebrifugine was recrystallized from ethanol and N-nitrosoisofebrifugine from ethanol and from butanone.

*Anal.* Calcd. for $C_{16}H_{18}O_4N_4$: C, 58.2; H, 5.5; N, 17.0. Found for febrifugine: C, 58.4; H, 5.7; N, 17.1. Found for isofebrifugine: C, 58.1; H, 5.7; N, 17.2.

**Absorption Spectra.**—The absorption spectra of febrifugine and isofebrifugine are almost identical. In Fig. 1 the ultraviolet absorption spectra for febrifugine, 2-methyl-4-quinazolone, and 3-allyl-4-quinazolone in ethanol are shown. The striking similarity of the spectrum of febrifugine and that of the 3-substituted-4-quinazolone is evident. The maxima of the spectra of febrifugine (and isofebrifugine) and 3-allyl-4-quinazolone show a bathochromic shift in acidic solution, but not in basic solution. The maxima of the spectrum of the 3-unsubstituted-4-quinazolone show a bathochromic shift in both acidic and basic solution. Molal extinctions calculated for the extremes of these various spectra, assuming a molecular weight of 301 for the alkaloids, likewise show a remarkable agreement, the difference in corresponding values being in general less than 10%.

Absorption spectra were taken in absolute ethanol which had been redistilled from all-glass apparatus. The spectra were taken at concentrations which gave extinctions between 0.3 and 0.9 as read with a Beckman quartz spectrophotometer, model DU.

2-Methyl-4-quinazolone was synthesized by the method of Niementowski,[20] m.p., 238–241°, and 3-allyl-4-quinazolone was synthesized by the method of Hanford, *et al.*,[21] m.p. 65–66°.

(20) J. Niementowski, *J. prakt. Chem.*, **51**, 564 (1895).

(21) W. E. Hanford, P. Liang and R. Adams, THIS JOURNAL, **56**, 2782 (1934).

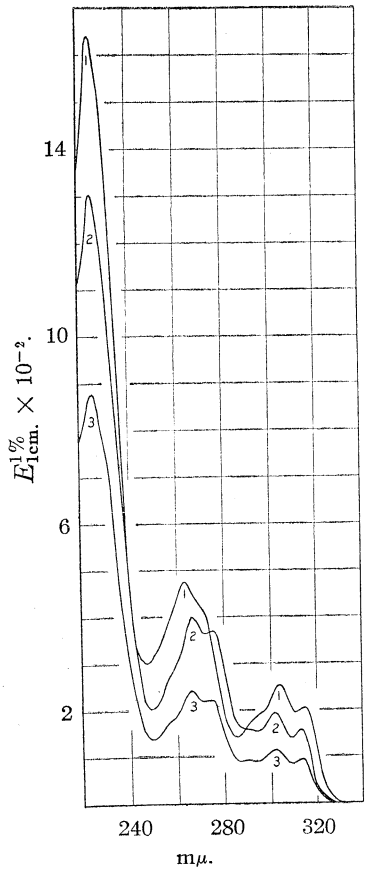

Fig. 1.—Absorption spectra in absolute ethanol: (1), 2-methyl-4-quinazolone; (2), 3-allyl-4-quinazolone; and (3), febrifugine.

**Reduction.**—In ethanol in the presence of platinum at room temperature and pressure both alkaloids take up one mole of hydrogen. Crystalline dihydro derivatives can be isolated, but in yields which suggest that each reduction leads to the formation of more than one product. In glacial acetic acid, febrifugine takes up one mole and isofebrifugine two or more moles of hydrogen, but in neither case could crystalline products be isolated.

Absorption spectra of the dihydro-alkaloids are very nearly the same as those of the original alkaloids. Dihydrofebrifugine does not form an oxime nor a semicarbazone. Neither of the dihydro-alkaloids reduces Tollens reagent, and both give negative results in N-methyl determinations.

**Dihydrofebrifugine.**—A 409-mg. sample of febrifugine was hydrogenated at room temperature and one atmosphere pressure in 50 ml. of absolute ethanol in the presence of 50 mg. of Adams catalyst. In one hour the volume of hydrogen taken up became constant and corresponded to one mole of hydrogen per mole of febrifugine. The catalyst was filtered off, the solution evaporated to dryness at reduced pressure and room temperature, and the crystalline residue recrystallized from hot ethanol to yield a first crop of 263 mg. (64%) of colorless crystals melting at 187–192° and a second crop of 34 mg. melting at 163–184°. The mother liquors taken to dryness gave 107 mg. of oil. The dihydrofebrifugine was recrystallized from ethanol to constant melting point, 192–193°.

*Anal.* Calcd. for $C_{16}H_{21}O_3N_3$: C, 63.3; H, 7.0; N, 13.9. Found: C, 63.3; H, 7.0; N, 14.1.

**Dihydroisofebrifugine.**—The same method was used as given for dihydrofebrifugine. A 400-mg. sample of isofebrifugine took up the theoretical amount of hydrogen in three hours. The residue on evaporation of the solvent was an oil which was crystallized from acetone to give a first crop amounting to 182 mg. (45%), m.p. 151–154°. A second crop from acetone–benzene amounted to 97 mg., m.p. 86–124°. The mother liquors, evaporated to dryness, left 127 mg. of oil. The dihydroisofebrifugine was recrystallized from acetone to constant melting point, 156.5–157.5°.

*Anal.* Calcd. for $C_{16}H_{21}O_3N_3$: C, 63.3; H, 7.0; N, 13.9. Found: C, 63.4; H, 6.9; N, 13.8.

**Oxidation.**—The alkaloids are relatively stable toward acid permanganate, but both are oxidized rapidly by alkaline permanganate to give good yields of 4-quinazolone. Either alkaloid is oxidized rapidly by periodate in neutral or slightly alkaline solution to give the same crystalline product. Although this periodate oxidation product has not been fully characterized and will be dealt with in a later paper, the analyses suggest that it is formed from either alkaloid by the loss of two hydrogens.

**Alkaline Permanganate Oxidation.**—An aqueous solution of 160 mg. of febrifugine dihydrochloride made alkaline with potassium hydroxide was treated dropwise with a saturated solution of potassium permanganate until the rapid decolorization had ceased. After centrifugation, the supernatant was neutralized with hydrochloric acid and evaporated to dryness. The residue was extracted with absolute ethanol, and the soluble portion recrystallized from ethanol and acetone to give 40 mg. of 4-quinazolone, m.p. 212–213°, identified by absorption spectra and mixed m.p. with a sample prepared by the method of Niementowski.[20]

*Anal.* Calcd. for $C_8H_6ON_2$: C, 65.7; H, 4.1; N, 19.2. Found: C, 65.3; H, 4.1; N, 19.0.

Oxidation of isofebrifugine under similar conditions gave the same result.

**Periodate Oxidation.**—A 270-mg. sample of isofebrifugine was dissolved in 30 ml. of water, and 150 ml. of 0.026 *N* disodium paraperiodate was added. After one hour, the solution was saturated with carbon dioxide and extracted with 150 ml. of chloroform in five equal portions. The chloroform solution was dried over anhydrous sodium sulfate and evaporated at reduced pressure. There was obtained 103 mg. of crude solid which, after several crystallizations from ethanol, gave 72 mg. of colorless clusters of needles, m.p. 165–166° (dec.).

*Anal.* Calcd. for $C_{16}H_{17}O_3N_3$: C, 64.2; H, 5.7; N, 14.0. Found: C, 64.4; H, 6.0; N, 13.7.

Febrifugine oxidized under the same conditions gave the same product.

**Hydrolysis.**—Both alkaloids are very stable toward acid hydrolysis. It was possible to isolate unchanged febrifugine from a solution of the alkaloid in 70% sulfuric acid after heating at 100° for one hour.

Both alkaloids are very susceptible to alkaline hydrolysis and at room temperature overnight in 2.5 *N* sodium hydroxide either is hydrolyzed to give a good yield of anthranilic acid, a low yield of ammonia, and formic acid. Oils and resins of unknown constitution also result on

alkaline hydrolysis, and these when heated give a positive pine splinter test.

Dihydrofebrifugine also is easily hydrolyzed under alkaline conditions, and such a hydrolysis, does not result in the formation of oils and resins, nor of ammonia, although anthranilic acid and formic acid are formed. It has been possible to isolate from such a hydrolyzate a benzenesulfonyl derivative with the tentative formula $C_8H_{13}ON_2(C_6H_5SO_2)_3$.

**Alkaline Hydrolysis of the Alkaloids.**—Several hydrolyses were carried out by allowing *ca.* 100-mg. samples of the alkaloids to stand one to two days at room temperature in 2.0 ml. of 2.5 *N* sodium hydroxide. In two experiments a closed system was used, nitrogen was passed through the solutions, and the effluent gas was passed through a known amount of standard hydrochloric acid. Back-titration indicated the formation of 0.044 milliequivalent of volatile base from 0.30 millimole of isofebrifugine and 0.015 milliequivalent from 0.27 millimole of febrifugine. That the volatile base was ammonia was confirmed by evaporating the titration solutions and preparing the characteristic octahedra of ammonium chloroplatinate.[22]

The alkaline hydrolyzates were next brought to *p*H 8–9 by adding hydrochloric acid, and the mixtures extracted with 1:4 butanol–chloroform. These extracts on drying and evaporating to dryness yielded about 20% of the original weight of alkaloid as a dark brown oil, soluble in dilute hydrochloric acid and precipitated from the acid solution by base. Attempts to prepare the acetyl derivative, the picrate and the chloroplatinate led to amorphous, colored precipitates. When this material was heated with 20% aqueous sodium hydroxide, a blob of resin collected rapidly. When this resin was heated in a dry test-tube, the vapors above it gave a pine splinter test for pyrrole.

The hydrolyzate was next acidified with hydrochloric acid to *p*H 3–4, and the mixture was extracted with chloroform. This chloroform extract when taken to dryness gave a light crystalline solid amounting to *ca.* 40% of the original weight of the alkaloid. It was sublimed, recrystallized from aqueous alcohol and proved to be anthranilic acid (m.p. 145–146° with no depression in mixed melting point with an authentic sample).

The aqueous phase from these extractions was next taken to dryness in a vacuum desiccator over sodium hydroxide. This residue if warmed with 20% aqueous sodium hydroxide gave very rapidly a blob of resin which gave a pine splinter test for pyrrole when heated with zinc dust. Attempts to prepare an acetyl derivative, a picrate, a chloroplatinate, an oxime and a phenacyl ester from this residue were unsuccessful.

A little of the original hydrolyzate when treated with magnesium in hydrochloric acid, and then warmed with chromotropic acid in 72% sulfuric acid gave a violet color, indicating the presence of formic acid.[23]

**Alkaline Hydrolysis of Dihydrofebrifugine.**—When 311 mg. of dihydrofebrifugine was allowed to stand with 4.0 ml. of 2.5 *N* sodium hydroxide for two days it slowly went into solution. The solution was then acidified with hydrochloric acid to *p*H 3–4, and extracted with chloroform to remove anthranilic acid (a previous experiment had shown that under these conditions a 75% yield of anthranilic acid was isolated). The solution was then evaporated on a steam-cone with a stream of air until the volume was *ca.* 5 ml. One-half gram of sodium hydroxide and 1 ml. of benzenesulfonyl chloride were added and the mixture shaken vigorously, with cooling. The solid which separated was crystallized from acetonitrile to give 98 mg. of colorless crystals which were recrystallized to constant melting point, 211–213°.

*Anal.* Calcd. for $C_{26}H_{28}O_7S_3N_2$: C, 54.2; H, 4.9; S, 16.7; N, 4.9. Found: C, 54.3; H, 5.1; S, 16.7; N, 5.1.

## Discussion of Results

With the exception of the alkaloids of the Cinchona type occurring in certain species of the Rubiaceae, those isolated from plants used in some of the native remedies for malaria have generally proven to be without plasmocidal activity. The alkaloids isolated from *D. febrifuga* are therefore of particular interest not only because they are the first to be found in a plant of the Saxifragaceae but also because one of them has high plasmocidal activity.

In avian tests the antimalarial activity of various samples of *D. febrifuga* leaf material has consistently been about twice that of the roots. However, we have always found five to ten times more febrifugine in root than in leaf material. The amount of febrifugine actually isolated was sufficient to account for *ca.* 25% of the activity of the roots but only 2% of the activity of the leaf material. These discrepancies, even though the bioassay cannot be relied on to better than a factor of two, are still so great as to suggest the presence, at least in leaf material, of some active principle other than febrifugine and isofebrifugine. This possibility is being investigated.

With respect to the relative quantities of febrifugine and isofebrifugine which may be present in *D. febrifuga*, we can only point out that we have consistently isolated from various samples of both root and leaf material more febrifugine than isofebrifugine, and in view of the interconvertibility of the alkaloids it is quite possible that there is little or no isofebrifugine in the intact plant.

Our analytical data for the free bases and their derivatives indicate that the empirical formula for febrifugine and isofebrifugine is $C_{16}H_{19}O_3N_3$. The formation of 4-quinazolone on oxidation, the formation of anthranilic and formic acids on hydrolysis, the ease of hydrolysis (atypical of 3-unsubstituted-4-quinazolones), and the striking agreement in absorption spectra leave little doubt that the aromatic portion of the molecules is a 3-substituted-4-quinazolone. The isolation of a $C_8$-fragment containing two nitrogen atoms from the hydrolyzate of dihydrofebrifugine not only confirms this conclusion but suggests that the 4-quinazolone nucleus is substituted only at the 3-position.

The quinazolone nucleus accounts for the function of two of the nitrogen atoms and one of the oxygen atoms in the alkaloids. There is reasonably good evidence that the third nitrogen atom forms a secondary aliphatic amine, for both alkaloids have basic groups, $pK_B$ *ca.* 6, both form non-basic, non-acidic dibenzenesulfonyl derivatives, and both form N-nitroso derivatives.

The function of the remaining two oxygen atoms is less clearly indicated. The formation of an oxime and a semicarbazone indicate the presence

(22) Chamot and Mason, "Handbook of Chemical Microscopy," John Wiley and Sons, Inc., New York, N. Y., 1931, Vol. II, pp. 75–76.

(23) F. Feigl, "Spot Tests," Elsevier Press, New York, N. Y., 3rd. ed., p. 397.

of a keto-group at least in febrifugine. The formation of dibenzenesulfonyl derivatives may indicate the presence of an alcoholic hydroxyl group. One benzenesulfonyl group is presumably attached to the secondary amine nitrogen, and the other to one of two atoms, either an oxygen which was originally a hydroxyl group or to the 1-nitrogen of the quinazolone ring. This latter possibility is indicated by the fact that the dibenzenesulfonyl derivatives are insoluble in dilute hydrochloric acid, although the 1-nitrogen of normal 4-quinazolones is sufficiently basic to render them soluble in dilute acid. The involvement of the 1-nitrogen atom in the formation of such a derivative is known in the case of rutacarpine, which forms a monoacetyl and a monobenzoyl derivative.[24]

Alkaloids containing a quinazolone ring system are comparatively rare, the only two previously known being rutacarpine and evodiamine. Furthermore, if as we believe the 4-quinazolone nucleus is attached only through its nitrogen at the 3-position to the other basic portion of the molecule, it will constitute a novel structural feature in alkaloidal chemistry. Lastly, febrifugine and isofebrifugine represent the first instance known to us in which two optically active isomeric alkaloids are so readily interconvertible.

It is evident from published reports that, quite independently of ourselves, investigators both here and abroad have been engaged on the chemistry of *D. febrifuga*. Thus Chou, *et al.*,[25] report the isolation of *three isomeric* alkaloids, $\alpha$-, $\beta$- and $\gamma$-dichroines. Despite some disagreement in melting points it is evident that the $\alpha$-dichroine of the Chinese investigators corresponds to our isofebrifugine, but contrary to their interpretation we believe their own physical data clearly indicate that their $\beta$- and $\gamma$-dichroines are not two different isomeric alkaloids but correspond to the two crystalline modifications of our febrifugine. Investigators[26] in this country have, without assigning names or mentioning the dimorphism of the higher melting alkaloid, reported results in substantial agreement with ours.

It would appear that some confusion has been occasioned by the way in which investigations of *D. febrifuga* in China have been reported.[25,27,28,29,30] We selected names derived from the plant species to avoid possible confusion with the "dichroin" of Hartwich[10] or the names "Dichroine A" and "Dichroine B" used by Jang, *et al.*,[27] for two incorrectly characterized alkaloids.[29,30] To avoid causing further confusion in the literature we prefer to adhere to the names febrifugine and isofebrifugine since they were the first to be proposed in a publication[6] which gives an adequate characterization of two isomeric alkaloids obtained from *D. febrifuga*.

**Acknowledgments.**—We are grateful to the many who have been of assistance and wish to thank particularly the following: Dr. K. K. Chen and Eli Lilly and Co., for most of the Chinese root material used in this work and for the continual chemical and pharmacological aid which made the investigation possible; Drs. E. H. Volweiler and Marlin T. Leffler and the Abbott Laboratories for botanically identified material and assistance; Dr. P. Z. King and the National Health Administration, Chungking, for root material; Dr. E. H. Walker of the Smithsonian Institution for botanical advice; and Dr. Arthur P. Richardson, Emory University, for many avian tests, especially in connection with the "chunine" problem.

Mrs. Lois Tow assisted with spectrophotometric and other technical work. Dr. N. Abrahamsen aided in synthetic work. Microanalyses were carried out by William Saschek, College of Physicians and Surgeons, Columbia University, and G. Oppenheimer and G. A. Swinehardt, Division of Biology, California Institute of Technology.

## Summary

Two interconvertible, isomeric, crystalline, optically active alkaloids, febrifugine and isofebrifugine, have been isolated from the roots and leaves of *Dichroa febrifuga*. Febrifugine is a powerful antimalarial, having about 100 times the activity of quinine against bird malaria.

An empirical formula, $C_{16}H_{19}O_3N_3$ is proposed, and evidence is given which indicates that structurally these alkaloids are 4-quinazolones substituted only on the 3-nitrogen.

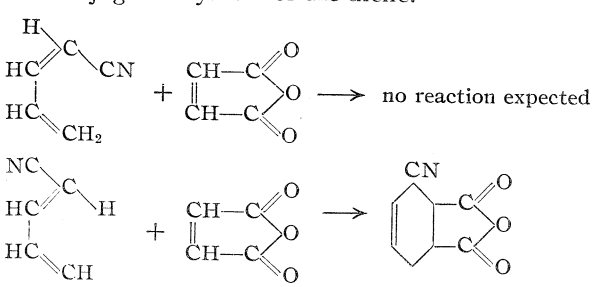
# 1-Cyano-1,3-butadienes: *cis, trans*-Isomers of 1-Cyano-1,3-butadiene[1]

BY H. R. SNYDER, JOHN M. STEWART[2a] AND ROBERT L. MYERS[2b]

In a study of the possible use of certain cyanodienes as replacements for styrene in butadiene–styrene copolymers, 1-cyano-1,3-butadiene has been prepared in quantity sufficient to permit the separation of the *cis*- and *trans*-forms. This substance has been studied previously,[3–15] but apparently only as a mixture of geometric isomers. In the present work the mixture was prepared by the pyrolysis[4–8] of the benzoate or acetate of crotonaldehyde cyanohydrin; the synthesis *via* the benzoate proved the more convenient. 1-Cyano-2-methyl-1,3-butadiene was prepared similarly from tiglic aldehyde.



$$CH_3CH{=}CHCHO \xrightarrow[C_6H_5COCl]{NaCN} CH_3CH{=}CHCHOCOC_6H_5 \xrightarrow{(575°)} CH_2{=}CHCH{=}CHCN + C_6H_5CO_2H$$

(CN)

The first indications that the 1-cyano-1,3-butadiene so prepared was a mixture were found in the slight variations in boiling point and index of refraction of the products of various runs and in the concomitant variations of reaction rates observed with samples of the different lots in copolymerizations with butadiene. Separation of the isomers was achieved by fractionation of the mixture through a twenty-five plate, helix-packed column. Two different fractions (I, b.p. 49.5° (31.5 mm.), $n^{20}D$ 1.4852; II, b.p. 57.3° (31.5 mm.), $n^{20}D$ 1.4960) were obtained. In the polymerization studies it was observed that the higher-boiling fraction underwent copolymerization with butadiene at a faster rate than the lower-boiling fraction. Of the two dried rubber-like polymers made in these copolymerizations only the one from the higher-boiling fraction had the strong odor previously associated with all the butadiene copolymers made from the mixture of cyanodienes.

The formation of a by-product of sufficient volatility to possess an odor, in the copolymerization of the higher-boiling isomer, suggested that a Diels–Alder reaction with butadiene might have occurred. In tests with liquid butadiene at 50°, in the absence of polymerization catalysts, only the higher-boiling 1-cyano-1,3-butadiene underwent reaction; the product was a liquid of a very strong, unpleasant odor (somewhat similar to that of isonitriles). The higher-boiling 1-cyano-1,3-butadiene also gave an adduct with maleic anhydride, whereas the lower-boiling isomer failed to react.

The observation of the greater reactivity of the higher-boiling 1-cyano-1,3-butadiene with maleic anhydride permits the tentative assignment of the *trans*-configuration to this isomer. This assignment is made on the basis of the analogy with the closely related piperylenes[16]; only the *trans*-piperylene undergoes Diels–Alder reactions with maleic anhydride, acrylonitrile or with a second molecule of the diene (dimerization).[17] The failure of the *cis*-isomer to react with maleic anhydride is ascribed to the fact that the shape of the molecule is such as to prevent close approach of the dienophile to the ends of the conjugated system of the diene.

## Experimental

**Crotonaldehyde Cyanohydrin Benzoate.**—To a well-stirred mixture of 420 g. (6 moles) of freshly distilled crotonaldehyde and 1200 ml. of benzene, maintained at −10°, was slowly added 843 g. (6 moles) of benzoyl chloride. Then 392 g. (8 moles) of reagent grade sodium cyanide in 2 l. of distilled water was added dropwise while the reaction mixture was kept at the same temperature. After the cyanide had been added the mixture was stirred for two

hours at −10° and then was allowed to warm to room temperature. The organic layer was separated, washed with two 200-ml. portions of 5% sodium carbonate solution, and dried over anhydrous magnesium sulfate. After distillation of the benzene, the residue was fractionated through a 12-inch, helix-packed, jacketed column. The fraction boiling at 125° (1 mm.), $n^{20}D$ 1.5220, was collected. The yield was 1085 g. or 89%.

*Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51. Found: C, 71.75; H, 5.58.

**Crotonaldehyde cyanohydrin acetate** was prepared by the same method with the substitution of acetic anhydride for the benzoyl chloride. From 271 g. (3.88 moles) of crotonaldehyde, 395 g. (3.88 moles) of acetic anhydride, and 275 g. (5.6 moles) of sodium cyanide there was obtained 371 g. (70%) of the crotonaldehyde cyanohydrin acetate, b.p. 78.5° (4 mm.), $n^{20}D$ 1.4340.

*Anal.* Calcd. for $C_7H_9O_2N$: C, 60.42; H, 6.52. Found: C, 60.34; H, 6.57.

**1-Cyano-1,3-butadiene.**—Pyrolysis of either the benzoate or acetate of crotonaldehyde cyanohydrin produced 1-cyano-1,3-butadiene. Pyrolysis of the benzoate was found to be more satisfactory because the separation of the cyanodiene from benzoic acid was much more convenient than separation from acetic acid. The esters were pyrolyzed by passage through a vertical, 18-mm. Pyrex tube packed for a distance of about 30 cm. with 4-mm. glass beads and heated to 575 ± 10° by means of a combustion furnace. The temperature was indicated by a thermocouple inserted in the tube. The material was introduced at a rate of one drop per second. A cooled distilling flask connected to the pyrolysis tube by a ground-glass joint served as the receiver for the pyrolysate. The yield of cyanodiene could be increased by the addition of an efficient polymerization inhibitor (such as picric acid) to the ester and the receiving flask. It was necessary to heat the tube (conveniently with an infrared lamp) between the furnace and the receiver to prevent the benzoic acid produced from solidifying. The 1-cyano-1,3-butadiene was separated from the benzoic acid by a flash distillation at reduced pressure. Redistillation through a 12-inch, helix-packed column yielded 1-cyano-1,3-butadiene; b.p. 49.5–53° (31 mm.), $n^{20}D$ 1.4852–1.4895. Coffman[2] reported b.p. 49–53° (30 mm.), $n^{20}D$ 1.4880, $d^{20}_4$ 0.8644.

The yield of redistilled material from the pyrolysis of the benzoate was 70%; from the acetate 55% (based on the recovery of 34% of the unchanged ester). A sample was redistilled for analysis.

*Anal.* Calcd. for $C_5H_5N$: C, 75.92; H, 6.37. Found: C, 75.90; H, 6.48.

1-Cyano-1,3-butadiene was separated into its geometric isomers by fractionation of the mixture through a twenty-five plate, helix-packed column at a reflux ratio of about 15:1. The two fractions (I, b.p. 49.5° (31.5 mm.), $n^{20}D$ 1.4852; II, b.p. 57.3° (31.5 mm.), $n^{20}D$ 1.4960) had nearly identical microanalyses.

*Anal.* Calcd. for $C_5H_5N$: C, 75.92; H, 6.37. Found (fraction I): C, 75.90; H, 6.48; (fraction II): C, 75.97; H, 6.50.

**Maleic Anhydride Adduct of 1-Cyano-1,3-butadiene.**—In two 2-oz., screw-cap bottles were placed 6.2 g. of maleic anhydride and 25 ml. of dry benzene. In the first bottle (A) was placed 5.0 g. of 1-cyano-1,3-butadiene (fraction I, $n^{20}D$ 1.4852). In the second (B) was placed 5.0 g. of 1-cyano-1,3-butadiene (fraction II, $n^{20}D$ 1.4960). A few crystals of picric acid were added to each bottle to prevent polymerization. The bottles were capped and placed in a 50° water-bath and rotated for forty-eight hours. The vessels were removed from the bath and cooled, and about 10 ml. of low-boiling petroleum ether was added to each. From bottle A only unchanged maleic anhydride, m.p. 58–59°, was isolated. From bottle B there was obtained a yellow oil, which was induced to crystallize by rubbing it against the side of the container. After six recrystallizations from dry benzene, the material had a constant melting point of 110–111°.

*Anal.* Calcd. for $C_9H_7O_3N$: C, 61.01; H, 3.98. Found: C, 60.86; H, 3.77.

These reactions were repeated several times and in each instance an adduct was obtained only from the higher-boiling fraction, $n^{20}D$ 1.4960.

**Diels–Alder Adduct of 1-Cyano-1,3-butadiene with 1,3-Butadiene.**—Five-gram samples of 1-cyano-1,3-butadiene, fraction I, $n^{20}D$ 1.4852, and fraction II, $n^{20}D$ 1.4960, an excess of 1,3-butadiene, and a few crystals of picric acid were placed in 2-oz., screw-cap bottles. The bottles were capped and placed in the 50° water-bath and rotated for forty-eight hours. The bottles were removed, and the unchanged 1,3-butadiene was allowed to evaporate. Distillation of the residual liquid from experiments with fraction I resulted only in the recovery of 1-cyano-1,3-butadiene. From experiments with fraction II, along with some unchanged cyanobutadiene, there was obtained a liquid boiling at 94° (8 mm.), $n^{20}D$ 1.4940, $d^{20}_4$ 0.9471. This liquid had the foul odor previously associated with the copolymers of butadiene and 1-cyano-1,3-butadiene (mixture of isomers). A sample of this material was redistilled for analysis.

*Anal.* Calcd. for $C_9H_{11}N$: C, 81.15; H, 8.33. Found: C, 81.05; H, 8.24.

Attempts to effect dehydrogenation of this compound with sulfur or with palladium-on-carbon at high temperature failed. When 13.3 g. (0.1 mole) of the adduct was reduced over Raney nickel catalyst there was obtained 10.2 g. of an amine, b.p. 96° (22 mm.), $n^{20}D$ 1.4653, $d^{20}_4$ 0.8461.

*Anal.* Calcd. for $C_9H_{19}N$: C, 76.51; H, 13.55; N, 9.92. Found: C, 76.45; H, 13.38; N, 10.08.

A picrate of this material was prepared, and after three recrystallizations from 95% ethanol it melted at 189–190° (dec.).

In an attempt to identify the adduct, *o*-cyanostyrene was reduced over nickel but it was not possible to prepare a crystalline picrate of the reduction product.

**1-Cyano-2-methyl-1,3-butadiene.**—The benzoate of tiglic aldehyde cyanohydrin was prepared by the same method used for the benzoate of crotonaldehyde cyanohydrin. From 63 g. (0.75 mole) of tiglic aldehyde (2-methylcrotonaldehyde), 106 g. (0.75 mole) of benzoyl chloride, and 45 g. (0.92 mole) of sodium cyanide there was obtained 120 g. (75%) of tiglic aldehyde cyanohydrin benzoate, b.p. 134° (2 mm.), $n^{20}D$ 1.5200.

*Anal.* Calcd. for $C_{13}H_{13}O_2N$: C, 72.54; H, 6.09. Found: C, 72.49; H, 6.23.

Pyrolysis of tiglic aldehyde cyanohydrin benzoate in a manner exactly analogous to that employed for the pyrolysis of crotonaldehyde cyanohydrin benzoate yielded 1-cyano-2-methyl-1,3-butadiene. From 120 g. of the benzoate there was obtained 29 g. (56%) of 1-cyano-2-methyl-1,3-butadiene, b.p. 65° (28 mm.), $n^{20}D$ 1.4986.

*Anal.* Calcd. for $C_6H_7N$: C, 77.38; H, 7.58. Found: C, 77.37; H, 7.68.

## Summary

The *cis*- and *trans*-isomers of 1-cyano-1,3-butadiene have been separated. The higher-boiling isomer undergoes Diels–Alder reactions with maleic anhydride and 1,3-butadiene. This isomer is considered to have the *trans*-structure, on the basis of the reaction with maleic anhydride. 1-Cyano-2-methyl-1,3-butadiene has been prepared, but no stereochemical study of the product has been made.

URBANA, ILLINOIS RECEIVED MAY 19, 1948

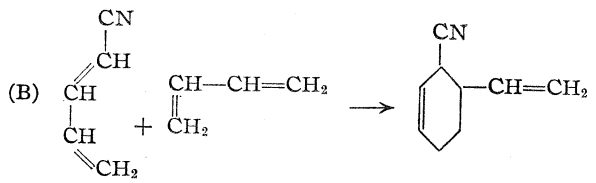
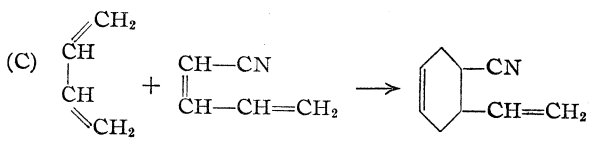
# 1-Cyano-1,3-butadienes. II. Carbon Structure of the Adduct Formed by the Diels–Alder Condensation of 1-Cyano-1,3-butadiene with 1,3-Butadiene



BY H. R. SNYDER AND GEORGE I. POOS



In an attempt to identify the amine obtained by the complete hydrogenation[1] of the adduct from 1-cyano-1,3-butadiene and butadiene, 2-ethylhexahydrobenzylamine was prepared by the catalytic hydrogenation of 2-ethylbenzonitrile. Reduction of the 2-ethylbenzonitrile at high pressure over Raney nickel catalyst produced 2-ethylbenzylamine, which resisted further hydrogenation under these conditions. However, in the presence of platinum catalyst 2-ethylbenzylamine was hydrogenated (2–3 atmospheres, 65°) to 2-ethylhexahydrobenzylamine. The phenylthiourea derivatives of 2-ethylhexahydrobenzylamine and the hydrogenated adduct had the same composition but were found to have different melting points. The difference may be attributed to *cis–trans* isomerism of the amine. The lower melting derivative was obtained from the reduction of 2-ethylbenzylamine and is presumably *cis*, inasmuch as low pressure catalytic hydrogenation of the benzene ring usually produces the *cis* isomer.[2] Attempts to isomerize the phenylthiourea derivatives of the amines thermally either had no effect or resulted in decomposition of the compounds.

Proof of the carbon structure of the adduct was obtained by aromatizing the substance and hydrolyzing the nitriles so obtained to 2-ethylbenzamide in one instance and to 2-vinylbenzamide in another (equation A). The aromatizations were carried out by bromination of the adduct with N-bromosuccinimide followed by dehydrobromination with a high-boiling tertiary amine. When an equivalent amount of the brominating agent was used in the first step, basic hydrolysis of the aromatic nitrile yielded 2-ethylbenzamide, identified by mixed melting point. When two equivalents of N-bromosuccinimide were employed, hydrolysis of the aromatic nitrile in the presence of hydrogen peroxide produced 2-vinylbenzamide. The identity of the latter amide was established by mixed melting point and analysis.

(A) 

1-Cyano-1,3-butadiene and 1,3-butadiene might condense in two ways to give a 2-cyano-1-vinylcyclohexene (equations B and C) and therefore it is not possible to assign the position of the cyclohexene double bond on the basis of the carbon structure. Furthermore, preliminary analyses of the infrared absorption spectrum of the adduct indicate that the substance possesses a conjugated olefinic bond. Apparently the initial condensation product is unstable and changes to a conjugated isomer during or before the distillation of the reaction mixture. The product of equation B would be expected to change readily to a conjugated isomer, and this equation may represent the course of the condensation.

(B) 

(C) 

## Experimental[2a]

**2-Ethylhexahydrobenzylamine.**—2-Ethylaniline was converted by means of the Sandmeyer reaction into 2-ethylbenzonitrile (60%); b.p. 103° (19 mm.) lit.,[3] 212° (atm. pressure); $n^{20}D$ 1.5232. In an attempt to hydrogenate 2-ethylbenzonitrile completely over Raney nickel catalyst at temperatures from 130 to 175° and pressures from 500 to 2800 p.s.i., only 31% of the theoretical amount of hydrogen could be added. The main product was 2-ethylbenzylamine, which rapidly forms the carbonate upon exposure to the atmosphere. The picrate after recrystallization from 95% ethanol melted at 215° with decomposition.

*Anal.* Calcd. for $C_{15}H_{16}O_7N_4$: C, 49.45; H, 4.43. Found: C, 49.52; H, 4.62.

In addition to the primary amine, there was obtained a small amount of the corresponding secondary amine. The hydrochloride of the secondary amine was recrystallized from high-boiling petroleum ether–absolute ethanol and after drying *in vacuo* over phosphorus pentoxide the hygroscopic salt melted at 158.5–159°.

*Anal.* Calcd. for $C_{18}H_{24}NCl$: C, 74.59; H, 8.35. Found: C, 74.59; H, 8.19.

To a solution of 10.0 g. of 2-ethylbenzylamine in 100 ml. of 75% ethanol in a low pressure hydrogenation bottle was added 1.1 g. of platinic oxide and 2 drops of concentrated hydrochloric acid. The bottle was heated to 65° and shaken in a Parr machine under 2–3 atmospheres of hydrogen. When 53% of the theoretical amount of hydrogen had been added, the reduction had stopped and it was necessary to filter the solution and add fresh catalyst. After a total of forty-seven hours, 87% of the theoretical amount of hydrogen had been added. The reaction mixture was then filtered, the low boiling material was removed by distillation and the residue was distilled through a small column. There was obtained 7.2 g. of an amine that could not be separated in a sufficient state of purity for analysis.

(1) Snyder, Stewart and Myers, THIS JOURNAL, **71**, 1055 (1949).

(2) Linstead, *et al.*, *ibid.*, **64**, 1985–2026 (1942).

(2a) All melting points are uncorrected.

(3) Giebe, *Ber.*, **29**, 2535 (1896).

From this amine and phenyl isothiocyanate there was obtained phenyl-2-ethylhexahydrobenzylthiourea as a heavy oil which hardened after standing for three days. When recrystallized twice from 50% ethanol and once from high-boiling petroleum ether it melted at 88°.

*Anal.* Calcd. for $C_{16}H_{24}N_2S$: C, 69.52; H, 8.75. Found: C, 69.52; H, 8.93.

**Phenylthiourea of the Reduced Adduct.**—From phenyl isothiocyanate and the amine obtained by the reduction of I[4] there was obtained an oil which was induced to crystallize by cooling its alcoholic solution to −80°. After being recrystallized twice from 50% ethanol and once from high-boiling petroleum ether the product melted at 146–148°.

*Anal.* Calcd. for $C_{16}H_{24}N_2S$: C, 69.52; H, 8.75. Found: C, 69.57; H, 8.98.

**Aromatization of I. A. Bromination with One Equivalent of Brominating Agent and Dehydrobromination.**—To a solution of 5.0 g. (0.038 mole) of I[4] in 50 ml. of ethylene dichloride was added 6.8 g. (0.038 mole) of purified N-bromosuccinimide, and the mixture was heated to boiling with stirring. After refluxing for one and one-half hours, the solution gave a negative test for active bromine with acidified potassium iodide solution. The mixture was cooled, the precipitated succinimide was removed by filtration and the ethylene dichloride was distilled. The bromide was separated from a small amount of succinimide by extraction of the residue with cold absolute ethanol. The alcohol was then removed by distillation. To the dark residual oil was added 12 g. of quinoline and the mixture was distilled (oil-bath temp. 170–180°) slowly under reduced pressure through a small column. The distillate boiling from 110–114° (16 mm.) was shaken with dilute hydrochloric acid to remove any quinoline and the nitrile was extracted with ether and redistilled.

Attempted hydrolysis of this mixture with 75% sulfuric acid yielded only tar. However, when 0.40 g. of the material was refluxed for forty-seven hours with 0.5 g. of potassium hydroxide in 6.5 ml. of 60% ethanol, in addition to unhydrolyzed nitrile, there was isolated a small quantity of a white crystalline material. After recrystallization from water and chloroform it melted at 151–152° and showed no depression in melting point when mixed with a sample of 2-ethylbenzamide.[3] There was not enough of this material for analysis.

**B. Bromination with Two Equivalents of Brominating Agent and Dehydrobromination.**—To a solution of 5.0 g. (0.038 mole) of I[4] in 85 ml. of benzene was added 13.7 g. (0.076 mole) of purified N-bromosuccinimide and the solution was heated to boiling with stirring. After refluxing for two hours a positive test for active bromine was still obtained. The reaction mixture was cooled to 0° and the precipitated succinimide was removed by filtration. Distillation of the benzene was accompanied by the evolution of hydrogen bromide. To the residual oil was added 16.8 g. of lepidine and the mixture was distilled slowly under reduced pressure through a small column. The distillate boiling at 80–88° (3 mm.) was collected, shaken with dilute hydrochloric acid, recollected in ether, and redistilled to yield a colorless oil that darkened rapidly.

A portion of this nitrile was hydrolyzed in alcoholic sodium hydroxide solution in the presence of 30% hydrogen peroxide.[5] The alcohol was removed by distillation and the cold aqueous residue was extracted with chloroform. Concentration of the extract yielded 2-vinylbenzamide, which after recrystallization from chloroform melted at 151.5–152°.

*Anal.* Calcd. for $C_9H_9ON$: C, 73.45; H, 6.16; N, 9.52. Found: C, 73.15; H, 6.16; N, 9.71.

This amide showed no depression in melting point when mixed with 2-vinylbenzamide prepared by hydrolysis of 2-cyanostyrene.

**2-Vinylbenzamide.**—Hydrolysis of 0.50 g. of 2-cyanostyrene[6] in the presence of 30% hydrogen peroxide by the same procedure as described above yielded 0.22 g. of crude 2-vinylbenzamide which melted at 143–147°. Recrystallization from chloroform raised the melting point to 151.5–152°.

*Anal.* Calcd. for $C_9H_9ON$: C, 73.45; H, 6.16. Found: C, 73.54; H, 6.36.

## Summary

The Diels–Alder adduct of 1-cyano-1,3-butadiene with 1,3-butadiene is shown to be a 2-cyano-1-vinylcyclohexene. Proof of the carbon structure is accomplished by bromination of the adduct, dehydrobromination and hydrolysis to 2-ethylbenzamide and 2-vinylbenzamide.

# Amine Replacement Reactions of α-Dimethylaminomethyl-β-methoxynaphthalene

BY H. R. SNYDER AND JAMES H. BREWSTER[1]

α-Dimethylaminomethyl-β-naphthol, a typical phenolic Mannich base, possesses a labile amino group which can easily be replaced by an activated aromatic nucleus,[2] by a cyano[3] group or by another amine residue.[4] A methylene quinone has been suggested as an intermediate in the amine exchange reaction[4]; such an intermediate could also participate in the other amine replacement reactions of phenolic Mannich bases. It has been suggested previously that a vinyl ketone is formed in the first step of amine replacement reactions of ketonic Mannich bases[5] and their quaternary salts.[6]

In a test of the hypothesis that amine elimination is the first step in amine replacement reactions of Mannich bases, it was desired to prepare α - dimethylaminomethyl - β - methoxynaphthalene (V) and its methiodide (VI) and to subject these compounds to the conditions of amine exchange and amine replacement reactions.

β-methoxynaphthalene failed to undergo the

(1) Present address: Department of Chemistry, University of Chicago, Chicago, Illinois.

Mannich reaction,[7] differing in this respect from 1-methylindole.[8] Mannich bases of β-naphthol could not be etherified with either methyl iodide or dimethyl sulfate, apparently because quaternary salt formation occurred more readily. The method shown in the diagram was finally adopted for the preparation of V. In this synthesis α-aminomethyl-β-methoxynaphthalene (IV) was prepared by hydrolysis of the amide (III) with hot 20% sodium hydroxide solution; the stability of the primary amine (IV) to the alkaline solution is in marked contrast to the lability of naphthol Mannich bases in the presence of alkali.[2] The tertiary amine (V) also was stable to alkali; it could be distilled, and it yielded an isolable methiodide. In all these respects it differs from α-dimethylaminomethyl-β-naphthol. It failed to react with piperidine, piperidine acetate, sodium cyanide in aqueous ethanol or malonic ester in the presence of powdered sodium hydroxide. The low reactivity of the substance (V) indicates that the lability of the amino group in a phenolic Mannich base is great only when amine elimination is possible.

The quaternary salt (VI) reacted with piperidine by amine exchange, and with sodium cyanide and sodiomalonic ester by amine replacement. The activity of the salt (VI) in these reactions is similar to that of quaternary salts of benzylamine,[9,10,11,12] and less than that of 1-methylgramine methiodide.[8]

## Experimental[13,14]

**α-Benzamidomethyl-β-methoxynaphthalene (III)** was prepared by modifications of the method described[15] for the analogous α-chloroacetyl derivative. A mixture of 100 ml. of methanol, 31.6 g. of β-methoxynaphthalene[16] and 30.2 g. of N-methylolbenzamide[17] was stirred at 35–40° while a rapid stream of hydrogen chloride gas was introduced until a clear solution formed. Introduction of the gas was discontinued, and after six hours at room temperature the mixture was poured into ice and water. The thoroughly washed solid was dried, boiled for three hours with 300 ml. of methanol, recovered by filtration of the cooled suspension, washed repeatedly with water, and dried over calcium chloride to give 56 g. (97%) of III of m.p. 152–153°; recrystallization from eight parts of ethanol raised the m.p. to 153.5–154° (lit.[18] 155°). Since the substance apparently has not been prepared previously by this method, a sample was analyzed.

*Anal.* Calcd. for $C_{19}H_{17}O_2N$: C, 78.35; H, 5.84; N, 4.82. Found: C, 78.26; H, 5.80; N, 4.75.

**α-Aminomethyl-β-methoxynaphthalene (IV).**—A mixture of 50 g. of III with a solution of 45 g. of sodium hydroxide in 50 ml. of water and 250 ml. of ethanol was refluxed twenty-four hours. The clear hot solution was poured into 1 l. of water; the solid was collected, washed, suspended in 1 l. of water and dissolved by the addition of about 25 ml. of 37% hydrochloric acid. The amine (IV) was recovered by the addition of alkali to the filtered, cooled solution. After washing and drying, the nearly pure IV (31.1 g., 96%) melted at 68–69° (lit. 41–42°[18]; *ca.* 100°[15]); it could be recrystallized from 75% ethanol or distilled at 141–142° (1 mm.).

*Anal.* Calcd. for $C_{12}H_{13}NO$: C, 77.01; H, 6.94. Found: C, 76.90; H, 7.10.

Saturated alcoholic picric acid solution was added to a warm alcoholic solution of the amine. The bright yellow *picrate* precipitated as micro-needles. After it had been recrystallized from 95% ethanol it melted at 197–198°. Dey and Rajagopalan[18] reported this picrate as melting at 215° and having a nitrogen content of 14.12 per cent., which they compared to the value of 14.00% based on the formula $C_{18}H_{16}N_4O_7$; however, the formula of the monopicrate is $C_{18}H_{16}N_4O_8$ and the theoretical nitrogen content thus becomes 13.46%. The analysis of our sample was satisfactory.

*Anal.* Calcd. for $C_{18}H_{16}N_4O_8$: C, 51.95; H, 3.85; N, 13.46. Found: C, 52.08; H, 4.02; N, 13.27.

**α-Dimethylaminomethyl-β-methoxynaphthalene (V)** was prepared from IV, 40% formalin and formic acid by modification of a standard procedure[19] for the Clarke–Eschweiler reaction; the tertiary amine V, b.p. 146–150° (2 mm.), $n^{20}D$ 1.6002, was obtained in 60% yield.

*Anal.* Calcd. for $C_{14}H_{17}NO$: C, 78.14; H, 7.91; N, 6.51. Found: C, 78.01; H, 7.86; N, 6.57.

**The picrate** was prepared as above. It crystallized from alcohol in large bright yellow plates, m.p. 164–165°.

*Anal.* Calcd. for $C_{20}H_{20}N_4O_8$: C, 54.05; H, 4.50; N, 12.61. Found: C, 54.02; H, 4.62; N, 12.55.

**The methiodide VI,** prepared (95% yield) in ether from a 40% excess of methyl iodide, melted at 158–159°.

*Anal.* Calcd. for $C_{15}H_{20}NOI$: C, 50.43; H, 5.64; N, 3.92; I, 35.53. Found: C, 50.14; H, 5.79; N, 3.73; I, 35.70.

**α-Piperidinylmethyl-β-methoxynaphthalene (VII).**—When a mixture of 1.78 g. of the methodide (VI) and 8.5 g. of piperidine was heated under reflux a gaseous amine was evolved rapidly. After about three hours the mixture was added to aqueous alkali, and the ether-soluble portion was collected and freed of piperidine by evaporation, finally under diminished pressure. The acid-soluble portion of the residue was recovered and recrystallized from aqueous ethanol to give 0.60 g. (47%) of VII, m.p. 65–66°.

*Anal.* Calcd. for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49. Found: C, 80.41, 80.34; H, 8.58, 8.61; N, 5.45.

**2-Methoxy-1-naphthaleneacetonitrile (VIIIa).**—When aqueous solutions of the methiodide (VI) and excess sodium cyanide were refluxed for as long as a week, no amine replacement reaction occurred. The method of von Meyer[11] was finally employed. To a solution of 3.57 g. of α-dimethylaminomethyl-β-methoxynaphthalene methiodide (VI) in 10 ml. of water in a 50-ml. distilling flask was added 2.5 g. of sodium cyanide. The mixture was warmed until the cyanide had dissolved; a heavy oil separated. Water was slowly distilled from the solution at water-pump pressure until the solid residue was nearly dry. The bulb of the distilling flask was placed in a Wood's metal-bath which was heated (about 140°) until the material began to froth vigorously. The bath temperature was slowly raised to 250°. When evolution of trimethylamine had ceased, the mixture was distilled. The waxy product, b.p. 154° (0.5 mm.), was recovered from the side-arm of the flask by extraction with a small amount of hot acetone and crystallized from 50% aqueous acetone to yield 0.86 g. (43.5%) of light yellow crystals of 2-methoxy-1-naphthaleneacetonitrile (VIIIa) which melted at 111.5–112.5° (lit.[20] 111°). Alkaline hydrolysis of a portion of the nitrile gave **2-methoxy-1-naphthaleneacetic acid (VIIIb),** m.p. 208–209° (lit. 208°,[21] 210–211°).[22]

**(β-Methoxy-α-naphthylmethyl)-malonic Acid (IXa).**—Freshly cut sodium (0.25 g.) was converted to sodium sand under xylene. The xylene was decanted and replaced by absolute diethyl carbitol[23] (25 ml.). Diethyl malonate (4.0 g.) was added, and the solution was stirred with cooling until all of the sodium had reacted. α-Dimethylaminomethyl-β-methoxynaphthalene methiodide (VI) (3.57 g.) was added and the mixture was heated with stirring at 120–130° for seventy-two hours and finally at 150–160° for one hour. Trimethylamine was evolved during the entire heating period. The cooled mixture was treated with 40 ml. of 10% hydrochloric acid and extracted with benzene. The benzene solution was extracted with 10% sodium hydroxide, then with 37% hydrochloric acid (to remove diethyl carbitol) and finally with water. The dried benzene solution was concentrated and the thick oily residue was treated with a hot solution of 5 g. of sodium hydroxide in 5 ml. of water and 2 ml. of ethanol. A thick white paste formed when the mixture was stirred. After one-half hour the saponification mixture was warmed for a few minutes on a steam cone. The substituted malonic acid, recovered by dilution with water and acidification, was recrystallized from 10% ethanol. The white micro-crystals of (β-methoxy-α-naphthylmethyl)-malonic acid (IXa) weighed 1.73 g. (61%) and melted at 158–159° (dec.).

*Anal.* Calcd. for $C_{15}H_{14}O_5$: C, 65.68; H, 5.15; neutral equivalent, 137. Found: C, 65.90; H, 5.39; neutral equivalent, 138.4.

**2-(β-Methoxy-α-naphthyl)-propionic Acid (IXb).**—The malonic acid (IXa) (0.4 g.) was heated under reflux for one hour with pyridine (4. g.).[24] The solution was cooled and 10% hydrochloric acid (40 ml.) was added. The white precipitate was collected and crystallized from a 10% ethanol. The propionic acid (IXb) formed white needles melting at 131–132° (lit.[25] 128°).

*Anal.* Calcd. for $C_{14}H_{14}O_3$: neut. equiv., 230. Found: neut. equiv., 230.2.

## Summary

α-Dimethylaminomethyl-β-methoxynaphthalene (V) was prepared by benzamidomethylation of β-naphthyl methyl ether, followed by hydrolysis of the amide so formed and methylation of the primary amine. The dimethylamino group of V could not be replaced by reaction with piperidine, sodium cyanide or ethyl malonate; the compound was stable to alkali. The phenolic hydrogen atom appears to participate in the amine exchange and replacement reactions of phenolic Mannich bases.

The methiodide of V reacted by amine replacement with piperidine, sodium cyanide and sodio malonic ester. The reactivity of this quaternary salt resembles that of quaternary salts of benzylamine.

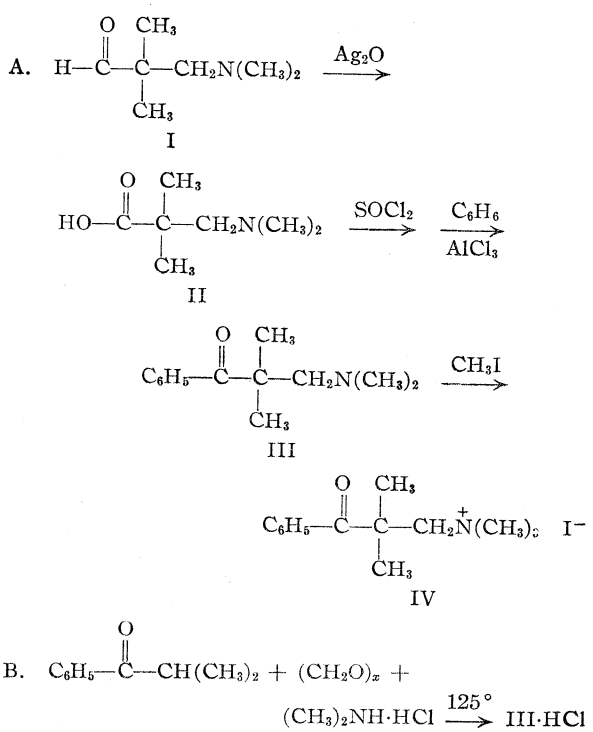
# Reactions of β-Dimethylaminopivalophenone and its Methiodide

BY H. R. SNYDER AND JAMES H. BREWSTER[1]

Ketonic Mannich bases and their quaternary salts alkylate active methylene compounds[2,3] by a process of amine replacement and react with secondary amines by amine exchange.[4] Amine replacement also occurs in the reaction of sodium cyanide with the hydrochlorides of ketonic Mannich bases.[5]



The ease with which vinyl ketones can be prepared from β-aminoketones[6,7] has suggested that amine elimination is the first step in amine replacement[2,3] and exchange[4] reactions. Nisbet has presented evidence that amine elimination precedes ring closure in the formation of pyrazolines from the phenylhydrazones of ketonic Mannich bases.[8]

In connection with studies of the reactions of Mannich bases which cannot suffer amine elimination,[9,10] β-dimethylaminopivalophenone (III) and its methiodide (IV) were prepared and subjected to the conditions of amine replacement and exchange reactions. These compounds (III and IV) would be expected to be extremely unreactive in such processes; not only is amine elimination impossible, but also $S_N2$ amine displacements[11] are prevented by the steric hindrance offered by the α-methyl groups,[12] and $S_N1$ amine replacements[11] are hindered because no resonance-stabilized "carbonium ion" (or its solvated equivalent)[13] can be formed as an intermediate.

Although isobutyraldehyde readily undergoes the Mannich reaction to form β-dimethylaminopivaldehyde (I),[14] isobutyrophenone (V) is not attacked under the conditions generally employed for this process.[15] The ketonic Mannich base (III) could, however, be prepared in low yield by the reaction of isobutyrophenone with dimethylamine hydrochloride and an excess of molten paraformaldehyde (eqn. B). The β-aminoketone so formed was identical with that prepared from β-dimethylaminopivalic acid (II) by the method of Dalmer, Diehl and Pieper[16] (eqn. A).

The β-aminoketone (III) failed to react with alcoholic alkali, morpholine or malonic ester. Although III apparently formed a phenylhydrazone, this derivative could not be crystallized, nor could it be cyclized to a pyrazoline, in contrast to the phenylhydrazone of the dimethylamino Mannich base of acetophenone.[17] When heated with aqueous-alcoholic sodium cyanide, III formed isobutyrophenone in 67% yield. A similar reverse Mannich reaction occurred readily when a dilute hydrochloric acid solution of III was distilled. A possible mechanism for this reaction is indicated in equation C.

The methiodide (IV) formed no appreciable amounts of neutral or acidic products when heated with aqueous sodium cyanide or sodiomalonic ester in diethyl carbitol. When an aqueous solution of IV and sodium cyanide was distilled to dryness, III was formed by demethylation of the quaternary salt. Hot aqueous alkali slowly converted IV to benzoic acid, trimethylamine and, perhaps, isobutylene, possibly by the mechanism shown in equation D.

## Experimental[18,19]

**β-Dimethylaminopivalophenone (III). 1. By the Friedel–Crafts Reaction.**—β-Dimethylaminopivaldehyde[14] (I, 14.8 g.) was added dropwise to a stirred suspension of thoroughly washed silver oxide (prepared from 39.2 g. of silver nitrate) in 150 ml. of water. The oxidation was completed by heating the mixture on the steam-bath for two hours. The crude amino acid (II), obtained by evaporation (at 25 mm.) of the filtered aqueous solution, was dissolved in a mixture of 200 ml. of acetone and 5 ml. of water, and the filtered hot solution was placed in the ice-chest. After twelve hours pure II was collected as glistening white needles melting at 98–99° (lit.[16] 100°); yield, 12.2 g. (74%). The amino acid was converted to the ketone (III) as previously described[16]; the ketone (III) was obtained as a nearly odorless, water-white liquid, b.p. 103–105° (2.5 mm.), $n^{20}D$ 1.5128; the yield of III from II was 32%.

**2. By the Mannich Reaction of Isobutyrophenone.**—In a 300-ml. Kjeldahl flask fitted with an air-cooled condenser a mixture of 7.4 g. of isobutyrophenone, 8.2 g. of dimethylamine hydrochloride and 7.5 g. of paraformaldehyde was heated for two hours at 140–150° (oil-bath temperature). The cooled mixture was diluted with 150 ml. of water, filtered and washed with ether. The aqueous layer was made alkaline and extracted with ether. Distillation of the residue from evaporation of the dried ether extracts gave 2.03 g. (19%) of III, b.p. 83–84° (1 mm.), $n^{20}D$ 1.5130.

*Anal.* Calcd. for $C_{13}H_{19}ON$: C, 76.05; H, 9.34; N, 6.82. Found: C, 76.03; H, 9.48; N, 6.88.

The hydrochloride[16] melted at 143–144°, alone or mixed with the hydrochloride prepared from the product of the first synthesis.

**The methiodide** (IV) formed when III was allowed to stand with a fivefold excess of methyl iodide for twelve hours or longer; it separated as a dark oil which crystallized when the mixture was diluted with ether. The salt could be recrystallized by the slow addition of dry ether to an absolute ethanol solution. It melted at 122–122.5°; samples prepared from the two lots of II were identical.

*Anal.* Calcd. for $C_{14}H_{22}ONI$: C, 48.42; H, 6.39. Found: C, 48.64; H, 6.49.

**Attempted Amine Exchange Reaction with β-Dimethylaminopivalophenone.**—β - Dimethylaminopivalophenone (III) (0.41 g.) and morpholine (4.35 g.) were refluxed for forty-eight hours under nitrogen. The solution was cooled and 20 ml. of water was added. The cloudy mixture was extracted with three 5-ml. portions of ether. The combined ether extract was distilled, finally under vacuum (water pump), to remove the morpholine that had been extracted along with the aminoketone. A large excess of methyl iodide was added to the residue; the methiodide of β-dimethylaminopivalophenone (IV), m.p. 122–123°, identical with that previously prepared, was obtained; yield, 0.45 g. (65%).

**Attempted Alkylation of Malonic Ester with β-Dimethylaminopivalophenone.**—To a solution of β-dimethylaminopivalophenone (III) (0.41 g.) and malonic ester (1.00 g.) in 5 ml. of xylene was added a small amount of powdered sodium hydroxide. The mixture was refluxed under nitrogen for forty-eight hours. No amine evolution was observed. The solution was cooled and extracted with three 5-ml. portions of 10% hydrochloric acid. The combined acid extract was made strongly alkaline and the oil which separated was taken up in ether; the ether was evaporated and the residue was treated with an excess of methyl iodide. The methiodide of the Mannich base was obtained; yield, 0.43 g. (62%), m.p. 122–123°.

**Reverse Mannich Reaction of Isobutyrophenone Mannich Base.**—β-Dimethylaminopivalophenone (2.05 g.) and sodium cyanide (1.00 g.) were heated together in 30 ml. of 50% ethanol for four days. A volatile amine was evolved. Water (70 ml.) was added to the cooled solution, which was then extracted with 20-ml. portions of ether. The combined ether extract was distilled, finally under reduced pressure. Isobutyrophenone, (1 g., 67.5%) b.p. 56° (1 mm.), $n^{20}D$ 1.5189 (lit.[20] $n^{20}D$ 1.5190), was the sole product obtained. The 2,4-dinitrophenylhydrazone melted at 162–162.5°.[20]

A similar reverse Mannich reaction occurred when the Mannich base was heated in acid medium.

β-Dimethylaminopivalophenone (1.00 g.) was dissolved in a mixture of 2 ml. of 37% hydrochloric acid and 10 ml. of water. The solution was slowly distilled almost to dryness from an oil-bath maintained at 130–140°. When no further distillation occurred more water was added and the distillation was resumed. This process was continued until only a clear distillate was obtained; there was a small amount of tarry residue.

The acidic, cloudy distillate (20 ml.) was extracted with ether. The ether was evaporated, and the residue, dissolved in 95% ethanol, was treated with 1 g. of 2,4-dinitrophenylhydrazine. The solution was brought to boiling, and, after it had been cooled slightly, 37% hydrochloric acid (1.3 ml.) was added. The acid solution was heated under reflux for one hour; the crude 2,4-dinitrophenylhydrazone of isobutyrophenone, m.p. 153–155°, 1.34 g. (81.8%), crystallized from the solution when it was chilled in ice. The reddish crystals were digested with ethanol to give 1.02 g. (62.3% from the Mannich base) of the pure derivative, m.p. 162.5–163°.[20]

β-Dimethylaminopivalophenone (1.0 g.) was heated with a solution of sodium hydroxide (2 g.) in 75% ethanol (20 ml.) for two days. No appreciable evolution of basic gases occurred. The flask was cooled and water (30 ml.) was added. The oil which separated was collected in ether and extracted with 10% hydrochloric acid. The ether solution left no residue on evaporation. The acid solution was made strongly basic and 0.75 g. (75%) of the unchanged Mannich base, b.p. 90° (1 mm.), $n^{20}D$ 1.5125 was recovered.

**Reaction of the Methiodide of β-Dimethylaminopivalophenone with Sodium Cyanide.**—A solution of the methiodide of β-dimethylaminopivalophenone (IV) (1.74 g.) and sodium cyanide (0.50 g.) in water (5 ml.) was distilled to dryness at atmospheric pressure in a flask with a low-set wide side-arm. The bulb of the flask was set in a Wood's metal-bath, and, while the pressure inside the flask was maintained at about 35 mm., the bath temperature was raised slowly to 180°. A liquid formed in the bulb of the flask but did not distil. After half an hour the mixture was allowed to cool somewhat and was distilled at 1.5 mm. pressure yielding a fraction of b.p. 100–120° (1.5 mm.).

The solid residue in the distillation flask was extracted with ether, and this ethereal solution was used in an extraction of the first (aqueous) distillate and was then added to the volatile material from the final distillation. The ether solution was extracted with 10% sodium hydroxide

(18) Microanalyses by Misses Theta Spoor and Betty Snyder.

(19) All melting points corrected.

(20) Evans, *J. Chem. Soc.*, 788 (1936).

solution and then with 10% hydrochloric acid. The neutral and base-soluble fractions contained only traces of material. The acid-soluble fraction was recovered and treated with methyl iodide to give 0.87 g. (50%) of the methiodide of β-dimethylaminopivalophenone; m. p. 122–123°. No melting point depression occurred on admixture of authentic IV to this salt.

**Reaction of Methiodide of β-Dimethylaminopivalophenone with Sodium Hydroxide.**—The methiodide (IV) (1.04 g.) was heated under reflux with 8 ml. of 5% sodium hydroxide for forty-eight hours. A basic gas was evolved rapidly during the first few hours. The cooled solution was filtered, the filtrate acidified, and the precipitated benzoic acid was collected in benzene; m.p. (and mixed m.p.) 122–122.5°, after recrystallization from water; yield 0.21 g. (57%).

## Summary

β-Dimethylaminopivalophenone has been prepared by the Mannich reaction of isobutyrophenone. This β-aminoketone cannot suffer amine elimination, is sterically hindered to amine displacement, and cannot form a resonance-stabilized "carbonium ion." It failed to undergo amine exchange and replacement reactions; it was stable to strong base, but it readily underwent the reverse Mannich reaction in weakly basic or acidic medium.

The methiodide of this Mannich base reacted with sodium cyanide by demethylation rather than by amine replacement. Hot aqueous alkali caused cleavage of the methiodide to benzoic acid.

# The Thiaxanthone Dioxide–Thiaxanthenol Dioxide–Thiaxanthene Dioxide Oxidation–Reduction System: A Sulfone Series Analog of the Anthraquinone–Anthrahydroquinone–Anthrone System[1]

BY EDWARD A. FEHNEL[2]

Several investigators have called attention to the peculiar color reactions of thiaxanthone-5-dioxide and substituted thiaxanthone-5-dioxides in the presence of zinc dust and alkali,[3] but no detailed study of these reactions has previously been reported and the nature of the chromogen has remained a subject for speculation.[3] Our interest in the physico-chemical properties of the sulfone function[4] led us to investigate the color reactions of thiaxanthone-5-dioxide in some detail, and we are now able to report the isolation and characterization of the substance responsible for color formation and to suggest a mechanism for the reactions involved.[5]

I II

On treatment with zinc dust or sodium hydrosulfite and alkali, alcoholic solutions of thiaxanthone-5-dioxide (I) give an intense blue color, which is discharged on shaking with air. The striking similarity of this behavior to that shown by anthraquinone[6] (II) under the same conditions immediately suggests that the color is to be attributed to the formation of a sulfone anion analogous to the deeply colored, readily oxidizable anthrahydroquinone anion formed in the familiar vatting reaction.[7] Our data on the oxidation–reduction reactions in the thiaxanthone dioxide series are in accord with this interpretation. The demonstration of a close parallelism in the reactions of the thiaxanthone dioxide and anthraquinone series of compounds is of particular interest in view of the fact that the formulation of a sulfone oxidation–reduction system analogous to the anthraquinone–anthrahydroquinone system requires

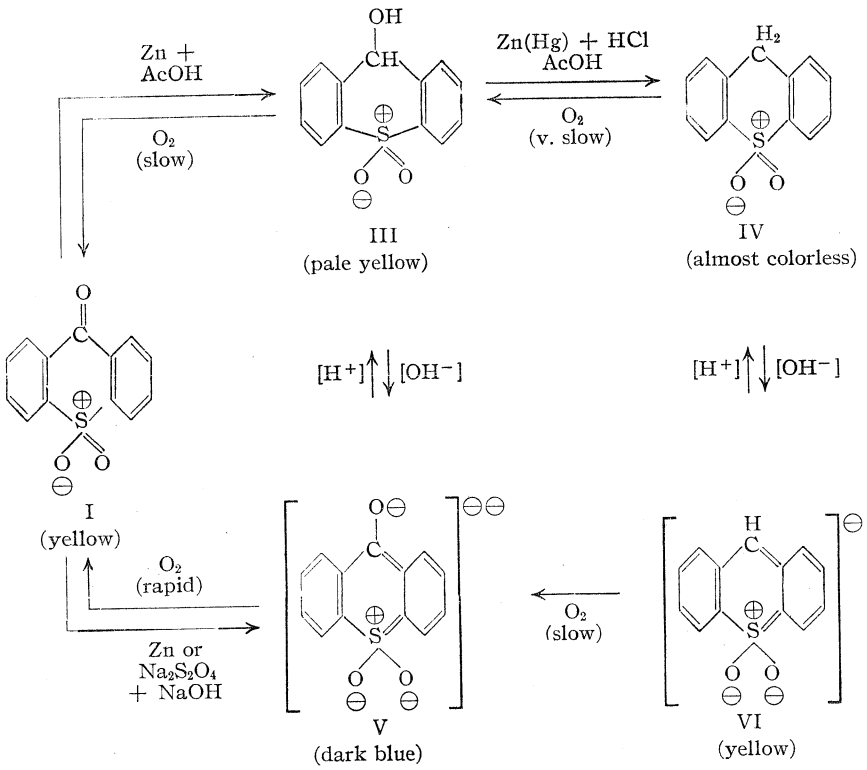
(5) NOTE ADDED IN PROOF.—While the present paper was in press, Heymann [*ibid.*, **71**, 260 (1949)] reported a closely related study of the thiaxanthone dioxide–thiaxanthenol dioxide oxidation–reduction system, in which essentially the same conclusions were reached with regard to the reaction mechanism.

(6) For a detailed discussion of the chemistry of anthraquinone and its reduction products, see Houben and Fischer, "Das Anthracen und die Anthrachinone," Georg Thieme, Leipzig, 1929, esp. pp. 143–172 and 197–206. An excellent concise summary of the more important oxidation-reduction reactions has been given by Fieser and Fieser, "Organic Chemistry," D. C. Heath, Boston, 1944, pp. 798–802.

(7) NOTE ADDED IN PROOF.—Strictly speaking, it is not entirely accurate to attribute the color to the simple ion, since the colored species is undoubtedly the semiquinone ion-radical which results from the loss of one electron by the doubly-charged anion (*cf.* Heymann, ref. in footnote 5). This idea is, of course, implicit in the present discussion of the thiaxanthone-enol dioxide oxidation–reduction system, since it follows from the analogy with the anthraquinone–anthrahydroquinone system, in which the blood-red color of the "anthrahydroquinone anion" is almost certainly due to the presence of the corresponding semiquinone ion-radical (see, however, Dufraisse and Priou, *Bull. soc. chim.*, [5] **6**, 1649 (1939), who postulate a biradical anion).

the assumption of an expanded valence shell for sulfur.[4]

The reactions in the thiaxanthone dioxide system are best described by reference to Fig. 1.



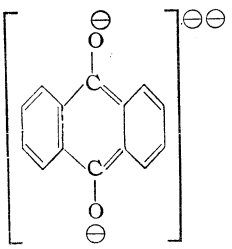


Fig. 1.

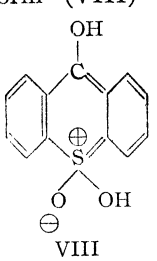


Reduction of thiaxanthone-5-dioxide (I) with zinc dust in dilute acetic acid affords a pale yellow crystalline compound, $C_{13}H_{10}O_3S$, which readily forms a monoacetyl derivative on treatment with acetic anhydride in the presence of sulfuric acid. This compound, which is undoubtedly thiaxanthenol-5-dioxide (III), dissolves in aqueous or alcoholic alkali with the production of a deep blue color. On shaking with air, the color is rapidly discharged and thiaxanthone-5-dioxide (I) precipitates from the solution. Neutral alcoholic solutions of thiaxanthenol-5-dioxide (III) also undergo oxidation on prolonged exposure to air, but the rate of reaction, as evidenced by the slow precipitation of the slightly soluble thiaxanthone-5-dioxide (I) is much lower under these conditions than in the presence of alkali. A slow autoxidation of crystalline thiaxanthenol-5-dioxide (III) is indicated by the gradual development of a deep yellow color when the solid is allowed to stand in contact with air for several weeks; no such change is observed with samples stored under nitrogen.

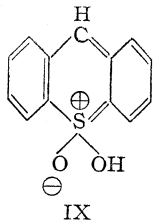
The crystalline product obtained on acidification of the deep blue solution from the alkaline sodium hydrosulfite reduction of thiaxanthone-5-dioxide (I) was shown, by the method of mixed melting points, to be identical with the thiaxanthenol-5-dioxide (III) obtained from the acid reduction. An oxidation–reduction cycle analogous to the anthraquinone–anthrahydroquinone system is thus established. The ground-state structure (V) assigned to the resonating anion responsible for the intense blue color is the sulfone series counterpart of the ground-state structure of the anthrahydroquinone anion (VII).[7] While structure

VII (blood-red)

V very probably represents the most stable electronic configuration for the sulfone anion, the addition of protons to the system is represented in Fig. 1 as resulting in the formation of the sulfone analog, not of anthrahydroquinone, but of its tautomer, oxanthrone. It seems likely, however, that the compound characterized as thiaxanthenol-5-dioxide (III) is at all times in equilibrium with a small but significant amount of the tautomeric form (VIII) corresponding to

VIII

anthrahydroquinone. This assumption seems necessary to account for the autoxidation of the compound in the crystalline state and in neutral solutions,[8] and it is strongly supported by the observation that thiaxanthenol-5-dioxide exhibits a blue fluorescence, since in the anthraquinone series the phenomenon of fluorescence is regarded as evidence for the presence of an *o*-quinonoid structure.[9]



(8) Thus, in the anthraquinone series, the ketonic forms of the reduction products (oxanthrone, anthrone) are resistant to air oxidation, while the enolic forms (anthrahydroquinone, anthranol) are very sensitive to oxidation by air (see ref. 6).

(9) Houben and Fischer, ref. 6, pp. 13–14.

With a reducing agent of sufficiently high potential, such as amalgamated zinc in the presence of hydrochloric acid, it is possible to complete the reduction of thiaxanthenol-5-dioxide (III) and thus to obtain thiaxanthene-5-dioxide (IV).[10,11] The identity of the nearly colorless crystalline product (m. p. 171–172°) obtained in this way was established by its failure to depress the melting point of authentic thiaxanthene-5-dioxide (m. p. 170–171°) prepared by the oxidation of thiaxanthene. Attempts to prepare the same compound (IV) by alkaline reduction of thiaxanthenol-5-dioxide have thus far been unsuccessful, possibly because the anion V undergoes ring cleavage at the sulfonyl group on prolonged treatment with hot alkali.

Although thiaxanthene-5-dioxide (IV) is much less sensitive to oxidation than thiaxanthenol-5-dioxide (III), its ability to undergo gradual oxidation in the presence of air, particularly in alkaline solutions, was demonstrated by treating solutions of the pure compound, after prolonged exposure to air, with zinc dust or sodium hydrosulfite and alkali. The appearance of a deep blue color indicated the presence of thiaxanthone-5-dioxide (I) in the solutions exposed to air; control solutions which were kept under nitrogen gave no color reaction.[12] As was anticipated, the thiaxanthenol-5-dioxide (III) (or, in alkaline solutions, its anion V) which was presumably formed as an intermediate in the oxidation could not be detected in these solutions, since the much greater susceptibility of these molecules to oxidation prevents their accumulating in the mixture.

Like anthrone, of which it is the sulfonyl analog, thiaxanthene-5-dioxide (IV) appears to be the more stable member of a tautomeric pair of isomers. The existence of an equilibrium system involving at least traces of the enolic form (IX) is indicated both by the tendency of alcohol solu-

IX

tions of thiaxanthene-5-dioxide to undergo autoxidation and by the blue fluorescence which this compound exhibits on exposure to ultraviolet light.

**Acknowledgment.**—The author wishes to express his appreciation to Dr. Marvin Carmack for many helpful suggestions and valuable discussions during the course of this work.

## Experimental[13]

**Preparation of Compounds.—Thiaxanthone,** prepared according to the directions of Graebe and Schulthess,[3a] was oxidized to **thiaxanthone-5-dioxide** by treatment with excess 30% hydrogen peroxide in acetic acid.[3d] The crude product (48% over-all yield based on anthranilic acid) was recrystallized from ethanol (Norit) to give yellow needles, m. p. 185.5–186° (reported[3a] m. p. 185°). **Thiaxanthene,** which has previously been prepared by reduction of thiaxanthone with hydrogen iodide and red phosphorus,[3a,14] was conveniently obtained in the present investigation by the Huang-Minlon modification[15] of the Wolff–Kishner reduction; from 1.80 g. of thiaxanthone there was thus obtained 1.15 g. (69%) of pale yellow microcrystalline powder, which afforded colorless needles melting at 127–127.5° (reported[3a] m. p., 128°) after recrystallization from ethanol (Norit). Oxidation of this product with excess hydrogen peroxide in acetic acid[12] yielded 97% of the theoretical amount of **thiaxanthene-5-dioxide** as almost colorless needles, which melted at 170–171° (reported[14] m. p., 170°) after recrystallization from ethanol (Norit).

**Reduction of Thiaxanthone-5-dioxide (I) to Thiaxanthenol-5-dioxide (III): (a) With Zinc Dust and Acetic Acid.**—A mixture of 12.2 g. (0.050 mole) of thiaxanthone-5-dioxide, 10 g. of zinc dust (activated by washing with dilute hydrochloric acid), and 150 ml. of 80% acetic acid was refluxed under nitrogen for thirty minutes, after which it was cooled, filtered, and diluted with 800 ml. of water. The resultant yellow precipitate was collected, washed with water and dried *in vacuo* over calcium chloride; yield, 8.6 g. (70%) of yellow powder, m. p. 165–168°. Recrystallization of this material from chloroform afforded pale yellow crystals, m. p. 184–185°, which exhibited a blue fluorescence on exposure to ultraviolet light; mixed m. p. with thiaxanthone-5-dioxide, *ca.* 146–152°. On treatment with aqueous or alcoholic sodium hydroxide, this product gave a dark blue solution from which the color was discharged on shaking with air.

*Anal.* Calcd. for $C_{13}H_{10}O_3S$: C, 63.39; H, 4.09. Found: C, 63.10; H, 4.11.

When a suspension of 0.50 g. of the above product in 2 ml. of acetic anhydride was treated with 1 drop of concentrated sulfuric acid and allowed to stand for fifteen minutes, a semicrystalline paste was obtained from which 0.58 g. of the acetyl derivative was separated by diluting the mixture with water and filtering off the insoluble product. Recrystallization from ethanol gave almost colorless crystals, m. p. 155.5–156°, which dissolved slowly in aqueous or alcoholic sodium hydroxide with the production of a deep blue color.

(10) The compound prepared by Amstutz and Neumoyer [THIS JOURNAL, **69**, 1925 (1947)] by brief treatment of 2,8-diaminothiaxanthone-5-dioxide with zinc dust in dilute acetic acid and designated 2,8-diaminothiaxanthene-5-dioxide monohydrate was in all probability *2,8-diaminothiaxanthenol-5-dioxide* (*Anal.* Calcd. for $C_{13}H_{12}N_2O_4S$: S, 11.60. Found: S, 11.57, 11.73). This possibility has been called to Dr. Amstutz' attention and is now being checked in the light of the results described in the present paper.

(11) NOTE ADDED IN PROOF.—The reference in Heymann's paper (see "Preparative Part" of ref. in footnote 4) to the previously reported zinc dust–acetic acid reduction of substituted thiaxanthone-5-dioxides to thiaxanthene-5-dioxides apparently refers to the above paper by Amstutz and Neumoyer (footnote 10), not to that by Amstutz, Fehnel and Hunsberger (footnote 3d) as erroneously indicated.

(12) The recent report (ref. 3d) that certain substituted thiaxanthene-5-dioxides give colored solutions on treatment with aqueous-alcoholic alkali is almost certainly in error. The color reactions observed with these compounds must in all probability be ascribed to the presence of traces of the corresponding thiaxanthenol-5-dioxides, formed either during the preparation of the compounds by hydrogen peroxide oxidation of the thiaxanthenes or by subsequent autoxidation of the pure thiaxanthene-5-dioxides. The problem of completely freeing samples of thiaxanthene-5-dioxide from thiaxanthenol-5-dioxide was overcome in the present investigation only by repeated, rapidly conducted recrystallizations, until the product no longer gave a blue color with aqueous-alcoholic alkali.

(13) Microanalyses were performed by Mrs. Sarah M. Woods. All melting points are corrected.

(14) Hilditch and Smiles, *J. Chem. Soc.*, **99**, 145 (1911).

(15) Huang-Minlon, THIS JOURNAL, **68**, 2487 (1946).

*Anal.* Calcd. for $C_{15}H_{12}O_4S$: C, 62.49; H, 4.20. Found: C, 62.27; H, 4.17.

(b) **With Sodium Hydrosulfite and Alkali.**—A solution of 1.0 g. of sodium hydrosulfite and 1.0 g. of sodium hydroxide in 10 ml. of water was added to a suspension of 0.60 g. of thiaxanthone-5-dioxide in 10 ml. of ethanol, and the mixture was warmed to *ca.* 50° under a nitrogen atmosphere for ten minutes. The resultant dark blue solution was cooled to room temperature, acidified with hydrochloric acid, and diluted with 100 ml. of water. The yellow precipitate was collected, washed with water, and dried *in vacuo* over calcium chloride; yield, 0.40 g. (66%) of yellow powder, m. p. 167–171°. Recrystallization of this material from chloroform afforded pale yellow crystals which melted at 181–183° and showed no depression in melting point when mixed with the acid-reduction product described above.

**Reduction of Thiaxanthone-5-dioxide (I) to Thiaxanthene-5-dioxide (IV).**—A mixture of 1.22 g. (0.0050 mole) of thiaxanthone-5-dioxide, 3 g. of amalgamated zinc dust, 15 ml. of acetic acid, and 3 ml. of hydrochloric acid was refluxed under nitrogen for three hours. Another 1 ml. of hydrochloric acid was added during the refluxing, and at the end of the three-hour period the unreacted zinc was filtered off and the filtrate as diluted with 100 ml. of water. The precipitate was collected, washed with water, and dried; yield, 1.08 g. (94%) of pale yellow microcrystalline powder, m. p. 150–155°, which gave a blue color on treatment with aqueous-alcoholic sodium hydroxide. After repeated recrystallization from ethanol, the pure product was obtained as almost colorless crystals, m. p. 171–172°, which gave *no color* on treatment with aqueous-alcoholic sodium hydroxide and which failed to depress the melting point of authentic thiaxanthene-5-dioxide prepared by the oxidation of thiaxanthene. This product exhibited a blue fluorescence on exposure to ultraviolet light.

**Reduction of Thiaxanthenol-5-dioxide (III) to Thiaxanthene-5-dioxide (IV).**—When an acetic acid solution of 1.23 g. (0.0050 mole) of thiaxanthenol-5-dioxide was treated with amalgamated zinc and hydrochloric acid in the same manner as in the preceding example, 0.85 g. (74%) of pale yellow powder, m. p. 139–144°, was obtained, which crystallized from ethanol in the form of almost colorless needles melting at 169–171°. No depression of the melting point was observed when this material was mixed with authentic thiaxanthene-5-dioxide.

**Air Oxidation of Thiaxanthenol-5-dioxide (III).**—A suspension of 0.62 g. of thiaxanthenol-5-dioxide in 10 ml. of ethanol was treated with 10 ml. of 10% aqueous sodium hydroxide, and air was blown into the mixture through a sintered glass gas-dispersion tube until the blue color was completely discharged (five to ten minutes). The resultant yellow suspension was diluted with water and filtered, thus affording 0.55 g. (90%) of yellow microcrystalline powder, m. p. 185–186°, which gave a blue color with aqueous-alcoholic alkali only after the addition of zinc dust or sodium hydrosulfite. This product failed to depress the melting point of thiaxanthone-5-dioxide prepared by the oxidation of thiaxanthone.

When a saturated solution of thiaxanthenol-5-dioxide in 95% ethanol was shaken with air for ten days in a mechanical shaker, a small amount of yellow insoluble material was precipitated which melted at 182–185° and showed no melting point depression when mixed with authentic thiaxanthone-5-dioxide.

**Air Oxidation of Thiaxanthene-5-dioxide (IV).**—A suspension of 0.20 g. of freshly purified thiaxanthene-5-dioxide in 10 ml. of 10% aqueous sodium hydroxide was refluxed for ten minutes while a stream of air was bubbled through the boiling mixture. Although the thiaxanthene-5-dioxide used in this experiment gave no color with alkali and sodium hydrosulfite, the yellow solid filtered out of the above suspension gave the characteristic blue color test for thiaxanthone-5-dioxide on treatment with these reagents.

When neutral, saturated solutions of pure thiaxanthene-5-dioxide in 95% ethanol were similarly aerated and refluxed for periods of several hours, addition of aqueous sodium hydroxide and sodium hydrosulfite resulted in the formation of a dark blue color. If the refluxing was carried out under nitrogen and no air was bubbled through the solution, no color test could be obtained even after four hours.

## Summary

The color reactions of thiaxanthone-5-dioxide in the presence of alkaline reducing agents have been studied and shown to be similar to the familiar vatting reactions of anthraquinone. The intermediate reduction product responsible for the characteristic color reactions has been isolated and identified as thiaxanthenol-5-dioxide, which dissolves in alkali with the formation of a highly colored, readily oxidizable anion analogous to the anthrahydroquinone anion. On the basis of the assumption that sulfur is capable of expanding its valence shell, the thiaxanthone dioxide–thiaxanthenol dioxide–thiaxanthene dioxide oxidation–reduction system is formulated as the sulfone series counterpart of the anthraquinone–anthrahydroquinone–anthrone system.

# Reactions of Vanillin and its Derived Compounds. VII.[1] Some New Esters of Vanillic Acid and Related Acids[2,3]

BY IRWIN A. PEARL AND DONALD L. BEYER

Several esters of vanillic acid were recently shown[4,5] to have high toxicity toward representative microörganisms and to be of value as food preservatives. These results led to the synthesis of the new esters of vanillic acid, orthovanillic acid, and 5-chlorovanillic acid described in Table I.

The new esters of vanillic acid reported herein comprise esters of polyhydric alcohols, their chlorohydrins, and their ethers. Most of these were prepared by the various methods described earlier.[4] The chlorohydrin esters were prepared by reaction of the chlorohydrin with vanillic

[a] All melting points and boiling points are uncorrected. [b] All compounds were recrystallized from petroleum ether (b. p. 65–110°) except where indicated. [c] Inhibiting concentrations were determined in accordance with the method described earlier.[4] Abbreviations used: *Aero. aero.* = *Aerobacter aerogenes; Bac. myc.* = *Bacillus mycoides; Asper. niger* = *Aspergillus niger*. [d] See Pearl, THIS JOURNAL, **68**, 429, 1110, 2180 (1946). [e] Prepared by the reaction of vanillic acid with 2-methoxyethanol in the presence of sulfuric acid. All esters were prepared by this general method unless otherwise indicated. [f] Recrystallized from petroleum ether (b. p. 30–60°). [g] Monohydrate from petroleum ether (b. p. 30–60°), m. p. 47–48°. *Anal.* Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 7.02. Found: C, 55.81; H, 7.02. [h] Prepared by reaction of acid with corresponding alcohol in presence of hydrogen chloride. [i] 59% by hydrogen chloride method from ethylene glycol. [j] Hydrogen chloride method from propylene glycol. [k] Hydrogen chloride method from trimethylene glycol. [l] 60% by hydrogen chloride method from glycerol. [m] Prepared by refluxing trichloro-*t*-butyl alcohol with vanillic acid in toluene under a water separatory head. Wolffenstein, German Patent 267,980 (Dec. 6, 1913), reported a m. p. of 130° for a compound prepared by heating trichloro-*t*-butyl alcohol with vanillic acid in the presence of zinc chloride. Wolffenstein's results could not be repeated. [n] Prepared by the reaction of potassium vanillate with the corresponding chlorohydrin. [o] 25% yield by refluxing vanillic acid with excess ethylene glycol without a condensing agent; 30% by reaction of carbethoxyvanilloyl chloride with ethylene glycol (see Pearl and McCoy).[4] [p] Recrystallized from chloroform. [q] Prepared by reaction of carbethoxyvanilloyl chloride with ethylene glycol through the intermediate, ethylene glycol biscarbethoxy vanillate, m. p. 139°. *Anal.* Calcd. for $C_{24}H_{26}O_{12}$: C, 56.91; H, 5.18. Found: C, 56.37; H, 5.24. [r] 20% yield by refluxing vanillic acid with excess ethylene glycol without a condensing agent (together with 2-hydroxyethyl vanillate). [s] Recrystallized from dilute ethanol. [t] See Pearl, *J. Org. Chem.*, **12**, 85 (1947). [u] This is a previously reported compound. [v] Dissolved in ethanol for all microbiological analyses. [w] Prepared by reaction of orthovanillic acid with phenol in the presence of phosphorus oxychloride. Method patterned after preparation of phenyl salicylate by Seifert, *J. prakt. Chem.*, [2] **31**, 472 (1885).

acid and by reaction of the parent glycols with vanillic acid in the presence of anhydrous hydrogen chloride. The structure of the dichloropropyl vanillate resulting from the reaction of glycerol with vanillic acid and anhydrous hydrogen chloride was established by its identity with 2,3-dichloropropyl vanillate prepared unequivocally from vanillic acid and glycerol 1,2-dichlorohydrin. Glycol esters were prepared by the carbethoxy route, reaction of the chlorohydrin with potassium vanillate, and by refluxing glycol with vanillic acid without a condensing agent. Esters of 5-chlorovanillic and orthovanillic acids were prepared by similar methods.

The inhibiting concentrations of these esters were determined for the three representative aerobic microörganisms—namely, non-sporeforming (*Aerobacter aerogenes*) and sporeforming (*Bacillus mycoides*) bacteria and molds (*Aspergillus niger*). Most of the vanillates were found to inhibit *Bacillus mycoides* and *Aspergillus niger* in low concentrations. The chlorohydrin esters,
