(7) French, Levine, Pazur and Norberg, THIS JOURNAL, **71**, 353 (1949).

(8) It is recognized that the rate of hydrolysis of the glycosidic bonds depends on such factors as the size of the molecule and the position of the bond within the molecule.

The rate of destruction of $\beta$ and the net rate of increase of H and R may then be expressed by the differential equations

$$d\beta/dt = -k_1\beta \quad (2)$$

$$dH/dt = k_1\beta - 6k_2H \quad (3)$$

$$dR/dt = k_1\beta + k_2(7\beta_0 - 7\beta - R) \quad (4)$$

with the corresponding solutions

$$\beta = \beta_0 e^{-k_1 t} \quad (5)$$

$$H = \beta_0 \frac{k_1}{(6k_2 - k_1)} [e^{-k_1 t} - e^{-6k_2 t}] \quad (6)$$

$$R = \beta_0 \left[7 - e^{-k_1 t} + \frac{6}{(k_2 - k_1)} (k_1 e^{-k_2 t} - k_2 e^{-k_1 t})\right] \quad (7)$$

The degree of purity of the amyloheptaose, assuming complete removal of unchanged beta dextrin and inorganic material, is $H/(\beta_0 - \beta)$.

Evaluation of $k_1$ was carried out by determining the initial rate of appearance of reducing groups (eqn. 4) as well as by recovery of unchanged beta dextrin after varying periods of hydrolysis; $k_2$ was approximated by plotting $R$ (eqn. 7) against $k_1t$ for trials values of $k_2/k_1$ and comparing with the observed reducing power.

Using $k_2/k_1$ thus determined, an extent of hydrolysis of 2% leads to an amyloheptaose of 95% purity. This limit was arbitrarily selected as a satisfactory compromise between purity of product and single-step yield.

## Properties of Amyloheptaose

A carefully purified batch of beta dextrin was hydrolyzed, using the principles outlined above, and 13.3 g. of amyloheptaose obtained. The product was a white glassy substance which has not yet crystallized. It is very soluble in water and insoluble in alcohol, forming a sirup when alcohol is added to an aqueous solution. It is only slightly sweet and the iodine coloration is scarcely noticeable. The observed rotation $[\alpha]_D$ +176° is somewhat lower than that calculated using Freudenberg's equation[9] and the customary constants for starch[10]: $[\alpha]_D$ +179.6°. The reducing power indicates a molecular weight of 1200 (alkaline ferricyanide method) or 1206 (iodine titration of aldoses) as compared with a calculated value of 1154. These discrepancies may be harmonized if one assumes that the glassy sample holds a small amount of difficultly removable water or other inert impurity (*i. e.*, about 3%). Chromatography of the amyloheptaose preparation failed to detect any glucose, maltose or trisaccharide although these substances are easily observed after more extensive hydrolysis of cycloheptaamylose.

The phenylhydrazone and potassium aldonate of amyloheptaose were prepared using standard procedures, and the nitrogen content of the phenylhydrazone and the potassium content of the aldonate were in good agreement with the values calculated for corresponding heptasaccharide derivatives.

(9) Freudenberg, Friedrich and Bumann, *Ann.*, **494**, 41 (1932).

(10) Levine, Foster and Hixon, THIS JOURNAL, **64**, 2331 (1942).

In studies to be reported subsequently it has been found that beta amylase degrades amyloheptaose to give a mixture of maltose and trisaccharide in the mole ratio of two to one. This indicates that the original oligosaccharide contains an odd number of glucose units, as beta amylase converts even-numbered amylose chains completely to maltose.[11] The mole ratio of maltose to trisaccharide as well as the increase in reducing power may be determined with sufficient precision to eliminate the possibility that the enzyme substrate was either a pentaose or a nonaose.

The chemical evidence concerning the identity and purity of the initial hydrolysis product of cycloheptaamylose, *i. e.*, amyloheptaose, is in harmony with the theoretical calculations within the experimental error of the methods used.

## Experimental

**Cycloheptaamylose.**—This substance was prepared using methods previously outlined[4,7] and had the following constants: water, 13.4%; $[\alpha]_D$ + 163.2 ± 0.5°, dry basis; ash by ignition, 0; ash by conductivity as sodium chloride, 0.005%.

**Determination of $k_1$.**—A ratio of one gram, dry weight, of cycloheptaamylose to 4 ml. of 0.001 *N* hydrochloric acid was uniformly used throughout all experiments and preparations in this paper. Tubes containing *ca.* 0.5 g. of cycloheptaamylose in 2 ml. of 0.001 *N* hydrochloric acid were stoppered and heated in a boiling water-bath for varying periods of time. The tubes were swirled occasionally to insure homogeneity of the reaction mixture. After a definite period of time a tube was removed, the contents transferred to a 300-ml. flask and the reducing power determined by the alkaline ferricyanide method.[10] The rate constant was calculated using the first term of eqn. 4 in integral form. After 180, 360, 540 min., $k_1 \times 10^5$ = 4.7, 6.5, 6.9.

Ten-gram samples of cycloheptaamylose dissolved in 40 ml. of 0.001 *N* hydrochloric acid were heated at 99° and after various periods of time the acid was neutralized and the mixtures were refrigerated. The crystals of cycloheptaamylose were collected quantitatively in weighed alundum filtering crucibles. The filtrates were treated with toluene by shaking twenty-four hours followed by refrigerating twenty-hour hours and the resulting precipitates collected in tared alundum crucibles. From the total dry weight of recovered cycloheptaamylose from each sample the $k_1$ values were calculated using eqn. 5: after 4,280, 7,130, 28,560 min., $k_1 \times 10^5$ = 4.0, 5.0, 4.6.

**Determination of $k_2/k_1$.**—The filtrate from the 28,560-minute sample above was collected quantitatively and the average molecular weight of the solids determined by iodine titration and specific rotation. From these figures the average number of reducing groups per mole of starting material was calculated to be 2.38. This value corresponded most closely to a value for $k_2/k_1$ of 0.64 on a plot of various values for $k_2/k_1$ in eqn. 7. Using $k_1 = 4.6 \times 10^{-5}$, $k_2 = 2.9 \times 10^{-5}$.

**Preparation of Amyloheptaose.**—A 100-g. sample of pure cycloheptaamylose was dissolved in 400 ml. of 0.001 *N* hydrochloric acid in a 1000-ml. flask fitted with a condenser. The flask was immersed in a boiling water-bath, 99°, and shaken frequently. After seven hours the flask was removed, the acid immediately neutralized with the calculated amount of lithium carbonate and the unhydrolyzed cycloheptaamylose allowed to crystallize on cooling to room temperature and refrigerating twenty-four hour. The crystals were removed by filtration and the remaining cycloheptaamylose removed by saturating the filtrate with *p*-xylene, shaking for twenty-four hours,

(11) Myrbäck and Leissner, *Arkiv Kemi, Mineral. Geol.*, **17A**, No. 18 (1943).

refrigerating twenty-four hours, and filtering off the precipitates. This final filtrate was then concentrated to one-fifth its original volume *in vacuo*. Six additional hydrolyses were carried to this stage and the concentrated filtrates combined. The resulting solution was again covered with *p*-xylene, shaken and refrigerated for twenty-four hour each, filtered, and the filtrate concentrated to a thin sirup *in vacuo*. In order to remove any lower saccharides and lithium chloride the amyloheptaose was precipitated by adding four volumes of absolute ethanol. The sirupy precipitate was taken up in a small amount of water and reprecipitated in like manner five times. Finally the precipitate was dehydrated with absolute ethanol to which a small amount of absolute butanol was added, filtered, and washed with dry butanol.[12] The material was finally dried to constant weight in the vacuum oven at 70°, $[\alpha]_D$ + 175.5° ($c$ = 2, water); another preparation, + 176.5°; theoretical, + 179.6°.[9,10] Molecular weight by alkaline ferricyanide,[10] 1200; by the Kline and Acree hypoiodite method,[13] 1206; theoretical, 1152.

**Potassium Amyloheptaonate.**—The method of Levine, Foster and Hixon[10] for the preparation of dextrinic acids was applied to 0.5 g. of amyloheptaose. After the final grinding and acetone extraction, the potassium salt was dried to constant weight and a weighed sample ashed with ammonium sulfate. The molecular weight was calculated from the potassium content: observed, K 3.34%, m. wt. 1167; calcd., m. wt. 1206.

**Amyloheptaose Phenylhydrazone.**—The phenylhydrazone was prepared by a modification of the method of Bergmann and Machemer[14] previously described.[10] Nitrogen was determined by the micro-Dumas method and the molecular weight of the derivative calculated assuming two atoms of nitrogen per molecule: observed, N 2.19%, 2.27%, m. wt. 1275, 1235; calcd., m. wt. 1242.

(12) The butanol was used to prevent condensation of water and consequent gumming of the amyloheptaose due to the evaporation of the ethanol during the filtration and drying.

(13) Kline and Acree, *Ind. Eng. Chem., Anal. Ed.*, **2**, 413 (1930).

(14) Bergmann and Machemer, *Ber.*, **63**, 322 (1930).

**Chromatographic Test for Lower Saccharides.**—A 20 mg. sample of the sugar was dissolved in 0.3 ml. of water and 4.8 ml. of absolute ethanol added. The resulting mixture was placed on a chromatographic column consisting of 12 g. of a 3:1 mixture of Florex XXX and Celite 535 as described by Lew, Wolfrom and Goepp.[15] The sugars were eluted with 90% ethanol and the concentration of sugar in the eluate determined colorimetrically by the diphenylamine method.[16] The rate of flow of the individual sugars was found to be sufficiently characteristic and the diphenylamine test sufficiently sensitive that an amount of glucose, maltose or trisaccharide as low as 0.01 mg./ml. could be readily detected.

On testing 20 mg. of amyloheptaose in this manner, there was no evidence whatsoever for contamination by glucose, maltose or trisaccharide. The column was then extruded, cut into 2-cm. portions and the individual portions extracted and tested for carbohydrate. The top 2-cm. portion was carbohydrate free, the next two 2-cm. portions contained carbohydrate, and the remainder of the column was carbohydrate free.

A cycloheptaamylose sample which was hydrolyzed for *ca.* 7000 minutes ($k_2t$ = 0.35) was similarly chromatographed, and glucose, maltose and trisaccharide were found to be present in sizable amounts (109 mg., 81 mg. and 62 mg.).

## Summary

Amyloheptaose has been prepared by controlled acid hydrolysis of cycloheptaamylose. The analytical constants of amyloheptaose, its potassium aldonate and its phenylhydrazone agree with those calculated for a heptasaccharide.

# The Reaction of Diethanolamine with Nitriles and Potassium Cyanide

BY WILLIAM H. RAUSCHER, IRVING S. GOLDSTEIN AND MAXWELL BRESLAU

Since ethanolamines have been used as agents for the reduction of organic compounds,[1] especially nitro compounds, it was though possible they might convert nitriles to amines. However, benzonitrile and benzyl cyanide, when refluxed with substantially dry diethanolamine, undergo hydrolysis rather than reduction to yield benzoic and phenylacetic acid, respectively, with concomitant evolution of ammonia. Maximum yields are obtained with a nitrile to diethanolamine ratio of 1:5 and a reflux period of forty-eight hours.

From larger scale runs, conducted in an attempt to isolate intermediate products, it was possible to obtain substantial quantities of water and piperazino-1,4-bis-(β-ethanol). It appears therefore that diethanolamine undergoes cyclization to the piperazine and water which effects hydrolysis of the nitrile. No other details of the mechanism have been established.

Under similar conditions, potassium cyanide yields ammonia and a mixture of potassium formate and succinate. The latter salt, the formation of which was unexpected, was always obtained in much larger amount than the formate. It was established that only a small amount of ammonia is evolved by refluxing diethanolamine alone and that the presence of a small amount of potassium cyanide in refluxing diethanolamine does not catalyze the evolution of ammonia from the amine or cause its cyclic dehydration to the piperazine. Potassium succinate was not formed by refluxing potassium formate with diethanolamine. The mechanism of the conversion of potassium cyanide to potassium succinate has not been determined.

Cohen, *ibid.*, **59**, 2660 (1937); (d) C. B. Kremer and B. Kress, *ibid.*, **60**, 1031 (1938); (e) C. B. Kremer and A. Bendich, *ibid.*, **62**, 1279 (1940).

## Experimental

**Materials.**—Diethanolamine was the Carbide and Carbon Chemicals Corporation product purified by redistillation at 3 mm. Benzonitrile and benzyl cyanide were redistilled Eastman Kodak Co. products. Potassium cyanide was the C. P. grade. All melting points are corrected. Typical runs are described.

**Benzoic Acid from Benzonitrile.**—Five grams (0.05 mole) of benzonitrile and 27.5 g. (0.25 mole) of diethanolamine were refluxed for forty-eight hours in an apparatus employing standard taper joints. The condenser was water cooled. Evolved ammonia was swept out through the condenser into a measured quantity of standard acid by a gentle stream of purified air. At the end of forty-eight hours the reaction mixture was cooled and diluted with 100 ml. of water, complete solution taking place. The solid which appeared immediately on acidification with concentrated hydrochloric acid was removed by filtration and recrystallized from water. The filtrate was warmed for several hours on the steam-bath and cooled, but no additional solid was obtained; weight recrystallized acid 3.1 g. or a 52.4% yield; m. p. 121–122°; neut. equiv. 120.5; m. p. of *p*-nitrobenzyl ester 88–89°. The values for benzoic acid are: m. p. 121.4; neut. equiv. 122.1; m. p. *p*-nitrobenzyl ester 89°. During the reflux period ammonia evolved corresponded to 61% of the nitrogen of benzonitrile.

**Phenylacetic Acid from Benzyl Cyanide.**—Five grams (0.05 mole) of benzyl cyanide and 28 g. (0.25 mole) of diethanolamine were refluxed similarly for forty-eight hours. On adding 100 ml. of water complete solution took place. The solution was made acid with hydrochloric acid and warmed on the steam-bath for one hour. After cooling it was extracted three times with 50-ml. portions of ether. The solid recovered from the ether solution was recrystallized from petroleum ether; weight recrystallized acid 4.5 g. or a 77.4% yield; m. p. 76.5–77°; neut. equiv., 135; m. p. of *p*-nitrobenzyl ester 64.5–65°. The values for phenylacetic acid are: m. p. 76.7°; neut. equiv., 136.2; m. p. of *p*-nitrobenzyl ester 65°. During the reflux period evolved ammonia corresponded to 71% of the nitrogen of benzyl cyanide.

**Piperazino-1,4-bis-(β-ethanol).**—One-half mole (58.5 g.) of benzyl cyanide and 2.5 moles (260 g.) of diethanolamine were refluxed in a 3-necked, 500-ml. flask provided with a water cooled condenser and thermometers placed in the liquid and the vapor, standard taper joints being used. After several hours refluxing the liquid temperature fell to 145° and the vapor temperature to 101°, both temperatures remaining quite constant to the end of reflux. After forty-eight hours 36.5 g. of water were removed through a short Vigreux column at atmospheric pressure. On further distillation at 3 mm. considerable decomposition resulted and very little material could be distilled. On cooling overnight the remaining reaction mixture became a pasty solid. Pyridine was added with warming until it constituted about one third of the homogeneous solution resulting. On cooling the solution in the refrigerator a yellowish crystalline solid was obtained. It was removed and washed with pyridine and acetone. The dried product weighed 45 g. After several recrystallizations from acetone a colorless crystalline solid melting at 134.6–135.2° was obtained. As the identity of the material was not suspected at this time it was extensively investigated and the following data collected. *Anal.* C, 55.22, 55.10; H, 10.44, 10.23; N, 15.99, 16.1; neut. equiv. (using methyl red) 175.6, 175.0; weight of base combining with 1 mole of hydrochloric acid (gravimetric) 86.86, 86.88; per cent. chlorine in hydrochloride 28.67, 28.66; m. p. *p*-nitrobenzoate 158–160°. Piperazino-1,4-bis-(β-ethanol) has the following values. *Anal.* C, 55.14; H, 10.41; N, 16.08; m. p. 135–135.5°; mol wt. 174.2; weight combined with 1 mole hydrochloric acid 87.12; chlorine in dihydrochloride, 28.67; m. p. *p*-nitrobenzoate 158–158.5°.[2]

**Potassium Formate and Potassium Succinate from Potassium Cyanide.**—Thirty-three grams (0.5 mole) of potassium cyanide and 260 g. (2.5 moles) of diethanolamine were refluxed for forty-eight hours as in the 0.5 mole benzyl cyanide run described above. Evolved ammonia corresponded to 74.4% of the nitrogen of potassium cyanide. Soon after reflux began the liquid temperature was 238° but gradually fell to 156°, where it remained fairly constant. On cooling the reaction mixture became very viscous and crystals appeared. Sufficient absolute alcohol was added to permit the solid to be removed by filtration. This solid (A) was washed with absolute alcohol and dried in a vacuum desiccator to give 19.4 g. of product. The alcohol in the filtrate from (A) was removed by distillation and chloroform added as long as its addition gave evidence of the precipitation of a solid (B). Solid (B) was collected on a filter, washed with chloroform and dried in a vacuum desiccator to give 3 g. of material.

Solid (A) was shown to be potassium succinate from the following data: Solid (A) yielded an acid of m. p. 187–188°; neut. equiv., 60.1; mixed m. p. with authentic succinic acid 186–187°; *p*-bromophenacyl ester m. p. 212–213°; *p*-nitrobenzyl ester m. p. 86–87°. For succinic acid the values are: m. p. 188°; neut. equiv. 59.05; m. p. *p*-bromophenacyl ester 211°; m. p. *p*-nitrobenzyl ester 88°. The equivalent weight of solid (A) by the sulfate method was found to be 93.0, 92.5. The equivalent weight of potassium succinate is 97.1.

Solid (B) was shown to be potassium formate from the following data: m. p. 166–167°; m. p. of *p*-bromophenacyl ester 138–139°; equiv. wt. by sulfate method 86.0, 89.0. For potassium formate the values are: m. p. 167.5°; m. p. *p*-bromophenacyl ester 140°; equiv. wt., 84.

## Summary

By refluxing with substantially dry diethanolamine, benzonitrile and benzyl cyanide are hydrolyzed to the corresponding acids. Water required for the hydrolysis is apparently supplied by a cyclic dehydration of diethanolamine to piperazino-1,4-bis-(β-ethanol). In the case of potassium cyanide a substantial yield of potassium succinate and a small yield of potassium formate result. No mechanism is suggested for the formation of the succinate.

# NOTES

## The Relation between Magneto-optic Rotation and Refractive Dispersion of Hydrocarbons

By A. Bondi

Inspection of data on the magneto-optic rotation (Verdet Constant, $V$) of hydrocarbons[1,2] suggested that they may be directly proportional to the refractive dispersion, $n_{\nu 1} - n_{\nu 2} = \Delta n$. The recent extensive and accurate data published by Foehr[3] make possible the quantitative comparison which is presented in Table I. It appears that $V/\Delta n$ is indeed very nearly independent of the hydrocarbon type at low molecular weights and substantially constant in the higher molecular weight range.

The greatest "exaltation" apparently occurs among the aromatic hydrocarbons, but too few measurements are available in this class of compounds to permit any valid generalization.

As a practical result this observation suggests that refractive dispersion and magneto-optic rotation may be used interchangeably. Since refractive dispersion data are usually more accessible[4,5] than Verdet constants, the ingenious scheme of (magneto-optic) hydrocarbon type analysis proposed by Foehr[3] may now be applied more extensively.

The theoretical background is contained in the Becquerel formula[6]

$$V = \gamma \frac{e}{2mc^2} \nu \frac{\partial n}{\partial \nu} \qquad (1)$$

where the universal factor $e/2mc.^2$ derives from the Larmor precession, $\nu$ = frequency of the light used, $\partial n/\partial \nu$ = refractive dispersion, $\gamma$ = "anomaly" factor. The constancy of the ratio $V/\Delta n$ thus means that for hydrocarbons $\gamma$ is a constant. For diamagnetic substances, according to Schütz[6]

$$\gamma = a_i + \frac{b}{2} \frac{\nu_i}{\Delta \nu_0} \qquad \text{if } \nu \ll \nu_i \qquad (2)$$

where $a_i$ = oscillator strength, $\nu_i$ = characteristic frequency of the electron transition which is active in the magneto-rotation and determines the dispersion of $V$ (as well as of the refractivity, v. i.), $\Delta \nu_0$ = multiplet splitting shift, and $b$ = a numerical factor of the order $-2/3$.[6] No data are yet available on the multiplet splitting term, $\Delta \nu_0$, of organic molecules, but it is likely to be equal for all hydrocarbons. Equation (2) therefore implies the existence of a linear relation between the oscillator strength and the characteristic frequency of the "dispersion-electron" of hydrocarbons.

As one can observe the constancy of $\gamma$ within other families of organic molecules,[6] this relation should hold more widely. The lack of reliable absolute intensity data, particularly in the vacuum ultraviolet where the characteristic absorption band of the saturated hydrocarbons is located, precludes a direct test of the postulate made. The constancy of $\gamma$ in spite of the wide variation in $\nu_i$ (0.8 to 2.5 $\times$ $10^{15}$ sec.$^{-1}$) and in $a_i$ encountered in the range of hydrocarbons reported in Table I suggests, however, that a relationship at least similar to the proposed one exists. (A plot of the oscillator strength $f_1$,[7] *versus* $\nu_1$ shows that the data lie on smoothly ascending curves, which are, however, characteristic of each family of (aromatic) hydrocarbons so tested, and not universal for all hydrocarbons as first hoped for.) The utility of Equation (2) for $\gamma$ = const. consists in the possibility of expressing the refractive dispersion of hydrocarbons as a function of $\nu_i$ alone, thereby facilitating the rational treatment of this easily determined physical property.

TABLE I

COMPARISON OF VERDET CONSTANT[a] AND REFRACTIVE DISPERSION[b] OF HYDROCARBONS

| Substance | $V_D \times 10^2$ | $V/\Delta n$[c] | $\Delta V/\Delta n$[d] |

(7) From unpublished experimental data by Spectroscopic Department, Shell Development Co., Emeryville, Calif.

Since the dispersion of both the refractivity and the Verdet constant is governed by the term $\Sigma A_i/(\nu_i^2 - \nu^2)$, constancy of the ratio $\Delta V/\Delta n$ would be indicative of the fact that the electronic transitions responsible for both are identical. The data in the last column show that this expectation is essentially fulfilled, as has also been found for various aliphatic oxygen compounds.[8]

## The Cryoscopic Behavior of 1,1-Dimethylcyclohexane Containing Certain Hydrocarbon Impurities[1]

BY G. L. EVANS,[2] K. W. GREENLEE, J. M. DERFER AND C. E. BOORD

A short investigation has been made concerning the cryoscopic behavior of 1,1-dimethylcyclohexane upon introduction of certain selected hydrocarbon impurities. This study was prompted by the observation that introduction of a small amount of *cis*-1,2-dimethylcyclohexane as an impurity in 1,1-dimethylcyclohexane caused an increase in the freezing point of the latter hydrocarbon, instead of the normal lowering. Although similar irregularities caused by solid solution formation have been observed in several binary hydrocarbon systems studied in detail by other workers,[3,4,5,6] it was thought that this new information would prove helpful because of the widespread reliance on cryoscopic data as criteria of purity.

The results of this investigation are summarized in Table I.

It will be noted that of the solutes used only *n*-heptane and *n*-butylcyclohexane produced normal freezing point lowering; *cis*-1,2-dimethylcyclohexane actually raised the freezing point, and the remaining solutes caused only a fraction of the normal lowering. In every case of abnormal behavior the apparent purity as calculated from the freezing point data was, of course, too high.

TABLE I

CRYOSCOPIC BEHAVIOR OF 1,1-DIMETHYLCYCLOHEXANE CONTAINING HYDROCARBON IMPURITIES

| Solute (impurity) | Total mole % impurity added | Freezing point (°C.) | Observed $\Delta t$ (°C.) | Expected[a] $\Delta t$ (°C.) | Actual purity[b] (mole %) | Apparent purity[a] (mole %) |
|---|---|---|---|---|---|---|

[a] These data were calculated from the approximate equation $\log_{10} p = 2 - (A/2.303)(t_{f_0} - t_f)$ where $p$ = purity (actual or apparent) in mole per cent., $t_{f_0}$ = freezing point at 100% purity $t_f$ = experimental freezing point (actual or expected) and $A = \Delta H_m^\circ/RT_{f_0}$ in which $\Delta H_m^\circ$ is the heat of fusion (per mole). Values for $t_{f_0}$ (−33.54°) and $A$ (0.0042 deg.$^{-1}$) had been given by the American Petroleum Institute Research Project 44 in Selected Values of Properties of Hydrocarbons (Circular of the National Bureau of Standards C461) Table 7z. [b] The original purity of each sample was calculated from its freezing point using the equation and data mentioned in footnote *a*, assuming that no impurity leading to abnormal behavior was already present. The subsequent (lower) purities were obtained from the original purities by subtracting the mole percentages of impurity added.

The ability to form mixed crystals (solid solutions) is common to all hydrocarbons having low heats and entropies of fusion, as has 1,1-dimethylcyclohexane. Such molecules rotate in the solid phase below their melting points and possess considerable mobility of structure, enabling solute molecules of similar size and shape to be accommodated in the crystal lattice without fusion of the crystal. Solute molecules such as *n*-heptane and *n*-butylcyclohexane which would interfere with the rotation cannot be incorporated into the crystal lattice of 1,1-dimethylcyclohexane, hence, solid solution formation does not occur, and normal cryoscopic behavior is observed. The fact that abnormal behavior occurs when 2,2,3-trimethylbutane is used as the solute confirms the idea that it is the over-all size and shape of the molecule rather than its molecular species which determines whether or not a solid solution will result.

### Experimental

**Hydrocarbons.**—The 1,1-dimethylcyclohexane and the hydrocarbons used as "impurities" were materials taken from the stock of the American Petroleum Institute Research Project 45 and were of good purity (99.0 mole % ± 0.5). When practicable, the 1,1-dimethylcyclohexane was separated from the "impurity" by fractional distillation at about 25-plate efficiency and re-used (after its freezing point had been checked) in the next determination, otherwise fresh solvent was used.

**Apparatus.**—The apparatus used in determining freezing points was essentially that described by Glasgow, Streiff and Rossini.[7] Temperatures were measured by means of a platinum resistance thermometer in connection with a Mueller resistance bridge (Leeds and Northrup, Type G-2). This thermometer was calibrated at the National Bureau of Standards.

**Acknowledgment.**—Grateful acknowledgment is made for the criticisms and suggestions of Drs. F. D. Rossini of the National Bureau of Standards and M. R. Cines of the Phillips Petroleum Company.

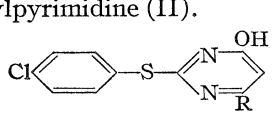
## The Reaction of Diazonium Salts with Some 2-Thiouracils



BY ELVIRA A. FALCO, GEORGE H. HITCHINGS AND PETER B. RUSSELL

Lythgoe, Todd and Topham[1] showed that pyrimidines suitably substituted in the 2,4-, 4,6- or 2,4,6-positions would undergo coupling with diazotized anilines in sodium carbonate or bicarbonate solution giving 5-phenylazo derivatives. They also investigated the structural conditions governing the coupling of pyrimidine derivatives. For this last purpose the dyes were not isolated, color being taken as an indication of coupling. They reported that 2-thiol-4,6-dihydroxy-, 2-thiol-4,6-diamino- and 2-thiol-4-hydroxy-6-methyl-pyrimidine underwent coupling.

In a recent paper Polonovski and Pesson[2] reexamined the reaction and arrived at the same general conclusions as the English authors regarding the nature of the products and the structural limitations of the reaction. They were, however, unable to couple 2-thiol-4-hydroxy-6-methylpyrimidine with diazonium salts, although they synthesized the brownish red 2-thiol-4-hydroxy-5-phenylazo-6-methylpyrimidine by condensation of thiourea with ethyl phenylazoacetoacetate.

Some time ago we examined the reactions of 2-thiol-4-hydroxypyrimidine and 2-thiol-4-hydroxy-6-methylpyrimidine with diazotized *p*-chloroaniline. When either of these compounds was allowed to react with the diazonium salt in carbonate or bicarbonate solution the following sequence of changes occurred. The solution turned pinkish red, solid separated and nitrogen was evolved. Examination of the solids revealed that they were not the expected 5-phenylazo compounds since on recrystallization from alcohol they were obtained colorless.

The product from 2-thiol-4-hydroxypyrimidine analyzed for $C_{10}H_7ON_2SCl$, while that from 2-thiol-4-hydroxy-6-methylpyrimidine gave analytical figures which agreed with the formula $C_{11}H_9ON_2SCl$. On heating with concentrated hydrochloric acid at 100° these compounds gave *p*-chlorothiophenol and uracil or 6-methyluracil, respectively. We concluded therefore that they were 2-(*p*-chlorophenylthio)-4-hydroxypyrimidine (I) and 2-(*p*-chlorophenylthio)-4-hydroxy-6-methylpyrimidine (II).

I, R = H
II, R = $CH_3$

The formation of *p*-chlorophenyl ethers of 2-thiolpyrimidines by this method is analogous to the formation of unsymmetrical diaryl and alkyl-aryl sulfides by the reaction of diazonium salts with the sodium salts of thiophenols or mercaptans.[3] In this instance the reaction proceeds *via* the diazosulfide (III) (R = alkyl or aryl). We did not isolate any product corresponding to III from the reaction of 2-thiolpyrimidines with

$$ArN_2^+X^- + RSNa \longrightarrow \underset{\text{III}}{ArN{=}NSR} \longrightarrow ArSR + N_2$$

diazonium salts. The fact that nitrogen is evolved in the cold would indicate that the 2-diazosulfides of pyrimidines are less stable than their aryl or alkyl analogs.

Unfortunately Polonovski's paper, no doubt unintentionally, gives the impression that previous students of the coupling reaction have been content to observe the appearance or non-appearance of a color reaction. In fact, Todd[1] demon-

strated by isolation and synthesis by alternative routes the nature of the coupling products in several instances and established the structural requirements for the occurrence of the reaction. Polonovski and Pesson have usefully extended these observations, but have failed to mention the considerable use to which the reaction already has been put in synthetic work.[4,5,6,7,8]

### Experimental

**2-(*p*-Chlorophenylthiol)-4-hydroxypyrimidine.**—Five grams of *p*-chloroaniline in 100 ml. of *N* hydrochloric acid was diazotized with 3.0 g. of sodium nitrite at 0°. Seven and one-half grams of sodium bicarbonate was added to the solution and then the whole was added rapidly with stirring to a solution of 5 g. of 2-thiol-4-hydroxypyrimidine in 4 l. of water. When the addition of the diazonium solution was complete, 10 ml. of a 15% solution of sodium carbonate was added. The solution turned pinkish in color, some gas was evolved and a solid began to form. After standing two hours the solution was neutralized with acetic acid and the solid filtered off. The pinkish powder (5.4 g.), after recrystallization from alcohol containing a little pyridine gave colorless octahedra, m. p. 243–245°.

*Anal.* Calcd. for $C_{10}H_7ON_2SCl$: C, 50.4; H, 3.0; N, 11.7. Found: C, 50.4; H, 2.9; N, 11.5.

**2-(*p*-Chlorophenylthio)-4-hydroxy-6-methylpyrimidine.**—To a solution of 5 g. of 2-thiol-4-hydroxy-6-methylpyrimidine in 3 l. of water was added a diazonium solution prepared from 8.9 g. *p*-chloroaniline (2 moles), followed by 16.6 ml. of a 15% solution of sodium carbonate. After standing for two hours, the solution was neutralized with acetic acid and the reddish solid was filtered off (8.3 g.). After washing with warm ethanol to remove some red material the substance was recrystallized from boiling ethanol. It formed colorless rectangular prisms, m. p. 223.5°.

*Anal.* Calcd. for $C_{11}H_9ON_2SCl$: N, 11.1. Found: N, 11.3.

**Hydrolysis of *p*-Chlorophenylthioethers with Hydrochloric Acid.**—One gram of each of the above compounds was refluxed with 25 ml. of 6 *N* hydrochloric acid for three hours. Steam distillation gave *p*-chlorothiophenol in about 75% yield, m. p. 53–54°; benzoyl derivative, m. p. 74–74.5°.[9] The acid solution on evaporation gave uracil or 6-methyluracil, according to the starting material, in about 80% yield. The compounds were identified by melting points, ultraviolet absorption spectra and analyses.

*Anal.* Calcd. for $C_4H_4N_2O_2$: C, 42.8; H, 3.6. Found: C, 42.5; H, 3.6. Calcd. for $C_5H_6N_2O_2$: C, 47.7; H, 4.8. Found: C, 47.6; H, 4.4.

## The Surface Area of Vermiculite

BY B. L. HARRIS

The surface area of vermiculite before and after exfoliation was measured by adsorption of nitrogen at −195° by the method of Brunauer, Emmett and Teller[1] in order to ascertain whether the area was large enough that the material might be used as a catalyst support. The area of the unexfoliated sample was measured by nitrogen adsorption and found to be 0.52 sq. m./g., giving a calculated average thickness of the platelets of 1.8 microns when the theoretical density of 2.13 is assumed. This indicates that the material was thoroughly fissured before exfoliation.

A sample of the vermiculite was exfoliated by heating for five minutes at 950°, resulting in a silvery-white accordion-like structure. The loss in weight on exfoliation was 19.6%. The surface area of this sample was 10.35 sq. m./g., giving a calculated platelet thickness of 0.091 micron. The structure of vermiculite consists of sheets of $(OH)_4Mg_6(Si, Al)_8O_{20}$ of 9.26 Å. thickness with alternate layers of 8 $H_2O$ spaced the order of 4.8 Å.[2] It was hoped that the platelet spacing might approximate this order of magnitude, resulting in a very large surface area. The smaller area, corresponding to a thickness some 200 times as great, agrees with the conclusion of Gruner that the structure collapses above 750° and that exfoliation is mechanical, due to the formation of steam.

## The Interaction of Purified Antibody with Homologous Hapten. Antibody Valence and Binding Constant

BY HERMAN N. EISEN[1] AND FRED KARUSH[2]

As part of a study of the relation between protein structure and specificity we are investigating the properties of soluble complexes formed between purified antibody and homologous haptens. Rabbits were immunized with sheep serum coupled with diazotized *p*-arsanilic acid. Purified antibody, homologous to *p*-azophenylarsonic acid (R), was obtained[3] by treating pooled antisera with human erythrocyte stromata coupled with diazotized *p*-arsanilic acid (R-stromata). After several washings with 0.16 *M* sodium chloride, the antibody was eluted from R-stromata by acidification (*p*H 3.8) with acetic acid. The R-stromata was removed by centrifugation and the supernate, which contained the antibody, was neutralized. In the antibody solutions thus prepared at least 90% of the protein was specifically precipitable with R-stromata, in agreement

with the observations of Campbell, *et al.*,[4] who also prepared purified antibody by exposure to acid *p*H (3.5). Controls involving the treatment with R-stromata of normal rabbit serum, a mixture of bovine γ-globulin and purified antibody, and bovine γ-globulin alone, showed no appreciable non-specific precipitation. Protein concentrations were determined by ultraviolet absorption[5]; the validity of this procedure was assured by low R-stromata blanks, and by the characteristic shape of the absorption curves.

The binding of homologous haptenic dye *p*-(*p*-hydroxyphenylazo)-phenylarsonic acid by purified antibody was determined by equilibrium dialysis. One ml. aliquots of an antibody solution of known protein concentration (0.15%) containing buffer and salt (*p*H 7.4, 0.01 *M* $PO_4$, 0.16 *M* NaCl) were placed inside 0.25-in. dialysis bags. These were equilibrated against equal volumes of hapten in buffered saline whose initial dye concentrations were accurately known. The free dye concentrations in equilibrium with the bound dye were determined by measuring the spectral absorption, at 440 mμ, of the outside solutions, after suitable dilution and adjustment to strongly alkaline *p*H. The concentrations of bound dye were calculated from the values for the free equilibrium and initial dye concentrations, the former ranging from $5 \times 10^{-6}$ *M* to $8 \times 10^{-5}$ *M*. This calculation required a correction, due to adsorption of dye on the dialysis bag, amounting to 11% of the free dye concentration. The following (which corresponds to the third point in Fig. 1) represents a typical calculation: initial dye concentration = $3.96 \times 10^{-5}$ *M*, free equilibrium dye concentration = $1.18 \times 10^{-5}$ *M*, concentration of bound dye = $1.35 \times 10^{-5}$ *M*, moles hapten bound per mole protein[6] (*r*) = 1.45.

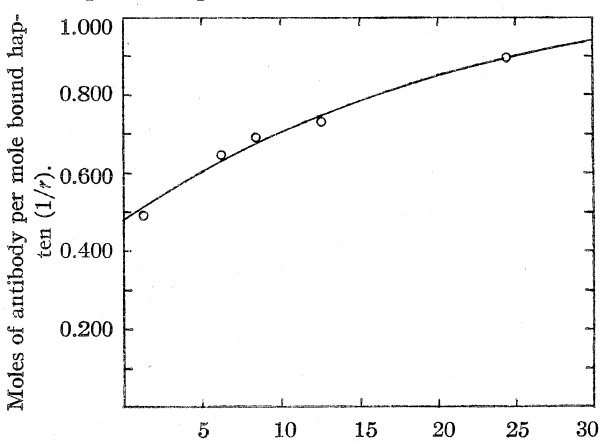

Fig. 1.

By plotting the reciprocal of moles hapten bound per mole antibody (1/*r*) against the reciprocal of free hapten concentration (1/*c*) the binding capacity is obtained from the extrapolated value of 1/*r*.[7] As could be anticipated from the known heterogeneity of antibodies,[3,8] the curve obtained was not linear. In such a situation the average intrinsic association constant can be shown to be equal to the value of 1/*c* at which one-half the binding sites are occupied, if it is assumed that the variation in the free energy of binding among the various sites can be described by a Gaussian distribution function.[9] Such an assumption has been made previously by Pauling, *et al.*,[8] to describe hapten inhibition data.

The binding data obtained at room temperature (29°) with the hapten indicated above are summarized in Fig. 1. Extrapolation yields a value of 2 for the binding capacity ("valence") of the antibody, within an accuracy of 10%. The value of the intrinsic association constant is $3.5 \times 10^5$, corresponding to $\Delta F^0 = -7.7$ kcal. per mole hapten.

Antisera prepared as in these experiments by Campbell, *et al.*,[4] contained about 1.0% antibody for R-group, whereas our yields of purified antibody correspond to an initial antibody concentration in antiserum of about 0.04%. Either our antisera were far less potent than Campbell's, or the antibody removed by our purification procedure comprised only a small fraction of the total antibody present in the antiserum, in which case the above association constant would measure the average binding energy of only the most reactive antibody molecules.

## Preparation and Properties of Several Cyclohexyl-alkyl-substituted Ketene Dimers

BY CARL M. HILL AND GILBERT W. SENTER

It has been demonstrated that tertiary aliphatic amines dehydrohalogenate acid halides with the formation of ketene monomers and dimers.[1] Sauer[2] has reported the dehydrohalogenation of several fatty acid halides by tertiary aliphatic amines to yield ketene dimers.

This paper describes the dehydrohalogenation of five omega-cyclohexyl-substituted acid chlorides (of type $C_6H_{11}\cdot(CH_2)_n\cdot COCl$) by triethylamine.

[a] Based upon the amount of unrecovered acid chloride. [b] Determined cryoscopically.

The ketene dimers thus formed have not been previously reported.

The dimers gave a negative test with silver nitrate; positive tests with potassium permanganate, and bromine. *p*-Nitrophenylhydrazine reacted with the dimers to yield the hydrazones.

### Experimental

The procedure followed in dehydrohalogenation of the the acid chlorides was similar to that reported by Sauer.[2] Equal molar quantities of acid chloride and triethylamine were allowed to react in dilute ether solution. Each dimer was isolated in its pure form by distillation under diminished pressure. A quantity of unreacted acid chloride was recovered from each experiment.

Analytical data and physical constants of the five ketene dimers are shown in Table I.

***p*-Nitrophenylhydrazones.**—The hydrazones were prepared according to the procedure described by McElvain.[3] The color of the hydrazones varied from lemon to deep orange.

Analytical data and physical properties of the hydrazones are given in Table II.

## The Preparation and Vapor Pressure of Bromopentachloroethane; the Vapor Pressures of Heptachloropropane and Dibromotetrachloroethane

BY TAKERU HIGUCHI,[1] NOBORU ENDOW[2] AND JOHN E. WILLARD

When confronted with a need for a sample of bromopentachloroethane we were not able to find any record of its preparation in the literature. We have prepared a sample by the photobromination of pentachloroethane at elevated temperature, using a technique similar to that previously employed in this laboratory for the preparation of bromotrichloromethane from chloroform and bromine.[3] The over-all reaction is

$$C_2Cl_5H + Br_2 \longrightarrow C_2Cl_5Br + HBr$$

Eastman Kodak Co. technical pentachloroethane was washed several times with concentrated sulfuric acid, with water, with 20% potassium hydroxide solution and again with water. After drying with phosphorus pentoxide, approximately 1 mole (125 cc.) was then mixed with one mole (55 cc.) of bromine and 75 cc. of carbon tetrachloride. This mixture was illuminated by two 500-watt Mazda projection bulbs placed next to the flask which was sealed to a water-cooled reflux condenser. The heat from the bulbs was sufficient to maintain the solution at or near the boiling temperature. Since the photobromination of chloroform has been found to be inhibited by both oxygen and water, the following precautions were taken to exclude gross amounts of these substances: (a) a slow stream of nitrogen was bubbled through the solution and allowed to pass out through the condenser throughout the course of the reaction; (b) 5 g. of phosphorus pentoxide was added to the reaction flask.

Initial attempts to prepare bromopentachloroethane by this method, from mixtures of bromine and pentachloroethane without carbon tetrachloride, led to a mixture of products. Because of the possibility that this might be the result of reactions favored by the relatively high temperature of the boiling point of the pentachloroethane (155°), carbon tetrachloride was added to reduce the boiling point.

After a week of continuous illumination the reaction solution solidified on cooling. The weight of this crude product was 200 g. Following three recrystallizations from small amounts of carbon tetrachloride large white crystals were obtained which melted with decomposition in the range of 180 to 200° when heated in sealed evacuated tubes. An estimate of the molecular weight and vapor pressure was obtained from this sample by measuring the gas pressure produced in a known volume by a weighed sample as a function of temperature. This was accomplished by placing the sample in an evacuated sealed bulblet in a sidearm of an evacuated thermostated flask which was connected to an open-end mercury manometer,[4] the middle section of which was made of flexible rubber suction tubing. The sample tube was broken with a glass-enclosed magnetic hammer. By means of a leveling bulb the mercury was maintained at an index mark on the glass side arm of the flask which connected with the manometer, thus maintaining a constant gas volume as the pressure

Details of modifications and applications are given in the Masters' degree thesis of Noboru Endow filed with the Library of the University of Wisconsin in January, 1948.

changed due to vaporization of the sample. The pressure was read as the difference in heights of the mercury columns. The connection from the flask to the manometer entered the mineral oil thermostating-bath through a bushing in the bottom of the silver-soldered copper can and the index mark was viewed through a window in the side of the can. Experiments showed that no correction was necessary for the vapor pressure of mercury, thus indicating that the time required for the mercury vapor (which was always at a lower pressure than the organic vapor) to diffuse from the narrow side arm into the flask was long compared to the time involved in the experimental measurements.

Three experiments made on the freshly purified samples believed to be bromopentachloroethane gave linear plots of the logarithm of the sublimation pressure against the reciprocal of the absolute temperature over the temperature range of about 110 to 160°. A sharp break in the curve was found in each case at the temperature of total vaporization of the sample. The average molecular weights calculated for the totally vaporized system at the break in the curve were 280, 280 and 285 as compared to the theoretical value of 281 for $C_2Cl_5Br$. Chemical analysis of a sample of the compound by the Carius wet oxidation method combined with the Moser–Miksh iodide metathesis method gave the results:

| | Experimental | Theoretical ($C_2Cl_5Br$) |
|---|---|---|
| Bromine | 27.8 | 28.3 |
| Chlorine | 61.2 | 63.2 |

Samples of the compound prepared by the photobromination of pentachloroethane with radiobromine of known specific activity showed a specific activity corresponding to the formula $C_2Cl_5Br$.

The average vapor pressure of the $C_2Cl_5Br$ over the range tested is given by the relation $\log p = (-2.32 \times 10^3/T) + 6.33$, where $p$ is the pressure in cm. of Hg and $T$ is the absolute temperature.

**Heptachloropropane.**—A single series of measurements of the vapor pressure of $CCl_3CCl_2CHCl_2$ as a function of temperature with the apparatus described above gave a straight line plot of $\log p$ *vs.* $1/T$ for five points taken over the range of 140 to 200°. These data gave the expression $\log p = (-1.82 \times 10^3/T) + 5.11$. The sample used was obtained from the Eastman Kodak Company, which specified its melting point as 30°. The fact that the molecular weight of the sample calculated from the observed pressure at the temperature of total vaporization was 278 as compared to the theoretical value of 285 indicates that the sample was probably not highly impure. Prins,[5] Farlow[6] and Henne and Ladd[7] have reported values for the boiling point of $CCl_3CCl_2CHCl_2$ at several pressures. Their values are shown in Table I for comparison with those determined from the equation given above.

TABLE I

| Pressure, mm. | Obs. b. p., other workers, °C. | B. p. from vapor pressure equation, °C. |
|---|---|---|
| 10 | 110–113 (Farlow) | 83 |
| 32 | 137–140 (Farlow) | 122 |
| 43 | 147 (Prins) | 133 |
| 90 | 164 (Prins) | |
| | 163–166 (Henne and Ladd) | 165 |

The relation of $\log p$ to $1/T$ for Farlow's data is not in agreement with that for Prins' data and neither is in agreement with our vapor pressure determinations. These latter show a consistent relationship over a 60° range under conditions of measurement which have given agreement with well established values for the vapor pressure of carbon tetrachloride and have given consistent vapor pressure and molecular weight values for a number of compounds tested.

**Dibromotetrachloroethane.**—A similar determination of the vapor pressure of $C_2Cl_4Br_2$ gave the expression $\log p = (-2.74 \times 10^3/T) + 7.18$ over the range from 110 to 180°. These results are in satisfactory agreement with those of Carrico and Dickinson[8] who made similar measurements from 50 to 150°. At 50° they observed a pressure of 0.4 mm. while the value calculated from our data is 0.5 mm. At 150° they found 51 mm. and our data indicate 50 mm. Following complete vaporization of the $C_2Cl_4Br_2$, the vapor was heated to 215° without more than a few per cent. decomposition over the period of about half an hour, indicating greater thermal stability than that of the $C_2Cl_5Br$ reported above.

The work reported here was done as part of a program to which support was given by the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

## The Structure of Pellitorine[1]

BY MARTIN JACOBSON

The isolation from plant materials of several pungent N-isobutylamides of aliphatic unsaturated acids has been reported, namely, spilanthol (N-isobutyl-4,6-decadienamide) (I) from the flower heads of *Spilanthes oleraceae* Jacquin[2] and *S. acmella* Murr.,[3] pellitorine (the N-isobutylamide of a decadienoic acid) from the roots of *Anacyclus pyrethrum* DC.,[4] N-isobutyl-2,6,8-decatrienamide (II) from the roots of *Heliopsis longipes* (A. Gray) Blake[5]; and herculin (N-isobutyl-2,8-dodecadienamide) (III) from the bark of *Zanthoxylum clava-herculis* L.[6]

Gulland and Hopton[4] had identified pellitorine as an isomer of spilanthol, but they did not determine the positions of the double bonds in the molecule. In view of the insecticidal activity of compounds I,[3,7] II[5] and III,[6] and since preliminary tests in the laboratories of the Bureau of Entomology and Plant Quarantine had indicated that pellitorine was also insecticidal,[6] it was of considerable interest to determine the points of unsaturation in this compound, with a possible consequent correlation between insecticidal activity and molecular structure.

The procedure used in this Laboratory for isolating pure pellitorine eliminated the repeated fractional distillations found by Gulland and Hopton to be necessary for its purification. A Skelly-

solve A extract of dry pellitory root (*Anacyclus pyrethrum* DC.)[8] was extracted with nitromethane, and the neutral fraction of the nitromethane-soluble portion was distilled. One crystallization, from Skellysolve A, of the fraction boiling at 155–165° (0.3–0.5 mm.) gave pure pellitorine in 0.14% yield, based on dry root.

Oxidation of pellitorine with alkaline permanganate resulted in the isolation of butyric, succinic and N-isobutyloxamic acids, showing that the double bonds occupy the 2- and 6-positions. Pellitorine is therefore N-isobutyl-2,6-decadienamide (IV).

In tests[9] conducted with house flies (*Musca domestica* L.), a Deobase (refined kerosene) solution of pellitorine, used as a spray, showed paralyzing action equal to, and mortality somewhat greater than one-half that of pyrethrins tested at the same concentration.

### Experimental[10]

**Isolation of Pellitorine.**—6070 g. of finely ground, dry pellitory root was extracted in a Soxhlet extractor with Skellysolve A. The solution was concentrated to *ca.* 700 ml. and extracted three times with 150-ml. and twice with 100-ml. portions of nitromethane. The combined nitromethane solution was freed of solvent under reduced pressure, the residue (27 g. of reddish-brown oil) taken up in ethyl ether, and the ether solution washed thoroughly with water, 5% hydrochloric acid solution, 5% potassium hydroxide solution, and finally with water. After being dried over sodium sulfate, the ether solution of the neutral fraction was freed of solvent completely, and the remaining 20 g. (0.33% of the bark) of viscous reddish-yellow oil solidified rapidly.

Vacuum distillation of this material, in an atmosphere of nitrogen, gave 8.5 g. of pale-yellow oil, b. p. 155–165° (0.3–0.5 mm.), which was dissolved in a small quantity of Skellysolve A, cooled in ice–salt, and filtered. The yield was 8.4 g. (0.14% based on dry bark) of colorless, feathery needles of pellitorine, m. p. 72° (lit.[4] m. p. 72°).

**Oxidation of Pellitorine.**—To a stirred suspension of 5 g. of pellitorine in 500 ml. of water, maintained at 70°, 18.8 g. of finely powdered potassium permanganate (equivalent to 4 moles of oxygen) was added in small portions. When the reaction mixture had become colorless, the manganese dioxide was filtered and washed thoroughly with warm water. The combined aqueous filtrates were concentrated down to 70 ml. and made acid to congo red with sulfuric acid. The solution was steam-distilled to remove the volatile acids and then extracted with ether in a continuous extractor. The ether solution was freed of solvent, and the residue was extracted with three 10-ml. portions of boiling Skellysolve B. Cooling of the hydrocarbon solution caused the separation of 2.5 g. (77%) of colorless feathery needles, m. p. 106–107°, containing nitrogen.

*Anal.* Calcd. for $C_6H_{11}NO_3$: N, 9.66; neut. equiv., 145. Found: N, 9.65; neut. equiv., 145.

The substance was identified as N-isobutyloxamic acid by a mixed melting-point determination with an authenic sample, m. p. 107°, prepared by the procedure of Malbot.[11]

The insoluble residue from the Skellysolve B extraction was taken up in a small amount of ethyl acetate, cooled in ice–salt mixture, and filtered. One recrystallization from a small amount of the same solvent gave 1.8 g. (69%) of colorless crystals in the form of clusters of needles, m. p. 188–189°.

*Anal.* Calcd. for $C_4H_6O_4$: mol. wt., 118. Found: mol. wt. (titration), 118.

The product was identified as succinic acid by a mixed melting point determination with an authentic specimen, m. p. 189°, and by preparing the *p*-phenylphenacyl ester, m. p. 208°.

The solution of steam-volatile acids obtained above was neutralized with sodium hydroxide solution, concentrated to a small volume on the steam-bath, and acidified to congo red with sulfuric acid. Steam distillation gave Duclaux values of 17.9, 15.9 and 14.6, identical with those given for butyric acid.[12]

The acid was shown to be butyric acid by evaporating the neutral solution to dryness and then preparing the *p*-phenylphenacyl ester, m. p. and mixed m. p. with an authentic sample, 81–82°.

## The Reaction of Diazoketones with Thioamide Derivatives[1]

BY L. CARROLL KING AND F. M. MILLER

Werner[2] found that the action of diazomethane on thiourea produced S-methylpseudothiourea. We have now observed that diazoketones react with thiourea and other thioamide derivatives to furnish substituted thiazoles. The reaction between diazoacetophenone and thiourea is illustrative.

The reaction is effected either by heating an intimate mixture of the reactants on the steam-bath, or by refluxing an alcoholic solution of the reaction components. The reaction in alcoholic solution is more satisfactory.[3]

Thiourea and ethyl diazoacetate react to give

[a] Based on the diazoketone. [b] The same compound was obtained with one or two molecular portions of diazoacetophenone, the latter giving the 78% yield, based on the dithiobiuret. [c] All melting points observed on a Fisher–Johns melting point block. [d] These compounds were compared with authentic material previously prepared in this Laboratory, reference 1.[a] [e] Hubacher, *Ann.*, **259**, 237 (1890). [f] Andreasch, *Monatsh.*, **8**, 424 (1887), reported a melting point of 208° (dec.) for this material prepared by a different method. The compound from the diazoketone reaction melted in this range above. Similar results were obtained by Allen and VanAllan, "Organic Syntheses," **27**, 71 (1947). [g] Not previously reported. [h] Analysis by Miss P. Craig. [i] Calcd.: N, 5.62. Found: N, 5.69.

2-amino-4-hydroxythiazole (pseudothiohydantoin). Thiourea and thiobenzamide yield with diazoacetophenone, 2-amino-4-phenylthiazole and 2,4-diphenylthiazole, respectively. With the same diazoketone dithiobiuret gives bis-(4-phenyl-2-thiazolyl)-amine (I).[4]

I

Evidence for the structure of I lies in the method of formation, the analysis of the compound and its N-acetyl derivative, and the fact that it was unaffected by both acid and alkaline hydrolytic conditions, contrary to the known sensitivity of the thioureido group.[5] Compound I was also prepared by the action of phenacyl bromide on dithiobiuret.

Data for the compounds prepared are listed in Table I.

This investigation was supported by a grant from the Abbott Fund of Northwestern University.

### Experimental

**Preparation of Materials.**—Diazoacetophenone was prepared as previously described.[3] Ethyl diazoacetate was prepared by the method of Curtius.[6] Thiobenzamide was prepared by suspending 60.5 g. (0.5 mole) of benzamide and 22.2 g. (0.10 mole) of phosphorus pentasulfide in 300 cc. of benzene and refluxing until the benzamide dissolved. The hot benzene solution was filtered and cooled, and the thiobenzamide collected. The material was recrystallized once from benzene m.p. 115–116°.[7] The dithiobiuret was a commercial sample, obtained through the courtesy of the American Cyanamid Company.

**Preparation of the Thiazoles.**—The techniques used will be illustrated by the following examples.

(a) **2-Amino-4-phenylthiazole.**—A solution of 1.46 g. (0.01 mole) of diazoacetophenone and 2.40 g. (0.012 mole) of thiourea in 20 cc. of absolute alcohol was refluxed for one hour. A portion of the alcohol was evaporated, a small amount of water and charcoal added, and the hot solution filtered and cooled. The separated material was collected and recrystallized from dilute aqueous alcohol.

(b) **bis-(4-Phenyl-2-thiazolyl)-amine.**—A solution of 2.92 g. (0.02 mole) of diazoacetophenone and 1.48 g. (0.011 mole) of dithiobiuret was refluxed for one hour in alcoholic solution. The product separated from the solution, was filtered and dissolved in excess acetone. Dilute aqueous alcohol was added and the acetone removed carefully on the steam-bath. The material crystallized on cooling and was recrystallized in the same manner.

bis-(4-Phenyl-2-thiazolyl)-amine was also prepared by refluxing 4.0 g. (0.02 mole) of phenacyl bromide and 1.50 g. (0.01 mole) of dithiobiuret in 25 cc. of alcohol for one hour. The separated material was suspended in alcohol and digested with ammonium hydroxide for one-half hour, filtered and washed with a small amount of alcohol. Recrystallization gave a material identical with that prepared above.

**Acetyl Derivatives of Thiazoles.**—These were prepared by the action of acetic anhydride on approximately 0.3 g. of the amino thiazole. The products were recrystallized from dilute aqueous alcohol.

**Attempted Hydrolysis of I.**—A solution of 0.1 g. of the material in 30 cc. of hot alcohol and 10 cc. of water was heated under reflux for three hours with 10 g. of barium hydroxide. Only the starting material was recovered, m.p. 217–218°.

Attempted acid hydrolysis performed in the same manner yielded identical results.

## The Verdet Constant of Certain Liquid Fluorocarbons

BY R. T. LAGEMANN

It is now known that certain fluorinated hydrocarbons possess some unusual physical properties. Although the density and viscosity are not particularly different from those of other liquids, the refractive index and ultrasonic velocity are both extraordinarily low. As an example, consider bis-(trifluoromethyl)-chlorononofluorocyclohexane. Here $n^{60}D$ is 1.3021,[1] only three liquids in Lange's "Handbook" have a lower value, and the ultrasonic velocity at 20° is 691.8 m./sec.,[1] also extremely low relative to other liquids. Since no values are known for the rotation of the plane of polarization of light by these liquids when placed in

(1) Lagemann, Woolf, Evans and Underwood, THIS JOURNAL, **70**, 2994 (1948).

a magnetic field (Verdet constant), it was considered of interest to measure the Verdet constant to note if it, too, was unusual. Indeed, such was found to be the case.

The eight fluorocarbons studied are listed in Table I along with the measured values of their Verdet constants at 25° and for 5893 Å. It will be noted that the Verdet constants for these fluorinated hydrocarbons are extraordinarily low. The lowest value, that belonging to hexadecafluoroheptane, is about one-half the lowest previous value listed for any compound in the "International Critical Tables."

TABLE I

VERDET CONSTANTS OF SOME LIQUID FLUOROCARBONS AT 25° AND FOR 5893 Å[a]

| Compound | Molecular weight | Density, 25°, g./cc. | Verdet constant, min./gauss-cm. |
|---|---|---|---|
| Hexadecafluoroheptane | 388 | 1.7208 | 0.003500 |
| (Trifluoromethyl)undecafluorocyclohexane | 350 | 1.7871 | .003751 |
| bis-(Trifluoromethyl)-decafluorocyclohexane | 400 | 1.8391 | .003950 |
| bis-(Trifluoromethyl)-chlorononofluorocyclohexane | 416 | 1.8711 | .005252 |
| Chlorotrifluoroethylene polymer | 713 | 1.9412 | .009093 |
| Chlorotrifluoroethylene polymer | 866 | 1.9681 | .009118 |
| Chlorotrifluoroethylene polymer | 911 | 1.9736 | .009168 |
| Fluorolube oil | 860 | 2.0081 | .004739 |

[a] The values of molecular weight and density found in this table were supplied by the Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee.

Enough data are present in Table I to enable a calculation to be made of the molecular magnetic rotation[2] (utilizing $MV/d$ for water at 25° and 5893 Å. as 0.2353). From this, values of the increment attributable to the fluorine atom may be made. For the cases presented here, the values vary, no doubt due to constitutive factors.

**Acknowledgments.**—It is a pleasure to acknowledge our indebtedness to Dr. Clifford Beck of the Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee, for the loan of the compounds studied and for data concerning them. The author is also indebted to the Department of Physics of Columbia University, particularly to Dr. Lucy Hayner, for permission to use the Faraday Effect equipment.

### Experimental

The measurements of the Verdet constant were made on the Faraday Effect apparatus of the Department of Physics, Columbia University. The procedures used were the same as those described by Slack[3] and the author[2] and will not be repeated here. The fluorocarbons were obtained through the courtesy of the Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee, where they had been subjected to fractional distillation and their molecular weight and density measured.

## A Synthesis of Symmetric Phosphinic Acids

BY GENNADY M. KOSOLAPOFF

Michaelis and Wegner[1] were the first to employ the Grignard reaction in the synthesis of aromatic phosphinic acids under conditions which precluded the formation of by-products, by the reaction of aryl magnesium halides with N-piperidyl dichlorophosphate. Their lone paper on this subject, however, failed to state the yields obtained, although these were said to have been "good." Because of the relatively high cost of piperidine, it was thought that an equally good reagent might be found among the more available aliphatic dialkyl amines, which can be readily converted to the corresponding dichlorophosphates. This belief has been realized and excellent yields of some symmetric aromatic and aliphatic phosphinic acids have been readily attained by using N,N-diethylamine to block one reactive group of phosphorus oxychloride. The reaction, thus, may be extended to the aliphatic series, which has not been done previously.

### Experimental

The yields and the properties of the products are given in the table.

SYMMETRIC PHOSPHINIC ACIDS PREPARED

| Derivative | Yield, % | M. p., °C. | Equiv. weight Calcd. | Found |
|---|---|---|---|---|
| bis-*p*-tolyl | 75 | 131–132 | ..... | ....[1] |
| bis-*p*-anisyl | 79 | 179–180 | 278 | 275 |
| bis-*o*-anisyl | 74 | 227–228 | 11.15%[a] | 11.1%[a] |
| Di-*n*-butyl | 82 | 70.5–71 | 178 | 176 |

[a] % Phosphorus.

**bis-*p*-Tolylphosphinic Acid.**—N,N-Diethylamidodichlorophosphate (19 g., 0.1 mole) was added during one hour to a gently refluxing solution of *p*-tolylmagnesium bromide, prepared from 34.2 g. of *p*-bromotoluene and 4.8 g. of magnesium, in 300 ml. of dry ether. After refluxing for two hours, the mixture was hydrolyzed by means of ice-water and ammonium chloride, and the organic layer was treated with 250 ml. of concentrated hydrochloric acid. Ether was distilled from the mixture and the residue was refluxed for four hours. After cooling, the product was filtered and was recrystallized from dilute ethanol It formed long colorless needles. Michaelis and Wegner[1] reported its m. p. 130–132°.

**bis-*p*-Anisylphosphinic Acid.**—The same procedure, using 37.4 g. of *p*-bromoanisole for the Grignard reagent, yielded this acid in the form of short colorless needles.

**bis-*o*-Anisylphosphinic Acid.**—The same procedure using *o*-bromoanisole gave this substance, in the form of needles; this preparation was also checked by synthesizing the product from phosphorus oxychloride and the Grignard reagent by an earlier procedure.[2] The rather unexpectedly high melting point, in comparison with the *p*-isomer, may be caused by interaction of the oxygen atom of the *o*-methoxyl group, with the $PO_2H$ group.

**Di-*n*-butylphosphinic Acid.**—A procedure similar to the above was used with 57 g. of the dichlorophosphate and the Grignard reagent from 82.2 g. of *n*-butyl bromide and 14.58 g. of magnesium; the addition period was two hours and the reflux period was three hours. After hydrolysis by refluxing with hydrochloric acid, the bulk of the latter was distilled, the residue made strongly alkaline with sodium hydroxide, and the regenerated

(1) Michaelis and Wegner, *Ber.*, **48**, 316 (1915).
(2) Kosolapoff, THIS JOURNAL, **64**, 2982 (1942).

amine was steam distilled. The crude product m. p. 66–69°, was isolated by ether extraction and converted to the corresponding chloride (for separation from possible traces of butanephosphonic acid) by warming with 51.5 g. of phosphorus pentachloride followed by distillation; b. p. 156–157° at 28 mm. Hydrolysis of the chloride with warm water and crystallization from hexane gave the pure acid in the form of long silky colorless needles. This acid was previously reported by Plets[3] who prepared it by hydrolysis of either $R_2PCl_3$ or $R_2POCl$, which were, in turn, derived from dibutylchlorophosphine; he gave m. p. 31–32° for the acid. The higher melting point of the present preparation indicates either higher purity or, possibly, an isomeric form.

## Preparation and Properties of Tetramethylene Sulfones

BY MARLIN T. LEFFLER AND W. D. KRUEGER

In the course of a search for new types of chemotherapeutic agents, several cyclotetramethylene sulfones were prepared and studied. These were synthesized by the addition of amines, alcohols and mercaptans to 2,5-dihydrothiophene-1-dioxide (butadiene sulfone) in a manner similar to that described by Delfs.[1] The general formula, I, illustrates the types prepared and listed in Table I, where (X) is either –NH–, –O– or –S–, and R is an alkyl or substituted alkyl group.

(I)

It is of interest to note that while the addition of amines to butadiene sulfone does not generally require a catalyst, alcohols and mercaptans react best in the presence of an alkaline agent. Triton-B was found to be an effective catalyst; sodium and potassium hydroxides serve also. Worth emphasizing is the fact that strongly basic amines such as aliphatic amines, phenethylamine, etc., add readily to the double bond of butadiene sulfone but less basic amines, aniline and benzylamine for example, do not react to give any appreciable yield under similar conditions.

Through the courtesy of the Division of Chemotherapy for Tropical Diseases, National Research Council, the products described herein were tested for activity against a variety of tropical diseases. None was found to have any significant activity in amebiasis, filariasis, schistosomiasis or leischmaniasis.

We are indebted to Mr. E. F. Shelberg of the Microanalytical Department for the microchemical analyses.

### Experimental

The sample of 2,5-dihydrothiophene-1-dioxide (butadiene sulfone) used in this work was furnished by the Shell Development Company under the trade name "Sulfolene."

The tetrahydrothiophene-1-dioxides listed in Table I were prepared by the following general procedures:

**3-Amino Derivatives.**—A mixture of 0.5 mole of butadiene sulfone and 2 moles of the primary or secondary amine was stirred and heated at 70–80° for twenty-four hours. The excess amine was then removed by distillation *in vacuo* and the residue was dissolved in 300 ml. of anhydrous ether, which solution was treated with excess dry, gaseous hydrogen chloride to form the salt. The solid salts were removed by filtration and recrystallized to constant melting point from absolute alcohol.

**3-Substituted Ethers.**—A mixture of 0.5 mole of butadiene sulfone, 1.0 mole of the desired alcohol and 2 to 4 ml. of Triton-B was heated at 70–80° for twenty-four hours. At the end of this time the Triton-B was neutralized with concentrated sulfuric acid and the excess of the alcohol used was removed by distillation *in vacuo*. The residue was then distilled under reduced pressure. In the case of the 3-diethylaminoethoxy derivative, the product was converted to the phosphate by the addition of a slight excess of phosphoric acid (85%) to an alcoholic solution of

the base. The phosphate was purified by recrystallization from a mixture of acetone and methanol (1:4).

**3-Substituted Thio-ethers.**—To a mixture of 0.2 mole of butadiene sulfone, 0.2 mole of the desired mercaptan and 75 ml. of water was added slowly and with good agitation 0.4 mole of powdered sodium hydroxide. During this addition, the temperature rose to and was held at 70–80°. Stirring was continued and the temperature was maintained at 70–80° for four hours longer. Then the reaction was cooled and extracted with two 250-ml. portions of ether. The combined ether extracts were washed with 150 cc. of water and dried over anhydrous magnesium sulfate.

In the case of the benzylthio ether, the product crystallized directly from the cold ether solution. It was purified further by recrystallization from dry ether. With the diethylaminoethyl thio-ether, the base was converted to the hydrobromide by treatment of the dry ether solution with gaseous hydrogen bromide. Purification was accomplished by recrystallizing the salt from absolute alcohol.

## Thermal Exchange Experiments with Radioactive Zinc

BY LEON LEVENTHAL[1] AND C. S. GARNER

Duffield and Calvin[2] have reported an intensive study of thermal exchange reactions of copper chelate compounds in pyridine, most of which reactions proceeded at measurable rates. Other exchange experiments of the type considered here include those of Drehmann[3] on manganese(II) ions with manganese acetylacetone and manganese benzoylacetone in methanol (half-times of exchange less than one hour), Sue and Yuasa[4] on vanadyl and vanadate ions with solid vanadium 8-hydroxyquinoline and solid vanadium cupferronate (relatively slow exchange), and Johnson and Hall[5] on nickel(II) ions with various nickel chelate compounds in acetone, methyl or ethyl cellosolve (rapid to slow exchanges).

We have examined the thermal exchange reactions of zinc ions with some zinc complex compounds of the kind referred to above, partly to find conditions under which the kinetics of such reactions might be studied and partly to learn which of these zinc compounds, if any, might be suitable for use in the Szilard–Chalmers method of concentrating radioisotopes.

Complete exchange of radioactive zinc was found between dipyridine zinc acetate and the following zinc complex compounds in pyridine solution at 25° after exchange times as short as thirty seconds in each case: zinc acetylacetone, zinc acetylacetone ethylenediimine, zinc benzoylacetone ammoniate, zinc nicotinylacetone and dipyridine zinc thiocyanate. In the case of the nicotinylacetone, the exchange solution in pyridine was 0.0034 $f$ in dipyridine zinc acetate and 0.0034 $f$ in the zinc chelate. In all other cases, the pyridine exchange solutions were 0.01 $f$ in the acetate and 0.01 $f$ in the complex compound. The acetylacetone exchange was also run at 0° without any apparent difference. Thus, it appears either that rapid exchange was induced by the separation procedure utilized or, more probably, that the above zinc complex compounds are comparatively unstable with respect to ionization or displacement reactions (stability apparently comparable with that of copper salicylaldehyde, copper salicylaldehyde anil, and copper salicylaldehyde methylimine in pyridine solution[2]). If the rapid exchange was not induced, the above zinc complex compounds would not be suitable for Szilard–Chalmers separations, at least in pyridine solution.

### Experimental

**Radiozinc Tracer.**—Several sections from a discarded copper cyclotron dee were obtained through the courtesy of Professor J. R. Richardson, to whom our thanks are hereby expressed. Since these copper parts had received lengthy deuteron and neutron bombardments and had been cooling for over a year, the principal activity in them was due to 250-day $Zn^{65}$, formed mainly by the reaction $Cu^{65}(d,2n)Zn^{65}$. Chemical separation and purification of the radiozinc was effected by a procedure similar to that outlined by Kamen,[6] giving a zinc fraction with the half-life and radiations characteristic of 250-day $Zn^{65}$.

**Procedure.**—Experiments were run in duplicate. All zinc compounds were synthesized and their identity established by chemical analyses. The pyridine was dried over potassium hydroxide and distilled through a column. Exchange mixtures were synthesized volumetrically from standardized stock solutions of the complex compounds and of radioactive zinc acetate in pyridine. After varying lengths of time the exchange mixtures were subjected to a separation procedure similar to that used by Duffield and Calvin[2] and consisting of the addition of water and chloroform followed by extraction of the complex compound into the chloroform–pyridine layer and of the acetate into the water–pyridine layer, re-extraction from each layer, then precipitation of zinc sulfide from the resulting extracts buffered with acetic acid–acetate mixtures. Since the zinc sulfide precipitates were found after drying to be of varying composition they were ignited to the oxide for weighing and subsequently mounted on filter paper discs. Both fractions from each experiment were counted in a reproducible geometry with a Geiger–Mueller counter and scale-of-64, the 0.45- to 1.14-Mev. gamma radiation associated with the decay of $Zn^{65}$ being counted through a compound absorber. The total activity in each experiment was of the order of 1000 counts per minute, and corrections for decay and changes in counter efficiency (by use of a standard $Zn^{65}$ aliquot) and for background were applied. The extent of exchange was calculated in the usual manner from the specific activities of the two fractions.

[a] Statistical counting error, taken as the square root of the sum of the squares of the standard deviations of sample and of background, was 1%. [b] Analyses gave same amount of chromium in each fraction, thus showing that oxidation of chromium(III) by perchloric acid is negligible under the experimental conditions. [c] Green form. [d] $H_2SO_4$ (pH 2–3). [e] 3.1 f. NaOH. [f] 0.067 f. HCl. [g] 0.050 f. HCl. [h] $CH_3COOH$ (pH 3–4).

Muxart, Daudel, Daudel and Haissinsky[1] that no appreciable exchange of radiochromium occurs between chromium(III) and dichromate ions in sulfuric acid solutions.

We have confirmed this observation and have extended the studies to exchange measurements in 2 *f* and 0.05 *f* perchloric acid and in 3.1 *f* sodium hydroxide. In addition, some exchange reactions of chromium(III) ions with hexathiocyanatochromate(III), hexacyanochromate(III), and trioxalatochromate(III) ions, respectively, have been investigated with radiochromium.

Table I summarizes the results. Appreciable exchange was observed only for Cr(III)—$Cr(CN)_6^{---}$ in low concentration of perchloric acid or acetic acid and for the pair hexaaquochromium(III) and dichromate ions in 0.05 *f* perchloric acid at 25° and 45°. In the latter case the exchange results obey approximately the exponential exchange law,[2,3] as is shown by Fig. 1. The half-time for the exchange under the stated conditions is 60 ± 6 days at 45° and greater than 430 days at 25°.

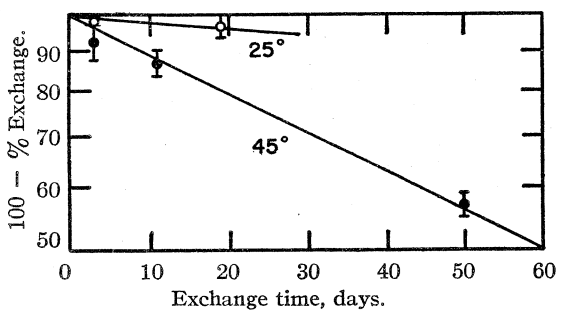

Fig. 1.—Hexaaquochromium(III)—dichromate exchange, 0.010 *f* $Cr^*(ClO_4)_3$, 0.0050 *f* $K_2Cr_2O_7$, 0.05 *f* $HClO_4$.

## Experimental

**Radiochromium Tracer.**—Radiochromium was prepared by the Cr(*n*, γ) reaction in the Oak Ridge pile and allocated by the U. S. Atomic Energy Commission. Chemical purification gave a chromium fraction with the half-life and radiation characteristics of 27-day $Cr^{51}$.

**Procedure.**—Experiments were run in duplicate. The exchange mixtures were synthesized volumetrically from the standardized stock reagent solutions, placed inside glass-stoppered flasks immersed in a thermostated bath, and subjected to chemical separation at the end of the exchange times. In the hexathiocyanatochromate (III) and hexacyanochromate (III) exchanges separation was effected by the addition of silver nitrate to precipitate $Ag_3Cr(SCN)_6$ and $Ag_3Cr(CN)_6$, respectively. Separation in the case of the trioxalatochromate (III) exchanges was achieved by the addition of barium chloride and ethanol to precipitate $Ba_3[Cr(C_2O_4)_3]_2$. In all other cases separation was brought about by precipitation of hydrous chromium(III) oxide. Both fractions in each exchange experiment were mounted and counted, in a few cases in the form precipitated (except for drying), but in most cases as $BaCrO_4$. Samples were suction-filtered onto Whatman No. 50 paper discs held in a cylindrical glass "chimney" device, then mounted on cardboard plates for counting. The 0.33-Mev gamma radiation associated with the decay of $Cr^{51}$ was generally used in the detection, the samples usually being counted through 108 mg./sq. cm. aluminum (to eliminate variable X-radiation) in a reproducible geometry with a Geiger–Mueller counter and scale-of-128. Corrections for decay and changes in counting efficiency (by use of a standard $Cr^{51}$ aliquot) and for background (~19 c./m.) were made.

## Penicillin G as Electrolyte and Colloidal Electrolyte[1]

BY J. W. MCBAIN, HARRIETTE HUFF[2] AND A. P. BRADY[2]

There is disagreement concerning the state of aggregation of penicillin salts in aqueous solution. On the basis of surface tension and ultramicroscopic observations, Hauser, Phillips and Phillips[3] have reported sodium benzyl penicillinate (penicillin G) as a colloidal electrolyte. On the other hand, Kumler and Alpen[4] concluded from conductivity and surface tension measurements that both potassium and sodium salts of penicillin G are only molecularly dispersed in water. Since neither of those lines of evidence is conclusive, it seemed worth while to make other types of measurement on the solutions to decide between these opposing views. This note presents measurements of the conductivity, surface tension, freezing points, and dye solubilization at various concentrations of aqueous solutions; showing that sodium pencillin G above 0.25 m. is indeed a colloidal electrolyte, but that in lesser concentration it is an ordinary electrolyte. The authors[3,4] referred to were dealing with dilute solutions such as 0.017 mole/liter or 0.6%.

### Experimental

Crystalline sodium penicillin G was kindly furnished by Bristol Laboratories, Inc., of Syracuse, New York, and according to their analysis was 96.9% G with the remainder being F, dihydro F, and K.

The conductivity was measured at 2000 cycles in an oil thermostat at 25 ± 0.005° with a Dike–Jones type bridge using an oscillograph to detect the balance point. The conductivity water was about $0.8 \times 10^{-6}$ mho.

The crystalline penicillin and its solutions were stored in a refrigerator. With the exception of the solubilization measurements, all determinations were made with solutions less than six hours old and with less than half an hour at room temperature.

### Results and Discussion

The results are given in Table I and plotted in Figs. 1 and 2. The freezing point results are expressed in terms of $g$, the practical osmotic coefficient, the ratio of the lowering to the ideal lowering for a uni-univalent salt. Figure 1 also includes the results of solubilization measurements both with water and with isotonic salt solution as solvents. Both freezing point and solubilization show that sodium penicillin G aggregates in concentrated solution, but the critical concentration of 0.25 m. (8.26% G) is so high that it is of little interest biologically. Solubilization experiments in the presence of isotonic salt solution

show little effect upon critical concentration. The equivalent conductivity curve shows no break or a very doubtful one at the critical concentration, as expected for this type of polycyclic compound. Bile salts and sodium abietate, both shown to be colloidal electrolytes by freezing point measurements, give no break in the conductivity curve.[5,6] The conductivity curve determined here ties in satisfactorily with the data given by Woodbury and Rosenblum,[7] converted from 30 to 25° by assuming that the salt has the same temperature coefficient as that of the sodium ion.

The surface tension of these solutions is fairly low, but relatively independent of concentration and may easily result from small amounts of impurities.

## A Preparation of Phenylmaleic Anhydride

BY LEONARD E. MILLER, HARLOW B. STALEY AND D. J. MANN

Although phenylmaleic anhydride (I) was first isolated in low yield as a by-product in the synthesis of phenylmalic acid by the reaction of phenylsuccinic acid with bromine and phosphorus tribromide,[1] no satisfactory procedure for the preparation of (I) has been reported.

I

When phenylsuccinic anhydride is permitted to react with N-bromosuccinimide in the presence of a catalytic amount of benzoyl peroxide, phenylmaleic anhydride can be isolated in 57–64% yield.

The use of N-bromosuccinimide as a dehydrogenating agent for several hydroaromatic compounds has been reported recently by Barnes.[2]

### Experimental[3]

Phenylsuccinic anhydride,[4] m. p. 53–54°, was prepared in 78–84% yield from phenylsuccinic acid.[5]

Into a 500-ml., two-necked flask, equipped with a mechanical Hershberg stirrer (made of nichrome wire) and a condenser fitted with a drying tube, were placed 17.8 g. (0.1 mole) of N-bromosuccinimide, 8.8 g. (0.05 mole) of phenylsuccinic anhydride, 200 ml. of carbon tetrachloride and 0.1 g. of benzoyl peroxide. The reaction mixture was heated under reflux with stirring for twenty-four hours, during which time the solution became bromine-red in color and a precipitate of succinimide formed. After the mixture was cooled to room temperature, the insoluble succinimide was separated on a filter and washed with several portions of hot benzene until the washes no longer gave a positive Baeyer test with potassium permanganate (about 150 ml. of benzene were required). When cool, the combined benzene and carbon tetrachloride solutions deposited an additional small quantity of succinimide which was separated. The clear solution was concentrated by distillation to a volume of 30 ml. and was then placed in a refrigerator for two hours. The crystals of phenylmaleic anhydride which formed were separated and recrystallized from dry acetone–petroleum ether (high boiling); yield 2.1–2.3 g., m. p. 119–120° (reported, 119–119.5°[1]).

After the evaporation of the carbon tetrachloride filtrate to dryness under reduced pressure (water pump) in a two-bulb distillation apparatus, the residue was distilled under reduced pressure (1.0 mm.). At 60–70° a few drops of a yellow liquid were collected; this forerun was discarded. At 130–145° a yellow solid was collected. This material was recrystallized twice from dry acetone–petroleum ether (high boiling) (Norite) to give 2.1–2.3 g. of phenylmaleic anhydride, m. p. 119–120°. From the combined recrystallization filtrates, 0.8–1.0 g. of equally pure product was isolated. The total yield was 5.0–5.6 g. (57–64%).

The percentage yield was slightly lower (53–57%) when four times these amounts were used.

## Displacement-chlorination of Dimethylaminopropanol-2

BY N. L. WENDLER AND M. TISHLER

The reaction of methanesulfonyl chloride with dimethylaminopropanol-2 in an inert solvent was found to give rise to the *o*-mesylate hydrochloride (II) admixed to a greater or lesser extent with the hydrochloride of the propanolamine (I). The *o*-mesylate hydrochloride (II) could be obtained directly and in pure condition by conducting the reaction in a solvent mixture consisting of equal parts of chloroform and acetone.

The *o*-mesylate hydrochloride was titrated with one equivalent of alkali and was converted thereby to the free ester base, characterized as its picrate. When heated above its melting point for a short time the *o*-mesylate hydrochloride was converted smoothly by internal displacement into dimethylamino-2-chloropropane (III). The latter was isolated and identified as its picrate.

$$\underset{\text{(I)}}{CH_3CHOHCH_2N(CH_3)_2} \longrightarrow \underset{\text{(II)}}{CH_3CH(OSO_2CH_3)CH_2NH(CH_3)_2Cl} \xrightarrow{138^\circ} \underset{\text{(III)}}{CH_3CHClCH_2N(CH_3)_2}$$

### Experimental

**Dimethylaminopropanol-2 *o*-Mesylate Hydrochloride.**—To a stirred solution of 10.5 g. of dimethylaminopropanol-2 in 25 cc. of chloroform at 0° was added portion-wise a solution of 12.5 g. of methanesulfonyl chloride in 25 cc. of chloroform. The homogeneous solution was treated with

50 cc. of acetone and stored in the cold for twenty hours. During this time the *o*-mesylate hydrochloride crystallized. The crystals were collected, washed with cold 50% acetone-chloroform and dried in a vacuum desiccator over solid potassium hydroxide; yield 9.5–10 g. (40–45%), m. p. 126.5–128°. A small sample was recrystallized from acetone affording colorless micro-rhombs, m. p. 130–131°.

*Anal.* Calcd. for $C_6H_{16}O_3NSCl$: N, 6.44; Cl, 16.20; neut. equiv., 217.5. Found: N, 6.59; Cl, 16.10; neut. equiv., 226.

A sample of the *o*-mesylate hydrochloride was neutralized with aqueous potassium hydroxide at 0° and the oil which separated was extracted with ether–petroleum ether and dried over solid potassium hydroxide. The filtered solution was concentrated to dryness and the residue was converted to a picrate in ethyl acetate–ether solution. Recrystallization from ethyl acetate–ether afforded the picrate of the *o*-mesylate base as fine yellow needles, m. p. 90–91°.

*Anal.* Calcd. for $C_{12}H_{18}O_{10}N_4S$: C, 35.12; H, 4.39; N, 13.66; S, 7.81. Found: C, 35.39; H, 4.39; N, 13.67; S, 8.53.

**Dimethylamino-2-chloropropane from *o*-Mesylate Hydrochloride.**—*o*-Mesylate hydrochloride (II), 3.8 g., was sealed under vacuum in an ampule and heated in xylene vapor for four hours. The ampule was cooled. The contents were dissolved in an equal volume of water and treated with an excess of 50% aqueous potassium hydroxide solution. The oil which separated was extracted with petroleum ether, dried over solid potassium hydroxide and the solvent evaporated. The residue was converted to its picrate in ethyl acetate–ether solution and recrystallized from the same solvent as fine yellow needles, m. p. 101–103°. A mixed melting point with authentic picrate of dimethylamino-2-chloropropane was undepressed; yield 3.8–4.2 g. (70–75%).

## An Application of the Delépine Reaction to β-Bromopropionic Acid

BY N. L. WENDLER

A modification of the Delépine reaction[1] has been applied to β-bromopropionic acid for its conversion to β-alanine. A quaternary betaine-complex was formed between β-bromopropionic acid and hexamethylenetetramine according to a method applied by Schubert[2] to iodoacetic acid. This complex was subsequently decomposed by hydrochloric acid in ethanol to afford β-alanine in good yield and high state of purity.

$$(CH_2)_6N_4 + BrCH_2CH_2COOH \xrightarrow{HCO_3^-} [(CH_2)_6N_4]^+—CH_2CH_2COO^- \xrightarrow[C_2H_5O^+H_2]{} H_3NCH_2CH_2COOH$$

### Experimental

To a solution of 5 g. of β-bromopropionic acid[3] in 15 cc. of water and 10 cc. of ethanol was added 2.74 g. of sodium bicarbonate. After neutralization was complete, a solution of 4.57 g. of hexamethylenetetramine in 10 cc. of water was added and the resulting solution allowed to stand at room temperature for fifteen hours. At the end of this time, 50 cc. of ethanol was added to the point of faint turbidity followed by scratching, whereupon voluminous crystallization of colorless needles of the betaine-complex ensued. The crystals were chilled in ice for one to two hours and filtered, 9 g. A second crop afforded 0.5 g. yielding a total of 9.5 g. of material.

The betaine-complex (9.5 g.) was treated with 120 cc. of ethanol and 15 cc. of concentrated hydrochloric acid and refluxed for fifteen hours. The mixture was concentrated to dryness *in vacuo* at 50° and the residue extracted with several portions of ethanol. The filtered extract was concentrated to dryness and the residue boiled under reflux with 50–75 cc. of water for one-half hour. The cooled aqueous solution was treated portion-wise with an excess of silver oxide with stirring to remove chloride ion and subsequently filtered, and the filtrate saturated with hydrogen sulfide gas. The precipitated silver sulfide was removed by centrifugation followed by filtration. The colorless solution was concentrated *in vacuo* to a volume of a few cc. and diluted with ethanol to the point of crystallization. After chilling and filtering there was afforded 2.5 g. (85%) of β-alanine, m. p. 199–200° dec. A mixed melting point with known material was undepressed.

## Explosive Properties of Metal Ammines[1]

BY W. R. TOMLINSON, K. G. OTTOSON AND L. F. AUDRIETH

The literature contains numerous references to the explosive nature of certain coördination compounds, but no generalization has thus far been formulated in which an effort has been made to relate chemical composition of such coördination compounds to explosive character. The experimental evidence which is presented below, together with information gleaned from the literature, demonstrates that metal compounds containing (a) coördinated ammonia and related nitrogen-containing donor molecules, and (b) coördinated and/or ionic groups of an oxidizing nature such as perchlorate, chlorate, nitrate, nitrite (or nitrato- and nitro-groups), will decompose violently under various conditions. As is known to be the case among substances classed as explosives, the sensitivity of various coördination compounds to impact, to friction, and to heat will vary widely; nevertheless, some of these same compounds can be caused to detonate when properly initiated. For this reason, due caution should be exercised in the preparation, handling and storage of compounds falling within the categories defined above.

It is significant that "metal nitrates with molecular ammonia" have been incorporated in explosive compositions containing ammonium nitrate as the principal ingredient.[2] Metallic chlorates and perchlorates containing coördinated hydrazine[3] have been found to be brisant and sensitive explosives. Other coördination compounds reported

| TNT (*sym*-trinitrotoluene) | 470 | 95 | 42.0 | .24 | .. | .. |

[a] This compound was unstable. [b] Requires tetryl. [c] Exposure to the temperature cited causes very rapid decomposition, or explosion, in 5 seconds. [d] All oxalates, chromates, carbonates, sulfates, and non-oxygenated complexes tested were non-explosive (*e. g.*, hexammine cobalt(III) chromate, oxalate and chloride). No compounds containing explosive groupings (*e. g.*, azide) were tested. [e] For details of tests see Picatinny Arsenal Technical Report No. 1401, 18 March 1944; Bureau of Mines Technical Bulletin No. 346, "Physical Testing of Explosives" at the Bureau of Mines Explosives Experiment Station, Bruceton, Pa.

to be explosive include: hexammine cobalt(III) chlorite,[4] chlorate,[3] and perchlorate,[3,5] aquopentammine cobalt(III) chlorate and perchlorate,[5] trihydrazine cobalt(II) nitrate,[6] hexahydroxylamine cobalt(III) nitrate,[7] the tetrammineauric halides[8] and trinitrotriammine cobalt.[9] In light of the evidence available in literature, it seems quite probable that the explosions reported to have occurred during evaporation of filtrates from cobalt determinations were caused, as suggested by Broughton, Laing and Wentworth,[10] by the formation of complex nitro- or nitro-cobaltates(III).

Samples of a number of cobalt(III) and chromium(III) coördination compounds[11] were subjected to standard tests to determine explosion temperature, impact sensitivity, power and sensitivity to initiation (ease with which explosion can be effected). Results of these tests are compared in Table I with values for TNT, mercuric fulminate and lead azide, representing respectively a relatively insensitive high explosive and two very sensitive initiating agents.

The data show quite clearly that oxygenated coördination compounds, particularly those which are "oxygen balanced," vary quite widely with respect to their sensitivities to heat and impact. They represent an extremely wide range in explosive types. Since most of the compounds are capable of exploding sharply and powerfully, and in some cases with but slight provocation, they are to be considered exceedingly dangerous. Some possess sufficient sensitivity to propagate explosion under water; the use or presence of non-solvent liquids is therefore no guarantee of safety. In the absence of specific information the same considerations may be expected to apply also to other metal ammines containing oxidizing radicals such as those of silver, gold, cadmium, lead and zinc.

## Preparation of Radioactive $CO_2$ from $BaCO_3$[1]

BY NORMAN ZWIEBEL,[2] JOHN TURKEVICH AND WARREN W. MILLER

To obtain the $C^*O_2$ from $BaC^*O_3$ either for introduction into a reaction system for synthesis of a

(1) Work done at the Brookhaven National Laboratory under the auspices of the Atomic Energy Commission. The work was started by one of us (W. W. M.) while a member of the Laboratory of Nuclear Science, Massachusetts Institute of Technology.
(2) Present address: Pyridium Corporation, Yonkers, New York

labeled compound, or for transfer to a gas activity measuring device such as an ionization chamber or gas counter, it has been common practice to drop either concentrated phosphoric or sulfuric acid on the $BaCO_3$.[3] This procedure often involves the use of a stopcock in contact with concentrated acid, does not permit the ready attainment of high vacuum and may entail the formation of a crust of insoluble barium sulfate or phosphate around the active barium carbonate. In practice a still more disconcerting factor has been the spattering of the dry powder on contact with acid with the consequent sweeping of a portion of the sample out of the reaction vessel by the evolving gas. The direct thermal evolution of the $C^*O_2$ from $BaC^*O_3$ by roasting the dry salt in a quartz tube has also been used[4] but the temperature necessary is inconveniently high.

These difficulties may be surmounted by using a thermal reaction between dry solids to evolve the carbon dioxide. Acids such as potassium bisulfate are unsuitable as the reaction will produce water as well as carbon dioxide. Inorganic acid anhydrides such as boric oxide and the pyro salts melt at too high a temperature to be used in Pyrex apparatus. Organic anhydrides sublime under vacuum. A convenient reaction, however, is a metathetic one producing a thermally unstable carbonate such as the reaction between barium carbonate and lead chloride. Lead chloride was used because it can be readily obtained in an anhydrous state, and has a low melting point and vapor pressure. Silver chloride can also be used.

To obtain the total carbon dioxide from a barium carbonate sample, two procedures have been worked out. In the micro-procedure the weighed barium carbonate, from 5 to 200 mg., is dropped into a Pyrex test-tube with attached ground joint. Over this is layered 5 to 10 times its weight of dry powdered lead chloride, and then a wad of glass wool is pushed down on top. After attaching the tube to the vacuum system and pumping at 100°, the carbon dioxide is released by carefully melting the lead chloride with a micro burner. The reaction is known to be at least 98% complete from gas buret and activity measurements. The fusion temperature may be lowered by using a 50–50 mixture of $PbCl_2$–AgCl instead of pure lead chloride. The melt should not fill a full diameter of the reaction vessel or the latter may crack on cooling. For macro-quantities we have employed the following procedure. The two solids, one part by weight of barium carbonate and six parts by weight of lead chloride, were intimately mixed and ground together before placing the mixture in a reaction tube. The latter was connected to a standard vacuum system by means of a stopcock and a standard taper ground glass joint. The reaction mixture was pumped overnight at room temperature to a pressure of $10^{-5}$ mm. A tubular woven glass heating mantle was used as a heat source and the temperature was controlled by a Variac. Evolution of gas began at about 180° and each increment of temperature caused a more rapid evolution of gas which gradually decreased with time. It was found that the most convenient procedure was to raise the temperature to 400° as rapidly as possible (about twenty-five minutes) and maintain the reaction mixture at this temperature. The evolution of carbon dioxide was 65% complete in one hour from the start of heating, 80% in two hours and 96% complete in four hours. 3–9 g. of barium carbonate was employed in these experiments. Thus this reaction has been found to proceed at temperatures well below the fusion temperature and the system may therefore be used as a convenient, clean, "virtual" source of active carbon dioxide.

# COMMUNICATIONS TO THE EDITOR

## METALLIC ALUMINUM IN SOLUTION IN LIQUID AMMONIA

*Sir:*

It has long been generally accepted that the alkali metals, in dissolving in liquid ammonia, dissociate into alkali metal cations and free (solvated) electrons,[1] and that the latter impart the characteristic blue color to such solutions. The alkaline earth metals are known to dissolve similarly, although to a smaller extent.[2] Makishima[3] included the dissolution of electrons among electrode reactions which may occur at a cathode in liquid ammonia solutions, and Laitinen and Nyman[4] have very recently pointed out that, theoretically, all metals should be in some degree soluble in liquid ammonia. According to the hypothesis

of these latter authors, however, the solubility of metals less active than calcium should be exceedingly small.

On the basis of the reaction of metallic aluminum with solutions of alkali metal amides in liquid ammonia, Bergstrom[5] postulated that aluminum must be soluble in this solvent to a slight extent. There is no record in the literature, however, of any actual observation of a blue solution of metallic aluminum in ammonia, although Booth and Merlub-Sobel,[6] in a study of the electrolysis of aluminum iodide, reported the formation at the cathode of a transitory blue-black film which they suggested might be a subiodide or subnitride of aluminum.

In the course of an investigation, recently begun in this Laboratory, of the anodic oxidation of aluminum in solutions of various salts in liquid ammonia, we have carried out several electrolyses with aluminum iodide as electrolyte. In every such case, we have observed the appearance, in the immediate vicinity of the *cathode*, of a deep blue color. This color is at first impermanent, disappearing upon diffusion into the body of the solution with the concurrent formation of a white precipitate, and being regenerated at the cathode. On prolonged electrolysis, however, the rate of disappearance gradually decreases, and the entire solution eventually becomes dark blue. The most striking results were obtained in a solution containing 0.3 g. of aluminum iodide in 48 g. of ammonia, which was electrolyzed at $-33°$ in an atmosphere of nitrogen between a bright platinum cathode and a chemically pure aluminum anode, at a cathode current density of about 0.01 amp. per sq. cm.

We are unable to account for these results in terms of any hypothesis other than the following. The cathode reaction appears to consist of the dissolution of electrons, which are able to exist in the presence of a considerable concentration of $Al^{+++}$ ion. The blue solute, consisting therefore of ionized metallic aluminum, at first reacts rapidly with the solvent, liberating hydrogen and yielding an insoluble white derivative of aluminum amide; subsequently, however, the rate of this reaction decreases, so that an appreciable concentration of aluminum metal is able to persist in the solution for as much as fifteen minutes after the current is discontinued.

This phenomenon is being studied further, and will later be the subject of a more complete report.

## A NOVEL REACTION IN ORGANIC CHEMISTRY

*Sir:*

In connection with studies designed to develop a new approach to ring enlargement of cyclic ketones, an interesting new reaction has been discovered. When 3-nitroso-1-oxa-3-azaspiro[4,5]-decan-2-one, III, is treated with alkali, nitrogen is evolved immediately and hexahydrobenzaldehyde is produced. This aldehyde has been isolated in over 50% yield as the semicarbazone,[1,2] m. p. 172–173° after sintering at 166°.

The nitroso compound was prepared by the following series of reactions

Further studies as to the generality and mechanism of this reaction are under way in this Laboratory.

The author wishes to acknowledge a grant from the Research Corporation which has greatly assisted in this work.

**Hydrazide of 1-Cyclohexanolacetic Acid, I.**—This compound, m. p.[3] 102.2–104.4°, was prepared in 78% yield.

*Anal.* Calcd. for $C_8H_{16}O_2N_2$: C, 55.8; H, 9.4; N, 16.3. Found: C, 55.6, 55.8; H, 8.9, 8.7; N, 16.3, 16.4.

**1-Oxa-3-azaspiro[4,5]decan-2-one, II.**—The hydrazide, I, was dissolved in dilute hydrochloric acid and treated with a slight excess of sodium nitrite at 10–15°. The reaction mixture containing the resulting oily azide was slowly heated to 45° when decomposition began. Rapid stirring and temp. control near 50° are necessary to prevent violent decomposition. The cyclic urethan,[4] II, was isolated in 82% yield as colorless crystals, m. p. 101.0–102.4°.

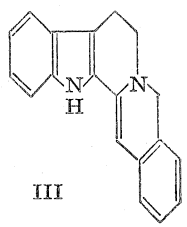
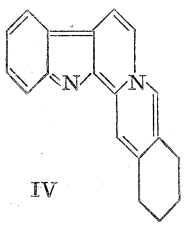
## THE STRUCTURE OF SEMPERVIRINE

*Sir:*

The alkaloid sempervirine, $C_{19}H_{16}N_2$, from *Gelsemium sempervirens*, Ait., is remarkable for its color and its high degree of unsaturation. In a recent elegant investigation, Prelog[1] has shown that the substance is transformed to the isomeric yobyrine (I, R = H) when heated with selenium, and to tetrahydroisoyobyrine (II) on treatment

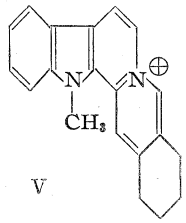


I

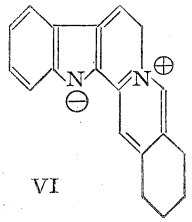


II

with Raney nickel. These results led to the proposal of structure (III) for sempervirine.



III



IV

We wish to propose a new structure (IV) for the alkaloid. In our view, the new formula is better in accord with the color of sempervirine, and with the formation from it of tetrahydroisoyobyrine. Beyond that we have been able to marshal new facts which provide further strong support for (IV). Thus, (i) the infrared spectrum of sempervirine *contains no band in the NH region*, while by contrast, all N-unsubstituted indole derivatives are characterized by an intense sharp band at 2.9 $\mu$; (ii) when sempervirine methochloride is heated with selenium, a new base, m. p. 103° [hydrochloride, m. p. 229°, picrate, m. p. 235°, (calcd. for $C_{26}H_{21}O_7N_5$: C, 60.58; H, 4.11. Found: C, 60.38; H, 4.15)], is formed, which is clearly N-methylyobyrine (I, R = Me), since its ultraviolet spectrum is nearly identical with that of yobyrine, and its infrared spectrum possesses no NH band.[2] These observations support the view that the metho-salts of sempervirine contain the cation (V). The expression IV implies of

V

VI

course an important contribution of the fully aromatic ionic structure (VI). Consideration of this fact makes understandable the formation of metho-salts of the structure (V), as well as the color of the alkaloid, and its high basicity ($pK_a$ 10.6). The formation from sempervirine of a mole of methane in the Zerewitinow determination can be attributed to the presence in (IV ⟷ VI) of a virtual (substituted) $\gamma$-picolinium system.

We wish to thank M. Raymond-Hamet (Paris) and Professor M.-M. Janot for their gracious gifts of sempervirine.

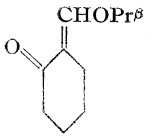
## THE SYNTHESIS OF SEMPERVIRINE METHOCHLORIDE

*Sir:*

It has been suggested on the basis of analytical and degradative evidence that the alkaloid sempervirine possesses the remarkable structure I ⟷ Ia.[1] We have now been able to provide conclusive evidence for the proposed structure through the synthesis of sempervirine metho-salts by an unambiguous route.

I ⟷ Ia



In model experiments, the lithium derivative of $\alpha$-picoline was condensed with isopropoxymethylene cyclohexanone[2] (II) [b. p. 64–65° (0.2 mm.), $n^{26}D$ 1.4980, calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.18; H, 9.40]. From the acid-treated reaction-mixture, salts of the dehydroquinolizinium cation (III) were readily obtained (picrate, m. p. 237–238°, calcd. for $C_{19}H_{16}O_7N_4$: C, 55.34; H, 3.91; N, 13.59. Found: C, 55.41; H, 4.17; N, 13.36; per-

chlorate, m. p. 187.1–187.8°, calcd. for $C_{13}H_{14}O_4NCl$: C, 55.05; H, 4.97. Found: C, 55.12; H, 5.05).

In a similar reaction, the use of the lithium derivative of N-methylharman[3] (IV) led to the smooth synthesis of salts of the methylsempervirinium cation (V). Synthetic samples of sempervirine methopicrate, m. p. 239–240°, and sempervirine methochloride, m. p. 330–332°, showed no depression in melting point on admixture with the corresponding salts of identical melting points prepared from natural sempervirine. The identity was further confirmed through the reproduction by synthetic sempervirine methochloride of the very characteristic ultraviolet absorption behavior of the salt from the natural alkaloid [$\lambda\lambda_{max.}$ (log $\epsilon$): 241 (4.56), ~250 (4.49), 292 (4.20), 330 (4.28), 395 (4.22); $\lambda\lambda_{min.}$ (log $\epsilon$): 280 (4.14) 305 (4.09), 365 (4.10)].

(3) *Cf.* Späth and Lederer, *Ber.*, **63**, 2102 (1930). Our material was made from N-methyltryptophan, which was itself prepared very smoothly by a new synthesis analogous to that used by Warner and Moe (THIS JOURNAL, **70**, 2766 (1948)) for the preparation of tryptophan. Our melting point (285°) for N-methyltryptophan agrees wth that (289°) of Wieland, Konz and Mittasch (*Ann.*, **513**, 23 (1934)) rather than that (225°) recently reported by Snyder and Eliel (THIS JOURNAL, **70**, 3855 (1948)).

# NEW BOOK

**Microdiffusion Analysis and Volumetric Error.** By EDWARD J. CONWAY, M.B., D.Sc., Professor of Biochemistry, University College, Dublin, and Member of the Royal Irish Academy. Crosby Lockwood and Son, Ltd., 20 Tudor Street, London, E. C. 4, England, 1947. xix + 357 pp. Illustrated. 14 × 22.5 cm. Price 21/- net.

Although the literature shows an ever-increasing application of the microdiffusion principle, the lack of a general description of the technique in books on methodology makes this detailed and carefully written book especially valuable.

Conway was the first to develop the microdiffusion technique to a point where full advantage is taken of the simplicity, accuracy and convenience inherent in this method. By eliminating distillation or aeration in the determination of volatile substances, labor, apparatus and time are saved particularly in serial analyses. It may surprise many that the diffusion time in the micro-ammonia procedure, for example, may be less than thirty minutes and that the accuracy is equal to that of the macro procedure.

The book is divided into three sections. The first deals with the design of the diffusion cell and the factors governing the rate of diffusion. The second section describes critically and in detail most of the published applications of the microdiffusion principle. The last section discusses the factors influencing variable error in volumetric analysis and establishes a rational basis for maintaining macro accuracy in micro procedure. This discussion should be of value to all analysts who wish to maintain given standards of accuracy in volumetric analysis.

# GIUSEPPE BRUNI

## 1873–1946

BY MARIO A. ROLLIER

Twenty-five years ago, in 1923, the chemists of Yale, Columbia and Ohio Universities, as well as of the Mellon Institute, had the opportunity to hear through the living voice of Giuseppe Bruni a series of lectures[1] which he delivered on "Solid Solutions."

Starting from van't Hoff's theories, Bruni in his lectures gave an extremely cogent exposition of all that was known on the solubility in the solid state at that time and which had been in large part due to his own contributions. He treated the subject from the several points of view of the diffusion in the solid state, the heat of formation of solid solutions, their constitution and the applicability of the laws of solutions to solid solutions. In these lectures and the resulting monograph Bruni condensed the results of twenty-five years of study, research and widespread scientific coöperation on the subject.

Having thus pointed out what is Bruni's chief claim to be remembered in the chemical world, it is timely to add something on his very brilliant scientific and academic career. Bruni was born on August 25, 1873, in Parma (Northern Italy). Immediately after he received his doctor's degree at Parma in 1896, he entered the best Italian School of Chemistry of that period, the Institute of Ciamician at Bologna University, the general trend of his research being already chosen (isomorphism and solid solutions) in his first paper. He remained with Ciamician for ten busy and quiet years, only interrupted by his trip to Germany and the long visit he paid to van't Hoff at Wilmersdorf in 1900–1901. During this decade he had the opportunity of applying the phase rule to the field of concentrated solid solutions, reaching the same results which Bakhuis–Roozeboom had arrived at independently, and gave proof of his clear and synthetic mind in a monograph on the general subject of his research, published in Germany in 1908 under the title "*Feste Lösungen und Isomorphismus.*" A few years before van't Hoff had occasion to pay a tribute to Bruni's contribution in this field, stating:

*Ce savant a contribué d'une partie prépondérante à l'adoption des lois sur les solutions solides et les mélanges isomorphes, qui, sans son intervention auraient été troublées par des notions confuses.*

Many years before Bragg and Laue's discoveries opened the road to modern structural chemistry, Bruni had already said that the distinctive function of the chemist, as compared with the physicist and the mineralogist, was to discover and explain chemical constitution and to use all the available data in the fields of isomorphism, crystallography, energetics, etc., to solve chemistry's central problem, namely, from physical properties of a substance to deduce and to predict the constitution and the actual position of atoms inside its molecules. What already had been van't Hoff's was also Bruni's chief concern: the position of

(1) Published with the same title in *Chem. Rev.*, I, No. 4, January, 1925, page 345.

atoms in space (*Die Lagerung der Atome im Raume*).

In 1907 Bruni was called to the University of Padua as full Professor of General and Inorganic Chemistry, and there he taught and worked for another active decade, advocating in the dispute between the "atomists" and the "energetists," the real existence of atoms and issuing accurate and valuable papers on diffusion in the solid state both in alloys and in ionic salts, and on the limits of validity of the cryoscopic method. The same year he became one of the founders of the periodical of scientific synthesis called "SCIENTIA" in which he was able to secure the active collaboration of such scientists as Russell, van't Hoff, Arrhenius, Nernst, Langevin, Poincaré, Ciamician and many others.

During World War I Bruni entered the arena of industrial chemistry, being first appointed chief consulting chemist and then chief of the Research Laboratories of "Pirelli," the rubber and tires manufacturing company. This appointment was connected with his discovery of ultra-accelerators for rubber vulcanization. Bruni's process of rapid, cold vulcanizing (1919) is based on the formation inside the rubber of N,N-diphenylthiourea (thiocarbanilide) bringing carbon disulfide to act on aniline in the presence of sulfur and zinc oxide. A few months later W. Bedford and W. Scott were obtaining the same results in the Goodyear Laboratories starting from piperidine instead of from aniline.

After the end of the war Bruni traveled extensively on behalf of the Pirelli Company, visiting Java and Malacca in 1921 and, in 1923 staying for a rather long time in the United States where he made connections which he held very dear and which he liked to recall, such as his acquaintance with Dr. Charles L. Parsons, the former Secretary of the American Chemical Society.

To the same period belongs one of the most important achievements of Bruni's scientific leadership: prepared as he was by his past works, he saw the decisive importance of X-ray investigations for the knowledge of the solid state. He sent Professor G. R. Levi, then his assistant, to Professor Debye in Zurich, and shortly thereafter the first laboratory equipped with all the necessary tools for X-ray structural research was operating in Italy at the Polytechnic School of Milan, whither in the meantime Bruni had been called as Professor of General and Inorganic Chemistry. For a little over twenty-five years Bruni was to teach chemistry at this Polytechnic School of Milan, an organization which, though on a smaller scale, comes nearest to something like the Massachusetts Institute of Technology.

Bruni is thus to be regarded as the founder of the Italian school of structural chemistry, to which scientists like G. R. Levi, G. Natta and A. Ferrari, all of them Bruni's students, belong, and which has done good and valuable work and has kept pace, under Bruni's influence and advice, with the developments of the newer techniques of structural research (electron diffraction, infrared spectra, dipole measurements, etc.).

Bruni was extremely brilliant in controversies involving industrial patents. His acute judgment was blended with humor and his advisory help was in great demand both in Italy and abroad. From his experience in this field, in his later years he turned his attention to the problems of intellectual property and in 1935–41 he published a series of papers on patent law, urging international recognition of the principle that "the inventor should have the right to patent an invention *even* if preliminary publications *by him* on the same subject were already circulating in the technical literature" and struggling for the introduction of the "provisional specification" in the Italian patent law.

Two months before Bruni died (January 3, 1946) he sent to the editors of "SCIENTIA" his last contribution, a letter on the large-scale use of nuclear energy in the atomic bomb, in which he hailed the event as the true beginning of a new era upsetting the balance of natural power at the disposal of mankind and scoffed with his customary clear-sightedness at the claims of "secrecy," all the secrecy being a question of industrial development and the theoretical basis of the large-scale transformation of nuclear in lower forms of energy being known. Though still without any connections with scientists of the western world, because of the war, he joined them in their deep concern about nuclear energy, writing:

> By far the most important problem is not that of the industrial applications of atomic energy but another one, which may be looked at with great anxiety. Will not the release of these formidable forces have a general and permanent influence on the world's economic arrangement, on its overall balance, both material and energetic, and on its evolution?

A question certainly yet unanswered.

Bruni earned many recognitions of his high scientific merit. He was awared the King's Prize for Chemistry by the *Academia dei Lincei* in 1913 and was elected a member of the same Academy in 1917. He was a member of the American Chemical Society from 1912, and in 1924 was elected (the only Italian) an Honorary Member of that body. He was a member of many other scientific societies and academies, as well as a member of the Board of Directors and Chairman of the Patent Committee of International Latex Processes Limited.

Bruni's participation in the public life of his country (he was a member of Parliament from 1929 on and was nominated Senator by the King early in 1943) was to end in sheer bitterness because, owing to his awareness and acute sense of responsibility, he foresaw the outcome of many absurdities he was witnessing but was unable to avail against them because his spirit of tolerance and moderation went unheeded in that tragic period. When the dictatorship collapsed in July,

1943, soon to be followed by the collapse of the monarchy, Bruni retired to strictly private life, but the writer received many demonstrations of his sympathy for the new birth of democracy in his country. Bruni's last concern and last working effort in the summer of 1945 were for his book, a treatise on general and inorganic chemistry for student use. In the foreword of the last edition, Bruni had written:

I give this book to the printer not without emotion because, thus enlarged and completed, it represents my scientific legacy.

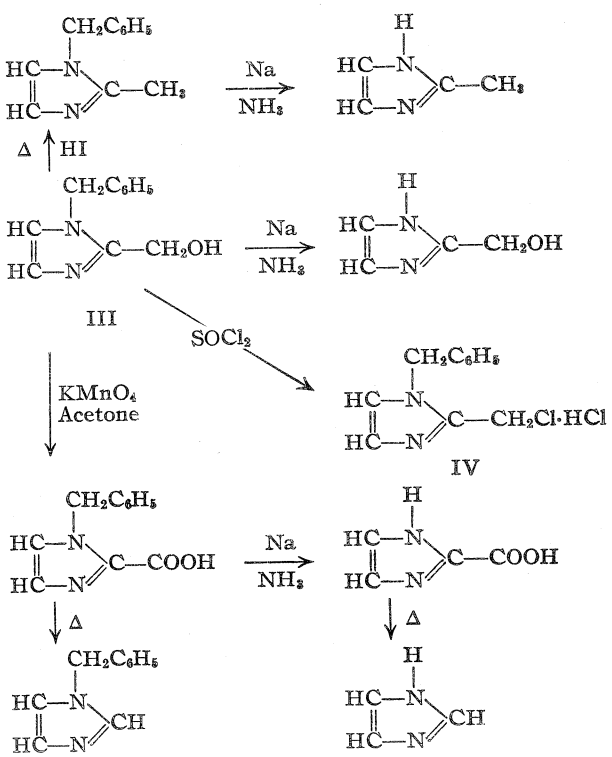
# Studies on Imidazole Compounds. I. A Synthesis of Imidazoles with Functional Groups in the 2-Position

BY REUBEN G. JONES

In connection with a broad study of possible relationships of chemical structure to biological activity, it was of interest to prepare the isomer (I) of histamine and the isomer (II) of histidine in which the side chains were attached to the 2-position of the imidazole nucleus.

These compounds have been synthesized by a method which appears to be generally applicable to the preparation of a variety of 2-substituted imidazoles. A number of other new members of this little-known class of compounds are also reported at this time.



It has been shown[1a,b,c] that certain imidazoles having a methyl group in the 1-position will condense with formaldehyde to yield the corresponding 2-hydroxymethylimidazoles. These compounds can then be converted to a variety of other derivatives.[1b] In the present investigation 1-benzylimidazole has been used as the starting material. When heated with an excess of aqueous formaldehyde, 1-benzylimidazole gave an almost quantitative yield of 1-benzyl-2-hydroxymethylimidazole (III) which was isolated easily as the crystalline hydrochloride. Proof that the hydroxymethyl group entered the 2-position was provided by hydriodic acid reduction of the compound to yield 1-benzyl-2-methylimidazole. This was dissolved in liquid ammonia and treated with sodium to remove the benzyl group according to the method of du Vigneaud and Behrens.[2] The known 2-methylimidazole was thus obtained. It was found that in general these 1-benzylimidazoles are easily debenzylated by the sodium–liquid ammonia method. On the other hand one attempt to cleave the benzyl group by catalytic hydrogenolysis[3] did not meet with success.

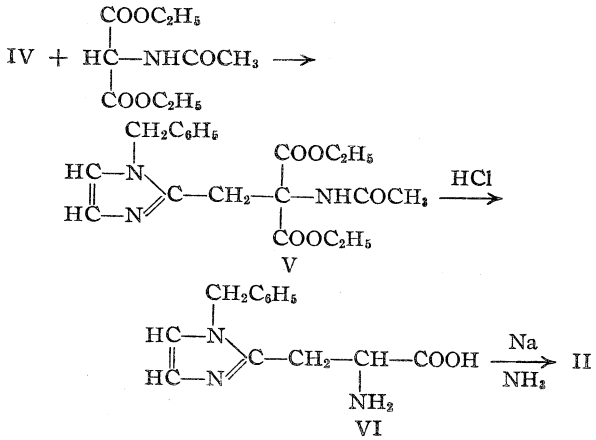
(2) du Vigneaud and Behrens, *J. Biol. Chem.*, **117**, 27 (1937).

(3) Cirkofer, *Ber.*, **75**, 429 (1942).

A number of transformations of 1-benzyl-2-hydroxymethylimidazole (III) are outlined in the reactions



For the synthesis of 2-β-aminoethylimidazole (I), 1-benzyl-2-chloromethylimidazole (IV) was converted to 1-benzyl-2-cyanomethylimidazole. This compound underwent smooth reduction with

lithium aluminum hydride[4] to give 1-benzyl-2-β-aminoethylimidazole which was debenzylated to yield (I).

The amino acid (II) was prepared from (IV) *via* acetamidomalonic ester.[5] The substituted malonic ester (V) was obtained as a sirup which was hydrolyzed directly with hydrochloric acid to form 1-benzyl-2-imidazolealanine (VI). Debenzylation of (VI) with sodium and liquid ammonia led to the desired 2-imidazolealanine (II).

1-Benzyl-2-chloromethylimidazole (IV) underwent normal condensation with sodium malonic ester. The resulting product was converted to 1-benzyl-2-β-carbethoxyethylimidazole which was debenzylated to yield 2-β-carbethoxyethylimidazole.

## Experimental

**1-Benzyl-2-mercaptoimidazole.**—N-Benzylaminoacetal was prepared in 80–85% yield by heating benzylamine with chloroacetal according to the method of Rügheimer and Schön[6] except that a threefold excess of benzylamine was used.

To a mixture of 223 g. (1.0 mole) of N-benzylaminoacetal, 95 g. (1.17 mole) of sodium thiocyanate and 500 ml. of 50% aqueous alcohol was added with stirring 100 ml. (1.2 mole) of 12 *N* hydrochloric acid. The resulting mixture in an open beaker was heated on the steam-bath for five hours during which time most of the alcohol evaporated leaving a violet colored, water insoluble, crystalline mass. The product was dissolved in sodium hydroxide solution. The solution was treated with carbon, filtered and acidified with hydrochloric acid to yield 165 g. (87%) of 1-benzyl-2-mercaptoimidazole. A sample for analysis was recrystallized from ethyl acetate; m. p. 144–145°.

*Anal.* Calcd. for $C_{10}H_{10}N_2S$: N, 14.74. Found: N, 14.75.

**1-Benzylimidazole.**—1-Benzyl-2-mercaptoimidazole (165 g., 0.87 mole) was added in portions to a stirred solution of 200 ml. of concentrated nitric acid in 500 ml. of water maintained at 40–50° by cooling in an ice-bath. When the reaction was complete, the solution was treated with 300 ml. of 12 *N* sodium hydroxide solution. The mixture was extracted with chloroform. The brown oil which remained after evaporation of the dried chloroform solution was distilled at reduced pressure to give 120 g. (87.5% yield) of 1-benzylimidazole; b. p. 187–189° (25 mm.), 166–167° (13 mm.); m. p. 71–72° (lit.[7] 70–71°). The picrate, recrystallized from water, melted at 75–76°.

*Anal.* Calcd. for $C_{16}H_{13}N_5O_7$: N, 18.20. Found: N, 18.00.

**1-Benzyl-2-hydroxymethylimidazole** (III).—A solution of 28 g. (0.177 mole) of 1-benzylimidazole in 45 g. of 40% formalin in a sealed Carius tube was heated at 140° for six hours. The tube was opened, and the colorless liquid was washed out with methanol. The methanol solution was evaporated *in vacuo* on the steam-bath leaving a viscous, colorless sirup which did not crystallize after standing for several days. The sirup was taken up in 100 ml. of alcohol, 25 ml. of 12 *N* hydrochloric acid was added, and the solution was evaporated to dryness in vacuum. The white crystalline residue was dissolved in 100 ml. of boiling absolute alcohol. The solution was cooled somewhat, 200 ml. of anhydrous ether added, then the mixture was chilled. The resulting crystalline product weighed 34.5 g. after air drying, and by working up the filtrate an additional 3.0 g. was obtained bringing the total yield of 1-benzyl-2-hydroxymethylimidazole hydrochloride to 37.5 g. (94.5%), m. p. 159–160°. A sample of the hydrochloride obtained from the picrate (see below) melted at 161.5–162°.

*Anal.* Calcd. for $C_{11}H_{12}N_2O\cdot HCl$: N, 12.47. Found: N, 12.55.

Equally good yields of the 2-hydroxymethyl compound were obtained by heating the 1-benzylimidazole–formalin mixture at 110–120° for fifteen hours instead of 140° for six hours.

1-Benzyl-2-hydroxymethylimidazole picrate obtained in 85% yield from the sirupy free base and hot aqueous picric acid melted at 132–133° after recrystallization from water.

*Anal.* Calcd. for $C_{17}H_{15}N_5O_8$: N, 16.78. Found: N, 16.72.

**1-Benzyl-2-methylimidazole and 2-Methylimidazole.**—A mixture of 10.0 g. (0.045 mole) of 1-benzyl-2-hydroxymethylimidazole hydrochloride, 1.3 g. of red phosphorus and 25 ml. of hydriodic acid (sp. gr. 1.7) in a sealed tube was heated at 160° for five hours. The contents of the tube were filtered, and the clear colorless filtrate was evaporated to a sirup. This was treated with excess 12 *N* sodium hydroxide solution and the mixture extracted with benzene. After drying over sodium carbonate the benzene was distilled and the residual product distilled *in vacuo* to yield 6.5 g. (85%) of 1-benzyl-2-methylimidazole as a colorless viscous liquid b. p. 125–127° (3 mm.). The picrate crystallized from water as bright yellow needles; m. p. 153–154°.

*Anal.* Calcd. for $C_{17}H_{15}N_5O_7$: N, 17.45. Found: N, 17.70.

To a solution of 6.0 g. (0.035 mole) of the above 1-benzyl-2-methylimidazole in 150 ml. of liquid ammonia was added sodium metal in small pieces until a permanent blue color was formed. This required 1.7 g. of sodium. The mixture was treated with 5 g. of ammonium chloride, and, after the ammonia had been removed by gentle warming, the residue was extracted with 200 ml. of hot benzene. Evaporation of this solution left 2.65 g. (92.5% yield) of 2-methylimidazole, m. p. 130–132°. The crude product was sublimed *in vacuo* and then recrystallized from benzene–petroleum ether to give white needles melting at 140–141°. Authentic 2-methylimidazole melted at 140.5–141.5° (lit.[8] 136–137°), and the mixed melting point was also 140.5–141.5°.

**2-Hydroxymethylimidazole.**—A solution of 19 g. (0.10 mole) of the crude sirupy 1-benzyl-2-hydroxymethylimidazole in 150 ml. of liquid ammonia was treated with small pieces of sodium metal until a permanent blue color was formed (6.8 g. of sodium). Then 25 g. of ammonium

chloride was added in small portions after which the mixture was allowed to evaporate to dryness. The residue was extracted with 200 ml. of boiling absolute alcohol. This solution was evaporated *in vacuo* to about 50 ml., filtered and the filtrate evaporated *in vacuo* to yield a sirup which could not be induced to crystallize. The sirup was dissolved in 25 ml. of water, and this solution was added to a hot solution of 25 g. of picric acid in one liter of boiling water. Nothing separated when the solution was cooled to room temperature, but after standing overnight 19 g. of large cubic crystals was deposited. This product, m. p. 144–145°, was recrystallized from 100 ml. of absolute alcohol to yield 15.5 g. (47.5%) of 2-hydroxymethylimidazole picrate as yellow needles, m. p. 151–152°.

*Anal.* Calcd. for $C_{10}H_9N_5O_8$: N, 21.41. Found: N, 21.42.

A mixture of 15.0 g. (0.046 mole) of the above picrate, 25 ml. of nitrobenzene and 25 ml. of 6 *N* hydrochloric acid in a small separatory funnel was shaken until all solid had dissolved. The nitrobenzene layer was drawn off, and the aqueous solution was washed with four 25-ml. portions of chloroform. The water solution was evaporated to dryness *in vacuo*. To the residue was added 50 ml. of absolute alcohol and again the mixture was evaporated to dryness *in vacuo* at 100°. The residue was dissolved in 25 ml. of hot absolute alcohol, and this solution was diluted with dry ether whereupon 6.1 g. (98% yield) of 2-hydroxymethylimidazole hydrochloride separated as white needles; m. p. 111–113°. The product was not hygroscopic.

*Anal.* Calcd. for $C_4H_6N_2O{\cdot}HCl$: N, 20.82. Found: N, 20.80.

**1-Benzyl-2-imidazolecarboxylic Acid.**—A solution of 19 g. (0.10 mole) of crude 1-benzyl-2-hydroxymethylimidazole in 200 ml. of acetone was cooled in an ice-bath and stirred while 22 g. (0.14 mole) of 100-mesh potassium permanganate was added in small portions during one-half hour. The temperature was maintained at 5–10°, and the mixture was stirred for one additional hour. The acetone was removed by evaporation at reduced pressure and the black residue was extracted with two one-liter portions of hot water. Evaporation *in vacuo* of the water solution left a white solid. The product was washed with chloroform and then recrystallized from absolute alcohol–ether to yield 13 g. of white crystalline solid which appeared to be a hydrated potassium salt; m. p. 94–96° with shrinking at 75–80°. No satisfactory analyses were obtained.

The above salt (12.0 g.) was dissolved in 20 ml. of water and the clear solution was treated with concentrated hydrochloric acid until the *p*H was about 2.0. The crystalline precipitate was collected on a filter and air dried. It weighed 9.5 (43% yield); m. p. 103–104° (dec.). A sample recrystallized from water melted at 106° (dec.). The analytical sample was dried *in vacuo* at 60° for one hour.

*Anal.* Calcd. for $C_{11}H_{10}N_2O_2.H_2O$: N, 12.72; neut. equiv., 220.2. Found: N, 12.54; neut. equiv., 213.

The acid decarboxylated very readily at the melting point, and even in hot water it slowly evolved carbon dioxide. A 1.0 g. portion was decarboxylated by melting, and the resulting product was sublimed *in vacuo* to yield 0.79 g. (99%) of 1-benzylimidazole, m. p. 72–73°; mixed with an authentic sample, m. p. 72–73°.

**2-Imidazolecarboxylic Acid.**—In 50 ml. of liquid ammonia was suspended 4.4 g. (0.02 mole) of 1-benzyl-2-imidazolecarboxylic acid monohydrate. Sodium in small pieces was added until a permanent blue color resulted (1.0 g. of sodium). The blue color was discharged with a little ammonium chloride, and the solution was evaporated to dryness, finally by gentle warming *in vacuo*. The residue was taken up in 25 ml. of water. The cloudy solution was stirred with a little carbon, filtered and acidified to *p*H 2.0 with concentrated hydrochloric acid. Soon the 2-imidazolecarboxylic acid separated as silvery platelets which, after cooling the mixture for one hour in an ice-bath, were collected on a filter and air dried. The yield was 1.95 g. (87%). A sample recrystallized from 80% alcohol melted at 163–164° (dec.).

*Anal.* Calcd. for $C_4H_4N_2O_2$: N, 25.00; neut. equiv., 112.09. Found: N, 24.53; neut. equiv., 113.5.

A 0.2 g. sample of the acid in a sublimation apparatus was heated until decarboxylation was complete, and the resulting imidazole was sublimed *in vacuo*. The yield was 0.1 g., m. p. 85–86°. A mixture with authentic imidazole melted at 87–88°.

**1-Benzyl-2-chloromethylimidazole (IV).**—To 60 ml. of thionyl chloride was added in small portions 68 g. (0.30 mole) of 1-benzyl-2-hydroxymethylimidazole hydrochloride. Reaction took place immmediately with heat evolution, and a clear solution resulted. The solution was heated on the steam-bath for fifteen minutes, and then the excess thionyl chloride was distilled under reduced pressure on the steam-bath. The residual crystalline 1-benzyl-2-chloromethylimidazole hydrochloride was washed with dry ether and air dried. It weighed 73 g. (100% yield), m. p. 181–182°.

*Anal.* Calcd. for $C_{11}H_{11}N_2Cl{\cdot}HCl$: N, 11.53; Cl, 29.17. Found: N, 11.76; Cl, 28.86.

**1-Benzyl-2-cyanomethylimidazole.**—A solution of 90 g. of potassium cyanide in 100 ml. of water was cooled to 5° and with continuous stirring a solution of 37 g. (0.15 mole) of 1-benzyl-2-chloromethylimidazole hydrochloride in 250 ml. of absolute alcohol was added during a period of one hour. The mixture was stirred at room temperature for three hours, then filtered and the salt washed with two 200-ml. portions of alcohol. The total filtrate was evaporated *in vacuo* to small volume and extracted with three 300-ml. portions of chloroform. The chloroform solution was washed with dilute sodium hydroxide solution, dried over magnesium sulfate and evaporated to dryness *in vacuo*. A brown oil remained which quickly crystallized. This crude product which melted over the range 65–80° was dissolved in 150 ml. of hot absolute alcohol and to it was added a solution of 35 g. of picric acid in 150 ml. of hot absolute alcohol. A brown oil separated which soon crystallized. The mixture was cooled to 70°, and the 1-benzyl-2-cyanomethylimidazole picrate was collected on a filter. It was washed by suspension in 100 ml. of warm absolute alcohol and air dried. The yield was 17.5 g. (27.5%), m. p. 160–162°.

In other runs lower temperatures and longer reaction periods were employed, but the yield could not be improved.

The above picrate was soluble in acetone or chloroform, sparingly soluble in absolute alcohol, insoluble in boiling water. A sample recrystallized from absolute alcohol melted at 166–167°.

*Anal.* Calcd. for $C_{18}H_{14}N_6O_7$: N, 19.72. Found: N, 19.48.

The picrate (23 g., 0.054 mole) was rubbed to a fine powder and placed in a separatory funnel with 160 ml. of nitrobenzene and 100 ml. of cold 6 *N* hydrochloric acid. The mixture was vigorously shaken until all solid had disappeared. After the nitrobenzene layer had been separated the aqueous solution was washed with three 75-ml. portions of chloroform. The nitrobenzene and chloroform solutions were then extracted with another 50 ml. portion of cold 6 *N* hydrochloric acid. The combined hydrochloric acid solution was immediately neutralized with excess sodium carbonate. The resulting mixture was extracted with four 50-ml. portions of chloroform. This chloroform extract was dried with magnesium sulfate and evaporated to dryness *in vacuo* leaving 10.3 g. (97% yield) of 1-benzyl-2-cyanomethylimidazole as a white, hard, crystalline solid, m. p. 114–115°. It was readily soluble in benzene, moderately soluble in hot petroleum ether.

*Anal.* Calcd. for $C_{12}H_{11}N_3$: N, 21.31. Found: N, 21.04.

**1-Benzyl-2-β-aminoethylimidazole.**—Eleven grams (0.056 mole) of powdered 1-benzyl-2-cyanomethylimidazole was placed in the thimble of a Soxhlet extractor above a boiling solution of 5 g. (0.13 mole) of lithium aluminum

hydride[4,9] in 500 ml. of dry ether. After about three hours, when all of the cyano compound had been dissolved and carried down into the lithium aluminum hydride solution, the latter was treated with 10 ml. of water, added dropwise, followed by 50 ml. of 12.5 *N* sodium hydroxide solution. The mixture was vigorously stirred for about one hour and then the ether was decanted into a clean flask. The mixture was extracted twice more by vigorously stirring with 300 ml. portions of ether. The total ether solution was dried with potassium carbonate and concentrated. Distillation of the residual liquid *in vacuo* gave 9.7 g. (88% yield) of 1-benzyl-2-β-aminoethylimidazole as a viscous colorless liquid, b. p. 161–163° (0.7 mm.), which crystallized to a hard, white, hygroscopic solid, m. p. 59–60°. The dipicrate, prepared in absolute alcohol, melted at 185–186°.

*Anal.* Calcd. for $C_{24}H_{21}N_9O_{14}$: N, 19.14. Found: N, 19.26.

The dihydrochloride, m. p. 224–225°, was soluble in water, absolute alcohol, insoluble in ether, and it was not hygroscopic.

*Anal.* Calcd. for $C_{12}H_{15}N_3 \cdot 2HCl$: N, 15.33. Found: N, 14.97.

**2-β-Aminoethylimidazole (I).**—A solution of 9.2 g. (0.046 mole) of 1-benzyl-2-β-aminoethylimidazole in 100 ml. of liquid ammonia was treated with 2.15 g. of sodium metal. Then 2.7 g. (0.05 mole) of ammonium chloride was added, and the ammonia was allowed to evaporate. Sodium carbonate (3 g.) and 25 ml. of water were added. The solution was evaporated to dryness *in vacuo* on the steam-bath, and the residue was extracted with two 100-ml. portions of hot absolute alcohol. This was evaporated *in vacuo* leaving a viscous oil which was dissolved in 25 ml. of water and the resulting solution was added to a solution of 30 g. of picric acid in 800 ml. of hot water. After the mixture had cooled to room temperature, the crystalline picrate was collected on a filter and recrystallized in two portions from 500 ml. of water. There was thus obtained 21 g. (80% yield) of 2-β-aminoethylimidazole dipicrate, m. p. 213–214° (dec.).

*Anal.* Calcd. for $C_{17}H_{15}N_9O_{14}$: N, 22.14. Found: N, 22.18.

The above picrate (21 g., 0.037 mole) was decomposed with 6 *N* hydrochloric acid using nitrobenzene in the usual manner, and there was obtained 6.7 g. (98% yield) of 2-β-aminoethylimidazole dihydrochloride, m. p. 229–230°. It was very sparingly soluble in hot absolute alcohol.

*Anal.* Calcd. for $C_5H_9N_3 \cdot 2HCl$: N, 22.83. Found: N, 22.46.

**1-Benzyl-2-imidazolealanine (VI).**—A solution was prepared by adding 87 g. (0.40 mole) of acetamidomalonic ester to 250 ml. of absolute alcohol in which had been dissolved 13.8 g. (0.60 g. atom) of sodium. This solution was cooled in an ice-bath and to it was added during one-half hour 49 g. (0.20 mole) of 1-benzyl-2-chloromethylimidazole hydrochloride dissolved in 350 ml. of absolute alcohol. The mixture was stirred for two hours at room temperature and then evaporated *in vacuo* on the steam-bath to remove most of the alcohol. The residue was dissolved in 400 ml. of ice-cold 2 *N* hydrochloric acid. This solution was extracted with four 200-ml. portions of ethyl acetate to remove the unchanged acetaminomalonic ester. The water solution was neutralized with excess sodium carbonate and extracted with three 200-ml. portions of ether. The ether solution was dried and evaporated leaving the 1-benzyl-2-imidazolemethylacetaminomalonic ester as a glass which did not crystallize.

The product was dissolved in 200 ml. of 12 *N* hydrochloric acid and the solution heated on the steam-bath for sixteen hours. Evaporation of this solution left a glass-like product which could not be induced to crystallize. It was dissolved in 200 ml. of water and the solution was brought to *p*H 8.15 with sodium hydroxide. This solution was evaporated *in vacuo* almost to dryness, and the residue was extracted with 500 ml. of hot 90% alcohol. The alcohol extract was evaporated in an open beaker to a volume of about 200 ml. After standing and cooling it deposited 24 g. of white crystalline solid; m. p. 203–204°. The solid was washed by suspension in 100 ml. of absolute alcohol and then in 25 ml. of water in which it was somewhat soluble. It was recrystallized from 140 ml. of 70% alcohol to yield 19.5 g. (38.4%) of 1-benzyl-2-imidazolealanine hemihydrate, m. p. 216–217° (dec.).

*Anal.* Calcd. for $C_{13}H_{15}N_3O_2 \cdot {}^1/_2H_2O$: C, 61.40; H, 6.34. Found: C, 61.27; H, 6.68.

**2-Imidazolealanine (II).**—A solution of 12.7 g. (0.05 mole) of 1-benzyl-2-imidazolealanine in 100 ml. of liquid ammonia was treated with sodium as described above. The residue, after evaporation of the ammonia, was dissolved in 50 ml. of water, and the solution was brought to *p*H 8.0 by the careful addition of concentrated hydrochloric acid. The white crystalline precipitate, 5.3 g. (68.5% yield crude), was recrystallized from 70 ml. of water using carbon to decolorize the solution. There was obtained 4.4 g. (57% yield) of pure 2-imidazolealanine, m. p. 254–255° (dec.).

*Anal.* Calcd. for $C_6H_9N_3O_2$: N, 27.05. Found: N, 26.81.

**1-Benzyl-2-β-carbethoxyethylimidazole.**—1-Benzyl-2-chloromethylimidazole hydrochloride was caused to condense with sodiomalonic ester in a manner similar to that described above for the condensation with sodioacetamidomalonic ester. The resulting crude 1-benzyl-2-imidazolemethylmalonic ester was heated with concentrated hydrochloric acid, and the sirupy 1-benzyl-2-β-carboxyethylimidazole hydrochloride thus obtained was esterified with absolute alcoholic hydrogen chloride to give 1-benzyl-2-β-carbethoxyethylimidazole in an over-all yield of 83%. It distilled at 164–166° (0.3 mm.) $n^{25}D$ 1.5352.

*Anal.* Calcd. for $C_{15}H_{18}N_2O_2$: N, 10.85. Found: N, 10.60.

**2-β-Carbethoxyethylimidazole.**—1-Benzyl-2-β-carbethoxyethylimidazole (20.8 g., 0.08 mole) in 300 ml. of liquid ammonia was debenzylated with sodium. After evaporation of the ammonia the product was extracted from the residue with chloroform. There was obtained 9.5 g. of crude product which was recrystallized from benzene–petroleum ether to yield 8.1 g. (60%) of 2-β-carbethoxyethylimidazole, m. p. 103–104°.

*Anal.* Calcd. for $C_8H_{12}N_2O_2$: N, 16.66. Found: N, 16.94.

An attempt to remove the benzyl group from 1-benzyl-2-β-carbethoxyethylimidazole by hydrogenolysis in glacial acetic acid using Adams catalyst was not successful. Although the theoretical quantity of hydrogen was absorbed no toluene was split off. Presumably the material underwent partial hydrogenation.

**Acknowledgment.**—The author is grateful to K. C. McLaughlin for valuable assistance and to W. L. Brown and H. L. Hunter for the microanalyses reported herein.

## Summary

A method for the preparation of 2-substituted imidazoles has been described.

The isomers of histamine and histidine and a number of other 2-substituted imidazole compounds have been prepared and characterized.

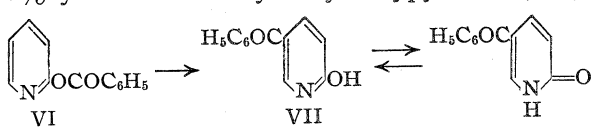
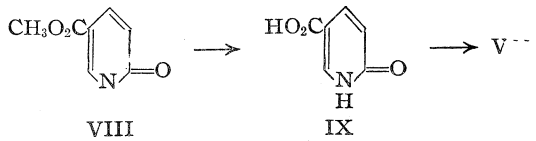
# Triarylpyridylmethanes

BY ROGER ADAMS, JACK HINE AND JOHN CAMPBELL



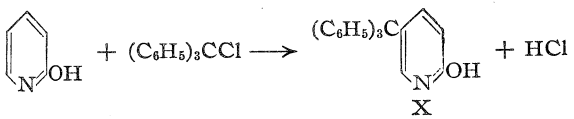
The absorption spectra of 2-pyridone (I) or its tautomer, 2-hydroxypyridine (II) and 1-methyl-2-pyridone (III) are very similar and suggest an analogous formulation. A considerable contribution of a "Zwitterion" resonance form of each (IV and V) to the total structure of the molecules is compatible with the physical properties of the compounds.[1]

I II III IV V



If this proposal is correct, analogous chemical reactivity of IV and V might be anticipated. Such similarity is exemplified in the halogenation,[2,3] nitration,[3,4] sulfonation[5] and arsonation[6] of 1-methyl-2-pyridone which leads to 5-mono- or 3,5-disubstituted products analogous to those obtained from 2-pyridone or 2-hydroxypyridine with the same reagents. Attempts to apply the Friedel and Crafts reaction with acyl and aroyl halides failed probably because of the complexing of the catalysts, aluminum chloride or boron trifluoride, with the pyridones. Thiocyanation and nitrosation were also unsuccessful.

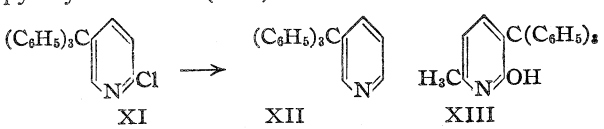
The application of the Fries rearrangement to the O-benzoate of 2-hydroxypyridine (VI) under the conditions used of fusion of the benzoate with anhydrous aluminum chloride gave only a 1% yield of 5-benzoyl-2-hydroxypyridine (VII).



VI VII

The structure of VII was proved by an unequivocal method. Methyl coumalinate (VIII) prepared by esterification of coumalinic acid formed from maleic acid, was converted by ammonia followed with alkali to 2-hydroxypyridine-5-carboxylic acid (IX). This was transformed to VII through the acid chloride and condensation with benzene in the presence of aluminum chloride.

VIII IX



2-Hydroxypyridine or 2-pyridone and 1-methyl-2-pyridone both condensed readily with triphenylchloromethane without catalyst or with triphenylcarbinol in the presence of a little sulfuric acid merely by heating. The N-methyl group in the latter was lost and the same product resulted, 5-triphenylmethyl-2-hydroxypyridine (X). The position of the triphenylmethyl radical is assumed on the basis of that taken by other groups when substituted in 2-hydroxypyridine. Thus, the reaction resembles that which

X

occurs between triphenylchloromethane or triphenylcarbinol and phenols or aromatic amines. The carbonium ions so readily formed from triphenylmethyl derivatives may account for the ease of substitution.

5-Triphenylmethyl-2-hydroxypyridine is transformed almost quantitatively by the action of phosphorus oxychloride in a sealed tube to 5-triphenylmethyl-2-chloropyridine (XI). The latter upon catalytic reduction yields triphenylpyridylmethane (XII).

XI XII XIII

The reaction appears to be a fairly general one. Triphenylchloromethane reacts readily with 3-methyl-2-hydroxypyridine, and diphenylxenylchloromethane or the corresponding carbinol reacts with 2-hydroxypyridine and with its 3-methyl derivative. The yields were 45–60% in all cases. 6-Methyl-2-hydroxypyridine, however, condenses with triphenylchloromethane to give only a 9% yield of product although with the carbinol a 22% yield results. It is assumed that the triphenylmethyl group has probably entered the 3-position (XIII) in this case since the condensation product unlike all the others could not be converted to the chloropyridine and is insoluble in aqueous ethanolic sodium hydroxide, presumably because of the steric hindrance of the *o*-triphenylmethyl group.

5-Triphenylmethyl-2-hydroxypyridine reacts similarly to 2-hydroxypyridine with organic

[a] Solvents as follows: A = glacial acetic acid, B = benzene, E = absolute ethanol, L = ligroin (b. p. 80–110°). Combinations denote recrystallization from mixed solvents. [b] All melting points above 200° were taken in a melting point block. [c] Double m. p.—solidified and remelted at 151–152°.

halides in alkaline solution. It is converted with potassium hydroxide and chloroacetic acid into N-carboxymethyl-5-triphenylmethyl-2-pyridone.

Triphenylpyridylmethane, like tetraphenylmethane, has a high melting point of 269–270°. Its solubility characteristics are likewise almost identical, insoluble in ether and petroleum ether, very slightly soluble in hot ethanol and glacial acetic acid and soluble in hot benzene.

It exhibits a marked phosphorescence after irradiation with ultraviolet light at room temperature. The brilliant blue-green afterglow from tetraphenylmethane has a visible duration of twenty-three seconds[7] and the greenish-white afterglow from triphenylpyridylmethane only one second.

The infrared absorption spectra of triphenylpyridylmethane and tetraphenylmethane are similar as shown in Chart I. In the infrared absorption spectra the CH deformational frequencies (1450, 1470 cm.$^{-1}$) and phenyl frequencies (1490, 1598 cm.$^{-1}$) are almost identical. Curve II shows additional absorption characteristics of the pyridine at 1412, 1570 and 1588 cm.$^{-1}$.

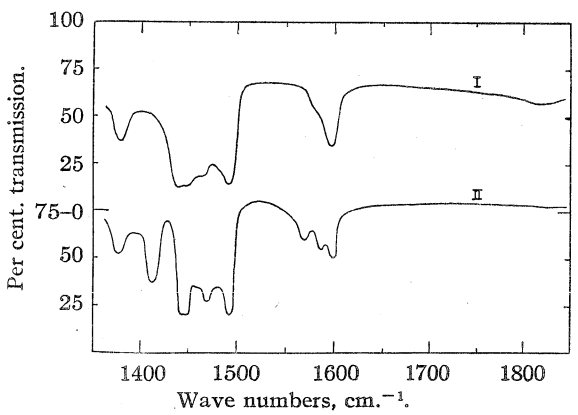

Fig. 1.—Curve I, tetraphenylmethane; Curve II, triphenyl-$\beta$-pyridylmethane. Both compounds were examined in mineral oil paste.

(7) Clapp, THIS JOURNAL, **61**, 523 (1939).

The properties of the various pyridones and pyridines are recorded in Table I.

## Experimental

**2-Pyridyl-$p$-nitrobenzenesulfonate.**—To 7.3 g. of melted $p$-nitrobenzenesulfonyl chloride was added slowly 3.86 g. of anhydrous sodium 2-hydroxypyridine. An exothermic reaction occurred. When this had subsided, the vessel was heated and the contents stirred, dissolved in benzene, filtered, and petroleum ether added to the cloud point. The solution was cooled, and the light yellow crystals which were removed by filtration weighed 7.4 g. (80%). Decolorization with Norit and two recrystallizations from benzene yielded material of m. p. 157–160° (cor.).

*Anal.* Calcd. for $C_{11}H_8O_5N_2S$: C, 47.17; H, 2.87; N, 10.00. Found: C, 47.33; H, 2.92; N, 9.83.

**2-Pyridyl Benzoate from Sodium 2-Hydroxypyridine and Benzoyl Chloride.**—This compound was prepared by a method somewhat different from any of the three used by Chichibabin and Oparina.[8] To 11.7 g. of anhydrous sodium 2-hydroxypyridine was added 15.0 g. of freshly redistilled benzoyl chloride. Heat was evolved, and a reddish color developed. The material was heated to 200° for an hour to complete the reaction and then distilled in vacuum. After a slight forerun, most of the remainder of the material was collected at 180–190° (25 mm.). The colorless liquid crystallized to a white solid which weighed 17 g. (85%) and melted at 35–40°.

**2-Pyridyl Benzoate from Benzoyl Chloride and 2-Hydroxypyridine in Pyridine.**—A solution of 14.1 g. of freshly redistilled benzoyl chloride and 4.75 g. of 2-hydroxypyridine in 39.5 (0.5 mole) of pyridine was refluxed for three hours. The solution was then distilled until the overhead temperature reached 120° in order to remove most of the pyridine. The residue was poured on ice and the mixture extracted with chloroform. The chloroform solution was dried over anhydrous sodium sulfate and distilled under vacuum. The material distilling between 180–195° (30

(8) Chichibabin and Oparina, *J. Russ. Phys.-Chem. Soc.*, **56**, 153 (1925).

mm. pressure) was collected and found to weigh 9.0 g. (90%). The yellow liquid began to crystallize when cooled to 30°, and was completely solid at 15°. It was identified as 2-pyridyl benzoate by its boiling point and by hydrolysis to benzoic acid. No crystals were obtained from the small amount of residue from the vacuum distillation.

**Fries Reaction with 2-Pyridyl Benzoate.**—To 11.1 g. of 2-pyridyl benzoate (m. p. 35–40°) was added 27 g. of freshly resublimed aluminum chloride. The material was stirred and heated by an oil-bath which was maintained at 180° for three hours. After the reaction mixture had cooled it was poured on ice. At this point the odor of benzoyl chloride was quite evident. The aqueous suspension was boiled and filtered. The precipitate was extracted with ether and filtered. The ether solution in turn was extracted with sodium bicarbonate in order to remove benzoic acid. The ether was evaporated, and the residue dried in a vacuum desiccator. It was then recrystallized from a mixture of chloroform and ligroin, yielding 0.09 g. (0.81%) of brown crystals melting at 152–170° (cor.). These were sublimed in vacuum at about 160° to give cream colored crystals, which were recrystallized from aqueous ethanol to give almost white crystals sintering at 188° and melting at 194–196° (cor.). The melting point of a mixture of this material with the 5-benzoyl-2-hydroxypyridine prepared from 2-hydroxypyridine-5-carboxylic acid showed no depression. The infrared spectra of the two compounds were identical.

*Anal.* Calcd. for $C_{12}H_9O_2N$: C, 72.35; H, 4.55; N, 7.03. Found: C, 72.36; H, 4.54; N, 7.07.

**5-Benzoyl-2-hydroxypyridine.**—This was prepared from 2-hydroxypyridine-5-carboxylic acid in a manner analogous to the synthesis by Kirpal[9] of 3-benzoyl-2-hydroxypyridine from 2-hydroxypyridine-3-carboxylic acid. To 1.05 g. of 2-hydroxypyridine-5-carboxylic acid[10] was added 3.5 g. of thionyl chloride. The mixture was maintained at a temperature of 80° for forty minutes; then the excess thionyl chloride was removed under vacuum. The acid chloride, after cooling, solidified. It was covered with 17.4 g. of benzene, and 8.0 g. of white, freshly resublimed aluminum chloride was added in several portions with stirring. The solution was refluxed for two hours, cooled, and poured on ice. The resulting solution was steam-distilled to remove the benzene, concentrated and filtered. The precipitate was decolorized with Norit and recrystallized from aqueous ethanol to give 1.0 g. (66%) of yellow crystals. These were sublimed in vacuum at 160°, and recrystallized from aqueous ethanol to give white crystals, m.p. 194–196° (cor.).

**2-Chloropyridine-5-sulfonyl Chloride.**—To a flask containing 13.5 g. of carefully dried 1-methyl-2-pyridone-5-sulfonic acid[5a] was added 26 g. of phosphorus pentachloride. The flask was heated in an oil-bath. When the temperature reached 110° liquid started to form, and gas was evolved so rapidly that a little material was lost. The oil-bath was kept at a temperature of 125° for two hours, at which time the evolution of gas had almost ceased. The mixture was then cooled to 0°, ground with ice, filtered, dried and found to weigh 11.35 g. (76%). Two recrystallizations from mixtures of petroleum ether (b.p. 50–80°) and benzene yielded white crystals of m.p. 50–51° (cor.). Naegeli, Kündig and Brandenburger[5b] report a melting point of 51.5°.

*Anal.* Calcd. for $C_5H_3O_3Cl_2NS$: C, 28.30; H, 1.51; N, 6.60. Found: C, 28.35; H, 1.48; N, 6.70.

**2-Chloropyridine-5-sulfonamide.**—To 11.35 g. of 2-chloropyridine-5-sulfonyl chloride was added 200 ml. of concentrated aqueous ammonia. The mixture was then heated to boiling while 200 ml. of additional concentrated aqueous ammonia was added. The solution was concentrated to 200 ml. and allowed to cool. The white crystals were removed by filtration, dried and found to weigh 6.79 g. (66%). Recrystallization from aqueous ethanol yielded crystals of m.p. 157–159° (cor.). This is the same melting point reported by Naegeli, Kündig and Brandenburger.[5b]

**2-Chloropyridine-5-(N-2-pyridyl-sulfonamide).**—To 0.140 g. of 2-chloropyridine-5-sulfonyl chloride dissolved in 5 ml. of benzene was added a solution of 0.23 g. of 2-aminopyridine in 5 ml. of benzene. The solution was evaporated and petroleum ether added until most of the benzene had been removed. It was then cooled in the ice-box, collected by filtration, dried, and washed with water to remove aminopyridine and its salts. The product weighed 0.12 g. (66%). Two recrystallizations from ethanol yielded material of m.p. 237–239° (cor.). Chichibabin and Vialatout[11] did not report a melting point.

**2-Methoxypyridine-5-sulfonamide.**—To a solution of 3 g. of sodium in 50 ml. of methanol, 6.76 g. of 2-chloropyridine-5-sulfonamide was added. The solution was refluxed for about sixty hours, most of the methanol was evaporated, water was added, the solution again concentrated, cooled overnight and filtered. The dark brown odoriferous material obtained was decolorized with Norit and recrystallized from water to yield 5.06 g. (77%). Further decolorization and recrystallization from water yielded white crystals, m.p. 149–150° (cor.).

*Anal.* Calcd. for $C_6H_9O_3N_2S$: C, 38.29; H, 4.28; N, 14.89. Found: C, 38.54; H, 4.27; N, 14.79.

**5-Triarylmethyl-2-hydroxypyridines.**—The reaction was carried out in the same fashion in all cases, by heating the 2-hydroxypyridines with the triarylchloromethane or with the triarylcarbinol and a few drops of concentrated sulfuric acid. A typical condensation is the preparation of 5-triphenylmethyl-2-hydroxypyridine.

A mixture of 3 g. of triphenylcarbinol and 3 g. of 2-hydroxypyridine was melted, two drops of concentrated sulfuric acid added and an air-cooled reflux condenser attached to the flask. It was heated in a metal-bath at 250° for twenty minutes, cooled, and 60 ml. of boiling absolute ethanol added. The precipitate was removed by filtration, washed with 30 ml. of hot absolute ethanol and dried to give a light cream-colored powder. Two recrystallizations from glacial acetic acid yielded a white powder, m.p. 365–368° (cor.). The compound is extremely insoluble in most organic solvents. The condensation of hydroxypyridines with triarylchloromethanes without addition of sulfuric acid was carried out under identical conditions. The yields were usually a few per cent. less than those from the carbinols. All the products were insoluble in aqueous 10% sodium hydroxide but readily dissolved upon the addition of an equal volume of ethanol.

In preparing 5-triphenylmethyl-3-methyl-2-hydroxypyridine, the product was soluble in hot ethanol and was recrystallized from the resulting solution with the use of Norit.

**3-Triphenylmethyl-6-methyl-2-hydroxypyridine.**—The condensation of triphenylcarbinol and 6-methyl-2-hydroxypyridine carried out as above afforded a dark brown product. After decolorizing twice with Norit and recrystallizing from benzene, a white powder was obtained in 22% yield. Only a 9% yield was obtained using triphenylchloromethane in the condensation. Three recrystallizations from benzene gave a product melting at 314–317° (cor.). It was insoluble in aqueous ethanolic sodium hydroxide and was recovered almost quantitatively on attempting to treat it with phosphorus oxychloride as described below.

*Anal.* Calcd. for $C_{25}H_{21}ON$: C, 85.43; H, 6.02; N, 4.00. Found: C, 85.38; H, 5.86; N, 3.97.

**5-Triarylmethyl-2-chloropyridines.**—The 5-triarylmethyl-2-hydroxypyridine and phosphorus oxychloride react under the following general conditions. A mixture of the hydroxypyridine and a six-fold excess of phosphorus oxychloride was sealed in a tube and placed on the steam-bath for forty-eight hours. After opening the cooled tube the resulting homogeneous solution was poured onto cracked ice and stirred. The mixture was boiled for

(9) Kirpal, *Monatsh.*, **27**, 371 (1906).

(10) v. Pechmann and Welsh, *Ber.*, **17**, 2384 (1884).

(11) Chichibabin and Vialatout, *Bull. soc. chim. France*, [5] **6**, 736 (1939).

several minutes to coagulate the gelatinous precipitate. The latter was removed by filtration, washed with water, dried, and recrystallized from the appropriate solvent. Yields were nearly quantitative. Refluxing with phosphorus oxychloride or heating with phosphorus pentachloride for forty-eight hours in an open vessel gave a product in only one case, and then in poor yield, indicating that a closed system was essential.

**5-Triarylpyridylmethanes.**—The 5-triarylmethyl-2-chloropyridines were reduced to the corresponding pyridines by the same general method, using Raney nickel catalyst in ethanolic potassium hydroxide solution. The reductions were run in very dilute solution and at 70° to effect solution of the reactants and products. A typical run is described.

One gram of 5-triphenylmethyl-2-chloropyridine and 0.50 g. of potassium hydroxide were dissolved in 200 ml. of hot absolute ethanol. One-half gram of Raney nickel was added and the mixture shaken for six hours at 70° under 45 lb. hydrogen pressure. After removing the catalyst by filtration the solution was evaporated until it became cloudy. Upon cooling, white crystals separated. Two recrystallizations from benzene–ethanol mixture (1:1) gave a product melting at 269–270° (cor.).

**N-Carboxymethyl-5-triphenylmethyl-2-pyridone.**—A suspension of 0.80 g. of 5-triphenylmethyl-2-hydroxypyridine, 0.67 g. of chloroacetic acid and 0.85 g. of potassium hydroxide in 25 ml. of absolute ethanol was refluxed for six hours. After removal of precipitated potassium chloride by filtration, the resulting solution was diluted with 25 ml. of water and acidified with hydrochloric acid. The bulky white precipitate which formed was removed by filtration, washed well on the filter with water and dried; yield, 0.84 g. (92%). Two recrystallizations from dioxane gave microscopic white crystals, m.p. 264–266° (cor.) with decomposition. The product forms an emulsion with aqueous 10% sodium hydroxide but dissolves upon the addition of an equal volume of ethanol.

*Anal.* Calcd. for $C_{26}H_{21}O_3N$: C, 78.97; H, 5.35. Found: C, 79.04; H, 5.04.

## Summary

1. The Fries rearrangement has been applied to the O-benzoate of 2-hydroxypyridine. A very small yield of 5-benzoyl-2-hydroxypyridine resulted. The structure of this latter product was determined by an unequivocal synthesis; methyl coumalinate was converted by ammonia followed by alkali to 2-hydroxypyridine-5-carboxylic acid which was transformed into the acid chloride and condensed with benzene in the presence of aluminum chloride.

2. Triphenylchloromethane and diphenylxenylchloromethane condense with 2-hydroxypyridine and 3-methyl-2-hydroxypyridine to give the corresponding 5-triarylmethyl-2-hydroxy- or 5-triarylmethyl - 2 - hydroxy - 3 - methylpyridines. Similar condensations occur with the triarylcarbinols and the 2-hydroxypyridines in presence of a few drops of sulfuric acid. With phosphorus oxychloride the triarylmethyl hydroxypyridines are converted to the chloropyridines which upon reduction yield triarylpyridylmethanes. Triphenylpyridylmethane resembles tetraphenylmethane in physical properties and in its phosphorescence after illumination with ultraviolet light.

3. 6-Methyl-2-hydroxypyridine condenses with triphenylchloromethane or the carbinol in low yields to give a product, presumably 3-triphenylmethyl-6-methyl-2-hydroxypyridine since it is alkali-insoluble and does not react with phosphorus oxychloride.

# Preparation and Properties of New Derivatives of Alloxan

BY G. BRÜCKMANN[1] AND S. D. ISAACS

The discovery by Shaw-Dunn and co-workers[2] that alloxan causes diabetes in experimental animals by selective destruction of the insulin-producing pancreatic islet cells has evoked considerable interest. An investigation undertaken in this Laboratory of the structural specificity of the effect required the preparation of a number of new members of the series, since the only previously described N-substituted alloxans are the 1-methyl,[3] 1-ethyl,[4] 1-phenyl,[5] 1,3-dimethyl,[6] 1,3-diethyl[7] and 1-methyl-3-ethyl[8] derivatives.

For preparation of several additional derivatives of interest for pharmacological study, an N-substituted urea was first condensed with malonic acid in the presence of acetic anhydride,[9] or with malonic ester in the presence of sodium methoxide (advantageous in the preparation of 1-phenylbarbituric acid). In accordance with the method of Biilman and Berg,[10] the resulting N-substituted barbituric acid (I) was then converted into the benzal derivative (II) and this was oxidized with chromic acid to the alloxan (III) and benzoic

(1) Dr. Brückmann was killed during the War in Israel. The revised version of the paper was prepared by L. F. Fieser.—*The Editor.*

acid. The benzal derivative can be prepared from the reaction mixture containing the barbituric acid without isolation of this intermediate. The alloxans are not very soluble and can be isolated from the oxidation reaction mixture, but in most cases it is preferable to reduce the crude product with stannous chloride and to isolate the resulting alloxantin, which subsequently can be reoxidized to the alloxan with nitric acid. A number of new N-alkyl and N-aryl alloxans and alloxantins were prepared by this process. When dried *in vacuo* over sulfuric acid, the alloxans invariably retained one molecule of water, whereas the alloxantins were obtained anhydrous or as mono- or dihydrates.

Attempts to prepare 2-thioalloxan by the method of Biilman and Berg were no more successful than the attempts of Robinson and Tomlinson[11] to prepare the compound by other methods. The substance apparently is unstable, possibly because of tautomerism to the sulfhydryl derivative and subsequent oxidation.

Aqueous solutions of the new alloxans all exhibited the following typical reactions in varying degree of intensity: (a) murexide formation in contact with the skin or when heated with α-amino acids; (b) reduction by ascorbic acid to a dialuric acid, as indicated by the formation of a violet precipitate on addition of barium hydroxide; (c) transient blue color on addition of traces of ferrous sulfate and alkali; (d) reaction with hydroxylamine hydrochloride to give a violuric acid recognizable from the intense, stable blue color resulting on the addition of ferrous sulfate.

Since a reaction analogous to the known ready decomposition of alloxan by alkali to alloxanic acid may possibly play a role in the inactivation of alloxan in the body, we compared various alloxan derivatives with respect to their stability to alkali. Known amounts of the compounds were added to 5-cc. portions of Krebs–Ringer phosphate buffer (*p*H 7.3) and the alloxan content of the solution was determined at two-minute intervals by the colorimetric method recently described.[12] The decomposition curves for the various alloxans studied were of similar shape and the percentages of unaltered material remaining after two minutes were as follows: alloxan, 68%; butylalloxan, 65%; dimethylalloxan, 34%; benzylalloxan, 29%; phenylalloxan, 12%. Similar figures were obtained when sodium hydroxide was used for alkalinization instead of phosphate buffer. Comparative determinations of the rate of α-amino acid oxidation by the same compounds have indicated that the order of decreasing activity is as follows: alloxan, butyl-, propyl-, methyl-, ethyl-, benzyl-, dimethyl- and phenylalloxan.[13] It is thus evident that high stability toward alkali corresponds to high potency in amino acid oxidation.

(12) Brückmann, *J. Biol. Chem.*, **165**, 103 (1946).

(13) Brückmann and Wertheimer, *ibid.*, **168**, 241 (1947).

The toxicity of the N-alkylalloxans increases sharply with increasing length of the aliphatic side chain. The disubstituted alloxans are particularly toxic, whereas phenylalloxan is practically non-toxic. Methyl-, ethyl- and propylalloxan possess diabetogenic activity.[13]

## Experimental[14]

**1-*n*-Propylbarbituric Acid.**—A mixture of carefully dried malonic acid (15 g.) and N-propylurea (13 g.) in glacial acetic acid (34 cc.) was heated in an oil-bath maintained at 70–80° and acetic anhydride (34 cc.) was added in the course of ninety minutes. The temperature was then raised to 90° for three hours, the red-brown mixture was cooled, treated with a little water (6 cc.), and concentrated in vacuum at 60° to a sirup. This was dissolved in hot ethanol, and the solution on cooling deposited 7.7 g. of crude yellow crystals. Repeated crystallization from water gave white needles of product, m. p. 104° (sparingly soluble in water).

*Anal.* Calcd. for $C_7H_{10}O_3N_2$: N, 16.48. Found (Kjeldahl): N, 16.08.

Treatment of the mother liquors with benzaldehyde (5 cc.) afforded 8 g. of the benzal compound.

**1-*n*-Propyl-5-benzalbarbituric Acid.**—Benzaldehyde (1.5 cc.) was added slowly to a refluxing solution of crude propylbarbituric acid (2.1 g.) in ethanol (12 cc.) and after one-half hour the mixture was cooled and the crystalline product collected and washed with alcohol and ether. The first crop of 2.2 g. of yellow plates, m. p. 168°, was directly pure; a further 0.3 g. was obtained from the mother liquor.

*Anal.* Calcd. for $C_{14}H_{14}O_3N_2$: N, 10.85. Found (Kjeldahl): N, 10.54.

**Di-(1-*n*-propyl)-alloxantin.**—1-*n*-Propyl-5-benzalbarbituric acid (2.6 g.) was added in small portions in the course of thirty minutes to a solution of chromic anhydride (2 g.) in water (0.7 cc.)–acetic acid (7 cc.) at 50–60°. The solution was cooled, treated with water (5 cc.) and hydrochloric acid (3.5 cc.), left for one hour at 0°. The benzoic acid that separated was removed by filtration and the filtrate was treated with stannous chloride (2 g.) dissolved in hydrochloric acid (2 cc.). The alloxantin that separated when washed with warm water until colorless weighed 1.4 g. Recrystallization from water (sparingly soluble) gave hexagonal plates, m. p. 214°, dec.

*Anal.* Calcd. for $C_{14}H_{18}O_8N_4 \cdot H_2O$: N, 14.42. Found (Kjeldahl): N, 14.36.

**1-*n*-Propylalloxan.**—A suspension of the above alloxantin (1 g.) in water (5 cc.) was treated at about 50° with concentrated nitric acid, added by drops, until the solid had dissolved. The solution, filtered if necessary, was kept in a desiccator over sulfuric acid until the product crystallized. The alloxan separated in small plates, m. p. 122° dec. The first crop amounted to 0.15 g.; a further crop of 0.16 g. was obtained from the mother liquor.

*Anal.* Calcd. for $C_7H_{10}O_5N_2$: N, 13.86. Found (Kjeldahl): N, 14.22.

**1-*n*-Butylbarbituric Acid.**—N-Butylurea (4.4 g.) was condensed with malonic acid (4.4 g.) in acetic acid (10 cc.) –acetic anhydride (10 cc.) by the procedure described above. Crystallization of the reaction product from ethanol gave yellowish needles, m. p. 136–140°, very sparingly soluble in water.

(14) In the alloxan series melting points are not very characteristic and in most cases represent temperatures of decomposition that depend upon such factors as the rate of heating and the nature of the capillary tube. Kjeldahl nitrogen determinations gave satisfactory results for all compounds studied except 1-phenylalloxan, for which the figures found for nitrogen were consistently low, even when copper sulfate was replaced by mercuric oxide, as recommended for the analysis of lysine by Miller and Houghton, *ibid.*, **165**, 103 (1946). Satisfactory results were obtainable only by the micro-Dumas method.

*Anal.* Calcd. for $C_8H_{12}O_3N_2 \cdot 2H_2O$: N, 12.72. Found (Kjeldahl): N, 12.31.

**1-*n*-Butyl-5-benzalbarbituric acid** was prepared without isolation of the butylbarbituric acid by the procedure described for the propyl homolog. The total yield of satisfactory product (two crops) from 4.4 g. of N-butylurea was 3.9 g. The substance crystallized in yellow plates, m. p. 154–156°.

*Anal.* Calcd. for $C_{15}H_{16}O_3N_2$: N, 10.28. Found (Kjeldahl): N, 9.99.

**Di-(1-*n*-Butyl)-alloxantin.**—Oxidation of 3.8 g. of the benzal compound and reduction of the crude product by the procedure described above afforded 1.8 g. of crude alloxantin. Crystallization from water afforded small white plates, m. p. 204°, dec.

*Anal.* Calcd. for $C_{16}H_{22}O_8N_4$: N, 14.13. Found (Kjeldahl): N, 13.89.

**1-*n*-Butylalloxan.**—Nitric acid oxidation of the alloxantin (1 g.) gave a first crop of 0.7 g. of product and 0.1 g. from the mother liquor. The substance crystallized in thin plates, m. p. 106–109°.

*Anal.* Calcd. for $C_8H_{12}O_5N_2$: N, 12.96. Found (Kjeldahl): N, 13.00.

**1-Isobutylbarbituric Acid.**—The sirup resulting from evaporation of the reaction mixture from isobutylurea (3 g.), malonic acid (3 g.), acetic acid (6.5 cc.) and acetic anhydride (6.5 cc.) when mixed with hot ethanol (7 cc.) afforded 1.8 g. of crystalline product. Crystallization from alcohol gave slightly pink plates, m. p. 138–140°, insoluble in water.

*Anal.* Calcd. for $C_8H_{12}O_3N_2$: N, 15.21. Found (Kjeldahl): N, 15.90.

**1-Isobutyl-5-benzalalloxan.**—Condensation of 1.5 g. of the barbituric acid with benzaldehyde (1.5 cc.) in ethanol (15 cc.) yielded 1.3 g. of yellow plates, m. p. 177–178°.

*Anal.* Calcd. for $C_{15}H_{16}O_5N_2$: N, 10.28. Found (Kjeldahl): N, 10.36.

**Di-(1-isobutyl)-alloxantin.**—The benzal compound (2.3 g.) was oxidized with chromic anhydride (1.7 g.) in acetic acid (5 cc.), and the alloxantin was obtained by addition of water (12 cc.) and stannous chloride (1 g.)–hydrochloric acid (1 cc.). The product separated as white plates (0.3 g.), m. p. 214–216°, moderately soluble in water.

*Anal.* Calcd. for $C_{16}H_{22}O_8N_4 \cdot 2H_2O$: N, 12.96. Found (Kjeldahl): N, 12.61.

**1-Isobutylalloxan** was obtained directly by cooling the above-described oxidation mixture; yield 0.5 g. (crude). Crystallization afforded white plates, m. p. 145–147°, dec.

*Anal.* Calcd. for $C_8H_{12}O_5N_2$: N, 12.96. Found (Kjeldahl): N, 12.70.

**1-Phenylbarbituric Acid.**—The method used was similar to that of Aspelund and Lindh,[15] but ethanol was replaced by methanol, as follows. To a cooled solution of sodium (4.2 g.) in absolute methanol (50 cc.), a solution of diethyl malonate (35 g.) and phenylurea (29 g.) in hot methanol (50 cc.) was added. The mixture was heated under reflux at 70–80° for six hours and poured into hydrochloric acid (25 cc.) and water (120 cc.) and cooled. The yield of the barbituric acid, washed with ethanol and ether, was 25 g.; recrystallized material melted at 262°.

**1-Phenyl-5-benzalbarbituric Acid.**—The condensation of crude phenylbarbituric acid (24 g.) with benzaldehyde (16 cc.) in boiling ethanol (180 cc.) afforded 31 g. of yellow, sharp-edged needles, m. p. 237–238°.

**1-Phenylalloxan.**[16]—The benzal compound (2.5 g.) was added in the course of twenty minutes to a mixture of chromic anhydride (3 g.), water (2.5 cc.) and acetic acid (13 cc.) at a temperature of 50–60°. The alloxan separated in a stiff paste and was collected and washed on the filter with acetic acid until the washings were nearly colorless. The product was dissolved in a little hot water and the solution treated with acetic acid and cooled, when 1.2 g. of silky white needles separated. The substance, m. p. 158°, is very soluble in water, ethanol or hot acetic acid and is sparingly soluble in chloroform.

*Anal.* Calcd. for $C_{10}H_8O_5N_2$: N, 11.87. Found (Dumas): N, 11.66.

Reduction with stannous chloride afforded the alloxantin (white needles from water, m. p. 255° dec.) described by Winslow.[16]

**1-Benzylbarbituric acid** was prepared by condensing benzylurea (2.9 g.) with malonic acid (2.2 g.) in acetic acid (5 cc.)–acetic anhydride (5 cc.). The crude product (2 g.) on crystallization from ethanol gave white prisms, m. p. 146–150°.

*Anal.* Calcd. for $C_{11}H_{10}O_3N_2$: N, 12.84. Found (Kjeldahl): N, 13.30.

**1-Benzyl-5-benzalbarbituric acid** was prepared from the barbituric acid (1.8 g.) by the usual process, yield 2.2 g. The substance formed thin yellow prisms, m. p. 200–204°.

*Anal.* Calcd. for $C_{18}H_{14}O_3N_2$: N, 9.15. Found (Kjeldahl): N, 9.08.

**Di-(1-benzyl)-alloxantin** was prepared by the general procedure described; yield 1 g. from 2 g. of benzal compound. Crystallization from hot water gave small needles, m. p. 199°.

*Anal.* Calcd. for $C_{22}H_{18}O_8N_4 \cdot H_2O$: N, 11.58. Found (Kjeldahl): N, 11.73.

**1-Benzylalloxan.**—The alloxantin (1.2 g.) was warmed with nitric acid until dissolved, and the white crystals that separated on cooling were washed with water and with chloroform; yield 0.7 g. The product, m. p. 140–143°, is soluble in acetone, ethanol, or ether, and sparingly soluble in water.

*Anal.* Calcd. for $C_{11}H_{10}O_5N_2$: N, 11.20. Found (Kjeldahl): N, 11.20.

## Summary

A number of new derivatives of alloxan and alloxantin have been synthesized. In the alloxan series, ability to oxidize α-amino acids runs parallel to the stability of the compounds to decomposition by alkali.

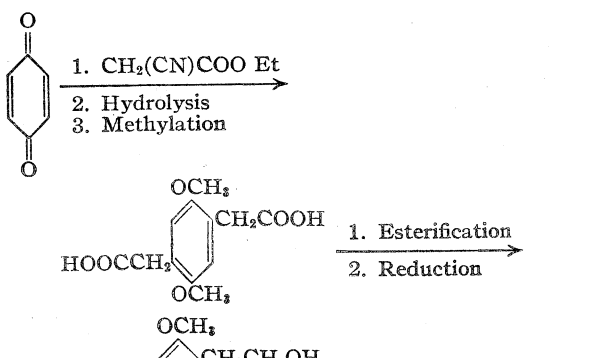
# Di-($\alpha$- and $\beta$-Substituted Aminoethyl)-benzenes. I. 2,5-bis-(2-Aminoethyl)-hydroquinones[1]

BY J. H. WOOD AND ROGER E. GIBSON[1a]



The aminoethyl function is a component common to a large number of physiologically active compounds. In the benzene nucleus, it gives rise to a series of compounds noted for their sympathomimetic activity, benzedrine and ephedrine being familiar examples. Studies so far made among these compounds relating structure with activity have been concerned with introducing substituents on the $\alpha$- and $\beta$-carbons, on the nitrogen and in the ring of the parent $\beta$-phenylethylamine. We have prepared for pharmacologic activity study a series of new compounds in which the $\beta$-aminoethyl function is repeated in a para relationship. Additional interest on our part in these compounds is occasioned by our need for them as intermediates in the preparation of certain heterocyclic types.

The parent of the series reported in this paper, 2,5-bis-(2-aminoethyl)-hydroquinone, I, was synthesized by two independent paths, as follows

(I)

The second method, important in the proof of structure, gave poor yields

I

The methods of preparation, analyses, and conversion into known compounds serve to characterize the new amines and their intermediates.

Pressor, bronchodilator and antihistamine activity tests, made by The Lilly Research Laboratories of Eli Lilly and Company on the hydrochloride salts of I and its O-methyl, N-dimethyl and O-methyl-N-dimethyl derivatives, revealed that these amines are inactive in these respects. They showed less than 10% "Egotrate" activity. Since the introduction of a second $\beta$-aminoethyl function does not significantly alter the chemical properties of the molecule the loss of activity must be ascribed to other effects. It is planned to continue this study by preparing and testing the activity of derivatives in which the positions of the aminoethyl functions are varied as well as the substituents on their $\alpha$- and $\beta$-carbon atoms.

## Experimental[2]

**2,5-bis-(Chloromethyl)-hydroquinone Dimethyl Ether.**—The following is an adaptation of Brunner's[3] general method for the chloromethylation of aromatic compounds. To a stirred solution of 103 g. (0.75 mole) of the dimethyl ether of hydroquinone, 600 ml. of dioxane and 100 ml. of concentrated hydrochloric acid was added three 50 ml. portions of 40% formalin (2 moles) at thirty-minute intervals. During the period of addition, hydrogen chloride gas was passed through. Stirring and the introduction of hydrogen chloride gas were continued for three hours longer and then 450 ml. of concentrated hydrochloric acid was added. After cooling, the solid material which had formed was removed by filtration and allowed to dry. One recrystallization from acetone gave 135 g. (77%) of white, crystalline material that melted at 163–164°. Further purification, which was unnecessary for most purposes, gave a product which melted at 167.5°. Brunner reported the melting point as about 165°.

*Anal.* Calculated for $C_{10}H_{12}O_2Cl_2$: Cl, 30.16. Found: Cl, 30.14.

**2,5-bis-(Cyanomethyl)-hydroquinone Dimethyl Ether.**—To a hot, stirred solution of 300 ml. of ethylene glycol monoethyl ether, 500 ml. of acetone and 117.5 g. (0.5 mole) of 2,5-bis-(chloromethyl)-hydroquinone dimethyl ether, in a reflux apparatus, was added slowly an aqueous solution containing 97.5 g. (1.5 moles) of potassium cyanide in 125 ml. of warm water. After refluxing four hours, the hot mixture was filtered. The residue consisted of a mixture of potassium chloride and the cyanomethyl compound. The filtrate, upon cooling in an ice-bath, deposited additional cyanomethyl compound in the form of grayish crystals. After filtering, the mother liquor was used to extract the cyanomethyl compound from potassium chloride in the residue obtained from the first filtration. This extraction was repeated (usually three times) until no solid was obtained upon cooling the filtered, hot extracting solution. The combined residues of the cyanomethyl compound, after washing with methanol, weighed 68 g., m. p. 193–195°. Recrystallization from dioxane gave 59 g. (54.5%) of white, crystalline material, m. p. 195–196.5°, which was pure enough for our work. A small portion was further purified for analysis and melted at 198°.

*Anal.* Calculated for $C_{12}H_{12}O_2N_2$: N, 12.96. Found: N, 12.99.

(1) Presented at the 114th meeting of the American Chemical Society, St. Louis, Missouri, September, 1948.

(1a) University of Tennessee Fellow, 1947–48.

(2) All melting points are corrected.

(3) Brunner, U. S. Patent 1,887,396 (1933).

**2,5-Dimethoxy-*p*-benzenediacetic Acid Diethyl Ester.**—A solution of 225 g. (0.88 mole) of 2,5-dimethoxy-*p*-benzenediacetic acid[4] (prepared from the hydroquinone[5]), 2 l. of absolute ethanol, and 750 ml. of benzene was placed in a 3-l. flask fitted with stirrer and a 75-cm. Vigreux column equipped with a variable take-off. Esterification was accomplished by keeping the solution saturated with hydrogen chloride gas over a four-hour reflux period during which time the low-boiling fraction was continuously removed. The volume of the reaction mixture was then increased to about 4 l. by the addition of 95% ethanol, heated to boiling and filtered. Upon cooling, the ester separated as grayish crystals which were removed by filtration. Evaporation of the filtrate to about one-third of its volume and cooling yielded an additional amount. Total yield of crude ester was 210 g. (76.5%). Further purification was achieved by recrystallization from alcohol and gave a colorless, crystalline material, m. p. 115.5°.

*Anal.* Calculated for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15. Found: C, 61.78; H, 7.11.

**2,5-bis-(2-Hydroxyethyl)-hydroquinone Dimethyl Ether.**—To 150 g. (6.5 g. atoms) of melted sodium dispersed in hot xylene contained in a 3-liter flask fitted with stirrer and condenser was slowly added a warm solution of 250 ml. of xylene and 500 ml. of absolute butanol containing 140 g. (0.45 mole) of 2,5-dimethoxy-*p*-benzenediacetic acid diethyl ester. Xylene was added at intervals in sufficient quantities to prevent the reaction mixture from setting to a gel. The mixture was then heated with stirring until all sodium had dissolved. Water was added and the mixture was steam distilled until the xylene and butanol had been removed. Upon cooling to 0°, 40 g. (39%) of the slightly impure alcohol separated. Recrystallization from water with decolorization gave white crystals, m. p., 133.5–134°.

*Anal.* Calculated for $C_{12}H_{18}O_4$: C, 63.69; H, 8.02. Found: C, 63.39; H, 8.12.

Acidification of the mother liquor from the above reaction yielded 54 g. of the acid formed by the hydrolysis of the unreduced ester.

**2,5-bis-(2-Aminoethyl)-hydroquinone Dimethyl Ether.**—Method No. 1: Into a steel bomb of 600-ml. capacity were placed 25 g. (0.12 mole) of 2,5-bis-(cyanomethyl)-hydroquinone dimethyl ether, 250 ml. of absolute ethanol saturated with ammonia, and about 10 g. of Raney nickel catalyst. After introducing hydrogen to a pressure of 1,900 lb./sq. in., the bomb was placed in the heating jacket of a hydrogenation apparatus and shaken at 120° for forty-five minutes. The pressure fall was very rapid the first fifteen minutes. After cooling, the contents were removed, filtered, and the filtrate evaporated under reduced pressure on the steam-bath, leaving a red oil. This oil was distilled at 150–155° at a pressure of less than 1 mm., using a very short path still with a large side arm. About 20 g. (77%) of the pure amine was thus obtained as a white, crystalline solid. The amine proved to be very basic, removing carbon dioxide from air. Freshly prepared, it melted at about 90°. Upon standing in air, its melting point changed very rapidly. It, as well as its sulfonamide and hydrochloride, proved to be identical with the amine obtained by method 2.

Method No. 2: A small excess of thionyl chloride was added to a mixture of 10 g. (0.044 mole) of 2,5-bis-(2-hydroxyethyl)-hydroquinone dimethyl ether and 100 ml. of dry ethyl ether. After carefully warming for a few minutes, the mixture was slowly evaporated to dryness on the steam-bath. The chloride thus presumably formed was not purified. Potassium phthalimide, 20 g. (0.11 mole), was added, a small air condenser attached, and the mixture heated for eight hours at 160–170° with occasional stirring. After cooling, the solid product was broken up and about 175 ml. of alcohol and 15 ml. of 40% hydrazine hydrate were added. After heating one hour on the steam-bath, excess hydrochloric acid was added and the mixture filtered. The filtrate was evaporated to about 100 ml. and then refiltered. The filtrate was made alkaline with excess sodium hydroxide and then boiled a few minutes to expel any hydrazine present. After extracting with ether, the amine was precipitated as the salt by passing hydrogen chloride into the ether solution. The yield was about 10%. The amine thus obtained was identical with the one obtained in method 1.

The **dihydrochloride** salt, a white, hygroscopic solid, melted at 335° dec.

*Anal.* Calculated for $C_{12}H_{22}O_2N_2Cl_2$: Cl, 23.86. Found: Cl, 23.91.

The **benzenesulfonamide** derivative was a white, crystalline solid after recrystallization from alcohol, m. p., 195.5°.

*Anal.* Calculated for $C_{24}H_{28}O_6N_2S_2$: N, 5.55. Found: N, 5.60.

**2,5-bis-(2-Aminoethyl)-hydroquinone.**—A solution of 15 g. (0.067 mole) of 2,5-bis-(2-aminoethyl)-hydroquinone dimethyl ether in 100 ml. of 48% hydrogen bromide was refluxed eight hours. Upon cooling, the amine hydrobromide precipitated as a tan material. Evaporation of the mother liquor to about one-third of its former volume gave a small additional amount. After drying to remove excess hydrogen bromide, the salt was dissolved in 80 ml. of water. The free amine was then obtained as a gray solid upon adding excess sodium bicarbonate. This phenolic amine, while stable in acidic solutions, was unstable in alkali solutions, its solution in sodium hydroxide rapidly forming a black precipitate. The amine freshly precipitated with sodium bicarbonate from an aqueous solution of the recrystallized hydrochloride salt was a slightly colored solid, m. p. 234° dec., soluble in alcohol, ether, acids and bases.

The **dihydrochloride** was prepared by adding a small amount of water to the gray solid obtained above and then adding an excess of concentrated hydrochloric acid. Upon evaporating to 75 ml. and cooling, the salt precipitated. After washing with absolute alcohol and then ether, the salt was twice recrystallized from an alcohol–water mixture to give 7 g. (39%) of a white, crystalline solid, m. p. 313° dec.

*Anal.* Calculated for $C_{10}H_{18}O_2N_2Cl_2$: Cl, 26.35. Found: Cl, 26.25.

**N,N'-Tetramethyl-2,5-bis-(2-aminoethyl)-hydroquinone Dimethyl Ether.**—This compound was prepared by the method of Icke, Wisegarver and Alles[6]: 22.4 g. (0.1 mole) of 2,5-bis-(2-aminoethyl)-hydroquinone dimethyl ether yielded the crude tertiary amine in the form of a red oil. This was distilled at 133–135° at less than 1 mm. to give 17.5 g. (62.5%) of a white, crystalline solid, m. p. 51–52°, soluble in alcohol and ether. A Hinsberg test indicated a tertiary amine.

The **dihydrochloride** melted at 275° dec.

*Anal.* Calculated for $C_{16}H_{30}O_2N_2Cl_2$: Cl, 20.07. Found: Cl, 19.97.

**N,N'-Tetramethyl-2,5-bis-(2-aminoethyl)-hydroquinone.**—This compound was prepared in a manner analogous to that described above for 2,5-bis-(2-aminoethyl)-hydroquinone. The free amine obtained from the hydrochloride salt was a light brown solid, m. p. 178, which darkened upon standing in air, and was soluble in ether, alcohol, acids and bases. The yield of pure hydrochloride was about 38%.

The **dihydrochloride** salt, m. p. 278° dec., was a white, crystalline solid.

*Anal.* Calculated for $C_{14}H_{26}O_2N_2Cl_2$: Cl, 21.80. Found: Cl, 21.92.

# Ethers of *p*-Hydroxydiphenylamine as Alkyl Halide Identification Derivatives

BY DAVID F. HOUSTON

The preparation of several ethers of *p*-hydroxydiphenylamine as intermediates for other syntheses drew attention to their value as derivatives for the identification of alkyl halides. These ethers offer an alternative choice to previously reported[2,3,4,5] derivatives.

The hydroxydiphenylamine is commercially available and can be readily purified. The synthesis of the ethers was convenient, and the products were easily crystallized. Ether formation from primary halides was general. *s*-Butyl chloride gave unreacted amine together with oil and tarry matter. Tertiary halides were not investigated. Mixtures of two ethers with closely similar melting points showed melting-point depressions of several degrees.

Data on the ethers are collected in the accompanying table. The melting points follow the usual trend for a homologous series, and those for the even-carbon alkyl ethers above the hexyl compound follow a smooth curve.

TABLE I

*p*-HYDROXYDIPHENYLAMINE ETHERS, $ROC_6H_4NHC_6H_5$

| Halide used | M. p., °C. | Empirical formula | Analytical data, % Carbon Calcd. | Carbon Found | Hydrogen Calcd. | Hydrogen Found | Nitrogen Calcd. | Nitrogen Found |

[a] Purified from commercial product; see text.

## Experimental

**Materials.**—The *p*-hydroxydiphenylamine was a sample of commercial product with a stated 92% purity. It was further purified by distillation with superheated steam,[6] collecting the product distilling at 170–180°. The dark still residue contained some diphenyl-*p*-phenylenediamine. Final recrystallizations from benzene–hexane gave material melting at 69–70° in agreement with the reported[7] value of 70°. Less rigorous purification may be satisfactory, as indicated by the fact that the octyl ether prepared directly from the commercial *p*-hydroxydiphenylamine, though remaining somewhat dark colored, melted at 45.5–46.2° in complete agreement with the analytical sample from the purified amine.

*n*-Propyl and *n*-amyl iodides, heptyl bromide, and *s*-butyl and benzyl chlorides were obtained from Eastman Kodak Company. The hexyl, octyl, dodecyl and hexadecyl bromides were research-grade chemicals (boiling within a two degree range) obtained from a commercial supplier of halogen chemicals. *n*-Butyl bromide had been prepared and fractionally distilled in this Laboratory.

The isopropoxydiphenylamine was a commercial product. It was distilled at reduced pressure, and the portion distilling at 140–145° at 1.5 mm. was purified by decolorizing a methanol solution with charcoal and crystallizing the product from aqueous methanol (1:3).

**Procedure.**—Preparation of the ethers, essentially the same in all cases, is illustrated by synthesis of the *n*-propyl compound. Equivalent amounts (0.02 mole) of *p*-hydroxydiphenylamine (3.70 g.) and *n*-propyl iodide (2.46 g.) were added to 18 cc. of 10% alcoholic potassium hydroxide (0.03 equivalent). The solution was refluxed three hours with stirring by magnetic stirrer, cooled, diluted to 200 cc. with water, acidified slightly with hydrochloric acid, and chilled to 0°. The dark solids were filtered off, and decolorized with charcoal in 85 cc. of alcohol. The filtrate was diluted with water to clouding, cooled to 0°, and again filtered. The yield at this point was 2.78 g. (61%). Two recrystallizations from aqueous alcohol gave pearly flakes melting at 40.9–41.3° (cor.).

The halides used, and the melting points and analytical data for the ethers formed, are presented in the table.

**Acknowledgment.**—I wish to express my appreciation to E. B. Kester for his interest in this

investigation, and to L. M. White and Geraldine Secor for performing the microanalyses.

## Summary

Alkyl ethers of *p*-hydroxydiphenylamine have been prepared from a variety of alkyl halides and have properties suitable for use in identification of alkyl halides. Ether formation from primary halides was general, but secondary alkyl halides did not always operate satisfactorily. Tertiary halides were not investigated.

# Pentachlorophenyl Derivatives. III. The Effect of Temperature on the Composition of the Product in the Chlorination of Ethylpentachlorobenzene

BY SIDNEY D. ROSS, MOUSHY MARKARIAN AND MATTHEW NAZZEWSKI

In previous reports from this Laboratory[1] it was shown that the major product isolated from the chlorination of ethylpentachlorobenzene was 1-pentachlorophenyl-2-chloroethane, I. Bromination, on the other hand, resulted in an almost quantitative yield of the $\alpha$-substitution product, 1-pentachlorophenyl-1-bromoethane. This difference in the direction of substitution was attributed to a combination of two factors—the greater reactivity of the chlorine atom[2] and steric hindrance about the $\alpha$-position. Evidence indicating the presence of steric hindrance in systems of this type has been presented in a previous report.[3] We have postulated that with ethylpentachlorobenzene the energy barrier for reaction is smaller for an attack at the $\alpha$-position but that this position is so shielded sterically by the ortho chlorine substituents that many collisions occur at the $\beta$-position before a collision occurs at the $\alpha$-position. The chlorine atom is so reactive that even a collision at the $\beta$-position is sufficiently effective to result in reaction, but with the less reactive bromine atom only a collision at the $\alpha$-position is effective and no $\beta$-bromide is formed.

On the above basis it would be predicted that $\beta$-chlorination would be favored over $\alpha$-chlorination at higher temperatures but that with decreasing temperature the ratio of $\beta$- to $\alpha$-chlorination would decrease. In our previous work we studied the products of the chlorination at both 200 and 68–73°. At both temperatures the predominant product was I. At the higher temperature the only other products isolated were hexachlorobenzene and a highly chlorinated ethylpentachlorobenzene which was not fully characterized. At the lower temperature the other isolable products were hexachlorobenzene and pentachlorostyrene, II, and it was suggested that II arose from decomposition of 1-pentachlorophenyl-1-chloroethane, III, during the distillation process and constituted indirect evidence for the occurrence of some $\alpha$-chlorination at the lower temperature. In both cases the yield of $\beta$-chloride, I, actually isolated was never more than 35% so that the possibility of some $\alpha$-chlorination even at the higher temperature was not eliminated. It is our present purpose to show that some $\alpha$-chlorination takes place at both 70–75° and 180° and that the relative amounts of $\beta$- and $\alpha$-chlorination at the two temperatures support the postulated mechanism to account for the difference in the direction of substitution on bromination and chlorination.

If ethylpentachlorobenzene, is chlorinated and then reacts, without purification, with benzene in the presence of aluminum chloride the major product is a mixture of two solids, one melting from 110.5–112.5° and the other from 153–155°. Although the two compounds distil at similar temperatures and pressures they can be readily separated by crystallization and both analyze correctly for $C_{14}H_4Cl_5$. The lower melting one, IV, was synthesized from both 1-pentachlorophenyl-1-bromoethane and pentachlorostyrene by reaction with benzene in the presence of aluminum chloride and must, therefore, be 1-pentachlorophenyl-1-phenylethane. The higher melting product, V, is the isomeric 1-pentachlorophenyl-2-phenylethane and was synthesized by treating I with benzene and aluminum chloride. V can result only from the presence of I in the crude chlorination mixture. IV can result either from III or from pentachlorostyrene. However, since pentachlorostyrene itself probably results from III it is still valid to assume that the amounts of IV and V isolated from the coupling reaction are indicative of the amounts of $\alpha$- and $\beta$-chlorination in the chlorination reaction and we have applied this criterion to the products obtained by chlorination at 180 and 70–75°.

Chlorination of 1000 g. of ethylpentachlorobenzene at 180° followed by coupling with benzene at 50° gave a crude product which yielded five fractions on distillation—a forerun weighing 229 g., the main fraction weighing 546 g., an intermediate fraction of 60 g., a high boiling fraction of 123 g., and a final fraction of 36 g. collected after decomposition of the pot residue had started.

(1) Ross, Markarian and Nazzewski, THIS JOURNAL, **69**, 1914, 2468 (1947).

(2) Schumacher, *Angew. Chem.*, **53**, 501 (1940).

(3) Ross, THIS JOURNAL, **70**, 4039 (1948).

Crystallization of the forerun yielded two pure products—11 g. of hexachlorobenzene and 110 g. of unreacted ethylpentachlorobenzene. The main fraction on crystallization gave 403 g. of V and 94 g. of IV. From the intermediate fraction the only pure product isolated was 32 g. of V. No more of IV or V was isolated from the subsequent fractions. The over-all yield of monophenyl-substituted ethylpentachlorobenzene is thus 41.4%. Of this 82.1% is the β-substituted product and 17.9% the α-substituted product, and based on this evidence the ratio of β-chlorination to α-chlorination is almost 4.6:1.

The final fraction was largely the product of decomposition and only hexachlorobenzene was isolated from it. The high boiling fraction proved to be a mixture which was particularly resistant to separation. By a combination of crystallization and flotation we succeeded in isolating two pure compounds. One, VI, melted from 143–143.5°, and the other, VII, from 132–133°. Both analyzed correctly for $C_{20}H_{13}Cl_5$, and they must, therefore, be isomeric diphenylethylpentachlorobenzenes. VI was synthesized by treating 1-pentachlorophenyl-1,2-dibromoethane with benzene in the Friedel-Crafts reaction and is 1-pentachlorophenyl-1,2-diphenylethane. VII is either 1-pentachlorophenyl-1,1-diphenylethane or 1-pentachlorophenyl-2,2-diphenylethane. The preponderance of β-chlorination makes the former structure extremely unlikely and we have assigned the latter structure to VII.

The product of chlorination at 70–75° after similar treatment gave three fractions—a forerun of 208 g., the main fraction of 683 g., and a high boiling fraction of 84 g. From the forerun we isolated three compounds; 42.5 g. of unreacted ethylpentachlorobenzene, 11 g. of hexachlorobenzene, and 22 g. of V. From the main fraction we obtained 369 g. of V and 253 g. of IV and from the final fraction we isolated only 5 g. of V and 5 g. of VI. The over-all yield of monophenyl substituted ethylpentachlorobenzene isolated is thus 51%. Of this 61% is the β-substituted product and 33% the α-substituted and the ratio of β-chlorination to α-chlorination is in this case slightly below 1.6:1.

These results clearly indicate that β-chlorination is favored at higher temperatures and that with decreasing temperature the ratio of β- to α-chlorination decreases. This finding is in accord with our postulation that the activation energy for the α-chlorination is lower than for the β-chlorination and lends support to the hypothesis which we previously advanced[1] to account for the difference in the directions of chlorination and bromination of ethylpentachlorobenzene.

## Experimental[4]

**1-Pentachlorophenyl-2-phenylethane, V.**—1-Pentachlorophenyl-2-chloroethane (63 g., 0.2 mole) in 200 cc. of benzene was added dropwise at room temperature over a two-hour period to a stirred suspension of aluminum chloride (2 g.) in 50 cc. of benzene. Stirring was continued until the evolution of hydrogen chloride ceased. The reaction mixture was decomposed with ice and dilute hydrochloric acid. The benzene layer was separated, washed with water, 10% sodium hydroxide, and again with water and finally dried over calcium sulfate. The benzene was removed and the crude product obtained was crystallized from ethanol–benzene (1:1) to yield 52 g. (73.4%) of product melting from 148–153°. Two recrystallizations raised the melting point to 153–155°.

*Anal.* Calcd. for $C_{14}H_9Cl_5$: C, 47.42; H, 2.62. Found: C, 46.93, 46.99; H, 2.79, 2.86.

**1-Pentachlorophenyl-1-phenylethane, IV.**—1-Pentachlorophenyl-1-bromoethane (71.5 g., 0.2 mole) in 250 cc. of benzene was reacted with aluminum chloride (2 g.) in 50 cc. of benzene exactly as above. The yield of crude product was in this case quantitative. A sample crystallized two times from ethanol for analysis melted from 110.5–112.5°.

*Anal.* Calcd. for $C_{14}H_9Cl_5$: C, 47.42; H, 2.62. Found: C, 47.01, 47.16; H, 2.95, 2.77.

When pentachlorostyrene was coupled with benzene as above the same product was obtained in 89% yield.

**1-Pentachlorophenyl-1,2-diphenylethane, VI.**—1-Pentachlorophenyl-1,2-dibromoethane (2 g.) in 40 cc. of benzene was added dropwise to a stirred mixture of aluminum chloride (0.5 g.) in 40 cc. of benzene. The reaction mixture was warmed for three hours after which it was decomposed with water and 10% sodium hydroxide. The benzene layer was separated and dried. The crude product, obtained by removing the benzene, was crystallized from ethanol yielding 1.1 g. of melting point 140–141°. Another crystallization raised the melting point to 143–143.5°.

*Anal.* Calcd. for $C_{20}H_{13}Cl_5$: C, 55.80; H, 3.04. Found: C, 56.11, 56.30; H, 3.10, 2.94.

**Chlorination of Ethylpentachlorobenzene at 70–75°.**—Redistilled ethylpentachlorobenzene (1000 g.) was illuminated with a 500-watt bulb and chlorinated at 70–75° to a gain in weight of 136 g. This total product in 750 cc. benzene was added to a stirred suspension of aluminum chloride (62.5 g.) in 1000 cc. of benzene and worked up in the usual manner. Distillation of the total product gave the following fractions: (1) 208 g. of b. p. 100–160° at 0.06 mm.; (2) 683 g. of b. p. 160–187° at 0.06 mm.; (3) 84 g. of b. p. 190–238° at 0.3 mm. Fraction 1 was first separated in the cold into trichloroethylene soluble material and trichloroethylene insoluble material. By repeated crystallization of the insoluble material first from trichloroethylene and then from benzene we isolated pure hexachlorobenzene and V. Removal of the solvent from the trichloroethylene soluble material and repeated crystallization first from benzene-alcohol (2:1) and finally from alcohol alone gave finally additional pure V and ethylpentachlorobenzene. In all we isolated 11 g. of hexachlorobenzene, 42.5 g. of ethylpentachlorobenzene and 22 g. of V from this fraction. Fraction 2 was first redistilled at 0.2 mm. to yield 669 g. boiling from 170–202°. This total product was crystallized by dissolving it in hot trichloroethylene and then adding ethanol until the hot solution began to get cloudy. On cooling V precipitated. The mother liquors were then concentrated until half of the original trichloroethylene had been removed and alcohol was again added to incipient crystallization. Both this crop and a third crop obtained by repetition of this process proved to be 1-pentachlorophenyl-1-phenylethane, IV. In all we obtained 369 g. of V and 253 g. of IV. Fraction 3 was first extracted with 3 300-cc. portions of ethanol and then each extract and the residue were repeatedly crystallized from benzene–ethanol (5:1). In this way we succeeded in isolating 5 g. of pure V and 5 g. of a compound melting from 132–133°. To this latter compound we have assigned the structure VI.

*Anal.* Calcd. for $C_{20}H_{13}Cl_5$: C, 55.81; H, 3.05. Found: C, 55.42, 55.49; H, 3.10, 2.89.

(4) The microanalyses were performed by Dr. Carl Tiedcke.

**Chlorination of Ethylpentachlorobenzene at 180°.**—Redistilled ethylpentachlorobenzene (1000 g.) was illuminated with a 500-watt bulb and chlorinated at 180° to a gain in weight of 132 g. and then reacted with benzene as above. Distillation gave the following fractions: (1) 229 g. of b. p. 100–160° at 0.15 mm.; (2) 546 g. of b. p. 168–180° at 0.2 mm.; (3) 60 g. of b. p. 186–205° at 0.3 mm.; (4) 123 g. of b. p. 210–232° at 0.8 mm.; (5) 36 g. of b. p. 232° at 2.5 mm. Fraction 1 was separated into material soluble in trichloroethylene in the cold and material insoluble in trichloroethylene in the cold. The insoluble material was crystallized from trichloroethylene yielding 11 g. of hexachlorobenzene. The soluble material was crystallized from ethanol yielding 110 g. of ethylpentachlorobenzene. Fraction 2 was crystallized as in the previous case from trichloroethylene-alcohol yielding 403 g. of V and 94 g. of IV. Fraction 3 was also crystallized from trichloroethylene-alcohol and gave only 32 g. of V. When Fraction 4 was crystallized from trichloroethylene–alcohol (1:2) both rods and a powder deposited. The two were separated by floating off the powder with mother liquor and were then crystallized separately to yield pure VII, m. p. 132–133° and pure VI, m. p. 143–143.5°. In all we isolated only 11 g. of VII and 7 g. of VI. Crystallization of Fraction 5 from trichloroethylene–alcohol (2:1) gave only 10 g. of hexachlorobenzene.

## Summary

To determine the relative amounts of $\alpha$- and $\beta$-chlorination of ethylpentachlorobenzene at 70–75° and 180° the crude chlorination products were treated in the Friedel–Crafts reaction with benzene and the products of this reaction were then separated by standard methods. To identify the products formed 1-pentachlorophenyl-1-phenylethane, 1-pentachlorophenyl-2-phenylethane and 1-pentachlorophenyl-1,2-diphenylethane were synthesized from starting materials of known structure.

At 70–75° the ratio of $\beta$- to $\alpha$-chlorination is approximately 1.6:1 and at 180° almost 4.6:1, thus indicating a lower activation energy for the $\alpha$-chlorination. This lends support to the mechanism previously postulated to account for the difference in the direction of chlorination and bromination of ethylpentachlorobenzene.

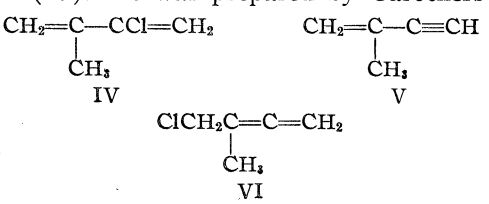
# The Reaction of Dialkylethynylcarbinols with Acidic Reagents

BY CHARLES D. HURD AND WARREN D. MCPHEE[1]

Several branched isomers of the formula $C_5H_7Cl$ are reported in the literature. One such is 3-chloro-3-methyl-1-butyne (I) formed by reaction of dimethylethynylcarbinol with hydrochloric



acid (at 20°) in the presence of cupric (or cuprous) chloride and ammonium chloride.[2] Apparently it was stable during distillation, b. p. 74–76°. The compound reacted with ammoniacal silver nitrate and underwent hydrolysis in the presence of calcium carbonate to the original carbinol. On standing in the presence of cuprous and ammonium chlorides, (I) gradually rearranged into isomers which were indifferent toward ammoniacal silver nitrate and which were assigned structures II (b. p. 101–104°) and III (b. p. 97.5–98°, $d^{20}_4$ 0.9543). II was indifferent, but III was reactive toward maleic anhydride, giving rise to four products of m. p. 210, 239, 298, 352°. Oxidation of II by potassium permanganate yielded acetone and $\alpha$-hydroxyisobutyric acid.

(1) Holder of Commercial Solvents Corporation Fellowship, 1938–1940. Present address: G. D. Searle and Company, Chicago, Illinois.

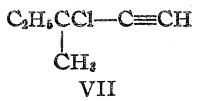
(2) Favorskiĭ and Favorskaya, *Compt. rend.*, **200**, 839 (1935); Favorskaya, *J. Gen. Chem.* (*U. S. S. R.*), **9**, 386, 1237 (1939); Favorskaya and Zakharova, *ibid.*, **10**, 446 (1940).

Another isomer is 2-chloro-3-methyl-1,3-butadiene (IV). It was prepared by Carothers and

Coffman[3] by addition of hydrochloric acid to methylbutenyne (V) in the presence of ammonium chloride and cuprous chloride. It possessed constants (b. p. 93° with some polymerization, 37° (105 mm.), $d^{20}_4$ 0.9593, $n^{20}D$ 1.4689) which are remarkably close to those given for III. The substance was volatile in steam and polymerizable to a jelly on standing for five days in a tube containing a trace of air. It underwent the Diels–Alder reaction with $\alpha$-naphthoquinone, the yield of adduct not being given. Oxidation of the adduct gave the known 2-chloro-3-methylanthraquinone, which is confirmatory evidence for structure IV.

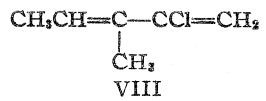
The present work also deals with a product of formula $C_5H_7Cl$ which was obtained by interaction of hydrochloric acid with dimethylethynylcarbinol. A chloride of structure IV would be expected (via V + HCl) on the basis of the behavior of other related ethynylcarbinols[4] toward acidic reagents. Certain facts agreed with this expecta-

(3) Carothers and Coffman, THIS JOURNAL, **54**, 4071 (1932); Carothers and co-workers, *ibid.*, **53**, 4203 (1931); **54**, 4066 (1932).



(4) Hurd and Jones, *ibid.*, **56**, 1924 (1934); Hurd and Christ, *ibid.*, **59**, 118 (1937).

tion. It was volatile in steam. It polymerized to a brown-black gum if kept for a few hours at room temperature. It underwent the Diels–Alder reaction (42% yield). The adduct with maleic anhydride melted at 124–126°. On the other hand, it was not distillable without polymerization unless quite low pressures were used. Also, the refractive index of the distilled material was low ($n^{20}$D 1.445). Any allene isomer VI that might have been present (also via V + HCl) should have caused a higher index of refraction, not a lower one. This follows from the observation that for the pair of lower homologs, 4-chloro-1,2-butadiene and chloroprene, the compound with the allene structure possesses[3] the higher refractive index (1.4775 and 1.4583, respectively).



In view of the above facts, ozonolysis was undertaken to help elucidate the structure. A compound of structure I should yield acids but no aldehydes, whereas IV should yield formaldehyde and acetic (or pyruvic) acid in a 2:1 ratio. Our chloride did yield formaldehyde in this operation. It was identified by its reaction with 2-naphthol, a procedure used by Carothers[3] in the identification of formaldehyde following ozonolysis of 4-chloro-1,2-butadiene. Reaction of the formaldehyde (present work) with methone revealed a yield of 36%. The quantity of IV actually present must, therefore, have been far in excess of 36%, since this value corresponds to the isolated yields[5] of aldehydes obtained by ozonolysis of olefins. A quantitative determination of acetic acid showed that two moles of formaldehyde were obtained on ozonolysis for each mole of acetic acid obtained after further oxidation. Direct oxidation of the substance also afforded acetic acid, characterized by means of Duclaux constants and its *p*-bromophenacyl ester. Since none of the other isomers could behave in this manner, this provides strong support for structure IV.

The question arises why this material differs from the chloroisoprene obtained by Carothers and Coffman. No certain answer is at hand, but since it was prepared from dimethylethynylcarbinol, possibly it contains some I as well as IV. This would explain the lower refractive index but would not account for the instability during vacuum distillation. Furthermore, if Carothers' sample of IV contained a little VI, the latter would bring about a higher refractive index. These questions cannot be answered definitely with the present evidence.

The study was extended to methylethylethynylcarbinol. Campbell[6] used concentrated hydrochloric acid, whereas Favorskaya and Zakharova[2] used this acid in the presence of cuprous and ammonium salts. Structure VII was assigned to the product. The chlorine in this compound (b. p. 48–50° (100 mm.), 51–52° (135 mm.), $n^{20}$D 1.4331) should be reactive, and we found that a comparable sample of it ($n^{20}$D 1.4332) did readily convert silver nitrate solution into silver chloride That some isomeric VIII was present also was confirmed by ozonolysis and characterization of formaldehyde. VIII has been synthesized previously (b. p. 57–60° (96 mm.), $n^{20}$D 1.4671) from 3-methyl-3-penten-1-yne.[3]

VII

VIII

Reaction of dimethylethynylcarbinol with formic acid has been stated by Rupe[7] to yield isopropylideneacetaldehyde, $(CH_3)_2C{=}CHCHO$, but no direct proof of this structure was offered. Traces of it may have been formed,[8] but probably the bulk of any $C_5H_8O$– material was the isomeric[4] 1-methylvinyl methyl ketone, $CH_2{=}C(CH_3)–COCH_3$. In the present investigation it was found that dimethylethynylcarbinol yields only traces of a carbonyl derivative when treated with formic acid. The main product was methylbutenyne (V), indicating that the initial reaction was one of dehydration. 1-Methylvinyl methyl ketone was obtained by first hydrating the ethynylcarbinol in the presence of mercuric acetate to 3-methyl-3-hydroxy-2-butanone and then dehydration of the latter by means of *p*-toluenesulfonic acid. This unsaturated ketone had been prepared previously by Morgan[9] in poor yield by the condensation of formaldehyde with methyl ethyl ketone followed by dehydration. Synthesis by this method demonstrated the identity from the two sources. The compound was shown to possess the structure indicated rather than ethyl vinyl ketone by ozonization to formaldehyde and diacetyl. Oxidation with chromic acid[10] gave 1.2 moles of acetic acid per mole of ketone. Hydrogenation of the unsaturated ketone afforded methyl isopropyl ketone, identified by its carbonyl derivatives.

## Experimental

### Reactions of Dimethylethynylcarbinol

**Hydrochloric Acid.**—When shaken at room temperature for ten to twenty minutes with an excess of concentrated hydrochloric acid, dimethylethynylcarbinol is easily converted to an organic chloride. In a typical experiment, 10 ml. (0.1 mole) of dimethylethynylcarbinol was shaken in a separatory funnel for fifteen minutes with 30 ml. (0.3 mole) of concentrated hydrochloric acid. The solution turned from light to dark green, and a light green-yellow oil separated. This was removed and dried in the refrigerator with anhydrous potassium carbonate. The weight of dried liquid after filtration was 7.5 g. or 73%.

Sometimes the oil was removed from the reaction mixture by distillation, then separated and dried. In general, the purity of the material isolated this way was no higher than if it was simply separated from the reaction mixture, because polymerization set in during distillation. The yields (60–70%) were usually less for the same reason.

(9) Morgan and Holmes, *J. Chem. Soc.*, 2667 (1932); British Patent 404,317; Morgan and Griffith, *ibid.*, 841 (1937).

(10) Hurd and Pollack, *ibid.*, **3**, 550 (1939).

Distillation at reduced pressure from a water-bath at 30–40° did not prevent polymerization nor give a purer product. The presence of such substances as hydroquinone or picric acid were ineffectual as inhibitors and a considerable tar was formed even when they were taken. Refractive index ($n^{20}D$) of product isolated in this manner ranged from 1.431 to 1.441.

**Dry Hydrogen Chloride.**—Dry hydrogen chloride was passed into 10 ml. (0.1 mole) of dimethylethynylcarbinol at 0° for thirty hours. The mixture became deep red, but never tarry or immobile as was often the case at higher temperatures. The product was treated with anhydrous sodium carbonate. The top layer was separated and dried with fresh carbonate. The yield of product, $n^{20}D$ 1.4440, was 6 g. or 52%.

*Anal.* Calcd. for $C_5H_7Cl$: Cl, 34.7. Found: Cl, 35.0.

In another experiment, 30 ml. (0.3 mole) of dimethylethynylcarbinol was saturated with dry hydrogen chloride at 0°. In thirteen hours the reaction mixture gained 13 g. in weight, after which it gained no more. The mixture was always mobile and free from tar. The product was worked up as in the preceding experiment; $n^{20}D$ 1.4447, yield 20 g. or 67%.

**Distillation.**—A 20-g. sample of the crude reaction product was distilled through a Davis column.[11] The flask was maintained at 0° in an ice-bath and the head of the column was cooled to −35° with Dry Ice and acetone. Pressure was lowered and adjusted until reflux was established. Ten grams of colorless distillate was collected at −8 to −7° and 5–6 mm.; $n^{20}D$ 1.4453.

**Ozonization.**—Five grams of product, $n^{20}D$ 1.4435, dissolved in 40 ml. of anhydrous carbon tetrachloride, was treated at 0° with the theoretical amount of ozone. After decomposition[5] of the ozonide, the total volume of aqueous solution was 38 ml. Five ml. of this solution was decolorized with Norit and then refluxed with one drop of concentrated hydrochloric acid and 0.1 g. of 2-naphthol. The crystals of methylenedi-2-naphthol were separated from the boiling solution and were recrystallized from dilute alcohol. The m.p.[12] and mixed m.p. was 203–204°.

The 2-naphthol method is not quantitative for formaldehyde. Dimethyldihydroresorcinol (methone), however, precipitates[13] formaldehyde from very dilute solutions (0.0018 g. per 100 ml.). To 2 ml. of the solution from the ozonization, after decolorization and neutralization, was added 250 ml. of an aqueous solution containing 1.5 g. of dimethyldihydroresorcinol. After twelve hours, 0.55 g. (0.0019 mole) or 36% yield of methylenebis-dimethyldihydroresorcinol was collected. It melted[14] at 187–188° after recrystallization from alcohol.

Another 5 ml. of the ozonized solution was treated with 50 ml. of 3% hydrogen peroxide.[15] The solution was refluxed until gases were no longer evolved (ninety minutes), then distilled. Since the Duclaux constants (7.7, 8.7, 10.8) corresponded to no acid, the solutions were recombined and oxidized for fifteen minutes with refluxing chromic acid solution[16] (6 g. of potassium dichromate, 15 ml. of concd. sulfuric acid, 100 ml. of water). The volatile acid was removed completely by exhaustive distillation[10] and shown to contain 0.0028 mole of acid. That it was acetic acid was shown by Duclaux constants: 6.5, 6.9, 7.4. The neutralized solutions were evaporated and the sodium salt was placed in reaction with 0.5 g. of *p*-bromophenacyl bromide to form *p*-bromophenacyl acetate, m.p. and mixed m.p. 84°.

Chromic acid solution as prepared above will oxidize formic acid quantitatively without affecting acetic acid. Hence the total acetic acid in the total ozonization mixture was 0.0213 mole. The total formaldehyde was 0.0365 mole. The ratio of formaldehyde to acetic acid was, therefore, 1.7 to 1.

**Reaction with Maleic Anhydride.**—Five ml. of the product ($C_5H_7Cl$) was treated with 2.3 g. of maleic anhydride. The mixture was boiled gently and the anhydride dissolved to form an amber solution. The solid obtained on cooling was recrystallized twice from dry pyridine. The white needles of 1,2,3,6-tetrahydro-4-chloro-5-methylphthalic anhydride melted at 124–126°; yield, 2 g. (42%). It dissolved readily in water.

*Anal.* Calcd. for $C_9H_9ClO_5$: equiv. wt., 100.3. Found: equiv. wt., 102.3, 98.06.

**Reaction of Methylethylethynylcarbinol with Hydrochloric Acid.**—Forty grams (0.4 mole) of methylethylethynylcarbinol was shaken for fifteen minutes with 200 ml. (2 mole) of concentrated hydrochloric acid. The mixture became warm and dark on shaking. The light yellow top layer was separated, dried at 0° with potassium carbonate, filtered, and distilled through a 60-cm. column packed with nichrome helices. The material was not of uniform composition, since of the 23 g. (48% yield) collected in several fractions, between 100–103°, $n^{20}D$ values change from 1.4222 to 1.4385. Of this, 10 g. had b.p. 102.5–102.7°, $n^{20}D$ 1.4332, which corresponds to the chloride described by Campbell.[4] This material is exceptionally more stable than the lower homolog obtained from dimethylethynylcarbinol.

**Oxidation.**—A mixture of 5.5 g. of this chloride (b.p. 102.5–102.7°) and 100 ml. of water was added to a chromic acid solution (48 g. potassium dichromate, 120 ml. concd. sulfuric acid, 400 ml. distilled water). The mixture was refluxed for three hours and the volatile acid was completely removed by exhaustive distillation. Titration revealed 0.0943 mole of acid, or 2.0 moles of acid per mole of substance oxidized. The distillate gave no test for sulfate or chloride. Duclaux constants were satisfactory for acetic acid (7.1, 7.5, 7.9). One gram of the dry salt, obtained by neutralizing the acid, was converted to *p*-bromophenacyl acetate, m.p. and mixed m.p. 84–85°.

**Ozonization.**—The product (9.1 ml.), b.p. 102.5–102.7°, was dissolved in 50 ml. of dry carbon tetrachloride and treated with ozone as above outlined to yield 35 ml. of an aqueous solution of formaldehyde, from which methylenedi-2-naphthol, m.p. 203–204°, was obtained by reaction as before with hydrochloric acid and 2-naphthol.

**Reaction of Dimethylethynylcarbinol with Formic Acid.**—When this reaction was carried out in the manner outlined by Rupe,[7] a pure product was never isolated. A typical run consisted in refluxing 24 ml. (0.6 mole) of 85% formic acid with 9.8 ml. (0.1 mole) of dimethylethynylcarbinol for two and one-half hours. The solution soon became dark. It was cooled, extracted thrice with ether, and the extracts were washed with sodium carbonate solution, dried and distilled. Three grams of the carbinol was collected between 100–107° ($n^{20}D$ 1.421) and 1.1 g. of distillate was collected in three fractions between 107–130° ($n^{20}D$ 1.425, 1.429, 1.447). All fractions, even the carbinol collected, gave semicarbazones of m.p. 214°. Rupe gives the m.p. of "isopropylideneacetaldehyde" semicarbazone as 244°, but recrystallization never raised the m.p. of our semicarbazone above 214°.

To isolate methylbutenyne, 17.2 g. (20 ml.) of dimethylethynylcarbinol and 50 ml. of 85% formic acid were refluxed under a condenser maintained at 50–60°. Volatile material was conducted into a trap at 5° and another at −78°. After fourteen hours of refluxing, 10.2 g. of volatile product was condensed by the cold traps. The yield of methylbutenyne, b.p. 31–34°, $n^{20}D$ 1.4105 was 9.7 g. or 72%. Similar boiling points were reported by Carothers[3] and Scheibler and Fischer.[17] The product gave definite voluminous precipitates with potassium mercuric iodide solution[18] and with ammoniacal silver nitrate.

**Dehydration of 3-Methyl-3-hydroxy-2-butanone.**—Thirty grams of 3-methyl-3-hydroxy-2-butanone, prepared by the method of Scheibler and Fischer,[17] was added

dropwise to 5 g. of *p*-toluenesulfonic acid in a distilling flask in an oil-bath at 150°. Of the 30 g., 14.5 g. was recovered. The 1-methylvinyl methyl ketone steam distilled directly. It was dried with Drierite and distilled, b.p. 94–98°; yield, 10 g. The yield, based on the unrecovered starting product, was 74%.

The semicarbazone of this ketone was prepared from 1 g. of the ketone and recrystallized twice from water. It melted at 178°.

*Anal.* (method of Smith and Wheat[19]). Calcd. for $C_6H_{11}N_3O$: $NNHCONH_2$, 51.74. Found: $NNHCONH_2$, 51.63.

**Preparation of 1-Methylvinyl Methyl Ketone.**—A modification of Morgan's method[9] was used, taking 108 g. of methyl ethyl ketone, 225 g. of 40% formalin, and 25 ml. of 2 *N* sodium hydroxide solution. The initial reaction is vigorous and requires a long, efficient reflux condenser. There was obtained 36 g. of 3-methyl-4-hydroxy-2-butanone, b.p. 95–110° (18 mm.). This was dehydrated to 1-methylvinyl methyl ketone by distillation with a trace of iodine, instead of with potassium acid sulfate as used by Morgan. The yield was increased by this change. The product was dried (sodium sulfate) and distilled; b.p. 94–97°, $n^{20}D$ 1.4224. The yield of 14 g. is an over-all yield of 11%. Morgan reported 4%. The semicarbazone of this ketone (m.p. 178°) did not depress the m.p. of that prepared above.

**Ozonization.**—A solution of 5.2 g. of 1-methylvinyl methyl ketone in 50 ml. of carbon tetrachloride (dried with Drierite) was treated at 0° with ozone as outlined above to form an aqueous solution (35 ml.) neutral to litmus, containing aldehydes and ketones. A 5-ml. sample of the solution, treated with 0.5 g. of semicarbazide hydrochloride and 0.5 g. of anhydrous sodium acetate and kept at 0°, gave rise to 0.46 g. (31% yield) of biacetyl semicarbazone. After recrystallization from alcohol, it melted at 273–275° (d.). When mixed with an authentic specimen, the m.p. of 277–277.5° was not depressed.

Another 5-ml. portion was treated with 0.02 g. of 2,4-dinitrophenylhydrazine in 5 ml. of aqueous alcoholic sulfuric acid solution. Gradually at 0°, yellow crystals of formaldehyde 2,4-dinitrophenylhydrazone, m.p. 165–167° (d.), appeared.

**Oxidation.**—Two and one-half grams of 1-methylvinyl methyl ketone was heated with a solution of 21 g. of potassium dichromate, 52 ml. of concentrated sulfuric acid and 175 ml. of water. After the evolution of carbon dioxide ceased (thirty minutes), the mixture was refluxed for thirty minutes. It was then distilled.

Duclaux constants: 7.4, 7.5, 8.0; 7.5, 7.9, 8.6; 7.0, 7.5, 8.2, agree better for acetic acid, 6.8, 7.1, 7.4, than for propionic acid, 11.9, 11.7, 11.3. The neutral solution from the Duclaux measurements was evaporated to 2 ml. and converted into *p*-bromophenacyl acetate, m.p. 83–84°.

A sample (0.670 g. or 0.00796 mole) of 1-methylvinyl methyl ketone was oxidized as above, but with the oxidizing mixture diluted to half the previous concentration. The acetic acid was distilled slowly in an all-glass system until crystals formed. The distillate, which gave no test for sulfate, contained 0.00897 mole of acetic acid, or 1.2 moles of acid per mole of ketone oxidized.

(19) Smith and Wheat, *Ind. Eng. Chem., Anal. Ed.*, **11**, 200 (1939).

**Hydrogenation.**—Twenty-six grams (0.31 mole) of 1-methylvinyl methyl ketone, dissolved in 25 ml. of pure pentane, was hydrogenated at 25° and 1000 pounds pressure in the presence of 3 g. of a reduced nickel catalyst.[20] The hydrogen absorbed was 0.31 mole. From the filtered solution was obtained 19.5 g. of methyl isopropyl ketone (75% yield), collected in several fractions. Of the total yield, 13.2 g. of the ketone had b.p. 93–98°, $n^{20}D$ 1.3875–1.3890.

All fractions also gave 2,4-dinitrophenylhydrazones, m.p. 119–122° after recrystallization from alcohol, and semicarbazones of m.p. 110–113° after recrystallization from water. The 2,4-dinitrophenylhydrazone of the known sample of methyl isopropyl ketone melted at 121° after recrystallization. Allen[21] lists the m.p. as 117°. The mixed m.p.'s were not depressed.

**Reaction of Dimethylethynylcarbinol with Ketene.**—The calculated quantity of ketene was passed into a cold (0°) solution of dimethylethynylcarbinol (10 ml.) in 10 ml. of dry carbon tetrachloride containing a drop of concentrated sulfuric acid. The solution was then neutralized with a little potassium carbonate and distilled to give 9.6 g. (74%) of a clear, pungent liquid, b.p. 126–128°. Nearly all the ester boiled sharply at 128°. Scheibler and Fischer[17] reported the b.p. as 128–136°. The dimethylpropargyl acetate gave a voluminous precipitate with ammoniacal silver nitrate solution. Its saponification equivalent was 125; calculated, 126.

## Summary

The reaction of dimethylethynylcarbinol with hydrochloric acid is not one of simple metathesis but gives rise to an extensive production of 2-chloro-3-methyl-1,3-butadiene or chloroisoprene. This conclusion is based on methods involving oxidation, ozonolysis, and reactivity toward maleic anhydride.

Methylethylethynylcarbinol reacts with hydrochloric acid to yield the metathetic product, 3-methyl-3-chloro-1-pentyne, but evidence was found for 2-chloro-3-methyl-1,3-pentadiene in this material. The product was much more stable than that from dimethylethynylcarbinol.

Ketene reacts smoothly with dimethylethynylcarbinol to produce 1,1-dimethylpropargyl acetate. With formic acid, however, the carbinol undergoes dehydration into methylbutenyne which was capable of being hydrated to 3-methyl-3-hydroxy-2-butanone. Evidence for the structure of the latter was dehydration into 1-methylvinyl methyl ketone which underwent catalytic hydrogenation to methyl isopropyl ketone.

# Electron Exchange-Polymers. I

BY HAROLD G. CASSIDY

## Introduction

This paper, and subsequent ones in this series, will describe experimental results and theoretical conclusions which had their inception in the author's idea that it should be possible to prepare polymeric substances capable of reversibly exchanging electrons with the molecules or ions of a contiguous phase.

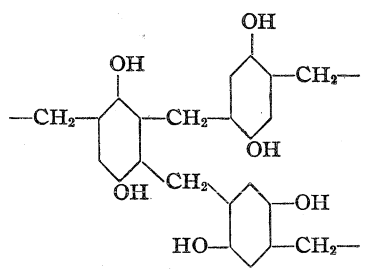
Polymeric substances of this character have been prepared and this unusual exchange property has been successfully demonstrated. The behavior is thus analogous to that of the cation exchange-polymers, some of which are able to exchange protons for other cations in a contiguous phase. It can now be stated that two of the fundamental particles, the electron and the proton, can be reversibly exchanged between polymeric substances and contiguous phases in much the same manner.

The exchange of a cation may be considered, in the sense of the generalized theory of oxidation and reduction,[1] to involve an oxidation and reduction, though electrons are only displaced in the process. The exchange of electrons would be an extreme case, and would correspond to the classical oxidation and reduction.

Analogies have frequently been pointed out between the behaviors of protons and electrons. Clark[2] has referred to this. Schwarzenbach[3] has proposed that an acid–base equilibrium be described by a normal acidity potential $E_{ac}$ defined by the equation

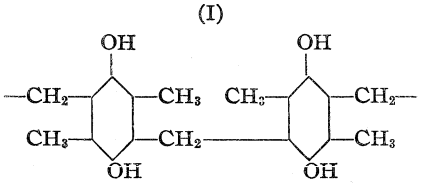
$$E = E_{ac} + \frac{RT}{F} \ln \frac{[\text{Acid}]}{[\text{Base}]}$$

in analogy to the oxidation–reduction equilibrium for which the normal oxidation potential of the system $E_{ox}$ is defined by



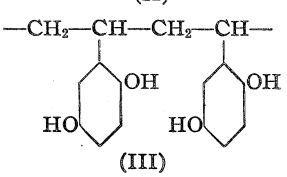
$$E = E_{ox} + \frac{RT}{F} \ln \frac{[\text{Ox.}]}{[\text{Red.}]}$$

Michaelis and Schubert[4] comment that in the field of ionization theory the acceptance of protons is the analog of the elementary reduction process. Schubert[5] has discussed the analogy between two-step ionization and two-step oxidation. There is thus ample background indicating the formal resemblance between proton exchange and electron exchange. However, the differences observed in working with the two phenomena has caused their theoretical treatments to proceed along different lines, as Schubert has pointed out.[5a]



Proton exchange by cation exchange-polymers is conditioned in part by the hydrogen ion concentration of the phase contiguous to the exchanger. The electron exchange would be expected to be controlled in part by the availability of electrons to the exchanger, where availability involves potential, and the ability of the exchanger to accept them. It remained to be investigated how close the analogy would be between the two processes. The problem of constructing and establishing an electron exchanger turned out to be more difficult than had been at first anticipated. However, I am now able to report successful verification of the concept.

The electron exchange-polymer consists of given residues, capable of entering an oxidation–reduction system, which are bound together by linkages which do not necessarily interfere seriously with (though they may influence) the functional oxidizable or reducible groups. This permits building up a polymeric structure with many sites capable of accepting or donating electrons.



In setting up this problem, two classes of polymeric substances were considered: (1) those in which the active group forms a part of the backbone of the polymer chain, and (2) those in which the active group is a substituent on the chain. Class 1 consists of substances of the types hydroquinone–formaldehyde resins (I), substituted hy-

(5a) Reference 4, p. 113.

droquinone-formaldehyde resins (II), and similar substances. To Class 2 belong substances like polyvinylhydroquinone (III).

The substances belonging to Class 1 would be expected to exhibit effects due to the constraints of linking and cross-linking; distortions of the ring so produced might be reflected in the observed potentials of half-reduction, or in the propensity toward semiquinone formation,[4,7] and the effects might be expected to be more marked than those exhibited for the same reason by compounds of the second class. The change from oxidized to reduced form might, in the first case (Class 1), be reflected in a marked change in polymer dimensions, since the longer diameter of the quinone ring is about 0.26 Å. longer than the diameter of the hydroquinine ring.[8] Changes in polymer dimensions and other physical properties with reduction or oxidation might also be expected in compounds of Class 2 if there were, for example, a dimerization of adjacent semiquinoid forms, or if resins of the type IV were on mild oxidation to cross-link (V) or form rings (VI).

A further classification of exchange-polymers in terms of charge-type of the oxidized form may be made: (a) the oxidized form carries no charge (*e. g.*, of III or IV), and (b) the oxidized form carries a positive charge, as would be the case with a polymer such as butyl polyvinylpyridinium halide (VII).[9] These charge-types might be found in polymers of Class 1 or Class 2. An example of a polymer belonging to Class 1b would be polyvinylpyridinium bromide cross-linked with the ethylene bridge (VIII).[10]

The idea of electron exchangers and the hypothesis based upon it have been illustrated with specific structures (I to VIII) but naturally many other chemical examples could have been chosen. These would differ in oxidizable groups, *e. g.*, indophenols might be used, or other groupings found in oxidation–reduction indicators and similar but colorless substances. They might differ in methods of linking of monomers, *e. g.*, instead of the illustrated type of linking, polyesters, ethers, polyamides, might be produced.

## Experimental

It seemed desirable to make an initial test of this hypothesis against a relatively simple polymeric substance, and for this reason polymerized vinylhydroquinone was chosen. This substance was prepared (see the following paper) from vinylhydroquinone, a new compound, prepared by decarboxylation of dihydroxycinnamic acid. This substance was prepared from *o*-hydroxycinnamic acid by the method of Neubauer and Flatow.[11] The resin was a pale yellow, polystyrene-like material, not very soluble in benzene, soluble in some organic liquids such as glacial acetic acid, and becoming tacky in water. It was extracted with benzene to remove monomer.

The oxidation titrations reported in this and the following paper were carried out in the conventional manner,[12] using a bright platinum electrode referred to a saturated calomel electrode. The potentials were read with an L. & N. Student Potentiometer. Equilibrium was taken to have been reached when the same potential was read at the end of each of three successive minutes following 30 sec. mechanical stirring and 30 sec. without stirring. The data were recorded to the nearest tenth of a millivolt and calculated to the standard of the normal hydrogen half-cell. The temperature was that of the room. In common with the observations of other workers,[13] the greatest variations in mid-point potential were found with changes in solvent systems.

The oxidation of polymerized vinylhydroquinone could be carried out in solution in 90% acetic acid according to the method of Michaelis and Hill.[14] In the experiment reported here 90 parts of glacial acetic acid was made up to 100 by adding water, and the *p*H (glass electrode) found was −0.45. Polymerized vinylhydroquinone (12.094 mg., 0.1777 me.) was dissolved in 10 ml. of acetic acid solution and titrated with 0.0359 *N* bromine solution in the same solvent. Room temperature was 23°. During the course of the titration the solution developed a pinkish-orange coloration. The system came to equilibrium slowly, but stable potentials were obtained except at the beginning and very end of the titration, when there was evident a tendency to a slow drift of the potential downwards. The course of the titration is shown in Fig. 1. The mid-point potential was −0.713 v.; the final *p*H approximately −0.6. The end-point, if all the hydroquinone residues had been available, should have come at 4.95 ml. bromine solution; found, a little over 4.90 ml. The abscissa of the curve in Fig. 1 is calculated on 4.95 ml. as 100% oxidation. Included in Fig. 1 for reference purposes are the titration data for hydroquinone and ethylhydroquinone. 10.043 mg. of recrystallized hydroquinone

in 10 ml. 90% acetic acid ($p$H 0.0) was titrated with bromine in the same solvent; final $p$H *ca.* −0.4; room temperature 24°. For the latter, 12.918 mg. of ethylhydroquinone in 10 ml. of acetic acid–water, $p$H −0.45, was titrated with bromine in the same solvent. The final $p$H was *ca.* −0.6. In Fig. 1, a curve is drawn through the points for the polymerized vinylhydroquinone for increased ease of visualization.

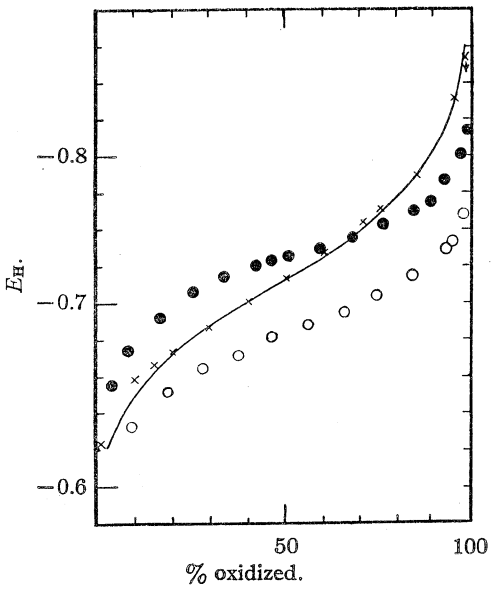

Fig. 1.—Oxidation of polymerized vinylhydroquinone, of hydroquinone and of ethylhydroquinone in solution in aqueous acetic acid with bromine in the same solvent: $E_H$ potential in volts referred to the normal hydrogen electrode: ×, polymerized vinylhydroquinone; $p$H, −0.45 to −0.6; temperature 23°. The line is drawn through the points to improve visualization of the curve. ⁑, this point showed a slight downward drift. ●, hydroquinone, $p$H 0.0 to −0.4, temperature 24°; O, ethylhydroquinone, $p$H −0.45 to −0.6, temperature 23°.

The oxidation of polymer in solution was thus shown to be possible. It was found difficult to show stoichiometric electron exchange when the polymer was in the solid form in bulk. When the polymer was dispersed by dissolving *ca.* 10 mg. in 0.1 ml. glacial acetic acid and adding 10 ml. of buffer in which the polymer was insoluble, milky-white suspensions were formed which with the first drop of oxidant became orange-opalescent, and which on further oxidation threw down a curdy, orange precipitate. The oxidized form of the resin is orange-yellow in color.

It was decided to disperse the polymer with a carrier or stabilizer. It then became possible to obtain more nearly quantitative oxidation and to obtain clear evidence of the reversible oxidation of the polymer. Polymerized vinylhydroquinone (14.871 mg., 0.2185 me.) was dissolved in 0.15 ml. of glacial acetic acid and treated with 10 ml. of buffer (sulfuric acid–potassium sulfate) containing 2.44 mg. ($3.5 \times 10^{-5}$ millimole) of bovine plasma albumin (Armour, crystalline). A milky suspension formed. This was titrated under nitrogen with ceric sulfate, $p$H 0.54, 0.0279 *N*. At the first drop of oxidant the suspension began to flocculate and a pinkish-orange color developed. The color became somewhat more intense as the titration progressed, and the precipitate, now brick-red, became dispersed. As the mid-point was passed the color of the precipitate became gradually less red until it was quite noticeably paler at the end-point. The potential changed quite suddenly, between 6.10 and 6.25 ml. cerate, from −0.466 to −0.72 v. (against the saturated calomel electrode). The calculated end-point for equivalence was 7.83 ml. assuming all hydroquinone residues available. The difference between the calculated and found volumes of ceric sulfate is ascribable to polymer inside the particles of precipitate and thus inaccessible to oxidant. At this point the titration was stopped, purified hydrogen gas led in, and 0.5 ml. palladium catalyst added[15] with stirring.

A platinized electrode came to a stable potential of −0.2730 v. against the calomel half cell ($p$H 0.46) after one and one-quarter hours. The vessel was then flushed with nitrogen for two and one-half hours, until the potential had fallen −0.13 v.[14] The suspension was now grayish (*i. e.*, polymer reduced) and there was a small amount of granular orange precipitate (unreduced polymer) present. Titration with ceric sulfate was again carried out, an orange color and flocculation of the precipitate appearing with the first drops of oxidant. The course of this titration followed closely that of the first one. The $p$H of the final solution was 0.50. The amount of cerate used at the end-point was 5.1 ml., indicating again that some polymer was unavailable. The potential data, calculated for per cent. oxidation based on the amount of oxidant actually used, are shown in Fig. 2 and indicate good agreement between the two experiments. A separate test of the albumin solution showed the amount of oxidant used to be inconsequential.

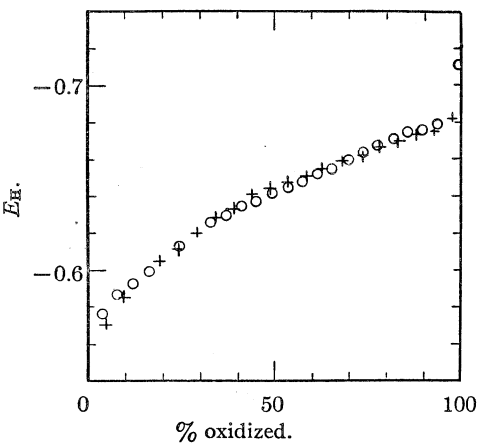

Fig. 2.—Oxidation, and reoxidation following reduction, of polymerized vinylhydroquinone suspended in the presence of albumin: $E_H$ potential in volts referred to the normal hydrogen electrode: O, oxidation with ceric sulfate, $p$H 0.54; +, repetition of above after reduction with hydrogen and removal of excess hydrogen; final $p$H 0.50.

A titration of polymerized vinylhydroquinone dispersed at another $p$H is given in the following paper, together with reference titrations of other substances and a summary of pertinent data. A large number of titrations of the polymer have been made under a variety of conditions. Some of the curves obtained have shown unusual features difficult as yet to interpret. The curves given in this and the following paper are quite reproducible on repetition of the given experiments.

## Discussion

The slopes of the curves which can be drawn for hydroquinone and ethylhydroquinone speak for a bivalent oxidation, while the slopes of the polymerized vinylhydroquinone curves are near that of a monovalent oxidation (see Figs. 1 and 2).

(15) 0.05 g. $PdCl_2 \cdot 2H_2O$ dissolved with 0.05 g. of gum arabic in 50 ml. of water. See J. Houben, "Die Methoden der organischen Chemie," 3rd ed., 2, p. 325 (method of Paal and Skita).

The interpretation of these curves is of interest, especially in connection with the use of these polymers as models of more complicated systems. Michaelis and his co-workers[16] have already formulated the theory for the slopes of the potentiometric titration curves. According to their analysis the rather flat curves are obtained when there is no appreciable semiquinone formation, and no appreciable dimerization; that is, when there is no appreciable formation of an intermediate compound during the oxidation of the reduced form of the substance or the reduction of the oxidized form.

For substances which form no intermediate the slope ($\delta$) at the mid-point of the curve is 0.026 volts per unit of $\mu$, where $\mu$ has the following meaning: at 0% oxidation $\mu = -1$; at 50% oxidation $\mu = 0$; at 100% oxidation $\mu = +1$. At the mid-point the index potential $E_i$, which is defined as the potential difference between 50% oxidation and 25% (or 75%) oxidation, is 0.0143 v. at 30°. If appreciable intermediate compound formation occurs it is recognized from the slope of the titration curve. With increase in intermediate formation $\delta$ increases and $E_i$ increases, and when the amount of intermediate formation becomes great enough points of inflection appear in the curves below and above the midpoint. The formation of semiquinone intermediate is increased if the *p*H of the medium is such that ionization of the substance is aided, for the increased number of resonance forms of the semiquinoid ion stabilize it as compared with the un-ionized semiquinone form. Thus the shapes of these curves will vary with *p*H.

Under the acid conditions employed in these experiments hydroquinone and ethylhydroquinone show no appreciable semiquinone formation. The semiquinone form of hydroquinone, and presumably of the other compound, is not stable in aqueous solution. In solution the rate of its dismutation is so great that little semiquinone can accumulate. Thus when quinhydrone is dissolved in acid a pale yellow solution is obtained rather than the highly colored solution which would be expected of this greenish-brown substance. Accordingly in the titrations (Fig. 1) hydroquinone showed $E_i$ 20, 14 mv.; $\delta$, 27 mv. per unit of $\mu$. Ethylhydroquinone showed $E_i$ 22, 22 mv.; $\delta$ *ca.* 42 mv. per unit of $\mu$.

When polymerized vinylhydroquinone is titrated in the dissolved state the initially colorless solution becomes pink-orange with the first drop of oxidant. With further addition of oxidant the pink-orange color becomes more intense, the pinkness becoming more marked. After the titration has proceeded some distance the solution begins to lose its pinkness and a yellow color supervenes. This sequence of colors could be produced if the polymer were in colloidal suspension and were to pass through a sequence of particle-size changes with its oxidation. This possibility has not been experimentally ruled out. The effective particle size might change if a thread-like molecule were to bunch up, or to become extended; or if many molecules were to clump together reversibly; and such behavior might occur under the influence of the added electrolyte or through a dimerization of semiquinoid forms within a molecule or between molecules, or through mechanisms such as discussed by Rabinowitch and Epstein.[17]

Against this interpretation of the color change are the observations that the same color sequence appears whether the oxidizing agent is bromine, cerate (or dichromate—see paper II), and whether the titration is carried out in a solution of a given concentration or in a solution one-tenth as concentrated. The same sequence of colors with these different oxidizing agents argues against a particle-size change due to the influence of added electrolyte, because the charge-type changes are so different. The lack of influence of dilution, the same shape of curve being obtained experimentally with a ten-fold difference in concentration, argues against an association of molecules. However, when the dispersed polymer is titrated with cerate the particles have been observed to flocculate, to be peptized, and to reflocculate at different stages during the titration (see above) when the stirring is stopped to enable a reading, but this behavior does not seem to influence the color of the solution and suspended matter. These present arguments are admittedly qualitative, and further pursuit of this phase of the problem is of course contemplated.

A more likely explanation of the color change seems to lie in semiquinone formation, with or without accompanying dimerization. In the polymeric molecules large numbers of oxidizable groups are held in a more or less constrained relation to each other. If some of these groups were to be oxidized to the semiquinone stage (the first step[16] in the oxidation) then even though the semiquinone were inherently easily dismutable (as judged by analogy with hydroquinone itself) yet since it requires the *conjunction* of two semiquinoid forms for dismutation to occur the constraints of the linkage might well hamper the dismutation. While this would not stabilize the semiquinone it would certainly allow it to accumulate. If optical examination of the polymer during the oxidation showed not a peak of color formation at 50% oxidation, but a plateau over a range of added oxidant, this supposition would receive support.

It seems to us, therefore, that the color change observed during the course of the titration can best be explained on the basis of the formation of some semiquinone. The formation of semiquinone would account for the appearance of the pink color, the yellow being attributable to the fully quinoid residues.

(16) L. Michaelis, *Chem. Revs.*, **16**, 243 (1935); L. Michaelis and M. P. Schubert, *ibid.*, **22**, 437 (1938); L. Michaelis, *Ann. New York Acad. Sci.*, **40**, 39 (1940).

(17) E. Rabinowitch and L. F. Epstein, THIS JOURNAL, **63**, 69 (1941).

There is in this interpretation a possible explanation of an observation by Haas[18] that the combination of the active group of yellow ferment with its specific protein in the presence of a large excess of triphosphopyridine nucleotide allows on reduction at *p*H 7 (0°) the appearance of an amount of the red free-radical form which is otherwise observed with the *free* active group only in strongly acid solution, where the increased ionization of the free substance allows increased resonance stabilization. It was inferred from this observation that the Michaelis relation of radical dismutation[16] was displaced toward the radical. The mechanism which our observations suggest is that the active group when combined with the specific protein into the ferment complex is so isolated from other active groups that accumulation of radical is favored by the hampering of dismutation, and not *necessarily* by a stabilizing of the radical form.

The formation of semiquinone would also account satisfactorily for the increased slope of the curve for polymerized vinylhydroquinone (Fig. 1). Here $E_i$ was found to be 32 and 35 mv., and $\delta$ *ca.* 70 mv. per unit of $\mu$. It has seemed to us, however, that there is another phenomenon which might and probably does contribute to the shape of the curve, and which would be adequate of itself to account for the slope were not the special color change observed during the titration. This other phenomenon is treated in the following paper.

The behaviors of all the polymers so far investigated indicate a certain instability toward very strong oxidizing agents, and tendency toward some further reactions. Thus in strong acid (hydrochloric, etc.) with ceric sulfate some oxidation of the quinones might be expected, as well as addition of the acid to the unsaturated system. Or, with the reduced polyvinylpyridinium compounds further reduction might be anticipated, or addition of reactants from the medium, as observed by, for example, Karrer, *et al.*,[19] when the dihydropyridinium products of hydrosulfite reduction were found to contain sulfur. These problems will be discussed in succeeding papers. It need only be mentioned here that strong oxidizing agents slowly destroy hydroquinone–formaldehyde resins, and a strong reducing agent seems to carry the reduction of polyvinylpyridinium polymer beyond the dihydro stage.

These results, together with those reported in the paper which follows, indicate quite conclusively that electron exchange-polymers can be and have been prepared. It will no doubt be possible by appropriate variations in structure, reaction medium and *p*H, to run the gamut of reduction potentials with these substances. Some control of *p*H is to be expected if ion exchange monomer were copolymerized with an electron exchanger.

Apart from the very interesting theoretical problems opened up by the development of these substances their production makes possible a systematic attack from a new direction on a number of important biochemical problems. Early in this work it was suggested to me by Dr. G. J. de Suto-Nagy that these polymers might serve as models for certain biological systems. It might be possible to investigate some of the problems stated by, for example, Korr,[20] for here one could work with a heterogeneous system in which structurally-known constraining arrangements (as in Class 1 polymers) might be introduced, or constraints of other kinds such as those due to copolymerization with basic or acidic monomer. The activating or deactivating effects of such constraints, reflected in the semiquinone formation constants, for example, might well find analogies in biological systems. It might be supposed,[21] for example, that the reduction–oxidation polymers might serve as catalysts in organic and other oxidations through their ability to take up electrons and pass them on to other molecules, in a function which has been laid to the coenzyme.[22]

We have in these electron exchange-polymers a new chemical instrument by means of which many interesting chemical and biochemical problems may be attacked. Emphasis should probably be laid on the value of these polymers as substances by means of which convenient, simplified models of much more complicated systems may be contrived.

**Acknowledgment.**—I would like to acknowledge the stimulating discussions of this problem held with Dr. Charles S. Cleaver, Dr. G. J. de Suto-Nagy, Dr. Joseph Fleischer, Mr. Robert A. Hardy, Mr. Harold K. Inskip, Dr. F. H. M. Nestler, Mr. Ivor H. Updegraff and Mr. Vincent Verplanck.

## Summary

The hypothesis that electron exchange-polymers could be produced has been advanced and tested by oxidation studies made on a polymerized vinylhydroquinone. Analogies to the proton exchange-resins have been pointed out. During the oxidation of the polymer, whether in solution or in a dispersed solid form, a pink color develops. This is interpreted to indicate the accumulation of semiquinoid residues the dismutation of which is hampered by the constraints of the polymer structure. An observation of E. Haas on the effect of the combination of yellow ferment with its specific protein on free-radical formation has been reinterpreted. The possible usefulness of electron exchange-polymers in attacking certain biochemical problems has been mentioned.

# Electron Exchange-Polymers. II. Vinylhydroquinone Monomer and Polymer

BY IVOR H. UPDEGRAFF AND HAROLD G. CASSIDY

## Introduction

A previous paper[1] set forth the requirements for an electron exchange-polymer and showed that these requirements are met by a polymerized vinylhydroquinone. This paper discusses, and describes the preparation and properties of, vinylhydroquinone and polymerized vinylhydroquinone.

The synthetic scheme is illustrated by structures I to V

Coumarin (I) was converted to *o*-coumaric acid (II) by refluxing it with sodium ethylate according to the directions of Ebert.[2] The *o*-coumaric acid was then converted to 2,5-dihydroxycinnamic acid (III) by treating it with potassium persulfate according to the method of Neubauer and Flatow.[3] The decarboxylation of 2,5-dihydroxycinnamic acid was carried out by heating the free acid under reduced pressure in a sublimation apparatus to a temperature slightly above its melting point. The vinylhydroquinone (IV) produced by the loss of carbon dioxide sublimed as it was formed together with some of the unchanged acid.

For polymerization, the vinylhydroquinone was sealed in a glass tube under reduced pressure and heated to 125° for many hours without added catalyst. Within the first minutes of heating the monomer melted to a pale amber, mobile liquid. This became very viscous within the course of an hour. After cooling, the polymer was extracted with hot benzene to remove unchanged or slightly polymerized monomer.

Vinylhydroquinone has not been previously described. It is a colorless crystalline solid which melts at 111°. Its identity was established by ultimate analysis as well as by catalytic hydrogenation to the known compound ethylhydroquinone.

(1) H. G. Cassidy, THIS JOURNAL, **71**, 402 (1949).

(3) O. Neubauer and L. Flatow, *Z. physiol. Chem.*, **52**, 375 (1907).

Polymerized vinylhydroquinone is a pale amber, brittle solid. It is soluble in polar organic solvents and insoluble in benzene. In the presence of water it becomes soft and tacky. An attempted catalytic hydrogenation failed to reveal unsaturation. The oxidation equivalent determined by mild oxidation is that which would be expected for the conversion from the hydroquinoid to the benzoquinoid form of a polymer in which the functional hydroxyl groups are not involved in cross-linking. The polyquinone so produced is a reddish-orange solid, insoluble in water but easily soluble in most organic solvents, and attacked by strong oxidizing agents.

## Experimental

***o*-Coumaric Acid.**—Coumarin (E. K. Co.) was converted to *o*-coumaric acid by refluxing it for four hours with sodium ethylate, diluting with water, removing most of the solvent *in vacuo*, and neutralizing with concentrated hydrochloric acid. The purified acid was obtained in a yield of 82%; m. p. 207–208° with dec.; neutralization equivalent calcd. 164, found 162.5.

**2,5-Dihydroxycinnamic Acid.**—Coumaric acid (93 g., 0.57 mole) was dissolved in a solution of 160 g. of sodium hydroxide in 3 liters of water. To this solution was added 170 g. of potassium persulfate as a slurry in 1 liter of water. The solution was swirled until all the persulfate had dissolved and was then allowed to stand for twenty-four hours. Concentrated hydrochloric acid was added in small amounts until the solution was red to methyl orange. It was then extracted with ethyl ether in a continuous extractor for twenty-four hours. The extract (35 g.) consisted principally of unchanged coumaric acid. The remaining solution was treated with 600 ml. of concentrated hydrochloric acid and the extraction continued for one week. The crude extract (54 g.) which remained after the evaporation of the ether was puddled with fresh ether and the solid retained on a Büchner funnel. The solid (crude 2,5-dihydroxycinnamic acid) was further purified by treatment with activated charcoal in boiling water. It crystallized from water in the form of needles. Even after repeated crystallization the acid retained a pale green color; yield 23 g. (0.13 mole, 23%); m. p. 208° with decomposition; neutralization equivalent calcd. 180, found 178.5.

**Vinylhydroquinone.**—2,5-Dihydroxycinnamic acid (5 g., 0.028 mole) was charged to a vacuum sublimation apparatus, the pressure reduced to approximately 0.01 mm., and the bulb heated in an oil-bath to 200°. Decarboxylation began at this temperature. The temperature was then slowly raised to 220° over a period of one hour. When the apparatus had cooled the crude sublimate was scraped from the cold surface. It was mixed with about 50 ml. of benzene and the mixture heated to boiling. The warm solution was then filtered to remove unchanged 2,5-dihydroxycinnamic acid which had sublimed with the vinylhydroquinone. On cooling the solution vinylhydroquinone separated as colorless needles; yield 1.45 g. (0.01 mole, 38%), m. p. 111°, cor.

*Anal.* Calcd. for $C_8H_8O_2$: C, 70.59; H, 5.92. Found: C, 70.17, 70.61; H, 5.83, 5.99.

Vinylhydroquinone (0.0934 g., 0.000686 mole) was dissolved in 15 ml. of ethyl acetate and treated with hydrogen at atmospheric pressure in the presence of Adams catalyst. Volume of hydrogen adsorbed (S.T.P.) 16.4 ml., calcd. 15.4. The hydrogenation mixture was decanted from the

catalyst and the ethyl acetate removed under reduced pressure. The residue was dissolved in about 3 ml. of warm benzene and allowed to cool. Colorless crystals were obtained, m. p. 115°. Ethylhydroquinone[4] melts at 113–114°. This material was titrated with ceric sulfate: oxidation equivalent calcd. 69.08, found 70.5.

**Polymerized Vinylhydroquinone.**—Approximately 1 g. of vinylhydroquinone was placed in a glass tube, evacuated to approximately 1 mm. and sealed off. The sealed capsule was placed in an oven at 125° for one hundred hours. After cooling, the brittle solid which had formed was powdered and treated three times with boiling benzene, the successive portions of benzene being decanted from the insoluble residue. The product was an amber, brittle solid, insoluble in benzene, soluble in alcohol, acetic acid, ether and acetone, somewhat soluble in boiling water, becoming soft and tacky in cold water. This material was titrated with bromine in 90% acetic acid.[5] Oxidation equivalent calcd. 68.06, found 68.

Oxidations were carried out[1] on polymerized vinylhydroquinone, hydroquinone and a number of related substances.

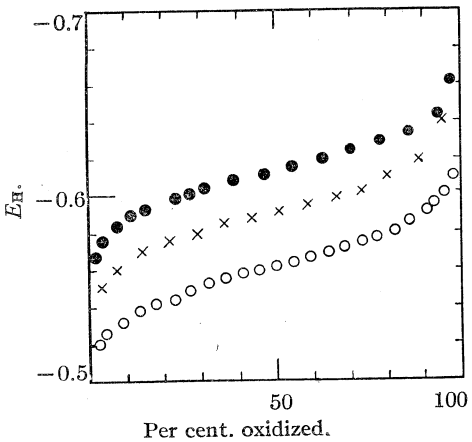

Fig. 1.—Oxidation of hydroquinone, vinylhydroquinone and ethylhydroquinone: $E_H$, potential in volts referred to the normal hydrogen electrode; ●, data for hydroquinone, *p*H 1.3, no. (1) in experimental part; ×, data for vinylhydroquinone, *p*H 1.3, (7); ○, data for ethylhydroquinone, *p*H 1.26, (4).

Figure 1 shows the data for hydroquinone, vinylhydroquinone and ethylhydroquinone oxidized in solution in 50% acetic acid; Fig. 2 shows the data for hydroquinone, ethylhydroquinone, and dispersed polymerized vinylhydroquinone; Fig. 3 shows the curve for dispersed polymerized vinylhydroquinone from Fig. 2, and the curve for a mixture of hydroquinone and ethylhydroquinone. Pertinent data from these titrations and those reported previously[1] are gathered below. $E_0$ is the mid-point potential referred to the normal hydrogen half-cell and calculated to a *p*H of 0. $E_i$ is the index potential, the potential difference between 50% oxidation and 25% (or 75%) oxidation. $\delta$ is the slope at the midpoint of the titration curve, and was determined graphically from our data. $\delta$ is given in millivolts per unit of $\mu$, where $\mu$ is −1 at 0% oxidation, 0 at 50% oxidation and +1 at 100% oxidation. The implications of these values are given in Paper I.[1] The nomenclature is that of Michaelis.[6]

**Oxidation of Hydroquinone.**—(1) (Fig. 1) 7.76 mg. in 10 ml. 50% acetic acid, oxidized with potassium dichromate in 50% acetic acid. Final *p*H 1.3; *T ca.* 28°.

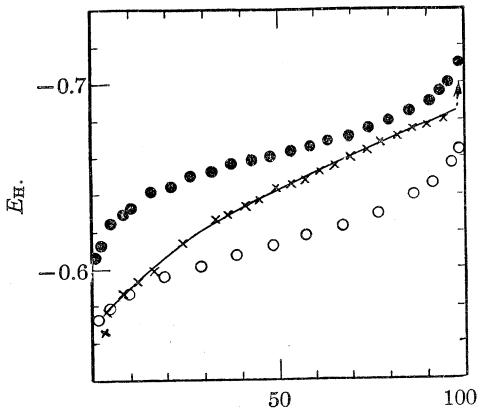

Fig. 2.—Oxidation of polymerized vinylhydroquinone compared with that of hydroquinone and ethylhydroquinone: $E_H$, potential in volts referred to the normal hydrogen electrode; ●, data for hydroquinone, *p*H 0.54, no. (2) in experimental part; ×, data for polymerized vinylhydroquinone, *p*H 0.54 to 0.50, (8); ○, data for ethylhydroquinone, *p*H 0.5, (5).

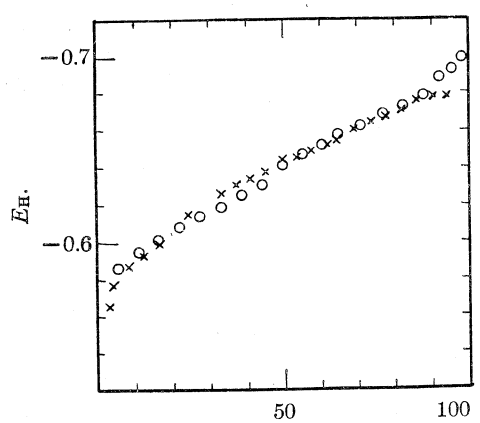

Fig. 3.—Comparison of oxidation of polymerized vinylhydroquinone with oxidation of a mixture of hydroquinone and ethylhydroquinone: $E_H$, potential in volts referred to the normal hydrogen electrode; ×, data for polymerized vinylhydroquinone, as in Fig. 2; ○, data for a mixture of hydroquinone and ethylhydroquinone, *p*H 0.54, (10). The correspondence of the two curves is probably fortuitous; the shapes are of chief interest.

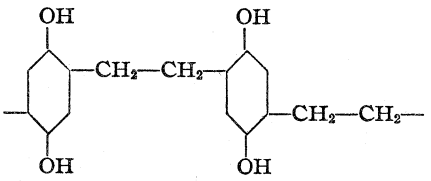
$E_0$ −0.697; $E_i$ 13 and 14 mv.; $\delta$ 26 mv. per unit of $\mu$. (2) (Fig. 2) 14.777 mg. in 10 ml. sulfuric acid–potassium sulfate buffer *p*H 0.53 oxidized with ceric sulfate, *p*H 0.54. $E_0$ −0.692; $E_i$ 13, 14 mv.; $\delta$ 24 mv./$\mu$. (3) (Fig. 1, Paper I) 10.043 mg. in 10 ml. 90% acetic acid (*p*H 0.0) titrated with bromine in 90% acetic acid. Final *p*H *ca.* −0.4; *T* 24°. $E_0$ −0.697; $E_i$ 20, 14 mv.; $\delta$ 27 mv./$\mu$.

**Oxidation of Ethylhydroquinone.**—(4) (Fig. 1) 17.311 mg. in 10 ml. 50% acetic acid, with dichromate. Final *p*H 1.26; *T* 20°. $E_0$ −0.636; $E_i$ 16, 14 mv.; $\delta$ 27 mv./$\mu$. (5) (Fig. 2) 9.5 mg. in 10 ml. sulfuric acid–potassium sulfate buffer, with cerate. *p*H 0.5; *T* 26°. $E_0$ −0.644; $E_i$ 14, 15 mv.; $\delta$ 23 mv./$\mu$. (6) (Fig. 1, Paper I) 12.918 mg. in 10 ml. acetic acid–water, *p*H −0.45. Titrated with bromine in same solvent. Final *p*H *ca.* −0.6. $E_0$ *ca.* −0.65; $E_i$ 22, 22 mv.; $\delta$ *ca.* 42 mv./$\mu$.

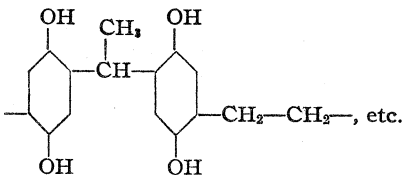
**Oxidation of Vinylhydroquinone.**—(7) (Fig. 1) 5.13 mg. in 10 ml. 50% acetic acid, with dichromate. Final *p*H 1.3, $E_0$ −0.667; $E_i$ 13, 12 mv.; $\delta$ 23 mv./$\mu$.

**Oxidations of Polymerized Vinylhydroquinone (PVH).**—(8) (Figs. 2 and 3) 14.871 mg. in 0.15 ml. acetic acid mixed with 10 ml. sulfuric acid–potassium sulfate buffer containing 2.44 mg. of albumin.[1] *p*H 0.54 to 0.5; *T* 25°. $E_0$ −0.673; $E_i$ 28 and 22 mv.; "$\delta$" 45 mv./$\mu$. (9) (Fig. 1, Paper I). 12.094 mg. in 10 ml. acetic acid–water, *p*H −0.45, with bromine in the same solvent. Final *p*H −0.6; *T* 23°. $E_0$ −0.679; $E_i$ 32, 35 mv.; $\delta$ *ca.* 70 mv./$\mu$. A number of titrations of PVH have been carried out with and without albumin and in solution and dispersed. The mid-point potentials ($E_m$) have hardly ever been more than 10 mv. different, but the slopes have varied considerably. The curves given are typical ones. The titration behavior of this polymer needs considerable study. The amount of albumin used was from 2 to 3 mg. in these experiments. In a separate experiment this was found equivalent to 0.052 to 0.08 ml. of 0.0279 *N* cerate at *p*H 0.5, with an $E_m$ of −0.680 v. The effect of this small amount of albumin seemed to be to render a little less sharp the end-point of the titration, the $E_m$ of the albumin lying usually well above that of the other reductant.



**Oxidation of Mixture.**—(10) (Fig. 3) 6.832 mg. (0.0696 me.) hydroquinone and 4.162 mg. (0.0603 me.) ethylhydroquinone in 1 ml. of acetic acid mixed with 10 ml. of sulfuric acid–potassium sulfate buffer and titrated with cerate. Final *p*H 0.54; *T* 27°; $E_0$ −0.672; $E_i$ 29, 27 mv.; "$\delta$" 55 mv./$\mu$.

## Discussion



It may appear odd that vinylhydroquinone should undergo polymerization readily when hydroquinone is an inhibitor for styrene polymerization. It was in fact found that vinylhydroquinone was somewhat more effective than hydroquinone itself in delaying the polymerization of styrene. This is in accord with the proposal of Cohen[7] concerning the relative ease of oxidation of hydroquinones and their effectiveness as inhibitors of polymerization. Vinylhydroquinone is more readily oxidized than hydroquinone (see above) and hence would maintain a lower concentration of free radicals in any polymerization mixture.

Vinylhydroquinone itself, however, polymerizes quite rapidly. Perhaps the rate of chain propagation is greater than the rate at which free radicals are destroyed by oxidizing vinylhydroquinone to vinylquinone. An alternative explanation may be that the interaction of a free radical with an hydroxyl group of vinylhydroquinone does not lead to an inert product because the odd electron may migrate to the vinyl group where further chain growth may be initiated. Hence the type of chain-terminating reaction characteristic of hydroquinone merely leads to chain transfer in the case of vinylhydroquinone. On this supposition one might expect vinylhydroquinone to be a chain transfer agent in styrene polymerization rather than an inhibitor. The fact that it does inhibit styrene polymerization throws some doubt on the second of the explanations given above.

Some suppositions may be made regarding the structure of the polymer formed from vinylhydroquinone. It has been suggested[8] that the very active *o*-hydrogens may become involved in the reaction, leading to a certain amount of linking of the types VI and VII. This possibility has not been excluded. The following considerations make it seem that we may be dealing with a polyvinyl hydroquinone: (1) The substance appears to be polymeric:

(VI)

(VII)

The monomer is soluble in benzene, while even boiling benzene did not dissolve the polymer appreciably. (2) The substance has the physical appearance of polystyrene and is soluble in polar organic solvents. When this is combined with the observation that hydroquinone–formaldehyde polymers are dark in color and insoluble it would appear a reasonable conclusion that there is not much cross-linking of the types VI and VII present. The analogy is not strict, however, for phenols are known to polymerize with formaldehyde in part through –OH interactions and this may account for the differences noted. (3) The majority of the –OH groups in the polymer are free to be oxidized and reduced, as shown by the oxidation data. (4) The mid-point potential falls at a reasonable value between those of hydroquinone and ethylhydroquinone, and close to that of vinylhydroquinone. This is strong evidence that there is not much substitution on the rings such as would be suggested by the structures VI and VII and similar ones. At the suggestion of a Referee experienced in this field we have used the term polymerized vinylhydroquinone to describe the polymer rather than polyvinylhydroquinone until more concrete evidence can be brought to bear on the structure.

The increased slope and the shape of the oxidation curve of the polymer were interpreted in the previous paper[1] as possibly due to the accumulation of semiquinone during the titration. This interpretation was based on the appearance of a pink color near the beginning of the titration, its persistence during the titration, and its diminution toward the end-point, and the relation between color-formation, semiquinone formation and increased slope of the titration curve as worked out by Michaelis and his co-workers.[6] A mechanism for the accumulation of semiquinone was suggested in the hampering of dismutation un-

(7) S. G. Cohen, THIS JOURNAL, **69**, 1057 (1947).

(8) By Mr. George W. Barber.

der the constraints put on the oxidizable residues by their being fastened on a long chain. It has seemed to us, also, that another phenomenon may contribute to the slope and shape of the titration curve of the polymerized vinylhydroquinone.

It may be assumed that the spatial arrangement of an oxidizable residue relative to other residues may affect its ease of oxidation through interactions such as might arise from hydrogen-bonding, dimerization, purely geometrical (steric) effects, as well as from actual differences in linkage such as were suggested in a previous paper.[1] If this were correct then it would follow that over these polymer chains there would be a spread of residues with different oxidizabilities, and during a titration the more easily oxidizable ones would go first (with the usual equilibrium restrictions), the more difficultly oxidizable ones requiring a higher potential. The titration curve would thus be "smeared out" over a wider potential range than for a single substance. To test this in a simple way a mixture of hydroquinone and ethylhydroquinone was titrated. The data obtained are shown in Fig. 3 in relation to the data for polymerized vinylhydroquinone. The slope of this curve ("$\delta$") was about 0.055 v. per unit of $\mu$. At no point during the titration was any color observed other than the pale yellow of the quinoid forms of the substances. A "statistical" effect such as this would complicate the interpretation of these curves. While we suspect that both the semiquinone formation and the statistical effect contribute to the total result we are not yet able to apportion to each its part. The correspondence of curves in Fig. 3 is probably fortuitous.[9]

The increased slope of the titration curve and the sequence of colors reported above for titrations of polymerized vinylhydroquinone in solution were observed also for the polymer dispersed in the presence of albumin. Another not unexpected observation was also made in these cases. With the dispersed polymer it was not possible to oxidize quite a number of the groups present. It seemed as though some of the groups, known to be present from in-solution oxidations of the resin, were unavailable when the resin was dispersed in a particulate form. The usual titration curves were obtained, however, when drawn on the basis of per cent. actually oxidized. When the resin was dispersed in the presence of a little albumin it seemed that more groups became available, though not all. In an experiment reported earlier[1] 77.8% were found in the presence of albumin, and upon reduction with hydrogen and retitration, 65% were reoxidizable. Some may have become unavailable due to conglomeration of the particles, or steric factors,[1] and some may have been destroyed by the oxidant. In another experiment with about 10 times as much albumin it seemed possible to titrate a larger percentage of the polymer groups, but the oxidation of albumin complicated matters. In a titration of the polymer (0.1863 me.) with bromine at a *p*H of 0.53 in the presence of 2.24 mg. of albumin (10 ml. solution) 86% of the groups could be titrated. Inaccessibility of certain groups to certain oxidizing agents might also affect the shape of the titration curve from an oxidant of one charge type or molecular size to another.

It will be interesting to determine the behavior of the polymer dispersed with polysaccharide and other natural and synthetic polymeric carriers. The stoichiometry of these combinations is also under investigation. It is further of interest to note that due to the constraints mentioned above the curves for the dispersed polymer are to a large extent linear, thus a normally logarithmic relationship has been converted to one substantially arithmetic.

(9) A Referee called our attention to a paper by Kern (W. Kern, *Z. physik. Chem.*, **A181**, 249 (1938)) on the titration of polyacrylic acids, where a spread of dissociabilities could be expected. The titration curve showed a slope different from that of isobutyric acid.

## Summary

Potentiometric titration curves are given for hydroquinone, ethylhydroquinone, vinylhydroquinone, and compared with the curve for polymerized vinylhydroquinone. Explanations are advanced for the differences observed, and the new features which appear in the titration of the electron exchange-polymer are discussed.

# The Electric Moments of Some Organic Molecules in the Vapor State[1]

BY EUNICE M. MOORE[2] AND MARCUS E. HOBBS

The desirability of measuring the electric moments of molecules in the gas phase is well recognized although, in the case of some substances, the experimental difficulties may make such measurements impracticable. The present series of determinations were undertaken with the object of increasing the number of electric moment values established from vapor phase measurements since, with such values, a detailed inquiry may be made into the basis and extent of various intramolecular interactions such as deviations from additivity of the vector bond moments of molecules. This paper reports the results of the first of a series of such vapor phase measurements carried out in this Laboratory.

## Materials and Method

The materials were Eastman Kodak Company best grade chemicals and each was fractionated in a 60-cm. Widmer column, the middle fraction being used for the measurement. The distilling temperatures and pressures (cor.) are given. The range when not indicated was of the order of 0.01°.

| | | |
|---|---|---|
| Fluorobenzene | 84.74– 84.76° | at 760.0 |
| Chlorobenzene | 131.24–131.25° | at 745.9 |
| *o*-Dichlorobenzene | 179.7° | at 746.2 |
| *o*-Fluorotoluene | 113.1° | at 755.0 |
| *m*-Fluorotoluene | 115.1° | at 755.0 |
| *p*-Fluorotoluene | 115.5° | at 755.0 |

*m*-**Difluorobenzene.**—This compound was prepared by Mr. Irving Waltcher in this Laboratory. The details of the preparation have been reported.[3] The n. b. p. of the fraction used was 83.05° and the f. p. −59.3°.

**Diethyl Ether.**—One sample of this material was Merck "pro analysi" grade and was subjected to no purification as the results of the measurements were to be compared with some values reported in the literature. The other sample was purified by refluxing over sodium and finally distilling from fresh sodium. The distillation range of the fraction used was 34.51–34.52° at 760 mm. (cor.).

**Methyl Ethyl Ether.**—This compound was prepared from ethyl bromide and sodium methylate by the Williamson reaction. The product was repeatedly fractionated until it was free of bromides when treated with alcoholic potassium hydroxide and was inactive toward metallic sodium. The approximate distillation temperature was 10.2° at 755 mm. (cor.).

The apparatus has been described elsewhere.[4] The method employed follows. The gas system was evacuated to < 0.05 mm. and flushed twice with the vapor to be measured. The vapor was then introduced until a usable pressure for the given temperature was obtained. After thermal equilibrium was established the gas condenser capacitance was placed in parallel with a high precision air condenser by an appropriate switching device and the pressure in the gas system slowly reduced to some lower level. After thermal equilibrium was established at the lower pressure the new setting of the high precision capacitor necessary to bring the total capacitance of the measuring circuit back to its original value was determined. Slight frequency drifts that took place during the manipulations and waiting periods were compensated for by making all readings with reference to a fixed air capacitance. The above procedure was repeated until the total pressure in the gas system was of the order of 20–30 mm.

The values of capacitance measured as above were then plotted against pressure and the resulting line extrapolated to zero pressure. The total change in capacitance caused by the gas was therefore the sum of all capacitance changes from zero pressure up to the particular pressure under consideration. The capacitance change caused by the gas was generally found to be linear with the measured values of the pressure in the pressure ranges involved, the small deviations from linearity being randomly distributed. All changes were measured in terms of a capacitance calibration unit ($\Delta S$) which was equivalent to about 0.4 mmf. In view of the observed linearity the average value of $\Delta S/p$ was generally used for calculating the molar polarization, $P$, of the gas at the particular temperature. In case of a real drift of $\Delta S/p$ values with $p$ the extrapolated value of $\Delta S/p$ at $p = 0$ was used. $P$ was calculated from

$$P = \frac{\Delta SRT}{p3C_{g_e}}$$

Here $R$ is the molar gas constant $T$ the temperature in °K. and $C_{g_e}$ is the insulator free "effective"[4] vacuum capacitance of the gas condenser. The use of this effective gas capacitance obviates the necessity of applying inductance corrections to the measured $\Delta S$ values. The average value of $C_{g_e}$ for the temperature range involved was 2685 $\Delta S$ units and since the temperature coefficient was very small the average value of $C_{g_e}$ was used. The values of $A$ and $B$ in the relation $P = A + B/T$ were obtained by least squares and the value of $\mu_{D(B)}$, in debyes was obtained from the relation

$$\mu_{D(B)} = 0.01281\sqrt{B}$$

An alternative way of calculating the moment is the method used by Wenzke,[5] Smyth[6] and others in which use is made of the relation

$$\mu_{D(R)} = 0.01281\sqrt{(P - R_D)T}$$

In the present work $\mu_D$ is calculated by both methods with $R_D$, the molecular refraction for the sodium lines, taken as[7]: $C_6H_6 = 26.14$, $C_6H_5CH_3$

## Results and Discussion

The data and derived values are given in Table I. The symbols in the table have their previously indicated meaning.

In Table II the essential quantities are recapitulated so as to bring the similarities and differences clearly into focus.

TABLE II

| Substance | $A$ | $R_D$ | $(A \overset{\Delta}{-} R)$ | $\mu_{D(B)}$ | $\mu_{D(R)}$ | $\Delta\mu_{(BR)}$ |
|---|---|---|---|---|---|---|
| Fluorobenzene | 25.4 | 26.0 | −0.6 | 1.61 | 1.60 | +0.01 |
| Chlorobenzene | 33.9 | 31.0 | +2.9 | 1.70 | 1.75 | −0.05 |
| *m*-Difluorobenzene | 27.3 | 25.9 | +1.4 | 1.58 | 1.62 | −0.04 |
| *o*-Dichlorobenzene | 30.7 | 35.9 | −5.2 | 2.54 | 2.48 | +0.06 |
| *c*-Fluorotoluene | 31.4 | 31.0 | +0.4 | 1.35 | 1.37 | −0.02 |
| *m*-Fluorotoluene | 31.6 | 31.0 | +0.6 | 1.85 | 1.86 | −0.01 |
| *p*-Fluorotoluene | 30.7 | 31.0 | −0.3 | 2.01 | 2.00 | +0.01 |
| Diethyl ether (A) | 24.7 | 22.3 | +2.4 | 1.18 | 1.23 | −0.05 |
| (B) | 26.0 | 22.3 | +3.7 | 1.14 | 1.22 | −0.08 |
| Methyl ethyl ether | 20.0 | 17.7 | +2.3 | 1.22 | 1.28 | −0.06 |

Some of the above compounds have had their electric moment reported in the literature. Those results that were obtained from gas phase measurements are, for purposes of comparison, recorded in Table III.

TABLE III

ELECTRIC MOMENTS (DEBYES)

| Substance | Present | Literature |
|---|---|---|
| Fluorobenzene | 1.61 | 1.57[a] |
| Chlorobenzene | 1.70 | 1.70,[a] 1.69,[b] 1.72[c] |
| *o*-Dichlorobenzene | 2.54 | 2.51,[c] 2.16[d] |
| Diethyl ether | 1.14 | 1.14,[e] 1.14,[h] 1.15,[f] 1.17[g] |

[a] MacAlpine and Smyth, *J. Chem. Phys.*, **3**, 55 (1935). [b] Groves and Sugden, *J. Chem. Soc.*, 1094 (1934). [c] Hurdis and Smyth, THIS JOURNAL, **64**, 2212 (1942). [d] Groves and Sugden, *J. Chem. Soc.*, 1782 (1937). [e] H. A. Stuart, *Z. Physik*, **51**, 490 (1928). [f] R. Sanger, *Physik. Z.*, **31**, 306 (1930). [g] Groves and Sugden, *J. Chem. Soc.*, 1779 (1937). [h] O. Fuchs, *Z. Physik*, **63**, 824 (1930).

The agreement of our values with those of Smyth (Table III) are reasonably good and our value of 1.14 *D* for diethyl ether agrees with Sanger's value within the experimental error. A least-squares recalculation of Groves and Sugden's data (g) for ether gives = 1.14 *D*. In view of the low value of $A$, we feel that our value of 2.54 *D* for *o*-dichlorobenzene is probably too high. A simplified analysis of the random error for this case indicates that an error of 1.5% in $\mu$ and 2.5 cc. in $A$ could be expected, therefore we suggest that the correct value of $\mu$ might be 0.04–0.05 *D* less than the reported value of 2.54 *D*. It may be remarked that all values of $\mu_{D(B)}$ of Table II are considered to be in error by <2% and that the error in $\mu_{D(R)}$ may be as much or considerably greater than the error in $\mu_{D(B)}$. Some of the error in $\mu_{D(R)}$ could be eliminated by making an allowance for atomic polarization, $P_A$, but such a procedure is, at best, somewhat arbitrary. In general, as the difference $(P - R_D)$ increases the influence of $P_A$ may become less and less; however, there are certain molecules where $P_A$ is rather

large,[9] therefore moments calculated from ($P - R_D$) should always be critically examined in light of the structure of the particular molecule.

The value of 1.18 $D$ obtained for unpurified ether (A) indicates that some of the previous data (Fuchs and Stuart, Table III, *e* and *h*, respectively) may be based on a sample of ether that contained a significant amount of polar impurity and that the agreement of these authors values with the others recorded may be fortuitous.

The value 1.22 $D$ for methyl ethyl ether falls between 1.14 $D$ for diethyl and 1.30 $D$[10] for dimethyl ether.

A comparison of the observed moment with that calculated for vector addition for the *o*-, *m*- and *p*-halogen toluenes is given in Table IV. The bond moments used were: $C_{ar}$–$CH_3$ (vapor) = 0.37, $C_{ar}$–$CH_3$ (solution) = 0.39, $C_{ar}$–F(vapor) = 1.61, $C_{ar}$–Cl (solution) = 1.56, $C_{ar}$–Br (solution) = 1.53 and $C_{ar}$–I (solution) = 1.38. The bond moment values for solution are taken from Tiganik,[11] the vapor $C_{ar}$–$CH_3$ from Baker[12] and the 1.61 for $C_{ar}$–F from the present investigation.

TABLE IV

ELECTRIC MOMENTS (DEBYES)

| Substance | Ortho Calcd. | Ortho Obs. | Meta Calcd. | Meta Obs. | Para Calcd. | Para Obs. |
|---|---|---|---|---|---|---|
| Fluorotoluene (vap.)[a] | 1.46 | 1.35 | 1.82 | 1.85 | 1.98 | 2.01 |
| Chlorotoluene (sol.)[b] | 1.41 | 1.43 | 1.79 | 1.77 | 1.95 | 1.94 |
| Bromotoluene (sol.)[b] | 1.38 | 1.44 | 1.76 | 1.75 | 1.92 | 1.93 |
| Iodotoluene (sol.)[c] | 1.24 | 1.33 | 1.61 | 1.67 | 1.77 | 1.80 |

[a] Present investigation. [b] Reference 11. [c] H. Poltz, *Z. physik. Chem.*, **B20**, 351 (1933).

Deviation from vector addivitity $\sim$ 0.1 debye occurs only for *o*-fluoro- and *o*-iodotoluenes and these are in opposite sense to each other. Until data for the chloro-, bromo- and iodo-toluenes in the vapor phase is available it is felt that a discussion of such deviations as exist is of limited value and would necessarily be somewhat speculative.

## Summary

The electric moments of several organic molecules have been determined from gas phase measurements of the dielectric constant at several temperatures and pressures. The results in debyes are: fluorobenzene—1.61, chlorobenzene—1.70, *m*-difluorobenzene—1.58, *o*-dichlorobenzene—2.54, *o*-fluorotoluene—1.35, *m*-fluorotoluene—1.85, *p*-fluorotoluene—2.01, diethyl ether—1.14 and methyl ethyl ether—1.22.

# The Catalytic Hydrogenation of the Benzene Nucleus. V. The Hydrogenation of Benzene, the Cyclohexadienes and Cyclohexene

BY HILTON A. SMITH AND HENRY T. MERIWETHER

## Introduction

It is a well known fact that the benzene nucleus is hydrogenated with considerably greater difficulty than a simple unsaturated system. This is presumably due to the large resonance energy of the benzene ring system. If this is the case, one would expect the conjugated 1,3-cyclohexadiene to hydrogenate less readily than either the unconjugated 1,4-cyclohexadiene or cyclohexene. In order to test this, a study of the rates of hydrogenation of cyclohexene, the cyclohexadienes, and benzene was undertaken.

## Experimental

Merck reagent thiophene-free *Benzene* was purified by fractionation in an 8-ft. Vigreux column. The fraction used for rate studies distilled at a temperature of 79.2° at 741 mm., and had a refractive index, $n^{20}D$, of 1.5003.

Eastman Kodak Co. technical *cyclohexene* was first distilled through the 8-foot column and the fraction boiling between 81.8 and 82.0° collected. This was mixed with an equal volume of methanol, and azeotropic fractionation carried out in the same column. The fraction boiling at 55.8° was washed five times with cold water in order to remove the methanol, and dried with anhydrous magnesium sulfate. Fractionation of this product gave a constant boiling cut with a head temperature of 81.8° at 738 mm. pressure; $n^{20}D$ was 1.4458.

1,3-Cyclohexadiene and 1,4-cyclohexadiene were prepared by dehydration of quinitol according to the method of Zelinskii and co-workers.[1] Quinitol was prepared by the reduction of hydroquinone over Raney nickel at 150° and 2,000 p. s. i. hydrogen pressure. The solvent, ethanol, was removed from the hydrogenated product by distillation and the quinitol recrystallized from acetone. The quinitol was then dehydrated by heating with potassium bisulfate in a stream of carbon dioxide gas. The hydrocarbon and water were condensed in a cold-finger containing a little hydroquinone, to prevent polymerization. The hydrocarbon layer was separated, washed with sodium bicarbonate, and distilled from a simple distilling flask. The fraction boiling between 75 and 125° was again washed with sodium carbonate solution, dried over potassium carbonate, mixed with an equal volume of methanol, and fractionated in an 8-ft. Vigreux column. Three fractions were collected, washed five times with cold water, dried over anhydrous potassium carbonate, and refractionated. Two constant boiling cuts were obtained. The 1,3-cyclohexadiene distilled at 79.3° at 738 mm., and had

(1) Zelinskii, Denisinka and Eventova, *Compt. Rend. Acad. Sci. U. S. S. R.*, **1**, 313 (1935).

a refractive index, $n^{20}D$, of 1.4746.[2] The 1,4-cyclohexadiene distilled at 88.3° at 738 mm.; $n^{20}D$ was 1.4720.[3]

The acetic acid solvent was prepared by fractionation in a five-foot helix-packed still. The platinum catalyst was prepared by standard methods.[4] The hydrogenations were carried out in a standard low-pressure Parr catalytic reduction apparatus. The volume of the hydrogen reservoir, reaction bottle, and connections during hydrogenation was 4.43 liters. The reaction bottle was equipped with a brass jacket through which water at any desired temperature could be circulated from a twenty-liter reservoir. At the start of each run, the solvent, hydrocarbon, and catalyst were placed in the reaction bottle which in turn was placed in the water jacket and allowed to attain the temperature of the circulating water before being fitted into the rocking cradle of the apparatus. The reaction was then started in the usual manner.[5] The temperature inside the bottle was taken at the end of the hydrogenation. Usually a slight rise was found. This was caused by the heat evolved during the course of the reaction. In all cases the amount of hydrogen absorbed corresponded to that necessary for complete hydrogenation of the ring.

## Experimental Calculations and Results

It was established that all of these hydrogenations were first order with respect to hydrogen pressure, zero order with respect to the concentration of hydrogen acceptor, and directly proportional to the amount of catalyst used. This is demonstrated by Table I. Therefore rate constants were calculated from the equation

$$\log \frac{p^{\circ}_{H_2}}{p_{H_2}} = \frac{kt}{2.303V}$$

by plotting $\log p^{\circ}_{H_2}/p_{H_2}$ against $t$, and multiplying the slope of the line thus obtained by $2.303V$.[6] These constants all referring to one gram of standard catalyst[5] are given in Table II together with the energies of activation for the hydrogenation.

TABLE I

EFFECT OF VARIABLES ON THE RATE OF HYDROGENATION

| Hydrocarbon | Ml. | Grams of catalyst | Initial pressure, (p. s. i.) | $k^{\circ} \times 10^3$ (liters/g. min.) |
|---|---|---|---|---|
| Cyclohexene | 5 | 0.02 | 64.2 | 2260 |
| Cyclohexene | 5 | .02 | 28.0 | 2395 |
| Cyclohexene | 5 | .005 | 64.3 | 2170 |
| Cyclohexene | 10 | .005 | 64.0 | 2260 |
| Cyclohexadiene-1,3 | 5 | .02 | 64.6 | 1840 |
| Cyclohexadiene-1,3 | 2.5 | .02 | 29.6 | 1983 |
| Cyclohexadiene-1,3 | 5 | .01 | 64.2 | 1640 |
| Cyclohexadiene-1,3 | 2.5 | .02 | 64.1 | 1995 |
| Cyclohexadiene-1,4 | 6 | .02 | 64.0 | 1240 |
| Cyclohexadiene-1,4 | 2.5 | .02 | 30.0 | 1330 |
| Cyclohexadiene-1,4 | 5.0 | .01 | 64.2 | 1110 |
| Cyclohexadiene-1,4 | 2.5 | .02 | 64.3 | 1165 |

TABLE II

RATE CONSTANTS AND ACTIVATION ENERGIES

| Hydrocarbon | $k^{\circ}_{30} \times 10^3$ (liters/g. min.) | Activation energy (cal./mole) |
|---|---|---|
| Cyclohexene | 2350 | 2400 |
| Cyclohexadiene-1,3 | 1900 | 4500 |
| Cyclohexadiene-1,4 | 1330 | 4000 |
| Benzene | 290 | 7400 |

Figure 1 shows typical plots for the calculation of rate constants, and Fig. 2 shows the graphs from which the activation energies were calculated. It is estimated that the error in these values is of the order of ±300 calories.

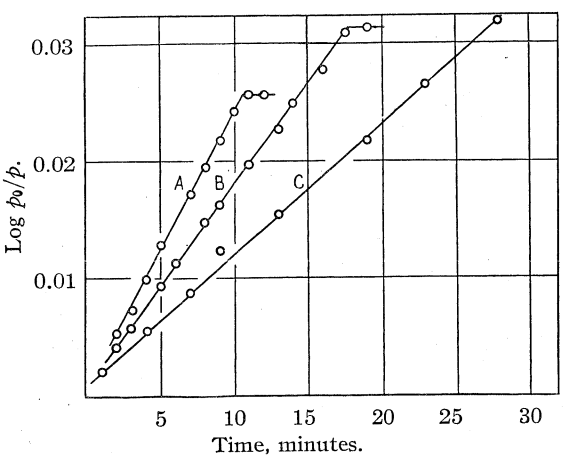

Fig. 1.—Plots for hydrogenation of the cyclohexadienes and benzene: A, 1,3-cyclohexadiene; B, 1,4-cyclohexadiene; C, benzene.

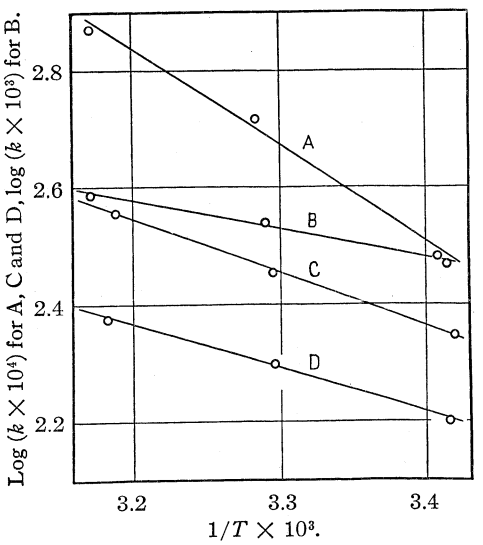

Fig. 2.—Temperature coefficients for hydrogenation reactions: A, benzene; B, cyclohexene; C, 1,3-cyclohexadiene; D, 1,4-cyclohexadiene.

## Discussion

Since these hydrogenations are all zero order with respect to the hydrogen acceptor, it follows that differences in the heats of adsorption of the cyclohexene, cyclohexadienes, and benzene on

platinum cannot be involved in the activation energies. Since all other factors remain constant, the differences in the apparent activation energies for the catalytic reactions must represent differences in the true activation energies for the hydrogenation of these compounds on platinum.

The heats of hydrogenation of cyclohexene, 1,3-cyclohexadiene, and benzene are −28,600, −55,400, and −49,800 cal. respectively.[2,7] The corresponding value for 1,4-cyclohexadiene may be estimated as twice that of cyclohexene, or −57,200. If one assumes that the hydrogenation of benzene proceeds by the path benzene → 1,3-cyclohexadiene → cyclohexene → cyclohexane, and that the first step is rate determining, it is necessary that the energy of activation for the hydrogenation of benzene, catalytically or otherwise, be at least 5600 calories. If, by any possibility, the hydrogenation of benzene should pass through the intermediate 1,4-cyclohexadiene, the energy of activation would have to be at least 7,400 calories. The actual energy of activation, 7,400 cal., is surprisingly close to either of these requirements.

The resonance stabilization of the benzene ring as calculated from the heats of hydrogenation is 36,000 calories.[2] One would probably expect the activation energy for the hydrogenation of benzene to be at least equal to this value. If this reasoning is correct, it would appear that the benzene molecule must be adsorbed on the platinum catalyst in such a manner that its resonance is destroyed, and that the slow rate of hydrogenation of the benzene nucleus when compared to that of simple unsaturated compounds cannot be attributed to resonance.

It is also interesting to note that the conjugated 1,3-cyclohexadiene has a faster rate of hydrogenation than is found for the unconjugated 1,4-cyclohexadiene. The difference in the activation energies is probably within experimental error.

(7) Kistiakowsky, Ruhoff, Smith and Vaughan, *ibid.*, **58**, 137 (1936).

## Summary

The catalytic hydrogenations of benzene, the cyclohexadienes, and cyclohexene on platinum have been studied from a kinetic viewpoint. Rate constants and activation energies have been determined for each of these reactions. The low value for the activation energy of the hydrogenation of benzene when compared with the resonance energy of the molecule indicates the probability that such resonance is destroyed when the benzene is adsorbed on the catalyst.

# Catalytic Hydrogenation of Furan and Substituted Furans on Platinum

BY HILTON A. SMITH AND JOHN F. FUZEK

Studies of the kinetics of catalytic hydrogenation of the benzene nucleus on Adams platinum catalyst have been previously reported.[1,2] This work has now been extended to include furan and several substituted furan compounds. The aim has been to determine in a quantitative manner the effect of structure on the rate of hydrogenation of the furan nucleus with Adams platinum catalyst in acetic acid solution. Particular attention has been given the effect of varying the type of the substituent group on the rate. The results obtained have been compared with those for corresponding benzene compounds. Where necessary for such comparisons, additional work was also done in the benzene series.

## Experimental

**Preparation of Materials.—Furan** and **2-methylfuran** (E. I. du Pont de Nemours and Company) were treated with Raney nickel catalyst, dried, and fractionated in a ten-foot Vigreux column.

**Furoic acid** (Eastman Kodak Company) was purified by recrystallization and subsequent conversion to the methyl ester. This was dried, treated with Raney nickel and activated charcoal, and fractionated. The product (b. p. 181.8–182.0 (736 mm.), $n^{20}D$ 1.3880) was converted to the acid which was recrystallized and dried.

**2,5-Dimethylfuran** (Eastman Kodak Company) was azeotropically distilled with methanol (azeotrope b. p. 60.8° (743 mm.), 35–40% by volume 2,5-dimethylfuran), separated after addition of water, dried and fractionated.

**Benzyl alcohol** and **benzoic acid** were Eastman products. The alcohol was treated with Raney nickel and anhydrous magnesium sulfate, and fractionated. As in previous work, the benzoic acid was used without further purification.

**Furfural** and **furfuryl alcohol** (Quaker Oats Company) were treated with Raney nickel catalyst, anhydrous magnesium sulfate and activated charcoal for several hours. The solids were removed by filtration and the furan derivatives distilled through a fourteen-foot Vigreux column. The center fractions boiled within a 0.1° range.

**Dibenzofuran** (diphenylene oxide) (The Reilly Tar and Chemical Corporation) was treated with Raney nickel catalyst and activated charcoal in hot ethanol solution. The solution was filtered several times and the crystals recovered on cooling. They were then recrystallized from benzene. This cycle was repeated three times. The resulting crystals when dry melted within a range of 0.5°. Further purification failed to narrow this melting range.

The **Adams platinum catalyst** was prepared from 3.5-g. batches of platinum chloride in the usual manner.[3] Several of these finished batches of catalyst were mixed and then standard rates obtained as in previous work.[1] The acetic

(2) Smith and Pennekamp, *ibid.*, **67**, 276 (1945).
(3) Adams, Voorhees and Shriner, "Organic Syntheses," **8**, 92 (1928).

acid used in the hydrogenations as a solvent was distilled through an eight-foot Vigreux column. The fraction boiling within the 0.1° range was retained. Tank hydrogen was used directly as in previous work.[1]

**Hydrogenation Procedure.**—The hydrogenations were carried out in a standard Parr low-pressure catalytic apparatus which was modified by substitution of a 0.790 liter hydrogen tank for the 4.02 liter tank supplied.[4] The runs were made as previously described,[1] except that due to the low boiling points of some of the materials used, the reaction bottle was not evacuated, but flushed several times with hydrogen prior to each run. It was also desirable to control the temperature of the reaction rather carefully. This was accomplished by the use of a brass jacket surrounding the reaction bottle. Water was circulated through this jacket at a rate of several gallons per minute from a constant-temperature-bath. A check of the temperature of the reaction mixture before and after the reaction indicated that the temperature of the circulating water leaving the jacket was within 0.1° of the crude temperature within the reaction bottle. The temperature during a run was maintained within ±0.2° in most cases.

**Hydrogenation Products.**—The products of hydrogenation were usually recovered from the acetic acid solution by neutralization of the acetic acid with sodium hydroxide solution with resulting separation of the layer of alcohol product. This product was dried over anhydrous magnesium sulfate and distilled through a four-foot Vigreux column or a twenty-inch Vigreux column depending on the quantity of material available. The fractions obtained were identified by their physical properties and the usual identification procedures. Difficulty was encountered in the isolation of the hydrogenation product of furfuryl alcohol since it was a dihydric alcohol and failed to separate from the neutralized acetic acid solution. Identification was affected by refluxing for several hours the filtered reaction mixture to which a small amount of concentrated sulfuric acid had been added. The diacetate thus formed proved to be easier to isolate. In the case of the product from the hydrogenation of furoic acid, the δ-hydroxyvaleric acid was converted partially to the lactone during the distillation; hence, the entire product was treated with a dehydrating agent and isolated as the lactone.

Properties of the reactants and products isolated are given in Table I.

TABLE I

PROPERTIES OF COMPOUNDS HYDROGENATED AND THEIR PRODUCTS

| Compound | $n^{20}D$ | Dist. temp., °C. B. p. | Mm. | M. p. |
|---|---|---|---|---|
| Furan | 1.4209 | 30.4 | 740 | |

(4) Fuzek and Smith, THIS JOURNAL, **70**, 3743 (1948).

## Experimental Calculations and Results

It has been established in previous work that the hydrogenation of the benzene nucleus is first order with respect to the hydrogen pressure, zero order with respect to the concentration of the hydrogen acceptor, and directly proportional to the amount of catalyst used.[1,2] Tables II, III and IV illustrate the fact that these conditions are true for the hydrogenation of the furan nucleus provided the shaking is adequate to maintain equilibrium. Table IV shows that for 2,5-dimethylfuran, the maximum amount of catalyst which can be used and still maintain shaking equilibrium is very low, namely, 0.03 g. This maximum amount of catalyst appears to be a function of the material undergoing hydrogenation.

TABLE II

EFFECT OF HYDROGEN PRESSURE ON THE RATE CONSTANT FOR THE HYDROGENATION OF THE FURAN NUCLEUS

| Furan compound | Rate constant $k$, (liters/g. min.) Pressure (p. s. i. a.) 60 | 45 | 40 | 35 | 30 | 20 |
|---|---|---|---|---|---|---|
| Furan | 0.518 | | | 0.502 | | 0.542 |
| 2-Methylfuran | .356 | | 0.390 | | | .384 |
| 2,5-Dimethylfuran | .576 | 0.560 | | | 0.574 | .599 |
| Furfuryl alcohol | .305 | | 0.328 | | | .319 |

TABLE III

EFFECT OF CONCENTRATION OF HYDROGEN ACCEPTOR ON THE RATE CONSTANT FOR THE HYDROGENATION OF THE FURAN NUCLEUS

| Furan compound | Rate constant, $k$, (liters/g. min.) Concn. (moles/l.) 0.11 | 0.22 | 0.30 | 0.66 | 1.20 |
|---|---|---|---|---|---|
| Furan | | | 0.518 | 0.542 | 0.507 |
| 2-Methylfuran | 0.328 | 0.356 | | .354 | |
| 2,5-Dimethylfuran | | .576 | | .551 | 0.552 |
| Furfuryl alcohol | .312 | .305 | | .316 | |

TABLE IV

EFFECT OF THE AMOUNT OF CATALYST ON THE RATE CONSTANT FOR THE HYDROGENATION OF THE FURAN NUCLEUS

| Furan compound | Rate constant, $k$ (liters/g. min.) g./catalyst 0.01 | 0.02 | 0.03 | 0.04 | 0.05 | 0.07 |
|---|---|---|---|---|---|---|
| Furan | | 0.475 | 0.479 | | 0.518 | 0.448 |
| 2-Methylfuran | | | .356 | | .366 | |
| 2,5-Dimethylfuran | 0.571 | .576 | .566 | 0.503 | .438 | |
| Furfuryl alcohol | | | .305 | | .321 | |

Calculations for the rate constant have been made according to the modified first order equation for heterogeneous reactions.[4] A sample hydrogenation curve is given in Fig. 1. This shows that a plot of log $p_0/p$ *versus* time results in a straight line. If the slope of this line is multiplied by 2.303 $V$, the value for the rate constant is obtained. Tabulation of such rate constants is given in Table V.

Since most of the reaction rate constants were determined at several temperatures, an apparent activation energy can be obtained from a plot of the Arrhenius equation. This equation may be represented as $k = Ae^{-E/RT}$ or $\log_e k = -E/RT + \log_e A$. Thus a plot of log $k$ *versus* $1/T$ should

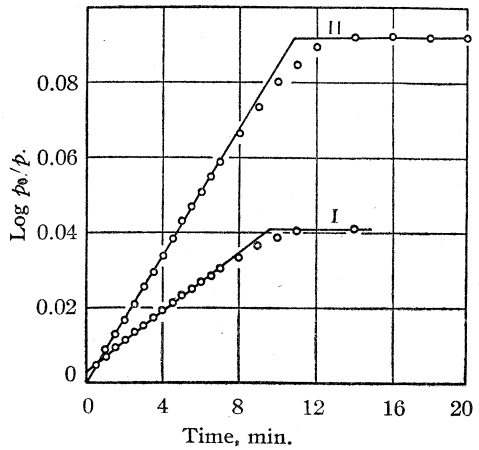

Fig. 1.—Sample hydrogenation curves: I, hydrogenation of 0.003 mole of dibenzofuran on 0.100 g. of platinum oxide in 50 ml. of acetic acid at 50°; II, hydrogenation of 0.015 mole of furan on 0.050 g. of platinum oxide in 50 ml. of acetic oxide at 26°.

TABLE V

RATE CONSTANTS FOR THE HYDROGENATION OF SOME BENZENE AND FURAN COMPOUNDS

| Derivative | $k^a$ (liters/g. min.) Furan cpd. | Benzene cpd. | Ratio F/B |
|---|---|---|---|
| Parent compound | 0.554 | 0.288 | 1.92 |

## Discussion

The products of hydrogenation in the case of the furan derivatives are interesting since not only are the two double bonds in the furan ring hydrogenated, but also the ring is usually broken. A single product results from cleavage of either furan or 2,5-dimethylfuran regardless of which of the two carbon–oxygen bonds is cleaved. The former results in butanol while the latter yields hexanol-2. In both instances, the yield is almost quantitative. However, for 2-methylfuran, furfuryl alcohol and furoic acid, there are two possible products in each case, depending on which carbon–oxygen bond is broken. Ring cleavage of furoic acid occurred at the carbon–oxygen bond nearest the carboxyl group. This was shown by the fact that the principal product isolated was δ-hydroxyvaleric acid which even under mild dehydrating conditions is unstable, losing water to give δ-valerolactone. This latter compound was easier to identify due to its stability. A trace of tetrahydrofuroic acid was also obtained; the quantity was estimated at less than 10% from both the amount isolated and the deficiency in the calculated hydrogen uptake during the hydrogenation process.

The hydrogenation of 2-methylfuran and furfuryl alcohol resulted in ring cleavage at the carbon–oxygen bond removed from the functional group. For the methyl derivative, about 80 to 90% of the product was *s*-amyl alcohol. The remainder was 2-methyltetrahydrofuran. This amount was accounted for also in the amount of hydrogen absorbed in the process of hydrogenation. The furfuryl alcohol was hydrogenated almost quantitatively to 1,2-pentanediol. This product was difficult to isolate in an acetic acid solution, hence was converted to the diacetate which was more readily recovered and identified.

The formation of the tetrahydro derivative in two cases arouses interest as to the possible mechanism of the hydrogenation reactions considered. Since in all hydrogenations of 2-methylfu-

ran and furoic acid some of the tetrahydro compound was obtained, it appears questionable that the tetrahydro derivative can be an intermediate in the reaction, as it failed to hydrogenate further even when a quantity of fresh catalyst was added to the reaction mixture. Further evidence was obtained by preparing pure tetrahydrofuran by the catalytic reduction of furan on Raney nickel catalyst in absolute ethanol. This compound was purified by distillation and then subjected to hydrogenation conditions using Adams platinum catalyst and acetic acid solvent. No observable reaction occurred even after three hours. Further support for the reaction mechanism not involving the tetrahydro derivative was obtained by Bradley,[7] who hydrogenated dihydrofuran on Adams platinum catalyst in dioxane and found that only one mole of hydrogen was absorbed per mole of acceptor while furan itself rapidly absorbed three moles. From the above-cited evidence, it appears that there are two modes of reaction which the hydrogenation can follow; first, to give the cleavage product, and second, to give the tetrahydro derivative. Apparently these are two competing reactions, with the former playing the more important role in the hydrogenation of furan compounds, but the second becoming detectable for 2-methylfuran and furoic acid. Further evidence that the tetrahydro compounds are not intermediates in the reaction was obtained by analysis of partially hydrogenated samples of the various furans under study. For the other reactions studied (excepting 2-methylfuran, furoic acid and dibenzofuran), the analysis showed only the initial product and the final cleavage product.

It thus appears that, in general, the furan compounds are completely hydrogenated to the cleaved product, *i. e.*, reaction occurs with three moles of hydrogen per mole of compound before desorption from the catalytic surface.

The hydrogenation of dibenzofuran was most interesting as the reaction in this case left the furan ring intact, thus requiring six moles of hydrogen per mole of compound.[7] When a sample which had been allowed to react with only three moles of hydrogen per mole of compound was analyzed only the original dibenzofuran and the final product dicyclohexylene oxide could be isolated. Also no break in the rate curve appears when three moles of hydrogen are adsorbed (see Fig. 1). Apparently hydrogenation proceeds in such a manner that both rings are hydrogenated before the molecule is desorbed from the catalyst. Furthermore, the presence of the two benzene rings probably stabilizes the furan ring and thus prevents cleavage. This was the only furan compound studied which did not cleave to a major extent on hydrogenation.

The study of the hydrogenation of furfural was greatly hampered by the unstable nature of the compound. Even when the reactions were carried out immediately after distillation, poisoning of the catalyst was so pronounced that only the rate of hydrogenation of the aldehyde to the alcohol could be determined with the small amount of catalyst used.[8] This small amount of catalyst was necessary in order to maintain shaking equilibrium as previously discussed. Further purifications proved to be of no value. Hence the rate constant and activation energy reported are obviously subject to considerable inaccuracies. It is estimated that the probable maximum error would be about $\pm 15\%$.

A comparison of the rate constants for the furan compounds and the corresponding benzene compounds is made in Table V. The values given for the benzene derivatives previously reported have been corrected for the volume of the hydrogen void according to an equation applicable to heterogeneous reactions.[4] The ratios of the rate constants for furan to benzene derivatives is given in the last column. This ratio varies from 1.32 to 3.76; the average value is 2.5. For every derivative, the furan compound gave a rate constant considerably higher than the corresponding benzene compound.

As Table VI shows, the activation energies, as well as the rate constants for the hydrogenation of furan compounds, are greater than for the corresponding benzene derivatives. The average ratio is about 1.34. Individual values are tabulated in Table VI. The higher activation energy for furan compounds may possibly be attributed to the greater energy requirement in ring cleavage. The frequency factor for the furan compounds is also much greater than for the corresponding benzene derivatives, being of the order of $10^3$ larger. This factor may account for the slower rates for benzene derivatives. It is also possible that the frequency factor as determined includes other variables dependent upon solubility relations.

In conclusion it should be indicated that the activation energies as determined should be reasonably accurate in every case except for furfural as already discussed. In the other cases, maximum deviation from the least-squares value was less than 4% while the average deviation was 2.2%. In the case of furfural, the maximum deviation was 15% and the average was 9.4%.

**Acknowledgment.**—The authors are indebted to the Office of Naval Research for financial support which made this research possible.

## Summary

A study has been made of the kinetics of catalytic hydrogenation of some furan compounds and comparison made with corresponding benzene derivatives. The reactions were carried out at pressures up to five atmospheres absolute, in acetic acid solution, using Adams platinum catalyst. The rate constants, activation energies and frequency factors have been tabulated.

It has been shown that the rate constants,

(7) Bradley, *Iowa State Coll. J. Sci.*, **12**, 108 (1937).

(8) Kaufmann and Adams, THIS JOURNAL, **45**, 3029 (1923).

activation energies, and the frequency factors are considerably higher for the furan compounds than for corresponding benzene derivatives.

# Ultrasonic Investigation of Molecular Properties of Liquids. IV. Cyclic Compounds[1]

BY ALFRED WEISSLER

Recent interest in the chemical applications of ultrasonics has prompted several studies[2-6] of the relation between sound velocity and molecular structure of liquids, mainly in the aliphatic field. An emerging conclusion is that the velocity of sound is a useful and important physical property, comparable to density or refractive index.

The present work was undertaken in order to extend the correlation between sound velocity and chemical structure into the classes of aromatic, alicyclic, and heterocyclic compounds. In order to simplify the interpretations, molecules containing a substituent instead of hydrogen on a ring carbon were excluded. For a few of the twenty-two liquids chosen, the velocity had been measured previously at scattered temperatures; these were included here because of the necessity for self-consistent data at a standard temperature.

## Experimental

The compounds were obtained from commercial sources, except for 1,4-thioxane, which was synthesized[7] from $\beta,\beta'$-dichlorodiethyl ether and alcoholic sodium sulfide. Each was purified before use by fractional distillation through a 40-cm. Widmer column. In order to free pyrrolidine from tenaciously-held water, it was let stand over sodium for a day, then distilled from sodium.

A three-megacycle ultrasonic interferometer, designed by Mr. Burton G. Hurdle, was used to measure sound velocities. This instrument is very similar to the one-megacycle interferometer previously described,[2] but it requires only 10 ml. of sample, because of the further scaling-down of physical dimensions permitted by the higher frequency.

If desirable, one could construct an ultrasonic interferometer which requires only a few drops of liquid sample, merely by going to a somewhat higher frequency. This illustrates the decisive advantage of ultrasonic frequencies in measuring the velocity of sound.

To minimize contamination by corrosion of the brass interferometer cell, all interior surfaces were gold plated. A 0.003-inch tantalum foil was used as the floor of the cell, directly beneath which lay the quartz crystal source of ultrasound.

Refractive indices for D light were determined with an Abbe refractometer, and densities with a 25-ml. pycnometer. Measurements of all three physical properties were made at 30°.

## Results and Discussion

The values of sound velocity, density and refractive index for the twenty-two compounds are listed in Table I. These velocities lie in the range 1100–1550 meters/second, just as is the case for the majority of unhalogenated liquids. The estimated accuracy for the velocities is about ±0.03%.

It is apparent from the table that a compound with two rings in the molecule possesses a higher sound velocity than that associated with either of the constituent rings. Other generalizations are difficult to find, however. For example, it is not true that a five-membered ring always has a lower (or a higher) velocity than its six-membered homolog; cyclopentane's is lower than cyclohexane's, but tetrahydrofuran's is higher than tetrahydropyran's.

The present data vitiate a conclusion drawn by Schaafs,[8] to the effect that in a pair of unhalogenated liquids of practically the same molecular weight, the one with the higher density also has the higher sound velocity. Both thiophene and dihydropyran have a molecular weight of 84.1, yet thiophene has the higher density but the lower sound velocity. Similarly, cyclopentene has a lower density than furan, but a higher velocity, although both have a molecular weight of 68.1.

Thus it appears that any correlations would have to take into account the specific force-interactions between molecules due to the chemical structure. For this purpose, the adiabatic compressibility is more suitable than the raw sound velocity.

**Adiabatic Compressibility.**—From the sound velocity $v$ and density $d$, the adiabatic compressibility $K_{ad}$ of a medium may be calculated readily, using the relation

$$K_{ad} = 1/v^2d \qquad (1)$$

The values so obtained, presented in Table I, support the following generalizations. Increasing the saturation of a six-membered ring, as from benzene to cyclohexane, causes the adiabatic compressibility to increase also. Even if a nitrogen or oxygen atom is substituted for one of the six carbons, as in the pyridine or pyran systems, the rate of increase of compressibility with saturation remains about the same (Fig. 1). In the five-membered rings, however, no such uniformity exists: furan has a greater compressibility than tetrahydrofuran, yet pyrrole's is smaller than that of pyrrolidine.

[a] Adiabatic compressibility $10^{-12}$ cm.²/dyne.

Replacing a ring carbon by a nitrogen, oxygen, or sulfur always causes a decrease in compressibility, no matter whether the ring is five- or six-membered, saturated or unsaturated. Substitution of a second hetero atom gives a still further decrease as in dioxane, morpholine and thioxane; nitrogen and sulfur have a greater effect than oxygen. This behavior is related to the electrical forces between molecules due to the hetero atom.

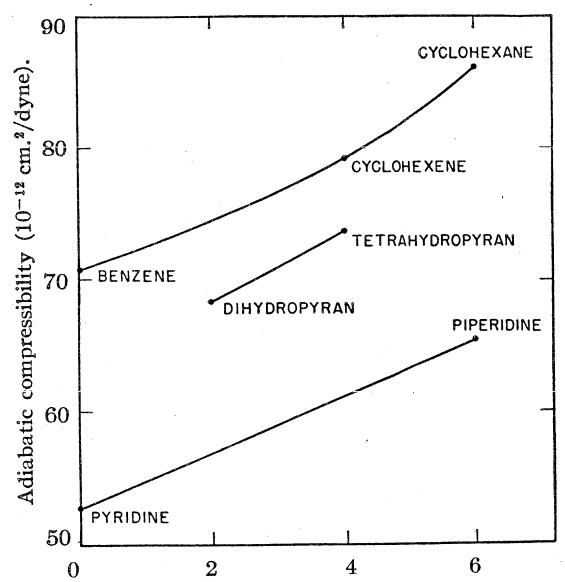

Fig. 1.—Compressibility of six-membered rings.

A compound which contains two rings has a lower compressibility than is associated with either of the individual rings.

**Molar Sound Velocity.**—Another useful quantity for studying the relation between molecular structure and sound velocity in liquids is the molar sound velocity $R$. This is defined[9] as the molar volume times the cube root of sound velocity

$$R = v^{1/3}M/d \qquad (2)$$

For most pure liquids, $R$ is independent of temperature.

Like the molar refraction, $R$ is an additive and constitutive property, which can be computed by summing the appropriate increments for all the bonds in the molecule. Some of the bond increments for molar sound velocity have been worked out by Lagemann.[10] These are listed in Table II,

TABLE II

BOND INCREMENTS FOR MOLAR CONSTANTS

| Bond | Molar sound velocity | Molar refraction |
|---|---|---|
| C—H | 95.2 | 1.69 |
| C—C | 4.25 | 1.25 |
| C=C | 129 | 4.16 |
| C—O (in ethers) | 44.5[a] | 1.51 |
| N—H | 90.7[a] | 1.81 |
| C—N | 20.7[a] | 1.54 |
| C=N | 145[a] | 3.90 |
| C—S | 99.5[a] | 4.35[a] |

[a] Previously unreported values, based on the present data and additional information from the literature.

(9) Rao, *J. Chem. Phys.*, **9**, 688 (1941).

(10) Lagemann and Dunbar, *J. Phys. Chem.*, **49**, 434 (1945).

together with previously unreported values for the N–H, C–N, C=N, C–O (in ethers) and C–S bonds, which are derived from the present work and additional data from the literature. The last column of Table II gives the corresponding increments for molar refraction, as determined by Denbigh[11] and Warrick.[12]

The values for molar sound velocity and molar refraction calculated from these bond increments are compared in Table I with the values from the observed physical properties of the liquids. It is notable that five-membered rings show the larger deviations, especially in the molar velocity. The molar refractions show an average deviation of 1.6% between observed and calculated values, while the molar sound velocities show an average deviation of only 1.2%. In the present case, therefore, the molar sound velocity appears to be more useful than the molar refraction for structure investigations, by being less subject to such anomalies as are due to ring structure and conjugation of double bonds. This conclusion is to be employed with caution, particularly in view of the relatively small number of compounds studied here.

**Acknowledgment.**—The author is grateful to Dr. G. R. Ringo for stimulating discussions, and to the du Pont Company for samples of the furans and pyrans.

## Summary

Through the use of a three-megacycle ultrasonic interferometer, the velocity of sound at 30° in twenty-two cyclic compounds has been determined. Densities and refractive indices at 30° are reported also.

Correlations have been found between molecular structure and sound velocity. For example, substituting nitrogen, oxygen or sulfur for a ring carbon causes a decrease in adiabatic compressibility.

For these liquids, the molar sound velocity is more nearly an additive property than the commonly-used molar refraction. It is possible, therefore, to predict the velocity of sound in pure liquids with an average accuracy of a few per cent., simply from the molecular structure and the density.

# Polarographic Studies of Some Hindered and Unhindered Aromatic Nitro Compounds

BY MELVIN FIELDS,[1] CLAUDE VALLE, JR., AND MARSHALL KANE

Steric inhibition of resonance results in marked alterations of physical and chemical properties of organic molecules. Familiar examples of this phenomenon are the reduction of the dipole moments of nitromesitylene and nitrodurene from the values characteristic of aromatic nitro derivatives to approximately those of the aliphatic nitro compounds,[2] the striking alterations in the ultraviolet absorption of diphenyl derivatives[3] and of aromatic amines bearing bulky ortho substituents,[4] and the anomalous acid and base strengths of certain phenols, hydrocarbons and aromatic amines.[5] That the rates of chemical reactions may also be modified by the steric inhibition of resonance in a reacting molecule is illustrated by the numerous examples cited by Wheland.[6]

In this communication we wish to report on the results of a study of the effects of the steric inhibition of resonance on the polarographic characteristics of certain aromatic nitro compounds. Although the polarograph has been employed in the investigation of such varied phenomena as hydrogen bonding in nitrophenols[7] and in amidines,[8] semiquinone formation[9] and keto–enol tautomerism,[10] this instrument does not appear to have been utilized for the study of the effects of damped resonance on the properties of organic molecules. Suppression of the normal resonance of a reducible group with an aromatic nucleus might be expected to affect not only the ease of reduction but also the nature of the products of the reaction. In terms of the polarographic characteristics of a substance there might be observed a shift in the half-wave potential of a given stage of reduction, a change in the total number of electrons involved per molecule of electrode reaction or perhaps an alteration in the number of polarographic waves or distinct steps in which the over-all reaction occurs.

The substances which we studied were nitro-

benzene, *o*-, *m*- and *p*-nitrotoluene, 2-nitro-1,4-dimethylbenzene, 3-nitro-1,2-dimethylbenzene, nitromesitylene and nitrodurene. Of these compounds only nitromesitylene and nitrodurene would be expected to exhibit the effects of inhibition of the resonance of a nitro group with a benzene ring. The other members of the group were investigated in order to determine how the polarographic behavior of the unhindered aromatic nitro compounds is affected by the introduction of one and of two methyl groups into the nucleus and to provide reliable data obtained under identical conditions for comparison of the characteristics of the hindered and unhindered compounds. Although nitrobenzene and other aromatic nitro compounds were studied polarographically by Shikata and co-workers,[11] the nitrotoluenes and nitroxylenes were not included in these investigations. Furthermore, since much of Shikata's work appeared before significance of the half-wave potential was understood, much of his data on "reduction potentials" are now of qualitative value only.

## Experimental

**Preparation and Purification of Materials.**—The samples of nitrobenzene, *o*-, *m*- and *p*-nitrotoluene, 2-nitro-1,4-dimethylbenzene, 3-nitro-1,2-dimethylbenzene and nitromesitylene used were Eastman Kodak Co. white label grade chemicals. The liquids were purified by distillation at reduced pressure through a 30″ Podbielniak column. The sample of *p*-nitrotoluene used melted at 52–53° after several crystallizations from methanol. Nitromesitylene, crystallized several times from methanol, melted sharply at 43–44°. The physical properties of the liquid nitro compounds used are listed in Table I.

TABLE I

PHYSICAL CONSTANTS OF LIQUIDS

| Compound | B. p., °C. | Mm. | $n^{20}D$ |
|---|---|---|---|
| Nitrobenzene | 72.8 | 10.0 | 1.5522 |
| *o*-Nitrotoluene | 95.0 | 10.0 | 1.5468 |
| *m*-Nitrotoluene | 95.4 | 10.5 | 1.5460 |
| 2-Nitro-1,4-dimethylbenzene | 105.8 | 10.5 | 1.5415 |
| 3-Nitro-1,2-dimethylbenzene | 110.0 | 10.0 | 1.5432 |

Nitrodurene was prepared by nitric acid oxidation of acetoxymercuridurene according to the procedure of Smith and Taylor[12]; the sample used melted at 113–114°.

**Instruments and Cells.**—Polarographic measurements were made using a manual apparatus similar to the one described by Lingane and Kolthoff.[13] The usual H-type polarographic cell with a saturated calomel reference electrode was employed. At a pressure of 60 cm. of mercury the capillary had a drop time of 4.6 seconds and an *m*-value of 1.530 mg. of mercury per second measured on open circuit in 80% aqueous dioxane solution 0.30 *M* in sodium hydroxide.

**Supporting Electrolytes.**—The polarograms of the nitro compounds were run in buffered 80% aqueous dioxane solutions in which the concentration of supporting electrolyte in the final solutions was 0.38 *M* for the *p*H 1.0 and *p*H 7.2 solutions and 0.30 *M* for the *p*H 12.0 solutions. The dioxane was purified by prolonged refluxing over sodium. Elimination of maxima was achieved by the addition of 0.01% gelatin.

The following supporting electrolytes were used: *p*H 1.0, sodium acetate–hydrochloric acid; *p*H 7.2, sodium dihydrogen phosphate–disodium hydrogen phosphate; *p*H 12.0, sodium hydroxide. The *p*H values mentioned refer to those determined by measurement with a glass electrode[14] and are uncorrected for the non-aqueous solution error.[15]

**Procedure.**—In order to decrease the time required for deaeration of the polarographic solutions and thus to reduce the loss of the nitro compound during the deaeration process, the distilled water, the dioxane and the stock buffer solutions were freed from dissolved oxygen by bubbling purified nitrogen through the refluxing liquids for a period of about one to two hours. The oxygen-free solutions were then stored under nitrogen. The volumetric flasks were flushed with nitrogen before use, and the polarographic solutions were made up and mixed so as to minimize contact with air. When prepared by this technique, the solutions in the polarographic cell required only ten minutes sweeping prior to measurement. The nitrogen used was purified by passage through a tube filled with freshly-reduced copper filings maintained at 400 to 450°. Most of the measurements were made at a concentration of nitro compound of about $1.0 \times 10^{-4}$ *M*; where it was desired to check the effect of concentration of reducible material on the half-wave potential and on the wave height, measurements were also made at a concentration of $5.0 \times 10^{-4}$ *M*. All potentials were measured against a saturated calomel reference electrode (S. C. E.); the half-wave potentials referred to in this paper have been corrected for the *iR* drops of the solutions. Diffusion currents were corrected for the residual current of the supporting electrolyte. All measurements were made at 25 ± 0.5°.

## Results and Discussion

The marked differences in the polarographic behavior of nitrobenzene and several other aromatic nitro compounds with an unhindered nitro group and that of nitromesitylene and nitrodurene are illustrated by the representative current–voltage curves shown in Figs. 1–6 for some of these compounds. Substances of the first group all yield two fairly well defined waves in buffered 80% aqueous dioxane solution at *p*H 1.0 and only a single distinct wave at *p*H 12.0. In alkaline solution the derivatives with a methyl substituent ortho to the nitro group reveal a tendency for the polarographic wave to break up near the diffusion current region into two separate steps. The polarogram of *p*-nitrotoluene also shows a barely perceptible indication of separating into two waves, but in this case the inflection occurs in the first third of the wave. Complete separation of the two waves is not achieved for any of the unhindered compounds under these conditions. On the other hand, nitromesitylene and nitrodurene each produce a single wave in strongly acid solution and two distinct waves in sodium hydroxide solution. At *p*H 7.2 a single wave is observed for compounds of both classes although with nitrodurene there is a slight indication of a second wave following the main one. In buffered 80% aqueous dioxane solution of *p*H 7.2 the half-wave potentials are

independent of and the wave heights proportional to concentration over the range of 1 × $10^{-4}$ to 5 × $10^{-4}$ *M* for all the compounds except nitrodurene whose low solubility prohibited extension of the measurements beyond 2 × $10^{-4}$ *M*. Nitrobenzene showed similar behavior at *p*H 1.0 and 12.0. The data in Table II indicate that the presence of one methyl group and, in the cases of the two nitroxylenes studied, of two methyl substituents has only a small effect on the half-wave potential of the first polarographic wave, $(E_{1/2})_1$. For these substances and for nitrobenzene itself the values of $(E_{1/2})_1$ fall within the narrow ranges of −0.22 to −0.26 v. at *p*H

1.0, − 0.60 to −0.66 v. at *p*H 7.2 and −0.82 to −0.84 v. at *p*H 12.0. The polarogram of *p*-nitrotoluene which at *p*H 12 shows a slight indication of separating into two waves has a half-wave potential, calculated from the total wave height, of −0.91 v. *vs.* S.C.E. The replacement of hydrogen by methyl groups, however, has a much more striking effect on $(E_{1/2})_2$, the half-wave potential of the second wave observed at *p*H 1.0. Although in some cases this step is poorly defined, estimates of $(E_{1/2})_2$ are sufficiently accurate to show that the effect of the methyl substituents is to shift toward more positive values the potential at which this stage of reduction occurs.

TABLE II

HALF-WAVE POTENTIALS VOLTS *vs.* S.C.E.

| Compound | *p*H 1.0 $(E_{1/2})_1$ | *p*H 1.0 $(E_{1/2})_2$ | *p*H 7.2 $(E_{1/2})_1$ | *p*H 12.0 $(E_{1/2})_1$ |
|---|---|---|---|---|
| Nitrobenzene | −0.24 | −0.84 | −0.62 | −0.83 |
| *o*-Nitrotoluene | − .26 | − .64 | − .66 | − .84 |
| *m*-Nitrotoluene | − .22 | − .71 | − .60 | − .82 |
| *p*-Nitrotoluene | − .24 | − .71 | − .62 | − .91[a] |
| 2-Nitro-1,4-dimethylbenzene | − .25 | − .58 | − .64 | − .82 |
| 3-Nitro-1,2-dimethylbenzene | − .25 | − .59 | − .65 | − .82 |
| Nitromesitylene | − .38 | .... | − .75 | − .88,[b] − 1.36[c] |
| Nitrodurene | − .38 | .... | − .75 | − .87,[b] − 1.42[c] |

[a] A slight inflection was observed in this case; since the "break" between the two steps is only barely perceptible, the value above refers to the total wave. [b] First wave. [c] Second wave.

One effect of the steric inhibition of resonance of a nitro group with a benzene ring is to render more difficult the reduction of the nitro group. At *p*H 1.0 the $(E_{1/2})_1$ values of nitromesitylene and nitrodurene are −0.38 v. *vs.* S.C.E., approximately 0.12 to 0.16 v. more negative than those for the other compounds studied; at *p*H 7.2 a similar shift in $(E_{1/2})_1$ is observed with the values for the hindered compounds approximately 0.09 to 0.15 v. more negative than those of the unhindered. Values of the half-wave potentials for nitromesitylene and nitrodurene at *p*H 12.0 are respectively −0.88 and −0.87 v. *vs.* S.C.E. for the first stage of reduction and −1.36 and −1.42 v. *vs.* S.C.E. for the second. These values are only approximate because of the poorly defined limiting heights of the waves.

The diffusion current constants of the nitro compounds listed in Table III were calculated from the Ilkovic equation using drop-times measured at the same potentials as the diffusion currents. For each of the compounds with an unhindered nitro group the ratio of the diffusion current constant of the first wave to that of the total wave at *p*H 1.0 is about 0.75. Since a value only slightly higher than this is obtained for the ratio of the diffusion current constant of the single wave of nitromesitylene or nitrodurene to the average value of the constant for the total wave of the unhindered compounds, the *n*-values of the over-all reactions in acid solution

TABLE III

DIFFUSION CURRENT CONSTANTS[a]

[a] Microamp./millimole/mg.$^{2/3}$sec.$^{1/2}$. [b] Calculated from the total wave height. [c] The single well-defined wave showed a slight tendency to break up into two waves; the diffusion current constant was calculated from the total wave height. [d] A slight inflection was observed in this case; since the "break" between the two steps is barely perceptible, the value above refers to the total wave height. [e] First wave. [f] Second wave.

are probably different for the two classes of aromatic nitro compounds. The marked decrease in the values of the diffusion current constants on going from acid to neutral and alkaline solutions suggests a change in the nature of the products of the electrode reactions. At *p*H 7.2 and *p*H 12.0 these constants for a compound with an unhindered nitro group are approximately six-tenths as large as that for the total wave of the compound at *p*H 1.0. Furthermore, the diffusion current constants of nitromesitylene and nitrodurene at *p*H 7.2 are only slightly lower than the average value for the unhindered compounds under these conditions, suggesting that the *n*-values of the electrode reactions may not be too dissimilar. Although at *p*H 12 the polarograms of nitromesitylene and nitrodurene consist of two distinct waves with the second two or three times the height of the first, the poor definition of the total wave heights in these cases makes it difficult to estimate reliable values for the diffusion current constants.

Although it is clear from the data already presented that there are pronounced differences in the polarographic characteristics of normal aromatic nitro compounds and those in which resonance of the nitro group with the benzene ring is inhibited by bulky ortho substituents, it would be interesting to compare the electron requirements of the electrode reactions. Unfortunately the lack of reliable data for the diffusion coefficients of these compounds in the supporting electrolytes used prevents calculation of the *n*-values from the Ilkovic equation, but coulometric measurements[16] should provide an unequivocal answer to the problem.

Comparison of the polarographic behavior of the substances studied here with that of aliphatic nitro compounds is of interest because it would be

(16) Lingane, THIS JOURNAL, **67**, 1916 (1945).

anticipated that the characteristics of the hindered aromatic nitro compounds would show certain similarities to those of the aliphatic nitro derivatives. Unfortunately, however, the only data reported for the aliphatic compounds were determined in solutions in which nitromesitylene and nitrodurene are not sufficiently soluble to permit measurements to be made. The straight-chain primary and secondary aliphatic nitro compounds. with one to four carbon atoms resemble the hindered aromatic compounds in that they have been reported to yield only a single polarographic wave in acid solution; on the other hand, the aliphatic compounds are apparently non-reducible in 0.1 *M* aqueous sodium hydroxide or tetramethylammonium hydroxide solution.[17] In 0.05 *M* aqueous sulfuric acid solutions the aliphatic compounds have half-wave potentials in the range −0.57 to −0.69 v. *vs.* S.C.E. and would appear to be somewhat more difficultly reducible in acid solution than any of the substances investigated in the present work. Although the shift in half-wave potentials toward more negative values on going fro 1 the unhindered to the hindered aromatic derivatives is in the direction anticipated from the values reported for the aliphatic nitro compounds, closer comparison of the polarographic behavior of nitromesitylene and nitrodurene with that of aliphatic nitro derivatives must await re-examination of the characteristics of the latter and determination of the *n*-values of the polarographic waves for members of both series.

## Summary

The polarographic characteristics of nitrobenzene, *o*-, *m*- and *p*-nitrotoluene, 2-nitro-1,4-dimethylbenzene, 3-nitro-1,2-dimethylbenzene, nitromesitylene and nitrodurene have been examined in buffered 80% aqueous dioxane solutions at *p*H 1.0, 7.2 and 12. The behavior of nitromesitylene and nitrodurene is distinctly different from that of the aromatic nitro compounds examined in which steric inhibition of resonance does not exist.

# Quantitative Interpretation of the Polarographic Hydrolysis Current of Chromic Ion

BY JAMES J. LINGANE AND ROBERT L. PECSOK[1]

Chromic ion undergoes stepwise reduction at the dropping electrode, the first wave corresponding to reduction to chromous ion and the second to complete reduction to the metal.[2,3] Kolthoff and Lingane[4] called attention to the fact that the height of the second wave is significantly larger than twice the height of the first when the supporting electrolyte is unbuffered, and they attributed the discrepancy to the simultaneous discharge of hydrogen ion from the hydrolysis of the chromic ion. This has also been noted by Willis.[5]

In the present study this phenomenon has been investigated systematically, and interpreted quantitatively on the basis of diffusion current theory. Relations have been derived which are of general applicability in polarographic studies of hydrolytic equilibria in metal salt solutions.

## Experimental

Polarographic measurements were made in an H-type cell provided with a saturated calomel electrode as previously described.[6] Atmospheric oxygen was removed by purified hydrogen or nitrogen. All measurements were made with the cell in a water thermostat at 25.0 ± 0.1°. The drop time of the capillary varied from three seconds with an open circuit to about two seconds at an applied potential of two volts, and was timed as necessary at each potential. An automatic *m*-measuring device[7] was employed.

Polarograms were either recorded with a Sargent Model XI Polarograph, or obtained with a manual apparatus based on a circuit previously described.[8]

Residual currents were obtained in all cases and the proper correction applied.

The *p*H of the solutions was measured with a glass electrode.

**Chromic Solutions.**—Stock solutions of 0.1000 *M* chromic chloride and chromic sulfate were prepared determinately by reduction of a known quantity of pure potassium dichromate with sulfur dioxide or hydrogen peroxide in the appropriate acid, and the excess reducing agent was removed by boiling. A neutral solution of chromic chloride was made up from the reagent grade hexahydrate and standardized by determination of the chromium content. The stock solutions were diluted to 0.01 *M* before use in order to increase the accuracy of measurement. The ionic state of the chromium in these solutions was believed to be an equilibrium mixture of the hexaaquo- and the dichlorotetraaquochromic ions.

A stock solution of 0.1 *M* chromic perchlorate was prepared by reduction of a known quantity of reagent grade sodium chromate with hydrogen peroxide in perchloric acid,

thus eliminating the presence of chloride ion. Solutions of chromic perchlorate were polarographed in a cell with an internal mercury anode, in order to exclude chloride ion.

Supporting electrolytes were prepared from reagent grade chemicals. Commercial "Chemically pure" sodium perchlorate was found to contain a large amount (*ca.* 6%) of a basic impurity, which, from the shape of the titration curve with standard hydrochloric acid, appeared to be a mixture of sodium bicarbonate and sodium carbonate. Therefore, sodium perchlorate supporting electrolytes were prepared by careful neutralization of pure perchloric acid solutions with carbonate-free sodium hydroxide solutions to a *p*H of 6.5 to 7.0.

## Results and Discussion

Figure 1 shows polarograms of various concentrations of chromic chloride in 0.1 *M* potassium chloride with 0.01% gelatin present as a maximum suppressor. The half-wave potential of the first wave, corresponding to

$$Cr(III) + e = Cr(II) \qquad (1)$$

is −0.91 v. *vs.* S.C.E., and that of the second wave, corresponding to

$$Cr(II) + e = Cr \qquad (2)$$

is −1.47 v. *vs.* S.C.E. These values are in good agreement with previous determinations.[4]

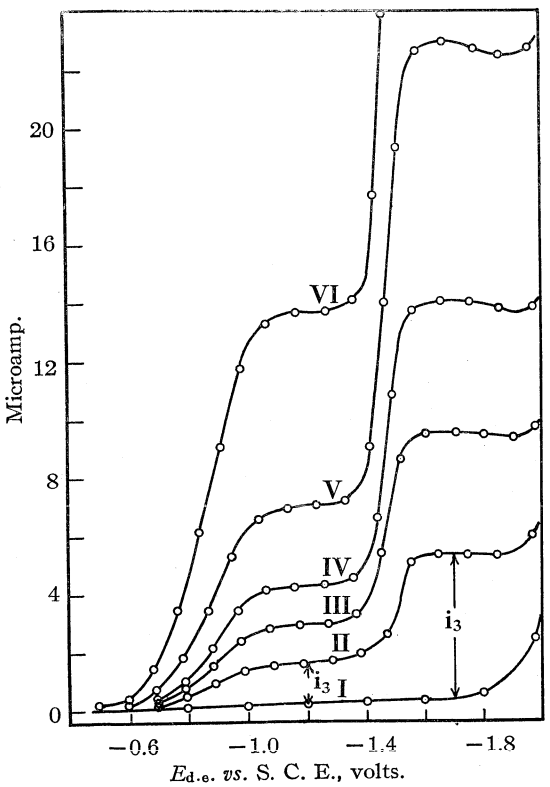

Fig. 1.—Polarograms of (I) 0, (II) 0.5, (III) 1.0, (IV) 1.5, (V) 2.5 and (VI) 5.0 millimolar chromic chloride in 0.1 *M* potassium chloride containing 0.01% gelatin.

Polarograms of chromous ion in 0.1 *M* potassium chloride, which will be described in a later paper, show a well-developed anodic wave. However, the half-wave potential of this wave is several tenths of a volt more positive than the cathodic wave of chromic ion, showing that reaction 1 does not proceed reversibly at the dropping electrode.

The influence of *p*H on the polarograms of chromic ion in 0.1 *M* potassium chloride containing 0.01% gelatin is demonstrated in Fig. 2. The natural *p*H of 1 millimolar chromic chloride in 0.1 *M* potassium chloride resulting from hydrolysis is approximately 3.8. From Fig. 2 it is seen that when the *p*H is made smaller than this value the magnitude of the second wave increases greatly because of the simultaneous discharge of hydrogen ion with the chromous ion. When the *p*H is made larger than about 3.8 the first wave becomes poorly developed and a third wave appears at −1.7 v. This latter wave doubtless results from the reduction of a more highly hydrolyzed species in sluggish equilibrium with chromic ion.

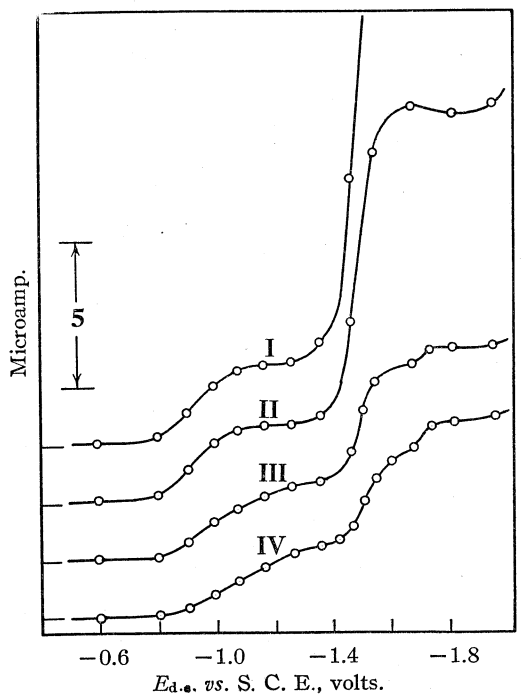

Fig. 2.—Effect of *p*H on the polarograms of 1 millimolar chromic chloride in unbuffered 0.1 *M* potassium chloride containing 0.01% gelatin. The *p*H values were (I) 2.80, (II) 3.38, (III) 4.63 and (IV) 5.00.

The effect of the concentration of potassium chloride in the supporting electrolyte was determined and a concentration of 0.1 *M* or less found to be optimum. With increasing chloride ion concentration, the magnitude of the diffusion current is decreased and the half-wave potentials shift to more negative values. This does not support the claim of Kalousek[9] that the reduction proceeds reversibly in solutions containing a very large concentration of chloride ion.

(9) M. Kalousek, *Collection Czech. Chem. Commun.*, **11**, 592 (1939).

The polarographic characteristics of chromic chloride in ammonium, lithium, barium and calcium chloride solutions, and in sodium perchlorate solutions were found to be essentially the same as in a supporting electrolyte of potassium chloride.

Diffusion current data obtained with various concentrations of chromic chloride in 0.5 *M* sodium perchlorate and 0.25 *M* potassium chloride are given in Tables I and II. The solutions contained 0.005% gelatin. The chromic chloride stock solution used was prepared from pure chromic chloride hexahydrate without added acid, and it had aged for fifteen months prior to to these experiments. The *p*H values listed are the "natural" values due to the hydrolysis of chromic ion, and they were measured for each solution with the glass electrode.

| 7.85 | 3.13 | .905 | 21.26 | 71.3 | 3.54 | 10.7 | 6.50 |

In these tables $i_1$ is the diffusion current of the first wave, measured at −1.2 v., and $i_3$ is the total diffusion current of the doublet wave measured at −1.7 v.

The sixth column shows the corresponding ratio of the diffusion current constants, where $I = i_d/(Cm^{2/3}t^{1/6})$. The theoretical value of $I_3/I_1$ is 3, corresponding to the successive 1- and 3-electron reductions. The observed values of this ratio in Tables I and II are much larger than the theoretical value and the discrepancy increases with decreasing concentration of chromic ion. The abnormally large observed values of $I_3/I_1$ reflect the simultaneous reduction of the hydrogen ion formed by the hydrolysis of chromic ion

$$Cr(H_2O)_6^{+++} = Cr(H_2O)_5OH^{++} + H^+ \quad (3)$$

The *relative* concentration of hydrogen ion in this equilibrium increases with decreasing total concentration of the chromic salt.

The diffusion current of the first wave is directly proportional to the total chromic salt concentration. In 0.5 *M* sodium perchlorate at 25° the diffusion current constant $I_1 = i_1/(Cm^{2/3}t^{1/6})$ was found to be 1.46 ± 0.01, and in 0.25 *M* potassium chloride it is 1.50 ± 0.015, when 0.005% gelatin is present.

The *p*H values observed are consistent with the values for the hydrolysis constants of $Cr(H_2O)_6^{+++}$ ($1.58 \times 10^{-4}$) and $CrCl_2(H_2O)_4^+$ ($1.9 \times 10^{-6}$) reported by Bjerrum,[10] Lamb and Fonda,[11] and Brönsted and King.[12] The predominant ion in perchlorate medium is $Cr(H_2O)_6^{+++}$, and in the chloride solutions the less-hydrolyzed $CrCl_2(H_2O)_4^+$ ion predominates.

The "hydrolysis current" resulting from the reduction of hydrogen ion is represented by $i_H$. The observed values of $i_H$ listed in Tables I and II were computed from the relation

$$i_H = i_3 - 3i_1(t_2/t_1)^{1/6} \quad (4)$$

The values of $t_2$ and $t_1$ were measured with each concentration of chromic ion at the same time that the diffusion currents were measured.

At potentials corresponding to the second diffusion current plateau both unhydrolyzed and hydrolyzed chromic ions are reduced, and the reduction of the latter liberates hydroxyl ion at the electrode surface

$$Cr(H_2O)_5OH^{++} + 3e = Cr + 5H_2O + OH^- \quad (5)$$

The hydroxyl ions thus produced neutralize in the diffusion layer an equal number of the hydrogen ions that are diffusing up to the electrode surface. In the body of the solution the number of hydrogen ions is equal to the number of hydrolyzed chromic ions, and if the diffusion coefficients of the two were equal all of the hydrogen ions in the diffusion layer would be neutralized and there would be no contribution by hydrogen ion reduction to the second diffusion current. Acutually, however, the diffusion coefficient of hydrogen ion is several times larger than that of the hydrolyzed chromic ion. Consequently the flux of hydrogen ion at the electrode surface is greater than that required to neutralize the hydroxyl ions produced by reaction 5, and it is the reduction of these additional hydrogen ions which produce the hydrolysis current $i_H$.

There is a larger proportion of hydrogen ion to chromic ion in the diffusion layer than in the body of the solution, and the proportion increases as the electrode surface is approached. As a con-

(10) H. Bjerrum, *Z. physik. Chem.*, **59**, 336, 581 (1907).

(12) J. N. Brönsted and C. V. King, *Z. physik. Chem.*, **130**, 699 (1927).

sequence, the hydrolytic equilibrium represented by eqn. 3 tends to shift to the left. Whether or not hydrolytic equilibrium is maintained in the diffusion layer during the life of each mercury drop obviously does not alter the net amount of hydrogen ion available for reduction, because it is immaterial whether hydrogen ion is neutralized by the hydrolyzed chromic ion (reversal of reaction 3) or by the liberated hydroxyl ion.

From well known diffusion relations at the dropping electrode,[13] the flux of hydrogen ion at the electrode surface would be $(7/3\pi)^{1/2}\,(C_H D_H^{1/2}/t^{1/2})$ if there were no neutralization, where $C_H$ and $D_H$ are the concentration and diffusion coefficient of hydrogen ion in the body of the solution, and $t$ is time during the life of each mercury drop. The flux of hydrolyzed chromic ion is expressable by an exactly similar relation, and, because of the neutralization, the net flux of hydrogen ion at any instant is the difference between the two, $(7/3\pi)^{1/2}(C_H D_H^{1/2} - C_{Cr}. D_{Cr}^{1/2})/t^{1/2}$, where $C_{Cr}$ and $D_{Cr}$ refer to the hydrolyzed chromic ion in the body of the solution. Since $C_{Cr} = C_H$, and expressing the several quantities in the customary units[13] and combining the numerical constants, the hydrolysis current at 25° should obey the equation

$$i_H = 605(D_H^{1/2} - D_{Cr}^{1/2})\,C_H m^{2/3} t^{1/6} \qquad (6)$$

It is more convenient to express $i_H$ in terms of the diffusion current constants $I$, which for the 1-electron reductions involved are defined by $605\,D^{1/2}$, and eqn. 6 then becomes

$$i_H = (I_H - I_{Cr})\,C_H m^{2/3} t^{1/6} \qquad (7)$$

This equation was used to compute the theoretical values of $i_H$ in Tables I and II.

Since the diffusion coefficients of the hydrolyzed and unhydrolyzed chromic ions must be nearly identical, $I_{Cr}$ was assumed equal to the measured diffusion current constant of the first wave (1.46 in 0.5 $M$ sodium perchlorate and 1.50 in 0.25 $M$ potassium chloride).

The diffusion current constant $I_H$ of hydrogen ion was determined from measurements of the diffusion current of known concentrations (0.1 to 1 millimolar) of hydrogen ion in the same supporting electrolytes used to obtain the data in Tables I and II, and the same value, 5.64 ± 0.02, was obtained in both cases. This value agrees well with the theoretical infinite dilution value 5.84 calculated from the equivalent conductance of hydrogen ion by means of the relation[4] $D^0 = 2.67 \times 10^{-7}\lambda^0$. Special experiments showed that $I_H$ was not altered by the simultaneous reduction of chromic ion.

Since $p$H numbers as ordinarily measured do not strictly correspond to either the concentration or activity of hydrogen ion, the glass electrode $p$H meter was calibrated empirically in each of the supporting electrolytes with known small concentrations of hydrochloric acid. The data thus obtained were used to compute the concentrations of hydrogen ion in each solution of Tables I and II from the measured $p$H numbers, and these concentrations were then employed in eqn. 7 to compute $i_H$.

From Table I the agreement between the observed and theoretical values of $i_H$ in 0.5 $M$ sodium perchlorate is seen to be very good over the entire concentration range. The average difference between the two is only ± 3%, which is well within the limits of error of the measurements.

In 0.25 $M$ potassium chloride the observed values of $i_H$ average 45% larger than the theoretical values. This discrepancy can be accounted for by two factors which both operate to increase the observed value of $i_H$. First, the smaller ionic strength of the potassium chloride solutions leads to a greater possibility of some contribution by electrical migration[4] to the total limiting current. Secondly, the predominant molecular state of the + 3 chromium in 0.25 $M$ potassium chloride is probably the $CrCl_2(H_2O)_4^+$ ion, rather than the $Cr(H_2O)_6^{+++}$ ion which predominates in the perchlorate medium.[10,11,12] The reduction of each chloro complex ion frees two chloride ions at the surface of the dropping electrode, which alters the potential gradient in the diffusion layer and produces a relatively larger negative charge at the electrode surface. This tends to accelerate the passage of hydrogen ion through the diffusion layer.

## Summary

1. The polarographic behavior of chromic ion in potassium chloride and sodium perchlorate solutions has been investigated systematically. The optimum conditions for a well developed doublet wave are: (1) a concentration of supporting electrolyte of 0.1 $M$ or less, (2) the natural $p$H (about 4) resulting from the hydrolysis of chromic ion, and (3) the presence of 0.005-0.01% gelatin as a maximum suppressor.

2. The first chromic wave is directly proportional to concentration. The second wave is relatively too large and becomes more so with decreasing concentration. The excess current results from the simultaneous reduction of hydrogen ion. The diffusion and reduction of the hydrolyzed chromic ion and hydrogen ion were analyzed with the aid of diffusion current theory, and equations were developed from which the magnitude of the "hydrolysis current" can be calculated. The latter was compared with the measured excess current, and the good agreement obtained verifies the interpretation.

# Equilibrium between Ammonia and Hydrogen Selenide

BY F. F. MIKUS AND F. J. POSS[1]

The equilibrium between ammonia and hydrogen sulfide was thoroughly investigated by Isambert[2] and Magnusson.[3] A careful survey of the literature revealed no quantitative data on the equilibrium between ammonia and the analog of hydrogen sulfide, hydrogen selenide, but merely a statement that the decomposition pressure of ammonium hydroselenide is small. In this work the equilibrium constants for the dissociation of ammonium hydroselenide according to the reaction, $NH_4HSe(s) \rightleftarrows NH_3(g) + H_2Se(g)$, have been determined in the temperature range of 15 to 30.1°.

## Experimental

**Hydrogen Selenide.**—Hydrogen selenide was prepared in an evacuated flask by dropping freshly boiled water upon a large excess of aluminum selenide which had been prepared by the ignition of an intimate mixture of one part powdered aluminum and two parts selenium. Drying of the gas was effected by the excess aluminum selenide. The hydrogen selenide was used immediately upon preparation, and the purity was determined at the time the sample was withdrawn for use.

**Ammonia.**—Ammonia was prepared by warming C. P. ammonium hydroxide and by passing the resultant gas through four drying towers containing soda lime, potassium hydroxide pellets, soda lime, and potassium hydroxide pellets plus metallic sodium, respectively. The effluent gas, when absorbed in sulfuric acid, always contained less than 0.4% unabsorbable gas.

**Determination of the Equilibrium Pressure.**—The apparatus (Fig. 1) used for the determination of the equilibrium pressure, when the excess hydrogen selenide or ammonia was expelled, consisted of two Hempel burets set parallel to each other and connected with glass tubing. These were surrounded by water jackets. The temperature was maintained constant to within 0.05° by circulating water from a constant temperature bath by means of a centrifugal pump. The temperature of the room was kept slightly higher than that of the water-bath. The mercury levels were read by means of a cathetometer placed at a distance of eight feet from the apparatus.

Ammonia and hydrogen selenide were brought together in buret B with the formation of a white crystalline solid on the inner surface. The excess gas was expelled by pushing the gas into the evacuated portion E F and pumping out through G. Buret C was evacuated with a Hyvac pump, and the leveling bulb D was adjusted to leave from 10 to 40 ml. of evacuated space above the mercury. The stopcocks, E and F, were turned to allow the gas formed from the dissociation of the ammonium hydroselenide to expand into buret C. The difference in the height of the mercury in this buret before and after expansion gave the equilibrium pressure. The second reading was corrected for the change in the level of the mercury in the leveling bulb. Equilibrium was attained rapidly; no change in pressure was noted after two minutes.

An advantage of the system employed lay in the fact that it was not necessary to consider barometric pressure in the measurements. Furthermore, since the second buret was not coated with ammonium hydroselenide the adsorption of ammonia was minimized. As a result, pressure readings were more easily reproduced than in the system using one buret. When excesses of either of the gases were used, the two buret system was not used. Here it was necessary to measure the total volumes of the gases, which was done more conveniently when one buret was used. All measurements were made according to the method of Magnusson.[3]

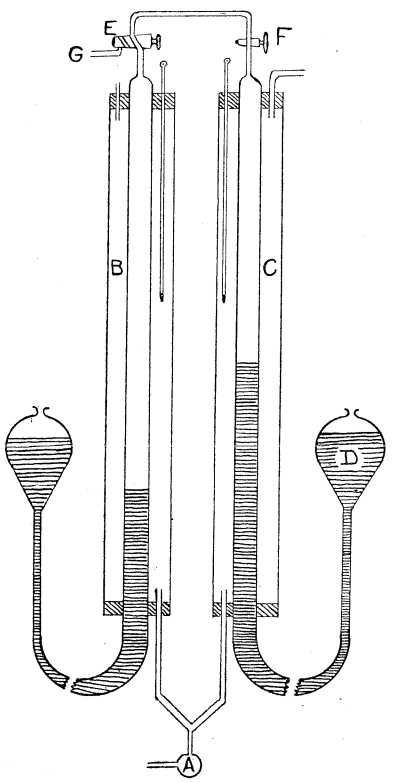

Fig. 1.

**Analysis of $NH_4HSe$.**—Considerable difficulty was encountered in attempting to analyze the white crystalline solid formed upon treating hydrogen selenide with ammonia. Traces of air coming in contact with the solid caused decomposition. A stoichiometric relationship between the two gases forming the solid was obtained by slowly introducing hydrogen selenide into a measured amount of ammonia in a buret until no decrease in volume of the gas in the buret was observed. Further addition of hydrogen selenide caused an increase. The hydrogen selenide was 93.4% pure.

## Data and Discussion

Table I shows the results of a series of determinations taken over a temperature range 15 to 30.1°. In this case, where the excess gases were expelled, $P_{NH_3} = P_{H_2Se} = P/2$, where $P$ is the observed pressure at equilibrium. The equilibrium constant then becomes, $K_p = (P/2)^2$. The dissociation pressures were found

to be independent of the volume when the volume was varied between 10 and 40 ml.

TABLE II

EQUILIBRIUM WITH EXCESS AMMONIA

Excess $NH_3 = 0.301 \times 10^{-4}$ mole; temp. = 30.0°; bar. P. = 748.1 mm.

| Height of mercury, mm. Leveling bulb | Buret | Observed pressure, mm. | Volume, ml. | $K_p \times 10^4$ |
|---|---|---|---|---|
| 72.0 | 778.3 | 41.8 | 15.50 | 1.7 |
| 250.0 | 967.0 | 31.1 | 30.10 | 2.6 |
| 257.8 | 980.0 | 25.9 | 50.35 | 2.4 |
| 263.7 | 987.2 | 24.6 | 64.85 | 2.3 |
| 267.1 | 992.0 | 23.2 | 83.10 | 2.1 |
| 268.5 | 994.0 | 22.6 | 92.60 | 2.1 |

TABLE III

EQUILIBRIUM WITH EXCESS HYDROGEN SELENIDE

Excess $H_2Se + H_2 = 1.013 \times 10^{-4}$ mole; temp. = 31.5°; bar. P. = 740.0 mm.

| Height of mercury, mm. Leveling bulb | Buret | Observed pressure, mm. | Volume, ml. | $K_p \times 10^4$ |
|---|---|---|---|---|
| 714.8 | 37.7 | 62.9 | 32.95 | 2.2 |
| 710.1 | 16.1 | 46.0 | 47.30 | 1.9 |
| 705.0 | 0.8 | 35.8 | 68.40 | 2.0 |
| 755.0 | 46.6 | 31.6 | 85.00 | 2.0 |
| 751.8 | 42.1 | 30.3 | 98.07 | 2.4 |

Tables II and III show the results obtained using excesses of ammonia and hydrogen selenide, respectively. In the former case the total pressure, $P$ is equal to $P_{H_2Se} + p'_{NH_3} + p''_{NH_3}$, where $p'_{NH_3}$ is the pressure due to the dissociation of the solid ammonium hydroselenide and $p''_{NH_3}$ is the pressure due to the excess ammonia. Hence the partial pressure of hydrogen selenide, $P_{H_2Se}$ is equal to $P - p''_{NH_3}/2$, and that of ammonia, $P_{NH_3}$ is equal to $p'_{NH_3} + p''_{NH_3}$.

The calculations in the case of the excess hydrogen selenide were further complicated by the presence of hydrogen, as a result of the decomposition of the hydrogen selenide into hydrogen and selenium. Here $p_{NH_3}$ is equal to $P - p_{H_2} - p'_{H_2Se}/2$ where $p'_{H_2Se}$ is the pressure due to the excess hydrogen selenide. The sample of hydrogen selenide used in obtaining the above data contained 6.6% hydrogen.

The small value of the equilibrium constants and the presence of an excess of one of the gases makes the partial pressure of the second gas very small. A small error in the measurements would cause a large error in calculating this pressure and also in the value of $K_p$. However, the values of the $K_p$ obtained when excesses were used were of the same order of magnitude as those obtained when the excess gases were expelled.

A plot of log $K_p$ *vs.* $1/T$, shown in Fig. 2, gives a straight line, indicating that the data herein presented satisfy the requirements of van't Hoff's equation, $\log K_p = -\Delta H/2.303\,RT + \Delta S/2.303\,R$. The slope of the line is −6,020,

hence $\Delta H$ for the dissociation is 27,600 calories within the indicated temperature range.

Results of the addition of hydrogen selenide to ammonia at 21°, Table IV, show that the two gases react mole for mole in the formation of the white crystalline solid. Therefore, the product must be $NH_4HSe$.

TABLE IV

| Ml. of $H_2Se + H_2$ | Ml. of $H_2Se$ | Ml. of $NH_3$ required |
|---|---|---|
| 26.6 | 25.0 | 25.0 |
| 23.4 | 21.9 | 22.2 |
| 27.7 | 25.9 | 25.8 |
| 22.4 | 20.9 | 21.1 |

## Summary

1. The equilibrium for the dissociation of ammonia hydroselenide, $NH_4HSe(s) \rightleftarrows NH_3(g) + H_2Se(g)$, was determined in the temperature range 15° to 30.1°.

2. $\Delta H$ for this reaction was found to be 27,600 calories in the indicated temperature range.

# Molecular Rotation in the Solid Forms of Some Long-Chain Alcohols[1]

BY JOHN D. HOFFMAN AND CHARLES P. SMYTH

X-Ray investigations on *n*-dodecyl alcohol conducted by Bernal[1a] resulted in the conclusion that the molecules rotate about their long axes several degrees below the freezing point. This result is not in accord with the more recent X-ray measurements of Ott[2] who found no evidence for rotation. Dielectric data on this substance obtained by Frosch[3] at audio frequencies disclosed strong frequency dispersion below the freezing point which would require molecular rotation in the solid if interpreted in the usual way, but the results showed great complexity and were not reproducible.

Dielectric measurements[4] on *n*-hexadecyl alcohol carried out at 0.5, 5.0 and 50 kc. indicated molecular rotation in a definite temperature range below the freezing point. It is noted that the dielectric loss factor, $\epsilon''$, in this range, which we term the "waxy" range to avoid the term "glassy," greatly exceeded the theoretical limit for orientation loss imposed on it by the relation $\epsilon''_{max} = (\epsilon_0 - \epsilon_\infty)/2$. Furthermore, the dielectric constant $\epsilon'$ rose sharply on freezing and was frequency dependent. The rise in dielectric constant would seem to demand greater molecular freedom in the solid than in the liquid, which is contrary to the fact that entropy must decrease on freezing. It must be pointed out, however, that X-ray observations[2] on *n*-hexadecyl alcohol showed that hexagonal close-packing of the molecular chains persisted for some degrees below the freezing point, which strongly suggests molecular rotation in the solid. Frosch explained the high value of the dielectric constant mentioned above as due to the co-existence of liquid and solid phases between the condenser plates, which resulted in Maxwell–Wagner polarization. The persistence of the liquid phase in contact with the solid for a long period of time at a temperature several degrees below the freezing point appears highly improbable, although a treatment based on this model accounted quantitatively for the observed dielectric constants.

The present work undertakes the study of the reported transition in *n*-dodecyl alcohol, and the investigation of the dielectric and thermal behavior of *n*-tetradecyl, *n*-octadecyl and *n*-docosyl alcohols with emphasis on the status of molecular rotation about the long axis and the isolation of the factors leading to time and frequency dependence of the abnormally high dielectric constants.

## Experimental Method

The bridge employed for the measurements was essentially that described in previous papers.[5] The frequency range and stability of the equipment were improved by using a Hewlett–Packard 200 oscillator as a signal generator and a TS12/AP amplifier (Presto Recording Corp.) as a null detector. Teflon spacers were inserted between the gold cylinders of the dielectric cell ($C_0$ = 38.6 $\mu\mu$f.; liquid capacity, 8 cc.) instead of the customary mica tabs with the result that loss across the tabs was eliminated. All temperature measurements were made with a calibrated platinum resistance thermometer.

The dielectric constants were determined by calculating the ratio, $\epsilon' = C/C_0$, where $C$ is the capacitance of the cell containing the material, exclusive of lead and insulator capacitance, and $C_0$ is the corresponding vacuum capacitance. The specific conductivity in ohms$^{-1}$ cm.$^{-1}$ was calculated from the relation $k = 0.0885/RC_0$ where $R$ is the resistance of the cell in ohms as measured in the bridge, $C_0$ being expressed in $\mu\mu$f. $\epsilon''$ was calculated from $k$ by using the relation $\epsilon'' = 1.8 \times 10^{12}\, k/f$, where $f$ is the frequency of the measurements in cycles/sec. The error in $\epsilon'$ never exceeds ±1%, and the reproducibility in the $\epsilon''$ measurements is better than ±3% except for very low values where the error becomes greater.

### Purification of Materials

*n*-Dodecyl alcohol ($C_{12}H_{25}OH$) was purified by crystallization from dry ether followed by five fractional distillations at 1 mm., f.p. 23.5°. Beilstein (I-432) gives the f.p. as 24°.

(1) This research was carried out with the support of the Office of Naval Research.

(5) Smyth and Hitchcock, *ibid.*, **54**, 4631 (1932); *ibid.*, **55**, 1830 (1935).

$n$-Tetradecyl alcohol ($C_{14}H_{29}OH$) was dried over calcium oxide and fractionally distilled twice at 1 mm. pressure; f.p. 36.4°, transition point 34.4°. Phillips and Mumford[6] list 37.7° and 35° for these points, respectively. Trapeznikov[7] gives the m.p. of the anhydrous crystals as 36.7° and of the hydrate as 40°.

$n$-Octadecyl alcohol ($C_{18}H_{37}OH$) was purified by crystallization from dry ether twice and benzine twice, and was distilled three times at 1 mm. pressure; f.p. 57.7°, transition point 53.4°. Phillips and Mumford[6] list 57.95° and 53.8° for these points, respectively. According to Trapeznikov[7] the melting point of the anhydrous crystals is 58.4°, and that of the hydrate 61.5°.

$n$-Docosyl alcohol ($C_{22}H_{45}OH$) synthesized by Mr. E. N. Stirewalt was kindly given us by Dr. Nathan L. Drake of the University of Maryland. This sample was subjected to a single high vacuum distillation (about $10^{-2}$ mm.) after drying for two weeks in a vacuum desiccator, f.p. 69.6°, transition point 64.5°. Francis, Collins and Piper[8] list the f.p. as 70.8°. The transition point has not been reported previously.

In all cases, the transfer of alcohols was performed under dry conditions and every effort was made to avoid contamination with water or ionic impurities. The cooling curves and low specific conductivities of the liquids indicate the purity of these compounds.

## Experimental Results

The dielectric constants, $\epsilon'$, the specific conductivities, $k$, and the loss factors, $\epsilon''$, obtained on cooling and on subsequent re-heating of each of the compounds are given in Table I. Many values of a confirmatory nature have been omitted, and only portions of the data near transitions are included. The data in Table I are plotted in Figs. 1, 2, 3 and 4. $n$-Octadecyl alcohol was also measured on a heterodyne beat apparatus[9] at a frequency of 525 kc. in the same dielectric cell used in the impedance bridge. The data are plotted in Fig. 3 (filled squares) but are not reproduced in Table I because of their closeness to the values at 50 kc. Arrows in the diagrams indicate the direction in which the temperature is changing. Figures 5 and 6 show the behavior of the dielectric constant at 0.25 kc. for $n$-tetradecyl and $n$-octadecyl alcohols, where the normal cooling process was intentionally halted for several hours in the waxy state by holding the temperature of the

[a] When the same sample was rewarmed *immediately* a value of 19.5 was reached. [b] These data are used in Table II to calculate $\epsilon'$.

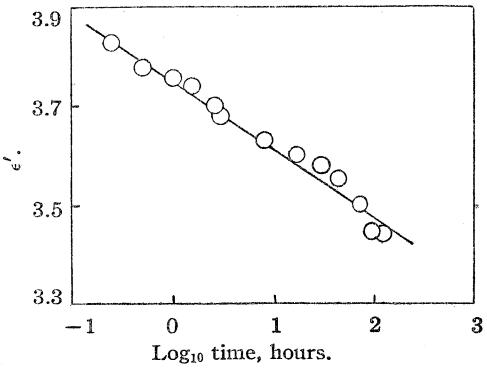

Fig. 8.—Dependence of dielectric constant of *n*-octadecyl alcohol on time at 0.25 kc. and 15.0°. The sample was rapidly cooled from 100 to 15° and held at this temperature.

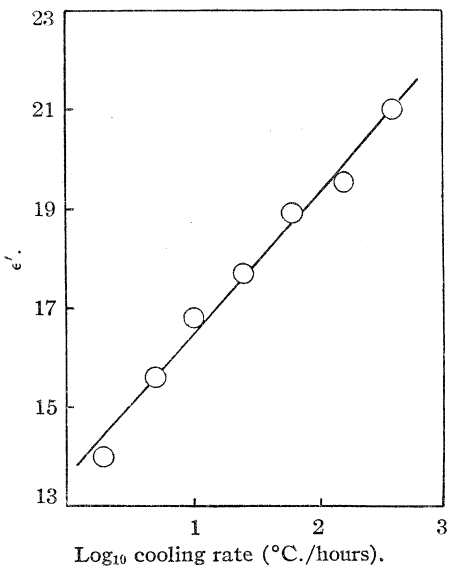

Fig. 9.—Dependence of maximum value of dielectric constant in waxy state on cooling rate of *n*-octadecyl alcohol. Data are for cooling rates as measured 1° above the freezing point and were obtained at 0.5 kc.

cooling rate measured 1° above the freezing point. The cooling and warming curves which were obtained concurrently with the dielectric runs are illustrated in Fig. 10. The dielectric data on impure *n*-dodecyl and *n*-octadecyl alcohols as received from the manufacturers are given in Fig. 11 to permit comparison of the properties of pure and impure materials.

## Discussion of Results

*n*-Dodecyl alcohol (Fig. 1) shows no transitions in the solid, either in the cooling curve or in the dielectric data, and exhibits typical rotational freezing of dipoles on solidification. The conductivity of the liquid alcohol is less than that found by Frosch[3] ($17 \times 10^{-10}$ compared to $42 \times 10^{-10}$). Inasmuch as water was difficult to remove and in view of the appearance of the curve for the impure sample (Fig. 11) it is suggested that water, which forms a higher melting hydrate,[7] or other impurities may have caused previous investigators to obtain results which might be interpreted as indicating molecular rotation.

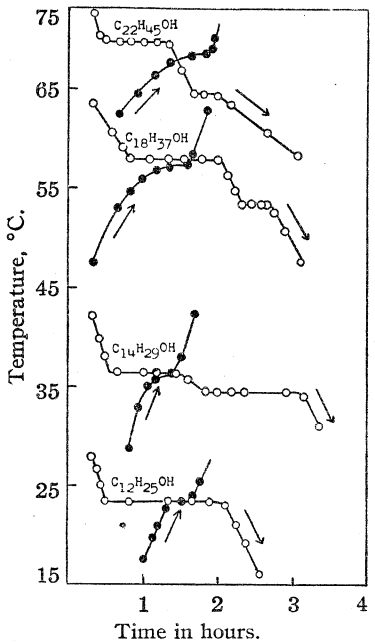

Fig. 10.—Temperature–time curves for *n*-dodecyl, *n*-tetradecyl, *n*-octadecyl and *n*-docosyl alcohols. Arrows indicate warming and cooling curves.

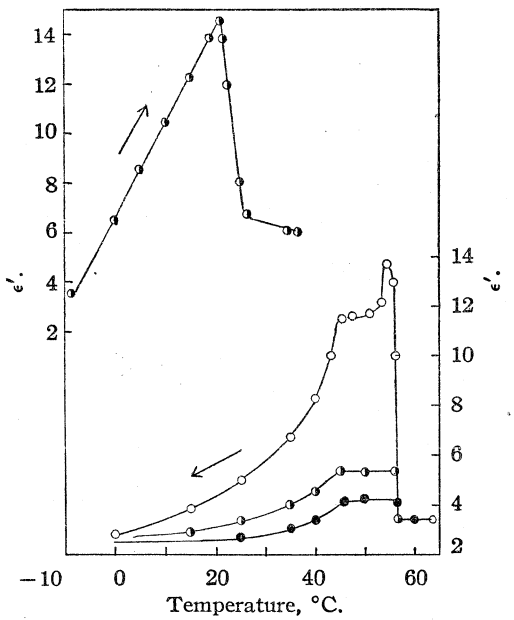

Fig. 11.—Temperature dependence of dielectric constant for impure alcohols. Upper curve, *n*-dodecyl alcohol, scale on left. Lower curve, *n*-octadecyl alcohol, scale on right. Hollow circles represent data at 0.5 kc., half-filled circles values at 5.0 kc., and filled circles data at 50 kc. Arrows indicate direction of temperature change.

*n*-Tetradecyl, *n*-octadecyl and *n*-docosyl alcohols show dielectric and thermal behavior similar to that of *n*-hexadecyl alcohol,[4] except that the waxy ranges are shorter, and that the transitions are not enantiotropic as previously reported.[10] The change of $\epsilon'$ with time at constant temperature (see Fig. 5, AB; Fig. 6, ABCD) indicates that the waxy state consists of a mixture of two solid phases, one of which is unstable. The alcohols change from clear-translucent to opaque-white on standing at constant temperature in the waxy state. The white regions appear first as small nuclei which slowly permeate the whole mass. This coexistence of two phases has been indicated by the X-ray measurements of Malkin[11] on *n*-hexadecyl alcohol, which simultaneously show the crystal spacings of the vertical and tilted forms.

The dielectric dispersion found in the waxy state of these alcohols may be quantitatively accounted for by Maxwell–Wagner polarization between two solid phases which we denote as $\alpha$ (unstable, clear) and $\beta_2$ (stable, white). The $\alpha$ form which crystallizes first from the liquid shows a much higher conductivity than the liquid or crystalline solid at low temperature. Frosch[3] arbitrarily pictured the two phase dielectric as two layers with interfaces parallel to the condenser plates, and, by the use of circuit analysis of the impedances, derived an equation for the observed capacitance as a function of the conductivities of the two phases. Using a similar method, we have obtained the following expression for the maximum observed dielectric constant

$$\epsilon'_m = \epsilon + \epsilon(k_1 - k_2)^2/4k_1k_2$$

where $k_1$ and $k_2$ are the specific conductivities of the two phases, and $\epsilon$ is the dielectric constant arbitrarily taken as the same for each phase. The observed maximum in $\epsilon'_m$ appears for an optimum thickness of a given layer. In the derivation of the above expression it was assumed that $\epsilon'' > \epsilon'$, which is true only for a dielectric possessing conductivity other than that due to orientation loss. The alcohols show sufficient conductivity in the waxy state to cause $\epsilon''$ to exceed $\epsilon'$ at moderately high frequencies, as may be seen in Table I. The supposition by Frosch that the liquid and solid alcohol coexist over long periods of time below the freezing temperature with the interface parallel to the cell plates is contrary to our observations, since the two solid phases are seen to coexist as a mixture over a range of temperature. Despite the fact that the material is not distributed in parallel slabs, there is enough similarity in the equivalent circuits to warrant application of the equation to the case where one phase is distributed as small platelets throughout the other. According to the equipotential surface theorem, the two-layer dielectric treated by Frosch is equivalent to a dielectric where the vertical slabs are split into any number of sheets, and arranged parallel to the condenser plates in any order. To a fair approximation these thin sheets may be subdivided into platelets of smaller area and distributed throughout the other material, thus approximating the two-slab model electrically as well as representing the mixture of solid phases observed experimentally. Hence, our equation should predict the behavior of the alcohols in the waxy state.

In order to apply the equation we take the dielectric constant of the liquid at the freezing point as $\epsilon$ and the specific conductivity of the $\alpha$ phase as that observed for the waxy state as a whole. Since the $\alpha$ phase conducts so much more than the $\beta_2$ and is much more abundant, this approximation is valid. The specific conductivity of the $\beta_2$ phase is assumed to be the same as that of the solid found a few degrees below the transition point after standing for a short time. These approximations are necessary because the phases cannot be physically separated. The data employed are marked with a "b" in Table I. In Table II $\epsilon'_m$ is compared with the value calculated by means of the equation.

TABLE II

COMPARISON OF THE CALCULATED AND THE OBSERVED VALUES OF $\epsilon'_m$

| | Calculated | | | Observed | | | |
|---|---|---|---|---|---|---|---|
| Alcohol | 0.5 | 5 | 50 kc. | 0.5 | 5 | 50 | 525 kc. |
| *n*-Tetradecyl | 9.0 | 4.8 | | 7.30 | 4.81 | | |
| *n*-Octadecyl | 22 | 7.3 | 4.0 | 16.8 | 5.80 | 4.25 | 4.15 |
| *n*-Docosyl | 24 | 7.5 | 3.2 | 15.9 | 5.10 | 3.88 | |

In general, the calculated values tend to be somewhat high, but it is clear that the equation holds fairly well and that the Maxwell–Wagner polarization drops off sharply with increase in frequency. Considering the fact that no precise knowledge of the actual specific conductivities of each pure phase may be had, and that a rough model has been used, the agreement between observed and calculated values is satisfactory.

Now that analysis has shown the large increase in $\epsilon'$ to be due to Maxwell–Wagner effect, it is possible to interpret the data free of this phenomenon in terms of dipole rotation. Table II and Figs. 2, 3, 4 and 7 indicate that the Maxwell–Wagner effect is not important at 50 kc. for *n*-tetradecyl, *n*-octadecyl and *n*-docosyl alcohols. The persistence of a near-liquid value of the dielectric constant in the waxy state at this frequency clearly indicates that a state of dipole rotation exists. *n*-Octadecyl alcohol shows an increase of dielectric constant on freezing of roughly 20% even at 525 kc., and *n*-docosyl alcohol shows an increase of about 30% at 50 kc., but these increases may be accounted for largely by the increase in density of these compounds on solidification. It is possible that the values for *n*-docosyl alcohol are still slightly high at 50 kc. because of some persistence of the Maxwell–Wagner effect. *n*-Tetradecyl alcohol shows no increase in $\epsilon'$ on freezing, but, instead, falls off with decreasing temperature. This is probably due to the rather rapid transformation of the $\alpha$-phase to

(10) Meyer and Reid, THIS JOURNAL, **55**, 1574 (1933).
(11) Malkin, *ibid.*, **52**, 3739 (1930).

the more stable form during the cooling process. The true anomalous dispersion region is doubtless at a much higher frequency than any employed here, and should not be confused with the Maxwell–Wagner dispersion.

X-Ray studies show[2,11] that the oxygen atoms are arranged in a plane in the crystal, so that a sheet of rotating dipoles may be said to exist. Dipole rotation appears to be synonymous with rotation of the hydrocarbon chain. This is indicated by the cooling curves which show sharp transitions in the solid concurrent with the freezing out of dipoles, and by the X-ray data of Ott,[2] which show that the transition involves a change from rotation to non-rotation of the molecular chain. Molecular rotation about the long axis appears for shorter chain lengths in the alcohols (14 carbons) than in the corresponding hydrocarbons where 22 carbon atoms are required before rotation appears in the solid.[12]

The origin of the high conductivity attributed to the $\alpha$ phase, which is necessary to the elucidation of the dielectric behavior remains to be explained. The planes of hydroxyls in this phase, possessing rotational freedom through rotation of the entire molecules, seem to provide a possible site for the proton transfer mechanism of conduction treated by Stearn and Eyring.[13] Two important requirements are proximity of the hydroxyl groups to one another, and rotation of these groups such that an optimum configuration conducive to the transfer of a proton from a positive ion (*e. g.*, a hydronium ion) to a neutral molecule may occur with reasonable frequency in an applied field. Both requirements seem to be met in the $\alpha$ phase of the waxy state in the long-chain alcohols. No extensive sheets of hydroxyls possessing rotational freedom occur in either the liquid[14] or the low-temperature crystalline solid, and the relatively lower conductivity of these media should be due to the absence of the rotation required in the proton-transfer mechanism. Baker and Yager[15] have invoked a mechanism of proton transfer to explain the high d. c. conductivity of linear polyamides. Despite precautions, contamination of our samples with a very small amount of water is possible, but this could not account for the appearance of appreciable conductance solely in the waxy state, and not in the liquid or low temperature crystalline solid.

It is possible to correlate the properties of the vertical and tilted forms of long chain compounds with the dielectric changes and cooling curve data of the alcohols. The vertical forms found in long-chain compounds are those in which the carbon chains are perpendicular to the plane of the end groups, and the tilted forms are those in which the carbon chains are inclined at an angle to the plane of the end groups. The latter show shorter crystal spacings between the end groups than the former. For a number of long-chain compounds, including hydrocarbons, esters and acids, the vertical form tends to be clear, have a lower entropy of fusion per methylene group, and greater inter-chain mobility than the tilted form.[16] Thus it seems reasonable to assign to the clear, rotating $\alpha$ phase the vertical configuration. Ott[2] has found that the rotating molecules in *n*-tetradecyl and *n*-hexadecyl alcohols show the long crystal spacing, which proves that the $\alpha$ phases of these two substances are the vertical form. The irreversible conversion of $\alpha$ to $\beta_2$ in the waxy state, which is accompanied by a drop in $\epsilon'$ (Figs. 5 and 6) with simultaneous increase in opacity, is probably due to the slow conversion of the vertical (rotator) into the tilted (non-rotator) form; the slowness of the process is likely due to the high viscosity of the medium in which the molecules must move to achieve the configuration of lowest energy.

The transformation of the $\alpha$ phase proceeds during the freezing process in which $\alpha$ is formed from the liquid, and thus we may expect the maximum value attained by $\epsilon'$ at a given frequency to depend on the cooling rate. Figure 9 illustrates this effect for cooling rates between 2 and 400° per hour. The transformation of the $\alpha$ phase lowers the $\epsilon'_m$. Differences in cooling rate as well as impurities may evidently be an important cause of discrepancies among the results on *n*-hexadecyl alcohol as reported by other workers.[3,4,17]

It is believed that a transition point is found in the solid because that portion of the $\alpha$ phase not yet converted into $\beta_2$ in the cooling process and retaining hexagonal close-packing of the chains collapses into what Ott terms a "monoclinic" lattice, with a considerable heat of transition. Since it has been shown[2] that the $\alpha$ form has the vertical configuration, it is plausible to suggest that the change to the "monoclinic" lattice at the transition point occurs while the chains are vertical. This would produce a form which we call $\beta_1$. It has been observed that the tilted form with the "monoclinic" carbon chain lattice is the stable form in the crystalline solid,[2,3] so that we might expect a slow rearrangement of $\beta_1$ into $\beta_2$ in the solid. Changes from vertical to tilted have been observed in the solid long chain iodides by X-ray techniques,[3] and an irreversible $\beta_1$ to $\beta_2$ transition in the solid similar to the present case has been found by polarization and coefficient of expansion measurements in ethyl docosanoate.[18] The data plotted in Fig. 8 for solid *n*-octadecyl alcohol at 15° at 0.25 kc. show that the dielectric constant drops slowly with time over a period of five days, and afford a strong indication of the expected $\beta_1$ to $\beta_2$ transition. Further evidence that a change is taking place in the crystalline solid below the transition point is afforded by the fact that the

dielectric data obtained on warming differed greatly in the maximum value of $\epsilon'$ attained, the difference depending on the time the solid had been allowed to stand. Thus, the highest value at 0.5 kc. reached on re-warming *n*-octadecyl alcohol which had been allowed to stand twenty hours at about 25° was 8.12 (Fig. 3), but immediate re-warming yielded a value of 19.5. A similar effect was found for *n*-docosyl alcohol. Finally, changes in melting and freezing point values give evidence for the $\beta_1$ to $\beta_2$ transition in the solid. For example, *n*-octadecyl alcohol which had stood overnight at room temperature remelted at 57.4° (Fig. 10) while that which was rewarmed immediately melted at 57.7°. An even more pronounced effect involving a temperature difference of 0.9° was observed for *n*-docosyl alcohol. These facts are in accord with the principle that those molecules which rotate in the solid tend to melt at a somewhat higher temperature than their non-rotating counterparts.[19] The thermal (Fig. 10) data illustrate the difference between freezing and melting point nicely.

The general picture proposed for the phase changes in these alcohols is the following: *n*-Dodecyl alcohol crystallizes directly into a stable form, but the higher alcohols crystallize from the liquid to a more or less transparent $\alpha$ form, which shows rotation about the long molecular axis. The $\alpha$ modification is unstable and begins to change to a more stable non-rotating form, $\beta_2$. This system, a non-equilibrium of two allotropic modifications, has the ability to exhibit Maxwell–Wagner polarization since the $\alpha$ phase is a conductor. At a transition point below the freezing point the $\alpha$ form which has not been converted to $\beta_2$ transforms into $\beta_1$. $\beta_1$ is not stable but slowly changes to the stable $\beta_2$ form. The $\beta_2$ forms melt below the original freezing point, as would be expected, since they do not possess molecular rotation.[19]

The chain length of fourteen carbon atoms at which molecular rotation is possible in the alcohols is shorter than for which it has been observed in other types of long molecules, which will be discussed in a later paper. In conformity with previous work, there is no indication that the rotation is that of the hydroxyl around the C—O bond.

## Summary

The dielectric constants and loss factors of *n*-dodecyl, *n*-tetradecyl, *n*-octadecyl and *n*-docosyl alcohols have been measured over a wide range of temperature and frequency in order to investigate the possibility of molecular rotation in the solid forms. When carefully purified, *n*-dodecyl alcohol gave no evidence of molecular rotation in the solid state. The other three alcohols, on cooling of the liquid, froze to waxy solids possessing dielectric constant values so high as to show the presence of strong Maxwell–Wagner polarization. The values were dependent on the cooling rate. An equation approximately representing the observed dielectric behavior of the waxy solid has been developed on the assumption of the coexistence of two solid phases of very different electrical conductivities. The two phases formed on freezing consisted of an unstable $\alpha$ phase observed to be translucent together with a small amount of a stable, opaque $\beta_2$ phase, which increased in amount with the passage of time. The $\alpha$ phase was found to show rotation of the molecules around their long axes, and its high electrical conductivity was attributed to proton transfer facilitated by the molecular rotation. On cooling, the $\alpha$ phase showed a transition to an unstable $\beta_1$ phase, in which the molecules did not possess rotational freedom. The $\alpha$ phase in *n*-tetradecyl alcohol appears to be less stable than that in *n*-octadecyl alcohol. The $\beta_1$ phase gradually changed to the $\beta_2$, which, possessing no rotational freedom, melted slightly below the freezing point. The setting-in of some dielectric dispersion just below the transition point was attributed to incompleteness of the conversion from $\beta_1$ to $\beta_2$. Differences in results obtained on warming and on cooling were related to phase changes in the solid.

# Experimental Equilibrium Constants for the Isomeric Hexanes

BY B. L. EVERING AND E. L. D'OUVILLE

In the course of the development of the naphtha isomerization process[1,2] the equilibrium constants for the isomeric hexanes were determined. Although the equilibrium constants for butanes and pentanes[3,4] have been repeatedly investigated, few experimental data have appeared for the hexanes. Two papers[5,6] have appeared on the direct experimental determination of the equilibrium constants for the hexanes but they were limited to 25 and 80°, respectively. The hexane equilibria were calculated over a wide range of temperatures from the precise measurements of the heats of combustion and best available entropy data.[7] In the present investigation the hexane equilibria were studied directly over the temperature range 21 to 204° and side reactions were reduced to a minimum by the use of hydrogen and cyclic decomposition inhibitors. The experiments were carried out on a fraction of Mid-Continent light naphtha containing both $C_5$ and $C_6$ hydrocarbons.

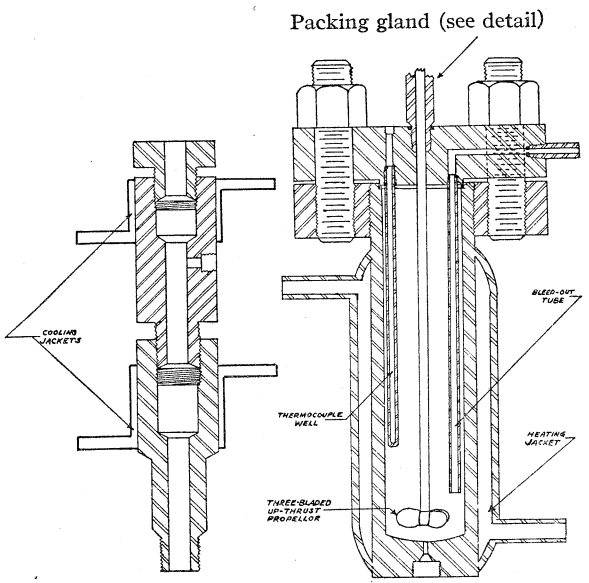

Fig. 1.

All experiments were made in a stirring reactor wherein efficient contact was obtained between the catalyst and the reactants.

## Experimental Method

A batch type stirring apparatus consisting of a 1490-cc. capacity carbon steel reactor (Fig. 1) was employed throughout this investigation. The reactor was heated with steam or hot oil by circulating these materials through a jacket surrounding the reactor. The reactor could be brought to reaction temperature in five minutes with steam and in half an hour with the hot circulating oil. In the case of steam the reactor could be quenched in five minutes by circulating cold tap water through the surrounding jacket. Cooling was somewhat slower with the hot oil since cold water could not be circulated through the jacket to cool the reactor.

The reactor was mechanically stirred at 1725 r. p. m. by a one-half horsepower electric motor driving a $^3/_8$ inch steel shaft operating through a double packing gland, the details of which are shown in Fig. 1. The lower packing holds the reactor pressure and any leakage past the main packing gland is measured by a gas meter attached to the vent between the lower and upper packing glands. In actual service, no difficulty has been experienced with leakage up to pressures of 5000 lb./sq. in. Successful operation depends primarily on the use of a drill rod shaft in conjunction with an asbestos type packing impregnated with a heavy oil and water cooling of the packing glands. The reactants were agitated with a 2.5 inch three bladed upthrust propeller placed near the bottom of the reactor. A bleedout tube dipped to near the bottom of the reactor so that liquid product could be withdrawn. The reactor system was equipped with the necessary accessory equipment to measure in known amounts of anhydrous hydrogen chloride from a calibrated pressure vessel by pressure drop and was also equipped for the addition of hydrogen.

An experiment was made as follows. Seventy-two grams of anhydrous aluminum chloride or its equivalent as aluminum chloride–hydrocarbon complex was placed in the reactor usually with one liter of light naphtha and promptly sealed. Twenty-two grams of hydrogen chloride was measured into the reactor as an activator. Hydrogen was added in the higher temperature runs until the total reactor pressure was 600 lb./sq. in. at room temperature. In the case of the experiments at 21°, anhydrous aluminum bromide, which is soluble in paraffins, was used as the catalyst in an effort to establish equilibrium more rapidly.

The reactor was heated to reaction temperature with stirring and sufficient time allowed for equilibrium to be established. At the end of this time the stirrer was stopped, the reactor was rapidly cooled and one-half hour allowed for settling the catalyst from the products. (It was experimentally established that no isomerization occurred during this cooling and settling period.) The liquid product was withdrawn from the reactor into a flask, the volatile products passed overhead through a soda lime tube to remove hydrogen chloride, then to a Dry Ice–acetone "knock back" to condense light hydrocarbons and finally to a wet test meter to measure the effluent hydrogen and any other non-condensable gases.

The products were distilled in a low-temperature column packed with glass helices equivalent to 20 theoretical plates to separate between butanes and lighter and the liquid product. Motor method octane numbers (CFR-ASTM D-357) were obtained on the liquid product for rapid estimation of the establishment of equilibrium. Those samples which had attained equilibrium were carefully fractionated in a wire gauze packed column testing 60—80

theoretical plates. The accuracy of the analyses attainable with this column is shown in Table I by the fractional analysis of a known synthetic sample. The largest discrepancy from the true composition of the hexanes is in the determination of 2,3-dimethylbutane as it must be determined primarily from the refractive index and this is partially obscured by the high index of cyclopentane. Mass spectrometer analyses (not available when the analyses were made) have invariably shown the concentration of 2,3-dimethylbutane determined by fractional analysis to be approximately 20% low; therefore the values reported for 2,3-dimethylbutane in this investigation have been corrected upward by this amount with an accompanying decrease in the value of 2-methylpentane.

TABLE I

ACCURACY OF FRACTIONAL ANALYSES OF HEXANE ISOMERS

| | Volume, % | |
|---|---|---|
| | Actual composition | Fractionation |
| Cyclopentane | 3.8 | 4.0 |
| 2,2-Dimethylbutane | 20.8 | 19.7 |
| 2,3-Dimethylbutane | 7.9 | 6.2 |
| 2-Methylpentane | 30.6 | 34.3 |
| 3-Methylpentane | 15.8 | 15.7 |
| *n*-Hexane | 14.2 | 12.2 |
| Methylcyclopentane | 5.4 | 7.0 |
| Benzene | 1.5 | 0.9 |

Materials.—The aluminum chloride was a product of the Hooker Electrochemical Company. The anhydrous hydrogen chloride was from the Harshaw Chemical Company and was guaranteed 96% pure. Hydrogen was Linde commercial grade and was used from cylinders without further purification.

The hydrocarbon used in this investigation was a 67° end-point cut of Mid-Continent naphtha containing 0.009 weight per cent. sulfur and having the composition shown in Table II. Although the hydrocarbon feed contained considerable amounts of material other than hexanes in the form of pentanes, naphthenes and a small amount of aromatics, they are not believed to have any detrimental effect on the equilibrium of the hexanes. In fact, the naphthenes and benzene serve the useful function of being decomposition inhibitors, thus reducing side reactions.

TABLE II

COMPOSITION OF MID-CONTINENT LIGHT NAPHTHA (67° End-point)

| | Volume, % |
|---|---|

| Benzene | 0.5 |

## Experimental Results

For accurate equilibrium data the first problem is assurance of the establishment of complete chemical equilibrium and the second is the reduction to a minimum of all side reactions that might affect this equilibrium.

In order to avoid the time-consuming fractional analysis of the products from all the experiments, a rapid method of determining the approach to and establishment of equilibrium was used. Since the octane numbers[8] of hydrocarbons increase with increase in the branching, determination of the octane number of the product gave a rapid estimate of the extent to which the isomerization had progressed. Series of experiments made at increasing reaction time are plotted against octane number and the leveling off of the octane number curve indicated the establishment of chemical equilibrium. Only those experiments for which chemical equilibrium was established, were analyzed by fractional distillation. Figure 2 shows that equilibrium is established quite rapidly at 161° and very slowly at the lower temperatures and especially at 21°.

The side reactions accompanying isomerization at 21 and 161° are shown in Fig. 2 where the percentage of butane and lighter (condensables) formed are taken as a measure of decomposition and plotted against time. Side reactions increase rapidly with increase in temperature so that at 161° and above hydrogen pressure was used to inhibit decomposition. Since hydrogen pressure has a slight suppression effect on the rate of isomerization it was not used at 102° and lower where the isomerization rate is very slow; instead, advantage was taken of the decomposition-inhibiting action of the naphthenes and benzene contained in the light naphtha. The inhibiting of side reactions accompanying isomerization will be reported in more detail in a subsequent paper.

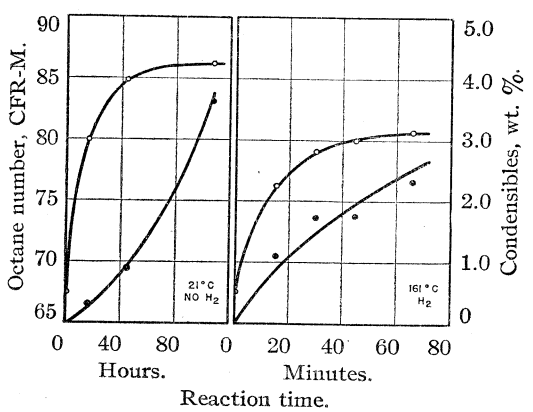

Fig. 2.— -O-, CFR-M; -●-, decomposition.

Side reactions can have a pronounced effect on chemical equilibrium and lead to erroneous results[9] due to the relative instability of one isomer compared to another and an unfavorable isomerization rate for the formation of the unstable isomer as it is depleted. For the equilibrium experiments at 21 and 161° the decomposition is sufficiently low that no appreciable error can be produced. Furthermore, although the decomposition curves in Fig. 2 are not linear, they do not indicate any

appreciable preferential decomposition of the more highly branched isomers as they are formed. At 102 and 204° the decomposition is considerably higher (Table IV) but does not lead to displacement of equilibrium. This was confirmed by isomerizing 2,3-dimethylbutane under insufficient hydrogen pressure so that a large amount of decomposition was produced and comparing with the results from an experiment in which the decomposition was substantially inhibited. The results reported in Table III indicate no significant difference for the two extreme cases.

[a] Anhydrous hydrogen bromide.

**Hexane Equilibria.**—Table IV shows the results of experiments at 21, 102, 161 and 204° in which equilibrium had been established. Since the contents of the reactor were cooled to room temperature before removal, the analyses reported in Table IV are for the combination of vapor and liquid phases which existed at reaction conditions. The true equilibrium values for the hexanes in the vapor and liquid phases were calculated from these data by finding the vapor and liquid composition that existed in the reactor at the experimental temperature and pressure. This was solved by trial and error knowing the fugacities of the various components in the system. The fugacities of the components in the reactor at experimental conditions were obtained from compressibility charts[10] using the best published vapor pressures and critical constants appearing in the literature. The physical properties of the isomeric hexanes were taken from the work of Willingham, Taylor, Pignocco and Rossini[11] for temperatures below the boiling point and from the work of Kay[12] at higher temperatures. The fugacities for hydrogen and hydrogen chloride are based on unpublished data from this Laboratory. The vapor and liquid phase equilibrium values for the isomeric hexanes are given in Table V together with the phase or vapor–liquid ratio calculated as existing at experimental conditions.

At 21° the phase is known to be entirely liquid and at 102° the vapor–liquid ratio can be calculated quite accurately. However, at 161°, which is relatively close to the critical and 204° which is just above the critical, the exact phase or vapor–liquid ratio cannot be known with great certainty. This uncertainty in the vapor–liquid ratio at the two higher temperatures cannot lead to any substantial errors as calculations assuming the found analyses to be either entirely vapor or entirely liquid are quite close at 161° and are equal at the critical. The composition limits for the several temperatures investigated are shown in Table V.

The vapor phase equilibrium values for the isomeric hexanes from the last column of Table V are plotted in Fig. 3. These values are compared with those obtained from the entropies and heats of combustion[7] and the experimental values of Koch and Richter[5] at 25° and Schuit, Hoog and Verheus[6] at 80°.

The agreement between the present values and those from the entropies and heats of combustion are good for *n*-hexane and 2,3-dimethylbutane but are in disagreement on 2,2-dimethylbutane and the methylpentanes. The temperature coefficient for all the isomers is in good agreement but the entropies and heats of combustion predict substantially more 2,2-dimethylbutane than has been found experimentally. Assuming that the difference lies entirely in the 2,2-dimethylbutane, then the discrepancy in the methylpentanes vanishes. Aside from the absolute values there is good agreement in the ratio of 2-methylpentane to 3-methylpentane.

The experimental equilibria determined for the hexanes by Koch and Richter[5] at 25° are in ex-

cellent agreement with the present experimental values and lend support to the lower experimental values for 2,2-dimethylbutane over the higher values calculated by Rossini and co-authors.[7] The values of Schuit, Hoog and Verheus,[6] at 80° cannot be compared to the present values since no distinction was made between 2,2-dimethylbutane and 2,3-dimethylbutane and the total of the dimethylbutanes is obviously far from equilibrium. Their values agree well with the present values in the case of *n*-hexane and in the ratio of 2-methylpentane to 3-methylpentane.

The values of $\Delta F/T$ for the isomerization of *n*-hexane to the various isomers were calculated from the experimental equilibrium constants using the relationship

$$\Delta F/T = -R \ln K \qquad (1)$$

The smoothed values are compared in Table VI with those reported by Rossini and co-authors[7] from the entropies and heats of combustion. The largest discrepancy appears in the values for 2,2-dimethylbutane.

Since $\Delta F/T$ is related to both $\Delta H$ and $\Delta S$ through the standard free energy equation and is also related by equation (1) to the equilibrium constant, it is possible to separate the discrepancies in Table VI and assign them to either errors in the entropy or heat of isomerization or both. From the relation

$$-R \ln K = \Delta H/T - \Delta S \qquad (2)$$

the heat of isomerization and entropy of isomerization were evaluated for the conversion of *n*-hexane to its isomers by plotting log $K$ against $1/T$. The values calculated for the entropy and heat of

isomerization from the present experimental work and from the calorimetric data of Rossini and co-authors are compared in Table VII. These are the values over the temperature range 25–200° and are directly comparable.

The agreement between the heats of isomerization obtained from the heats of combustion and the present experimental work are quite good. The disagreement in the equilibrium values may be traced largely to discrepancies in the entropies of isomerization. Further work will be necessary to resolve this discrepancy.

**Pentanes.**—Although this paper deals primarily with hexane equilibria, similar data were obtained simultaneously for the pentanes since the feed contained 37% pentanes. The pentanes were handled in the same fashion as described for the hexanes. The equilibrium values are shown in Table VIII for all temperatures except 21° which was obviously in error. This was due to the loss of a small amount of isopentane when

TABLE VIII

EQUILIBRIUM VALUES FOR THE PENTANES

| | | Mole % | | |
|---|---|---|---|---|
| Temperature, °C. | | 102 | 161 | 204 |
| Liquid phase | Isopentane | 84.9 | 74.8 | |

washing out the very soluble aluminum bromide used in this experiment before fractionation. These values are compared with the values of Pines, Kvetinskas, Kassel and Ipatieff[4] for the gas phase in Fig. 4. The temperature coefficients are widely different and the only agreement is in the neighborhood of 100°.

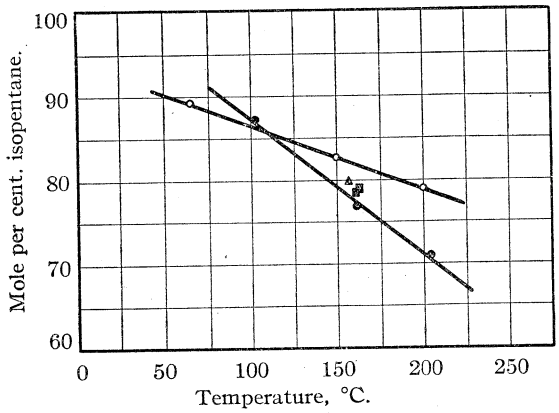

Fig. 4.— -●-, Experimental; -O-, Pines *et al.*; ■, check experiments; ▲, no hydrogen.

Since this discrepancy in the pentane equilibria at the higher temperatures might lead one to question the complete establishment of equilibria in the present work, three special experiments were made starting with compositions of pentanes corresponding to the values found by Pines and co-authors and that found in the present work. The results are shown in Table IX. The compositions of the pentane products were accurately determined by mass spectrometer analyses and further checked with infrared analysis. Neopentane was never found as a product of isomerization and is never produced except possibly in minute amounts. Due to the high pressure employed, Experiments 1 and 2, Table IX, were in the liquid phase. These values were converted to the gas phase using the Pines, Kvetinskas, Kassel and Ipatieff[4] ratio of $K_G°/K_L$ after slight extrapolation to 160° for more direct comparison. These experiments establish the equilibrium at 78.5% which is in substantial agreement with the value of 77.5% taken from the curve drawn for the values obtained from the present light naphtha work. This agreement establishes that chemical equilibrium had been obtained in the light naphtha reaction system. However, the heat of isomerization and entropy of isomerization calculated from the present experimental values for pentane are

completely in disagreement with those obtained by Rossini and co-authors[7] as shown in Table X; while the experimental values of Pines, Kvetinskas, Kassel and Ipatieff are in excellent agreement. The reason for this difference is unknown and further work will be necessary to resolve this discrepancy.

Experiment 3, Table IX, was made in the absence of hydrogen pressure to determine its effect on the pentane equilibrium. There was approximately a 1% increase in isopentane composition indicating no significant effect due to hydrogen pressure. Likewise side reactions to the extent of 44.6% had no important effect on the chemical equilibrium.

**Acknowledgment.**—The authors are indebted to the numerous members of the Standard Oil Company (Indiana) Research Laboratories who contributed their advice and services and especially to Dr. W. E. Kuentzel for design of the reactor and Mr. J. E. Swearingen for help in calculation of the fugacities.

## Summary

1. The experimental equilibria among the isomeric hexanes were determined in the range 21 to 204° using activated aluminum halide catalysts on a 67° end-point light naphtha stock containing both pentanes and hexanes.

2. The results for hexanes agree with the equilibrium values calculated from the heat of combustion and entropy for *n*-hexane and 2,3-dimethylbutane but there is considerable discrepancy for 2,2-dimethylbutane and the methylpentanes. However, there is substantial agreement in the ratio of 2-methylpentane to 3-methylpentane.

3. The experimental equilibria for the pentanes were also determined and show a higher temperature coefficient than that obtained by Pines, Kvetinskas, Kassel and Ipatieff.

4. Hydrogen and extensive side reactions were found not to have any appreciable effect on the equilibria.

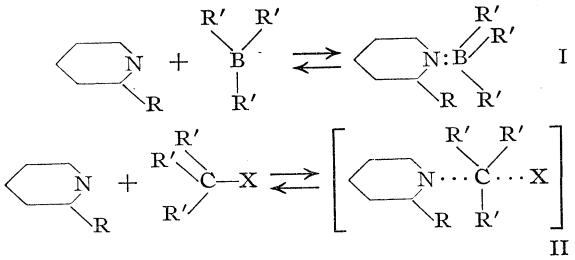
# Studies in Stereochemistry. XIV. Reaction of Triethylamine and Quinuclidine with Alkyl Halides; Steric Effects in Displacement Reactions[1]

BY HERBERT C. BROWN[2] AND NELSON R. ELDRED[3]

In previous papers of this series, it has been demonstrated that the stability of addition compounds of the type $R_3N:BR'_3$ invariably decreases as the steric requirements of either R or R′ increase. Information gained regarding the effect of structure on the stability of addition compounds should aid in understanding the factors involved in typical displacement reactions.[4]

(1) This paper is based upon a dissertation submitted by Nelson R. Eldred in August, 1946, to the Graduate School of Wayne University in partial fulfillment of the requirements for the degree of Master of Science.



(2) Present address: Department of Chemistry, Purdue University.

(3) Present address: Department of Chemistry, Pennsylvania State College.

(4) Brown and Barbaras, THIS JOURNAL, 69, 1137 (1947).

Consider the reaction of amines with alkyl halides. It is well established that an increase in the steric requirements of the amine increases the steric strain in the addition compound (I) and results in a marked decrease in stability. Similarly, an increase in the steric requirements of the amine should result in a marked increase in steric strain in the activated complex (II) formed from the amine and alkyl halide. In the first instance, a decrease in the heat of dissociation is observed, corresponding in magnitude to the increase in steric strain; in the second, an increase in the energy of activation should be noted, corresponding to the increased strain in the activated complex.

Increase in the steric requirements of the groups

I

II

R′ attached to either boron in the addition compound or to carbon in the activated complex should also bring about increase in steric strain with similar results.[5]

Considerations of this kind lead to the following generalizations for the effects of changing steric requirements on the reactions of amines with alkyl halides. 1. Of two amines of equal base strengths but different steric requirements, the base with the lower steric requirements will react more rapidly with a given alkyl halide. Moreover, the reactions of the base with the greater steric requirements will involve higher activation energies, corresponding to the increase in steric strain. 2. The greater the steric requirements of the alkyl halide, the slower should be the reaction with a given amine. Thus the rate should decrease in the order MeX > EtX > *i*-PrX > *t*-BuX, and the energies of activation should increase in the opposite order. 3. The lower the steric requirements of the alkyl halide, the smaller should be the effect of differences in the steric requirements of the bases. Conversely, the greater the steric requirements of the alkyl halide, the larger should be the effect of differences in the steric requirements of the bases.

To test the validity of these generalizations, as well as the validity of the proposed similarity between the formation of addition compounds and the formation of activated complex, it was decided to measure and compare the rates of reactions of a series of alkyl halides with two amines of similar base strength but with markedly different steric requirements.

In the preceding paper of this series evidence was advanced to support the conclusion that the steric requirements of triethylamine (Fig. 1) are markedly greater than those of quinuclidine (Fig. 2).[6] Although the strengths of the two bases in aqueous solution are not markedly different, their addition compounds with trimethylboron show an amazing difference in stability. Quinuclidine forms an exceedingly stable addition compound, with heat of dissociation of 19.94 kcal., whereas the corresponding addition compound of triethylamine exists only at low temperatures and its heat of dissociation has been estimated to be as low as 10 kcal.[7]

Quinuclidine and triethylamine appeared to fill all the requirements for the two test amines. Accordingly, a study was made of the rate of reaction of quinuclidine with methyl, ethyl and isopropyl iodides and of triethylamine with ethyl iodide. The results, together with other rate data available in the literature, permit a thorough test of the proposed generalizations.

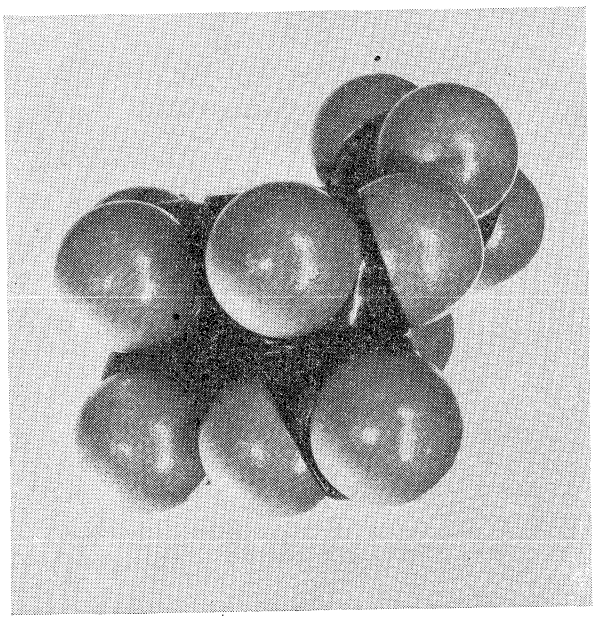


Fig. 1.—Molecular model of triethylamine (note hindered approach to nitrogen atom).

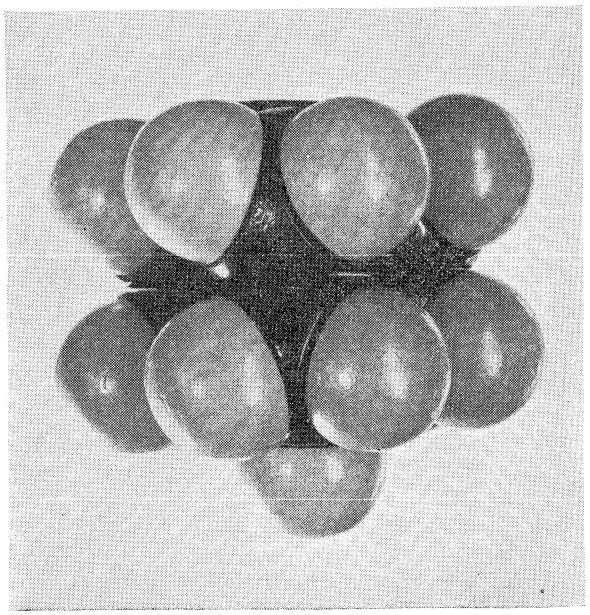

Fig. 2.—Molecular model of quinuclidine (note free approach to nitrogen atom).

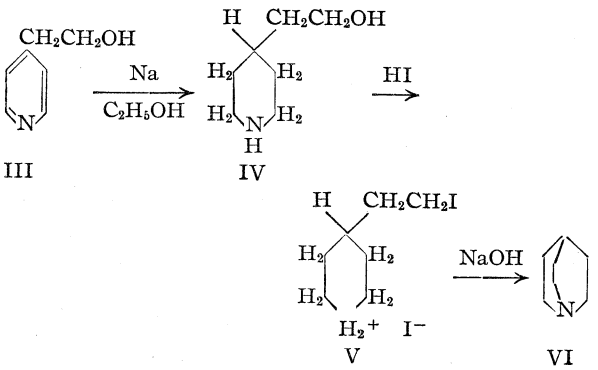

(5) In this discussion it has been assumed that the changes in the groups R and R′ would be of such a nature as not to alter significantly the inherent donor and acceptor properties of the base and acid, respectively.

## Results

Quinuclidine (VI) was conveniently synthesized by the following series of reactions,[8] starting with the commercially available 4-pyridineëthanol (III).

The rates of reaction with the alkyl iodides were determined in nitrobenzene solution. The reaction was followed by estimation of the free amine by titration.

The results, together with earlier data from the literature for triethylamine and pyridine are listed in Table I.

TABLE I

RATE DATA FOR THE REACTION OF TERTIARY AMINES WITH ALKYL IODIDES IN NITROBENZENE SOLUTION

| Amine | Alkyl iodide | $k_{25°}$ (liters mole$^{-1}$ sec.$^{-1}$) | $E_{exp.}$, kcal. | log $PZ$ |
|---|---|---|---|---|
| Triethylamine | Methyl[a] | $3.29 \times 10^{-2}$ | 9.7 | 5.65 |
| | Ethyl[b] | $1.92 \times 10^{-4}$ | 12.5 | 5.44 |
| | Isopropyl[a] | $1.13 \times 10^{-6}$ | 16.0 | 5.86 |
| Quinuclidine | Methyl[b] | 1.88 | 9.5 | (7.2)[c] |
| | Ethyl[b] | $4.87 \times 10^{-2}$ | 10.9 | 6.68 |
| | Isopropyl[b] | $7.97 \times 10^{-4}$ | 13.6 | 6.86 |
| Pyridine | Methyl[a] | $3.43 \times 10^{-4}$ | 13.6 | 6.50 |
| | Isopropyl[a] | $1.55 \times 10^{-6}$ | 16.7 | 6.43 |

[a] Laidler and Hinshelwood, *J. Chem. Soc.*, 852 (1938). [b] Present investigation. [c] Reaction was so very rapid that the possibility of considerable error exists, in spite of the satisfactory precision of the experimental data.

Examination of the data from the point of view of the proposed generalizations on the effects of steric requirements is quite interesting.[9] 1. Comparing quinuclidine and triethylamine, two bases of approximately equal base strength but with markedly different steric requirements, it is noted that quinuclidine, the amine of lower steric requirements, reacts considerably faster than triethylamine with each of the three alkyl iodides investigated. At 25°, $k_Q/k_T = 57$, 254 and 705 for methyl, ethyl, and isopropyl iodides, respectively.[10] Again, the reaction of quinuclidine with a given alkyl halide involves the lower energy of activation in each case. 2. The rates show a marked decrease from methyl to ethyl to isopropyl iodide and the energies of activation show a corresponding increase. This accords with the predicted behavior based on the effect of increasing steric requirements of the alkyl groups. 3. Finally, it is observed that the greater the steric requirements of the alkyl halide, the greater are the effects of differences in the steric requirements of the bases. Thus, in the case of methyl iodide, where the steric requirements of the methyl group are relatively small, the differences in the rate constant and activation energy with the two bases, quinuclidine and triethylamine, are relatively small: at 25°, $k_Q/k_T = 57$; $E_T - E_Q = 0.2$ kcal. However, as the steric requirements of the alkyl group become larger, these differences become greater. For ethyl iodide at 25° $k_Q/k_T = 254$ and $E_T - E_Q = 1.6$ kcal., and for isopropyl iodide $k_Q/k_T = 705$ and $E_T - E_Q = 2.4$ kcal.

The results clearly support the proposed generalizations on the effect of steric requirements on the rate of a typical displacement reaction of the type under consideration.

These generalizations were primarily based upon a postulated similarity between the formation of addition compounds and the formation of activated complexes in displacement reactions. Experimental verification for the proposed generalizations also lends credence to the proposed relationship, and indicates that the study of addition compounds may contribute considerably to a better understanding of the effect of structure on the rates of displacement reactions.

One further point of interest should be mentioned. Hammett[11] has pointed out that reactions involving meta and para derivatives of benzene involve constant entropies of activation and lend themselves particularly well to quantitative treatment. Apparently, the rigidity of the benzene ring and the location of the substituent far from the reaction center causes the substituent to have little effect upon the entropy of activation. On the other hand, structural changes in aliphatic compounds produce marked changes in the entropy of activation and the effect of substituents in such compounds cannot be simply treated.

It is, therefore, of interest that the data in Table I indicate that with the exception of methyl iodide (see note [c] in Table I), the entropies of activation

(8) Meisenheimer, Neresheimer and Schneider, *Ann.*, **420**, 190 (1920).

(9) It has long been recognized that in the absence of important steric effects, the stronger of two amine bases should react faster with a given alkyl halide. This generalization results from the Polanyi picture of the displacement reaction [Evans and Polanyi, *Trans. Faraday Soc.*, **34**, 11 (1938)]. Although this generalization is well established and accepted, it is of interest that the experimental results are in complete agreement. Thus, quinuclidine and pyridine are two bases of similar (low) steric requirements, but of markedly different base strength. In accordance with prediction, quinuclidine, the stronger of the two bases, reacts much more rapidly with either methyl iodide or isopropyl iodide. Moreover, the reactions with quinuclidine involve lower energies of activation.

(10) In the ensuing discussion the symbols, $k_Q$, $k_P$, and $k_T$ will be used to refer to the specific rate constants for quinuclidine, pyridine and triethylamine, respectively, and the symbols $E_Q$, $E_P$, $E_T$ to the energy of activation for the amine indicated.

(11) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, New York, N. Y., 1940, pp. 121–124

for the reactions of quinuclidine and alkyl iodides are in close agreement with the corresponding quantities for the pyridine reactions. This suggests that the cage system of quinuclidine gives the molecule sufficient rigidity that in its effect upon the entropy factor quinuclidine resembles more closely the rigid aromatic ring systems than it does the flexible, open-chain aliphatic compounds.

More detailed studies of the reactions of quinuclidine and pyridine (and their derivatives) with alkyl halides are underway. It is hoped that more extensive and more accurate data from these investigations will permit a detailed analysis of this interesting problem.

## Discussion

It has long been recognized that the rates of reactions involving nucleophilic displacements on carbon vary with the alkyl group in the order, methyl > ethyl > isopropyl > *t*-butyl.[12] Two different interpretations of the observed order have been advanced. Meer and Polanyi[13] attributed the observed order to steric hindrance effects. However, this interpretation was not widely adopted by workers in the field. Prevailing opinion has appeared to favor the idea that the decrease in rate in these reactions with increasing branching was primarily a polar effect. The increasing number of alkyl groups attached to the reaction center was considered to increase the electron density at that center (+I effect of alkyl groups) and thereby hinder the approach of the nucleophilic reagent.

Typical of the viewpoint is the discussion by Hinshelwood, Laidler and Timm.[14] These workers attribute the pronounced rise in activation energy observed in the reactions of amines with methyl and isopropyl iodides to "the diminished positive charge on the carbon atom which attracts the approaching base." The increase in activation energy in passing from methyl iodide to isopropyl iodide is considerably larger for the stronger base, triethylamine, than for the weaker base, pyridine ($E_{\text{T-}i\text{-PrI}} - E_{\text{T-MeI}} = 6.3$ kcal.; $E_{\text{P-}i\text{-PrI}} - E_{\text{P-MeI}} = 3.1$ kcal.). The authors consider these differences in the energies of activation to be especially significant and to offer strong support for the polar interpretation they favor.

The argument follows. It is considered that the nitrogen atom of the stronger base, triethylamine, will carry a considerably higher negative charge than the nitrogen atom of the weaker base, pyridine. With the increased number of methyl groups attached to the reaction center of the alkyl halide, the increased negative charge at that center (or decreased positive charge) will hinder the approach of the amine, but the hindrance should be particularly effective for the amine with the higher negative charge, namely, triethylamine. The reaction will, therefore, require a considerable increase in the energy of activation to overcome the large electrostatic repulsion forces.

This interpretation satisfactorily accounts for the observed differences in the behavior of triethylamine and pyridine in terms of their marked difference in base strength. However, it cannot be extended to cover the behavior of quinuclidine. The present study reveals that, in these displacement reactions, this base, one comparable in strength to triethylamine and much stronger than pyridine, is much more like pyridine in its behavior than like triethylamine. For example, the difference in the energies of activation for the reactions of quinuclidine with isopropyl and methyl iodides ($E_{\text{Q-}i\text{-PrI}} - E_{\text{Q-MeI}}$) is 4.1 kcal., whereas the corresponding quantities for reactions involving pyridine and triethylamine are 3.1 and 6.3 kcal., respectively.

The electrostatic hypothesis favored by Hinshelwood, Laidler and Timm does not appear capable of accounting for the behavior of quinuclidine. Moreover, the data offer no support for the widely-held view that the decreased susceptibility of isopropyl and *t*-butyl halides to attack by nucleophilic reagents is primarily a result of increased electron accession at the reaction center. Until definite evidence of the importance of such electron accession on the rate of nucleophilic displacements is available, it appears preferable to interpret the results of displacement reactions of alkyl halides primarily in terms of the nucleophilic characteristics of the displacing agent and the steric requirements of the reagents, as outlined in the generalizations presented in this paper.

It is hoped that an extensive investigation of the problem, now underway at Purdue University and supported by the Office of Naval Research, will aid in clarifying the situation.

## Experimental Part

**Materials.**—With the exception of quinuclidine, the chemicals were commercially available products, which were purified by standard procedures. The nitrobenzene was purified by partially freezing the material which melted in the range from 5.1 to 5.7°, with most of the material melting from 5.5 to 5.7°. A total of 4 l. was prepared and used to make up all solutions.

**Quinuclidine.**—Quinuclidine was originally prepared by Löffler and Stietzel[15] in impure form and later prepared in pure form by Meisenheimer and his co-workers.[8] These authors isolated 4-picoline from commercial picoline in poor yield. By treatment with formaldehyde the 4-picoline was converted to 4-pyridineëthanol in yield of but 1.5%. Although the yields in subsequent stages of the synthesis (III–VI) were satisfactory, this minute yield in the initial stages deterred other investigators from following the Löffler–Meisenheimer synthesis. Other syntheses were, therefore, developed and utilized.[16]

The commercial availability of 4-pyridineëthanol from the Reilly Tar and Chemical Corporation led to the selection of the Löffler–Meisenheimer synthesis as most convenient.

(15) Löffler and Stietzel, *Ber.*, **42**, 124 (1909).

(16) Clemo and Metcalfe, *J. Chem. Soc.*, 1989 (1937); Prelog, *et al.*, *Ann.*, **525**, 292 (1936); **532**, 69 (1937); **535**, 37 (1938); **545**, 229 (1940).

The commercial product was purified by distillation through a Vigreux column. The fraction which distilled at 146–147° at 8 mm. was utilized. Various fractions gave values for the refractive index of $n^{25}D$ 1.5388 ± 0.0003. The product was very viscous and exceedingly hygroscopic—considerable difficulty was encountered in obtaining satisfactory melting or freezing points. However, a number of fractions, previously frozen, melted in the range from 13.1 to 13.3°.

Attempts to dry the compound by contacting the material with solid potassium hydroxide led to the conversion of the 4-pyridineëthanol to 4-vinylpyridine (b. p. 54° at 7 mm.; $n^{25}D$ 1.5490–1.5495). The 4-pyridineëthanol apparently undergoes a base-catalyzed elimination reaction with remarkable ease. It is probable that the attack is on the active hydrogen atoms, alpha to the pyridine ring.

Several attempts were made to hydrogenate the 4-pyridineëthanol in an Aminco hydrogenator over Raney nickel or U. O. P. nickel catalyst. However, no evidence of hydrogen absorption was observed at 2000 lb. pressure and temperatures as high as 200°. Instability of the compound prevented investigation of higher temperatures. The compound was successfully hydrogenated with sodium and alcohol. The piperidine derivative (IV) was isolated in 75% yield, b. p. 148–153° at 18 mm., $n^{25}D$ 1.4980.

The piperidine derivative was converted into 4-(β-iodoethyl)-piperidine hydroiodide (V) by treatment with concentrated hydriodic acid and red phosphorus. The product, after purification by recrystallization, was obtained in 50% yield. Further recrystallized from a mixture of 60 parts ethyl acetate to 20 parts ethanol it was obtained as nearly colorless crystals which melted at 198–199° as compared to the 190–191° value reported by Meisenheimer.

Previous workers[8] had cyclized the hydroiodide by addition of sodium hydroxide to a dilute solution of the salt in water. The free quinuclidine was distilled from the reaction with water and recovered as the picrate. The picrate was then transformed into the free base. This procedure for isolating the quinuclidine was found to be tedious and the yields unsatisfactory. It was, therefore, discarded in favor of isolation of the base as the hydrochloride. The procedure follows.

The aqueous distillate containing quinuclidine was collected in a flask containing 15 ml. of 15% hydrochloric acid (excess). The distillation was stopped as soon as the distillate was no longer basic to litmus, and the distillate evaporated to dryness. The yield of crude salt was 5.1 g., 75% of the theoretical from the 4-(β-iodoethyl)-piperidine hydroiodide. The hydrochloride was recrystallized from 50 ml. of *n*-butyl alcohol. It was obtained in the form of brilliant white crystals, which melted with decomposition and sublimation at 369–374° in a sealed tube. The salt was analyzed for chloride ion: Calcd. for $C_7H_{14}NCl$: Cl, 24.01. Found: Cl, 24.04.

The free base was prepared by running a concentrated aqueous solution of the hydrochloride into an evacuated flask containing a large excess of potassium hydroxide pellets. The free base was distilled under high vacuum at room temperature from the flask into a U-tube fitted with stopcocks at the entrance and exit. Traces of water which co-distilled could be removed by treatment with sodium or by fractional distillation through a series of such U-tubes, the water being removed as the more volatile component. The yields were practically quantitative. The quinuclidine was obtained as a transparent, glassy solid, which, when dry, crumbled easily.

Vapor pressure data for quinuclidine are reported in an earlier paper.[6]

**Kinetic Studies.**—Equimolar solutions of amine and alkyl iodides in nitrobenzene were prepared. Usually the concentration of the stock solutions was 0.200 *N*, so that on mixing equal volumes of the two stock solutions the concentration would be 0.100 *N*. For the faster reactions, where it was desirable to have less concentrated solutions, the stock solutions were diluted with the solvent before they were mixed. For temperatures other than 25°, the concentrations of the reactants were corrected for expansion or contraction of the solvent.

The reactants, brought to constant temperature, were placed in a Kjeldahl flask closed with a tightly fitting stopper. After suitable intervals, 5-ml. samples were withdrawn and run into standard *N*/50 hydrochloric acid and the excess acid was back-titrated with *N*/50 barium hydroxide, using methyl red as the indicator.

The rate constants were then calculated using the expression for a second-order reaction in which the two components are present in equal concentrations

$$k = \frac{1}{t} \times \frac{x}{a(a - x)}$$

where $t$ is the time in seconds, $x$ is the moles per liter of amine or alkyl iodide reacted at time $t$, and $a$ is the initial concentration of amine and alkyl iodide in moles per liter.

The energy of activation for each reaction and the $PZ$ term of the equation

$$k = PZe^{-E/RT}$$

were calculated from the rate constants determined at three to four temperatures, using the method of least squares.

In order to test the procedure, a study was made of the reaction of triethylamine and methyl iodide at 25°. The results are reported in Table II. The value of the rate constant, 0.0329 at 25°, is in satisfactory agreement with the value 0.03085 at 24.8° reported by Laidler and Hinshelwood.[17]

TABLE II

REACTION RATE DATA FOR TRIETHYLAMINE AND METHYI IODIDE IN NITROBENZENE AT 25°

| Time, sec. | $x$($a$ = 0.0198) | $k$(liters mole$^{-1}$ sec.$^{-1}$) |
|---|---|---|
| 1200 | 0.00876 | 0.0334 |
| 1800 | .01066 | .0327 |
| 2400 | .01208 | .0329 |
| 3600 | .01392 | .0332 |
| 4500 | .01476 | .0328 |
| 5400 | .01538 | .0325 |
| | Average $k$ = | 0.0329 |
| Duplicate determination, average $k$ = | | 0.0329 |

The small quantity of quinuclidine available for these studies made it necessary to limit the number of individual samples taken in the course of a determination to 3 or 4. The precision of the data for quinuclidine are, therefore, somewhat

(17) Laidler and Hinshelwood, *J. Chem. Soc.*, 852 (1938).

lower than those reported in Table II for triethylamine and methyl iodide and similar data obtained for triethylamine and ethyl iodide. Moreover, the reaction of quinuclidine with methyl iodide is so rapid (it is essentially complete in four minutes at room temperature with reagents present in as low concentrations as 0.0132 mole per liter), that in this reaction especially the results are subject to considerable uncertainty. It is estimated that the errors in the energies of activation may be as large as 500 cal.

The rate constants obtained are listed in Table III.

TABLE III

RATE CONSTANTS FOR THE REACTION OF TRIETHYLAMINE AND QUINUCLIDINE WITH ALKYL IODIDES

| Amine | Alkyl iodide | $T$, °C. | $k$ (liters mole$^{-1}$ sec.$^{-1}$) |
|---|---|---|---|
| Triethylamine | Methyl | 25.0 | $3.29 \times 10^{-2}$ |
| Triethylamine | Ethyl | 25.0 | $1.92 \times 10^{-4}$ |
| | | 35.0 | $3.81 \times 10^{-4}$ |
| | | 45.0 | $7.24 \times 10^{-4}$ |
| Quinuclidine | Methyl | 5.5 | 0.610 |
| | | 15.0 | 1.06 |
| | | 25.0 | 1.88 |
| Quinuclidine | Ethyl | 5.5 | $1.27 \times 10^{-2}$ |
| | | 15.0 | $2.55 \times 10^{-2}$ |
| | | 25.0 | $4.87 \times 10^{-2}$ |
| | | 35.0 | $8.34 \times 10^{-2}$ |
| Quinuclidine | Isopropyl | 25.0 | $7.97 \times 10^{-4}$ |
| | | 35.0 | $17.2 \times 10^{-4}$ |
| | | 45.0 | $31.6 \times 10^{-4}$ |

Values for the energies of activation and log $PZ$ calculated from these values for the specific rate constants are listed in Table I.

**Acknowledgment.**—The authors wish to acknowledge their debt to Mr. Arno Cahn of the Department of Chemistry of Purdue University for his valuable assistance in checking the calculations of the rate constants and in applying the least squares procedure to the estimation of the energies of activation.

## Summary

1. Quinuclidine has been prepared in good yield starting with the commercially available 4-pyridineëthanol. Quinuclidine hydrochloride has been prepared and characterized.

2. Kinetic studies have been made of the reaction of triethylamine with ethyl iodide and of quinuclidine with methyl, ethyl and isopropyl iodide in nitrobenzene solution at several temperatures.

3. A number of generalizations are proposed for the effects of changing steric requirements on displacement reactions. These generalizations, based largely on analogy with the effect of steric requirements on the stability of addition compounds, permit a simple interpretation of the experimental data. The results do not support previous interpretations based primarily on postulated polar effects of structural changes in alkyl groups.

# Monolayers of Pepsin and of Insulin

BY HECTOR A. DIEU[1] AND HENRY B. BULL

Monolayers of egg albumin and of β-lactoglobulin have been investigated at surface pressures below one dyne per centimeter.[2] The equation represents the relation between the area $A$ and the film pressure $F$ for monolayers of these proteins in the low pressure region. When $FA$ is plotted against $F$, the slope of the line ($\alpha$) yields the gaseous area of the film and at 25° the intercept $\beta$ is equal to $24.6 \times 10^2$/mol. wt. where mol. wt. is the number average molecular weight of the film molecules.

$$FA = \alpha F + \beta \qquad (1)$$

It has been found that spread films of pepsin and of insulin obey eqn. 1, and it has thus been possible to calculate the film molecular weights as well as the gaseous area of these proteins.

## Experimental

The pepsin was prepared according to Northrop,[3] and its activity was found to be 0.19 Hb. U. per mg. of nitrogen. The pepsin solutions were dialyzed against 0.2 $M$ acetate buffer at $p$H 5.2 before use. The pepsin concentration was determined by micro-Kjeldahl using the factor indicated by Northrop.[3]

We are grateful to Armour and Company for a supply of crystallin insulin. Before use the insulin was dialyzed against a buffer at $p$H 3.5 for seventy-two hours at 0°. The concentration of insulin was determined by micro-Kjeldahl.

A Wilhelmy balance has been used to register the film pressures. The wettability of the slides has been improved by the addition of glycerol to the 5% ammonium sulfate solution to the extent of 2% by volume. It is necessary to exercise care in the preparation of the substrate solutions, and the glycerol was exhaustively extracted with petroleum ether and the ether removed completely before addition to the ammonium sulfate solution. The ammonium sulfate solutions were treated with activated charcoal and the charcoal removed by filtering before the addition of the glycerol. The protein solutions were added to the surface with a Blodgett pipet which delivered 0.085 cc. of solution.

## Results

The molecular weights and the gaseous areas of spread films of pepsin and of insulin have been calculated with the aid of eqn. 1. Tables I and II

(1) Research Fellow of the Belgian American Foundation.
(2) Bull, THIS JOURNAL, **67**, 4 (1945); **68**, 745 (1946).

| 120 | 1.13 | 37,200 |

## Discussion

Apparently, the film molecular weight of pepsin is influenced neither by the spreading process nor by the composition of the substrate solution. The average value of the film molecular weight of pepsin is 34,400 which compares favorably with that reported for the molecular weight of pepsin in solution.[4] We did find a film molecular weight of about 18,000 for a pepsin solution which had been incompletely dialyzed and no doubt contained split products of pepsin. Curiously, the addition of copper sulfate to the substrate solution in this case restored the molecular weight to 35,000.

The gaseous area of pepsin films is greatly dependent both on the spreading concentration and on the elapsed time between spreading and compression. It appears from Table I and particularly from Table II that at short time intervals and

(4) Northrop, Kunitz and Herriott, "Crystalline Enzymes," Columbia University Press, New York, N. Y., 1948.

at higher spreading concentrations that the gaseous area is considerably smaller than 0.80 sq. meters per milligram which is the area occupied by a fully compressed monolayer of peptide chains.[5] The fact that the correct value for the molecular weight of pepsin was obtained indicates that all the pepsin applied to the surface remained on the surface. The expansion of the film with time arises, therefore, from the expansion of individual pepsin molecules and not from the appearance of additional pepsin molecules on the surface. The initial step in the spreading of pepsin appears to be the formation of a duplex film. A monomolecular film is quickly formed from the duplex film and this transformation is followed by a slow expansion of the individual gaseous molecules. Twenty hours after spreading, the gaseous area of pepsin is about 1.60 sq. meters per milligram. It can be estimated that the area of a β-keratin chain lying flat on the surface would be about 1.70 sq. meters per milligram.[5] Evidently, after a time the pepsin approaches the condition of a β-keratin film on the surface. This slow expansion of the gaseous area may be regarded as a type of surface denaturation.

Insulin molecules tend to dissociate on the surface as shown in Table V. It will be recalled that insulin in solution likewise tends to dissociate.[6] The gaseous area of the insulin film expands with time and after twenty-four hours reaches the area of a β-keratin chain lying flat on the surface. The results given in Table VI demonstrate that a small amount of copper sulfate in the substrate solution prevents the dissociation of the insulin molecules. This parallels the behavior of films of β-lactoglobulin.[2]

We have investigated the coefficient of compressibility of pepsin and of insulin films at higher film pressures spread on 5% ammonium sulfate solutions. The minimum coefficient of compressibility of a pepsin film compressed fifteen minutes after spreading was 0.0275 centimeter per dyne which corresponded to a film pressure of 5 dynes per centimeter and to an area of 0.82 sq. meter per milligram. A pepsin film compressed six hours after spreading yielded a minimum compressibility coefficient of 0.025 centimeter per dyne corresponding to a film pressure of 10 dynes per centimeter and to an area of 1.08 sq. meters per milligram. Evidently, the area of a film at higher pressures depends significantly on the time between spreading and compression. The results shown in Tables I and II indicate that the amount of protein on the surface is independent of time and, accordingly, the variation of area with time is simply a reflection of the expansion of the individual protein molecules. This consideration means that some of the variable protein film areas reported in the literature may not be due to loss of protein in the substrate solution but unequal expansion of the surface protein molecules.

The insulin film was compressed within two minutes of spreading and the coefficient of minimum compressibility was 0.025 centimeter per dyne which corresponded to an area of 0.90 sq. meter per milligram and to a surface pressure of 7.6 dynes per centimeter. In accord with the discussion elsewhere,[5] it is believed that the point of minimum compressibility represents the smallest area to which a film can be compressed without partial collapse of the film occurring.

(6) Gutfreund, *Biochem. J.*, **42**, 156 (1948).

## Summary

1. The film molecular weights and the gaseous areas of films of pepsin and of insulin have been determined as a function of several variables.

2. The film molecular weight of pepsin is about 34,400 and pepsin molecules do not dissociate on the surface.

3. The gaseous area of the pepsin film increases with time and is smaller the greater the spreading concentration. It appears that the initial step in the spreading of pepsin is the formation of a duplex film which quickly changes into a monolayer. Following the transformation, the gaseous pepsin molecules slowly expand to an area which would be occupied by a β-keratin chain lying flat on the surface.

4. Insulin molecules dissociate on the surface but a small amount of copper ions in the substrate solution prevents this dissociation.

5. The pepsin and insulin films have also been examined in the high pressure region and the coefficients of compressibility of these films calculated and reported.

# Sulfonation of 2-Pentene by Chlorosulfonic Acid[1]

BY SIMON MIRON[2] AND GEORGE HOLMES RICHTER

The reaction of chlorosulfonic acid with 2-pentene in chloroform solution at 0–5° gave a mixture of isomeric pentenesulfonic acids. It was shown, by reducing the double bond of the isomers and comparing the reduced mixture with pentane-2-sulfonic acid and pentane-3-sulfonic acid, that sulfonation had occurred on the carbon atoms comprising the original position of the double bond, approximately 80% having taken place on carbon atom 2 and 20% on carbon atom 3. The exact position of the double bond in the resulting products was not demonstrated; it would be in the 2 position if no isomerization occurred during the reaction or isolation of the products.

## Experimental

**Raw Materials.**—The 2-pentene was prepared by dehydration of 2-pentanol[3] and was purified by distillation through a laboratory bubble column consisting of eight bubbler units.[4] The fraction collected for use had a boiling range 35.8–36.3° at 763 mm. It probably consisted of approximately 75% *trans*-2-pentene and 25% *cis*-2-pentene[5] and may also have contained a small amount of 1-pentene.[6]

The chlorosulfonic acid (Eastman Kodak Co. "practical" grade) was dark brown in color, and was used without further purification.[7]

**Sulfonation of 2-Pentene.**—The sulfonation was carried out in a 500-ml. flask surrounded by cracked ice and equipped with agitator (mercury sealed), dropping funnel, thermometer and ice-water condenser. A solution of 35.0 g. (0.50 mole) of 2-pentene in 50 ml. of dry chloroform was introduced in the flask and treated over three hours time, under good agitation, with a solution of 53.6 g. (0.46 mole) of chlorosulfonic acid in 70 ml. of dry chloroform, after which the chloroform solution was extracted with water until neutral. Sulfuric acid was removed from the extract by treatment with barium carbonate and filtration, and most of the chloride ion was removed from the evaporated filtrate by mixing the salt with 85% phosphoric acid[8] and keeping the paste at low pressure over solid potassium hydroxide for several days, with occasional warming. Neutralization of the mixture with barium carbonate resulted in a crude barium salt whose chloride ion content was appreciably diminished; yield, 37 g. (0.085 mole) of crude barium salt (37%).

*Anal.*[9] Calcd. for $C_{10}H_{18}O_6S_2Ba$: Ba, 31.54. Found: Ba, 31.66.

**Properties of the Barium Pentenesulfonate Mixture.**—A solution of the barium salt reduced both potassium permanganate solution and bromine water. The salt was slightly soluble in absolute ethanol and quite soluble in warm *i*-amyl alcohol and in 1,4-dioxane, but warm solutions in the latter two solvents tended to gel upon cooling.

**Sodium Pentenesulfonates.**—A portion of the barium pentenesulfonate mixture was converted to the corresponding sodium salt by treatment of an aqueous solution with sodium sulfate solution until no more barium sulfate precipitated. The suspension was filtered and the filtrate evaporated to dryness. The sodium salt was soluble in hot ethanol and could be freed of most of the contaminating sodium chloride by recrystallization from this medium.

*Anal.* Calcd. for $C_5H_9O_3SNa$: Na, 13.37. Found: Na, 13.02.

**Free Pentenesulfonic Acid Mixture.**—The purified barium salt was dissolved in water and treated with excess sulfuric acid followed by excess basic lead carbonate. The supension was filtered and the hot filtrate saturated with hydrogen sulfide. After removal of the excess hydrogen sulfide and treatment with "Norite" carbon, the resulting solution was evaporated to complete dryness over phosphoric anhydride at reduced pressure. The acid was highly viscous, having almost a glassy consistency at room temperature; $d^{20}_4$ 1.277,[10] $n^{20}D$ 1.4735, $MR_D$ (molecular refraction) 33.03. It was soluble in absolute ethanol, chloroform, *i*-amyl alcohol and acetic acid and insoluble in carbon tetrachloride and carbon disulfide. In water it dissolved with considerable evolution of heat. It decolorized bromine water and a carbon tetrachloride solution of bromine, forming an insoluble liquid product without evolution of hydrogen bromide.

**Reduction of the Double Bond.**—The unsaturated barium sulfonate (8.4 g.) was dissolved in 100 ml. of water and reduced in the conventional manner over 0.25 g. of finely powdered platinum oxide catalyst at 30 p.s.i. gage pressure of hydrogen, reduction being complete in one-half hour. The resulting solution, filtered free of platinum, was completely inert to potassium permanganate, and was evaporated to crystallization. Unlike the unsaturated barium salt, the saturated compound crystallized readily from hot water. The dry salt was white; it burned upon ignition and gave a slight test for chlorides. This saturated barium salt was reserved for proof of structure as described below.

**Pentane-2-thiol.**—This was prepared from 2-bromopentane[11] by the method of Noller and Gordon.[12] The crude product was oxidized directly to the sulfonic acid.[13]

**Barium Pentane-2-sulfonate.**—The mixture of pentane-2-thiol and water obtained by reduction of the disulfide

(6) H. J. Lucas and A. N. Prater, *ibid.*, **59**, 1683 (1937).

(7) A run made with freshly distilled, colorless chlorosulfonic acid gave no substantial improvement in yield.

(8) Phosphoric acid appeared to have less tendency to cause charring of the product than did concentrated sulfuric acid.

(9) The analysis was carried out on a sample of the barium salt which had been treated exhaustively to remove chloride ion.

(10) By capillary pycnometer; measurements made only to the third decimal place because of the viscous and hygroscopic nature of the liquid.

(11) Produced by reaction of 2-pentanol and phosphorus bromide at room temperature. Since the tendency of secondary alkyl bromides to isomerize is quite common, the structure of the bromide was confirmed by converting a small portion to the Grignard reagent and reacting with phenyl isocyanate, according to the method of Schwartz and Johnson (A. M. Schwartz and John R. Johnson, THIS JOURNAL, **53**, 1063–1068 (1931)), resulting in N-phenyl-2-methylvaleramide, m. p. 84.5–88.5°.

(12) C. R. Noller and J. J. Gordon, *ibid.*, **55**, 1090–1094 (1933).

(13) A small portion of the crude mercaptan was purified by distillation in order to record its properties, the main fraction boiling in the range 112.9–114.0° at 772 mm.; $d^{20}_4$ 0.828; $n^{20}D$ 1.4395. The lead mercaptide, prepared from an ethanolic solution of the thiol and aqueous lead acetate, came down as a canary-yellow oil which failed to crystallize.

*Anal.* Calcd. for $C_{10}H_{22}S_2Pb$: Pb, 50.12. Found: Pb, 49.86.

was added slowly to excess 10 *M* nitric acid on the steam-bath, and the mixture was heated until a test sample showed the absence of nitric acid by failing to color a droplet of diphenylamine–sulfuric acid reagent. After dilution with water and treatment with excess barium carbonate, the mixture was filtered and the filtrate purified by extraction with ether and treatment with activated carbon. On evaporation of the ensuing filtrate the barium salt separated in characteristic, lustrous white crystals.

*Anal.* When dried at 110–120° for 80 min. the salt apparently retained a molecule of water. Calcd. for $C_{10}H_{22}O_6S_2Ba\cdot H_2O$: Ba, 30.01. Found: Ba, 30.07.

**Pentane-2-sulfonic Acid.**—This acid has been only incompletely described in the literature.[14,15] A solution of barium pentane-2-sulfonate was converted to the lead salt and treated with hydrogen sulfide as described previously. The aqueous solution was concentrated *in vacuo* over phosphoric anhydride. White crystals separated when the water was almost entirely removed, but further drying resulted in complete liquefaction, suggesting that the acid may form a crystalline hydrate. The resulting acid had the following properties: $d^{20}_4$ 1.173, $n^{20}D$ 1.4502, $MR_D$ 34.89.

**Phenylhydrazine Pentane-2-sulfonate.**—The phenylhydrazine salt was selected as a characterizing derivative and was prepared according to Latimer and Bost,[16] using 0.55 g. (0.0013 mole) of recrystallized barium pentane-2-sulfonate and 0.24 ml. (0.0026 mole) of phenylhydrazine. The phenylhydrazine salt separated from the ethanol–ether solution as small white flakes, which were washed with ether and dried in a desiccator, m.p. 121.6–123.6°.

*Anal.* Calcd. for $C_{11}H_{20}O_3N_2S$: C, 50.74; H, 7.74. Found: C, 50.75; H, 7.55.

**Barium Pentane-3-sulfonate.**—This was prepared by oxidation of the disulfide of 3-bromopentane.[17] A solution of 46.5 g. (0.194 mole) of sodium sulfide nonahydrate and 8.8 g. (0.271 mole) of powdered sulfur in aqueous methanol was heated to boiling and 41.0 g. (0.271 mole) of 3-bromopentane was added. After seventy minutes of refluxing the mixture was poured into water and the disulfide layer separated and washed with water; yield of wet disulfide, 26 g.

Six grams of the disulfide was oxidized by 40 ml. of hot 10 *M* nitric acid, in the manner described for pentane-2-thiol. The barium salt crystallized in lustrous white platelets; yield, 8.6 g. (62.4% theoretical yield).

*Anal.* Calcd. for $C_{10}H_{22}O_6S_2Ba\cdot H_2O$: Ba, 30.01. Found: Ba, 30.29.

**Pentane-3-sulfonic Acid.**—No reference to this acid is found in the literature through 1947.

The free acid was obtained from the barium salt by the procedure described for pentane-2-sulfonic acid, and as in that instance, white crystals were observed when the acid was almost dry but disappeared on further removal of water; $d^{20}_4$ 1.186, $n^{20}D$ 1.4525, $MR_D$ 34.66. The similarity in molecular refractions for pentane-2 and -3 sulfonic acids is as expected for isomers.

**Phenylhydrazine Pentane-3-sulfonate.**—This product was prepared as described for the isomeric salt. The crystals were deposited as feathery white needles. The m.p. was 97.4–99.2° after ordinary drying, but after fusion to removal all traces of water was 104.7–106.8°.

*Anal.* Calcd. for $C_{11}H_{20}O_3N_2S$: C, 50.74; H, 7.74. Found: C, 50.91; H, 7.48.

**Phenylhydrazine Salt of the Reduced Pentenesulfonic Acid Mixture.**—A portion of the semi-pure barium pentanesulfonate mixture from the catalytic reduction of the unsaturated salt was carefully freed of contaminating chloride ion and converted to the phenylhydrazine salt, m.p. 111–117.4°.

In order to determine the relative ratio of the two isomers in the above salt, mixtures of the two pure derivatives in stepwise concentrations varying by 10% were prepared, fused, resolidified and powdered finely. The capillary melting points (cor.) were taken, the bath temperature being allowed to rise very slowly, and the point of complete disappearance of the crystals observed with a lens and recorded as the melting point. A melting point diagram was then prepared, shown in Fig. 1.

According to Fig. 1, the reduced mixture appeared to consist of approximately 80% of the "2" isomer. As a further check, mixed melting points were taken using equal parts of the reduced mixture and the known 80% "2"–20% "3" mixture, as well as with samples of the known 90–10 and 70–30 mixtures. Results are shown in Table I.

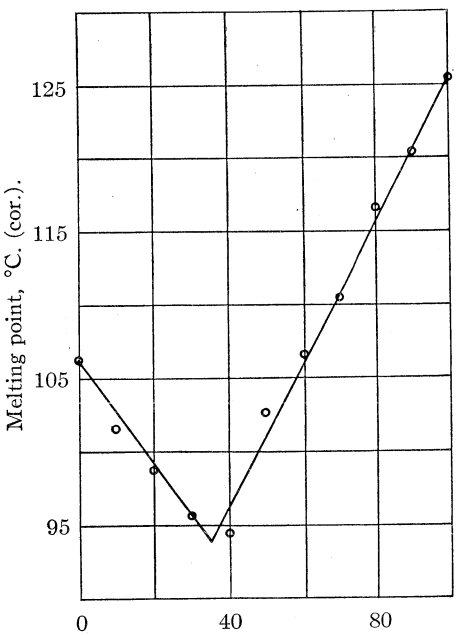

Fig. 1.—Melting points of phenylhydrazine pentane-2-sulfonate and phenylhydrazine pentane-3-sulfonate mixtures.

TABLE I

| Mixture | M. p., °C. (cor.) |
|---|---|
| 90% "2"–10% "3" | 120.3 |
| 80% "2"–20% "3" | 116.6 |
| 70% "2"–30% "3" | 110.4 |
| Reduced derivative (average) | 117.4 |
| Equal parts reduced + (90-10 mixture) | 121.5 |
| Equal parts reduced + (80-20 mixture) | 117.2 |
| Equal parts reduced + (70-30 mixture) | 114.8 |

The fact that the melting point of the reduced mixture was unchanged upon incorporation with the 80–20 mixture, and that incorporation with the 70–30 mixture served to *raise* the melting point of the latter would indicate the relative non-interference of incidental impurities. It was, therefore, concluded that the reduced derivative consisted of approximately 80% of phenylhydrazine-pentane-2-sulfonate and 20% of phenylhydrazine-pentane-3-sulfonate, and that, consequently, the sulfonation of 2-

(17) Prepared from 3-pentanol and phosphorus tribromide at room temperature. Reaction of the corresponding Grignard reagent with phenyl isocyanate gave N-phenyl-2-ethylbutyramide, m. p. 121–124.5°, thus confirming the structure of the bromide.

pentene by chlorosulfonic acid had taken place largely on carbon atom 2, with about 20% on carbon atom 3.[18]

## Summary

1. Sulfonation of 2-pentene by chlorosulfonic acid in chloroform solution at 0–5° gave a mixture of isomeric pentenesulfonic acids.

2. By comparison of the catalytically-reduced mixture with pentane-2 and -3-sulfonic acids, the sulfonation was shown to have occurred to the extent of approximately 80% on carbon atom number 2 and 20% on carbon atom number 3.

HOUSTON, TEXAS RECEIVED APRIL 12, 1948

(18) Inasmuch as Lucas, Schlatter and Jones[5] claim that 2-pentene derived from 2-pentanol consists of approximately 75% *trans*- and 25% *cis*-isomer, it is possible that the *trans*-isomer may have sulfonated in the 2-position and the *cis*- isomer in the 3-position. However, proof of this possibility would rest upon sulfonation experiments with the pure isomers.

# Synthetic Antimalarials. Some Derivatives of 8-Aminoquinoline. II[1]

BY NATHAN L. DRAKE, ROBERT A. HAYES, JOHN A. GARMAN, ROBERT B. JOHNSON, GORDON W. KELLEY, SIDNEY MELAMED AND RICHARD M. PECK

Continuing the research that led to the synthesis of pentaquine (SN 13,276),[2,3] a number of new 8-aminoquinolines have been synthesized. In eleven of these, only the terminal amino group of SN 13,276 has been varied; in seven more, the length of the side chain has been changed. One compound containing an additional nuclear substituent has also been made.

Two general methods were used for the synthesis of all but one of the drugs. Method I consisted of heating 8-amino-6-methoxyquinoline in the presence of water with the appropriate side chain chloride hydrochloride in much the same manner as was reported for the synthesis of SN 13,276.[3] Method II consisted of the reductive alkylation of the appropriate 6-methoxy-8-aminoalkylaminoquinoline with the requisite aldehyde or ketone in ethanol solution in the presence of Adams catalyst at room temperature.[4] The condensation of isopropyla-

[a] This compound was prepared from trimethylene chlorohydrin and 3-aminopentane. [b] This compound was not distilled. It was isolated by crystallization from petroleum ether and melted at 79.0–80.5°.

minoamylbromide hydrobromide with 8-amino-6-methoxy-5-(4-methoxyphenoxy)-quinoline gave only starting material when Method I was attempted but proceeded satisfactorily when the reactants were refluxed in alcohol.[5] Most of the drugs were finally purified as monohydrochlorides, hydrobromides or hydriodides; four of them were purified as dihydrobromides, and one as a diphosphate. All but one of the drugs prepared are listed in Table I.

The synthesis of all but one of the side chains for the compounds prepared by Method I was carried out by the action of thionyl chloride on the appropriate aminoalcohol. 3-Methoxy-N-neopentyl-1-propylamine was heated with an excess of constant-boiling hydrobromic acid. In most cases the side chain was used for the condensation without purification. The side chains prepared are listed in Table II.

The desired alkylaminoalcohols were prepared by (A), reductive alkylation of the appropriate aminoalcohol with the appropriate aldehyde or ketone, or (B), in the case of several of the alkylaminoamyl alcohols, from dihydropyran according to the procedure used in the preparation of isopropylaminopentanol.[3] All of the aminoalcohols prepared are listed in Table III.

Short-term chronic toxicities of the compounds are listed in Table IV.

## Experimental

**2-Aminopentane.**[6]—A mixture of 258 g. of 2-pentanone and 250 ml. of anhydrous ammonia was heated at 140° with hydrogen and Raney nickel at 4000 p. s. i. After the reduction mixture was filtered, it was made acidic with hydrochloric acid and steam distilled to remove non-basic impurities. The aqueous residue was then made strongly basic, extracted with ether and the dried extracts were carefully distilled; 170 g. of product which boiled at 89° was obtained (66%).

**3-Aminopentane.**[7]—This compound was synthesized from diethyl ketone by the reductive amination method used in the preparation of 2-aminopentane; the reduction

| UM 183Q | .5 | Pamaquine |

[a] We are indebted to Dr. L. H. Schmidt, Christ Hospital, Mount Auburn, Cincinnati, Ohio, for the data from which this table was compiled. The test, which is for short term chronic toxicity in Rhesus monkeys, has been described (see "Survey of Antimalarial Drugs 1941–1945," Wiselogle ed., Vol. I, Edwards Bros., Ann Arbor, Michigan, 1946, p. 508).

was carried out at 150°. The yield was 59.7%,[8] and the boiling point of the amine was 91–92°.

**Alkylaminoalcohols, Method (A).**—A mixture of 1 mole of the primary amine and 1.25 moles of the desired aldehyde or ketone was heated with hydrogen in the presence of Adams catalyst at 100° and 2000 p. s. i.; the reduction was complete in about four hours. The catalyst was removed by filtration and the filtrate was distilled under diminished pressure. The yield varied from 56–83%.

**Alkylaminopentanols, Method (B).**—A solution of 20.4 ml. of concentrated hydrochloric acid in 250 ml.of distilled water was cooled to 0–5° in an ice-bath. The ice-bath was removed and 84 g. (1.0 mole) of dihydropyran was added all at once. The resulting mixture was stirred until it became homogeneous, allowed to stand for ten minutes, and then cooled in an ice-bath to 10–15°. To this solution was added slowly with cooling 1.25 moles of the desired amine while the temperature was kept below 25°. The resulting mixture was shaken with hydrogen and Adams catalyst at 25° and an initial pressure of 2000 p. s. i. The process was complete in about two hours. The catalyst was removed by filtration, and the solution was saturated with solid sodium hydroxide. The upper layer was separated and distilled under diminished pressure. The yield varied from 61–76%.

**3-(3-Amylamino)-1-propanol.**—A mixture of 38.8 g. of trimethylene chlorohydrin and 72 g. of 3-aminopentane was allowed to stand at room temperature for eighty hours, according to the method of Elderfield.[9] The precipitate was removed by filtration and the filtrate was heated at 115° to remove excess amine. After acidification with hydrochloric acid and re-addition of the original precipitate, the solution was extracted with ether, and the extracts were discarded. The aqueous portion was saturated with potassium hydroxide and extracted with ether. The extracts were dried and concentrated, and the residue was distilled under diminished pressure; 30.5 g. (51%) of product which boiled at 102–105° (12.5 mm.) was obtained. The neutral equivalent was 148 (calcd. 145) and the refractive index was $n^{25}D$ 1.4466.

**ω-Chloro-N-alkyl-1-alkylamine Hydrochlorides.**—To a stirred solution of 1 mole of the appropriate aminoalcohol in 600 ml. of petroleum ether (90–100°) was added slowly 138 g. (1.1 moles) of thionyl chloride. The mixture was stirred and refluxed for three hours and then allowed to stand overnight. The crude product was removed by filtration and washed well with petroleum ether. In most cases the product was used without further purification. The product can be purified by recrystallization from absolute ethanol and ether.

**3-Bromo-N-neopentyl-1-propylamine Hydrobromide.**—A solution of 63 g. of 3-methoxy-N-neopentyl-1-propylamine in 420 g. of 48% hydrobromic acid was warmed overnight on a steam-bath, and the solution was then evaporated to dryness under reduced pressure. The crude semisolid residue was used directly in the next step. Recrystallization of a small portion from acetone yielded a white crystalline material which melted at 252–253°.

*Anal.* Calcd. for $C_8H_{19}NBr_2$: C, 33.22; H, 6.57. Found: C, 33.42, 33.27; H, 6.61, 6.69.

**5-Bromo-N-isopropyl-1-amylamine Hydrobromide.**—This compound was prepared by the reaction of 5-isopropylamino-1-pentanol[3] and 48% hydrobromic acid at reflux temperature for four hours.The product was isolated by removal of the excess hydrobromic acid under diminished pressure, and the crude material was used directly in the next step.

**8-(ω-Alkylaminoalkylamino)-6-methoxyquinoline, Method I.**—A mixture of 1 mole of the side chain, 2 moles of 8-amino-6-methoxyquinoline, and 100 ml. of water was heated and stirred at 80° for twenty hours, and then at 100° for four hours. The melt was poured into an equal volume of water, and alkali and sodium acetate were added successively until the *p*H rose to 5.0. The mixture was then heated to 60° and extracted with several portions of benzene.[10] The aqueous portion was cooled to 20°,[11] treated with aqueous alkali, and extracted with ether. The product was obtained from the dried, concentrated ether solution by distillation under diminished pressure.

**8-(ω-Alkylaminoalkylamino)-6-methoxyquinoline, Method II.**—An aqueous solution of 28.5 g. (0.07 mole) of 8-(4-aminobutylamino)-6-methoxyquinoline dihydrochloride hemihydrate[4] was treated with aqueous alkali and extracted with chloroform. The concentrated extracts were dissolved in 75 ml. of albsolute ethanol, 0.20 mole of the desired aldehyde or ketone was added and the solution was hydrogenated over Adams catalyst at 2000 p. s. i. The reduction required about one hour. After removal of the catalyst by filtration, the solution was evaporated to dryness, and the residue was distilled in a molecular still.

The substitution of 26.9 g. (0.07 mole) of 8-(5-aminoamylamino)-6-methoxyquinoline dihydrochloride trihydrate[12] in the above procedure yields the desired alkylaminoamylaminoquinoline.

**8-(5-Isopropylaminoamylamino)-6-methoxy-5-(4-methoxyphenoxy)-quinoline Monohydriodide.**—A mixture of 30.9 g. of 8-amino-6-methoxy-5-(4-methoxyphenoxy)-quinoline, 35 g. of 5-bromo-N-isopropyl-1-amylamine hydrobromide, 100 ml. of absolute ethanol, and 75 ml. of ethylene glycol was refluxed for seventy-two hours, cooled,

(8) This compound was also prepared in 29% yield by the catalytic reduction of 3-pentanone oxime. The oxime was prepared by the method of "Organic Syntheses," Coll. Vol. II, John Wiley & Sons, Inc., New York, N. Y., p. 313. See also R. Scholl, *Ber.*, **21**, 506 (1888).

(9) R. C. Elderfield, THIS JOURNAL, **68**, 1579 (1946).

(10) The small amount of crystalline material that usually separated from the cooled benzene extracts was returned to the aqueous mixture, as was a 200-ml. aqueous extract of the combined benzene extracts. About 1 mole of 8-amino-6-methoxyquinoline was recovered from the benzene solution by concentration and distillation under diminished pressure.

(11) In some cases the product crystallized at this point in the procedure. If so, it was removed by filtration and then treated with alkali.

(12) Baldwin, *J. Chem. Soc.*, 2959 (1929).

and poured into an aqueous solution of 13.6 g. of sodium acetate trihydrate. The *p*H of the solution was adjusted to 4.5 and the mixture was extracted with chloroform. The chloroform solution was shaken first with 10% sodium hydroxide solution and then with salt water. It was dried, concentrated to 500 ml., and 250 ml. of petroleum ether (60–80) was added. The product was adsorbed by passing the solution through a column of activated alumina and was eluted with a mixture of chloroform and petroleum ether. The eluate, when concentrated under diminished pressure yielded 15 g. of a viscous oil. The oil was dissolved in aqueous hydrochloric acid and, after the *p*H had been adjusted to 5.0 with sodium acetate, a 10% excess of potassium iodide was added. An oil precipitated which, after decantation of the solution, was taken up in hot methanol. Addition of ether precipitated an impure salt which was recrystallized from methanol–ether; 5 g. (11.4%) of monohydriodide which melted at 159.0–160.5° was obtained.

*Anal.* Calcd. for $C_{25}H_{33}N_3O_3$.HI: C, 54.5; H, 6.17. Found: C, 54.26, 54.11; H, 6.42, 6.12.

**Monohydrochlorides and Hydrobromides of 8-Alkylaminoalkylaminoquinolines.**—Two general methods for the preparation of these salts were used. The first consisted of dissolving the base in dilute acetic acid and adding and excess of a concentrated aqueous solution of sodium bromide or sodium chloride. The other method consisted of dissolving the base in a slight excess of dilute hydrochloric or hydrobromic acid and adding a concentrated aqueous solution of sodium acetate until the *p*H of the mixture was 5.0. The salts were recrystallized from water, ethanol, or ethanol and ether.

**Dihydrobromides and Diphosphates of 8-Alkylaminoalkylaminoquinolines.**—These salts were prepared by adding a slight excess of 48% hydrobromic acid or 85% phosphoric acid to a refluxing ethanol solution of the base. The solution was cooled and the crystals removed by filtration. The product was recrystallized from ethanol or ethanol and ether.

## Summary

1. Eighteen new relatives, and one nuclear substitution product of pentaquine (SN-13,276), together with the intermediates necessary for their preparation, are described.

2. Short-term chronic toxicities, determined in Rhesus monkeys, are given.

3. None of the drugs is less toxic than pentaquine.

# Alkane-choleic Acids: Compounds of Paraffin Hydrocarbons with Desoxycholic Acid[1]

BY ERNEST H. HUNTRESS AND RALPH F. PHILLIPS[2,3,4]

The number of addition products of desoxycholic acid with organic compounds of widely diverse types is legion, but the only choleic acids from alkanes reported at the time of our work was carried out (February, 1938–June, 1939) were two products incidentally mentioned[5] without details in a report on polycyclic carcinogenic hydrocarbons. Furthermore, Rheinboldt had long been concerned with studies on desoxycholic acid addition products, but none of his work involved alkanes until a paper published[6] after our experiments had been completed. This included certain data on desoxycholic acid compounds of the normal alkanes with 11, 12, 13, 14, 15, 16, 35 and 43 carbon atoms.

Under suitable conditions every one of the thirty-four alkanes which were studied in our work combined with desoxycholic acid in methanol solution to give in good yield a definite compound containing from two to eight moles of desoxycholic acid per mole of hydrocarbon. The composition of this resultant alkane-choleic acid was established by determination of the neutralization equivalent of the complex by titration with standard alkali. In the consolidation of our many experiments to the simple form of Table II, we have taken the mean neutralization equivalent of several runs rarely differing among themselves by more than 3–4 units out of 400–440. Comparison of the values of Table II with the various Kz values for a given composition (Table I) shows that the nearest correspondence is rarely in doubt. Our results show that in general the number of coördinated molecules of desoxycholic acid diminishes with increased forking of the hydrocarbon chain, but that this effect is not sufficiently critical to serve as an infallible means of distinction.

TABLE I

CALCULATED NEUTRALIZATION EQUIVALENTS OF ALKANE-CHOLEIC ACIDS

N = number of molecules of desoxycholic acid (mol. wt., 392) per mole of alkane = Kz (coördination number)

Neutralization Equivalent = (392 N + M.W.)/N = 392 + (M.W./N)

| N | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|
| $C_6H_{12}$ | 464 | 428 | 416 | 410 | 406.4 | 404 | 402.3 | 401 |
| $C_8H_{14}$ | 478 | 435 | 420.7 | 413.5 | 409.2 | 406.3 | 404.3 | 402.7 |
| $C_7H_{16}$ | 492 | 442 | 425.3 | 417 | 412 | 408.6 | 406.3 | 404.5 |
| $C_8H_{18}$ | 506 | 449 | 430 | 420.5 | 414.8 | 411 | 408.3 | 406.3 |
| $C_9H_{20}$ | 520 | 456 | 434.7 | 424 | 417.6 | 413.3 | 410.3 | 408 |
| $C_{10}H_{22}$ | 534 | 463 | 439.3 | 427.5 | 420.4 | 415.7 | 412.3 | 409.8 |

## Experimental Part

**Materials Used.**—For many of the samples of highly purified alkanes used in this work the authors are indebted to Messrs. H. Beatty, J. H. Bruun, G. Calingaert, P. L. Cramer, N. L. Drake, G. Egloff, A. V. Grosse, F. D. Rossini and the late F. C. Whitmore as individuals, and

[a] Heated two hours unless otherwise specified. [b] Heated thirteen hours. [c] Heated three hours. [d] Heated four hours. [e] With these especially volatile alkanes a large excess of hydrocarbon (2 or 3 ml.) gave better yields than the usual 1 ml. [f] Three runs on one sample and two on a different sample all agreed closely. [g] Unlike any of the other heptanes, these isomers required chilling to start precipitation of the alkane-choleic acid. They appear to represent transitional cases from Kz = 4 to Kz = 2 at 20°. [h] The product from this hydrocarbon was the only alkane-choleic acid below $C_{14}H_{30}$ which was not completely soluble in the original boiling methanol solution. [i] Of the isomeric octanes the choleic acid from this isomer ("isoöctane") was slowest in forming and required 1 ml. of alkane instead of usual 0.5 ml. [j] Fieser and Newman[5] were unable to obtain a choleic acid of this isomer. [k] The choleic acids of these isomers were the most difficult to prepare and were the only ones for whose formation heating was essential. [l] This was the only branched chain case observed where the coördination number of the choleic was unchanged by heating.

to the Ethyl Gasoline Corporation, General Motors Corporation, Sun Oil Company and Universal Oil Products Company as companies. The desoxycholic acid (Riedel-de-Haen, Inc.) proved of high purity[7] and was therefore used directly.

**Standard Procedure for the Preparation of Alkane-choleic Acids.**—Each choleic acid was prepared simply by adding the hydrocarbon (0.5 ml. for those with $C_8$ or above; 1.0 ml. for those below $C_8$) to 5 ml. of a filtered solution of desoxycholic acid (10 g.) in acetone-free methanol (50 ml.). The clear solution was then allowed to stand at room temperature for fifteen minutes. If no precipitation had then occurred the solution was chilled in ice water for half an hour, and filtered cold. Blank experiments demonstrated that under these circumstances the original bile acid itself remained completely in solution. If the solid jell produced by chilling was gently warmed in the mother liquor it generally redissolved completely and on cooling would reprecipitate as before. With some hydrocarbons this resolution appeared to effect a slight improvement in yields, which varied from 50–90%. With certain of the higher, less soluble highly branched paraffins the rewarming cycle was essential to choleic acid formation.

The alkane-choleic acid thus precipitated was dried at the pump for half an hour or more to remove excess solvent and/or hydrocarbon. The product may not be dried in the oven since such treatment results in removing sufficient hydrocarbon to mask observation of the decomposition temperature. Although methyl alcohol (contrary to the literature) was found to form a choleic acid itself, the resultant compound is quite soluble in excess methanol as compared to the alkane-choleic acids and does not precipitate under the conditions of our experiments. Other organic solvents may not be employed because of interference from their respective choleic acids, nor may the alkane-choleic acids be recrystallized even from methanol because of their tendency toward dissociation. Attempts to dispense with any solvent and use only the alkane itself with desoxycholic acid were unsuccessful.

**Method of Analysis of Alkane-choleic Acids.**—Since because of the molecular magnitudes carbon-hydrogen analyses of these products can have no determinative significance, the various alkane-choleic acids were characterized by their individual neutralization equivalents. Although special manipulative care in weighing and titration were required, experience soon convinced us that consistent values could be reproducibly obtained. Subsequent experiments by entirely different workers on analogous types of compounds have confirmed our procedure. Weighings were made on a long beam balance set to a sensitivity of two divisions per milligram and were by difference to four places. Titrations were made on samples of 50–80 mg. dissolved in neutral methanol (or ethanol) using aqueous 0.01 *N* sodium hydroxide with phenolphthalein as indicator. Frequently better results were obtained by dissolving the sample in excess standard alkali and titrating back with 0.01 *N* hydrochloric acid. The acid and alkali were frequently restandardized to eliminate errors attributable to slight changes of titer. Recognition of the end-point required some experience but was then readily determined. The end-point was delicate but achievable by working in daylight over a white surface particularly by comparison of the titration solution with a water-white blank placed beside it.

**Decomposition Temperature of Alkane-choleic Acids.**—Although the literature contains many records of melting points observed on other types of choleic acids, it is our observation that alkane-choleic acids do not melt AS SUCH at all. On heating they begin to dissociate at some fairly definite temperature, some of the component hydrocarbon is given off, and the corresponding desoxycholic acid remains, eventually to liquefy at its usual melting point (if pure) or somewhat below it if any hydrocarbon remains. At the temperature of decomposition (*DT*) the initial alkane-choleic acid shrinks sharply with marked softening and coalescence into a small worm-like shape, or some-

(7) Sobotka and Goldberg, *Biochem. J.*, **26**, 555–568 (1932).

times even globules. These always display a *convex* surface, do not form liquids (with concave upper surfaces) in the capillary melting point tube, and hence are not true melting phenomena. Frequently the solid becomes momentarily translucent changing with continued heating to an opaque condition, and finally melting (often quite sharply) at the melting point of the residual desoxycholic acid.

The loss of alkane probably is incomplete at the decomposition temperature, but slowly continues up to and perhaps beyond the melting point of the residual desoxycholic acid. When the temperature is raised at the rate of 4–8° per minute the decomposition temperature is readily reproducible within a degree or two. More rapid rates of heating lead to erratic and erroneous results; slower heating fails to produce deacholation at a rate sufficient to display in the sample the characteristic change of appearance required for easy recognition of the temperature.

Although the decomposition temperatures for the alkane-choleic acids are not in general sufficiently distinctive to warrant their use as a diagnostic tool, they are, at the request of the referees, reported in this paper. While by proper technique the loss of alkane can occur in such fashion as to give easily reproducible DT's, it is also true that the coördination number varies with temperature. Although a given alkane-choleic acid is perfectly stable at a given temperature, if it is maintained at a higher temperature, hydrocarbon is slowly lost without any corresponding change in appearance, DT, or final melting point. The change is evident only from the marked increase in coördination number as detected by diminution of neutralization equivalent. Of the thirty-four alkane-choleic acids here reported, only that from 2,7-dimethyloctane failed to lose achole on heating. This general change of coördination number with temperature emphasizes the necessity for its determination prior to any heating whatever.

**The Deacholation of *n*-Heptane-choleic Acid by Heat.**—In order to convince ourselves that our products really did obtain hydrocarbon some relatively large-scale experiments were carried out on the choleic acid from *n*-heptane. For example, a 19.3-g. sample of heptane-choleic acid (neut. equiv. 407) prepared from 10 g. of *n*-heptane and 25 g. of desoxycholic acid was placed in a 125-ml. distilling flask with a thermometer dipping into the powdered solid and the whole heated in an oil-bath. No observable effect was noted until after three hours (by which time the inside thermometer had attained 150°) when a visible crack appeared in the powdered solid and the latter began to shrink. During a final hour of heating the inside thermometer rose from 150° to 171°, the flask contents melted to a clear viscous liquid, and about 0.5 ml. of clear distillate weighing 0.2852 g. was collected. This product had a b. p. of 98–99° (recorded for *n*-heptane 98.4°) and had refractive index $n^{23}D$ 1.3842 (original *n*-heptane used 1.3845, recorded $n^{20}D$ 1.3877). This was taken as evidence that it was in fact *n*-heptane. The recovery was 36.5% theoretical.

In a second experiment entirely similar except that the *n*-heptane-choleic acid had previously been washed with ether (to see if exchange of ether for hydrocarbon would occur) 16.05 g. gave 0.4431 (67.6%) of *n*-heptane, b. p. 97–98.5°, $n^{23}D$ 1.3848. (Note the value for ether is much lower, *viz.*, 1.3526.) Furthermore, the loss in weight of the charge was 0.653 g. representing 4.07%; the per cent. of *n*-heptane in *n*-heptane-hexacholeic acid is 4.08%. During neither of these two distillations was any trace of carbon dioxide detectable in an attached barium hydroxide bubbler.

**The Action of Aqueous Alkali on Alkane-choleic Acids.**—Two samples of *n*-heptane-hexacholeic acid were dissolved, one in excess aqueous sodium hydroxide, the other in excess aqueous ammonium hydroxide. Both solutions were completely clear and showed no sign of any hydrocarbon. Upon acidification of these solutions and vacuum drying of the products, the latter shrank around 100–120°, gave a *DT* of 148° and finally melted at 168–169°. Further drying of the product from ammonium hydroxide in the oven at 85° for eighteen hours, then at 110° for seven hours gave material which still showed a *DT* of 147–150° with no sign of softening or shrinking. This is definite evidence for the survival of the original *n*-heptane-choleic acid.

## Summary

1. Thirty-four paraffin hydrocarbons have been shown to form with desoxycholic acid (in methyl alcohol) easily reproducible definite molecular compounds in which one mole of hydrocarbon is combined with from two to eight molecules of the bile acid.

2. Although the characteristics of these alkane-choleic acids proved inadequate to constitute a general means of identification, their ability to retain the hydrocarbon in alkaline solutions may be found useful in other fields of interest.

# Optically Active Compounds Related to Methadon

BY ALBERT POHLAND, FREDERICK J. MARSHALL AND THOMAS P. CARNEY

*l*-Methadon,[1] *l*-6-dimethylamino-4,4-diphenyl-3-heptanone, has been reported to have twice the analgesic activity of *dl*-Methadon.[2,3] The greatly increased activity of the levo isomer as compared with the racemic mixture led to the preparation of the optical isomers of compounds related to Methadon for pharmacological examination.

*dl*-4-Dimethylamino-2,2-diphenylvaleronitrile was resolved through the *d*-bitartrate salt by essentially the procedure of Thorpe, Walton, and Ofner.[3] The yield of both isomers was over 70% of the theoretical amount. The *d*- and *l*-nitriles were readily converted to the ketones by means of ethylmagnesium bromide. The observed rotations for *d*- and *l*-Methadon hydrochlorides were $[\alpha]^{25}D$ +126° and −127° ($c$ = 1.0 in water). The calculated specific rotations for the cations in water are +141° and −142°. Thorpe, Walton, and Ofner[3] reported $[\alpha]D$ +143° and −145° for the cations of *d*- and *l*-Methadon in water. Brode and Hill[4] resolved Methadon through the *d*-bitartrate and obtained $[\alpha]^{28}D$ +127.5° and −127.8° ($c$ = 2.96 in water) for *d*- and *l*-Methadon hydrochlorides.

[a] Melting points are uncorrected. [b] Subcutaneous. [c] Compared with *dl*-Methadon at 2 mg./kg.

Catalytic reduction of *dl*-Methadon has been reported to give only one of the two possible pairs of diastereoisomeric carbinols.[5,6] *d*- and *l*-Methadon were reduced catalytically to yield only two of the four possible optical isomers. These are designated as the *α*-isomers. The direction of optical rotation changed. *d*-Methadon hydrochloride was reduced to *α-l*-6-dimethylamino-4,4-diphenyl-3-heptanol hydrochloride, $[\alpha]^{25}D$ −34° (*c* = 0.30 in water). *l*-Methadon hydrochloride was reduced to *α-d*-6-dimethylamino-4,4-diphenyl-3-heptanol hydrochloride, $[\alpha]^{25}D$ +34° (*c* = 0.26 in water).

The *α-d*- and *α-l*-carbinol hydrochlorides were acetylated in pyridine solution by means of acetic anhydride. The observed rotations for *α-d*- and *α-l*-5-acetoxy-2-dimethylamino-4,4-diphenylheptane hydrochlorides were $[\alpha]^{25}D$ +57° and −59° (*c* = 0.2 in water).

The *d*- and *l*-nitriles were hydrolyzed by means of 70% sulfuric acid to the acids and, without isolation, converted to the ethyl esters. The observed rotations of the *d*- and *l*-ethyl 4-dimethylamino-2,2-diphenylvalerate hydrochlorides were $[\alpha]^{25}D$ +39° and −38° (*c* = 0.2 in water).

A preliminary evaluation of the analgesic activity of these compounds was made by means of the rat tail burn method. The subcutaneous threshold dosages and activities as compared with *dl*-Methadon are shown in Table I. Detailed results will be reported elsewhere.

We are indebted to Dr. K. K. Chen, Dr. C. C. Scott and Mr. E. B. Robbins for the pharmacological data reported.

## Experimental

**Resolution of *dl*-4-Dimethylamino-2,2-diphenylvaleronitrile.**—A warm solution containing 83 g. (0.3 mole) of *dl*-nitrile[7] and 45 g. (0.3 mole) of *d*-tartaric acid in 500 cc. of acetone and 50 cc. of water was cooled to yield 62 g. of *l*-nitrile *d*-bitartrate, m. p. 110–115°. After one recrystallization from aqueous acetone solution, the *l*-nitrile *d*-bitartrate melted at 114–117°, $[\alpha]^{23}D$ + 14° (*c* = 1.0 in water). The *l*-nitrile was regenerated with dilute sodium hydroxide and recrystallized from aqueous ethanol, m. p. 99–101°, wt. 31 g. (75%), $[\alpha]^{23}D$ −50° (*c* = 1.0 in ethanol).

The acetone mother liquor was concentrated to dryness *in vacuo*, treated with dilute sodium hydroxide, and the *d*-nitrile recrystallized three times from aqueous ethanol solution, m. p. 97–100°, wt. 30 g. (72%), $[\alpha]^{25}D$ + 47° (*c* = 1.0 in ethanol).

***α-dl*-, *α-d*- and *α-l*-6-Dimethylamino-4,4-diphenyl-3-heptanol Hydrochlorides.**—The nitriles were readily converted to the ketones by means of excess ethylmagnesium bromide.[3]

The ketone hydrochlorides in water solution were readily converted to the carbinol hydrochlorides at 3 atmospheres pressure of hydrogen using Adams platinum oxide catalyst. The water was removed *in vacuo* and the product crystallized from ethanol–ether solution. *d*-6-Dimethylamino-4,4-diphenyl-3-heptanone hydrochloride was reduced to *α-l*-6-dimethylamino-4,4-diphenyl-3-heptanol hydrochloride. *l*-6-Dimethylamino-4,4-diphenyl-3-heptanone hydrochloride was reduced to *α-d*-6-dimethylamino-4,4-diphenyl-3-heptanol hydrochloride.

***α-dl*-, *α-d*- and *α-l*-5-Acetoxy-2-dimethylamino-4,4-diphenylheptane Hydrochloride.**—A reaction mixture containing one part of the alcohol hydrochloride, one part of acetic anhydride, and two parts of pyridine was heated overnight at 50°. The resulting solution was diluted with ether until cloudy and chilled. The product was recrystallized from ethanol–ether solution.

***dl*-, *d*-, and *l*-Ethyl 4-Dimethylamino-2,2-diphenylvalerate Hydrochloride.**—A solution of 100 g. (0.36 mole) of *dl*-2,2-diphenyl-4-dimethylaminovaleronitrile in 300 g. of 70% sulfuric acid was stirred and heated in an oil-bath at 150° for eighteen hours.

The oil-bath was cooled to 120° and the flask fitted with a dropping funnel and distilling condenser. One liter of absolute ethanol was added during ten hours, allowing the alcohol to distill. The reaction mixture was poured onto ice and made basic with 50% sodium hydroxide solution. The oil was extracted with ether, dried over magnesium sulfate, and then distilled *in vacuo*. The fraction boiling at 158–168° (0.70 mm.), wt. 62 g., was collected. The hydrochloride was prepared in ether and recrystallized from ethanol–ether solution, m. p. 178.5–180°,[8] wt. 42 g. (32%).

The *d*- and *l*-isomers were prepared by the same procedure using the resolved nitriles.

## Summary

The optical isomers of *α-dl*-6-dimethylamino-4,4-diphenyl-3-heptanol, *α-dl*-5-acetoxy-2-dimeth-

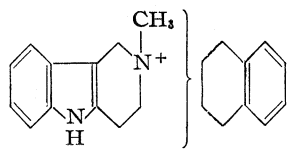
# Curariform Activity and Chemical Structure. III. Syntheses in the 3-Indolylmethylamine Series[1]

BY L. E. CRAIG[2] AND D. S. TARBELL



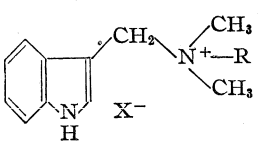
The most physiologically effective of the curare alkaloids belong to the calabash curare group. Of the eighteen alkaloids which have been isolated from calabash curare, the most active is C-toxiferine-I, which paralyzes frogs in doses of 0.005–0.009 mg./kg.[3]

Karrer and Schmid[4] showed that C-curarine-I chloride ($C_{20}H_{21}ClN_2$) contains a secondary, non-basic nitrogen, which is the nitrogen of an indole ring-system, and a quaternary nitrogen present in a tetrahydroisoquinoline ring system, common to two rings, and containing a methyl group. On the basis of this, the following structure can be drawn

Since the benzene ring must be attached in a position to give a tetrahydroisoquinoline, fourteen isomeric hexahydrobenzoindoloquinolizines are possible.

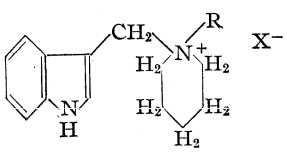
The most probable structures are those in which the quaternary nitrogen is separated from the indole ring by one carbon. On the basis of similarity of color reactions, Schmid and Karrer[3] postulated that C-toxiferine-I might be related to tetrahydro-9-pyrido(3,4-b)indoles, which would mean that the above proposed structure would have the β-carboline arrangement of the nitrogen atoms. Wieland, Witkop and Bähr[5] isolated isoquinoline, skatole and impure 3-ethylindole from a zinc dust distillation of another of the calabash curare alkaloids, C-dihydrotoxiferine-I chloride ($C_{20}H_{23}ClN_2$). The isolation of the 3-ethylindole supports the β-carboline structure proposed by Schmid and Karrer; however, the isolation of skatole suggests the γ-carboline structure, as follows:

(Four possible isomers)



The present papers reports the synthesis of, and the preliminary pharmacological tests on, compounds containing a quaternary nitrogen in the γ-carboline structure, that is, 3-indolylmethylammonium salts.

The 3-indolylmethylamines were prepared conveniently by the Mannich reaction, essentially by the method of Kühn and Stein.[6]



When the Mannich reaction was attempted with indole, formaldehyde and 1,2,3,4-tetrahydroisoquinoline hydrochloride, methylene-bis-(N,N'-1,2,3,4-tetrahydroisoquinoline) and a polymeric material[7] were obtained. The methylene-bis-compound was obtained in good yield when the amine hydrochloride and aqueous formaldehyde were heated together. Attempts to prepare derivatives of this previously unreported compound led to some anomalous results.

On treatment of the methylene-bis-compound with ethanolic picric acid, the picrate of 1,2,3,4-tetrahydroisoquinoline was obtained. Treatment of the bis-compound with methyl iodide yielded N,N-dimethyl-1,2,3,4-tetrahydroisoquinolinium iodide. The cleavage of the methylenediamine linkage with ethanolic picric acid is not without precedent, as Elderfield and Kreysa[8] reported a similar reaction.

The tertiary 3-indolylmethylamines were converted by conventional methods into various quaternary salts.

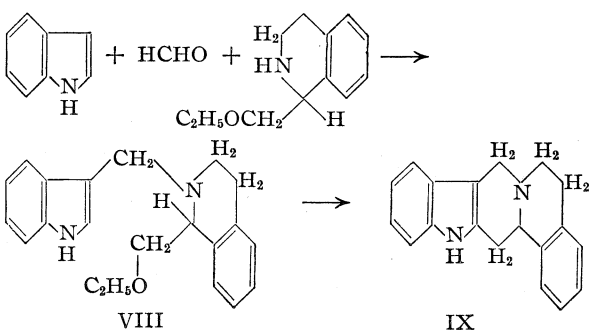
VI



Compound VI is an open-chain analog of the γ-carboline ring system which was suggested for the calabash curare alkaloids.

Unsuccessful attempts were made to synthesize the complete hexahydrobenzoindoloquinolizine ring system (IX) by ring closure of 1-ethoxymethyl-2-(3-indolylmethyl)-1,2,3,4-tetrahydroisoquinoline (VIII). 1-Ethoxymethyl-1,2,3,4-tetrahydroisoquinoline (VII) was obtained by hydrogenation of the 1-ethoxymethyl-3,4-dihydroisoquinoline prepared by the Bischler–Napieralski reaction from N-(β-phenylethyl)-ethoxyacetamide; by condensation of VII with indole by the Mannich

VII

reaction, 1-ethoxymethyl-2-(3-indolylmethyl)-1,2,3,4-tetrahydroisoquinoline (VIII) was obtained in good yield.

VIII IX

Conventional methods for ether cleavage were applied to compound VIII with the hope that ring-closure to the indole ring might occur simultaneously with the cleavage of the ethoxyl group, thus forming the hexahydrobenzoindoloquinolizine (IX). The Mannich base (VIII) was treated with anhydrous aluminum bromide in refluxing benzene, concentrated hydriodic acid at reflux, boron tribromide[9,10] in refluxing benzene, zinc chloride in refluxing acetic acid, and phosphorus trichloride in refluxing benzene. Very dark tars were obtained which did not yield any desired product on attempted purifications by crystallizations and chromatography.

Compounds I, II, V and VI exhibited typical curare-like activity in mice. Compound VI was effective when injected intraperitoneally in doses of less than 16 mg./kg. and when given orally in doses of approximately 80 mg./kg. Compounds I, II and V were effective when injected intraperitoneally in doses of 40, 60 and 80 mg./kg., respectively. Compound III was ineffective in doses of 60 mg./kg. and Compound IV was a convulsant poison. While the most effective of these compounds, compound VI, has only a very small fraction of the activity of C-toxiferine-I, it is significant to note that the 3-indolylmethyl group greatly enhances curariform activity, because N,N-dimethyl-1,2,3,4-tetrahydroisoquinolinium iodide was found to be ineffective in doses of 200 mg./kg.[11]

## Experimental[12]

**3-Indolylmethyltrimethylammonium Iodide (Gramine Methiodide)[6,13] (I).**—A solution of 25 g. (0.144 mole) of gramine and 21 g. (0.148 mole) of methyl iodide in 200 cc. of absolute ethanol was allowed to stand in the dark for twenty hours. The precipitate was collected, slurried with cold ethanol, and again collected by filtration to give 30.8 g. (97.5%) of colorless leaflets which darken at 150–200° but do not melt under 300°.[14]

**Benzyldimethyl-3-indolylmethylammonium Bromide (II).**—A solution of 1.74 g. (0.01 mole) of gramine and 1.71 g. (0.01 mole) of benzyl bromide in 25 cc. of absolute ethanol was allowed to stand at room temperature for sixteen hours. Upon adding ether to the orange solution, 1.2 g. (35%) of tan powder was obtained, which gave 1.0 g. (29%) of colorless crystals on recrystallization from methanol–ether. The product darkens at 130–135° and melts with decomposition over a temperature range between 145–155°. It is soluble in ethanol and methanol, only very slightly soluble in water and insoluble in ether.

*Anal.* Calcd. for $C_{18}H_{21}BrN_2$: C, 62.61; H, 6.13. Found: C, 62.22; H, 5.80.[15]

**Dimethyl-3-indolylmethyl-β-phenylethylammonium Bromide (III).**—A solution of 2.5 g. (0.014 mole) of gramine and 2.6 g. (0.014 mole) of β-phenylethyl bromide in 50 cc. of absolute ethanol was allowed to stand for six days at room temperature. The light pink precipitate (1.9 g., 37%) was collected and recrystallized from methanol–ether to give 1.6 g. (31%) of colorless needles, m. p. 171°. The product is soluble in methanol, only very slightly soluble in water and insoluble in ether and benzene.

*Anal.* Calcd. for $C_{19}H_{23}BrN_2 \cdot {}^1/_2H_2O$: C, 61.96; H, 6.57. Found: C, 61.76, 61.86; H, 6.30, 6.23.

**N-(3-Indolylmethyl)-piperidine.**—To a cooled solution of 8.5 g. (0.1 mole) of piperidine and 8.6 g. (0.1 mole of formaldehyde) of 35% formaldehyde in 100 cc. of 50%

(9) Gamble, Gilmont and Stiff, THIS JOURNAL, **62**, 1257 (1940).

(10) Benton and Dillon, *ibid.*, **64**, 1128 (1942).

(11) The authors are indebted to F. M. Berger, M.D., the University of Rochester School of Medicine and Dentistry, for the pharmacological tests on these compounds.

(12) All melting points are uncorrected; analyses by Mrs. G. L. Sauvage.

(13) Snyder, Smith and Stewart, THIS JOURNAL, **66**, 200 (1944).

(14) Kühn and Stein[6] reported that the compound darkens at 175° but does not melt under 350°.

(15) High hydrogen and low carbon values were obtained until the product was dried at elevated temperatures under reduced pressure. In subsequent experiments, the quaternary salts of the Mannich bases discolored and decomposed on heating, and the high hydrogen and low carbon values were assumed to be due to fractional molecules of water of crystallization.

acetic acid was added 11.7 g. (0.1 mole) of indole. A slight exothermic reaction occurred as the indole went into solution. After the light yellow solution had stood at room temperature for twelve hours, it was made strongly basic with sodium hydroxide and the precipitate collected by filtration. After recrystallization from dilute ethanol, 15.5 g. (74%) of colorless needles were obtained, m. p. 159–159.5°.[16]

**N-(3-Indolylmethyl)-N-methylpiperidinium Iodide (IV).**—A solution of 2 g. (0.0094 mole) of N-(3-indolylmethyl)-piperidine and 2 cc. (0.032 mole) of methyl iodide in 20 cc. of absolute ethanol was allowed to stand at room temperature for twenty-four hours. The oil which separated when ether was added crystallized slowly on standing in the refrigerator. Recrystallization of the product from methanol–ether gave 1.8 g. (55%) of colorless prisms, m. p. 142–143°. The product is soluble in methanol, ethanol and warm water, and insoluble in ether and petroleum ether.

*Anal.* Calcd. for $C_{15}H_{21}IN_2 \cdot {}^1/_4H_2O$: C, 49.94; H, 6.01. Found: C, 49.77; H, 5.98.

**N-Benzyl-N-(3-indolylmethyl)-piperidinium Bromide (V).**—A solution of 1 g. (0.0047 mole) of N-(3-indolylmethyl)-piperidine and 0.8 g. (0.0047 mole) of benzyl bromide was allowed to stand at room temperature for six days. The fine white powder that precipitated was recrystallized from ethanol–ether to give 1.1 g. (61%) of product, m. p. 147–151° with decomposition after darkening at 132–134°. The product is soluble in ethanol and warm water and insoluble in ether.

*Anal.* Calcd. for $C_{21}H_{25}BrN \cdot {}^1/_4H_2O$: C, 64.68; H, 6.59. Found: C, 64.92; H, 6.94.

**Methylene-bis-(N,N′-1,2,3,4-tetrahydroisoquinoline).**—A solution of 3.4 g. (0.02 mole) of 1,2,3,4-tetrahydroisoquinoline hydrochloride and 1 g. (0.02 mole) of 35% formaldehyde in 30 cc. of 20% acetic acid was heated on a steam-bath for one hour. The oil which separated when the solution was made basic was extracted from the mixture with two 50-cc. portions of ether. The light yellow oil left on evaporation of the ether was taken up in ethanol and crystallization induced by adding a few drops of water to give 2.1 g. (75%) of light tan powder, m. p. 88–88.5°.

*Anal.* Calcd. for $C_{19}H_{22}N_2$: C, 81.97; H, 7.97. Found: C, 82.30; H, 7.95.

A small amount of the above product was heated for a few minutes in saturated ethanolic picric acid. On cooling a picrate separated in long needles, m. p. 200–201° after softening and darkening at 185–190°.

*Anal.* Calcd. for the picrate of 1,2,3,4-tetrahydroisoquinoline, $C_{15}H_{14}N_4O_7$: C, 49.72; H, 3.89. Found: C, 50.00; H, 4.14.

As this analysis checked for the picrate of 1,2,3,4-tetrahydroisoquinoline, a mixed melting point of this picrate with that of an authentic sample of 1,2,3,4-tetrahydroisoquinoline (m. p. 201–202°) was taken. There was no depression.

A solution of 1 g. (0.0036 mole) of the bis-compound and 2.8 g. (0.02 mole) of methyl iodide in 25 cc. of dry ether was allowed to stand at room temperature for twenty-four hours. The light yellow needles which formed amounted to 0.4 g., m. p., after recrystallization from methanol–ether, 187–188°.[17] Evaporation of the filtrate to dryness left 0.5 g. of the unreacted bis-compound. The 0.4 g. of product, which was shown by analysis to be N,N-dimethyl-1,2,3,4-tetrahydroisoquinolinium iodide, represents a yield of 40% based on the unrecovered starting material.

*Anal.* Calcd. for N,N-dimethyl-1,2,3,4-tetrahydroisoquinolinium iodide, $C_{11}H_{16}IN$: C, 45.69; H, 5.59. Found: C, 45.97; H, 5.68.

(16) Kühn and Stein[6] reported a m. p. of 161°.

(17) Gulland and Virden, *J. Chem. Soc.*, 1791 (1929), reported a melting point of 192° for N,N-dimethyl-1,2,3,4-tetrahydroisoquinolinium iodide. They obtained the product as yellow leaflets from which it was very difficult to remove the color.

**N-(3-Indolylmethyl)-1,2,3,4-tetrahydroisoquinoline.**—A water solution of 5 g. (0.03 mole) of 1,2,3,4-tetrahydroisoquinoline hydrochloride was made strongly basic with alkali and the free base taken up in ether. After removing the ether by distillation, the residue was taken up in 20 cc. of 50% acetic acid. To this solution was added 3.4 g. (0.04 mole) of 35% formaldehyde and 3.5 g. (0.03 mole) of indole. After the light yellow solution had stood at room temperature for twelve hours, it was made strongly basic and the mixture extracted with three 50-cc. portions of ether. The residue left from the evaporation of the ether solution was recrystallized from dilute ethanol to give 4.7 g. (60%) of essentially colorless product, m. p. 139–140°. It was necessary to purify the product by chromatography, using chloroform–petroleum ether as the solvent and alumina as the adsorbent, before a satisfactory carbon–hydrogen analysis could be obtained. The melting point was not raised by this purification, but consistently high carbon values were obtained until the product was chromatographed.

*Anal.* Calcd. for $C_{18}H_{18}N_2$: C, 82.41; H, 6.91. Found: C, 82.10; H, 7.05.

The hydrochloride of the Mannich base was prepared by passing dry hydrogen chloride gas through a dry ether solution. Upon recrystallization from ethanol–ether, pink prisms were obtained, m. p. 179.5–180°.

*Anal.* Calcd. for $C_{18}H_{19}ClN_2$: C, 72.34; H, 6.41. Found: C, 71.92; H, 6.45.

**N-(3-Indolylmethyl)-N-methyl-1,2,3,4-tetrahydroisoquinolinium Iodide (VI).**—A solution of 1 g. (0.0038 mole) of N-(3-indolylmethyl)-1,2,3,4-tetrahydroisoquinoline and 2 cc. (0.032 mole) of methyl iodide was allowed to stand for two hours at room temperature. The light tan, flaky precipitate amounted to 1.6 g. (quantitative), m. p. 75–80° with darkening. When the product was dissolved in methanol and a large amount of ether added, a gummy solid invariably formed, which became completely solid on washing with large amounts of ether. Several repetitions of this procedure gave an essentially colorless powder that melted at 110–112° with darkening and decomposition. The product is soluble in ethanol and methanol, rather insoluble in water and insoluble in ether.

*Anal.* Calcd. for $C_{19}H_{21}IN_2 \cdot {}^1/_4H_2O$: C, 55.82; H, 5.29. Found: C, 56.02; H, 5.32.

**Ethoxyacetyl Chloride.**—The preparation of ethoxyacetyl chloride by treatment of ethoxyacetic acid[18] with thionyl chloride according to the usual procedures was found to be unsatisfactory (13% yield), considerable cleavage of the ethoxyl group apparently taking place. The procedure used by Brown[19] for preparing various volatile acid chlorides was found to be the most satisfactory. In a 100-cc. flask, fitted with a short Vigreux column, were placed 56 g. (0.4 mole) of benzoyl chloride and 21 g. (0.2 mole) of ethoxyacetic acid. The flask was heated in an oil-bath so that a slow distillation was maintained. In one experiment, 19.8 g. (crude yield, 80%) of colorless liquid was obtained at 95–130°, the major portion coming over between 120–125°.[20] The best results were obtained when this product was used without refractionation in the subsequent experiment.

**N-(β-Phenylethyl)-ethoxyacetamide.**—The 19.8 g. (0.16 mole) of crude ethoxyacetyl chloride from the above experiment was added slowly with cooling to a solution of 48 g. (0.4 mole) of β-phenylethylamine in 100 cc. of benzene. After standing several hours, the precipitated β-phenylethylamine hydrochloride was removed by filtration. After drying the benzene solution over anhydrous magnesium sulfate, the benzene was removed by distillation and the residue distilled to give 15.3 g. (46%) of colorless liquid, b. p. 144–150° (0.6–0.9 mm.), $n^{23}D$ 1.5172.

(19) Brown, THIS JOURNAL, **60**, 1325 (1938).

(20) Rothstein, *Bull. soc. chim.*, **51**, 838 (1932), reported a b. p. of 123–124°.

*Anal.* Calcd. for $C_{12}H_{17}NO_2$: C, 69.53; H, 8.27. Found: C, 69.36; H, 8.01.

**1-Ethoxymethyl-3,4-dihydroisoquinoline.**—To a solution of 12 g. (0.06 mole) of N-(β-phenylethyl)-ethoxyacetamide in 150 cc. of refluxing xylene was added portionwise, over a period of fifteen minutes, 14 g. (0.1 mole) of phosphorus pentoxide. Reflux was maintained for another fifteen minutes. After decanting the xylene from the dark brown solid, 150 cc. of water was added and the mixture shaken until all had gone into solution. The water solution was extracted with two 50-cc. portions of ether to remove the xylene and any other ether-soluble material. The mixture which formed when the water solution was made strongly basic with alkali was extracted with four 50-cc. portions of ether. After drying the ether solution and removing the ether by distillation, the dark red-brown residue was distilled to give 4.9 g. (45%) of colorless liquid, b. p. 106–115° (1–1.5 mm.), $n^{22}D$ 1.5495. The liquid rapidly turned yellow on exposure to air.

*Anal.* Calcd. for $C_{12}H_{15}NO$: C, 76.15; H, 7.99. Found: C, 75.48; H, 7.55. The sample had turned yellow before the analysis was made; oxidation could account for the low carbon–hydrogen values.

The picrate was obtained as yellow needles from ethanol, m. p. 138–139° with decomposition.

*Anal.* Calcd. for $C_{18}H_{18}N_4O_8$: C, 51.68; H, 4.34. Found: C, 51.94; H, 4.38.

The hydrochloride precipitated when dry hydrogen chloride gas was bubbled through a dry ether solution of the distilled free base. It was very hygroscopic and difficult to handle, recrystallization from ethanol–ether giving colorless needles, m. p. 85–86° with darkening and decomposition.

*Anal.* Calcd. for $C_{12}H_{16}ClNO \cdot 1/4H_2O$: C, 62.60; H, 7.22. Found: C, 62.84; H, 7.28.

**1-Ethoxymethyl-1,2,3,4-tetrahydroisoquinoline (VII).**—A solution of 3.6 g. (0.019 mole) of the distilled 1-ethoxymethyl-3,4-dihydroisoquinoline in 50 cc. of absolute ethanol, in the presence of about 1.0 g. of Raney nickel, was shaken for five hours at room temperature under hydrogen at 3.8 atmospheres. After removing the catalyst by filtration and the ethanol by distillation, the residue was distilled under reduced pressure to give 3.4 g. (94%) of colorless liquid, b. p. 90–103° (0.5–0.6 mm.), $n^{21}D$ 1.5360. The liquid turned light yellow on standing.

*Anal.* Calcd. for $C_{12}H_{17}NO$: C, 75.35; H, 8.97. Found: C, 74.66; H, 8.83. The colorless sample had turned light yellow before the analysis was run.

The picrate formed very slowly as tiny yellow needles from ethanol, m. p. 164–165°.

*Anal.* Calcd. for $C_{18}H_{20}N_4O_8$: C, 51.43; H, 4.80. Found: C, 51.32; H, 4.50.

The hydrochloride was prepared by bubbling dry hydrogen chloride gas through an ethanol solution of the free base and adding ether to induce crystallization. Recrystallization from ethanol–ether gave colorless prisms, m. p. 155–156°.

*Anal.* Calcd. for $C_{12}H_{18}ClNO$: C, 63.28; H, 7.97. Found: C, 63.39; H, 7.80.

**1-Ethoxymethyl-2-(3-indolylmethyl)-1,2,3,4-tetrahydroisoquinoline (VIII).**—To a solution of 1.9 g. (0.01 mole) of 1-ethoxymethyl-1,2,3,4-tetrahydroisoquinoline in 30 cc. of 50% acetic acid was added 0.4 g. (0.05 mole) of 35% formaldehyde and 1.1 g. (0.01 mole) of indole. After the light yellow solution had stood at room temperature for seven hours, it was made basic with dilute sodium hydroxide, a light yellow oil separating. The mixture was extracted exhaustively with ether, and the ether removed from the combined extracts by distillation. The residue was taken up in 25 cc. of ethanol and a few cc. of water added dropwise until precipitation was complete. Recrystallization of the product from dilute ethanol gave 2.2 g. (69%) of tiny colorless needles, m. p. 100–102°. A small sample recrystallized again from dilute ethanol melted at 102–103°. Although the melting point was not changed, it was necessary to purify the product by chromatography (using chloroform–petroleum ether and a column of alumina) before a satisfactory analysis was obtained. Consistently high carbon values were obtained until this was done.

*Anal.* Calcd. for $C_{21}H_{24}N_2O$: C, 78.71; H, 7.55; N, 8.75. Found: C, 78.80; H, 7.50; N, 8.60.

## Summary

A number of previously unreported 3-indolylmethylammonium salts, compounds which are analogous to the structures postulated for the calabash curare alkaloids, have been prepared. Some of these quaternary salts exhibit marked curariform activity, the most effective, N-(3-indolylmethyl)-N-methyl-1,2,3,4-tetrahydroisoquinolinium iodide, causing paralysis in mice in doses of 16 mg./kg.

# Curariform Activity and Chemical Structure. IV. Syntheses in the Piperidine Series[1]

BY L. E. CRAIG[2] AND D. S. TARBELL

Substituted 4-piperidones, 4-hydroxypiperidines and various piperidinium salts have been reported to exhibit rather intense curariform activity.[3,4] The present paper reports the syntheses of and the results of preliminary pharmacological tests on 4-piperidonium and 4-hydroxypiperidinium salts.

Di-β-carbomethoxyethylmethylamine (I), obtained by the addition of methylamine to methyl acrylate by the method of Mozingo and McCracken,[5] was treated with powdered sodium in xylene by the procedure of McElvain[6] to give 1-methyl-3-carbomethoxy-4-piperidone (III). Compound III, on acid hydrolysis, gave 1-methyl-4-piperidone (V), which was readily converted to 1-

methyl-4-hydroxypiperidine (VIII) by catalytic hydrogenation.

Previous workers[7,8,9] obtained a hydrochloride of 1-methyl-4-piperidone which melted at 94–95°. When dry hydrogen chloride gas was bubbled through a dry ether solution of distilled 1-methyl-4-piperidone, a hydrochloride was obtained which melted at 164–167°. It is probable that the hydrochloride melting at 94–95° contains water of crystallization (no analyses were reported). On distillation of the 1-methyl-4-piperidone, a considerable amount was left as a viscous residue in the distilling flask. As the distilled product also increased noticeably in viscosity on standing, it seems probable that it undergoes an aldol-type condensation.

The piperidone, hydroxypiperidine and the tertiary amine intermediates were converted into quaternary salts by conventional methods. The reactions carried out are summarized as

All of the quaternary salts, with the exception of compound II which produces a marked muscarinic action, cause curariform paralysis in mice. Compounds IV, VI, VII and IX are effective in doses of 180–280 mg./kg. when injected intraperitoneally. Compound IX is effective when given orally in doses of 1000 mg./kg.[10]

## Experimental

**Di-β-carbomethoxyethylmethylamine (I).**—This compound was prepared by the procedure used by Mozingo and McCracken[5] for the preparation of the corresponding carbethoxy compound. In a typical experiment, 172 g. (2.0 moles) of methyl acrylate and 31 g. (1.0 mole) of methylamine gave 183 g. (90%) of colorless liquid, b. p. 108–112° (3–4 mm.).[11]

**3-Carbomethoxy-1-methyl-4-piperidone (III).**—This compound was prepared by the procedure used by McElvain[6] for the corresponding carbethoxy compound. In one experiment, 41 g. (0.2 mole) of di-β-carbomethoxyethylmethylamine in 100 cc. of xylene was treated with 4.6 g. (0.2 mole) of powdered sodium to give 20.4 g. (60% crude yield) of light yellow oil. Attempts to distil this product resulted in considerable loss. The light yellow liquid rapidly became dark and viscous on heating and only 40–50% of the material distilled, b. p. 85–90° (1 mm.). It was found advisable to convert the entire crude product to the hydrochloride by bubbling dry hydrogen chloride gas through an ether solution (the conversion was essentially quantitative), m. p., after recrystallization from ethanol–ether, 164–165°.[12]

**1-Methyl-4-piperidone (V).**—This product was obtained by hydrolysis of 3-carbomethoxy-1-methyl-4-piperidone according to the procedure of Bolyard and McElvain.[7] The product was obtained by this procedure as the hydrochloride, m. p. 94–95°.[13] In one experiment, this crude hydrochloride was converted to the free base and the free base distilled, b. p. 54–56° (9 mm.), $n^{25}D$ 1.4588.[14] Much of the free base was not recovered on distillation and a viscous, dark residue was left in the distilling flask. The distilled product also increased noticeably in viscosity on standing. For this reason, the product was used immediately after distillation in subsequent reactions.

A stream of dry hydrogen chloride gas was bubbled through a benzene solution of the distilled free base. The hydrochloride so obtained was recrystallized from anhydrous chloroform–ether to give colorless crystals melting at 164–167°.

*Anal.* Calcd. for $C_6H_{12}ClNO$: C, 48.16; H, 8.09. Found: C, 48.11; H, 8.10.

A small amount of this hydrochloride was dissolved in water and the solution evaporated to dryness. The product so obtained melted at 94–95°. It is apparent that the hydrochloride previously reported contains water of crystallization.[15,15a]

**4-Hydroxy-1-methylpiperidine (VIII).**—The hydrochloride from 4.6 g. (0.004 mole) of freshly distilled 1-methyl-4-piperidone was dissolved in 75 cc. of ethanol and the solution shaken, in the presence of 0.3 g. of Adams platinum oxide catalyst, under hydrogen at 3.3 atm. at room temperature for eight hours. After removing the catalyst by filtration and the solvent by distillation, the residue was treated with a few cc. of concentrated alkali and the mixture exhaustively extracted with ether. The ether solution was dried over magnesium sulfate, the ether removed, and the residue distilled to give 3.1 g. (64%) of colorless

[a] All melting points are corrected. [b] Analyses by Mrs. G. L. Sauvage. [c] Recrystallized from ethanol. [d] Recrystallized from methanol–ether. [e] Not recrystallized. [f] Howton[9] obtained a quaternary salt which analyzed for one molecule of methanol of crystallization, m. p. 187.6–188°.

liquid, b. p. 80–87° (5–6 mm.), $n^{21}D$ 1.4718.[16] The hydrochloride melted at 155–156°.[16]

**Preparation of Quaternary Salts.**—The tertiary amines prepared in the above experiments were converted into quaternary salts by allowing benzene solutions of the distilled amine and excesses of the alkyl halide to stand at room temperature for twenty-four hours, the quaternary salts precipitating as they formed. The salts prepared are listed in Table I.

(16) Mills, Parkin and Ward, *J. Chem. Soc.*, 2613 (1927), reported a b. p. of 105° (18 mm.) and a m. p. for the hydrochloride of 157–158°. Riegel and Reinhard, THIS JOURNAL, **48**, 1334 (1926), reported a b. p. of 116–118° (36 mm.).

## Summary

A number of previously unreported 4-piperidonium and 4-hydroxypiperidinium salts have been prepared. They were found to exhibit mild curariform activity, and one was found to be effective when administered orally.

# Isomeric Dihydroxanthopterins[1]

BY GEORGE H. HITCHINGS AND GERTRUDE B. ELION

Dihydroxanthopterin (2-amino-4,6-dihydroxydihydropteridine) has been prepared by three routes[2,3,4] involving the reduction of a pteridine. Purrmann[2] reduced xanthopterincarboxylic acid catalytically and found the resultant dihydro-acid to be readily decarboxylated to dihydroxanthopterin. Totter[3] was able to isolate the same compound from the reduction of leucopterin (2-amino-4,6,7-trihydroxypteridine) by sodium amalgam, and O'Dell, *et al.*,[4] obtained it directly by the catalytic reduction of xanthopterin (III). The latter were the first to assign a structure to the compound. They made the logical suggestion that the two hydrogen atoms might add across the 7,8 double bond to give 7,8-dihydroxanthopterin (V). The synthesis of (V) by an apparently definitive method, however, has led to a dihydroxanthopterin distinct from that formed by reductive methods. For convenience the compound produced by reductive methods will be called α-dihydroxanthopterin and the synthetic compound, β-dihydroxanthopterin.

The existence of two dihydroxanthopterins where a single substance would have been expected recalls the suggestion (not clearly established) that stable tautomers of certain dihydropyrazines may exist.[5] The establishment of this instance of isomerism has important implications in the field of pteridine chemistry; the resistance of the β-dihydroxanthopterin structure to oxidation may have some bearing on the role of oxidative reactions in the synthesis of folic acid.

β-Dihydroxanthopterin was prepared in these laboratories several years ago as a possible intermediate in the synthesis of xanthopterin, which at that time was believed to have a number of important biological functions.[6,7,8] This compound is, indeed, convertible to xanthopterin but in poor yield (20%) and only under relatively drastic conditions (concentrated sulfuric acid at 210° for fifteen minutes). The α-isomer, on the other hand, can be converted to xanthopterin by a wide range of oxidative procedures, quantitatively by exposure to oxygen in alkaline solution with[2] or without platinum catalyst or by alkaline permanganate oxidation at room temperature.[9] Other properties of the two are compared in Table I. In addition to the observed differences in oxidizability the difference in stability to acid and alkali is noteworthy. The α-isomer is gradually decomposed by acid, giving unidentified colored

products, but is stable to alkalies. The β-isomer is stable to strong acid, but, as will be shown, the pyrazine ring is cleaved when the compound is warmed with aqueous barium hydroxide. The ultraviolet absorption spectra of the two isomers are similar but distinct (Figs. 1–4). The spectrum of the α-form at *p*H 3 resembles closely that of the β-isomer at *p*H 1, and that of the former at *p*H 1 is similar to that of the latter at *p*H 3 (Figs. 1 and 2). At *p*H 7 the two spectra are dissimilar but at *p*H 11 they are almost indistinguishable (Figs. 3 and 4). The spectra leave little doubt that the two are very closely related.

TABLE I

COMPARISON OF PROPERTIES OF DIHYDROXANTHOPTERINS

| Reagent | α | β |
|---|---|---|
| Hot acetic acid | Decomposition | Recrystallization |
| $O_2$ (Pt catalyst) | To xanthopterin | Not oxidized |
| $O_2$ (air-alkali) | To xanthopterin | Not oxidized |
| Permanganate | 2/5 mole → xanthopterin<br>4/5 mole → glycol (?) | 2/5 mole → glycol(?) |
| Barium hydroxide | Barium salt | Ring fission |
| Ferric chloride | Red color | No color |

The first synthesis of xanthopterin by Purrmann[10] was carried out by treatment of 2,4,5-triamino-6-hydroxypyrimidine (I) with dichloroacetic acid, followed by heating the silver salt of the dichloroacetamide (II) in the presence of silver carbonate to effect ring closure to xanthopterin (III). The synthesis of 7,8-dihydroxanthopterin, which is reported here, follows a similar route. The pyrimidine (I) is heated with monochloroacetic acid to give the chloroacetamide (IV) and ring closure follows a relatively mild treatment (aqueous bicarbonate at 95°) to give the dihydroxanthopterin (V). This synthesis is straightforward and the validity of the structures assigned to the intermediate (IV) and product (V) must be regarded as highly probable on *a priori* grounds. However, it is worth while to consider other possible reaction mechanisms and products. Such considerations have led to additional evidence confirming the structure of β-dihydroxanthopterin and incidentally to the discovery of a new heterocyclic, the oxazinopyrimidine, system.

(10) Purrmann, *Ann.*, **546**, 98 (1941).

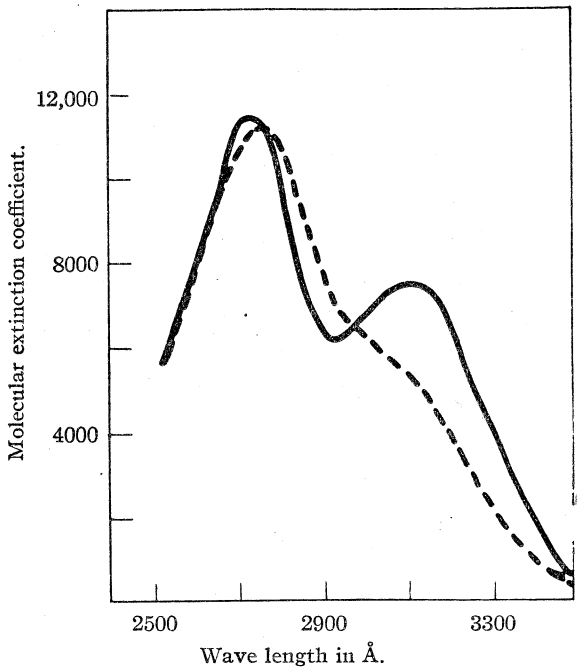

Fig. 3.—Ultraviolet absorption spectra of α-dihydroxanthopterin: —, at *p*H 7.0; ---, at *p*H 11.0.

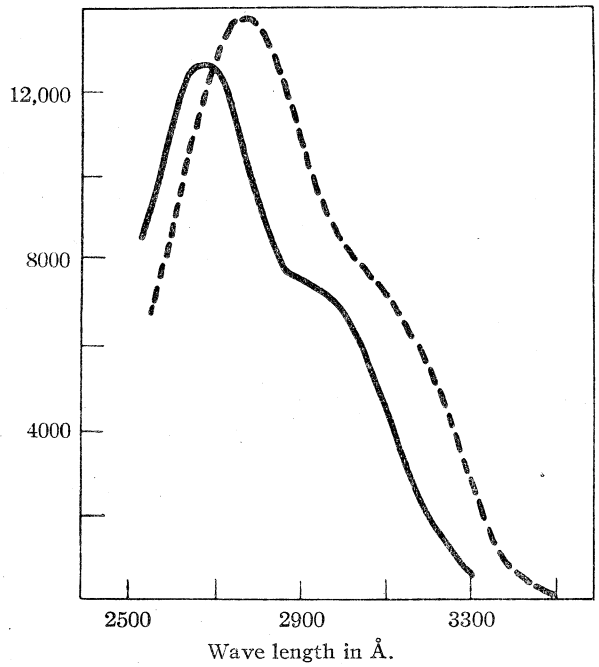

Fig. 4.—Ultraviolet absorption spectra of β-dihydroxanthopterin: —, at *p*H 7.0; ---, at *p*H 11.0.

The allocation of the chloroacetyl group of the intermediate (IV) to the 5′ position rests ultimately on the purine syntheses of Traube[11,12,13] who found 4,5-diaminopyrimidines to be acylated to monoacyl derivatives which could be converted to purines. By methylation of 1,3-dimethyl-2,6-dihydroxy-4 (or 5)-amino-5 (or 4)-formamidopyrimidine, Traube[12] obtained a trimethyl derivative from which caffeine was obtained on ring closure. On the basis of this evidence the formyl group was assigned to the 5′ position, since only the formamido group could provide the acidic hydrogen necessary for methylation. By analogy the other acylamino groups were believed to occupy the 5-position and the greater reactivity of the 5-amino group, in acylations, as compared with the 4 is a generally accepted principle of pyrimidine chemistry,[11,14] to which no exceptions have been published. To this evidence may now be added that afforded by spectrography. Using 2,4-diamino-5-formamido-6-hydroxypyrimidine and the parent triaminohydroxypyrimidine (I) as reference compounds, it is seen that acylation of the 5-amino group results in little change in the absorption spectrum at *p*H 1, but prevents the shift of absorption bands which characterizes the alkaline (*p*H 11) spectrum (Figs. 5 and 6). The chloroacetyl derivative (IV) resembles the formyl derivative so closely as to leave little doubt as to their similarity in structure (Fig. 7). Moreover, the relation of these spectra to those of the parent compounds shows a marked resemblance to that between 5-chloroacetamido-2-amino-4,6-dihydroxypyrimidine (Fig. 8) and 2,5-diamino-4,6-dihydroxypyrimidine (Fig. 9).

If the structure (IV) for the chloroacetamido derivative be granted, there remain to be considered the purine (VI) and the oxazine (VII) as possible products of the ring closure. The more remote possibility that one molecule of (IV) might alkylate another with subsequent hydrolysis and the formation of an hydantoin derivative[15] can be eliminated since such reactions could yield at most 50% of the theoretical amount of product whereas in practice a yield of 70% was obtained. The closure of the imidazole ring to give 8-hydroxymethylguanine (VI) would be expected to require much more drastic conditions than those employed.[13] Actually, attempts to form this compound by heating the sodium salt of either (IV) or the corresponding hydroxyacetyl derivative failed to give isolable amounts of this compound. However, (VI) would be expected to have an ultraviolet absorption spectrum nearly identical with that of 8-methylguanine. The dissimilarity of the spectra of the latter (Fig. 10) and β-dihydroxanthopterin (Figs. 2 and 4) is at once apparent.

The oxazine derivative (VII) can be eliminated from consideration in this connection by comparison of β-dihydroxanthopterin with derivatives of the oxazinopyrimidine structure. Compounds related to (VII) but lacking the 4-amino group (thereby excluding the pteridine structure) have been prepared from 4-methyl-5-chloroacetamido-

6-hydroxypyrimidines by heating with aqueous barium hydroxide.[15] There is, indeed, spectrographic evidence that the diamino derivative (VII) is formed under these conditions, though it has not yet been obtained in a pure state. Moreover, β-dihydroxanthopterin is unstable under the conditions of formation of the oxazine derivatives. The α-isomer gives only a barium salt, but the β-isomer adds the elements of water to give an acid (VIII) which can be esterified (IX). Both acid and ester revert to β-dihydroxanthopterin, the ester spontaneously in aqueous solution, the acid on warming with mineral acid. The ultraviolet absorption spectrum of the acid (VIII) is given in Fig. 11. It is consistent with that of a pyrimidine with a free amino group in the 5-position (*cf.* Compound 1 in Fig. 5). Moreover, the grouping —$NHCH_2CO_2H$ is indicated by the positive ninhydrin reaction obtained with the product of permanganate oxidation. The spectrum of (IX) is similar to that of the acid (VIII) at *p*H 1 but at *p*H 11 it is that of the β-dihydroxanthopterin indicating rapid and nearly quantitative ring closure.

The structure of β-dihydroxanthopterin appears to be established. No definitive evidence to decide the structure of the α-isomer is available. It is obviously possible to formulate the structure in a great many ways, but most of the formulations, such as (X), would be expected to be tautomeric with (V). Structures (XI) and (XII) represent types which are not necessarily obvious equivalents of (V) and for which some precedents exist. Each would be derived by hydrogenation of a C—N double bond of a xanthopterin of type (XIII) or (XIV). Biltz[16] has shown the existence among substituted uric acids of bond arrangements similar to those of (XI), (XII) and (XIII) while van Veen and Baars[17] have proposed a structure for toxoflavin with a bond arrangement simi-

lar to that of (XIV). Obviously a considerable body of facts may be required to establish the fine structure of α-dihydroxanthopterin.

## Experimental

**2,4-Diamino-5-chloroacetamido-6-hydroxypyrimidine (IV).**—A well-ground mixture of 8 g. of 2,4,5-triamino-6-hydroxypyrimidine[11] and 24 g. of monochloroacetic acid was heated in a boiling water-bath for one hour, with intermittent evacuation of the reaction flask. After cooling, the reaction mixture was leached several times with ether to remove the excess chloroacetic acid and then recrystallized from 300 ml. of 0.2 *M* sodium acetate–acetic acid buffer of *p*H 5. The precipitate after standing overnight at 5° consisted partly of pale yellow platelets and partly of amorphous material. It was washed with water and acetone and air dried. Yield was 12.7 g. (95%). A sample was recrystallized twice from dilute acetate buffer for analysis. The crystalline monohydrate loses its water of crystallization at 130° *in vacuo*, but regains it completely on exposure to air for twenty minutes. This rapid absorption of water from the air probably accounts for the low analytical value obtained for water of crystallization.

*Anal.* Calcd. for $C_6H_8O_2N_5Cl \cdot H_2O$: C, 30.42; H, 4.23; N, 29.6; $H_2O$, 7.6. Found: C, 30.64; H, 4.10; N, 29.5; $H_2O$, 5.7.

**β-Dihydroxanthopterin (V).**—A solution of 11.9 g. (0.05 mole) of 2,4-diamino-5-chloroacetamido-6-hydroxypyrimidine and 8.4 g. (0.1 mole) of sodium bicarbonate in 350 ml. of water was kept at 95° for two hours. A yellow precipitate formed gradually. After cooling, the product was filtered, washed with water, and dried at 100°. The yield was 6.2 g. (68.5%). It loses no water on drying at 150°. For analysis, a sample was recrystallized from glacial acetic acid.

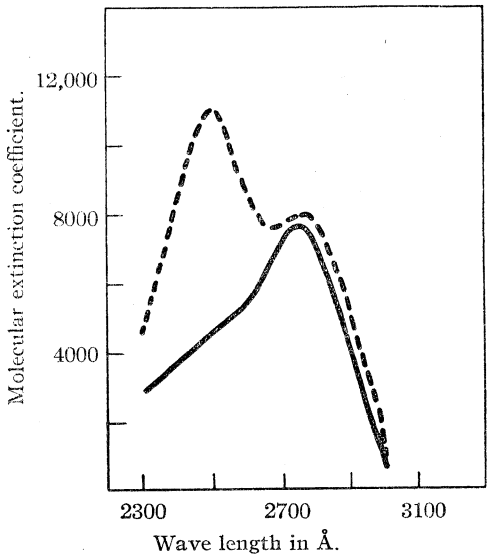

Fig. 10.—Ultraviolet absorption spectra of 8-methylguanine: —, at *p*H 1.0; --- at *p*H 11.0.

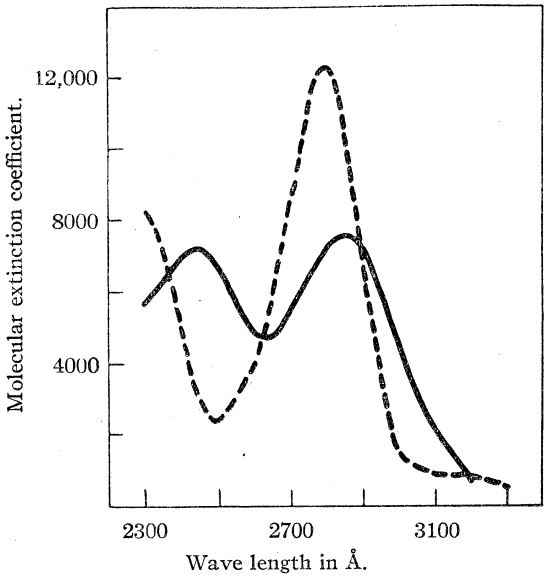

Fig. 11.—Ultraviolet absorption spectra of acid VIII (2,5 - diamino - 6 - hydroxy - 4 - carboxymethylaminopyrimidine): —, at *p*H 1.0; ---, at *p*H 11.0.

*Anal.* Calcd. for $C_6H_7O_2N_5$: C, 39.79; H, 3.87; N, 38.7. Found: C, 39.77; H, 4.17; N, 38.5.

The compound is soluble in about 5000 parts of boiling water, readily in warm 2.5 *N* hydrochloric acid, from which the monohydrochloride crystallizes on cooling as needles.

*Anal.* Calcd. for $C_6H_7O_2N_5 \cdot HCl$: Cl, 16.3. Found: Cl, 16.7.

The sulfate crystallized in colorless prisms from 3 *N* sulfuric acid as a tetrahydrate. Three moles of water were lost at 120°, leaving a monohydrate which does not lose the remaining mole of water at 150°.

*Anal.* $(C_6H_7O_2N_5)_2 \cdot H_2SO_4 \cdot 4H_2O$: Calcd. for 3 $H_2O$, 10.03. Found: 10.03 (after drying at 150° for two hours). Calcd. for $(C_6H_7O_2N_5)_2 \cdot H_2SO_4 \cdot H_2O$: C, 30.13; H, 3.76. Found: C, 30.44; H, 3.77.

The picrate crystallized in bundles of small, dark yellow needles when aqueous picric acid was added to a hot aqueous solution of β-dihydroxanthopterin. After recrystallization from 30% aqueous acetic acid containing 0.3% picric acid, the picrate sinters at about 185° and melts with decomposition at about 265°.

**Oxidation of β-Dihydroxanthopterin.**—Attempts to oxidize β-dihydroxanthopterin to xanthopterin catalytically in alkaline solution or in glacial acetic acid, as described by O'Dell, *et al.*, for the oxidation of α-dihydroxanthopterin,[4] led only to recovery of the starting material. With silver oxide considerable decomposition occurred.

Treatment of β-dihydroxanthopterin with neutral permanganate solution resulted in the consumption of two equivalents of permanganate to form a soluble compound with no absorption band in the ultraviolet. This product, which is presumably a glycol, gives a strong ninhydrin reaction after being boiled with alkali.

A solution of 250 mg. of β-dihydroxanthopterin in 5 ml. of concentrated sulfuric acid was heated at 210° for fifteen minutes. The mixture was allowed to cool and then poured over 25 g. of ice. An amorphous brown precipitate was centrifuged off. The supernatant liquid was neutralized to about *p*H 6 with sodium hydroxide solution and the amorphous orange precipitate removed at once by centrifugation. This precipitate, after purification, consisted of 50 mg. of xanthopterin, as shown by its ultraviolet absorption spectrum. The neutralized reaction mixture, on longer standing, deposited 40 mg. of unreacted β-dihydroxanthopterin also.

**Alkaline Degradation of β-Dihydroxanthopterin to the Acid (VIII).**—A solution of 0.4 g. (0.0022 mole) of β-dihydroxanthopterin in 15 ml. of hot water containing 0.63 g. (0.002 mole) of barium hydroxide octahydrate was heated in a boiling water-bath for six hours and allowed to stand at room temperature overnight. The reaction mixture was diluted to 50 ml. and treated with an excess of sodium sulfate to remove the barium ion. After removal of the barium sulfate the solution was acidified with acetic acid. The yellow crystalline precipitate which formed was filtered off, washed with water and alcohol and air dried (0.2 g.). A sample of this precipitate was purified for analysis by solution in very dilute sodium hydroxide, treatment with carbon and acidification of the hot solution with acetic acid. On cooling, bunches of small colorless needles were formed. The compound does not melt below 350°. It loses its water of crystallization at 120°.

*Anal.* Calcd. for $C_6H_9N_5O_3 \cdot 1.5H_2O$: C, 31.86; H, 5.32; N, 31.0; $H_2O$, 11.95. Found: C, 32.33; H, 6.06; N, 31.0; $H_2O$, 12.20.

When the degradation product (VIII) was boiled with 0.2 *N* hydrochloric acid for a few minutes and the solution neutralized with sodium acetate, the precipitate which formed was identified as β-dihydroxanthopterin by its absorption spectrum.

**Esterification of the Acid (VIII).**—To 12.5 ml. of absolute methanol containing 1 g. of hydrogen chloride was added 150 mg. of VIII. The solution was allowed to stand at room temperature overnight and then evaporated to dryness *in vacuo* below 40°. The solid yellow residue was dissolved in 3 ml. of absolute methanol and precipitated by the slow addition of 125 ml. of absolute ether. The yield of the ester dihydrochloride was 180 mg. (83%). The compound is converted to β-dihydroxanthopterin by heating to about 200°, by solution in alkali, or simply on standing in aqueous solution. Attempts to purify the ester further led in general to less pure material presumably because of the tendency to spontaneous ring closure.

*Anal.* Calcd. for $C_7H_{11}N_5O_3 \cdot 2HCl$: C, 29.38; H, 4.55; Cl, 24.8. Found: C, 29.95; H, 4.50; Cl, 24.0.

The ultraviolet absorption spectrum of the ester (IX) is almost identical with that of the acid (VIII) at *p*H 1 (Fig. 11). When an attempt was made to measure the spectrum of IX at *p*H 11, the spectrum was found to be identical with that of β-dihydroxanthopterin at *p*H 11 (Fig. 4). This ring closure was confirmed when the

alkaline solution was reacidified to *p*H 1 and the spectrum found to be identical with that of β-dihydroxanthopterin at *p*H 1 (Fig. 2).

**α-Dihydroxanthopterin.**—This isomer was prepared by the reduction of leucopterin by sodium amalgam[3] and by the decarboxylation of dihydroxanthopterincarboxylic acid.[2] The ultraviolet absorption spectra of the samples prepared in these two ways are identical and agree with the published spectrum of the product prepared by O'Dell, *et al.*,[4] by the catalytic reduction of xanthopterin (Figs. 1 and 3).

The sample prepared by the reduction of leucopterin was purified *via* the sodium salt as described by Elion, Light and Hitchings[9] and then recrystallized from 250 parts of hot water. The pale yellow elongated prisms which precipitated on cooling contained one mole of water after being dried at 100°. One half of the water of crystallization is lost at 130°, the other half at 150°. When the anhydrous compound is exposed to the air, it quickly regains one-half mole of water to form the stable hemihydrate.

*Anal.* Calcd. for $C_6H_7O_2N_5 \cdot H_2O$: C, 36.2; H, 4.52; $H_2O$, 9.05. Found: C, 36.44; H, 4.44; $H_2O$ (dried at 130° for two hours), 4.52; $H_2O$ (dried at 150° for two hours), 9.10.

When α-dihydroxanthopterin was boiled with glacial acetic acid, the solid material as well as the solution turned dark red. This red product no longer has the spectrum of α-dihydroxanthopterin and has not yet been identified. Its analysis is: C, 36.90; H, 3.42; N, 31.4. Calcd. for $C_7H_8N_5O_4$: C, 37.2; H, 3.54; N, 31.0.

An attempt to cleave α-dihydroxanthopterin by hot barium hydroxide solution led only to the precipitation of an insoluble barium salt which remained unchanged.

The sulfate monohydrate was prepared by the addition of 4 ml. of concentrated sulfuric acid to a solution of 0.5 g. of α-dihydroxanthopterin in 25 ml. of 2 *N* sulfuric acid. It was filtered, washed with acetone and air dried.

*Anal.* Calcd. for $(C_6H_7O_2N_5)_2 \cdot H_2SO_4 \cdot H_2O$: C, 30.13; H, 3.76. Found: C, 29.77; H, 3.73.

The picrate, formed on the addition of one volume of saturated aqueous picric acid solution to a hot aqueous solution of α-dihydroxanthopterin, crystallized as pinkish-orange needles and prisms. It turned brown at about 330° and did not melt at 370°.

**Oxidation of α-Dihydroxanthopterin.**—The spontaneous oxidation of this isomer to xanthopterin in alkaline solution as well as its catalytic oxidation in glacial acetic acid have been previously described.[2,4] It is also oxidized to xanthopterin by silver oxide[3] and by alkaline potassium permanganate.[9] The oxidation with permanganate proceeds beyond the xanthopterin stage if more than two equivalents are used, forming a soluble substance which may be a glycol since it no longer exhibits the ultraviolet absorption band characteristic of the pyrimidine ring structure. After alkaline solutions of this substance have been boiled, the resulting solutions give a strong ninhydrin reaction.

**2,5-Diamino-4,6-dihydroxypyrimidine.**—This compound was prepared by the method of Traube[18] except that the reduction of the 2-amino-5-nitroso-4,6-dihydroxypyrimidine was carried out more easily and in better yield by addition of an excess of sodium hydrosulfite to the ammoniacal suspension of the unisolated nitroso compound rather than by the use of hydrogen sulfide.

**2-Amino-5-chloroacetamido-4,6-dihydroxypyrimidine.**—A mixture of 5 g. of 2,5-diamino-4,6-dihydroxypyrimidine and 13 g. of chloroacetic anhydride was heated in a boiling water bath for one hour, cooled, leached several times with ether and filtered. The insoluble residue was then leached with 150 ml. of sodium acetate–acetic acid buffer of *p*H 5, filtered, washed with water and acetone and dried at 100°. The yield of this crude material was 6.7 g. (80%). A sample was recrystallized from 150 parts of hot water for analysis and dried at 100°.

*Anal.* Calcd. for $C_6H_7N_4O_3Cl \cdot H_2O$: C, 30.44; H, 3.8. Found: C, 30.85; H, 4.05.

**8-Methylguanine.**—This was prepared by the method of Traube[13] from 2,4-diamino-5-acetamido-6-hydroxypyrimidine.

**Ultraviolet Absorption Spectra.**—The spectra were measured with a Beckman spectrophotometer using solutions containing 10 mg. per liter. For solutions of *p*H 1, 0.1 *N* hydrochloric acid was used; for *p*H 3, 0.001 *N* hydrochloric acid; for *p*H 7, a Sörensen phosphate buffer; for *p*H 11, a glycine–sodium hydroxide buffer.

**Acknowledgment.**—We are indebted to Walter S. Ide and Samuel W. Blackman for the microanalyses reported here.

## Summary

The synthesis of 7,8-dihydroxanthopterin from 2,4 - diamino - 5 - chloroacetamido - 6 - hydroxypyrimidine is reported. This isomer, called β-dihydroxanthopterin, differs from the α-dihydroxanthopterin, which is formed by the reduction of pteridine derivatives, in several chemical properties. It is more resistant to oxidation and more stable to acid but more readily cleaved by alkali than the α-isomer. The significance of these observations in relation to the arrangement of the double bonds in pteridine derivatives is discussed.

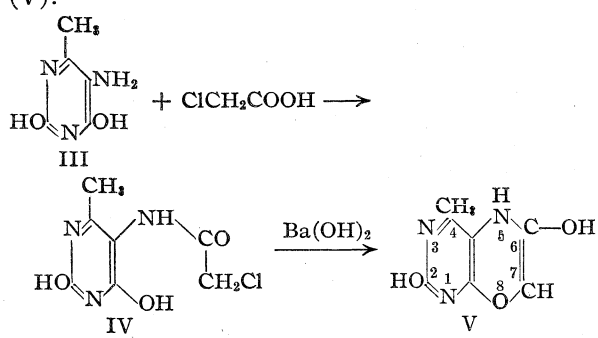
# A New Condensed Pyrimidine System: Some *p*-Oxazino[2,3-*d*]pyrimidines[1]

BY PETER B. RUSSELL, GERTRUDE B. ELION AND GEORGE H. HITCHINGS



The synthesis of a new isomer of dihydroxanthopterin (II) by the ring closure of 5-chloroacetamido-2,4-diamino-6-hydroxypyrimidine (I) with sodium bicarbonate solution has been reported.[2]

I II

During the investigation of methods for closure of the dihydropyrazine ring other alkaline reagents were studied, and barium hydroxide was found to give a product whose ultraviolet absorption spectrum was different from that of I, II or the $\alpha$-dihydroxanthopterin of O'Dell and co-workers.[3] Although this new compound was not isolated in pure form, the possibility that ring closure involving the 6-hydroxyl group had taken place was suggested. By analogy with the formation of 3-hydroxy-[benz-*p*-oxazine][4] from *o*-chloroacetamidophenol by treatment with potassium hydroxide solution, it appeared probable that the product obtained by the action of barium hydroxide on I was a member of the hitherto unknown group of substances, the *p*-oxazino[2,3-*d*]pyrimidines.

In order to eliminate the possibility of pteridine formation, 5-chloroacetamido-6-hydroxypyrimidines were prepared which did not carry amino groups at position 4 and these were heated with aqueous barium hydroxide. After failure to isolate any of the desired compounds from 5-chloroacetamidouracil or from 5-chloroacetamido-2-amino-6-hydroxypyrimidine, an experiment with 5-chloroacetamido-2,6-dihydroxy-4-methylpyrimidine, (IV) produced a colorless, crystalline compound, $C_7H_7O_3N_3$, which was believed to be 2,6-dihydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine (V).

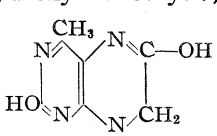
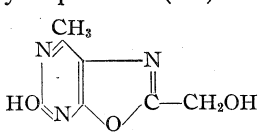
(3) O'Dell, Vandenbelt, Bloom and Pfiffner, *ibid.*, **69**, 250 (1947).

(4) Aschan, *Ber.*, **20**, 1524 (1887).



Similar compounds (VI, VII and VIII) were formed from the 2-amino-, 2-methylamino- and 2-dimethylaminopyrimidines corresponding to IV, and two 4,7-dimethyl-*p*-oxazino[2,3-*d*]pyrimidines, IX and X, were prepared from the appropriate 5-$\alpha$-bromopropionamido derivatives. The reaction failed to occur with the 2-methyl analog of IV or with 5-($\alpha$-chlorophenylacetamido)-4-methyl-2,6-dihydroxypyrimidine.



| | | |
|---|---|---|
| VI | X = $NH_2$ | R = H |
| VII | X = $CH_3NH$ | R = H |
| VIII | X = $(CH_3)_2N$ | R = H |
| IX | X = OH | R = $CH_3$ |
| X | X = $NH_2$ | R = $CH_3$ |

In order to prove the structure of these substances, compound V was chosen for more intensive study. The absorption spectrum of V (Fig. 1) was found to have two bands, one of them in the region usually associated with the pyrimidine ring, the second in the higher wave lengths. Hence, the spectrum was consistent with the formulation of the compound as a condensed pyrimidine system. Hydrolysis of V with concentrated hydrochloric acid at 100° resulted in recovery of the pyrimidine (III) showing that there had been no structural changes in the original pyrimidine nucleus during treatment with barium hydroxide. It also ruled out the possibility that one of the nitrogens of the pyrimidine ring may have been alkylated either inter- or intramolecularly by the chloroacetyl group with a subsequent hydrolysis of the amide linkage or linkages. Hydantoin formation would give a product with the observed empirical composition; however, the pyrimidine-N-acetic acids do not hydantoinize.[5] Moreover, such a pyrimidine-N-acetic acid derivative would not be split to the parent pyrimidine III under the rather mild conditions employed.

Additional evidence in favor of the *p*-oxazinopyrimidine structure was obtained when V was heated with concentrated ammonium hydroxide at 120° in a closed system. The product obtained gave an analysis corresponding to the formula $C_7H_8O_2N_4$ and had an absorption spectrum resembling that of a dihydropteridine (Fig. 2), *cf.* ref. (2). It is therefore considered to be 2,6-dihydroxy-4-methyl-7,8-dihydropteridine(XI).

XI

XII

There remained one further possibility to be

considered before the structure of V could be regarded as unequivocally established, namely, that a hydroxymethyloxazolo[2,3-*d*]pyrimidine of type XII had been formed. The mode of formation,[6] the structural requirements for ring closure,[7] and the physical properties[7] of the two groups of compounds are so widely different as to leave little doubt that this oxazolo structure can be eliminated from consideration here.

In view of the limitations of this method for the synthesis of *p*-oxazinopyrimidines, it was decided to investigate further the mechanism of the ring closure. The oxazines are formed as a result of reaction A, but the low yields indicate that other reactions, of which B and C are the most probable, are competing with it.

The extent to which reaction A proceeds would be expected to depend on the ease of ionization of the 6-hydroxyl group, and the acid strength of this group would be governed by resonance of the type shown

Thus a greater excess of barium hydroxide is necessary to obtain the maximum yield of (VI), X = NH, than is necessary for (V), X = O (Fig. 3). Where X is a group incapable of taking part in resonance of this type (*e. g.*, methyl), the formation of the oxazine would be expected only at com-

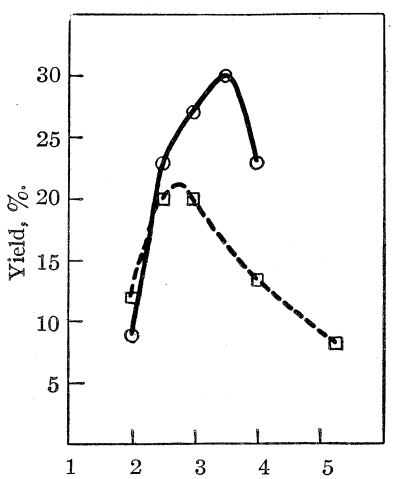

Fig. 3.—Relationship between barium hydroxide concentration and yield of: —⊙—, 2-amino-6-hydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine; - - -⊡- - -, 2,6-dihydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine.

paratively high concentrations of barium hydroxide, conditions which favor reactions B and/or C. This may account for the failure to isolate any *p*-oxazinopyrimidine in the case of 5-chloroacetamido-2,4-dimethyl-6-hydroxypyrimidine. Similar considerations may explain the failure of sodium hydroxide and sodium methoxide to effect ring closure in any of several attempts.

## Experimental

**5-Chloroacetamido-2,6-dihydroxy-4-methylpyrimidine (IV).**—An intimate mixture of 0.5 g. of 5-amino-2,6-dihydroxy-4-methylpyrmidine[8] and 2 g. of chloroacetic acid was heated in a boiling water-bath under vacuum for two hours. The cooled mass was extracted with ether, washed with sodium bicarbonate solution and recrystallized from 50% aqueous ethanol. It formed colorless needles, m. p. 257–258° (dec.), (0.75 g., 98%).

*Anal.* Calcd. for $C_7H_8O_3N_3Cl$: C, 38.6; H, 3.5. Found: C, 38.9; H, 3.7.

**2,6-Dihydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine (V).**—5-Chloroacetamido-2,6-dihydroxy-4-methylpyrimidine (0.5 g.) was heated with 30 ml. of a solution containing 1.12 g. of barium hydroxide hydrate (3 equivs. of $Ba(OH)_2 \cdot 8H_2O$). After about one-half hour a crystalline barium salt separated; heating was continued for another hour. The warm solution was treated with an excess of sodium sulfate, the barium sulfate filtered off and the solution made faintly acidic with acetic acid. On standing, the oxazinopyrimidine separated as colorless prisms (0.10 g., 30%). On crystallization from water, it formed elongated prisms, m. p., 348–349° (dec.).

*Anal.* Calcd. for $C_7H_7O_3N_3$: C, 46.4; H, 3.9; N, 23.2. Found: C, 46.5; H, 3.7; N, 23.5.

**Hydrolysis of V with Hydrochloric Acid.**—One hundred mg. of V was dissolved in 5 ml. of concentrated hydrochloric acid and the solution was heated on the steam-bath for twenty hours. The hydrochloric acid and water were removed by evaporation to dryness several times in an open dish. The residue was dissolved in 2 ml. of water and saturated sodium acetate solution was added until the *p*H was about 7. Slightly yellow plates separated (80 mg.) with a m. p. of 257° (dec.). Mixed with an authentic sample of 5-amino-2,6-dihydroxy-4-methylpyrimidine (m. p., 256–259°), the m. p. was 258–260°. Its absorption spectrum in acid and in alkaline solution was identical with that of 5-amino-2,6-dihydroxy-4-methylpyrimidine.

**Treatment of V with Ammonium Hydroxide.**—One hundred mg. of V was heated in a sealed tube with 10 ml. of concentrated ammonium hydroxide solution at 120° for six hours. The contents were filtered and evaporated to dryness on the steam-bath. The residue was treated with 5 ml. of water and acidified with acetic acid; the solution had a blue fluorescence. The brownish material was filtered off, dissolved in water, treated with carbon and the filtrate was evaporated to dryness. It decomposed at 305–310° without melting.

*Anal.* Calcd. for $C_7H_8O_2N_4$: C, 46.6; H, 4.5; N, 31.1. Found: C, 47.0; H, 4.4; N. 31.2.

**5-α-Bromopropionamido-2,6-dihydroxy-4-methylpyrimidine.**—This was prepared by heating 0.5 g. of 5-amino-2,6-dihydroxy-4-methylpyrimidine with 2.5 g. of α-bromopropionic acid. The product was obtained in almost quantitative yield. It was almost insoluble in hot alcohol. Recrystallized from water it formed colorless needles, m. p. 275–276° (dec.).

*Anal.* Calcd. for $C_8H_{10}O_3N_3Br$: C, 34.9; H, 3.3. Found: C, 35.0; H, 3.3.

**2,6-Dihydroxy-4,7-dimethyl-*p*-oxazino[2,3-*d*]pyrimidine (IX).**—The α-bromopropionamido derivative (0.3 g.) described above was heated with 30 ml. of an aqueous solution of barium hydroxide containing 0.57 g. (3 equiv.) of the hydrate in a boiling water-bath for one and one-half hours. After precipitation of the barium as sulfate, the solution was filtered and acidified with acetic acid. The oxazinopyrimidine crystallized slowly (0.08 g.). When recrystallized from water it formed stout colorless needles, m. p. 338–340° (dec.).

*Anal.* Calcd. for $C_8H_9O_3N_3$: C, 49.2; H, 4.6; N, 21.4. Found: C, 49.3; H, 4.6; N, 21.4.

**5-Benzeneazo-2-amino-6-hydroxy-4-methylpyrimidine.**—Guanidine hydrochloride (19.2 g.) was added to a solution of 44 g. of ethyl benzeneazoacetoacetate[9] in 250 ml. of absolute alcohol. The mixture was stirred while a sodium ethoxide solution (9.2 g. of sodium in 200 ml. of absolute alcohol) was added over three and one-half hours. After the mixture had stood two days at room temperature, the orange solid was filtered off and dissolved in 1 liter of water. The solution was acidified with acetic acid and the precipitate collected. After washing with 1 liter of 5% sodium bicarbonate solution and then with water, it was dried at 100° (30 g.). On recrystallization from pyridine, it formed orange-red prisms, m. p. 274° (dec.).

*Anal.* Calcd. for $C_{11}H_{11}ON_5$: C, 57.6; H, 4.8. Found: C, 57.9; H, 4.8.

**2,5-Diamino-6-hydroxy-4-methylpyrimidine.**—The above azo compound (3.5 g.) was suspended in 100 ml. of 50% aqueous ethanol and reduced catalytically at 60° using a platinum catalyst and two to three atmospheres of hydrogen. Reduction was complete after three hours. The solution was filtered and evaporated to dyness on a steam-bath under diminished pressure. The residue was washed with acetone to remove aniline, and the almost colorless residue recrystallized from water (1.0 g.). The m. p. was 280°. This compound had previously been prepared by Jaeger[10] in poor yield from the corresponding 5-bromo compound and ammonia and reported to have a m. p. of 275°.

*Anal.* Calcd. for $C_5H_8ON_4$: C, 42.9; H, 5.7. Found: C, 43.0; H, 5.8.

**5-Chloroacetamido-2-amino-6-hydroxy-4-methylpyrimidine.**—The above diaminopyrimidine (0.5 g.) was heated with 2 g. of chloroacetic acid in a boiling water-bath under vacuum. After two hours, the mixture was cooled and the excess chloroacetic acid dissolved in ether. The residue was recrystallized from 30% aqueous ethanol and formed colorless needles, m. p. 285–290° (dec.). Yield was 0.73 g., 95%.

*Anal.* Calcd. for $C_7H_9O_2N_4Cl$: C, 38.8; H, 4.2; N, 23.9. Found: C, 38.6; H, 4.6; N, 23.5.

**2-Amino-6-hydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine (VI).**—The above chloroacetamide (0.4 g.) was dissolved in 10 ml. of water and treated with 20 ml. of an aqueous solution of barium hydroxide (1.04 g. of hydrate). The solution was heated in a boiling water-bath for three hours, the barium removed in the usual manner and the filtrate acidified with acetic acid. The small colorless needles (0.15 g.) after recrystallization from water darkened at about 290° but did not melt below 350°.

*Anal.* Calcd. for $C_7H_8O_2N_4 \cdot 2H_2O$: C, 38.9; H. 5.6; N, 25.9; $H_2O$, 16.7. Found: C, 38.5; H, 5.3; N, 26.1; $H_2O$, 17.2 (dried at 120° *in vacuo*).

**Hydrolysis of VI with Hydrochloric Acid.**—The oxazinopyrimidine, V, (150 mg.) was heated with 5 ml. of concentrated hydrochloric acid on the steam-bath for three hours. The mixture was evaporated to dryness in an open dish. The residue was dissolved in 3 ml. of water and neutralized to *p*H about 6.5 by adding a saturated sodium acetate solution dropwise. The precipitate of fine needles was recrystallized from water and dried at 120°. The melting point was 283° (dec.) and was not depressed on admixture with an authentic sample of 2,5-diamino-6-hydroxy-4-methylpyrimidine.

**5-α-Bromopropionamido-2-amino-6-hydroxy-4-methylpyrimidine.**—This was prepared in a similar manner to the 5-chloroacetamido compound. It was very difficult to

crystallize, solutions tending to form gels on cooling. However, a small sample was obtained as needles from 60% aqueous ethanol. It decomposed at about 300°.

*Anal.* Calcd. for $C_8H_{11}O_2N_4Br$: C, 35.1; H, 4.0. Found: C, 34.8; H, 4.2.

**2-Amino-6-hydroxy-4,7-dimethyl-*p*-oxazino[2,3-*d*]-pyrimidine (X).**—One gram of the crude 5-α-bromopropionamido derivative was heated with 50 ml. of barium hydroxide solution (2 g. of hydrate, 3.5 equivs.). The product was isolated in the usual manner. The fine colorless needles (0.35 g.) melt at 299° (dec.).

*Anal.* Calcd. for $C_8H_{10}O_2N_4$: C, 49.5; H, 5.2; N, 28.9. Found: C, 49.3; H, 5.4; N, 28.9.

**5-*p*-Chlorobenzeneazo-2-methylamino-6-hydroxy-4-methylpyrimidine.**—*p*-Chloroaniline (3.2 g.) was dissolved in 60 ml. of *N* hydrochloric acid, diazotized with sodium nitrite solution (2 g. in 10 ml. of water) and 5 g. of sodium bicarbonate was added. The neutralized diazonium solution was added to a solution of 3.5 g. of 2-methylamino-6-hydroxy-4-methylpyrimidine[11] in 500 ml. of water. The solution was allowed to stand for four to five hours, the orange precipitate filtered off, washed well with water and then alcohol and dried at 100° (5.5 g., 80%). After recrystallization from pyridine, the orange prisms melted at 244° (dec.).

*Anal.* Calcd. for $C_{12}H_{12}ON_5Cl$: C, 51.9; H, 4.3. Found: C, 52.2; H, 4.5.

**5-Amino-2-methylamino-6-hydroxy-4-methylpyrimidine.**—The above azo compound (4.5 g.) was suspended in 20 ml. of ethanol and reduced with hydrogen in the presence of platinum catalyst. The solution was filtered from the catalyst and some insoluble yellow material. The residue was washed with alcohol and the combined filtrate and washings were evaporated to dryness. The residue was washed with a mixture of 60 parts ether and 40 parts acetone. Recrystallized from alcohol it formed almost colorless needles (0.94 g.), m. p. 208–210°.

*Anal.* Calcd. for $C_6H_{10}ON_4$: C, 46.8; H, 6.5. Found: C, 46.5; H. 6.2.

With benzoyl chloride in alkaline solution it gave a benzoyl derivative which separated as colorless needles from water, m. p. 289–290° (dec.).

*Anal.* Calcd. for $C_{13}H_{14}O_2N_4 \cdot H_2O$: C, 56.5; H, 5.8. Found: C, 56.3; H, 5.6.

**5-Chloroacetamido-2-methylamino-6-hydroxy-4-methylpyrimidine.**—The above aminopyrimidine (0.75 g.) was heated with 3 g. of chloroacetic acid in a boiling water bath in vacuum for four hours. The product was worked up as usual and recrystallized from water. The colorless needles melt at 227–228° (dec.) (1.05 g.).

*Anal.* Calcd. for $C_8H_{11}O_2N_4Cl$: C, 41.7; H, 4.8. Found: C, 41.8; H, 4.7.

**2-Methylamino-6-hydroxy-4-methyl-*p*-oxazino[2,3-*d*]-pyrimidine (VII).**—Five hundred mg. of the above chloroacetamide was treated in the usual manner with 1.3 g. of barium hydroxide hydrate in 40 ml. of water. The oxazinopyrimidine was isolated as needles (0.145 g., 35%) decomposing at 340–350° without melting. The crystals contained one-half mole of water of crystallization which was lost at 120° *in vacuo*.

*Anal.* Calcd. for $C_8H_{10}O_2N_4 \cdot {}^1/_2H_2O$: C, 46.3; H, 5.4; N, 27.6. Found: C, 46.3; H, 5.2; N, 27.6. Calcd. for $C_8H_{10}O_2N_4$: C, 49.5; H, 5.2. Found: C, 49.1; H, 5.2.

**2-Dimethylamino-6-hydroxy-4-methylpyrimidine.**—2-Ethylmercapto-4-methyl-6-hydroxypyrimidine[12] (10 g.) was heated with 30 g. of a 33% ethanolic solution of dimethylamine in a sealed tube at 100° overnight. The mixture was evaporated to dryness in an open dish and the residue extracted with ether containing sufficient acetic acid to render the solution faintly acidic. The ethereal solution was filtered, concentrated to about 50 ml., and an equal volume of petroleum ether (b. p. 30–60°) was added. The first crop of needles which separated was slightly purple but successive crops were white, m. p. 106°, yield 9.4 g.

*Anal.* Calcd. for $C_7H_{11}ON_3$: C, 55.0; H, 7.2. Found: C, 55.4; H, 7.2.

**5-Benzeneazo-2-dimethylamino-6-hydroxy-4-methylpyrimidine.**—A solution of 2.6 g. of *p*-chloroaniline in 50 ml. of *N* hydrochloric acid was diazotized with 1.4 g. of sodium nitrite and neutralized with 4.5 g. of sodium bicarbonate. This diazonium solution was added to a solution of 7 g. of the above pyrimidine in 300 ml. of water and the *p*H adjusted to 7 with sodium carbonate. The orange precipitate which separated was filtered off after two hours, washed well with water and dried at 100° (2.3 g.). Recrystallized from pyridine, it formed orange-red prisms, m. p. 217°.

*Anal.* Calcd. for $C_{13}H_{14}ON_5Cl$: C, 53.6; H, 4.0. Found: C, 53.9; H, 4.4.

**5-Amino-2-dimethylamino-6-hydroxy-4-methylpyrimidine.**—The above azo compound (10 g.) in 30 ml. of ethanol was reduced catalytically in two hours using a platinum catalyst at 60°. The catalyst and a small amount of insoluble yellow material was removed by filtration. The mother liquors were concentrated to about 20 ml. and 40 ml. of ether added. The product separated in glistening prisms (4.5 g.) and was reprecipitated from 10 ml. of ethanol by the addition of 30 ml. of ether, m. p. 204–205°.

*Anal.* Calcd. for $C_7H_{12}ON_4$: C, 50.0; H, 7.2. Found: C, 50.2; H, 7.0.

**5-Chloroacetamido-2-dimethylamino-6-hydroxy-4-methylpyrimidine.**—The above aminopyrimidine (0.5 g.) was heated with 2 g. of chloroacetic acid in a boiling water-bath under vacuum. The product was isolated in the usual manner (0.6 g.) and recrystallized from water. The needles melt at 258°.

*Anal.* Calcd. for $C_9H_{13}O_2N_4Cl$: C, 44.3; H, 5.3. Found: C, 44.7; H, 5.7.

**2-Dimethylamino-6-hydroxy-4-methyl-*p*-oxazino[2,3-*d*]pyrimidine.**—The above chloroacetamide (0.3 g.) was heated with 30 ml. of a solution of barium hydroxide (0.63 g. of hydrate, 3.5 equivs.) for two and one-half hours in a boiling water-bath. The product was isolated in the usual manner: white needles, m. p. 311–312° (dec.), yield 0.15 g. On heating in the melting point tube it sublimed at 220–250°, forming fine colorless needles.

*Anal.* Calcd. for $C_9H_{12}O_2N_4$: C, 52.0; H, 5.8. Found: C, 52.0; H, 5.5.

**5-*p*-Chlorobenzeneazo-2,6-dihydroxy-4-phenylpyrimidine.**—One gram of 4-phenyluracil[13] in 2 liters of water was treated with a diazonium solution prepared from 0.6 g. of *p*-chloroaniline in 12 ml. of *N* hydrochloric acid diazotized with 0.4 g. of sodium nitrite and neutralized with 1 g. of sodium bicarbonate. After standing one hour the yellow precipitate was filtered off and washed with water and methanol (0.65 g.). Several recrystallizations from pyridine produced orange-red prisms, m. p. 240° (dec.). Because of the low solubility of 4-phenyluracil and the resultant poor yield of this coupling reaction, the reduction of the azo compound to the corresponding 5-amino compound was abandoned.

*Anal.* Calcd. for $C_{16}H_{11}O_2N_4Cl$: C, 59.1; H, 3.4. Found: C, 59.4; H, 3.5.

**Effect of Concentration of Alkali on the Yield of *p*-Oxazinopyrimidines.**—The chloroacetamidopyrimidines (0.5 g.) were heated with a solution of the required amount of barium hydroxide hydrate in 25 ml. of water in a boiling-water-bath for one and one-half hours. The mixture was then treated with a 10% excess of sodium sulfate, warmed to coagulate the barium sulfate and filtered. The solution was adjusted to *p*H 5–6 with acetic acid and allowed to stand sixteen hours. The crystalline material was collected, washed well with water, then with ethanol and air dried. The dry material was weighed, allowance being

made for any combined water of crystallization in calculations of yield. Results are reported in Fig. 3.

**Acknowledgment.**—We are indebted to Samuel W. Blackman for the microanalyses which are reported here.

## Summary

The formation of *p*-oxazino[2,3-*d*]pyrimidine derivatives from 6-hydroxy-5-α-chloroacylamidopyrimidines by treatment with aqueous barium hydroxide solution is described. This ring closure has been found to be dependent on the nature of the substituent in the 2-position of the pyrimidine ring.

# Substituted-Amino Ketones and Alcohols Related to 4,4′-Dichlorobenzoin[1]

BY ROBERT E. LUTZ AND ROBERT S. MURPHEY[2]

In the light of evidence for the necrotizing action against mammalian tumors of several substituted-amino ketones and alcohols derived from benzoin,[3] it seemed worth while to investigate analogous compounds carrying in one or both phenyl nuclei substituents which might have the effect of enhancing the pharmacological activity. The present paper is the first of a series dealing with this phase of the problem. The 4,4′-dichloro series was chosen for study because of the well-known influence of halogen in increasing other types of pharmacological activity such as antimalarial and insecticidal.

The starting material, 4,4′-dichlorobenzoin (I),[4] has to date been obtainable only in poor yields by the benzoin condensation with *p*-chlorobenzaldehyde. By modification of the procedure developed by Willgerodt and Ucke[5] for the preparation of 4,4′-diiodobenzoin, the dichloro analog has been obtained consistently in yields of 80–88%. It is noteworthy that this product is exceptionally easily oxidized to 4,4′-dichlorobenzil upon manipulation involving contact with air.

The secondary amino ketones (II, see table) were made by the action of primary amines on 4,4′-dichlorobenzoin (the Voigt reaction[3,6]). In most runs phosphorus pentoxide was used as a catalyst; however, in one test using ethanolamine, an equally successful preparation resulted when the catalyst was omitted. All of the products were stable as the salts; however, in the form of the bases they underwent ready hydrolysis and oxidation to 4,4′-dichlorobenzil. Only one arylamino ketone, but none of the alkylamino ketones, was obtainable as a crystalline free base.

The amino ketones were reduced by means of aluminum isopropoxide to the amino alcohols (IV). Since only one of the two theoretically possible stereoisomers was isolated in each case, it is to be presumed that the configurations are of the same type (Type-A "erythro") and are analogous to those of the majority of the compounds prepared correspondingly in the parent benzoin series.[3] This presumption is supported by the synthesis of one of these (REL 691) through the *trans*-*p*,*p*′-dichlorostilbene oxide (see below).

4,4′-Dichlorodesyl chloride[4d] (III) was readily made by the action of thionyl chloride on 4,4′-dichlorobenzoin, but in poor yields (*ca.* 33%). It proved to be unstable and exceptionally easily converted into 4,4′-dichlorobenzil under various manipulations in contact with air.

Representative tertiary-amino ketones (V) were made by condensation of 4,4′-dichlorodesyl chloride (III) with the appropriate amine. These were reduced to the amino alcohols (VI) by means of aluminum isopropoxide. Since here also only one of the two possible diastereoisomers was obtained in each case, these compounds are presumed to be of the type-A ("erythro") configuration.

Two ethanolamino ketones were made. The monoethanolamino compound itself (II, R = $CH_2CH_2OH$) was made by the Voigt reaction from 4,4′-dichlorobenzoin, and was readily re-

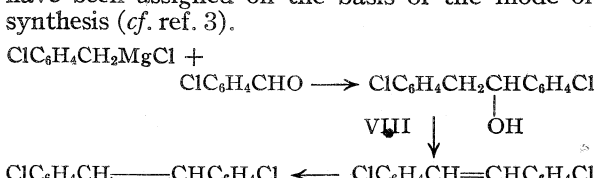
[a] Code number from this Laboratory. [b] See descriptions in the experimental part. [c] But. = butanone, EtOH = 95% ethanol, acet. = acetone, ligr. = ligroin, $Et_2O$ = ethyl ether. [d] Prepared by James A. Freek. [e] Calcd. for N, 3.76; found, 3.58. [f] Calcd. for N, 3.60; found, 3.63. [g] The base melts at 80–81° *in vacuo*. It was not analyzed. [h] The base was liberated from the pure salt by means of alkali and was isolated by extraction with ether and evaporation of the solvent. It was not distilled. [i] This product gave no mixture melting point depression with the first sample. [j] Unsuccessful attempts were made to prepare this compound through reduction of 4,4′-dichlorobenzil monoxime by stannous chloride and by sodium–alcohol reductions, and to prepare the stereoisomer by condensation of *p*-chlorobenzaldehyde with glycine [*cf.* Erlenmeyer, *Ann.*, **307**, 97 (1899)]. [k] Crystallized from acetone–methanol–isoöctane mixture.



duced by aluminum isopropoxide to the di-alcohol (IV, R = $CH_2CH_2OH$). The ethylethanolamino analog (V, $NR_2$ = $N(C_2H_5)CH_2CH_2OH$), however, evidently has the cyclic structure (VII) since it is not reduced to a significant extent by aluminum isopropoxide under the conditions usually effective.[7]

VII

The corresponding tertiary-amino dialcohol (VI, $NR_2$ = $N(C_2H_5)CH_2CH_2OH$), and also the ethanolamino analog (IV, R = $CH_2CH_2OH$) and the parent amino compound (VI, $NR_2$ = $NH_2$), were successfully made by condensation of *trans*-4,4′-dichlorostilbene oxide (IX) with ethylethanolamine, ethanolamine and ammonia, respectively. The type A ("erythro") configurations are assumed in view of this mode of synthesis.

The *trans*-oxide, used above, was made from *trans*-4,4′-dichlorostilbene (X, known[8]) which has been obtained in a new and improved way by the action of *p*-chlorobenzylmagnesium chloride on *p*-chlorobenzaldehyde and dehydration of the resulting carbinol (VIII). The *trans* configurations have been assigned on the basis of the mode of synthesis (*cf.* ref. 3).

Chem. Soc.*, 333 (1946); (e) Meerwein, Büchner and van Emster, *J. prakt. Chem.*, **157**, 237 (1939).

The *p*-diethylaminoanilino ketone hydrochloride [IV, R = $NHC_6H_4N(C_2H_5)_2$-*p*] was made in order to test the influence of an extra basic group. In the form of the free base this compound was extremely unstable; the salt, although relatively much more stable, deteriorated to a red resinous mass on standing in the air. The compound was reduced by means of aluminum isopropoxide to the corresponding alcohol which in contrast proved to be stable in the form of the free base.

The results of pharmacological tests, especially those dealing with tumor necrosis, which are in progress at the National Cancer Institute, will be reported elsewhere.[9]

## Experimental[10]

**The Preparation of 4,4′-Dichlorobenzoin (I).**[4]—Due apparently to the low melting point and high solubility in ethanol, this compound separated as an oil under the usual conditions of the benzoin condensation.[11] For the best results it was important to remove all unreacted *p*-chlorobenzaldehyde. It was advantageous to diminish the reaction time in order to minimize side reactions such as oxidation of the desired product to the corresponding benzil. The compound crystallized well only from petroleum ether.

A saturated aqueous solution of 5 g. of a pure grade of potassium cyanide was added slowly to a refluxing solution of 500 g. of freshly distilled *p*-chlorobenzaldehyde in 300 ml. of methanol. A strongly exothermic reaction ensued. The mixture was refluxed for twenty minutes, and the methanol was evaporated under reduced pressure. The residual red, pasty mass was taken up in benzene. The benzene solution was extracted repeatedly with 20% sodium bisulfite until the extract liberated no aldehyde when treated with alkali; the solution was then washed with water and evaporated under reduced pressure. The residue crystallized as fine, colorless needles from petroleum of boiling range 70–110°; yield 440 g. (88%). After several recrystallizations it melted at 87–88°.[4a,c,d] On standing in air the surface of the white benzoin becomes coated with the yellow benzil.

*Anal.* Calcd. for $C_{14}H_{10}Cl_2O_2$: C, 59.80; H, 3.58. Found: C, 59.61; H, 3.34.

**4,4′-Dichlorodesyl Chloride (III).**—A solution of 140.5 g. (0.5 mole) of 4,4′-dichlorobenzoin in 50 g. of pyridine at 5° was treated dropwise under cooling with 75 g. (0.63 mole) of thionyl chloride. The resulting viscous yellow mixture was extracted repeatedly with cold water until the test for chloride ion was negative, and was then extracted with petroleum ether to remove unchanged 4,4′-dichlorobenzoin; the product was crystallized from 95% ethanol, yield 53.3 g. (36%), colorless needles of melting point 60–61°.

*Anal.* Calcd. for $C_{14}H_{9}Cl_3O$: C, 56.12; H, 3.03. Found: C, 55.29; H, 2.96.

**4,4′-Dichlorobenzil monoxime** was made from 4,4′-dichlorobenzil by the procedure for the 4,4′-dibromo analog,[12] yield 90%, crystallized from dilute ethanol, m.p. 143–144°.

*Anal.* Calcd. for $C_{14}H_9Cl_2NO_2$: N, 4.76. Found: N, 4.50.

**1,2-Di-(4-chlorophenyl)-ethanol (VIII).**—A solution of 119 g. (0.848 mole) of *p*-chlorobenzaldehyde in 800 ml. of ether was added slowly under stirring to 4-chlorobenzylmagnesium chloride in 700 ml. of ether [made from 154 g. (0.956 mole) of 4-chlorobenzyl chloride and 46 g. (1.89 mole) of magnesium]; the mixture was heated for one hour, hydrolyzed with dilute acetic acid, washed with sodium hydroxide and then with sodium bisulfite, and was concentrated. The residual oil crystallized and the crude product was used in the next experiment. A small sample was recrystallized from isoöctane, hexagonal plates, m.p. 74–75°.

*Anal.* Calcd. for $C_{14}H_{12}Cl_2O$: C, 62.94; H, 4.53. Found: C, 62.99; H, 4.96.

***trans*-4,4′-Dichlorostilbene (X).**[8]—The crude alcohol (VIII) (above) was heated with 1 ml. of 48% hydrobromic acid at 230° for twenty minutes (evolution of water had ceased), and the product was distilled at 215–230° under 10 mm., yield 161 g. After two crystallizations from toluene the yield was 120 g. (57% calculated from VIII), m.p. 175–176°. *Anal.* Calcd. for C, 67.49; H, 4.05. Found: C, 67.55; H, 3.79.

***trans*-4,4′-Dichlorostilbene Oxide (IX).**—A solution of 93.5 g. of X in 3 liters of xylene was added to a solution of 83 g. of perbenzoic acid in 1.1 liters of chloroform. The mixture was allowed to stand for twenty-four hours at room temperature and five hours at 60°. (The reaction was very slow; a number of other solvents were tried but without improvement.) Evaporation to a volume of about 1.5 liters under reduced pressure, washing with sodium hydroxide, drying over sodium sulfate and evaporation of the rest of the solvent, and crystallization of the residual oil from ethanol, gave colorless needles, 50 g. (50%), m.p. 114–115.5°. Treatment in acetone with permanganate to remove unchanged X gave a product melting at 123–124°.

*Anal.* Calcd. for $C_{14}H_{10}Cl_2O$: C, 63.42; H, 3.80. Found: C, 63.41; H, 4.10.

**General Procedures. (1) The Preparation of the Secondary Amino Ketones from 4,4′-Dichlorobenzoin.**—A mixture of 0.25 mole of the benzoin, 0.27 mole of the primary amine and 2 g. of phosphorus pentoxide was heated on a water-bath. (a) When no solvent was used the water formed in the reaction was not removed. (b) When benzene was used as solvent the water formed in the reaction was removed by distillation of the azeotrope; and heating was continued until further distillation failed to give evidence of further formation of water in the reaction. In this case the solvent was removed under diminished pressure before working up the product. (c) In several experiments the amine and catalyst were added to the molten benzoin, and no further heat was applied. (d) In one experiment the catalyst was omitted. The amine was added to the benzoin which had been melted and brought to 110°. Without the application of heat the temperature of the mixture dropped to 85°, and upon slight shaking to mix the materials, it rose sharply to 112°. The mixture was allowed to cool slowly to room temperature and was worked up in the usual way.

α-Anilino-4,4′-dichlorodesoxybenzoin was purified as the base, and the hydrochloride was obtained in the usual way.

In the preparation of the α-monobutylamino-4,4′-dichlorodesoxybenzoin the reaction product was taken up in ether, the unreacted amine was extracted by water, the ether solution was dried over sodium sulfate, and the amino ketone salt was precipitated by the addition of ethereal hydrogen chloride. The corresponding octylamino ketone was purified by removing the unreacted amine under diminished pressure and obtaining the hydrochloride as in the case of the butylamino compound.

**(2) Preparation of the Tertiary-Amino Ketones from 4,4′-Dichlorodesylchloride.**—The α-diethylamino-4,4′-dichlorodesoxybenzoin (V) was prepared by allowing a mixture of 0.4 mole of diethylamine and 0.2 mole of 4,4′-dichlorodesyl chloride (III) to stand at room temperature, with exclusion of air, for the period of time stated in the table. The reaction mixture was dissolved in ether, and the unreacted diethylamine was extracted from this solution by water. The ether solution was dried over

(12) Biltz, *Ber.*, **43**, 1815 (1910).

sodium sulfate and the amino ketone hydrochloride was precipitated by the addition of ethereal hydrogen chloride, yield 59%.

It was observed that the amino ketones were sensitive compounds and in several experiments the yields were very poor. The diethylamino compound, for example, suffered decomposition with the formation of appreciable amounts of 4,4′-dichlorobenzil. Each successive crystallization of the hydrochloride of this amino ketone from the methanol–butanone mixture involved the formation of significant amounts of 4,4′-dichlorobenzil which was difficultly soluble in the solvent and crystallized out during the manipulation.

In one preliminary experiment V was obtained in only 26% yield upon heating a solution of 0.2 mole of III and 0.424 mole of diethylamine in benzene on the water-bath without the precaution of excluding air.

**(3) Preparation of the 1,2-Di-(4-chlorophenyl)-N-substituted-ethanolamines by Reduction of Amino Ketones.**—The amino ketones prepared as above were reduced to the corresponding alcohols (IV and VI) in the usual way by means of an excess of 1.5 *N* aluminum isopropoxide. The butylamino and octylamino alcohols were purified as the free bases, while all the other amino alcohols were purified as the hydrochlorides.

**(4) The Preparation from 4,4′-Dichlorostilbene Oxide.**—A mixture of X and a large excess of the amine was heated at (a) 130° and (b) 150°, respectively, taken up in (c) benzene or (d) ether, washed with water to remove excess amine, dried over sodium sulfate, and treated with ethereal hydrogen chloride to precipitate the salt. (e) The condensation using 28% concd. aqueous ammonium hydroxide in dioxane as solvent (sealed tube) was at 100°.

## Summary

An improved preparation of 4,4′-dichloro-benzoin and 1,2-di-(4-chlorophenyl)-ethanol, and the syntheses of 4,4′-dichlorodesyl chloride, *trans*-4,4′-dichlorostilbene and 4,4′-dichlorostilbene oxide, are described.

From these compounds a series of secondary and tertiary-amino desoxybenzoins and the corresponding amino and substituted-amino alcohols, have been prepared.

Resistance to aluminum isopropoxide reduction of the ethylethanolamino ketone as contrasted with the facile reduction of the monoethanolamino analog, indicates a cyclic hemiacetal structure for the former.

# Polymerization. IX. Metalation during Alfin Polymerization of Butadiene and the Formation of Gel[1]

BY AVERY A. MORTON, RICHARD P. WELCHER,[2] FRANCES COLLINS, SIEGFRIED E. PENNER AND ROBERT D. COOMBS

The previous paper[3] showed that metalation of rubber caused gel to form in proportion to the metalating activity, and the paper[4] before that showed that an Alfin[5] catalyst was a poorer metalating agent than the allylsodium component of the catalyst. It seemed likely, therefore, that the amount of gel formed during Alfin polymerization would have a direct connection with the lack of correct proportioning of alkoxide with alkenylsodium, or, in the absence of a specific combination, would have a connection with the quantity of catalyst in excess of that needed for polymerization. In either event the relation would be expressed by the rule that minimum gel would accompany maximum polymerizing activity. The idea of a specific combination has been confirmed with two moderately active catalysts and that of quantity with an extremely active catalyst that is less sensitive to proportioning.

The first catalyst ($PB_1$)[5] was made from sodium isopropoxide and 1-butenylsodium. Two series of reagents, A and B, were used. A was made by combining the two components after each had stood for some time. Figure 1 shows clearly that in four separate trials during a period of over two months the peak of activity (with reagent no. 4) was also the one with minimum gel. B was made by mixing immediately after preparing the two components separately. Figure 2 shows again the relationship but only after the catalyst had aged for some time (test no. 3). The aging process (in B) unquestionably would have been accelerated if the mixing had been done in the high-speed stirring apparatus. Figure 3 confirms this action of the B series with a mixture of butadiene and isoprene, the latter being added to slow down the action, erase part of the gel formation (isoprene[5] forms little or no gel when polymerized) and bring out the action more distinctly. The particular proportions for maximum activity with A and B have no significance since particle size of the two components was probably not the same. The method of combination was not ideal, but was chosen because it permitted proportioning from stock preparations of the two components. The total amount of each present, therefore, has less significance than the composition of the available surface.

The second catalyst was made from sodium phenylmethyl carboxide and allylsodium and a

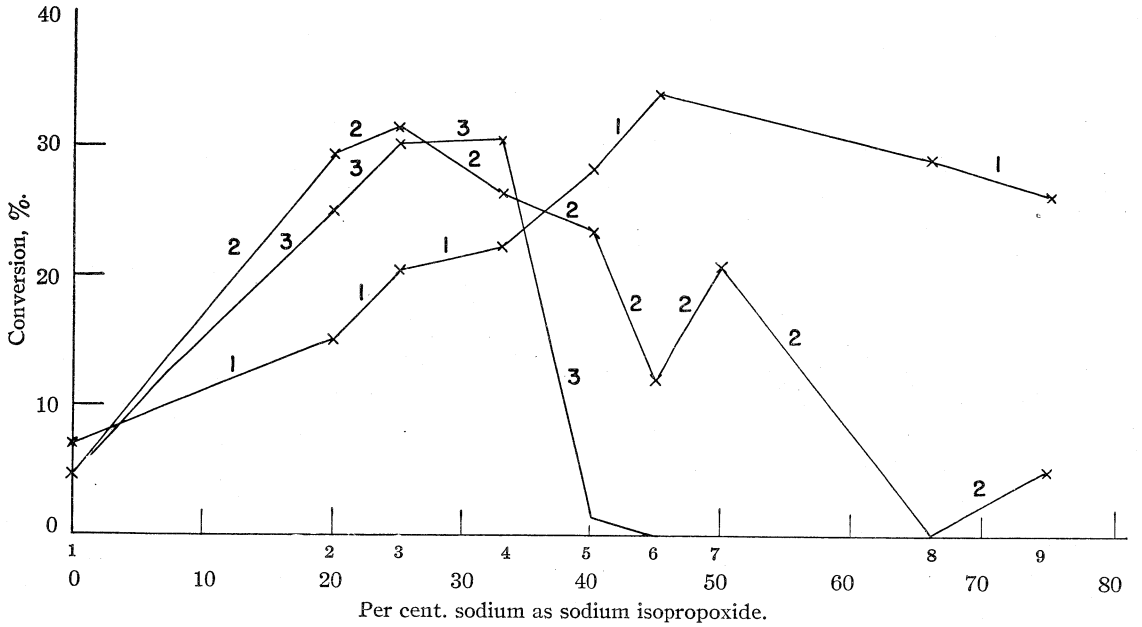
Fig. 1.—Polymerization of butadiene by $PB_1$ catalyst, series A.

different method was used to adjust the proportions. In the first preparation, C, phenylmethylcarbinol was allowed to react with part of the amylsodium, after which propylene was added to the remainder, so that allylsodium was prepared in the presence of the alkoxide and combination occurred before either component had much chance to agglomerate. This method is the one usually employed for making Alfin catalysts but is less suitable for proportioning the components because of variations in the yields of amylsodium. The product, C, gave good conversion with very low gel (see Table I). D was a similar preparation, the initial behavior of which was clearly similar to those of A and B that had high proportions of alkoxide. Accordingly two small portions of allylsodium, each equal to approximately one-twentieth of the allylsodium originally present, were added, each time with vigorous stirring, and allowed to age for a short or moderate time. A point of maximum activity and zero gel was thus reached (see Table I).



The third catalyst (PP) was from sodium isopropoxide and allylsodium. This pair had extraordinarily high activity, did not lose activity in the presence of excess alkoxide (as do the other two) and gave a product of very high intrinsic viscosity which unquestionably increased the tendency to form gel. The usual percentage of gel from such a catalyst is around 60 to 90. Just once out of well over two hundred preparations of catalyst was one obtained that produced, by bottle polymerization, a rubber with gel as low as 23%. When, however, the quantity of catalyst was reduced to one-fourth, the percentage of gel fell. Values below 20%, some as low as 2%, became

common. Conversions, on the other hand, remained high, some as high as 70%. The efficiency was obviously higher and the percentage of gel was lower.

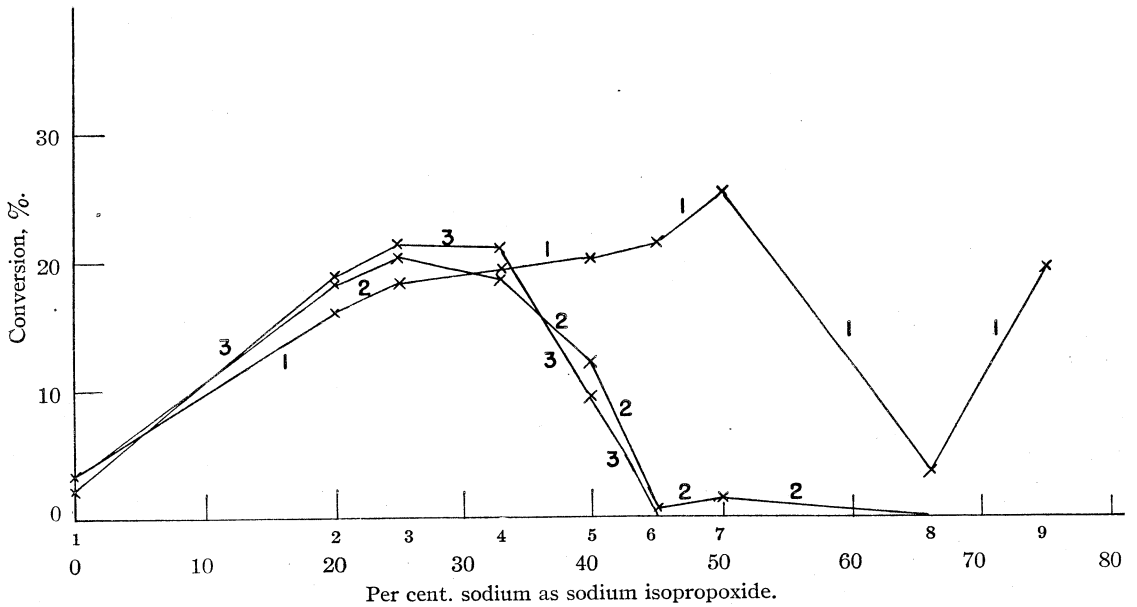
The authors are indebted to Christiana Clapp and Jeanne Kilduff for valuable technical assistance and determination of the constants of the polymers.

## Experiments

**General Methods.**—The operations of preparing amylsodium, metalating the olefins, and polymerizing the dienes have now become routine. The description below will suffice for this paper and others to come, the small variations introduced by each operator having been found to have little effect that exceeds the variation necessarily imposed on any reaction where the reagents are in different phases.

The amylsodium necessary for metalation of the olefins was prepared by drop-wise addition at −10° of 63 ml. (0.5 + mole) of amyl chloride on 23 g. of sodium sand in 500 ml. of pentane under an atmosphere of nitrogen in the high-speed stirring apparatus[6] in the usual manner as described in a previous publication.[5] This size preparation is referred to hereafter as the standard. Larger preparations were made with proportionately larger amounts. They are referred to as two or three times the standard, depending on the amount.

Allylsodium was prepared by bubbling propylene (Phillips Petroleum Company, pure grade) into the amylsodium suspension at 10° to room temperature and with high-speed stirring for about five hours. 1-Butynylsodium was made by addition of 1-butene at −10° to amylsodium. The temperature was then allowed to rise gradually over a one and a half to three and a half hour period to around 20°. Two additions of 60 ml. of 1-butene each per standard batch (total 120 ml.) were thus made in the preparation of Series A reagents; and a single addition of 120 ml. per twice the standard batch was made in preparing the Series B reagents. All reaction mixtures were allowed to stand overnight to complete the metalation.



If metalation of the olefin was to be carried out in the presence of an alkoxide, the alcohol was added to the reaction mixture at 0° just before addition of the olefin. The time needed for metalation of the olefin in the presence of alkoxide was only about half that in the absence of alkoxide. The common practice, however, was to allow all such reaction mixtures to stand overnight.

The alkoxide for the stock solutions was prepared by addition of alcohol to amylsodium. This method probably ensured the same state of subdivision that was present in the alkenylsodium suspension, although this precaution might have been unnecessary.

All preparations were transferred from the reaction flask to glass bottles through a siphon tube under pressure of nitrogen. The glass bottle, used for storage, was a common narrow-mouth 500-ml. container, roughly calibrated, which had previously been rinsed with dry pentane and flushed with dry nitrogen. After the contents were transferred to the bottle together with the pentane rinsings from the reaction flask, more pentane was added to bring the volume to a desired amount, the bottle was stoppered with a well rolled cork stopper, and the top covered with a glyptal resin spread. The contents were well shaken, and the mixture set aside until needed. These suspensions settled very little. Some have kept for months without clarifying at the top more than one-quarter inch out of a total height of about 4 in. No appreciable sediment collected in the bottom. The stock preparations were handled in the same way except for proportionately larger bottles.

Before removal of an aliquot portion for compounding or for a polymerization, the bottle was shaken vigorously by

Fig. 3.—Polymerization of mixture of 25 parts isoprene and 75 parts butadiene by $PB_1$ catalyst, Series B.

hand. The suspension was then transferred through a siphon tube under nitrogen pressure into the new container or into a transfer tube, if for a polymerization. These transfer tubes, if for 20 ml. or more of suspension, were graduated tubes of about 12 mm. diameter, with a stopcock large enough to permit rapid draining, a size as large as 8 mm. i. d. being preferred. Later, as 5 ml. were used in the tests, the exclusion of traces of moisture became necessary. The tube and siphon was therefore replaced by a two-holed stopper carrying a nitrogen inlet tube and a small pipet, the lower end of which was not constricted. Rapid drainage was thus insured. The suspension was forced into this pipet by nitrogen pressure, the suspension allowed to drain back, and then forced up again to the graduated mark, after which the aliquot part was transferred quickly to the reaction vessel.

The butadiene (Phillips research grade) was condensed in a 28 × 4 cm. test-tube cooled to −72° from which it was poured through a dry cotton plug in a funnel into a graduated dropping funnel. The dry cotton removed a little cloudiness in the liquid butadiene. The diene, which was by that time at a temperature just below its boiling point, was admitted rapidly to the bottle.

Later, as 5 ml. of catalyst was used, and the need for more careful exclusion of water became apparent, the end of the line that led the butadiene into the large test-tube was fitted with a one in. sintered glass disc, the butadiene was collected over anhydrous magnesium sulfate, and was then transferred to the dispensing pipet by pressure of dry gas that forced the butadiene through the sintered glass filter. The dispensing pipet was an ordinary graduated dropping funnel fitted with a three-way stopcock at the bottom and a nitrogen inlet at the top. This stopcock permitted removal of excess butadiene in order to adjust the volume without passing the cold liquid through the delivery tube with consequent condensation of moisture on that member. After delivery of butadiene from the pipet to the reaction bottle, a stream of dry nitrogen was passed through the pipet and delivery tube so that no moisture condensed on the inside of the tube.

Isoprene (Phillips research grade) was freshly distilled and poured from the container as desired.

The polymerization vessel was a 12-oz. soft drink bottle. The order of admission of all components used was 180 ml. of pentane, especially dried with amylsodium (see under PP catalyst) when 5 ml. of catalyst was used, dry nitrogen, catalyst, and butadiene. The bottle was promptly capped, and shaken vigorously by hand for about thirty seconds in order to disperse the catalyst in the medium. The bottle was then transferred to an air-pump shaking machine[7] for moderate agitation. When the desired period (30 min. unless otherwise stated) for polymerizing was over, the bottle was removed, and, in case the mixture had warmed a little, cooled under the water tap for a minute—included in the time of polymerization—then opened with the bottle inverted and so placed that the contents would be blown out by the pressure of unused butadiene into a 2-liter beaker. This blowing-out process was slow and gradual if the polymerization was 70 to 80% complete, and was violent if around 20%. For polymerizations 90% or better the contents were pulled out of the bottle with forceps.

The heat evolved in these reactions was scarcely noticeable to the hand unless the polymerization was 50% or more complete. Above that amount the bottle became warm but not hot. The relatively large volume of solvent used, and the heat of vaporization of pentane inside the bottle apparently kept the temperature within bounds. If a preliminary test showed that a reaction went too fast the quantity of catalyst was reduced. A close regulation of temperature was not deemed essential at this stage of the work where the nature of the several catalysts, their

(7) Morton, *Ind. Eng. Chem., Anal. Ed.*, **6**, 469 (1934).

characteristics and polymerizing activities were being surveyed. An increase in temperature from increased conversion would magnify the greater polymerizing activity shown by a particular catalyst, but in the range studied did not increase the proportion of gel that was formed, and possibly caused only a slight decrease in gel. This point will be clearly seen in the experiments reported for the sodium methylphenyl carboxide and allylsodium pair in which 20, 40 and 60 ml. of catalyst suspension, caused 35, 75 and 82% conversion to products that had 5, 2 and 0% gel, respectively, all with about the same intrinsic viscosity. Such small differences in gel are not regarded at this time as having any real significance.

The 2-liter beaker contained about 500 ml. of petroleum ether, 10 ml. of methanol to destroy the catalyst and 1 to 10 ml. of a reagent ether solution of N-phenyl-β-naphthylamine (PBN), the amount being so varied that the quantity of antioxidant would be 2% of the expected polymer. This mixture was usually allowed to stand overnight in order to soften the rubber gel a little, or the rubber gel was removed, cut into chunks, put into a meat chopper with solid carbon dioxide and cut into small bits in order to hasten the process. The rubber was then stirred mechanically in petroleum ether for five minutes with about 200 ml. of distilled water, more pentane being added in order to get the rubber into solution or homogeneous dispersion. The lower aqueous layer was removed by a siphon and the washing with stirring repeated with another 200 ml. of distilled water. This operation had to be repeated about three or four times before the wash water was neutral to litmus and free from chloride ion. The final pentane solution was milky with scarcely any solid particles if the polymer was free from gel but contained small particles of suspended matter if the gel were high.

An aliquot portion sufficient to contain two grams of rubber in the pentane solute was removed for analysis of intrinsic viscosity and gel. The solvent was removed first at room temperature by a water pump and then overnight by an oil pump, at a temperature not exceeding 40°. The remainder was evaporated on the steam-bath and then in the vacuum oven at room temperature in order to determine the percentage conversion.

Intrinsic viscosities and gels were determined by the method employed[8] by Rubber Reserve Co. on 0.2 g. of the polymer. This method was not developed for polymers that had such high intrinsic viscosities as did some of the products from Alfin polymerization. Use of 0.1 g. of material frequently gave more consistent results.

**$PB_1$ Catalyst** (by R. P. W.).—For Series A the stock suspension of butenylsodium was made by combining three standard preparations as described before. The stock suspension of sodium isopropoxide was also made by combining three lots each obtained by addition of 26 g. of isopropyl alcohol to a standard preparation of amylsodium. For Series B the stock reagents were prepared in single batches, each twice the size of the standard one. Enough pentane was added to each suspension to make the mixture reasonably fluid. The final volumes of the Series A stock solutions were 3600 and 2400 ml. respectively for 1-butenylsodium and sodium isopropoxides and for the corresponding pair of Series B reagents were 2400 and 1600 ml. The estimated amount of 1-butenylsodium per ml. in each preparation was 0.00033 mole and the known amount of sodium isopropoxide was 0.0005 mole.

A better knowledge of the concentration of the components in each stock preparation was unnecessary and probably without significance. The stock reagents differ in their state of aggregation, and the combination to form the catalyst makes a third insoluble product besides the various aggregates in which occlusion of one or another component occurs. Analysis of organosodium reagents is difficult even in the case of soluble compounds—Conant[9] and McEwen[10] claim only 10–15% accuracy in their studies of ether-soluble reagents—and for the case of even more reactive reagents in an insoluble medium, it is much more difficult. For these tests the object was to prepare enough reagents to cover a wide range, and to compound and test them under as uniform conditions as possible and to make enough tests of each reagent over long enough periods of time to insure that a relatively constant state of reactivity has been attained.

As a first approximation, this compounding was done on the assumption that an 80% yield of amylsodium had been obtained and that the conversion to butenylsodium had been quantitative; and the mole percentages of sodium isopropoxide from this reckoning were used as the abscissas in Fig. 1. Had the estimate been correct and had there been no occlusion, all reagents to the left of no. 5 inclusive would have had the same amount of catalyst but would have had increasing amounts of butenylsodium except, of course, reagent no. 1 which contained no isopropoxide. Correspondingly, all reagents to the right of number 5 inclusive would have had a constant amount of catalyst but would have contained increasingly large amounts of isopropoxide. Of the eight reagents prepared, the graph shows that number four actually had the maximum rate of conversion and hence contained the largest number of available catalyst units. Accordingly, reagents 3 and 2 should have contained the same amount of catalyst as no. 4 because each contained the same amount of sodium isopropoxide and more than enough 1-butenylsodium to combine with this alkoxide; and reagents 5 to 8 inclusive should each contain the same amount of catalyst, although less than reagent 4. This method covers a broad range and is largely independent of an exact knowledge of the composition of the stock preparations.

The compounding of the reagents was carried out as shown in Table II.

TABLE II

COMPOUNDING OF REAGENTS FROM STOCK SOLUTIONS

| Reagent no. | Series A Volume in ml. of P[a] | $B_1$[b] | $PB_1$[c] | Series B Volume in ml. of P[a] | $B_1$[b] | $PB_1$[c] |
|---|---|---|---|---|---|---|

| 9 | 120 | 180 | 600 | 240 | 120 | 400 |

[a] P refers to the isopropoxide suspension used. [b] $B_1$ refers to the 1-butenylsodium suspension used. [c] $PB_1$ shows the volume of the mixture after pentane has been added as a diluent.

The stock preparations for the Series A reagents stood for several days before the compounding. The mixtures were first shaken together in the bottle by hand but developed no catalytic activity even after two days. Each was then stirred vigorously in the high-speed stirring apparatus. The aging of the reagent, as given in the Table, dates from the time they were stirred together. For the Series B reagents the mixing was done by hand shaking the day after preparation of the stock solutions. They were then catalytically active but did not attain a stable state until some time later.

The quantity of catalyst used in the polymerizations was 20 ml. for the 600 or 400 ml. of $PB_1$ suspension or twice that amount in the case of the 1200 or 800 ml. lots.

**Sodium Methylphenyl Carboxide and Allylsodium** (by F. C.).—Methylphenylcarbinol was prepared by catalytic reduction[11] of acetophenone over Raney nickel at 110° and 1800 lb., which frequently proved unsatisfactory, or by the reactions of benzaldehyde with methylmagnesium iodide

(8) Baker, Mullen and Walker, private communication.

(9) Conant and Wheland, THIS JOURNAL, **54**, 1212 (1932).

(10) McEwen, *ibid.*, **58**, 1124 (1936).

(11) Adkins, "Reactions of Hydrogen," University of Wisconsin Press, Madison, Wis., p. 30.

according to a typical procedure.[12] The first product boiled at 92° (12 mm.) and had a refractive index, $n^{20}D$ 1.5280, the second one had a refractive index of 1.5282. The recorded[13] value is 1.5275.

The catalyst, C, was prepared by passage of propylene into a standard preparation of amylsodium to which 0.2 mole of methylphenylcarbinol had been added. Twenty ml. of this catalyst caused 35% conversion of 30 ml. of butadiene during one hour to a polymer that had an intrinsic viscosity of 5.8 and a gel of 5%; 40 ml. caused 75% conversion and the viscosity and gel were 5.2 and 2%, respectively; 60 ml. caused 82% conversion and the polymer had 4.9 viscosity and zero gel. The approximate constancy of intrinsic viscosity as the catalyst is doubled and tripled accords with the general behavior of Alfin catalyst. When applied to 20 ml. of isoprene, the conversion values for 20, 40 and 60 ml. of catalyst suspension were 8, 19 and 35% respectively, the corresponding intrinsic viscosities were 1.8, 2.8 and 2.3, and the respective gels were 0.6 and 19%.

In the making of catalyst D, this preparation was repeated with three times the proportions of reactants. The catalytic activity of D as tested by 20, 40 and 60 ml. of catalyst with butadiene was 16, 37 and 43% respectively, the corresponding intrinsic viscosities 1.0, 0.6 and 0.8 and the respective gels were 34, 15 and 33%.

Addition of 30 ml. of standard preparation of allylsodium suspension to 1675 ml. of the above catalyst suspension followed by thirty minutes of high-speed stirring to give D, altered the catalytic activity so that the conversions caused by 20, 40 and 60 ml. of catalyst, after three days of aging, $D_{1-3}$, were 28, 58 and 89%, respectively. The corresponding intrinsic viscosities were 6.0, 5.3 and 4.3 and the respective gels were 14, 19 and 22%. After this suspension had aged for fifteen days, $D_{1-18}$, the corresponding three sets of values were 32, 62, 79%, 6.7, 6.6, 5.3 and 4, 6, 7%. Another quantity of 30 ml. of allylsodium was added to give $D_2$. The remaining tests used only 20 ml. of catalyst suspensions. These results with others are listed in Table I.

**Tests with PP Catalyst** (by R. P. W., S. E. P., and R. D. C.).—Four separate preparations of PP catalyst were made by passage of propylene through standard batches of amylsodium in the presence of different quantities of isopropoxide (see Table III).

Each lot of catalyst was analyzed for its content of organosodium compound by addition of 8 g. of fluorene to 100 ml. of catalyst suspension, followed by high-speed stirring for three hours, standing overnight, carbonation on solid carbon dioxide, recovering the 9-carboxylic acid, and weighing.

The activity of these four catalysts was tested with only 5 ml. of the catalyst suspension. The results recorded in Table II show that the percentages of gels were uniformly low and the activity of the catalyst on the excess alkoxide side decreased no more within one month's time than it did on the excess allylsodium side.

The use of such a small quantity of catalyst as 5 ml. required extra precautions to eliminate moisture or other material that would destroy the catalyst. The pentane was therefore treated with amylsodium in the proportion of 100 ml. per gallon. The mixture was shaken by hand for about a minute and allowed to stand overnight by which time the solid, largely free from its color, had settled to the bottom and left the pentane layer water-white. This pentane was used as a rinse for the polymerization vessel (12 oz. soft drink bottle) as well as for the medium of the reaction. The moisture or air on the wall[14] of these glass bottles would destroy most of the color of 2 ml. of catalyst suspension added to 200 ml. of the above dried pentane within a few minutes of gentle agitation. When 2 ml. more of the catalyst suspension was added, the color of the solid was more permanent, although it, too, was decolorized by overnight standing in the sealed bottle. By rapid handling of all reagents the effect of moisture on the glass walls was minimized. Satisfactory polymerizations were carried out with as little as 3 ml. of catalyst suspension. Below 1.5 ml. of catalyst the amount of polymer formed was as low as 1 mg. even in an indefinitely long period of time.

The results with the above PP catalysts are typical of many now being obtained. Many polybutadienes that contain no gel have been obtained, although occasionally one as high as 70% is still formed.

TABLE III

PREPARATION OF PP CATALYSTS AND POLYMERIZATIONS CAUSED THEREWITH

| Reagent no. | | 1[a] | 2[a] | 3[b] | 4[b] |
|---|---|---|---|---|---|

| | Intrinsic viscosity | 12.8 | 15.1 | 13.9 | 13.0 |
| | Gel, % | 7 | 9 | 4 | [low] |

[a] The color of these suspensions was gray-green to blue-green and the fluidity was high. [b] The color of these two catalysts was slate-blue and the fluidity was low. When used as the polymerization agent they show a tendency to form clumps of insoluble polymer at the beginning of the reaction. [c] The moles of isopropoxide was calculated from the amount of isopropyl alcohol added. [d] Calculated from the weight of fluorene-9-carboxylic acid isolated. [e] Calculated from the quantity of that one of the two components present in lesser amount. [f] Polymerization test one day after preparation of the catalyst. [g] Polymerization test one month after preparation of the catalyst.

## Summary

In Alfin polymerization of butadiene a minimum of gel appears to accompany a maximum of conversion. Incorrect proportioning of the catalyst component or a large excess of catalyst beyond that needed for high efficiency may cause the formation of gel during polymerization.

# Polymerization. X. Metalation of Alkylaryl Hydrocarbons and their Use in the Polymerization of Butadiene[1]

BY AVERY A. MORTON AND ERNEST L. LITTLE, JR.[2]

Alkylaryl compounds are metalated either in the ring or on the alpha carbon of the side chain. If the metal enters the ring, the product can function as a catalyst for the polymerization of butadiene in the same way as did phenylsodium.[3] If it enters the side chain it can function as the Alfin catalyst[4] with sodium isopropoxide, provided that a double bond in the benzene ring can serve in place of the double bond in the olefin. Accordingly a large number of these hydrocarbons were metalated in order to see where metalation occurred, and whether any of the products had interest as a catalyst for the polymerization of dienes.

TABLE I

METALATION OF HYDROCARBONS BY AMYLSODIUM

[a] The abbreviations refer respectively to ethylbenzene, isopropylbenzene, *t*-butylbenzene, *p*-cymene, $\beta$-methylnaphthalene, dibenzyl, diphenylmethane, triphenylmethane, fluorene and acenaphthene. The quantity of hydrocarbon added in each case was 0.22 mole except in the second experiment with *t*-butylbenzene in which 0.44 mole was added. [b] In each experiment 0.5 mole of amyl chloride and 1 g. atom of sodium were used in the preparation of amylsodium. In all cases, except the second experiment with *t*-butylbenzene, 0.2 mole of isopropyl alochol was used. Hence the actual amount of amyl chloride is as if only 0.3 mole were used. Yields were calculated on this quantity. [c] The yield of amylsodium is usually around 80% of the amyl chloride used; hence, this amount was assumed to be present. [d] Caproic acid represents unused amylsodium. [e] This experiment was the only one in which no sodium isopropoxide was used. [b] The crude mixture weighed 17.5 g. from which some of the same dicarboxylic observed before and isolated as the dimethyl ether was obtained. Some mono carboxylic acid was possibly present in the crude mixture.

Of the hydrocarbons tested two were metalated in the ring and the remainder in the side alkyl group (see Table I). All except fluorene and acenaphthene had a little catalytic activity (see Table II) but only benzylsodium could be said to be moderately good with respect to percentage conversion and intrinsic viscosity of product. The metalation of toluene to give benzylsodium has previously[5] been shown to yield some disubstitution products as the quantity of toluene is made less. Accordingly the benzylsodium catalyst was prepared with three proportions of toluene (see Table III). The best activity with respect to conversion and the intrinsic viscosity and gel of the product was found with the catalyst that should contain the smallest amount of phenylene disodium.

Acenaphthene and fluorene formed no catalyst. The failure of these compounds to yield a catalyst was confirmed by adding each to an allylsodium–sodium isopropoxide (PP) catalyst and observing the destruction of catalytic activity. Acenaphthene gradually reduced the conversion activity to zero over a 100-day interval during which the intrinsic viscosity of the polymer formed also fell from 15 to 0. Fluorene caused the same changes within one day. In each case carbonation of the destroyed catalyst showed only the expected products from fluorene and acenaphthene. By contract the addition of toluene to the same catalyst caused a drop in intrinsic viscosity to 13 in a period of fifty-one days, and the percentage conversion remained at 100.

Incidental matters of interest with respect to the metalation of the hydrocarbon are (a) the high percentage of para substitution in the metalation of isopropylbenzene and *t*-butylbenzene; (b) the metalation of the methyl group of *p*-cymene in preference to the isopropyl group; (c) the formation of *meso*-$\alpha,\beta$-diphenylsuccinic acid from metalation and carbonation of dibenzyl,

[a] The abbreviations in this column have the same significance as those in Table I with addition of toluene (Tol.) and the three xylenes (Xy.). The quantity of hydrocarbon used in each preparation was 0.22 mole, except in the second experiment with toluene where 1 mole was used. [b] Amylsodium only was used in this test. [c] In the preparation of this catalyst 1 mole of toluene was added to the standard preparation of amylsodium. [d] This reagent is the only one that contained no sodium isopropoxide.

TABLE III

VARIATION IN CATALYTIC ACTIVITY OF THE BENZ PP CATALYST AS THE PROPORTION OF PHENYLENE DISODIUM COMPOUND IS INCREASED

indicating that the two sodium ions had taken positions as far apart as possible, (d) the freedom of tarry products[6] from acenaphthene when the metalation–carbonation process is carried out under the present improved conditions and (e) the general success of metalation–carbonation with many of the hydrocarbons such that the process is a good preparative one for certain carboxylic acids.

**Acknowledgment.**—The authors are greatly indebted to Christiana Clapp and Jeanne Kilduff for valuable technical assistance and determination of intrinsic viscosity.

## Experiments

**Metalation of Hydrocarbons.**—The hydrocarbons were Eastman Kodak Co. grade, the physical constants of which either agreed with accepted values or did so after redistillation or recrystallization. Each hydrocarbon (0.22 mole) was added to a standard preparation[13] of amylsodium to which sodium isopropoxide (0.2 mole) had previously been added. Larger amounts were used in the same proportions. The mixture was stirred for four hours after which the contents were transferred to a bottle. Samples were withdrawn when tests of catalytic activity (see Table II) were made, after which the mixture was carbonated by pouring onto solid carbon dioxide. The aqueous layer of the sodium salts was usually extracted once with petroleum ether to remove traces of organic material. Hydrochloric acid was then added. Any solid that precipitated was separated by filtration, the aqueous layer was then extracted with petroleum ether. The remaining aqueous layer was saturated with salt and extracted with ethyl ether. In the following paragraph these three fractions will be referred to as the initial precipitate, the petroleum ether fraction and the ethyl ether fraction. The weights of products are those actually obtained but the percentage yields given in Table I are corrected for the quantity of suspension removed for the polymerization test.

The gray-colored suspension from ethylbenzene yielded 7.3 g. of an oil from the petroleum ether portion. Fractionation gave 6.3 g. of liquid that boiled at 120–125° (4 mm.) and 1 g. of a resinous product. The liquid was identified as *α*-methylphenylacetic acid by its neutralization equivalent of 150.8 (calcd. 150) and the melting point of its amide, 90.7–91.7 cor. (reported[7] value is 91–92°). A yellow gum (1.5 g.) was obtained from the ethyl ether fraction.

The purple colored suspension from isopropylbenzene yielded 19.5 g. of an oil from the petroleum ether portion. Fractionation separated the oil into 13.8 g. that boiled at 104–114° (3 mm.), 4.9 g. that boiled at 114–117° (3 mm.) and 1 g. of a reddish gum. The first fraction was dissolved in 10 ml. of petroleum ether and placed in a refrigerator. Crude crystals of *p*-cuminic acid separated. When recrystallized from 80–20 alcohol–water solution, 11.2 g. of the pure acid, m. p. 115–116° (reported[8] value 115–116°) was recovered. The neutralization equivalent was 163 (calcd. 164). The amide melted at 152–153° cor. (153° reported[9]). The oil recovered from the mother liquor was dissolved in 10 ml. of ethanol and 2 ml. of water and again cooled. *o*-Cuminic acid (2 g.) separated. The neutralization equivalent was 164 (calcd. 164) and the melting point was 48.5–50° (51° reported[10]). The fraction that distilled at 114–117° crystallized in the receiver and, after crystallization from 50 ml. of ethyl alcohol–water (80-20 mixture), yielded 4.1 g. of pure *p*-cuminic acid. The ethyl ether fraction yielded 2 g. of a reddish gum.

The black colored suspension from *t*-butylbenzene yielded 15.5 g. in the initial precipitate and only traces of material from the other two fractions. Extraction of the precipitate with petroleum ether left a residue which yielded 7.1 g. of crystals from 100 ml. of aqueous 80% alcohol. These crystals proved to be *t*-butylbenzoic acid by the neutralization equivalent of 178, the melting point

(10) Kothe, *ibid.*, **248**, 62 (1888).

of 161.5–162.5° (160–161° reported)[11] and by the amide derivative that melted at 170.5–171° uncor. (171° reported[11]). The crystals (8.4 g.) from the mother liquor melted at 85–90° and proved to be a mixture of the *p*-acid with a little of the *m*-isomer. The mixture was first subjected to multiple fractional extraction[12] which divided it into 8 portions. The first seven portions melted at 90–95° the last melted at 290° and yielded 0.8 g. of a dicarboxylic acid after crystallization from aqueous alcohol. The first seven fractions were then recombined and subjected to alternate crystallizations from benzene and then from aqueous 80% alcohol until 2.9 g. of pure *m*-*t*-butylbenzoic acid and 3.9 g. of the pure para isomer were obtained. The *m*-acid was identified by its neutralization equivalent of 179, its melting point of 127–127.5° cor. (reported[13] 127°) and the melting point of its amide 128–129° (reported[13] 130°). The dicarboxylic acid separated in the extraction process possibly contained one carboxyl group ortho to the *t*-butyl group since the principle by which the separation process operates would insure that the strongest acid would be in that portion and *o*-*t*-butylbenzoic acid is much stronger[14] than the other two isomers. Furthermore this position would be the focus of all the directing influences present after initial metalation on the methyl group.

The products from the metalation of *t*-butylbenzene in the absence of isopropoxide yielded no initial precipitate, but the petroleum ether fraction contained 8 g. of *p*-*t*-butylbenzoic acid and 18 g. of caproic acid, the latter from unused amylsodium which was recovered by distillation after the crystals had separated. The residue from the distillation was subjected to alternate crystallizations from benzene and the aqueous alcohol solution until 4.1 g. of the *p*-acid and 1.1 g. of the *m*-isomer were recovered. The ethyl ether fraction yielded 1 g. of a brownish solid from which 0.6 g. of a dicarboxylic acid (m. p. 310–315° in a sealed tube) was obtained after decoloration with carbon and recrystallization from aqueous alcohol.

The green colored suspension from *p*-cymene yielded 9 g. of an oil from the petroleum ether portion. Fractionation at 118–123° (3 mm.) gave 6.5 g. that solidified, had a neutralization equivalent of 176.5 (calcd. 178) and a melting point of 50–51°, near to the 51–52° reported[15] for 4-isopropylphenylacetic acid. The amide melted at 169–170° cor. (170° reported[15]). Two grams of a resinous material was left as a residue from the distillation. The ethyl ether portion yielded 3 g. of a red gum which was treated with decolorizing carbon in boiling water. A dicarboxylic acid (2.5 g.) was recovered, m. p. 189–190° cor.

The purple colored suspension from β-methylnaphthalene yielded 17 g. in the initial precipitate. Recrystallization from water gave 16.5 of β-naphthylacetic acid that melted at 141.0–141.5° (reported[16] 141–142°). The neutralization equivalent was 186 (calcd. 186). The amide melted at 200–201° uncor. (reported[17] 200°).

The brown colored suspension from dibenzyl yielded 1 g. of a yellow gum from the petroleum ether extract and 8 g. of meso-α,β-diphenylsuccinic acid from the ethyl ether extract. Recrystallization of the latter from aqueous alcohol yielded 7.3 g. of pure acid that melted at 229–230° uncor. (reported[18] value is 229–230°). The neutralization equivalent was 135.6 (calcd. 135). The dimethyl ester was prepared with diazomethane and melted at 220.5–221.5° (reported[18] 219–220°).

The yellow colored suspension from diphenylmethane yielded 31.5 g. of diphenylacetic acid in the initial precipitate. When recrystallized from water, it melted at 147.5–148.5° (148° recorded[19]). The neutralization equivalent was 214 (calcd. 212). The amide melted at 167–168° cor. (167.5–168.5° reported[20]). The ether extract yielded 0.5 g. of a red gum.

The red colored suspension from triphenylmethane yielded 37.2 g. of triphenylacetic acid in the initial precipitate. It melted at 266.3–267.3 cor. (267° reported[21]). The methyl ester melted at 185–185.5° cor. (186° reported[21]).

The yellow colored suspension from fluorene yielded 38.7 g. of crude 9-fluorenecarboxylic acid which melted at 220–222° (222–225° reported[22]) when recrystallized from glacial acetic acid. The neutralization equivalent was 210 (calcd. 210). The methyl ester melted at 62–63° (63° recorded[22]).

The green colored suspension from acenaphthene yielded as an initial precipitate 17.5 g. of a yellow solid that was a mixture of acids. Treatment with diazomethane yielded the dimethyl ester of the carboxylic acid already reported.[6]

**The Carbonation Product from Benzylsodium and Sodium Isopropoxide Mixture.**—Phenylacetic acid (0.033 mole) was obtained from the petroleum ether portion. Homoisophthalic acid was obtained from the ethyl ether fraction. No other acids could be found.

**Polymerization Tests.**—The suspensions of metalated hydrocarbons were tested for catalytic activity in the manner described in the previous publication. Twenty ml. of each catalyst was used with 30 ml. of butadiene for one hour. The results are recorded in Tables II and III.

**Effect of Acenaphthene and Fluorene on the PP Catalyst.**—Two molar equivalents of hydrocarbon per estimated mole of catalyst were stirred together for four hours at room temperature. The respective green and yellow colored suspensions were then tested for catalytic activity in the usual way.

**Attempted Use of Cyclohexene.**—Cyclohexene (20 g.) was metalated by a standard quantity of amylsodium to which had been added 7.5 g. of isopropyl alcohol. Before addition of cyclohexene the organosodium reagent (20 ml.) caused the polymerization within one hour of 4% of the butadiene (30 ml.) to a polymer that had an intrinsic viscosity of 0.5 and a gel of 5%. After addition of cyclohexene, the metalated hydrocarbon caused 6% conversion to a polymer that had an intrinsic viscosity of 0.6 and no gel.

## Summary

A number of alkylaryl hydrocarbons have been metalated by amylsodium in order to observe the position of metalation and the behavior of the products as catalysts for the polymerization of butadiene.

Isopropylbenzene and *t*-butylbenzene are metalated in the nucleus. Ethylbenzene, *p*-cymene, β-methylnaphthalene, diphenylmethane and triphenylmethane are metalated on the side carbon atom, preferably on a methyl group if there is more than one possibility.

Benzylsodium yields an Alfin catalyst of moderate activity. Other alkylaryl compounds, when metalated, yield poor catalysts. Acenaphthene and fluorene destroy the activity of an Alfin catalyst and show no catalytic action when metalated.

# Synthesis of Tetrafluorocyclobutanes by Cycloalkylation

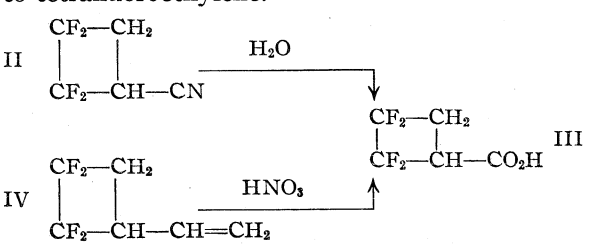
BY DONALD D. COFFMAN, PAUL L. BARRICK, RICHARD D. CRAMER AND MAYNARD S. RAASCH

## Introduction

Recent publications[1a,b,c,d] have described a new reaction which involves the addition of a fluoroolefin to itself, *e. g.*, the dimerization of tetrafluoroethylene[1a] or of chlorotrifluoroethylene,[1b] and to certain olefin derivatives such as chlorotrifluoroethylene,[1c] acrylonitrile[1d] and methyl methacrylate,[1d] to give cyclobutane derivatives. This new reaction has now been studied in considerable detail, and has been extended to the addition of tetrafluoroethylene to a wide variety of olefins. The general nature of this cycloalkylation method of preparing cyclobutane derivatives has been established. Thus, with ethylene, tetrafluoroethylene gives tetrafluorocyclobutane (I).

I

Analogous reactions of tetrafluoroethylene with various unsaturated compounds have given the corresponding tetrafluorocyclobutanes substituted by halogen, vinyl, ethynyl or other groups.



## Generality of the Cycloalkylation

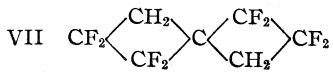
The cycloalkylation of tetrafluoroethylene with unsaturated compounds occurs at a lower temperature and apparently with greater facility than does the dimerization of tetrafluoroethylene.[1a] Under the conditions employed, the synthesis yields 4-membered ring compounds without the competitive dimerization of tetrafluoroethylene to octafluorocyclobutane and without the appreciable formation of 6-membered or larger rings and open-chain polymers. Qualitatively, the ease of reaction varies with the unsaturated reactant. Reactants containing a terminal methylene group combine more readily than do 1,2-disubstituted ethylenes such as 2-butene or trichloroethylene, while reactants having conjugated unsaturation, for example, 1,3-butadiene, acrylonitrile, methyl methacrylate and styrene, are even more reactive.

**Reactions with Vinyl Compounds.**—The cycloalkylation with vinyl and vinylidene compounds is illustrated by the formation of tetrafluorocyclobutane (I) from tetrafluoroethylene and ethylene, and by the substituted tetrafluorocyclobutanes formed in the reaction of tetrafluoroethylene with monolefins such as styrene, with chloroolefins typified by vinyl chloride, and with vinyl acetate, acrolein, allyl alcohol and the related unsaturates listed in Tables I, II, III.

Evidence for the tetrafluorocyclobutane structure is found in the mode of formation, the composition, and the properties of the products. The product from tetrafluoroethylene and a monoölefin has an empirical composition corresponding to that of one molecule of tetrafluoroethylene plus one molecule of olefin. The product is stable to aqueous permanganate, does not react with a solution of bromine in carbon tetrachloride, is unaffected under the usual conditions of catalytic hydrogenation, and its infrared absorption spectra show no absorption bands characteristic of the carbon–carbon double bond. The fluorohydrocarbon is resistant to oxidation as indicated by incomplete combustion in attempts to analyze the cyclobutanes from ethylene, propylene, isobutylene and 2-butene.

Further proof of structure is found in the transformations of products from acrylonitrile and from butadiene. Tetrafluoroethylene and acrylonitrile combine to form in good yield a nitrile which corresponds in composition to cyanotetrafluorocyclobutane (II). On acid hydrolysis, the nitrile gives the saturated tetrafluorocyclobutane carboxylic acid (III). The same acid (III) is obtained by the nitric acid oxidation of the unsaturated product (IV) formed by the addition of one molecule of tetrafluoroethylene to 1,3-butadiene. These transformations establish the identity of (III) as 2,2,3,3-tetrafluorocyclobutane carboxylic acid and of (IV) as 1-vinyl-2,2,3,3-tetrafluorocyclobutane formed by the 1,2-addition of butadiene to tetrafluoroethylene.

**Reactions with 1,3-Dienes.**—As already indicated, cycloalkylation occurs in the reaction of tetrafluoroethylene with terminally unsaturated dienes. The initial 1:1 products are tetrafluorocyclobutanes containing an unsaturated side chain. By further reaction with another molecule of tetrafluoroethylene, a bicyclic product containing two tetrafluorocyclobutane rings is formed. The simplest cases are the products from 1,3-butadiene and from allene. 1,3-Butadiene and tetrafluoroethylene form 1-vinyl-2,2,3,3-tetrafluorocyclobutane (IV) and not the tetrafluorocyclohexene that might have been expected by a Diels–Alder reaction. By hydrogenation, IV was converted to 1-ethyl-2,2,3,3-tetrafluorocyclobutane.



(1) (a) J. Harmon, U. S. Patent 2,404,374 (July 23, 1946); (b) A. L. Henne and R. D. Ruh, THIS JOURNAL, **69**, 279 (1947); (c) P. L. Barrick, U. S. Patent 2,427,116 (September 9, 1947); (d) P. L. Barrick and R. D. Cramer, U. S. Patent 2,441,128 (May 11, 1948).

Reaction of IV with another molecule of tetrafluoroethylene gave 2,2,2′,2′,3,3,3′,3′-octafluorobicyclobutyl (V). Similarly, in reactions with tetrafluoroethylene, allene gave the 1-methylene-2,2,3,3-tetrafluorocyclobutane (VI) and 1,1,2,2,5,5,6,6-octafluorospiro[3.3]heptane (VII).

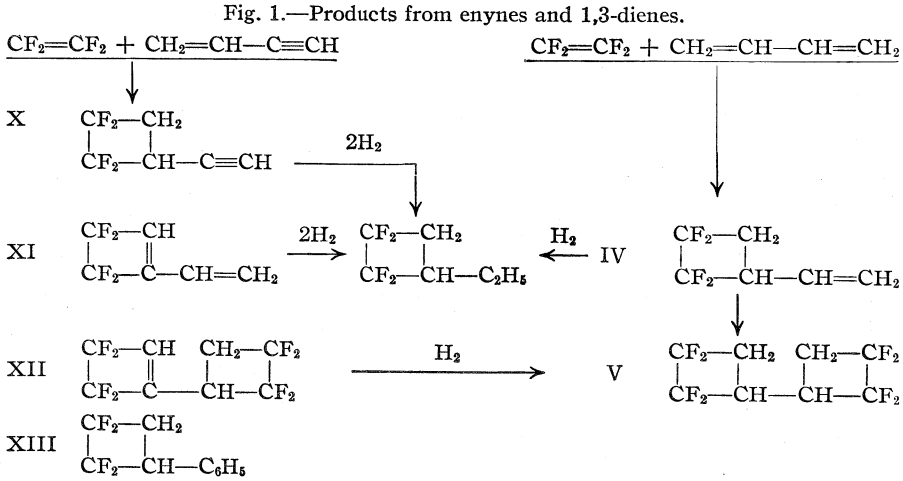
IV $CF_2(-CF_2)-CH(-CH=CH_2)$

V $CF_2(-CF_2)-CH(-CH(-CF_2)-CF_2)$

VI $CF_2(-CF_2)-C(=CH_2)$

VII 

Isomeric products are obtained from tetrafluoroethylene and unsymmetrical dienes. Thus 2-chloro-1,3-butadiene gave the isomers VIII and IX.



VIII $CF_2(-CF_2)-C(Cl)-CH=CH_2$

IX $CF_2(-CF_2)-CH(-C(Cl)=CH_2)$

The structures of compounds VIII and IX are believed to be those shown in view of (1) their compositions which correspond to a 1:1 tetrafluoroethylene/2-chloro-1,3-butadiene mole ratio; (2) their molecular refractivities which are in agreement with that for a tetrafluorocyclobutane derivative; (3) the conversion of IX to 1-ethyl-2,2,3,3-tetrafluorocyclobutane by hydrogenation; and (4) inability to obtain a chlorine-free product by the hydrogenation of VIII. Two isomeric 1:1 adducts were also obtained from tetrafluoroethylene and 2-fluoro-1,3-butadiene.

**Reactions with Enynes.**—Cycloalkylations with tetrafluoroethylene and an enyne proceed with participation of both the ethylenic and the acetylenic groups of the enyne. The products include the isomeric 1:1 tetrafluoroethylene/enyne adducts and also the bicyclic 2:1 adduct. Four clearly identified products have been obtained from monovinylacetylene. The first of these is 1-ethynyl-2,2,3,3-tetrafluorocyclobutane (X) Fig. 1, formed by reaction of tetrafluoroethylene at the ethylenic linkage of monovinylacetylene. Compound X contained an acetylenic hydrogen as shown by reaction with aqueous silver nitrate. By hydrogenation, X was converted to the 1-ethyl-2,2,3,3-tetrafluorocyclobutane independently synthesized from tetrafluoroethylene and 1,3-butadiene. Monovinylacetylene also reacted by 1,2-addition at the acetylenic linkage with the formation of compound XI. The structure XI was established as 1-vinyl-3,3,4,4-tetrafluorocyclobutene by its polymerizability, by its hydrogenation to 1-ethyl-2,2,3,3-tetrafluorocyclobutane, and by reaction with a second molecule of tetrafluoroethylene to obtain 2′,2′,3′,3′-tetrafluorocyclobutenyl-2,2,3,3-tetrafluorocyclobutane (XII). By hydrogenation, XII gave 2,2,2′,2′,3,3,3′,3′-octafluorobicyclobutyl (V), which was also synthesized from butadiene and two molecules of tetrafluoroethylene. The fourth product obtained from tetrafluoroethylene and monovinylacetylene was 1-phenyl-2,2,3,3-tetrafluorocyclobutane XIII, identical with the adduct of tetrafluoroethylene and styrene. The formation of XIII suggests that under the reaction conditions monovinylacetylene dimerized to styrene[2] which combined with tetrafluoroethylene.

Fig. 1.—Products from enynes and 1,3-dienes.

**Physical Properties.**—The physical properties of selected tetrafluorocyclobutane derivatives are given in Tables I to IV, inclusive. In general, the introduction of fluorine in the cyclobutane ring lowers the refractive index and increases the density of the products. The observed molecular refractivity was calculated by means of the Lorenz–Lorentz equation. The atomic refraction of fluorine was determined by subtracting the sum of the commonly used values (Eisenlohr's) of all the other increments from the experimental value and dividing the difference by the number of fluorine atoms. The atomic refraction of fluorine in these compounds, $AR_F$, varied from 1.04–1.64 and averaged about 1.16.[3] The tetrafluorocyclobutanes containing only carbon, hydrogen and fluorine in Table I have an average $AR_F$ of 1.08 which agrees with the reported value for a fluorohydrocarbon containing four fluorine atoms per molecule.[4] The introduction of other atoms such as chlorine, oxygen, and/or nitrogen, and special configurations such as present in unsaturated substituents

[a] The reactants were agitated at 150° under autogenous pressure for about eight hours. [b] These products were prepared by hydrogenation of the 1:1 reaction products of tetrafluoroethylene with 1,3-butadiene, 1,3-pentadiene, 2-methyl-1,3-butadiene and 2-fluoro-1,3-butadiene. [c] Extremely low C and H values were obtained due to incomplete combustion of the compounds.

appear to cause some variation in the values for the atomic refraction of fluorine. For example, the tetrafluorocyclobutanes from chloroölefins (Table II) have an average $AR_F$ value of 1.30, while the products of Table III and IV have average $AR_F$ values of 1.20 and 1.12, respectively.

## Experimental

**Preparation of Tetrafluorocyclobutanes.**—The procedure for carrying out the cycloalkylation of tetrafluoroethylene with most of the unsaturated compounds listed in Tables I through IV consisted in charging 100 to 150 g. of the unsaturated compound containing a small amount of polymerization inhibitor, such as hydroquinone or "Terpene B" hydrocarbon,[5] into a 400 ml. high-pressure shaker tube lined with silver or stainless steel. A tube capable of withstanding operating pressures up to 500 atm. should be used when the unsaturated compound to be treated with tetrafluoroethylene is a gas at room temperature. The tube was cooled and evacuated to remove oxygen, and 50 g. of tetrafluoroethylene was added. The reaction mixture was heated under autogenous pressure with agitation at 150° for about eight hours. The pressure varied with the different reactants, but was initially about 45 atm. when the unsaturated compound was a liquid, and decreased as the reaction proceeded. After cooling and releasing any pressure, the liquid product was removed and steam distilled to separate the monomeric products from any non-volatile residue. The steam-volatile tetrafluorocyclobutane derivatives were fractionated.

A detailed study of synthesis conditions was not made. Accordingly, the yields given in the tables are not necessarily optimum. The yields are based on the amount of tetrafluoroethylene charged and are not corrected for the amount of tetrafluoroethylene which did not react. In general where low yields have been reported, reaction was incomplete and for the most part unaccompanied by polymerization of the individual reactants. Typical preparations are described in the following paragraphs.

**Caution.**—Information is not available concerning the toxicity of the various fluorine-containing products described. Acordingly, the products should be regarded with suspicion and handled with appropriate care.

**Analysis.**—It will be noted that the values obtained for carbon in the combustion analyses were frequently higher than the theoretical values. The apparently high carbon values for products containing appreciable proportions of fluorine result from the absorption of hydrogen fluoride formed during combustion and carried over into the Ascarite carbon dioxide absorber. Spongy silver placed in the absorption train preceding the Ascarite is beneficial in minimizing the carry over of hydrogen fluoride, but the silver must be replaced frequently.

**1,1,2,2-Tetrafluorocyclobutane.**—A silver-lined, high-pressure shaker tube was evacuated and charged with 35 g. of tetrafluoroethylene and 75 g. of ethylene. The sealed reactor was then heated under autogenous pressure at 150° with agitation for eight hours. After cooling the tube and bleeding off the gases slowly, there was obtained 17.9 g. of condensate (40% of theory). Characterization showed the condensate to be 1,1,2,2-tetrafluorocyclobutane which had the following properties: b. p. 50–50.7°, $n^{25}D$ 1.3046, $d^{25}_4$ 1.2752, $MR_D$ 18.8.

*Anal.* Calcd. for $C_4H_4F_4$: F, 59.37. Found: F, 59.44.

**Warning.**—Care should be exercised in preparing and heating mixtures of ethylene and tetrafluoroethylene since a violent explosion occurred when a mixture of 50 g. of tetrafluoroethylene and 125 g. of ethylene was heated at 160° and 480 atm. No difficulty was experienced with the other unsaturated compounds. Particular precau-

(5) A terpene fraction consisting principally of dipentene and terpenolene boiling at 176–196° and having refractivity and density values of $n^{20}D$ 1.470–1.478, and $d^{15.5}_4$ 0.855–0.870.

[a] The reactants were agitated at 150° under autogenous pressure for about eight hours. [b] Added 0.5 g. of hydroquinone as polymerization inhibitor. [c] Heated at 225°.

tions should be taken to exclude all oxygen from tetrafluoroethylene and the reaction system.

Propylene, isobutylene and styrene reacted readily, yielding the methyl-, 1,1-dimethyl- and 1-phenyl-2,2,3,3-tetrafluorocyclobutanes, respectively, as given in Table I, whereas butene-2 and camphene were less reactive.

**1-Chloro-2,2,3,3-tetrafluorocyclobutane.**—A stainless steel-lined shaker tube was flushed with nitrogen, evacuated, cooled in a Dry Ice–methanol mixture, and then 132 g. of vinyl chloride and 50 g. of tetrafluoroethylene were added. The sealed tube was heated under autogenous pressure at 150° for eight hours. The tube was cooled and excess gas bled off slowly. The condensate amounted to 19 g. (23% yield) of 1-chloro-2,2,3,3-tetrafluorocyclobutane which had the following properties: b. p. 73–74°, $n^{25}D$ 1.3462, $d^{25}_4$ 1.4251, $MR_D$ 24.15.

*Anal.* Calcd. for $C_4H_3ClF_4$: C, 29.53; H, 1.84; F, 46.8; Cl, 21.85. Found: C, 30.43; H, 1.86; F, 47.56; Cl, 21.78.

Allyl chloride, methallyl chloride, vinylidene chloride, trichloroethylene and methyl α-chloroacrylate reacted with tetrafluoroethylene to yield the corresponding tetrafluorocyclobutanes listed in Table II.

**1-Cyano-2,2,3,3-tetrafluorocyclobutane.**[1d]—A 400 ml. stainless steel-lined shaker tube was flushed with nitrogen and charged with 125 g. of freshly distilled acrylonitrile. The tube was cooled and evacuated. After adding 50 g. of tetrafluoroethylene which contained approximately 0.1 g. of "Terpene B" hydrocarbon,[5] the sealed tube was heated at 150° with agitation under autogenous pressure for about eight hours. The reaction mixture was steam distilled, and the steam-volatile, lower, water-insoluble layer was separated, dried, and distilled. After separating a foreshot of unreacted acrylonitrile, an 84% yield (64 g.) of 1-cyano-2,2,3,3-tetrafluorocyclobutane was obtained which had the following properties: b. p. 148°, $n^{25}D$ 1.3568, $d^{25}_4$ 1.3909. *Anal.* Calcd. for $C_5H_3NF_4$: C, 39.2; H, 1.96; F, 49.7; N, 9.15. Found: C, 37.0; H, 2.07; F, 49.19; N, 9.24. There was also obtained a non-volatile residue (1.2 g.) that contained about 7% fluorine.

The tetrafluorocyclobutanes which contain functional substituents undergo transformations characteristic of such substituents as illustrated by the hydrolysis of 1-cyano-2,2,3,3-tetrafluorocyclobutane to 2,2,3,3-tetrafluorocyclobutane carboxylic acid and by the conversion of this acid to simple carboxylic acid derivatives.

**2,2,3,3-Tetrafluorocyclobutanecarboxylic Acid.**[1d]—Ten grams of 1-cyano-2,2,3,3-tetrafluorocyclobutane was hydrolyzed by warming with 30 ml. of 70% sulfuric acid on a steam-bath for one-half hour. The upper oily layer was separated, and the lower sulfuric acid layer was diluted with cold water and extracted with ether. The combined oil and ether extracts were dried, and the ether was removed. An 87% yield (9.8 g.) of 2,2,3,3-tetrafluorocyclobutane carboxylic acid was obtained having the following properties: b. p. 100–100.5° at 24 mm., $n^{25}D$ 1.3684,[6] $d^{25}_4$ 1.5103.[6] The acid solidified on cooling. It melted at 61.5–63°.

*Anal.* Calcd. for $C_5H_4O_2F_4$: C, 34.9; H, 2.33; F, 44.2; neut. equiv., 172. Found: C, 35.62; H, 2.60; F, 43.91; neut. equiv., 174.8.

2,2,3,3-Tetrafluorocyclobutanecarboxylic acid formed the customary acid derivatives such as the anhydride, the chloride, the amide, and the anilide.[1d]

**Methyl 1-Methyl-2,2,3,3-tetrafluorocyclobutanecarboxylate.**[1d]—A stainless steel-lined shaker tube was flushed with nitrogen and charged with 125 g. of methyl methacrylate containing 0.5 g. of hydroquinone as polymerization inhibitor. The tube was cooled in Dry Ice–methanol mixture, evacuated, and 50 g. of tetrafluoroethylene containing about 0.2 g. of "Terpene B" hydrocarbon[5] was added. The sealed tube was heated under autogenous pressure at 150° for eight hours. At the end of this time, there was no appreciable gas pressure in the tube. The reaction mixture was steam distilled, and the volatile, water-insoluble material was dried over anhydrous sodium sulfate and fractionated. The first fraction was unreacted methyl methacrylate (b. p. 32–36° at 57 mm.). Methyl 1-methyl-2,2,3,3-tetrafluorocyclobutanecarboxylate (64 g. or a 64% yield) was obtained next, boiling at 70° at 56 mm. and having the following properties: $n^{25}D$ 1.3656, $d^{25}_4$ 1.2890, $MR_D$ 34.6.

*Anal.* Calcd. for $C_7H_8O_2F_4$: C, 42.0; H, 4.00; F, 38.0; saponification number, 280.5. Found: C, 35.18; H, 4.24; F, 37.34; saponification number, 280.5. There was also obtained 5 g. of higher boiling liquid (b. p. 135–152° at 52 mm.), and 11 g. of polymer containing 6.8% fluorine.

Saponification of methyl 1-methyl-2,2,3,3-tetrafluorocyclobutane carboxylate with alkali gave the corresponding carboxylic acid[1d] melting at 41–43°.

A wide variety of ethylenically unsaturated oxygen-containing compounds including acrolein, methacrolein, vinyl acetate, allyl alcohol, methyl vinyl ketone, methyl vinyl ether, 2-vinylfuran, safrole and butadiene monoxide have been treated with tetrafluoroethylene to obtain the corresponding tetrafluorocyclobutane derivatives listed in Table III.

**1-Vinyl-2,2,3,3-tetrafluorocyclobutane.**—A stainless steel-lined high pressure shaker tube was flushed with nitrogen, evacuated, and charged with 125 g. of 1,3-buta-

(6) Values were determined on the supercooled liquid.

[a] The reactants were agitated at 150° under autogenous pressure for about eight hours. [b] Added 0.5 g. of hydroquinone as polymerization inhibitor. [c] Heated at 135° for ten hours.

diene and 100 g. of tetrafluoroethylene. The tube was heated under autogenous pressure at 125° with agitation for eight hours. After cooling to room temperature and releasing the pressure, the reaction mixture was steam distilled. The volatile water-insoluble liquid was dried and fractionated to give 140 g. (90%) of 1-vinyl-2,2,3,3-tetrafluorocyclobutane having the following properties: b. p. 83–85°, $n^{25}D$ 1.3489, $d^{25}_4$ 1.1866; $MR_D$ 27.87.

*Anal.* Calcd. for $C_6H_6F_4$: C, 46.76; H, 3.92; F, 49.32. Found: C, 46.45; H, 4.11; F, 50.02.

The nitric acid oxidation of 1-vinyl-2,2,3,3-tetrafluorocyclobutane[1d] gave a dense, green oil only sparingly soluble in water. By extraction with sodium bicarbonate solution and acidification, there was obtained 18 g. of an oil denser than water. Distillation gave a colorless product which boiled at 100° at 25 mm. and was identified as 2,2,3,3-tetrafluorocyclobutane carboxylic acid.

*Anal.* Calcd. for $C_5H_4O_2F_4$: C, 34.9; H, 2.33; F, 44.2; neut. equiv., 172. Found: C, 36.9; H, 2.60; F, 44.2; neut. equiv., 180.

**2,2,2′,2′,3,3,3′,3′-Octafluorobicyclobutyl.**—A stainless steel-lined shaker tube was charged with 90 g. of 1-vinyl-2,2,3,3-tetrafluorocyclobutane. After cooling the tube in Dry Ice–methanol mixture and evacuating, 50 g. of tetrafluoroethylene was added and the mixture was heated at 150° under autogenous pressure for eight hours. The tube was cooled to room temperature, and the pressure released. The liquid reaction mixture was fractionated to remove the unchanged 1-vinyl-2,2,3,3-tetrafluorocyclobutane, and then about 14 g. (11% conversion) of 2,2,2′,2′,3,3,3′,3′-octafluorobicyclobutyl distilling at 150–158° was obtained. The material solidified on cooling to room temperature and appeared to melt at 49–50°, but the boiling and melting points were not sharp.

*Anal.* Calcd. for $C_8H_6F_8$: F, 59.84. Found: F, 59.87.

A mixed melting point with the 2,2,2′,2′,3,3,3′,3′-octafluorobicyclobutyl obtained from the hydrogenation of 2′,2′,3′,3′ - tetrafluorocyclobutenyl - 2,2,3,3 - tetrafluorocyclobutane (a tetrafluoroethylene/monovinylacetylene reaction product) showed no depression.

**1-Vinyl-1,2,2,3,3-pentafluorocyclobutane and 1-(1-fluorovinyl)-2,2,3,3-tetrafluorocycobutane.**—A stainless steel-lined shaker tube was evacuated and charged with 128 g. of 2-fluoro-1,3-butadiene and 100 g. of tetrafluoroethylene. It was then heated at 125° with agitation for eight hours. After opening and discharging the tube, the reaction mixture was steam distilled to yield 142 g. of volatile, water-insoluble liquid. Fractionation gave equal amounts (each about 60 g.) of two isomeric products boiling at 85 and 95°, respectively, and 20 g. of a complex mixture of higher boiling products. The two isomeric products had the following properties: b. p. 85°,

[a] The reactants were agitated under autogenous pressure for about eight hours at 100–125°. [b] Added 1.0 g. of hydroquinone as polymerization inhibitor. [c] Heated at 150°. [d] Heated at 190°. A 9% yield of $C_2F_4 \cdot 2C_5H_6$, b. p. 102–107° (17 mm.), $n^{25}D$ 1.4570, was also obtained.

$N^{25}D$ 1.3405, $d^{25}_4$ 1.2941, $MR_D$ 27.9; and b. p. 95°, $n^{25}D$ 1.3458, $d^{25}_4$ 1.3193, $MR_D$ 27.5.

*Anal.* Calcd. for $C_6H_5F_5$: C, 41.85; H, 2.91; F, 55.24. Found for 85° fraction: C, 44.01; H, 3.30; F, 55.63. Found for 95° fraction: C, 42.90; H, 3.14; F, 56.36.

Tetrafluorocyclobutanes from tetrafluoroethylene and other dienes are listed in Table IV.

**1-Ethyl-1,2,2,3,3-pentafluorocyclobutane.**—Fifteen grams of 1-vinyl-1,2,2,3,3-pentafluorocyclobutane (boiling at 85°) was dissolved in 100 g. of absolute ethyl acohol, and was hydrogenated using 4 g. of Raney nickel catalyst and 1500 lb./sq. in. hydrogen pressure at 80°. After removing the catalyst, the solution was diluted with water, the water-insoluble layer was separated, dried over calcium chloride and distilled. 1-Ethyl-1,2,2,3,3-pentafluorocyclobutane was obtained boiling at 89–90° and having the following properties: $n^{25}D$ 1.3295, $d^{25}_4$ 1.2570, $MR_D$ 28.1.

*Anal.* Calcd. for $C_6H_7F_5$: F, 54.6. Found: F, 54.79.

The structure of 1-ethyl-1,2,2,3,3-pentafluorocyclobutane was assigned because of the resistance of fluorine atoms substituted in the cyclobutane ring to elimination by hydrolysis.

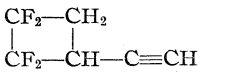
Hydrogenation of 1-(1-fluorovinyl)-2,2,3,3-tetrafluorocyclobutane (boiling at 95°) under similar conditions gave a product which was hydrolyzed by water. Hydrolysis with loss of fluorine is evidence that a fluorine atom was present in an aliphatic side chain. The fluorine atoms in a tetrafluorocyclobutane ring are quite resistant to hydrolysis.

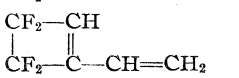
**1-Vinyl-1-chloro-2,2,3,3-tetrafluorocyclobutane and 1-(1-chlorovinyl)-2,2,3,3-tetrafluorocyclobutane.**—A silver-lined shaker tube was charged with 100 ml. of water, 88.5 g. of 2-chloro-1,3-butadiene and 1 g. of hydroquinone. After cooling and evacuating, 100 g. of tetrafluoroethylene was added, and the tube was heated with agitation at 100° for about eight hours. The recovered mixture was steam distilled to yield 115 g. of volatile liquid and 11 g. of non-volatile material. Fractionation of the liquid gave two distinct products: (1) 1-vinyl-1-chloro-2,2,3,3-tetrafluorocyclobutane (96 g.): b. p. 108°, $n^{25}D$ 1.3838, $d^{25}_4$ 1.3483, $MR_D$ 32.8, and (2) 1-(1-chlorovinyl)-2,2,3,3-tetrafluorocyclobutane (19 g.): b. p. 122–124°, $n^{25}D$ 1.3868, $d^{25}_4$, 1.3654, $MR_D$ 32.4.

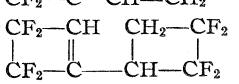
*Anal.* Calcd. for $C_6H_5ClF_4$: C, 38.21; H, 2.67; F, 40.30; Cl, 18.80. Found: (1) C, 39.46; H, 3.19; F, 40.03; Cl, 18.84. (2) C, 37.37; F, 40.03; Cl, 18.69.

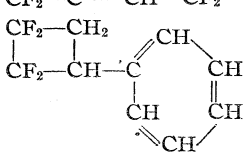
The hydrogenation of fraction (1) in absolute ethyl alcohol using Raney nickel catalyst at 80° and 1500 lb./sq. in. pressure gave a product boiling at 113° which analyzed for nearly the theoretical amount of chlorine but which still contained a little unsaturated material as evidenced by oxidation with aqueous permanganate solution. The physical properties of the compound were $n^{25}D$ 1.3690, $d^{25}_4$ 1.2954, $MR_D$ 33.2. The increase in the molecular refraction of 0.4 checks with that expected from saturation of a double bond by two hydrogen atoms.

*Anal.* Calcd. for $C_6H_7ClF_4$: F, 39.9; Cl, 18.65. Found: F, 40.17; Cl, 15.25.









The hydrogenation of fraction (2) in absolute ethyl alcohol using Raney nickel catalyst at 80° and 1500 lb./sq. in. pressure resulted in practically complete removal of the chlorine to yield 1-ethyl-2,2,3,3-tetrafluorocyclobutane boiling at 90–91.5°.

The assignment of the structures for fractions (1) and (2) involves the assumption that chlorine in an aliphatic side chain is more readily eliminated during hydrogenation than is chlorine substituted in the ring.

**1-Ethyl-2,2,3,3-tetrafluorocyclobutane.**—One mole (154 g.) of 1-vinyl-2,2,3,3-tetrafluorocyclobutane was hydrogenated at 80° using about 10 g. of Raney nickel catalyst

TABLE V

REACTION PRODUCTS FROM TETRAFLUOROETHYLENE AND MONOVINYLACETYLENE

X. This product reacted with dilute aqueous silver nitrate, did not polymerize readily, and on hydrogenation gave 1-ethyl-2,2,3,3-tetrafluorocyclobutane.

XI. This product did not react with aqueous silver nitrate, polymerized readily, and on hydrogenation gave 1-ethyl-2,2,3,3-tetrafluorocyclobutane.

XII. Hydrogenation of XII gave a product identical with the 2,2,2′,2′,3,3,3′,3′ octafluorobicyclobutyl obtained from butadiene and two molecules of tetrafluoroethylene.

XIII. This compound was identical with the 1-phenyl-2,2,3,3-tetrafluorocyclobutane obtained from styrene and tetrafluoroethylene (see Table I).

and 1000–1500 lb./sq. in. hydrogen pressure. The hydrogenation was exothermic. About one mole of hydrogen was absorbed, and 150 g. (96% yield) of 1-ethyl-2,2,3,3-tetrafluorocyclobutane was obtained boiling at 90–91° and having the following properties: $n^{25}D$ 1.3370, $d^{25}_4$ 1.1506, $MR_D$ 28.0.

*Anal.* Calcd. for $C_6H_8F_4$: F, 48.7 Found: F, 48.25.

1-Ethyl-2,2,3,3-tetrafluorocyclobutane was also obtained by hydrogenation of the two isomeric products from tetrafluoroethylene and monovinylacetylene, namely, 1-ethynyl-2,2,3,3-tetrafluorocyclobutane and 1-vinyl-3,3,-4,4-tetrafluorocyclobutene.

**1-Ethynyl-2,2,3,3-tetrafluorocyclobutane and 1-Vinyl-3,3,4,4-tetrafluorocyclobutene.**—A 400-ml. shaker tube was flushed with nitrogen, evacuated, and charged with 50 g. of monovinylacetylene and 50 g. of tetrafluoroethylene (containing less than 20 p. p. m. of oxygen). The sealed tube was heated at 100° for sixteen hours, and was then cooled to room temperature. After releasing the pressure, the light yellow liquid reaction product (82 g.) was removed and steam distilled to obtain about 60 g. of steam-volatile, colorless liquid which was heavier than water, and about 20 g. of light yellow, non-steam-volatile polymer. Analysis of the polymer indicated 26% fluorine, corresponding to a tetrafluoroethylene/monovinylacetylene mole ratio of 1:3.7. Fractionation of the liquid products through a precision column yielded the four products listed in Table V in about a 45:45:5:5 ratio, respectively. There was also a small amount of higher boiling material which was not identified.

**1-Methylene-2,2,3,3-tetrafluorocyclobutane and 1,1,-2,2,5,5,6,6-Octafluorospiro[3.3]heptane.**—Thirty grams of allene and 75 g. of tetrafluoroethylene were heated in a silver-lined shaker tube at 150° under autogenous pressure for eight hours. The excess gas was bled through a Dry Ice-trap, and 18 g. of liquid was obtained from the tube. Fractionation of the liquid gave two distinct products: (1) 1-methylene-2,2,3,3-tetrafluorocyclobutane (14 g.), b. p. 64–66°, $n^{25}D$ 1.3318, $d^{25}_4$ 1.2288, $MR_D$ 23.4, and (2) 1,1,2,2,5,5,6,6-octafluorospiro[3.3]heptane (4 g.), b. p. 107–109°, $n^{25}D$ 1.3325, $d^{25}_4$ 1.5137, $MR_D$ 32.7, $AR_F$, 1.30.

*Anal.* (1) Calcd. for $C_5H_4F_4$: C, 42.87; H, 2.88; F, 54.25. Found: C, 42.98; H, 3.72; F, 52.9. (2) Calcd. for $C_7H_4F_8$: C, 35.01; H, 1.68; F, 63.31. Found: C, 35.69; H, 2.35; F, 61.8.

Fraction (1) instantly decolorized neutral permanganate solution, whereas fraction (2) did not. Ozonolysis of fraction (1) in carbon tetrachloride gave formaldehyde. When 10 g. of fraction (1) was heated with 30 g. of tetrafluoroethylene in a bomb for eight hours at 150° an 18% conversion to fraction (2) was obtained.

**Acknowledgment.**—The authors are indebted to Dr. Paul R. Austin and Dr. W. E. Hanford for helpful suggestions and to Dr. J. W. Stillman under whose supervision the analyses were carried out.

## Summary

A new family of substituted tetrafluorocyclobutanes has been synthesized by the cycloalkylation of tetrafluoroethylene under non-polymerizing conditions with terminally unsaturated ethylenic and acetylenic compounds, and with 1,3-dienes. Typical members of the family include 2,2,3,3-tetrafluorocyclobutane and this fluorohydrocarbon substituted in the 1 position by alkyl, halogen, cyano, carboxy, carbalkoxy, and other groups. As a class, the tetrafluorocyclobutanes are resistant to ring cleavage.

# Rate Constants in Free Radical Polymerizations. I. Methyl Methacrylate

BY MAX S. MATHESON, E. E. AUER, ELLEN B. BEVILACQUA AND E. J. HART

Until recently, the absolute rate constants of vinyl polymerization have not been measured. Now, however, Burnett and Melville[1] and Swain and Bartlett[2] have applied the rotating sector method of Briers, Chapman and Walters[3] to the measurement of the absolute rate constants of vinyl acetate addition polymerization in the liquid phase. A new and elegant method has recently been devised by Bamford and Dewar[4] and applied to the measurement of the absolute rate constants of polymerization of styrene and methyl methacrylate. In their method, changes in intrinsic viscosity of a photopolymerizing system during and after irradiation and knowledge of the molecular weight of a thermal or photopolymer permit the evaluation of all the rate constants. A further very ingenious method applicable to emulsion polymerization has been developed by Smith and Ewart[5] for the measurement of the propagation rate constant. In this Laboratory, we have studied several monomers with the rotating sector method and this paper reports the work on methyl methacrylate.

## Theoretical

The usual studies on polymerization yield the ratios of rate constants rather than their individual values. This is made clear by consideration of the mechanism below, which includes simultaneous initiation by a free radical source such as benzoyl peroxide and by monomer.

| *Free Radical Initiation* | *Rate* |
|---|---|
| $\text{Init.} \xrightarrow{k_d} 2\text{R}\cdot$ | $2k_d\,(\text{Init.})$ |
| $2\text{R}\cdot \xrightarrow{k_r} \text{Stable product}$ | $2k_r\,(R\cdot)$ |
| $\text{R}\cdot + \text{M} \xrightarrow{k_a} \text{M}_1\cdot$ | $2k_a(\text{R}\cdot)\,(\text{M})$ |
| *Initiation by Monomer* | |
| $\text{M} + \text{M} \xrightarrow{k_i} \cdot\text{M}_2\cdot$ | $2k_i(\text{M})^2$ |
| *Propagation* | |
| $\text{M}_r\cdot + \text{M} \xrightarrow{k_p} \text{M}_{r+1}\cdot$ | $k_p(\text{M}_r\cdot)(\text{M})$ |
| $\cdot\text{M}_r\cdot + \text{M} \xrightarrow{k_{p1}} \cdot\text{M}_{r+1}\cdot$ | $k_p(2[\cdot\text{M}_r\cdot])(\text{M})$ |
| *Termination* | |
| $\text{M}_r\cdot + \text{M}_s\cdot \xrightarrow{k_t} \text{M}_{r+s}$ | $2k_t(\text{M}_r\cdot)(\text{M}_s\cdot)$ |
| $\text{M}_1\cdot + \cdot\text{M}_s\cdot \xrightarrow{k_{t1}} \text{M}_{r+s}\cdot$ | $2k_t(2[\cdot\text{M}_s\cdot])(\text{M}_r\cdot)$ |
| $\cdot\text{M}_r\cdot + \cdot\text{M}_s\cdot \xrightarrow{k_{t2}} \cdot\text{M}_{r+s}\cdot$ | $2k_t(2[\cdot\text{M}_r\cdot])(2[\cdot\text{M}_s\cdot])$ |
| *Transfer with Monomer* | |
| $\text{M}_r\cdot + \text{M} \xrightarrow{k_{tr}} \text{M}_r + \text{M}_1\cdot$ | $k_{tr}(\text{M}_r\cdot)(\text{M})$ |
| $\cdot\text{M}_r\cdot + \text{M} \xrightarrow{k_{tr1}} \text{M}_r\cdot + \text{M}_1\cdot$ | $k_{tr}(2[\cdot\text{M}_r\cdot])(\text{M})$ |

where

- Init. = initiator or source of free radicals
- R· = radical from initiator
- M = monomer
- $\text{M}_r\cdot$, $\cdot\text{M}_r\cdot$ and $\text{M}_r$ = respectively, monovalent polymer radical, bivalent polymer radical and stable polymer molecule of $r$ monomer units
- $k$'s = rate constants. Rates are given for formation or consumption of free valencies in initiation or termination, and for consumption of monomer in propagation or transfer.

Implicit in the mechanism are the following assumptions: (1) Although the "Cage" mechanism[6] is given, the essential assumption is that free radical induced initiation is proportional to (Init). Further, monomer initiation gives a biradical.[7] (2) The rate constants of propagation, termination, and transfer are independent of the length[8] or bivalent character of the polymer radicals. (3) The growing polymer radicals terminate by combining.[9] It is further assumed that: (4) Kinetic chains are long. (5) The monomer concentration is constant. In our work, except where specifically stated, no polymerization was carried beyond 5 to 10%. (6) A steady state is attained.

On the basis of the above, one obtains

$$R_i = 2k_d f(\text{Init.}) + 2k_i\,(\text{M})^2 \qquad (1)$$

where $R_i$ = rate of initiation of polymer radicals, $2k_d f(\text{Init.})$ = rate of initiation by initiator, and $f = k_a(\text{M})/(k_r + k_a(\text{M}))$ = constant if (M) held constant.

$$R_p^2 = [k_p^2(\text{M})^2/k_t]\,[k_d f(\text{Init.}) + k_i(\text{M})^2] \qquad (2)$$

where $R_p$ = rate of polymerization $= -\text{d(M)}/dt$.

$$\frac{1}{\bar{P}} = \frac{k_d f(\text{Init.})}{R_p} + C \qquad (3)$$

(9) J. H. Baxendale, S. Bywater and M. G. Evans, *Trans. Faraday Soc.*, **42**, 675 (1946), and M. G. Evans, private communication, give evidence for combination in methyl methacrylate; M. S. Kharasch, H. C. McBay and W. H. Urry, *J. Org. Chem.*, **10**, 401 (1945), show a large proportion of $\text{MeOC}_6\text{H}_4\text{CHCH}_2\text{CH}_3$ radicals dimerize with no evidence of disproportionation.

where $\bar{P}$ = number average degree of polymerization, $C$ = transfer constant = $k_{tr}/k_p$.

These equations show that if $R_p$ and $\bar{P}$ are studied as a function of (Init.) the quantities $k_p^2/k_t$, $k_d f$, and $C$ may be obtained. A further relation to evaluate $k_p$, $k_t$ and $k_{tr}$ individually may be obtained by measuring $\tau_s$, the time average lifetime of the growing polymer radical.

The theory of the rotating sector is fully presented elsewhere.[10] However, some monomers, especially styrene, exhibit "dark" reactions, and we have extended the theory to cover these systems using the mechanism below and following the procedure of Dickinson.[10]

| *Initiation* | *Rate* | *Definitions* |

**The Assumptions for Photopolymerization in Intermittent Light.**—(1) Initiation: The essential assumption is that the rate of initiation, $R_i$, is proportional to the absorbed light intensity, $I_a$. In our work thermal initiation during light periods in all sector experiments was negligible compared to the photosensitized initiation. During dark periods it is assumed that there is a "dark reaction," whose magnitude is equal to that which would be caused by stray light of intensity $nI_a$ (the dark rate, of course, is induced either by thermal initiation by the monomer as in styrene or by "catalysts" such as peroxides as in methyl methacrylate) where $I_a$ corresponds to the total initiation in the cell when the sector is open and $n$ equals a quantity less than one. Evidence for the mechanism as given has been found by Schulz and Husemann,[11] Schulz and Blaschke[12] and Mark and Josefowitz.[13] (2) Assumptions 2, 4, 5 and 6 of previous mechanism held valid. (3) The irradiating light is absorbed in the cell uniformly, both as to space and as to time during light periods. (4) The magnitude of the "dark" rate of initiation is unaffected by light. (5) The dark–light and light–dark transitions in the cell are instantaneous at the beginning and end of a light flash; precautions to insure the correctness of assumptions 3 to 5 will be found under Experimental Procedure.

From the assumptions about the initiation

$$d(M\cdot)/dt = 2qfI_a - 2k_t(M\cdot)^2 \qquad (4)$$

is derived for the light period while during the dark period the following is derived

$$-d(M\cdot)/dt = 2k_t(M\cdot)^2 - 2qfnI_a \qquad (5)$$

Following Dickinson, we obtain as the final result

$$\frac{(\overline{M\cdot})}{(M\cdot)_s} = \frac{1}{p+1}\cdot\frac{1}{b}\left\{b + n^{1/2}pb + \ln\left[\frac{1+\frac{(M\cdot)_2}{(M\cdot)_s}}{1+\frac{(M\cdot)_2}{(M\cdot)_s n^{1/2}}}\right]\left[\frac{1+\frac{(M\cdot)_1}{(M\cdot)_s n^{1/2}}}{1+\frac{(M\cdot)_1}{(M\cdot)_s}}\right]\right\} \qquad (6)$$

where

$(\overline{M\cdot})/(M\cdot)_s$ = the ratio of $R_p$ in intermittent light to $R_p$ in steady light

since

$(\overline{M\cdot})$ = the time average concentration of M· in intermittent light

and

$(M\cdot)_s$ = the concentration of M· in steady light,

and where

$p$ = ratio of the dark period to the light period = 3 in our work

$b$ = ratio of the time of flash, $t_1$, to the time average duration of growth, $\tau_s$, where $\tau_s$ is the lifetime of the kinetic chain from the initiation of a chain to its termination by mutual interaction with another growing radical

$(M\cdot)_1$ = concentration of M· at the beginning of each dark period

$(M\cdot)_2$ = concentration of M· at the end of each dark period

Further

$$\frac{(M\cdot)_1}{(M\cdot)_s} = \frac{\tanh b + \frac{(M\cdot)_2}{(M\cdot)_s}}{1 + \frac{(M\cdot)_2}{(M\cdot)_s}\tanh b} \qquad (7)$$

and

$$\frac{(M\cdot)_2}{(M\cdot)_s} = \frac{-(1-n)\tanh b\cdot\tanh(n^{1/2}pb)}{2[n^{1/2}\tanh b + \tanh(n^{1/2}pb)]} + \frac{\sqrt{(1-n)^2\tanh^2 b\cdot\tanh^2(n^{1/2}pb) + 4[n^{1/2}\tanh b + \tanh(n^{1/2}pb)][n^{1/2}\tanh b + n\tanh(n^{1/2}pb)]}}{2[n^{1/2}\tanh b + \tanh(n^{1/2}pb)]} \qquad (8)$$

The curves obtained by the use of eqns. (6), (7) and (8) are plotted in Fig. 1 for various values of $n^{1/2}$. $n^{1/2}$ is the ratio of the steady dark rate to the steady light rate. The use of Fig. 1 in the measurement of the kinetic chain lifetime, $\tau_s$, is illustrated under Experimental Procedure.

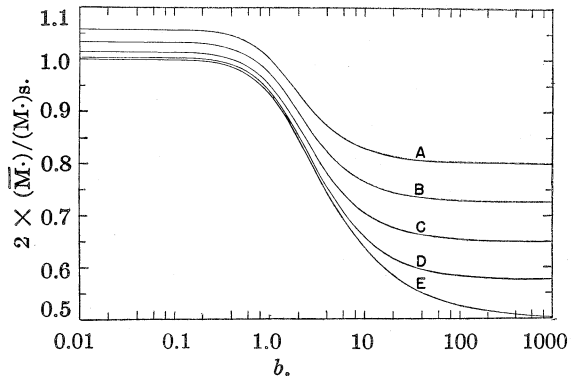

Fig. 1.—The ratio of intermittent light rate to steady light rate as a function of time of flash and dark rate: $A - n^{1/2} = 0.20$, $B - n^{1/2} = 0.15$, $C - n^{1/2} = 0.10$, $D - n^{1/2} = 0.05$, $E - n^{1/2} = 0.0$.

From the mechanism of photopolymerization, the following equations obtain in steady light

$$R_p = k_p(M\cdot)_s(M) \quad (9)$$

$$(M\cdot)_s = R_i\tau_s \quad (10)$$

$$R_i = 2k_t(M\cdot)_s^2 \quad (11)$$

whence

$$R_p\tau_s/(M) = k_p/2k_t \quad (12)$$

Thus, by measuring $\tau_s$ we can get $k_p/2k_t$ whereas by initiator studies we can get $k_p^2/2k_t$ and $k_{tr}/k_p$. The combination yields the individual values of $k_p$, $k_t$ and $k_{tr}$.

## Experimental

**Purification of Materials.**—Rohm and Haas methyl methacrylate was distilled through a 50-plate column under nitrogen: $n^{20}D$ 1.4152, b. p. 45.0° at 105 mm. This product was kept in the dark at −25° until further use. Subsequently, this material was recrystallized five times under dry nitrogen to a constant freezing point 0.3°[13a] above that of the distilled material with an over-all yield for all recrystallizations of 50%. The recrystallized material was stored in an evacuated tube containing 0.1% hydroquinone at −25° in the dark. Recrystallization and all subsequent operations were carried out in a dark room. Earlier experiments showed the necessity for filling the reaction cells by distillation into the cells *in vacuo* and in the absence of light if high dark reactions were to be avoided. Therefore, the vacuum bench and rotating sector equipment were located in a dark room. Eastman Kodak Co. biacetyl was distilled through a Vigreux column and the middle cut retained. Mallinckrodt Chemical Works photographic grade hydroquinone was used without further purification.

**Apparatus.**—A plan view of the rotating sector apparatus is shown diagrammatically in Fig. 2.

This apparatus enables sector studies to be made on two pairs of cells simultaneously, each pair being at a different temperature. The arcs A are Hanovia constant intensity high pressure mercury arcs, Type AH-8 with photocell feedback, supplied from two Sola constant voltage transformers in cascade. Experimentally the intensity was found to be constant to ±1% after a half hour warmup. The a. c. ripple in the light output was shown to be less than 3% of the total intensity. The light was made monochromatic by filters at F, using Corning no. 5840 and no. 738 filters to isolate the 3660 Å. line, except for the slow 30° experiment where the following combination was used: one 5840 + one 738 + three 5113. All lenses were crystal quartz 10 cm. f. l. and 4.6 cm. diameter free aperture. The lenses $L_1$ focused the narrow arc image at the sectors S, so that the transition time from dark to light and *vice versa* was about 2% of the light period. The sectors were made of 11 in. diameter aluminum disks divided into eight equal sectors and every fourth sector cut out to a radial depth of 2 in. These disks were driven by readily interchangeable synchronous motors. By means of these motors the disk speeds could be varied in steps from $^1/_{60}$ to 1800 r. p. m., each step corresponding approximately to a fourfold change in speed. The lenses $L_2$ were placed close to the sectors and considered to be located at the arc image. These lenses focused the image of the $L_1$'s in cells C to assure uniform light intensity over the cell and also to provide for simultaneous transition from dark to light throughout the cell. The images of the $L_1$'s overlapped the front windows of the cells 3 mm. all around. However, at the front of the cell a diaphragm limited the beam to just fill the inside of the cell. These cells were cylindrical cells with plane-polished faces, American Instrument Company Grade 1, 1 cm. internal depth and 3.7 cm. internal diameter. They were surmounted by a 25 cm. length of 2-mm. precision bore capillary. Gaertner M930–342 cathetometers were used to read the liquid levels in the capillaries to 0.01 mm. The cells were placed in holders in the baths B, so designed that inverted clear Pyrex cylindrical Dewars could be placed over the capillaries, the lower end of the Dewar dipping into the bath. Water was drawn up into the Dewar to cover the capillary, and for bath temperatures above room temperature, convection currents within the Dewar kept the temperature at the top of the capillary within 2° of that of the bath, even at a bath temperature of 60°. However, for bath temperatures below room temperature the difference at the top of the capillary was greater, since convection no longer played such an important part in heat transfer up the Dewar, but even in this case a more constant capillary temperature was assured, and in all cases the Dewar served to prevent condensation of the monomer in the capillary tip. Liquid level readings were taken through the transparent Dewar and this arrangement enabled the use of baths of moderate depth.

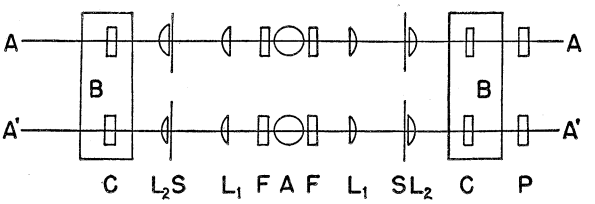

Fig. 2.—Apparatus for rotating sector studies.

During an experiment the constancy of the arcs was checked by the RCA935 photocells shown at P. A 6 cm. diameter quartz lens of 7.5 cm. focal length at the front of the photocell housing intercepted all of the light passing through the cell. The output of the 935 photocells was amplified by General Radio 715AE amplifiers and the amplified output recorded by Esterline Angus 5 ma. Model AW d. c. milliammeters. The output of the arcs was measured behind only one of the baths. The baths were fitted both front and rear with double windows of Corning no. 791 glass, having $^1/_4$″ of sealed air space. The double windows plus an air stream served to eliminate moisture condensation on the windows when the bath was operated at low temperatures. The temperatures of the baths were regulated to ±0.01°. Temperatures below room temperature were obtained by circulating an ethylene glycol–water mixture from an auxiliary American Instrument 4-86LE cooling bath through coils in the baths B. The optical paths in the diagram are designated AA and A′A′ and were thoroughly baffled and sealed against all stray light from other parts of the apparatus or originating externally.

(13a) F. p. of purified monomer −48.2° (Rohm and Haas Co. private communication). Using a thermocouple not absolutely calibrated we obtained a slightly higher value.

**Procedure.**—Filling of cells: Purified monomer was placed in a reservoir containing hydroquinone, and attached to a Pyrex glass vacuum system and degassed to a non-condensable gas pressure of $10^{-4}$ mm., while the monomer was at −80°. The process of melting, refreezing, and pumping on the monomer was repeated several times. The first 10% was distilled off *in vacuo* and rejected. Part of the remaining monomer was then distilled simultaneously into the bulbs B, as shown in Fig. 3. The volume of monomer in B was adjusted at 0° to a volume calibration mark on the bulb. The distilled biacetyl (the sensitizer used in all experiments) was also sealed to the vacuum system in a bulb containing hydroquinone. The required amount of biacetyl (calculated to give not more than 25% absorption in 1 cm. of depth when dissolved in the given volume of monomer in B) was distilled into a calibrated capillary for measuring at 0° and then into B. The apparatus of Fig. 3 was then sealed off at the constriction $C_1$. Next, the apparatus was inverted and the liquid level in the capillary of C adjusted to a suitable height. Both legs were cooled simultaneously to a few degrees above the freezing point of the monomer and the cell C sealed off at constriction $C_2$. The cell was stored at −25° in the dark until used.

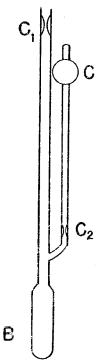

Fig. 3. — Device for filling cells.

**Irradiation.**—The cells were placed in the bath for a sufficient period before irradiation to get an accurate determination of the dark reaction, which in most cases was measured overnight. The cells were initially irradiated with the sectors in the open position to get the rate of polymerization in steady light. Then the sectors were started at known speeds and the rates of polymerization followed in intermittent light. The continuous and sectored irradiations were alternated during the day. Readings were taken at equal time intervals beginning a few minutes after the start of an irradiation so the method of Orthogonal Polynomials[14] could be used to get the least squares slope for the plot of liquid level *versus* time. Our method, it is believed, eliminates not only random reading errors but also errors due to slight heating and cooling effects in the cells at the beginning and end of a given irradiation as a result of the heat of reaction. If the experiments with a given cell were carried out over a period more than one day, the overnight dark reaction was checked each night. It was necessary to take the evening reading at least one hour after the end of an irradiation, otherwise the measured dark rate was affected by the decaying light-induced reaction.

**Densities.**—Since the rate was followed dilatometrically, the densities of monomer and polymer were determined as a function of temperature. The monomer used was freshly distilled, and the pyknometric determinations were carried out immediately in red light to avoid contamination by polymer. Constancy of the monomer density at 0° at the beginning and end of the experiment showed polymerization to be negligible. The polymer was prepared by allowing purified monomer to polymerize in sunlight in a pyrex flask in the presence of a trace of air. After apparent completion of polymerization the polymer was heated *in vacuo* at 100° for sixteen hours, after which the amount of monomer which could be pumped from shavings of the polymer at 100° was negligible. A portion of the polymer was cut to fit a mold and subjected to 2000 p. s. i. at 165° for one hour.

Recently Schulz and Harborth[15] have found the apparent density of polymethyl methacrylate to be greater in solution than in the pure solid state. To check this result two experiments were carried out. In one, freshly distilled monomer containing 0.2% tetrachloroquinone was poured into 100-cc. volumetric flasks containing weighed amounts of polymer and the volume determined after solution of the polymer. In the second experiment the monomer was distilled into 100-cc. volumetric bulbs *in vacuo*, 0.2 g. of benzoquinone being used in each flask as the inhibitor. Air was then introduced into each flask to compress the bubbles formed in the viscous solution. In each case density results were corrected for the small amount of inhibitor present. All of our samples of polymer initiated polymerization of the monomer, probably because of peroxides in them, necessitating the use of considerable inhibitor. The solution density results are given in Table II.

|---|---|---|---|
| 5.26 | 1.195 | 16.09 | 1.227 |
| 10.39 | 1.213 | 26.93 | 1.224 |
| 15.40 | 1.213 | 39.72 | 1.219 |
| 38.78 | 1.218 | | |

[a] Ref. 15 gives 1.213 at 25°.

**Calculation of Results.**—In cases where the dark rate amounted to more than 1% of the steady light rate, two corrections were made. First, least squares values of the rates were corrected for the dark reaction taking place in the unilluminated appendages to the cell, by subtracting the proper fraction of the dark rate, about 20%, from both continuous and sector rates. The ratio of the corrected sector rate to the corrected continuous light rate was then obtained. This is necessary since the theory considers the volume subject to illumination, and in the experimental setup the side tubes and capillary were completely shielded. For all cells used, both the volume in the barrel of the cell and the volume of monomer in the side tubes and capillary were measured. The effect of the dark reaction within the irradiated volume is considered next. By the use of the curves plotted in Fig. 1, the values of $b$ corresponding to the corrected rate ratio were found for values of $n^{1/2}$ of 0, 0.05, 0.10, 0.15 and 0.20 and from these data a plot of $b$ *vs.* $n^{1/2}$ was made ($n^{1/2}$, which will be called the fractional dark rate, is, as noted previously, the ratio of the steady dark rate of polymerization to the steady light rate of polymerization, both rates being

(14) Tables of Orthogonal Polynomial Values Extended to $N$ = 104: R. L. Anderson and E. E. Houseman, Research Bulletin 297, April, 1942, Ames, Iowa.

(15) G. V. Schulz and G. Harborth, *Angew. Chem.*, **59A**, 90 (1947).

limited to the cell barrel). The value of $b$ corresponding to the measured fractional dark rate which obtained during the experiment was then found by interpolation from the plot. The lifetime, $\tau_s$, is the ratio of $t_1$, the time of flash for the given sector speed, to $b$. An example in which a sector speed of 1/15 r. p. m. was used in experiment 19L will make this calculation clear.

| | | | |
|---|---|---|---|
| Rates | Cm./min. | Ratio | .315 |
| Dark | 0.000110 | 2 × Ratio | .630 |
| Dark correction outside cell | .000024 | $t_1$ sec. | 112.5 |
| | | $n^{1/2}$ | .021 |
| Corrected dark rate in cell | .000086 | $b$ measured for $n^{1/2}$ = .021 | 11.5 |
| 11th continuous | .00396 | $\tau_s$ | 9.79 |
| 12th continuous | .00403 | Rate % contraction per hr. | .0724 |
| Av. continuous | .00400 | $\tau_s$ @ 0.5% contraction per hr. | 1.42 |
| Corrected continuous | .00398 | 2 × ratio for $n^{1/2}$ = 0 | .625 |
| 8th sector | .001280 | | |
| Cor. sector | .001256 | | |

In any run ratios were measured at several different sector speeds. In order to obtain an average value of $\tau_s$ from these results, the rate ratios were plotted against the log of the time of flash (log $t_1$) and the position of best fit with the proper theoretical curve of Fig. 1 found. As seen from Fig. 1 and from eqn. (12), the experimental results will depend on the fractional dark rate and the rate of polymerization; therefore, it is necessary to correct the results with each sector to the same $n^{1/2}$ and the same $R_p$ before plotting as above. Further, if a series of experimental points is fitted to one of the curves shown in Fig. 1, the statistical weight for each point will depend in some manner on whether its abscissa corresponds to a flat or steep portion of the theoretical curve at the position of best fit. The points at the extremes of the curves have little effect on the average value of $\tau_s$, but do test whether the theory is obeyed. In view of these considerations it was deemed advisable in adjusting results to a common basis to follow a procedure which would not change appreciably the position of a given point relative to the proper theoretical curve.

The rate ratios were first corrected to the nearest dark rate of Fig. 1. For methyl methacrylate, since the fractional dark rates were small, this meant correcting the given rate ratio to that corresponding to the same experimental value of $b$ but at zero dark reaction ($n^{1/2} = 0$). In the example above the measured ratio for $n^{1/2} = 0.021$ is 0.630 and this is changed to 0.625 at $n^{1/2} = 0.00$, the value of $b$ remaining unchanged at 11.5.

From eqn. (12) $\tau_s$ is inversely proportional to $R_p$, also $b = t_1/\tau_s$, therefore it is seen that if a certain ratio and value of $b$ are measured for a given rate of polymerization, $R_{PA}$, and time of flash, $t_{1A}$, then this result is experimentally the same as obtaining the same ratio and same $b$ at $R_{PB}$ and $t_{1B}$ where $R_{PA}/R_{PB} = t_{1B}/t_{1A}$. On the basis of this, all ratios for a given run were corrected to a common $R_p$ adjusting the $t_1$'s inversely. Then on semi-transparent paper the ratios were plotted *vs.* the log $t_1$ on the same scale as the proper curve of Fig. 1. The plot of ratios *vs.* log $t_1$ was placed over the theoretical curve with ordinates matching and moved back and forth horizontally to several different positions about the position which appeared to give the best fit. At each position the vertical deviations of the experimental points from the curve were measured and the sum of the squares of the deviations calculated. The sum of squares for each position was plotted *vs.* ($t_1$ on experimental curve)/($b$ on theoretical curve) and the position of the minimum taken as $\tau_s$. The agreement between experiment and theory is indicated for a typical run (no. 17L-b) in Fig. 4. The $t_1$ and $b$ scales are displaced with respect to each other so that the best statistical fit of $t_1/b = \tau_s$ is obtained.

The results of all lifetime runs on methyl methacrylate are summarized in Table III. While the samples are small it is believed that the table as a whole indicates that the average results are reproducible to within 25% or less of the indicated values.

TABLE III

LIFETIMES OF POLYMETHYLMETHACRYLATE RADICALS

[a] Results in each experiment corrected to the same rate, the selected rate being very close to the experimental rates.

## Results and Discussion

For the case where thermal initiation is rela-

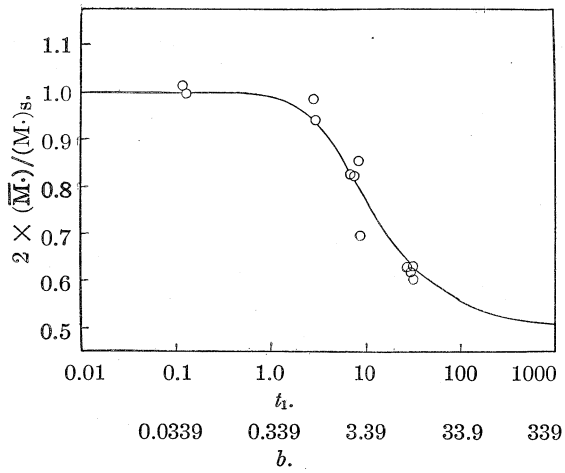

Fig. 4.—Rate of polymerization of methyl methacrylate in intermittent light for different times of flash: Curve, theory for zero dark rate; points, run 17L-b.

tively unimportant as in methyl methacrylate eqn. (2) reduces to

$$R_p = (k_p(M)/k_t^{1/2})\sqrt{k_d f\,(Init.)} \qquad (13)$$

and eqn. (3) to

$$\frac{1}{\bar{P}} = \frac{\sqrt{k_d f\,(Init.)}}{k_p(M)/k_t^{1/2}} + C \qquad (14)^{16a}$$

Schulz[11,12] has previously developed similar equations for this case and shown how by plotting $R_P$ *vs.* $\sqrt{(Init.)}$ and $1/\bar{P}$ *vs.* $\sqrt{(Init.)}$ values of $k_p^2/2k_t$ and $C$ may be obtained. We have combined the data of Schulz and Blaschke[12] with those of Schulz and Harborth[16] to obtain Table IV.

TABLE IV

| | 50°C. | 70°C. |
|---|---|---|
| $k_d f \times 10^7$ | 8.76 | 119 |
| $(k_p^2/2k_t) \times 10^3$ | 4.57 | 11.1 |
| $C \times 10^5$ | 4.77 | 8.07 |

$k$'s in this paper in moles, liters, seconds.

The results in Table IV differ from the average of those given in refs. 12 and 16 for three reasons. First, our calculations are based only on the results at different peroxide concentrations, ignoring the work in which the monomer concentration was varied as the experimental results are acknowledged by the authors to be less accurate at the lower monomer concentrations. Second, our least-squares plot of the data yields values differing slightly from those given for the peroxide studies. Third, although these authors assume termination by combination of radicals, their equation relating the degree of polymerization to kinetic chain length and the transfer constant corresponds to disproportionation. Because of this latter, our values of $k_p^2/2k_t$(or $k_B^2/k_C$) are very nearly half of those given by Schulz and coworkers. The revised values of Table IV constants recently published by Schulz and Harborth are considered by them to be more accurate. However, we have not used these values alone because (1) if only the studies in which the peroxide concentration is varied are used, $k_p^2/2k_t$ from the combined data is but little changed from that calculated from the same studies in ref. 12, (*e. g.* from ref. 12, we calculate $k_p^2/2k_t$ to be $4.52 \times 10^{-3}$ at 50° and $11.2 \times 10^{-3}$ at 70°); (2) a wider range of peroxide concentrations is used in ref. 12 as compared with 16.

If $(R_p\tau_s)/(M)$ is calculated from the data of Table III, the monomer densities of Table I and polymer solution densities of Schulz and Harborth[15,17a] for each experimental temperature, then Table V is obtained. The log of $k_p/2k_t$ is plotted *vs.* $1/T$ in Fig. 5.

TABLE V

(16) G. V. Schulz and G. Harborth, *Die Makromolekulare Chemie*, **1**, 106 (1947).

(16a) The work of Nozaki and Bartlett, THIS JOURNAL, **68**, 1686 (1946), shows that with benzoyl peroxide induced polymerization of styrene, transfer with the initiator occurs, so that eqn. (14) should include a term for this effect. However, the data of Schulz, *et al.*,[12,16] show the plot of $1/\bar{P}$ *vs.* $\sqrt{(Init.)}$ to be a good straight line with no hint of the upward curvature to be expected if transfer with the peroxide were important. F. R. Mayo has pointed out to us that polar effects would favor the transfer reaction of polystyrene radical with benzoyl peroxide as compared with polymethylmethacrylate radical plus the peroxide.

(17a) Use of the solid polymer densities of Table I would lower the calculated values of $k_p$ about 4–8% and change $E_p$ by 200 calories.

runs made in obtaining that point (see Table III), and then calculating the least-squares line. The runs at the low rates of polymerization at 30° were not included in these calculations and would not affect the result much anyway. Also plotted in Fig. 5 is the line for $k_p^2/2k_t$ as obtained from Table IV. From Fig. 5 and a plot of $C$ (Table IV) the values in Table VI have been calculated.

TABLE VI

| | 30° | 60° | $T$ |
|---|---|---|---|
| $k_p$ | 143 | 367 | $5.13 \times 10^6 e^{-6310/RT}$ |
| $2k_t$ | $1.22 \times 10^7$ | $1.87 \times 10^7$ | $1.36 \times 10^9 e^{-2840/RT}$ |
| $k_{tr}$ | $3.75 \times 10^{-3}$ | $22.9 \times 10^{-3}$ | $2.75 \times 10^6 e^{-12280/RT}$ |

In our calculations on our lifetime results the value of (M) was varied from temperature to temperature according to the data of Table I while Schulz and Blaschke appear to have used the same concentration of monomer at all temperatures for the pure monomer disregarding the variation due to expansion with temperature. This means that their values of $R_p$ and $k_p^2/2k_t$ need small corrections before they can be considered to correspond to the rate constants in terms of the actual moles per liter for a given temperature. This correction when made would, however, affect the log of the $k_p^2/2k_t$ *vs.* $1/T$ line only slightly.

The rate constants as represented by the last column of Table VI have the following ratios to the values found by Bamford and Dewar at 0°[4] for methyl methacrylate: for $k_p$ 1.05, $k_t$ 1.52, and for $k_{tr}$ 0.59. The excellent agreement is well within the experimental precision of the two methods. Indeed, if we used termination by disproportionation as do Bamford and Dewar our values of $k_p$ and $k_t$ would double. A consideration of the experimental quantities involved in the determination of the rate constants indicates that the decreasing order of precision is $k_p$, $k_t$, $k_{tr}$. The quantities entering the $k_p$ and $k_t$ values are similar except that $\tau_s$ enters $k_p$ to the first power and $k_t$ to the second, so that the errors in the lifetime are doubled in effect in the determination of $k_t$. In $k_{tr}$ the greatest source of uncertainty derives from the molecular weight measurements since $C$ is determined as the intercept of $1/\bar{P}$ *vs.* $\sqrt{(\text{Init.})}$

The activation energies in Table VI are of about the expected order of magnitude. The frequency factor for the termination reaction, which involves the interaction of two free radicals, approaches normality, whereas the factors for the propagation and transfer reactions, which involve a free radical plus an olefinic compound, are lower. The low frequency factor in the propagation reaction is in accord with the theories of Harman and Eyring.[17]

**Effect of Chain Length on the Termination Constant.**—The theory used in this work assumes the rate constants are independent of the radical chain length. However, Burnett and Melville[1] found that $k_t$ decreased 20% when the radical chain length was doubled in vinyl acetate. Therefore, it seemed desirable to determine whether such an effect existed in methyl methacrylate. In Table III the results of such a test carried out at 30° are given.

The ratio between the experimental rates in the two series of experiments was 6. If $k_t$ decreases 10% as the chain length is doubled it may be calculated that $\tau_s$ measured at the low rate of polymerization should be 40% longer than predicted by eqn. (12) from the value of $\tau_s$ at the high rate of polymerization. Actually, in Table III it is seen that the experimental $\tau_s$ is shorter, not longer, at the low rate of polymerization when the results are corrected to a common rate by eqn. (12). Applying statistics to these admittedly small samples, it is estimated that there is less than a 1% chance that the rate constant does decrease by as much as 10% when the polymer radical length is doubled. We conclude, therefore, that the rate constant for termination is independent of chain length at least up to about 10% conversion.

**Experiments at High Conversion.**—Schulz and Blaschke[18] in investigating the benzoyl peroxide-induced polymerization of methyl methacrylate noted that the rate strongly accelerated after about 20% conversion was obtained at 70°. Trommsdorff[19] subsequently found this rate acceleration to be accompanied by a corresponding increase in the degree of polymerization, and suggested this effect is due to a decrease in the termination constant as the system becomes more viscous. Later, Schulz and Harborth[16] confirmed that even under isothermal conditions at 50 and 70° this strong acceleration persisted and that $\bar{P}$ increased approximately in the same ratio as the rate of polymerization, at least up to 40% conversion and where transfer was not too important. In their interpretation also the growing chains find it more difficult to diffuse together in the viscous medium.

Burnett and Melville[1] found this acceleration to occur at about 25% conversion in the photopolymerization of vinyl acetate and also to appear even earlier in vinyl acetate photopolymerized in a poor solvent such as *n*-hexane.[20] This "gel effect," as they call it, is also attributed by them to a decrease in $k_t$ as the polymer–monomer mixture becomes more viscous. From sector measurements they estimated approximate values of $k_t$ at some point in the gel stage. The results in *n*-hexane were explained as due to a coiling up of the molecule which prevented the active ends of the growing radicals coming together. However,

(18) G. V. Schulz and F. Blaschke, *Z. physik. Chemie*, **B50**, 305 (1941).

(19) Trommsdorff, "Colloquium on High Polymers," Freiburg, 1944.

(20) Burnett and Melville, *Proc. Roy. Soc. (London)*, **A189**, 494 (1947).

more plausible to us is the explanation Schulz and Harborth used to account for the results of Norrish and Smith[21] on methyl methacrylate polymerizations in poor solvents. They attribute the acceleration to precipitation of the polymer which then absorbs monomer to give an inhomogeneous mixture, portions of which correspond in composition to high conversion.

To test the effect of high conversion on the lifetime of polymethyl methacrylate radicals, two cells were prepared by the usual procedure and irradiated with steady light of the usual intensity at 30° until a conversion of ~37% was attained. At this point, sector measurements were made. Since the rate had increased so much on attaining this conversion, it was necessary to reduce the rate by reducing the light intensity 12.6-fold in order to make accurate measurements of the lifetime. Table VII summarizes the results.

TABLE VII

| Cell | Init. rate contraction, %/hr. | Conversion at which rate increased, % | (Rate at 37% conv.)/(Init. rate), av. | Lifetime measurements $\tau_s$ sec. | Rate contraction %/hr. | Conversion |
|---|---|---|---|---|---|---|
| 1 | 0.496 | 16.0 | | 111 | 0.755 | 33.9 |
| | | | 6.43 | 105 | .946 | 36.3 |
| 2 | .395 | 12.9 | | 100 | .746 | 36.5 |
| Av. | .451 | 14.5 | 6.43 | 105 | .816 | 35.6[a] |

[a] Because irradiation and reaction occur in fixed volume, conversion of 35.6% of the original monomer in the irradiation zone yields a solution corresponding to 33.2% conversion as monomer enters from capillary.

In the work of Schulz and Harborth the increase in molecular weight fully accounts for the accelerated rate and the rate of initiation may be considered constant up to a considerable conversion. The theory of the "cage effect" indicates, however, that $R_i$ may depend upon (M) and the following

TABLE VIII

PHOTOPOLYMERIZATION METHYL METHACRYLATE AT 3660 Å. AND 30° BIACETYL SENSITIZER[a]

| $R_p$ | $\bar{P}$ | Quantum yield $R_p/I_a$ | $Cb$ | $\bar{\nu}$ | $qf$ |
|---|---|---|---|---|---|
| $2.36 \times 10^{-4}$ m./l./sec. | 1963 | 43.1 | $2.6 \times 10^{-5}$ | $1.03 \times 10^3$ | 0.021 |

[a] These experiments yield $k_p/\sqrt{2k_t}$ 30% higher than Fig. 5. [b] From Table IV data. $\bar{\nu}$ = number av. kinetic chain length.

(21) R. G. W. Norrish and R. R. Smith, *Nature*, **150**, 336 (1942).

averages from three experiments enable us to make the assumption as to this dependence.

If $q$, the quantum yield for dissociation of biacetyl, is near 1.0 (experimentally we have found the quantum yield of biacetyl disappearance in ethyl alcohol was approximately 0.7), then $f$ is seen to be low and is therefore $\simeq(k_d/k_r)(M)$. Thus, $R_i$ may be assumed proportional to (M). The result of combining the lifetime data with either the assumption that $R_i$ is constant or is proportional to (M) is given in Table IX.

TABLE IX

| | ($k_p$ initial)/($k_p$ at 33% conversion) | ($k_t$ initial)/($k_t$ at 33% conversion) |
|---|---|---|
| $R_i$ = constant | 0.62 | 216 |
| $R_i \alpha$ (M) | .89 | 151 |

We may conclude that at 33% conversion the propagation constant is unchanged while the termination constant has decreased over 100-fold. Thus, at low conversions we have found the termination constant to be independent of radical chain length while at high conversions the presence of a considerable amount of polymer has decreased the termination constant considerably. It is probable that in the presence of appreciable polymer the termination constant is no longer independent of chain length.

**Acknowledgment.**—The authors wish to express their appreciation to Dr. H. M. Smallwood for his advice and encouragement during the course of this work.

## Summary

The average lifetime of growing polymethyl methacrylate radicals in the photosensitized polymerization of the liquid monomer has been measured as a function of temperature. Combining the lifetime data with studies by Schulz on the rate of polymerization and polymer molecular weight *vs.* free radical initiator concentration gives the rate constants for propagation, termination, and transfer with the monomer. In the initial stages the termination rate constant is independent of chain length. The accelerated polymerization rate occurring in the later stages is due to a decrease in the termination constant.

The theory of the rotating sector has been extended to include those cases having appreciable "dark" rates of polymerization.

# On the Thermodynamics of Solutions. IV. The Determination of Liquid–Vapor Equilibria by Measuring the Total Pressure[1,2]

BY O. REDLICH AND A. T. KISTER

It has been repeatedly noticed[3] that the knowledge of the total pressure over a binary solution as a function of the composition of the liquid at constant temperature is sufficient for a complete description of the liquid–vapor equilibrium at this temperature. In other words, the activity coefficients can be derived, in principle, from the total pressure without knowledge of the composition of the vapor. In spite of this considerable advantage, the method has not been used very often. One reason is obvious, namely, the difficulty of the calculation. Indeed, none of the various calculation methods appears to be satisfactory. Another reason may have been the suspicion that small experimental errors may entail unduly large errors in the resulting activity coefficients. This question appears to deserve a careful examination.

The present paper is restricted to a special case of some practical importance. The efficiency of distillation columns containing a large number of plates is frequently investigated by means of binary solutions of closely boiling hydrocarbons. The relative volatility of the binary system must be known with a fairly high accuracy since in a column of $n$ plates the error in the resulting efficiency is $n$ times the relative error in the relative volatility. A sufficiently accurate analysis of the liquid and the vapor presents, in general, serious difficulties since the properties of closely boiling hydrocarbons are not sufficiently different. The advantage of the measurement of the total pressure therefore is important. At the same time, convenient calculation methods can be developed for these systems which deviate only slightly from perfect solutions.

## Experimental

To obtain the full advantage of the method, one has to observe two conditions: (a) The composition of the liquid should be obtained by weighing the components. Accordingly the vapor space over the boiling liquid should be small so that the correction for the change of composition by vaporization is negligible or small. (b) Especially for systems of closely boiling components, a differential method is preferable in which the vapor pressure of a solution is directly compared with the vapor pressure of one component boiling at the same temperature. The temperature difference between the two boilers is measured by means of a thermocouple, which requires less vapor space than a resistance thermometer.

The vapor pressure of the component used for reference and the pressure difference between the two boilers are determined by means of a mercury manometer. Capillary depression is eliminated by the use of 20 mm. tubing. The boiling temperature of the reference substance is calculated from the vapor pressure.

Between the manometer legs and the boilers are buffer bulbs (2 liters), Dry Ice traps and short condensers. The manometer and the buffer bulbs are enclosed in an air thermostat. The connecting lines between the manometer and the condensers are filled with nitrogen, the amount of which is precisely controlled by means of needle valves in side lines leading to a nitrogen tank and a vacuum pump. Pressure fluctuations are avoided by maintaining a steady flow rate of the cooling liquid (water or acetone cooled by means of Dry Ice) in the condensers.

The Cottrell boilers (Fig. 1) are enclosed in silvered vacuum jackets j. The kettle is heated by a coil fitting in the cylindrical space h. The thermocouple is introduced into the well w. The liquid thrown up to the well by the Cottrell pump returns through the line r and mixes there with the reflux from the condenser c so that there is practically no holdup of condensed vapor. After the measurement the boiler is drained through the tube d. The boilers are charged each with 85 ml. of liquid. The vapor space up to the level of condensation amounts to 185 ml. The heaters are arranged in series and operate at 60 watts each. The resistances of the heaters are made equal within 1%.

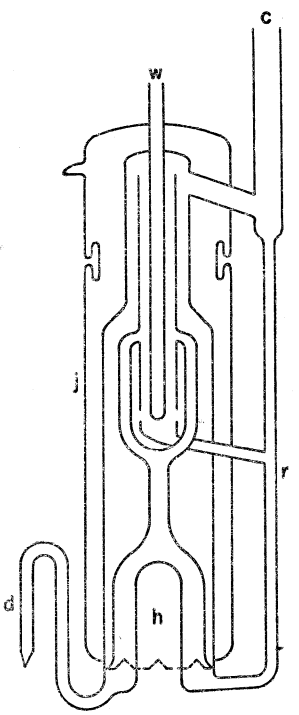

Fig. 1.—Boiler.

The desired boiling temperature is obtained by adjusting the amount of nitrogen in the connecting lines between manometer and boilers. The temperature difference is easily maintained below 0.02° and measured within 0.001°. Only a crude calibration of the thermocouple is therefore required, easily obtained by letting the same pure substance boil in the two boilers at different pressures.

The filling hole is in the connecting line above the Dry Ice-trap so that any contact between vapor and glass stopper is avoided. The solutions, however, are filled into the boiler through a glass tube extending through the trap so that the vapor cannot be carried into the manometer lines.

The purity of the components must be checked by comparing the difference of their vapor pressures with adopted values. Small impurities are harmless if the consistency of the results is maintained by a suitable correction.

The errors introduced by the determination of the pressures and the temperature difference and by weighing influence the total pressure (at about one atmosphere) only by a few thousandths of one per cent. The change of concentration by vaporization into the vapor space is of the

same order of magnitude for closely boiling systems. The main error, especially for low boiling mixtures, appears to be due to vaporization during the preparation of the solution. The possible error during the filling of *n*- and isopentane into the weighing flask was estimated and a correction of one half its amount was applied. The maximum correction corresponded to 0.025% in the total pressure. Altogether, errors of a few hundredths of one per cent. are to be expected.

## Results

The results obtained at approximately atmospheric pressure are shown in Figs. 2 to 5. The ordinate is the ratio

$$\pi = P/(x_1P_1 + x_2P_2) \qquad (1)$$

($x_1$ and $x_2$ are the mole fractions of the liquid). The functions $P_1$ and $P_2$ are sufficiently approximated[4] for the present purpose by

$$\ln P_1/p_1^\circ = (V_1 - \beta_1)(P - p_1^\circ)/RT \qquad (2)$$

($p_1^\circ$ vapor pressure, $V_1$ molal volume of the liquid, $\beta_1$ second virial coefficient). Since

$$x_1\gamma_1P_1 = y_1P \qquad (3)$$

($\gamma_1$ activity coefficient), the total pressure is

$$P = x_1\gamma_1P_1 + x_2\gamma_2P_2 \qquad (4)$$

The calculation of the activity coefficients presents no difficulty if, as in the present case, the approximation

$$\log \gamma_1 = Bx_2^2, \quad \log \gamma_2 = Bx_1^2 \qquad (5)$$

is sufficient. In this case we calculate the function $\pi$ of eqn. (1) for a few suitably chosen values of $B$ according to (1), (4) and (5), draw the corresponding curves in a diagram containing the experimental points and find the best value of $B$ by interpolation. This method has the advantage that the influence of experimental errors on the result is immediately seen.

The diagram furnishes a direct indication if the approximation (5) is insufficient and a second term of a Margules series is to be added. In this case the experimental points are consistently above the closest fitting curve in one part of the diagram and consistently below in the other part. The graphical method can be extended to this case without serious difficulty.

For small values of $B$ an even simpler method can be used. Equation (5) is approximated by

$$\gamma_1 - 1 = 2.303\ Bx_2^2, \qquad \gamma_2 - 1 = 2.303\ Bx_1^2 \qquad (6)$$

so that

$$\pi = 1 + 2.303\ Bx_1x_2(x_1P_2 + x_2P_1)/(x_1P_1 + x_2P_2) \qquad (7)$$

This approximation is sufficient for $P_1/P_2 = 1$ if $B < 2.1\ (d\pi)^{1/2}$ and for $P_1/P_2 = \infty$ if $B < 0.6\ (d\pi)^{1/2}$ where $d\pi$ is the permissible error in $\pi$.

The figures contain the curves representing the adopted values of $B$. The vapor pressures of Rossini and his co-workers[5] were used for the calculations. The second virial coefficients were calculated from Berthelot's equation. The values of $B$ may be in error by a few units of the fourth decimal place, corresponding to a maximum error of 0.1% in the relative volatility.

In measurements of this type, the correction for the imperfection of the vapor (Eqn. 2) may be important even at atmospheric pressure. In the system iso- and *n*-pentane the value of $B$ would be $-0.0023$ without the appropriate correction instead of $-0.0008$.

**Acknowledgment.**—The authors are indebted to Mr. L. T. Carleton for valuable advice regarding the construction of the apparatus.

## Summary

Small deviations from the perfect solution are conveniently and accurately determined by measurement of the total pressure. The experimental procedure is described. Results are given for the six binary systems formed by the three xylenes

# Physical Properties of Some Organic Insect Repellents[1]

BY W. J. SVIRBELY, W. M. EARECKSON III, K. MATSUDA, H. B. PICKARD, I. S. SOLET AND W. B. TUEMMLER

Under the Insecticide and Insect Control Research and Development Program carried out for the Department of National Defense, a large number of organic compounds were prepared and tested for their insect repellent effectiveness. It was thought that a critical study of the physical properties of some successful repellents might be of value in determining whether or not a correlation existed between repellent effectiveness and certain physical characteristics. However, the data required to make such a study were not available. We, therefore, were asked to provide certain physical data for a large number of compounds. The results which we have obtained up to the present are recorded in Table I.

## Experimental

**Purification of Materials.**—About 25 to 30 ml. of starting material (all that was available) was vacuum distilled. A Vigreux column, 1 cm. diameter and 15 cm. long, provided with a chromel heating jacket, was used for all distillations except for isobutyric acid, α-hydroxy-, phenethyl ester and *dl*-malic acid, dibutyl ester. The middle fraction (50–60%) was collected under the conditions given in Table I.

**Refractive Indices.**—Measurements were made using an Abbe refractometer with temperature control. Check results agreeing to 0.0001 unit were obtained. The refractometer was calibrated against water (obs., 1.3325; lit., 1.3325) and with a test plate (obs. 1.5185; manufacturer's value for plate, 1.5185).

**Boiling Points.**—The boiling points were determined by a micro method.[2] The average of five to ten readings for each compound was always within 0.4° of the extreme readings. All boiling points were corrected to 760 mm. Based on the results for the reference materials listed in Table II and on the behavior of the test materials which did not decompose, we estimate the boiling points in Table I to be within 0.3°.

**General Information for Remaining Measurements.**—Due to the limited amounts of material available for the tests, it was necessary to design apparatus whose total volume was not over 2 cc. This necessitated the use of capillary tubing wherever possible. Such apparatus was usually cleaned with acetone, water, potassium chromate–sulfuric acid cleaning solution, water and distilled water. The apparatus was then dried with a current of clean dry air for about an hour while it was kept in the oven at about 45°.

Material was usually introduced into measuring apparatus by suction. All possible precautions to avoid picking up moisture in the course of an experiment were taken.

All thermostats (except the one used for refractive index measurements) were maintained at 35 ± 0.02°.

All thermometers were calibrated against thermometers previously calibrated by the Bureau of Standards.

After the test material was introduced into a measuring apparatus, the unit was allowed to come to temperature equilibrium in a minimum period of fifteen minutes.

**Density.**—Ostwald-Sprengel type pycnometers, volume about 1 ml., were used. Check weighings, agreeing to 0.1 mg., were made on a pycnometer and its contents. The precision is estimated to be 0.01%.

**Viscosity.**—Ostwald viscosimeters, volume between marks was 0.7 to 1.0 ml., were used. Five viscosimeters (small bore capillary) were calibrated with water, while one viscosimeter (large bore capillary) was calibrated with phthalimide, N-*s*-butyl-, after its viscosity was determined. The large bore viscosimeter was used for compounds whose viscosity was greater than 180 millipoises. The times of efflux on check runs agreed to 0.2%. Considering reproducibility and agreement with the value for benzene, we consider the results in Table I to be accurate to at least 0.2%.

**Solubility.**—The method discussed by Sobotka and Kahn[3] was used. The test material is added drop by drop from a calibrated, water-jacketed, 1-ml. microburet, to a definite amount of water contained in a thermostated, glass-stoppered flask, until the end-point is reached (corresponding to the saturation of the water by the test material). Sudan IV was used as the indicator. From the density and volume of the material used, its solubility in grams per 100 ml. of water is calculated. The results, given in Table I, are based on duplicate runs.

A test run made on diethyl succinate gave a value of 1.73 g./100 ml. of water compared to a value of 1.78 g./100 ml. of water obtained by saponification with subsequent titration of a saturated solution of diethyl succinate in water. Benzyl alcohol, *p*-methoxy-, gave a solubility of 3.83 g./100 ml. of water compared to a value of 3.84 g./100 ml. of water obtained from a refractive index calibration curve.

**Surface Tension.**—In the first part of this work, measurements were made by the capillary tube method. The radius of each of six different tubes was determined using both benzene and water as standards. The results for each tube agreed to 0.5%. Heights of liquid in the tube and in the reservoir were measured with a cathetometer reading to 0.1 mm. A duplicate run was made on each material using a different capillary. The reproducibility of data and the agreement with the ring method used on phthalic acid, dimethyl ester and phthalimide, N-*s*-butyl-, indicate that the results given in Table I are within 1% in all cases and within 0.5% in the majority of cases (*i. e.*, those values not designated by the letter R).

Difficulty was experienced in getting equilibrium heights by the capillary tube method in the case of some of the compounds. In those cases, the surface tensions were measured by the ring method, using a Cenco du Noüy precision direct reading tensiometer. The test liquid was placed in a weighing bottle surrounded by a jacket through which the bath water was circulated. The average of eight readings was used in each case to get the approxi-

mate surface tension. This approximate value was then corrected by the method given by Harkins.[4]

The surface tensions, marked R in Table I, are the values obtained by the ring method. Based on reproducibility of data and on the agreement with the literature values for the reference materials given in Table II, the surface tensions by the ring method are estimated to be accurate within 0.4%.

**Interfacial Tension.**—The interfacial tensions of the test material against water were measured by the drop-volume method.[5] The volume of the pipet in terms of distance between divisions was determined by calibration with mercury. The position of the meniscus was determined with a cathetometer, reading to 0.1 mm. The

# The Use of Radioactive Tracers in a Study of Activator Distribution in Infrared-Sensitive Phosphors[1,2]

BY R. W. MASON, C. F. HISKEY AND ROLAND WARD

The preparation and some of the properties of infrared-sensitive phosphors of the alkaline earth sulfides and selenides have been described by Urbach,[3] Smith,[4] Primak[5] and Stripp.[6] It has been found that reproducible samples are most conveniently prepared by the use of presumably non-reactive fluxes such as lithium fluoride or strontium chloride. The flux effects a complete recrystallization of the base material[5] and serves to introduce the activators during the recrystallization. Since the luminescent properties are quite sensitive to variation in the concentration of the activators, the relationship between these and the brightness of the phosphors under stimulation was investigated.[6] While the results were empirically satisfactory, the absolute activator concentration was not known since the activators at equilibrium conditions must be distributed between the base and the flux. The determination of distribution coefficients of rare earth ions at such low concentrations (0.02% or less) in alkaline earth compounds would be very difficult by the usual analytical procedures, but the availability of radioactive isotopes of europium, cerium and samarium offered a possible solution.

The main difficulty in the application of the tracer technique lay in the separation of the intimately mixed phases. A separation method based on the difference in specific gravities of the base and flux was only partially successful. A much more satisfactory procedure was devised which involved filtration at the fluxing temperature (about 1000°) using a platinum Munroe crucible. Since the method may find some application in studying solubility phenomena in molten salt systems, the procedure is described here in some detail.

## Experimental

**Materials.**—Strontium sulfide and selenide were prepared as previously reported.[3,4] The fluxes, strontium chloride and lithium fluoride, contained only spectroscopic traces of the other alkaline earths and the alkali ions.

## Procedure

(1) **Separation of Base and Flux by Filtration.**—The preparation of a Munroe crucible has been described by Snelling[7] and Swett.[8] Although the platinum mat is reasonably resistant to attack by the phosphor mixtures at 900 to 1100° in a nitrogen atmosphere, it eventually develops pinholes or cracks. These may be sealed by dipping in chloroplatinic acid and heating at 500° or by decomposing a layer of ammonium chloroplatinate on the mat and burnishing and compressing with a glass rod.

The mixtures containing strontium chloride separated readily by gravity filtration but those containing lithium fluoride required suction. For this purpose the apparatus shown in Fig. 1 was constructed. A smooth flange was forged on the Munroe crucible (1) and one end of the

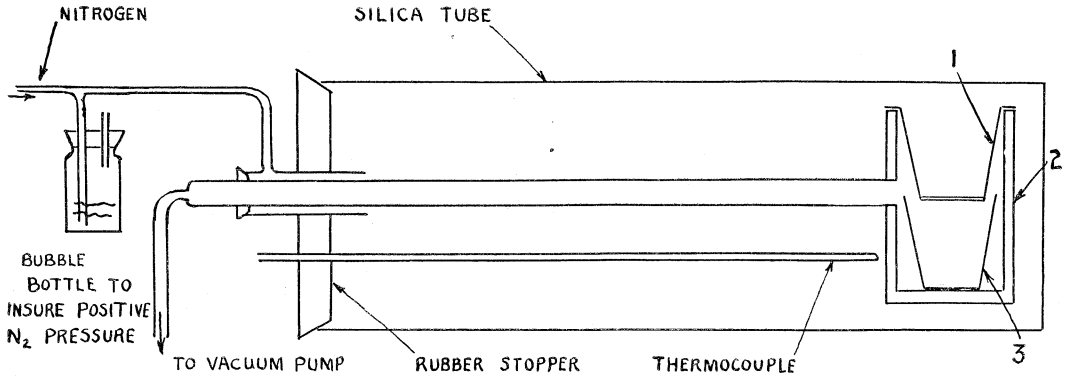

Fig. 1.—Apparatus for suction filtration.

silica tube (2) was faced by grinding with carborundum. The flange seated on this surface gave a sufficiently tight joint so that suction filtration could be rapidly completed. The filtrate was collected in the platinum receptacle (3). The platinum mat usually required repair after two or three suction filtrations. This may have been due to the applied pressure or to the more corrosive action of the lithium salts. It has been found that for some systems nickel is more resistant than platinum. Preliminary experiments showed that filtration could only be accomplished with mixtures containing a much higher proportion of flux than is used in the phosphor preparation (about 10%). For the systems strontium sulfide–strontium chloride and strontium selenide–strontium chloride, 60 to 85 weight per cent. of strontium chloride was found most suitable. Because of the high solubility of strontium sulfide in lithium fluoride, it was necessary with this system to use mixtures in the range of 40 to 60 per cent. flux.

The mixtures for distribution studies were prepared by adding to a weighed quantity of flux europium, cerium or samarium and an adequate amount of the radioisotope as solutions of their chlorides. The mixture was dried at 200° and mixed with the appropriate amount of base. To bring the system as close to equilibrium as possible before filtering, the mixture was pre-heated at the filtering temperature for one hour and cooled in an atmosphere of nitrogen. It was then transferred to the Munroe crucible and heated in a nitrogen atmosphere to the desired temperature. About one-half hour was sufficient for gravity filtration of the mixtures with strontium chloride. The lithium fluoride mixtures were heated for half an hour before filtering by suction which usually took less than a minute.

After cooling under nitrogen, the filtrate and residue were powdered and samples of each reserved for counting and for chemical analysis. The solubilities of the base materials in the molten fluxes are given by analyses of the filtrates.

**(2) Analyses of the Fractions.**—For the strontium chloride–strontium sulfide mixtures, the determination of the sulfide sulfur was made by taking a portion of the fraction, adding it to a standard iodine solution, and after acidification titrating the excess iodine with thiosulfate solution. The strontium chloride was found by difference and the total strontium by conversion to the sulfate. The same general method was followed with the strontium chloride–strontium selenide mixtures except that selenium was determined by oxidation with bromine in acid solution and precipitation as selenium by hydrazonium ion. The lithium fluoride–strontium sulfide mixtures were taken to dryness with sulfuric acid and weighed. The lithium sulfate was dissolved in water and alcohol was added to give a 50% solution. The strontium sulfate was filtered and weighed and the lithium determined by difference. These procedures were checked by more complete standard analyses and were found to be sufficiently precise for this work. The precision was about ±0.2% for the strontium chloride systems and about ±0.5% for the lithium fluoride–strontium sulfide mixtures.

Some of the results are given in Tables I, II and III. From the analyses of the filtrates it can be seen that the solubilities of the strontium sulfide and strontium selenide in the strontium chloride are quite low compared with the solubility of

|---|---|---|---|
| 16 | 940 | 35.8 | 82.0 |
| 17 | 1000 | 37.3 | 82.0 |
| 18 | 1000 | 38.3 | 79.0 |
| 19 | 1000 | 37.6 | 80.0 |
| 20 | 1100 | 45.2 | 90.0 |

strontium sulfide in lithium fluoride. The solubilities of the sulfide in the strontium chloride and in the lithium fluoride show an average deviation of about 4%, but for the selenide the average deviation is about 9%. An appreciable increase in solubility with rising temperature is apparent in each of the systems.

(3) **Activator Distribution.**—Samples of the filtrates and residues were prepared for counting by a slight modification of the procedure described by Kamen.[9] In most instances the sample was ground, a 50- or 100-mg. portion suspended in symmetrical tetrachlorethane and filtered through a circular paper in a gooch crucible. The paper, thus covered with an even layer of solid, was transferred to a copper plate, dried and fixed in position with scotch tape. The sample was then bent to fit around the counter tube. The reproducibility was quite satisfactory. It was found that no correction was required for self-absorption. A few samples were prepared by dissolving the sample and evaporating an aliquot on absorbent paper. The precision of the counting including the preparation of samples was about ± 5%.

In Table IV are given the characteristics of the radioactive samples. They were prepared at

TABLE IV

CHARACTERISTICS OF RADIOACTIVE ACTIVATOR SAMPLES[10]

| Irradiated sample | Radioisotopes present | Half-life | Radiation (MEV) Beta | Gamma |
|---|---|---|---|---|
| Europium | Eu 152 | 9.2h | 1.61 | |
| | 154 | 5.8y | 0.34, 0.82 | 1.4 et al. |
| Cerium | Ce 141 | 28d | 0.55 | 0.21 |
| | 143 (Parent of Pr 143) | 33h | 1.35 | 0.50 |
| | Pr 143 | 13.8d | 0.95 | None |

| | 155 (Parent of Eu 155) | 25m | 1.9 | 0.3 |
| | Eu 155 | 2y | 0.3 | 0.084 |

the Oak Ridge laboratories by pile irradiation of pure compounds of the elements. The compounds used were europium oxide (furnished by the late Herbert N. McCoy), cerous nitrate and samarium oxide (prepared in Luigi Rolla's laboratory). In counting the cerium samples the beta-radiation was eliminated by means of aluminum foil so that only the gamma-radiation from the cerium isotopes was counted. A standard sample was counted periodically during the course of the measurements. The data, plotted in Fig. 2 against the theoretical decay curve for a twenty-eight day half-life, indicate the possibility that a longer lived contaminant was present, but in negligible amounts. The decay of the samarium sample is shown in Fig. 3 to be close to the theoretical forty-seven hour half-life curve which indicates that the contribution of europium 155 to the total count is unimportant.

(10) Data taken from Radioisotopes Catalog and Price List No. 2, U. S. Atomic Energy Commission, Oak Ridge, Tennessee, revised September, 1947.

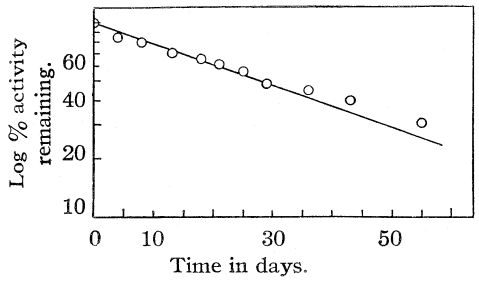

Fig. 2.—The line represents the theoretical decay for twenty-eight day half-life.

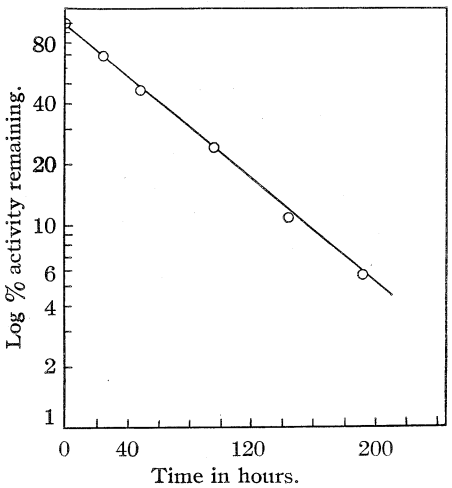

Fig. 3.—The line represents the theoretical decay for forty-seven hour half-life.

The quantities of irradiated europium, cerium and samarium which gave convenient counts in the distribution studies were approximately 10, 200 and 3 parts per million of the base material respectively. Additional quantities of the non-radioactive activators were added so that the distribution could be determined at different activator concentrations.

(a) **Distribution of Europium.**—The data obtained for the calculation of the distribution coefficient of europium in the different systems are listed in Tables V, VI and VII. The numbers in brackets refer to the sample numbers in Tables I, II and III. A four- to eightfold variation in activator concentration was used.

In this report the distribution coefficient is defined as the ratio of the mole fractions of europium in the solid phase and in the liquid phase, *i.e.*

$$K = \left[\frac{n_{Eu}(s)}{(n_{Eu}(s) + n_B)}\right]_{\text{solid phase}} \times \left[\frac{n_{Eu}(l) + n_B + n_F}{n_{Eu}(l)}\right]_{\text{liquid phase}}$$

where $n_{Eu}(s)$ and $n_{Eu}(l)$ are the number of moles of europium in the solid and liquid phases, respectively, and $n_B$ and $n_F$ are the number of moles of base and flux, respectively. This involves the reasonable assumption that none of

the flux dissolves in the base but that only base dissolves in flux. Hence at equilibrium we have the pure base in contact with a saturated solution of the base in the fluid flux. It can be seen that this does not quite represent the distribution in the actual phosphor which consists of a mixture of crystals of pure flux and base. Where the solubility of the base in the flux is low, however, it may be assumed that the distribution coefficient in the solids is not very different.

The distribution coefficient may be calculated from the formula[11]

$$K = \frac{(a + b)[x - y(c/a)]}{y[d - b(c/a)]}$$

where $a$ = moles flux per 100 g. of filtrate
$b$ = moles base per 100 g. of filtrate
$c$ = moles flux per 100 g. of residue
$d$ = moles base per 100 g. of residue
$x$ = counts per standard weight of residue
$y$ = counts per standard weight of filtrate

The values listed for $K$ in Tables V to VII indicate that equilibrium had been fairly well established. With the strontium chloride flux, the activator distribution is not appreciably affected by change of temperature, variation of flux to base ratio or by change of total activator concentration. The concentration of the activator in the liquid phase is somewhat more than one third of the concentration in the solid phase. In the actual phosphor mixture, which contains only about 10% flux, however, about 97% of the added activator resides in the base material.

TABLE V

DISTRIBUTION OF EUROPIUM BETWEEN STRONTIUM CHLORIDE AND STRONTIUM SULFIDE

| | Parts Eu per million parts SrS in unfiltered mixture | Counts per minute: Filtrate | Residue | $K$ |
|---|---|---|---|---|
| (1) | 200 | 1069 | 2045 | 2.8 |
| (2) | 100 | 1158 | 1970 | 2.5 |
| (3) | 400 | 1233 | 2219 | 2.7 |
| (4) | 800 | 1084 | 1977 | 2.6 |
| (5) | 100 | 98.4 | 230 | 3.2 |
| (6) | 400 | 127.0 | 231 | 2.3 |
| (7) | 100 | 68.0 | 157 | 2.8 |
| (8) | 400 | 66.8 | 137 | 2.5 |

(11) This expression is derived from the distribution coefficient defined above in the following manner: (a) It is apparent that the number of moles of activator, $n_{Eu}$, is trivial in comparison to the number of moles of the base or the flux. Thus

$$(K = [n_{Eu}(s)/n_B]_{solid}\,[n_B + n_F)/n_{Eu}(1)]_{liquid}$$

(b) The determination of $[n_{Eu}(s)/n_B]_{solid}$ would, under ordinary filtration techniques, merely involve weighing the undissolved base and making a count to estimate the europium present. Unfortunately, this cannot be done in this case because along with the undissolved base there is always a significant quantity of filtrate retained on the filter, and this filtrate contains dissolved base as well as radioactive Eu. It becomes necessary, therefore, for us to subtract this dissolved base from the total base concentration in the residue and the radioactivity count from the total count observed for the residue. In terms of the analytical quantities $a$, $b$, $c$, $d$, $x$ and $y$ defined previously, the expression for $n_B$ is thus $[d - b(c/a)]$ and for $n_{Eu}(s)$ is $k[x - y(c/a)]$ where $k$ is a proportionality constant. (c) The filtrate is merely analyzed for its count and the number of moles of flux and base in it. The term $[n_{Eu}(l)/(n_F + n_B)]_{liquid}$ is thus equal to $ky/(a + b)$.

TABLE VI

DISTRIBUTION OF EUROPIUM BETWEEN STRONTIUM CHLORIDE AND STRONTIUM SELENIDE

| | Parts Eu per million parts SrSe in unfiltered mixture | Counts per minute: Filtrate | Residue | $K$ |
|---|---|---|---|---|
| (9) | 50 | 761 | 1217 | 2.4 |
| (10) | 100 | 744 | 1142 | 2.3 |
| (11) | 400 | 790 | 1206 | 2.2 |
| (12) | 800 | 677 | 1085 | 2.6 |
| (13) | 100 | 978 | 1503 | 2.5 |
| (14) | 400 | 768 | 1206 | 2.5 |
| (15) | 400 | 937 | 1345 | 2.1 |

TABLE VII

DISTRIBUTION OF EUROPIUM BETWEEN LITHIUM FLUORIDE AND STRONTIUM SULFIDE

| | Parts Eu per million parts SrS in unfiltered mixture | Counts per minute: Filtrate | Residue | $K$ |
|---|---|---|---|---|
| (16) | 150 | 207 | 1647 | 35.3 |
| (17) | 500 | 320 | 1623 | 21.9 |
| (18) | 1000 | 370 | 1690 | 20.7 |
| (19) | 150 | 314 | 1734 | 24.4 |
| (20) | 150 | 611 | 2272 | 13.2 |

In the case of the strontium sulfide–lithium fluoride system, on the other hand, the values of the distribution coefficient (Table VII) are much higher and there is a pronounced decrease with rising temperature. At 1000° the distribution coefficient for this system is more than ten times that for the strontium chloride system. The solubility of the sulfide in the lithium fluoride is also about ten times that in strontium chloride. This means that when the mixture is cooled from 1000° the portion of the sulfide which crystallizes out from solution will have a much lower activator concentration than that which was undissolved at 1000°. With the usual phosphor mixture containing about 10% flux, only 3 to 4% of the sulfide would have dissolved at 1000° and this portion on solidification of the mixture would have an activator concentration about one seventh of that of the main bulk of the sulfide if we assume that no activator remains with the lithium fluoride solid phase. The assumption that the activator concentration in the solid lithium fluoride is essentially zero was justified by the separation of the solid phases into several fractions containing different proportions of flux and base. This was accomplished by taking separate samples of the filtrate and residue from a filtration carried out at 1100° and grinding them under tetrabromoethane to a paste containing particles about 10–20 microns in size. The paste was suspended in a mixture of tetrachloro- and tetrabromoethanes and centrifuged. This was repeated with liquids of progressively higher densities containing more tetrabromoethane so that a series of floating fractions with increasingly higher concentrations of the heavier component were obtained. The fractions were analyzed and counted and the results extra-

polated to the count corresponding to one of the pure components.

The results given in Table VIII are plotted in Fig. 4 which shows two curves, one connecting the points representing the separated fractions of the filtrate and one connecting the points representing the fractions of the residue. The two curves are due to the different concentrations of europium in the residue and filtrate. Both curves extrapolate to zero concentration of europium in the lithium fluoride. The deviation from linearity is probably due to inhomogeneous distribution of the europium.

TABLE VIII

LITHIUM FLUORIDE–STRONTIUM SULFIDE–EUROPIUM SINK-FLOAT SEPARATIONS

| | Sp. gr. of fraction | % of total sample | Wt. % SrS in fraction | Counts per min. per 0.05 g. of fraction |
|---|---|---|---|---|
| Residue from filtration | <2.75 | 0 | .. | .. |
| (69.7% SrS | 2.75–2.85 | 3.5 | 27.8 | 232 |
| 1364 counts per min. | 2.85–2.95 | 18.2 | 27.7 | 482 |
| per 0.05 g. sample) | >2.95 | 78.3 | 89.0 | 1835 |
| Filtrate | <2.77 | 10.7 | 12.9 | 69 |
| (39.7% SrS | 2.77–2.88 | 42.2 | 25.9 | 193 |
| 366 counts per min. | 2.88–2.93 | 17.8 | 25.2 | 195 |
| per 0.05 g. sample) | >2.93 | 29.3 | 81.4 | 814 |

From the results it would appear that in these phosphor systems the assumption can be made that essentially all of the europium added to the mixture finds its way into the lattice of the base material. With the lithium fluoride flux, the phosphor will be slightly inhomogeneous.

**(b) Distribution of Cerium and Samarium.**—The experimental results for the distribution of

TABLE IX

DISTRIBUTION OF CERIUM AND SAMARIUM. COMPOSITION OF FILTRATES AND RESIDUES

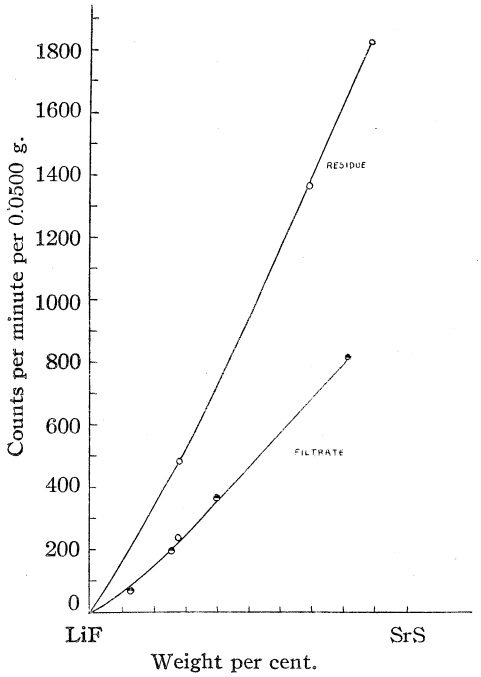

Fig. 4.—Distribution of europium in the LiF–SrS system by sink-float separation of phases.

cerium and samarium in the same systems are given in Tables IX and X. Again it can be seen that the distribution coefficients are much larger for the strontium sulfide–lithium fluoride system than for the systems with the strontium chloride flux. The distribution coefficients for cerium in the strontium sulfide systems are lower than those for samarium.

TABLE X

DISTRIBUTION OF CERIUM AND SAMARIUM IN THE VARIOUS SYSTEMS

| Sample[12] | Parts activator per million parts base in unfiltered mixture | Counts per minute Filtrate | Residue | $K$ |
|---|---|---|---|---|
| 1 | 800 Ce | 128 | 168 | 1.4 |
| 2 | 500 Ce | 122 | 149 | 1.2 |
| 3 | 223 Ce | 91 | 110 | 1.1 |
| 4 | 200 Sm | 540 | 1642 | 4.7 |
| 5 | 25 Sm | 543 | 1186 | 2.7 |
| 6 | 800 Ce | 123 | 216 | 3.0 |
| 7 | 500 Ce | 104 | 142 | 2.0 |
| 8 | 223 Ce | 111 | 122 | 1.3 |
| 9 | 200 Sm | 829 | 1333 | 2.7 |
| 10 | 25 Sm | 1555 | 968 | 0.24 |
| 11 | 200 Ce | 66 | 200 | 15 |
| 12 | 200 Ce | 67 | 239 | 16 |
| 13 | 100 Sm | 219 | 1845 | 45 |
| 14 | 100 Sm | 127 | 1491 | 58 |

There is, however, a marked difference in the distribution coefficients for these activators with changing composition of the original mixtures.

(12) Samples correspond to those in Table IX.

In these experiments, unfortunately, both the percentage base and the activator concentration were changed so that it is not clear from the data whether the distribution coefficients decrease with decreasing activator concentration or decrease with increasing percentage of base. It seems reasonably certain from additional experiments that the latter alternative represents the situation. The solubility of strontium oxide in strontium chloride has been found to be quite high and its presence in the flux causes a pronounced decrease in the distribution coefficient of the activators. The effect with the different activators increases in the order europium–cerium–samarium. The strontium sulfide and selenide contain small amounts of oxide which dissolve in the flux so that increasing proportions of the base material in the original mixtures give rise to increasing concentrations of oxide in the flux. This leads to smaller distribution coefficients. The results of a systematic study of this phenomenon will be presented in a later publication.

**Acknowledgment.**—The authors wish to thank Dr. John R. Dunning and various members of the Radiochemical Laboratories at Columbia University for their friendly coöperation. We are particularly indebted to Mrs. Adele Weil for advice on tracer techniques.

## Summary

A technique for filtering fused salt solutions at 1000° has been described.

The distribution of small quantities of europium, cerium and samarium between phosphor base materials (strontium sulfide and strontium selenide) and saturated solutions of the bases in the fluxes (strontium chloride and lithium fluoride) has been studied in the neighborhood of 1000° with the aid of radioactive tracers.

# Some Physical Properties of Isoquinoline

BY HENRY FREISER[1] AND WILLIAM L. GLOWACKI[2]

This paper is the second in a series[3] describing the work of a program for the determination of physical constants of coal tar bases, sponsored by the Koppers Company.

**Purification of Isoquinoline.**—Seventeen gallons of commercial isoquinoline (Koppers Company 2° isoquinoline having a freezing point of 23.8°) was subjected to eight successive fractional crystallizations until the final material (about 2 kg.) had a freezing point of 26.6°. Further purification was effected by a careful fractional distillation at atmospheric pressure through the rectifying column previously used.[3] Fifty-eight fractions of 30 ml. each were collected at the rate of 30 ml./hr., and after the first three fractions boiled within 0.1°. It is interesting to note that the distillation separated a high-melting impurity more volatile than isoquinoline. This material was identified as naphthalene and is believed responsible for the difficulty encountered in the purification by crystallization. The distillation cuts were further screened by measuring freezing points. For all of the physical properties determined, those central cuts whose freezing points differed by less than 0.05° were combined to give a material having a freezing point of 26.41 ± 0.02° and an estimated purity of at least 99.5 mole per cent.

**Determination of Properties.**—The properties reported here were determined using the same apparatus and procedures previously described.[3]

**Freezing Point.**—The freezing point of pure isoquinoline is estimated at 26.48 ± 0.1°. Quinoline was found to depress the freezing point of isoquinoline by 0.5 ± 0.1° per mole per cent. If the only impurity in the isoquinoline used were quinoline, the material might be as high as 99.8 mole per cent. pure.

**Density and Expansion Coefficient.**—The density values at every 10° from 30 to 80° were found to be 1.09101, 1.08309, 1.07519, 1.06731, 1.05945, and 1.05143 g./ml. with an average reproducibility of 0.00004 g./ml. The values of the expansion coefficient in this temperature range varied from 0.000722 at 30° to 0.000776 at 80°. Values of the density at high temperatures were determined as follows: 1.03540 at 100°, 1.01547 at 125°, 0.99498 at 150°, 0.97421 at 175°, and 0.95300 g./ml. at 200°, with an average reproducibility of 0.00006 g. per ml. The corresponding expansion coefficient values varied from 0.000765 to 0.000899.

**Viscosity.**—The results are presented in Table I.

TABLE I

VISCOSITY OF ISOQUINOLINE

| Temp., °C. | Viscosity, cp. | Temp., °C. | Viscosity, cp. |
|---|---|---|---|
| 30 | 3.2528 | 100 | 1.0230 |
| 40 | 2.6034 | 125 | 0.7787 |
| 50 | 2.1323 | 150 | .6217 |
| 60 | 1.7872 | 175 | .5067 |
| 70 | 1.5269 | 200 | .4223 |
| 80 | 1.3223 | | |

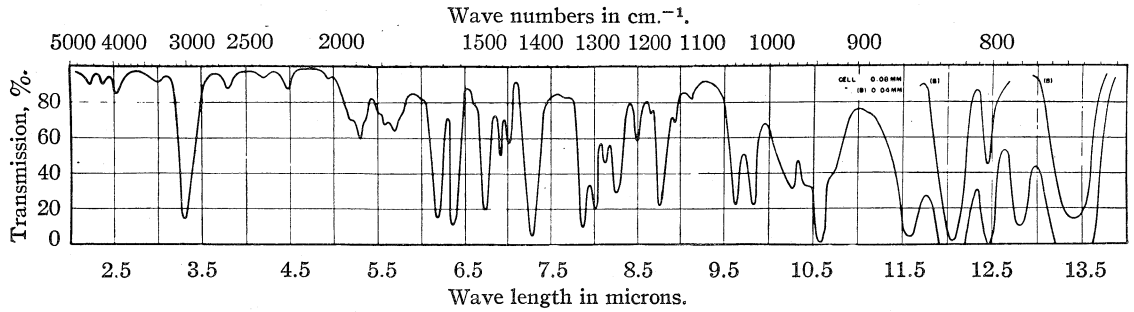

Fig. 1.—Cell, 0.08 mm.; cell 8, 0.04 mm.

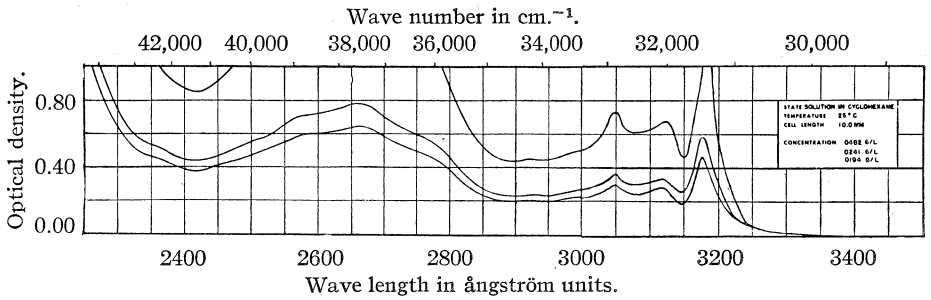

Fig. 2.—State solution in cyclohexane: temperature, 25°; cell length, 10.0 mm.; concn., 0.0482 g./l., 0.0241 g./l., 0.0194 g./l.

**Boiling Point.**[4]—The boiling points of isoquinoline at various pressures were found to be 242.242° at 743.05 mm., 242.026° at 739.33 mm. and 241.832° at 736.14 mm. These values were determined in a differential Swietoslawski ebulliometer using platinum resistance thermometers certified by the National Bureau of Standards to measure the boiling and condensation temperatures of isoquinoline as well as the boiling point of water in a second ebulliometer to establish the pressure value. A further check on the purity of the isoquinoline was obtained in the small difference, 0.007°, between the boiling and condensation temperatures. The average rate of change of boiling temperature with pressure $dT/dp$, calculated from the above values, was 0.0594 ± 0.0009° per mm. From this the boiling point at 760 mm. pressure was calculated at 243.25°. Extrapolation of a plot of values of the temperature difference between the boiling points of isoquinoline and water against the pressure to a value at 760 mm. pressure gave the same result. From the values of the boiling point at 760 mm. pressure and that of $dT/dp$, the heat of vaporization has been calculated by means of the Clausius–Clapeyron equation as 11.7 ± 0.5 kcal. per mole.

**Refractive Index.**—Values of the refractive index of isoquinoline are $n^{30}D$ 1.62078, $n^{30}_{5461\text{ Å.}}$ 1.62806, and $n^{30}_{\infty}$ $1.5799_2$ (calcd.).

**Dipole Moment.**—The dielectric constants $\epsilon$ and densities $d$ of the solutions containing mole fraction $f_2$ of the polar solute and the molar polarization of the solute are given in Table II.

TABLE II

DIELECTRIC POLARIZATION OF ISOQUINOLINE AT 30.0°

| $f_2$ | $\epsilon$ | $d$ | $P_2$ |
|---|---|---|---|
| 0.00000 | 2.2627 | 0.868231 | (168.1 ± 0.3) |
| .006112 | 2.3360 | .870837 | 166.4 |
| .014719 | 2.3954 | .872983 | 164.5 |
| .025562 | 2.4930 | .876380 | 162.1 |
| .029533 | 2.5316 | .877705 | 162.4 |

The sum of $P_E$ and $P_A$ was taken to be 43.3 (the value of the molar refraction at infinite wave length plus 10%), giving a value of the dipole moment of isoquinoline of 2.49 ± 0.01 $D$ in fair agreement with previously determined values.[5]

**Absorption Spectra.**—In Figs. 1 and 2 are presented the infrared and ultraviolet absorption curves, respectively, for isoquinoline. The main infrared absorption maxima are presented in Table III. The main ultraviolet absorption maxima are located at 266, 304, 312, and 318

millimicrons. The data were obtained by the Koppers Spectrographical Research Laboratory at Mellon Institute under the direction of Dr. J. J. McGovern.

## Summary

1. Isoquinoline has been purified by fractional distillation and extensive recrystallization to a purity of over 99.5 mole per cent.

2. The following properties have been determined for the purified material: f. p., b. p., density, expansion coefficient and viscosity at frequent temperature intervals between 30 and 200°, refractive index at 5893 and 5461 Å. at 30°, the dipole moment, and the infrared and ultraviolet absorption spectra.

# 1,3-Dinitropropane

BY J. P. KISPERSKY, H. B. HASS AND D. E. HOLCOMB

## Introduction

Keppler and Meyer[1] reported 1,3-dinitropropane, prepared by reaction between silver nitrite and 1,3-diiodopropane, to be a yellow, unstable, undistillable oil which changed after several days to a viscous, brown material. On the basis of our present knowledge there seemed to be no adequate reason for expecting 1,3-dinitropropane to be instable. The researches of Kornblum and students[2] in this Laboratory have shown that substantial amounts of organic nitrates are formed in the Victor Meyer reaction and can be removed from the nitro compounds by treatment with sulfuric and phosphoric acids.

3-Nitro-1-propyl nitrate and the corresponding nitrite would be expected to be instable because the primary nitro group tautomerizes to an acidic nitronic acid and neither nitrites nor nitrates are stable to acid.

It, therefore, seemed advisable to repeat the synthesis of 1,3-dinitropropane and to apply the recent purification procedures. As a result, 1,3-dinitropropane has been prepared for the first time in pure form. It is a stable, colorless liquid, distillable at low pressures, b. p. 103° at 1 mm., m. p. −21.4°, molal f. p. const. 4.5, ht. of fusion 27, cal./g., $n^{25}D$ 1.4638, density 1.353 g./ml. at 25.5°, $n_D$ 20.0° − 1.4654; 21.6° − 1.4649; 30.0° − 1.4622.

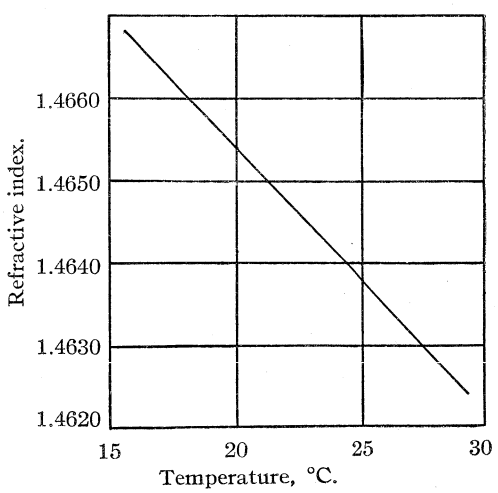

Fig. 1.—Change of refractive index with temperature.

## Experimental

The silver nitrite was prepared according to the directions of McElroy.[3] A slurry was formed of five moles (770 g.) of silver nitrite in 1100 ml. of ether and two moles (592 g.) of 1,3-diiodopropane was added with stirring from a dropping funnel. The flask was cooled externally and the rate of addition regulated to cause gentle refluxing of the ether. After the addition was complete, stirring was continued at room temperature in the dark for twenty hours. Afterward the ether solution was removed by decantation and the residue extracted twice with 300 ml. portions of ether, filtered with suction and washed again with 300 ml. of ether. The ether was evaporated over a steam cone, washed with an equal volume of water and dried over Drierite. The orange-colored liquid residue from two such preparations weighed 300 g.

Distillation in a column resulted in decomposition but an ordinary vacuum distillation gave 90 g. of a fraction b. 100–110° at 1 mm. which gave a positive test with diphenylamine in sulfuric acid. Contrary to Mulliken[4] this color test is not given by pure, primary mononitro paraffins.

The material was then added to three times its volume of 96% sulfuric acid at 0°, stirred for several minutes, poured over ice, and the insoluble layer washed with water. After drying with Drierite the 18 g. remaining distilled at 103° at 1 mm. Qualitative tests showed the presence of nitrogen and absence of halogen. The diphenylamine test now showed the absence of nitrite or nitrate ester.

An estimate of the purity of the sample from the freezing point curve showed it to be 98.2 mole per cent. 1,3-dinitropropane. Nitromethane was added as the known impurity.

*Analysis* by Huffman Microanalytical Laboratories gave the following: Calcd.: H, 4.51; C, 26.87; N, 20.90. Found: H, 4.55, 4.53; C, 26.89, 26.95; N, 21.03, 20.95.

Molar refractivity calculated from Eisenlohr's values is 27.30. Calculated from observed data, 27.33.

Storage of 1,3-dinitropropane at room temperature from September, 1947, to July, 1948, produced no visible alteration.

## Summary

1,3-Dinitropropane has been prepared for the first time in a state of high purity and the common physical constants determined.

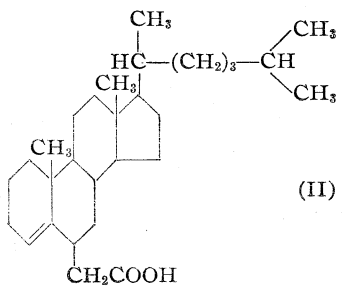
# The Preparation of Isomeric Cholesterylmalonic Acids. III. Rearrangement of *i*-Cholesterylacetic Acid and *i*-Cholesteryl malonamide

BY EMIL KAISER AND J. J. SVARZ

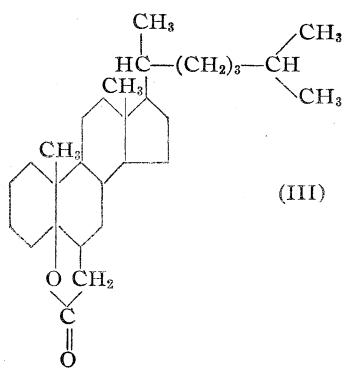
*i*-Sterol derivatives with a substituent connected by a carbon-to-oxygen bond to carbon atom six of the nucleus are known to rearrange to 3-substituted, 5–6 unsaturated sterols by treatment with acids.[1] In this paper the acid rearrangement of such *i*-cholesteryl derivatives is described in which a carbon-to-carbon bond links the substituent to position six of the ring. *i*-Sterols of this type are the *i*-cholesterylmalonic acid[2,3] and the *i*-cholesterylacetic acid (I).



(I)

The *i*-cholesterylacetic acid was prepared by two different procedures. One was the decarboxylation of the *i*-cholesterylmalonic acid. The other method was the saponification of the *i*-cholesterylmalonamide in alkaline glycol solution. The *i*-cholesterylmalonamide not only saponified but was simultaneously decarboxylated to *i*-cholesterylacetic acid.

The *i*-cholesterylacetic acid was dextrorotatory $[\alpha]^{25}D$ + 32°, m.p. 111–112°. When treated with small amounts of sulfuric acid in glacial acetic acid solution a rearrangement occurred. Two compounds were isolated from the reaction mixture. One product was an isomeric cholesterylacetic acid, m.p. 173–174°, $[\alpha]^{25}D$ + 46°. Perbenzoic acid titration showed the presence of one double bond in the compound. The other rearrangement product was also an isomer of the *i*-cholesterylacetic acid, but was found to be neutral to alkali. Perbenzoic acid titration indicated a saturated ring structure. The isomeric neutral product had a m.p. 108–109°, $[\alpha]^{25}D$ + 80.5°.



The acid and neutral products of the *i*-cholesterylacetic acid rearrangement were found to be interchangeable. Either of these compounds yielded a mixture of the two derivatives when heated in glacial acetic acid solution in the presence of sulfuric acid. Such an interchange is known to be typical for γ-unsaturated acids and their corresponding lactones.[4,5]

The mechanism of the *i*-cholesterylacetic acid rearrangement is different from the rearrangement mechanism of *i*-derivatives having substituents connected by carbon-to-oxygen[1] or carbon-to-nitrogen[6] bonds to the six position of the sterol nucleus. Cholesteryl-3-acetic acid[2] was not formed in the rearrangement of the *i*-cholesterylacetic acid and both products isolated from the rearrangement mixture were strongly dextro-rotatory. Therefore, a shift of the substituent from the six to the three position did not take place. Only the cyclopropane ring opened up and a γ-unsaturated acid, the $\Delta^4$-cholestene-6-acetic acid (II) was formed. This acid partly lactonized and yielded the cholestane-6-acetic acid lactone, the neutral rearrangement product.

(II)

The cholestane-6-acetic acid lactone was heated to temperatures above 200°[5] to prove a γ or δ configuration. Since cholestene-6-acetic acid was not formed by heating, the lactone was assigned the structure of cholestane-6-acetic acid-γ-lactone (III).

(III)

The acid rearrangement procedure was also applied to the *i*-cholesterylmalonamide. The reaction product was separated into two fractions

of different solubilities in methanol. Both fractions were saponified separately with alkali in propylene glycol. From the methanol less soluble fraction the $\Delta^4$-cholestene-6-acetic acid was isolated. The methanol soluble fraction yielded the cholestane-6-acetic acid lactone as the main product.

## Experimental[7,8]

**i-Cholesterylacetic Acid from i-Cholesterylmalonic Acid.**—In a 500-cc. flask immersed in an oil-bath, 10 g. of *i*-cholesterylmalonic acid was heated in a vacuum maintained by a mercury vapor pump. At 168° bath-temperature evolution of carbon dioxide started. The bath-temperature was slowly raised to 175° and kept there for ten minutes. Then the temperature was slowly raised again to 200° and heating continued for ten more minutes. After that the flask was cooled to room temperature and the reaction product crystallized from acetone. After recrystallization from acetone 6.8 g. of *i*-cholesterylacetic acid, m.p. 111.5–112.5°, was obtained.

*Anal.* Calcd. for $C_{29}H_{48}O_2$: C, 81.27; H, 11.28, neut. equiv., 428.0. Found: C, 81.29; H, 11.34; neut. equiv., 428; $[\alpha]^{25}D$ + 32° (in abs. alcohol). Perbenzoic acid titration: one-tenth of a gram dissolved in chloroform did not consume oxygen after seventy-two hours at −4°.

**i-Cholesterylmalonamide.**—The previous procedure was slightly modified. In 10 cc. of thionyl chloride 5 g. of *i*-cholesterylmalonic acid was suspended and the mixture kept at room temperature for two hours. Material still undissolved was brought into solution by heating on the steam-bath for ten minutes. The excess of thionyl chloride was distilled off under reduced pressure and the crude acid chloride transformed into the amide as described before.[3] Yield of crystalline *i*-cholesterylmalonamide was 2.5 g., m. p. 224–226°.

**Saponification of i-Cholesterylmalonamide.**—Twenty grams of potassium hydroxide was dissolved by warming in 100 cc. of propylene glycol. Seven grams of *i*-cholesteryl malonamide was added and the mixture refluxed for ten hours. Saponification of the amide was indicated by evolution of ammonia during the heating. The clear propylene glycol solution was then diluted with water, filtered and acidified with hydrochloric acid. A precipitate was formed which was extracted with ether. The ether extract was washed with water and dried over sodium sulfate. The ether was evaporated, the residue dissolved in methanol and the solution treated with charcoal. After filtration and chilling needles were obtained which were twice recrystallized from methanol; yield 4.2 g., m.p. 110.5–111.5°. The melting point remained unchanged when mixed with *i*-cholesterylacetic acid prepared by pyrolysis of *i*-cholesterylmalonic acid.

*Anal.* Calcd. for $C_{29}H_{48}O_2$: C, 81.27; H, 11.28; neut. equiv., 428.0. Found: C, 81.55; H, 11.40; neut. equiv., 429.8; $[\alpha]^{25}D$ + 32°.

Attempts were made to saponify the *i*-cholesterylmalonamide in isopropyl alcohol. Two grams of potassium hydroxide and 0.5 g. of *i*-cholesterylmalonamide was dissolved in 10 cc. of isopropyl alcohol. The solution was refluxed for ten hours, cooled, diluted with water and filtered. The filtrate was acidified; no precipitation occurred. The solid residue was crystallized from ethyl acetate and identified as *i*-cholesterylmalonamide.

The same result was obtained when heating of the isopropyl alcohol solution was done under pressure at 130°.

**Attempt to Decarboxylate i-Cholesterylmalonic Acid.**—One gram of *i*-cholesterylmalonic acid and 3 g. of potassium hydroxide were refluxed with 10 cc. of propylene glycol for ten hours. *i*-Cholesterylmalonic acid was the sole product isolated from the propylene glycol solution.

**Rearrangement of i-Cholesterylacetic Acid.**—Four grams of *i*-cholesterylacetic acid was dissolved in 120 cc. of glacial acetic acid. Ten drops of concentrated sulfuric acid was added and the solution heated on the steam-bath for two hours. The reaction mixture was cooled and poured into one liter of 10% aqueous sodium chloride solution. The precipitate was filtered off, dried and dissolved in 20 cc. of glacial acetic acid. After filtration the solution was kept at room temperature for several days. Crystals deposited and were removed by filtration. The mother liquor was concentrated to half its volume under reduced pressure. A second crop of crystals was obtained; yield 1.9 g. of $\Delta^4$-cholestene-6-acetic acid, m.p. 173°. After recrystallization from glacial acetic acid the melting point was 173–174°.

*Anal.* Calcd. for $C_{29}H_{48}O_2$: C, 81.27; H, 11.28; neut. equiv., 428.0. Found: C, 81.28; H, 11.36; neut. equiv., 427.3; $[\alpha]^{25}D$ + 46° (in abs. alcohol). Perbenzoic acid titration: one-tenth of a gram dissolved in chloroform consumed 3.32 mg. of oxygen after ninety-six hours at −4°. *Anal.* Calcd. for $C_{29}H_{48}O_2$: 1 g. atom of oxygen (16 g.). Found: 0.89 g. atom of oxygen (14.2 g.). Control: one-tenth of a gram of cholesteryl acetate dissolved in chloroform consumed 3.29 mg. of oxygen after ninety-six hours at −4°. Calcd. for $C_{29}H_{48}O_2$: 1 g. atom of oxygen (16 g.). Found: 0.88 g. atom of oxygen (14.1 g.).

After the $\Delta^4$-cholestene-6-acetic acid crystallized out from the concentrated glacial acetic acid solution, the mother liquor was evaporated to dryness under reduced pressure. The oily residue was dissolved in ether and repeatedly extracted with a 5% potassium hydroxide solution. The combined alkaline extracts, after acidification and crystallization of the precipitates from glacial acetic acid, yielded an additional amount 0.5 g. of $\Delta^4$-cholestene-6-acetic acid, m.p. 173°.

The ether layer was washed with water, dried over sodium sulfate and the ether evaporated. The residue was crystallized from methanol. The cholestane-6-acetic acid-$\gamma$-lactone crystallized in beautiful needles; yield 0.3 g., m.p. 108–109°, mixed melting point with *i*-cholesterylacetic acid 86–88°. Two-tenths of a gram dissolved in ethanol did not consume 0.1 *N* sodium hydroxide solution at room temperature.

*Anal.* Calcd. for $C_{29}H_{48}O_2$: C, 81.27; H, 11.28. Found: C, 81.21; H, 11.28; $[\alpha]^{25}D$ + 80.5°. Perbenzoic acid titration: one-tenth of a gram in chloroform did not consume oxygen after seventy-two hours at −4°.

**Rearrangement of i-Cholesterylmalonamide.**—In 200 cc. of glacial acetic acid 2.25 g. of *i*-cholesterylmalonamide was dissolved and 1 cc. of concentrated sulfuric acid added. The mixture was kept on the steam-bath for one hour. A slight purple color developed. Then 500 cc. of water was added. The precipitate was filtered off, washed with water and dried. The dry material was dissolved in 15 cc. of methanol and the solution kept at −4° for twelve hours. Swollen lumps deposited and were separated by filtration. After drying, 0.55 g. of a slightly colored powder was obtained. This substance was soluble in ether and benzene and was designated as Fraction I.

The mother liquor filtered off from Fraction I was diluted with water. A white precipitate was formed. This precipitate, Fraction II, amounted to 1.55 g.[9]

**Hydrolysis of Fractions I and II.**—One gram of potassium hydroxide was dissolved in 10 cc. of propylene glycol and 0.50 g. of Fraction I was added. The solution was refluxed for two hours, cooled and diluted with 100 cc. of water. The precipitate was filtered off, washed with water and dried. The dry material, weighing 0.3 g., was crystallized from glacial acetic acid. After recrystallization from methanol 0.12 g. of a substance melting 173–174° was obtained. The melting point was not depressed when mixed with $\Delta^4$-cholestene-6-acetic acid, which was obtained from *i*-cholesterylacetic acid.

(7) All melting points are uncorrected.

(8) Microanalyses were made by Mr. C. W. Beazley, Skokie, Illinois.

(9) The rearrangement of *i*-cholesterylmalonamide resulted in loss of nitrogen. Found in *i*-cholesterylmalonamide: N, 6.01; in Fraction I: N, 4.66; in Fraction II: N, 3.02

*Anal.* Calcd. for $C_{29}H_{48}O_2$: neut. equiv., 428.0. Found: neut. equiv., 428.5.

One and a half gram of Fraction II was refluxed in 25 cc. of propylene glycol containing 2.5 g. of potassium hydroxide. After two hours of refluxing the solution was cooled, diluted with 400 cc. of water (clear solution) and acidified. The precipitate was filtered off, washed with water and dried. This substance, weighing 0.95 g. was dissolved in 20 cc. of methanol. After dilution with 100 cc. of water the mixture was extracted with petroleum ether. The petroleum ether was evaporated. The residue was twice crystallized from methanol. Three-tenths of a gram of large needles was obtained, m.p. 108–109°. No melting point depression was observed when mixed with the cholestane-6-acetic acid-γ-lactone, isolated from the *i*-cholesterylacetic acid rearrangement.

**Interchange of $\Delta^4$-Cholestene-6-acetic Acid and Cholestane-6-acetic Acid-γ-lactone.**—(a) Two-tenths of a gram of cholestane-6-acetic acid-γ-lactone was dissolved in 20 cc. of glacial acetic acid containing one-tenth of a cc. of concentrated sulfuric acid. The mixture was heated for one hour on the steam-bath, then diluted with a saturated sodium chloride solution. The precipitate was filtered off, washed with water and dissolved in about 20 cc. of boiling methanol. Crystals deposited in the cold and were separated from the liquid. After recrystallization from glacial acetic acid, 0.05 g. of a substance was obtained with a m.p. of 173–174°; mixed melting point with $\Delta^4$-cholestene-6-acetic acid 173–174°. From the methanol mother liquor 0.06 g. of unchanged cholestane-6-acetic acid-γ-lactone was isolated.

(b) Half a gram of $\Delta^4$-cholestene-6-acetic acid was treated with sulfuric acid in glacial acetic acid solution in an identical manner as the lactone. The acid treated product was first crystallized from glacial acetic acid. Unchanged $\Delta^4$-cholestene-6-acetic acid was recovered, yield, 0.25 g. From the mother liquor a solid was precipitated with saturated sodium chloride solution. This was twice crystallized from methanol. Cholestane-6-acetic acid-γ-lactone was obtained, m.p. 108–109°, yield, 0.1 g.

(c) Two-tenths of a gram of cholestane-6-acetic acid-γ-lactone was heated for eight hours to 205–210°.[5] The brown-colored product was three times recrystallized from methanol, m.p. 108–109°, mixed melting point with cholestane-6-acetic acid-γ-lactone 108–109°. The mother liquors yielded an additional amount of cholestane-6-acetic acid-γ-lactone.

## Summary

*i*-Cholesterylacetic acid was prepared by pyrolysis of *i*-cholesterylmalonic acid and by alkaline hydrolysis of *i*-cholesteryl malonamide. The *i*-cholesterylacetic acid was rearranged in acid solutions. Two products were obtained; the $\Delta^4$-cholestene-6-acetic acid and the cholestane-6-acetic acid-γ-lactone. The mechanism of the *i*-cholesterylacetic acid rearrangement was shown to be different from the rearrangement mechanism of *i*-compounds connected by carbon-to-oxygen or carbon-to-nitrogen bonds to substituents in the six position.

*i*-Cholesterylmalonamide was also rearranged and the rearrangement products saponified. The same compounds were isolated as obtained from the *i*-cholesterylacetic acid rearrangement mixture.

# Amine Bisulfite Addition Products of Aldehydes and Ketones. I

BY ROGER ADAMS AND R. D. LIPSCOMB[1]

Aldehydes and ketones are frequently purified through their sodium bisulfite addition products. The adducts are seldom used for identification purposes since they usually do not have sharp melting or decomposition points and suffer the shortcoming of being essentially insoluble in organic solvents. Amine bisulfite addition products of aldehydes and ketones, which have been inadequately investigated, should be formed with equal ease. They offer several possibilities for utilization (1) as compounds for characterization of ketones and aldehydes; (2) for the resolution of aldehydes and ketones and (3) for the replacement of aldehyde and ketone adducts of sodium bisulfite as intermediates in various organic syntheses. The preparation of several representative tertiary amine bisulfites with typical aldehydes and ketones and the characterization of the adducts are described in this first communication.

The procedure usually followed for preparation of the amine bisulfites was to pass sulfur dioxide into the tertiary amines mixed with sufficient water to form the bisulfites. Invariably heat was evolved when sulfur dioxide was first introduced and in many of the conversions, a white solid was observed to separate. This white solid, probably the amine sulfite, gradually dissolved in the reaction mixture as the addition of sulfur dioxide was continued. Whether or not this solid was observed, the reaction mixture always became viscous during the intermediate stage of the conversion. In the final stages, the color of the solution changed to yellow or orange and the viscosity decreased. The reaction was no longer exothermic after the intermediate viscous stage had been reached. The volume of product was often nearly double the volume of starting materials. This volume increase was most noticeable during the latter stages of the reaction.

The resulting mixtures were obviously not pure amine bisulfites but complexes of amine bisulfites with sulfur dioxide. They are relatively stable to air oxidation over long periods of time, probably due to the presence of the excess sulfur dioxide. These mixtures were kept for several years in ordinary reagent bottles in a refrigerator; they may be kept in tightly closed containers at room tem-

| Pyridine | Acetone | 85[a] | | | | |
| Pyridine | Benzaldehyde | Oil | | | | |

[a] These compounds were, in general, less stable than the others, and decomposed sufficiently on standing a short time to vitiate the analyses. [b] These compounds gave analyses indicating the probable presence of a molecule of water of crystallization which was not removed by drying at 50–60° or by recrystallization from ether–ethanol mixtures. [c] % sulfur

perature. In open bottles at room temperature, sulfur dioxide is evolved, the color is gradually lost and the mixtures become more viscous. The amine bisulfite complexes are, in general, insoluble in ether and carbon tetrachloride, slightly soluble in benzene, soluble in methanol and ethanol and very soluble in chloroform and water. With an increase of the carbon content of the amine, the solubility of the amine bisulfite in benzene increases but the solubility in water decreases only slightly.

Bisulfites from trimethylamine, triethylamine, N-*n*-butylpiperidine, N-*n*-butylmorpholine, N-benzylpiperidine, N-methylpiperidine, N-laurylpiperidine, N-cetylpiperidine and pyridine were studied. The amine bisulfite complexes varied in color from yellow to orange, and in viscosity from the very limpid N-butylmorpholine bisulfite to the extremely viscous N-benzylmorpholine bisulfite. Several amines gave abnormal results and have not yet been further studied; dimethylaniline and sulfur dioxide reacted to form a red unstable liquid, triethanolamine gave an intermediate glass which could not be completely converted to the bisulfite, quinaldine and sulfur dioxide formed an orange powder, and tetrahydroquinoline an orange, low-melting crystalline solid.

The reaction of the amine bisulfites with aldehydes and ketones was carried out following a general procedure. The bisulfite reagent was mixed with a slight excess of the carbonyl compound. After crystallization started, the mixture was allowed to stand for some time at room temperature. In most cases where the aldehyde or ketone was reactive, mixing was followed immediately by evolution of heat and sulfur dioxide and an accompanying loss of orange color. Crystallization and loss of color often set in at once, or within a few minutes, although in a few instances as much as forty-eight hours was required for crystals to appear. Once crystallization had started, it was observed to proceed rapidly throughout the liquid. Only with the trimethylamine and triethylamine bisulfites and one or two others were "non-crystallizable oils" obtained with aldehydes and ketones, and these were not further investigated. As typical ketones and aldehydes, the following were used: acetone, cyclohexanone, cyclopentanone, benzaldehyde, methyl *n*-propyl ketone, and 2-ethylhexanal.

The addition products could often be obtained pure merely by alternately suspending the crystals in dry ether and collecting them on a filter. In general, they were recrystallized from absolute

ethanol or ethanol–ether mixtures. They all formed well-defined small white needles or plates which possessed sharp melting points. Two of those studied indicated the probability of crystallization with one molecule of water of crystallization which was not removed by recrystallization from ethanol–ether mixtures or drying in air at 50–60°; at least the analyses conformed to this assumption. The N-lauryl- and N-cetylpiperidine bisulfite derivatives were much less soluble in water than the others presumably owing to the long hydrocarbon side-chain. At the same time they were the most stable of the compounds prepared. The stability of the adducts varied considerably. Gradual decomposition, in some cases, started within a few days but others showed no appreciable change over a period of many months. Like the sodium bisulfite addition products, these amine bisulfite addition products are readily decomposed by the action of dilute mineral acids or bases, and the amines are readily recovered.

The melting points of all the compounds prepared (Table I) were within the temperature range from 69 to 136°. A wider range would be preferable if the melting points are to be used for identification purposes. Other amine bisulfites more satisfactory from this standpoint may be found.

## Experimental

**Triethylamine and Trimethylamine Bisulfites.**—A mixture of 0.22 mole of triethylamine and 0.55 mole of water was immersed in an ice-bath, and a stream of sulfur dioxide was passed slowly into the mixture for two hours. A strongly exothermic reaction at the beginning was followed by crystallization of a white solid in the upper amine layer. As the reaction progressed, the solid dissolved and the mixture became one phase, at first colorless, then yellow, and finally orange. The viscosity passed through a stage comparable to that of molasses, then decreased until the mixture was limpid.

This product did not form solid derivatives with acetone, benzaldehyde or *p*-chlorobenzaldehyde although reactions occurred with the evolution of heat.

The formation of trimethylamine bisulfite was essentially comparable except that the amine and water were used in molar ratios. The addition of acetone, cyclohexanone or benzaldehyde resulted in oils which could not be purified.

**Alkylated Piperidines and Morpholines.**—Piperidine and morpholine were alkylated by dissolving the amine (1.2 moles) in 125–200 ml. of dry benzene, and adding the appropriate alkyl halide (0.6 mole) dropwise with stirring at room temperature. When the addition was completed the mixture was stirred and warmed under reflux for several hours. The morpholine or piperidine hydrohalide, which precipitated from the solution, was collected on a filter and washed with benzene. Finally, the combined filtrate and washings were fractionally distilled to obtain the pure N-alkylamine.

The constants of these products, compared with those found in the literature, are shown in Table II.

**N-*n*-Butylpiperidine Bisulfite.**—N-*n*-Butylpiperidine, b. p. 67–67.5° (18 mm.), which contained one molecular equivalent of water was cooled in an ice-bath and sulfur dioxide was introduced. The gas inflow was continued for fifteen minutes after the upper layer had disappeared. The product was light orange and only slightly viscous.

In a similar manner, N-methylpiperidine and pyridine were converted to their bisulfites.

TABLE II

ALKYLATED PIPERIDINES AND MORPHOLINES

| Amine | B. p., °C. (lit.) | B. p., °C. (found) | Ref |
|---|---|---|---|
| N-Methylpiperidine | 105.9 | 105–107 | 2 |
| N-*n*-Butylpiperidine | 175.8 | 67–67.5 (18 mm.) | 2 |
| N-*n*-Laurylpiperidine | 161 (5 mm.) | ..... | 3 |
| N-*n*-Cetylpiperidine | 176–177 (1 mm.) | 175–179 (1 mm.) | 3 |
| N-Benzylpiperidine | 245 | 117–119 (13 mm.) | 4 |
| N-*n*-Butylmorpholine | 67–68 (10 mm.) | 67–67.5 (11 mm.) | 5 |
| N-Benzylmorpholine | 135–136.5 (14 mm.) | 129–131 (13 mm.) | 6 |

**N-*n*-Butylmorpholine Bisulfite.**—N-*n*-Butylmorpholine, b. p. 67–67.5° (11 mm.), was converted to its bisulfite in the same manner as described for the *n*-butylpiperidine. The intermediate viscosity, however, was much greater in this case and the final product was deeper orange in color.

**N-*n*-Benzylpiperidine Bisulfite.**—When sulfur dioxide was passed into N-*n*-benzylpiperidine, b. p. 117–119° (13 mm.), the reaction mixture became so viscous that when this stage was reached the gas was allowed to flow in a slow stream over the surface of the liquid for two days with occasional stirring. Toward the end the viscosity decreased.

**N-*n*-Benzylmorpholine Bisulfite.**—N-*n*-Benzylmorpholine, b. p. 129–131° (13 mm.), exhibited the same characteristics as *n*-benzylpiperidine when treated with sulfur dioxide. The viscosity was such that only by prolonged treatment with sulfur dioxide could part of it be converted to the bisulfite.

**N-Lauryl- and N-Cetyl-piperidine Bisulfites.**—When N-laurylpiperidine and N-cetylpiperidine were used, white solids formed as intermediates which made it necessary to pass the sulfur dioxide over the surface for a long period. The supernatant orange-colored liquid which formed on the surface was poured off from time to time until the conversion was complete.

**Formation of Bisulfite Addition Products.**—The general procedure consisted in addition of a slight excess of aldehyde or ketone to the amine bisulfite complex at room temperature. The color of the reagent was discharged completely only in the presence of an excess of the aldehyde or ketone. Usually, solution took place and the mixture became clear with a slight evolution of heat and a copious evolution of sulfur dioxide. In about one to five minutes the mixture had become colorless, and white crystals usually appeared. After fifteen minutes following solidification, dry ether was added and the crystals filtered. They were then recrystallized from absolute ethanol or absolute ethanol–ether mixtures and dried at 50°.

Some of the reaction mixtures required one hour or more before crystallization started; in particular, benzaldehyde, methyl *n*-propyl ketone or 2-ethylhexanal with N-*n*-butylpiperidine bisulfite, benzaldehyde with N-benzylpiperidine bisulfite and cyclohexanone with N-methylpiperidine bisulfite. The N-benzylmorpholine bisulfite was so insoluble as to require excess of acetone to take it into solution. Pyridine bisulfite and benzaldehyde did not decolorize, and no product crystallized.

The yields in practically all the reactions were entirely satisfactory, and losses by recrystallization were only slight.

## Summary

A variety of tertiary amines, N-methyl-, N-*n*-butyl-, N-benzyl-, N-lauryl-, and N-cetyl-piperidines, N-butyl- and N-benzyl-morpholines were converted to their bisulfites. These bisulfites were allowed to react with representative aldehydes

and ketones; acetone, cyclopentanone cyclohexanone, methyl *n*-propyl ketone, benzaldehyde and 2-ethylhexanal.

The amine bisulfite adducts were characterized. In general they are white crystalline solids, readily crystallized from ethanol or ethanol–ether mixtures. Like the corresponding sodium bisulfite adducts, they are decomposed with acids or alkalies into the amines.

# Amine Bisulfites. II. Their Use as Resolving Agents for Aldehydes and Ketones

BY ROGER ADAMS AND JOHN D. GARBER[1]

The addition products formed from tertiary amine bisulfites and aldehydes or ketones have been described in the first communication.[2] The extension of this study to certain primary amine bisulfites has now been made. The bisulfites of benzylamine, *s*-butylamine, β-phenethylamine, α-phenethylamine, and β-naphthol phenylaminomethane have been allowed to react with acetone, cyclopentanone, cyclohexanone, 3-methylcyclohexanone, benzaldehyde, heptaldehyde, isovaleraldehyde and valeraldehyde. The reactions usually proceeded smoothly and the adducts are white crystalline compounds, readily purified from absolute ethanol or ethanol–water mixtures in the case of the higher molecular weight substances. The melting points range between 100 and 160° as shown in Table I. Although stereoisomers in certain of the adducts are possible one form predominated, for only a single substance was isolated in good yield.

The gradation in properties of the compounds listed in Table I is interesting. It was noticed that if the molecular weight of either the amine or carbonyl compound was increased, the salt-like properties of the bisulfite addition compound became more indefinite, and the solubility in water and ethanol decreased. The stability also was found to vary between wide limits, an observation which made the temperature of recrystallization an important factor. Thus, the *s*-butylamine bisulfite of *n*-valeraldehyde was formed in the usual manner, but the solid, after isolation, immediately began to evolve sulfur dioxide. It could be recrystallized, but by the time the sample was dry enough for analysis it was impure again. On the other hand, the addition compounds of β-naphthol phenylaminomethane bisulfite with most of the carbonyl compounds listed could be boiled in ethanol without appreciable decomposition.

When sulfur dioxide was allowed to bubble through an equimolar mixture of the amine and water, usually with the addition of a little ether or in certain cases of ethanol, a white precipitate was formed. This product, chiefly the amine sulfite, was not isolated, but the introduction of sulfur dioxide was continued until a homogeneous, yellow, viscous liquid was produced. It is postulated that the yellow color of the resulting product is due to a complex, perhaps of the type $(RNH_2)_x:(SO_2)_y$. Such a complex, in the presence of water and a suitable carbonyl compound, reacts to form an amine bisulfite addition compound. The evolution of sulfur dioxide in the latter reaction may be cited as evidence that $y$ is greater than $x$. Moreover, Bright and Jasper[3] have shown that the 1:1 trimethylamine–sulfur dioxide complex is colorless.

The procedure for forming the adducts with aldehydes and ketones was essentially that previously described.[2] A few isolated experiments were unsuccessful. No reaction product could be isolated from the following combinations: camphor or carbethoxycyclohexanone and *dl*-α-phenethylamine bisulfite; glucose and *dl*-*s*-butylamine bisulfite; benzaldehyde and aniline bisulfite; propiophenone and benzylamine bisulfite (too unstable). In a few instances indicated in the table, no crystalline products formed.

If an optically active amine bisulfite were allowed to react with a racemic aldehyde or ketone, it is apparent that the product would be a mixture of four stereoisomers since a new asymmetric carbon holding the hydroxyl group would be introduced.

$$\underset{dl}{RCHO} + \underset{d \text{ or } l}{R'NH_3SO_3H} \longrightarrow \underset{dl\ dl}{RCHOHSO_3H_3NR'}\ \underset{d \text{ or } l}{}$$

Whether or not all four isomers are formed is of minor significance since the success in resolution will depend upon the ease of isolation of a single optically pure product. If this could be accomplished, a relatively simple method of resolving racemic aldehydes and ketones would be available.

Woodward, Kohman and Harris[4] have enumerated the known resolving reagents for ketones and aldehydes, most of which suffer the disadvantages of difficulty in preparation and of failure to give crystalline derivatives with many carbonyl compounds. They proposed a new reagent *l*-menthyl N-aminocarbamate, which was used by them merely to resolve *dl*-camphor, but which probably will prove to be a much more satisfactory general reagent than any of the others. Sobotka,

*et al.*,[5] have employed this reagent successfully in the resolution of *dl*-α-ionone.

Of the three optically active amines thus far studied, the two forms of α-phenethylamine were found to be very satisfactory, particularly with respect to the formation and purification of the bisulfites and the adducts with aldehydes and ketones. *l*-Menthylamine and *d*-β-naphthol phenylaminomethane were employed with indifferent success.

When the bisulfite addition compound of *d*-α-phenethylamine and *dl*-3-methylcyclohexanone was crystallized four times from ethanol an optically pure fraction was obtained in 29% yield. This salt was decomposed and the ketone converted to a semicarbazone, $[\alpha]^{20}D$ −21.0°. Adams, Smith and Loewe[6] previously reported a value of −20.7° for the *d*-3-methylcyclohexanone derivative. When the *l*-α-phenethylamine bisulfite addition compound of the *dl*-ketone was treated in a similar manner, the semicarbazone of *l*-3-methylcyclohexanone was isolated.

*p*-*s*-Butylbenzaldehyde was prepared in yields of 66% from N-methylformanilide and the aryl lithium compound that resulted from the action of lithium on *p*-iodo-*s*-butylbenzene.[7] The bisulfite of *d*-α-phenethylamine formed a well-crystallized product with *p*-*s*-butylbenzaldehyde and a constant melting fraction amounting to 40–48% of the total mixture was isolated. This may indicate that a large portion of the crude reaction product consisted primarily of a single compound. However, decomposition of the salt, gave a *s*-butylbenzaldehyde of such low rotation, $[\alpha]^{33}D$ −0.19°, semicarbazone $[\alpha]^{28}D$ −2.3° that the effectiveness of the resolution is in doubt. The salt may have been a compound composed of two diastereoisomers and only partial resolution was thus realized.

*l*-Menthylamine bisulfite with *p*-*s*-butylbenzaldehyde yielded a salt which appeared to be pure but, upon decomposition, only optically inactive aldehyde was recovered. This same aldehyde reacted with *d*-β-naphthol phenylaminomethane bisulfite abnormally to form a Schiff base instead of the desired addition compound. The Schiff base is a well-crystallized and easily purified substance with a high optical rotation, $[\alpha]^{30}D$ +240°. This type of Schiff base may offer a convenient intermediate for resolution of certain aldehydes and possibly ketones and is being explored. Sobotka, *et al.*,[5] refer to their attempts (unpublished) to resolve α-phenylpropanol with *d*-β-naphthol phenylaminomethane. The regeneration of the aldehyde in optically active form was unsuccessful because of the conditions of hydrolytic scission. This particular aldehyde is prone to racemization through enolization induced by the reagents used.

An improved synthesis for *dl*-β-methylhydrocinnamaldehyde[8] was developed. β-Bromoisopropylbenzene[9,10] was prepared in 60% yields by the action of allyl bromide on benzene in the presence of sulfuric acid. When the Grignard reagent was formed and allowed to react with N-methylformanilide, there was isolated 35% of the theoretical amount of β-methylhydrocinnamaldehyde. The crude product that resulted from the action of *d*-α-phenethylamine bisulfite on this racemic aldehyde yielded after one recrystallization a fraction $[\alpha]^{32}D$ −20.7°. This fraction was decomposed and the resulting aldehyde was converted to the optically active 2,4-dinitrophenylhydrazone, $[\alpha]^{27}D$ −39.6°. The enantiomorph was obtained by the use of the *l*-amine bisulfite in a similar series of reactions.

A quantitative procedure for the determination of sulfur in these addition compounds has been investigated. The "sulfites" and "bisulfites" first reported by Schiff[11] were analyzed for sulfur gravimetrically. He reported that an iodine titration method gave irreproducible results. Since the initial work of Ripper,[12] a great deal has been done on the quantitative determination of aldehydes by means of sodium bisulfite. In a comparison of the modified Ripper method with the excess iodine method, Parkinson and Wagner[13] reported that in general the latter was superior.

Notwithstanding the fact that the reverse reaction of decomposition was involved in the present investigation, the excess iodine method was chosen as a basis for the determination of sulfur. Eventually, a procedure was developed which gave excellent results. The sample was decomposed with aqueous alkali and the solution was poured into water containing a 10% excess of

$$RCHOHSO_3H_3NR' + 2OH^- \longrightarrow RCHO + R'NH_2 + SO_2^= + 2H_2O$$

standard iodine and a slight excess of acid. Back-titration with standard sodium thiosulfate followed immediately. Although several of the addition compounds listed in Table I gave rather poor sulfur analyses, this was undoubtedly due to the difficulty encountered in preparing a pure analytical sample.

## Experimental

**Amine Bisulfite Addition Compounds.**—The following general procedure was adopted for the formation of the amine bisulfite addition compounds listed in Table I. Sulfur dioxide was bubbled through a mixture of amine (0.10 mole) and ether (25 ml.) that contained a slight excess of water (0.11 mole.) The introduction of sulfur dioxide was continued until the initially formed solid was replaced by a homogeneous yellow liquid. This bisulfite solution was poured into an excess (0.20 mole) of the carbonyl compound. Immediately the solution was decolorized, sulfur dioxide was evolved, the reaction mixture became very warm and soon solidified.

It was found more convenient to use ethanol rather than ether in the preparation of the β-naphthol phenyl-

aminomethane bisulfite addition compounds. In all cases the product was collected by filtration and washed with ether before it was recrystallized from either absolute ethanol or an ethanol–water mixture.

**Analytical Method for the Determination of Sulfur.**—The sample (0.3 g.) of amine bisulfite addition compound was weighed into a small erlenmeyer flask and treated with 10 ml. of water. It was immaterial whether complete solution was effected. After 5 ml. of 5% aqueous potassium hydroxide had been added, the flask was stoppered and allowed to stand at room temperature for one hour. It was found that this time could be shortened considerably without affecting the results. The alkaline reaction mixture was poured into an aqueous solution of a 10% excess of standard iodine and just enough 5% sulfuric acid to neutralize the alkali used originally and also the amine formed by the decomposition of the sample. One drop excess of the acid solution was then added, and the iodine titrated with standard sodium thiosulfate. Analyses were carried out in which the sample was heated at 50° with alkali. This modification gave excellent results if the flask was swept out with nitrogen before it was stoppered and heated.

***d*-α-Phenethylamine Bisulfite Addition Compound of *d*-3-Methylcyclohexanone.**—The bisulfite solution was formed in the usual manner from 12 g. of *d*-α-phenethylamine,[14] 2.7 g. of water and 20 ml. of ether. To the viscous, yellow liquid was added 22 g. of *dl*-3-methylcyclohexanone in one portion. Immediately, bubbles of sulfur dioxide were evolved and much heat was produced. Crystallization was induced by scratching and cooling the solution, and after the reaction mixture had solidified ether was added and the paste broken down with a spatula. A yield of 30 g. (96%) of the *d*-α-phenethylamine bisulfite addition compound of *dl*-3-methylcyclohexanone, m.p. 106–113°, resulted. Four recrystallizations of this racemic addition compound from the minimum amount of absolute ethanol at 40° yielded 4.3 g. (29%) of the *d*-α-phenethylamine bisulfite addition compound of *d*-3-methylcyclohexanone, m. p. 126–127°.

*Anal.* Calcd. for $C_{15}H_{25}O_4NS$: C, 57.11; H, 7.99. Found: C, 57.20; H, 7.24. *Rotation.* 0.1068 g. made up to 5 ml. with water at 26° gave $\alpha_D$ + 0.03°; *l*, 1; $[\alpha]^{26}D$ + 1.4°.

**Semicarbazone of *d*-3-Methylcyclohexanone.**[6]—A sample of 0.8 g. of the purified addition compound was decomposed with 10 ml. of 20% hydrochloric acid at 45°. The ketone was extracted with ether, and converted to the semicarbazone in the usual manner. This derivative was recrystallized several times from aqueous ethanol, m.p. 183–183.5°.

*Anal.* Calcd. for $C_8H_{15}ON_3$: C, 56.78; H, 8.94. Found: C, 57.04, H, 9.09. *Rotation.* 0.0738 g. made up to 5 ml. with ethanol at 20° gave $\alpha_D$ −0.31°; *l*, 1; $[\alpha]^{20}D$ −21.0°.

***l*-α-Phenethylamine Bisulfite Addition Compound of *l*-3-Methylcyclohexanone.**—Identically the same procedure was used for the formation of the *l*-amine bisulfite and the corresponding addition compound as was used in the case of the *d*-amine. From 12 g. of *l*-α-phenethylamine and 22 g. of *dl*-3-methylcyclohexanone was obtained 29 g. (93%) of the bisulfite addition compound, m. p. 106–113°. The crude material was recrystallized four times from the minimum amount of absolute ethanol at 40°, and 3.9 g. (27%) of the pure bisulfite addition compound of *l*-α-phenethylamine and *l*-3-methylcyclohexanone was removed by filtration, m. p. 126–127°.

*Anal.* Calcd. for $C_{15}H_{25}O_4NS$: C, 57.11; H, 7.99. Found: C, 57.16; H, 8.02. *Rotation.* 0.2137 g. made up to 5 ml. with water at 28° gave $\alpha_D$ −0.06°; *l*, 1; $[\alpha]^{28}D$ −1.4°.

**Semicarbazone of *l*-3-Methylcyclohexanone.**—This compound was prepared from 0.8 g. of the *l*-amine bisulfite addition compound of the *l*-ketone in the same manner as its stereoisomer. After the product had been recrystallized several times from aqueous ethanol the semicarbazone of *l*-3-methylcyclohexanone was pure, m. p. 183–183.5°.

*Rotation.* 0.0840 g. made up to 5 ml. with ethanol at 20° gave $\alpha_D$ + 0.35°; *l*, 1; $[\alpha]^{20}D$ +20.8°.

***p*-Iodo-*s*-butylbenzene.**[7]—A mixture of 160 g. of *s*-butylbenzene, 127 g. of iodine, 39 g. of iodic acid, 50 ml. of water and 350 ml. of glacial acetic acid was allowed to reflux in a 1-l. flask (ground glass connections) equipped with a water-cooled condenser. Heating was continued for several hours and then the solution was decanted from the excess iodine into an equal volume of water. The lower layer was separated and boiled with an equal volume of methanolic potassium hydroxide for thirty minutes. The lower layer was separated, washed with water, dried over anhydrous magnesium sulfate, filtered and distilled *in vacuo*. A total of 84 g. (53%) of *s*-butylbenzene was recovered from the fore-run, and 81 g. (55%, based on *s*-butylbenzene actually consumed) of *p*-iodo-*s*-butylbenzene was obtained, b. p. 115–118° (12 mm.); $n^{30}D$ 1.5642.

***p*-*s*-Butylbenzaldehyde.**—The technique of Adams and Carlin[15] for the preparation of aldehydes from aryl lithium

(14) Ingersoll, *Org. Syntheses*, Coll. Vol. II, p. 506.

(15) Adams and Carlin, THIS JOURNAL, **65**, 360 (1943).

compounds and N-methylformanilide[16] was used. A 500-ml. three-necked round-bottomed flask was provided with a mercury-sealed Hershberg wire stirrer, a reflux condenser, a nitrogen inlet tube and an outlet tube fitted with a stopcock. The stirrer and condenser mounts were each equipped with ground glass joints, and the top of the reflux condenser was made so that a special ground glass joint dropping funnel could be inserted. A rapid stream of dry, oxygen-free nitrogen was passed through the flask, which contained 25 ml. of anhydrous ether; and, simultaneously, 2.78 g. of lithium was cut into small pieces and allowed to fall through the central neck. The rate of flow of nitrogen was reduced to one bubble (through a 6″ column of sulfuric acid) per second, the stirrer started and a solution of 46 g. of *p*-iodo-*s*-butylbenzene in 60 ml. of anhydrous ether was added at such a rate that refluxing was maintained throughout the addition.

The solution was stirred for one hour, and then a mixture of 26 g. of N-methylformanilide with an equal volume of ether was added dropwise. Enough heat was generated to cause the solvent to reflux. The solution was stirred overnight and then poured into a mixture of 200 ml. of water, 11 ml. of concentrated sulfuric acid and 100 g. of ice. The ether layer was separated and the aqueous layer was extracted three times with 100-ml. portions of ether. The combined ether extract was dried over anhydrous sodium sulfate, filtered and the solvent removed. The fraction that boiled at 116–118° (15 mm.) was *p*-*s*-butylbenzaldehyde, $n^{25}D$ 1.5240; yield 19.8 g. (66%).

**d-α-Phenethylamine Bisulfite Addition Compound of l-p-s-Butylbenzaldehyde.**—Sulfur dioxide was passed into a mixture of 25.4 g. of *d*-α-phenethylamine, 4.0 g. of water and 75 ml. of ether. The amine bisulfite solution was poured into 44 g. of slightly yellow *dl*-*p*-*s*-butylbenzaldehyde. After the reaction mixture had solidified, 300 ml. of ether was added, the flask stoppered and the mixture allowed to stand overnight in the ice-box. The addition compound was collected on a filter and washed with ether until white. The yield was 71 g. (92%) of crude product, m. p. 90–95°. A solution of 20 g. of the above addition product in 350 ml. of chloroform at 45° was allowed to stand at room temperature but no crystals appeared. After addition of 200 ml. of dry ether, the solution was placed in an ice-box overnight. It thus yielded 4 g. of white crystals, m. p. 103–104°. Further recrystallization from either chloroform or ethanol failed to yield a fraction of higher melting point.

*Anal.* Calcd. for $C_{19}H_{27}O_4NS$: S, 8.79. Found: S, 8.68. *Rotation.* 0.3911 g. made up to 25 ml. with ethanol at 27° gave $\alpha_D + 0.11°$; *l*, 2; $[\alpha]^{27}D + 3.52°$.

**l-p-s-Butylbenzaldehyde.**—A sample of 10 g. of the addition compound from *d*-α-phenethylamine bisulfite and *l*-*p*-*s*-butylbenzaldehyde, m. p. 103–104°, was decomposed with 75 ml. of 5% hydrochloric acid, and the aldehyde extracted with ether. The combined ether extract was dried over anhydrous magnesium sulfate, filtered and distilled under diminished pressure. The yield of *l*-*p*-*s*-butylbenzaldehyde, b. p. 115–116° (13 mm.), $n^{25}D$ 1.5247, was 2.6 g. (59%).

*Anal.* Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.69. Found: C, 81.16; H, 8.94. *Rotation.* 2.1345 g. made up to 6.63 ml. with ethanol at 33° gave $\alpha_D -0.06°$; *l*, 1; $[\alpha]^{33}D -0.19°$.

**Semicarbazone of l-p-s-Butylbenzaldehyde.**—A small sample of addition compound, m. p. 103–104°, was decomposed with 15% sulfuric acid. The aldehyde was recovered by an ether extraction and converted to the semicarbazone. Two recrystallizations from ethanol yielded a white product, m. p. 206–207°.

*Anal.* (racemic modification) Calcd. for $C_{12}H_{17}ON_3$: C, 65.73; H, 7.81. Found: C, 65.63; H, 7.91. *Rotation.* 0.0765 g. made up to 10 ml. with ethanol at 28° gave $\alpha_D -0.01°$; *l*, 1; $[\alpha]^{28}D -1.3°$.

**Reaction of d-β-Naphthol Phenylaminomethane Bisulfite and dl-p-s-Butylbenzaldehyde.**—In a 125-ml. erlenmeyer flask which contained 15 ml. of a 50% mixture of ethanol and ether and 3.0 g. of water, 5 g. of *d*-β-naphthol phenylaminomethane, $[\alpha]^{28}D + 45.8°$, was added. Sulfur dioxide was introduced until the solid dissolved and the solution had a characteristic yellow color. To this bisulfite solution was added 5 g. of *dl*-*p*-*s*-butylbenzaldehyde. There was no evidence of reaction after the mixture had stood in the ice-box for a week, but when the flask was kept at room temperature for two days, beautiful acicular crystals appeared, m. p. 164–165°, which may be recrystallized from ethanol. Since this product did not decolorize iodine, it was assumed that it was not a bisulfite addition compound.

*Rotation.* 0.1069 g. made up to 10 ml. with chloroform at 30° gave $\alpha_D + 2.56$; *l*, 1, $[\alpha]^{30}D +240°$.

Since it was thought the product might be a Schiff base it was synthesized by a direct method. To a solution of 0.2 g. of *d*-β-naphthol phenylaminomethane in 15 ml. of ethanol was added a few drops of *dl*-*p*-*s*-butylbenzaldehyde and one drop of 10% aqueous sodium hydroxide. The precipitate, which formed immediately, was recrystallized several times from ethanol, m. p. 166–166.5°. The mixture of this product and the one obtained above showed no depression when melted.

*Anal.* Calcd. for $C_{28}H_{27}ON$: C, 85.46; H, 6.92. Found: C, 85.31; H, 7.09.

**l-Menthylamine Bisulfite Addition Compound of dl-p-s-Butylbenzaldehyde.**—Sulfur dioxide was passed into a mixture of 14.3 g. of *l*-menthylamine (Eastman Kodak Co.), 3.0 g. of water and 25 ml. of ether. When the formation of the amine bisulfite was complete, 18 g. of *dl*-*p*-*s*-butylbenzaldehyde was added. Although there was very little heat effect, the reaction mixture soon solidified. The product was collected on a filter and washed thoroughly with absolute ether, m. p. 109–114°. The yield was 11.6 g. (32%).

*Rotation.* 0.2220 g. made up to 25 ml. with ethanol at 27° gave $\alpha_D -0.21°$; *l*, 2; $[\alpha]^{27}D -11.6°$.

A solution of 11 g. of the crude product from the *d*-amine bisulfite and the *dl*-aldehyde in 50 ml. of absolute ethanol at 50° was allowed to stand at room temperature. When this solution was filtered, 7 g. of addition compound, m. p. 112–115°, was obtained. This fraction was dissolved in the minimum amount of ethanol at 45° and the resulting solution again allowed to stand at room temperature. A crop that weighed 1.02 g. was isolated, m. p. 117–118°. The semicarbazone of the aldehyde obtained by decomposition of this fraction was optically inactive.

*Anal.* Calcd. for $C_{21}H_{37}O_4NS$: S, 8.02. Found: S, 7.80. *Rotation.* 0.1375 g. made up to 10 ml. with ethanol gave $\alpha_D -0.16$; *l*, 1; $[\alpha]^{33}D -11.6°$.

**β-Bromoisopropylbenzene.**[9,10]—A 1-l., three-necked flask was fitted with a mercury-sealed Hershberg wire stirrer, a water-cooled condenser and a dropping funnel. Into the flask was introduced 420 ml. of benzene (dried over anhydrous calcium chloride) and 81.5 ml. of concentrated sulfuric acid. The stirrer was started and the temperature maintained at 40 ± 2° throughout the addition of 175 g. (1.45 moles) of allyl bromide. Vigorous stirring was continued for five hours and then the reaction mixture was allowed to stand overnight. The benzene layer was separated, washed consecutively with 30 ml. of concentrated sulfuric acid, 50 ml. of water which was saturated with sodium sulfate, 50 ml. of 10% aqueous sodium hydroxide and finally with 50 ml. of water. The benzene layer was placed in a 1-l. round-bottomed flask arranged for steam distillation. When no more oil appeared in the condensate, the layers were separated and the water layer extracted with 100 ml. of benzene. The combined organic extract was dried over anhydrous magnesium sulfate, filtered and the solvent removed. The yield of β-bromoisopropylbenzene was 166 g. (58%); b. p. 109–111° (16 mm.); $n^{25}D$ 1.5462.

**β-Methylhydrocinnamaldehyde.**[8]—The Grignard reagent was formed from 6.0 g. of magnesium, 51 g. of β-bromoisopropylbenzene and 100 ml. of dry ether. After this solution was heated under reflux for one hour, 35 g. of

(16) Fieser and Jones, *Org. Syntheses*, **20**, 66 (1940).

N-methylformanilide in an equal volume of ether was added. A vigorous reaction ensued, and when the addition was complete the solution was heated under reflux for two hours. The Grignard reaction mixture was decomposed with 100 ml. of 5 *N* sulfuric acid. When all of the solid had dissolved, the ether layer was separated and shaken for thirty minutes with an equal volume of saturated sodium bisulfite. The sodium bisulfite addition compound was collected on a filter and washed with ether. Upon decomposition of the salt with aqueous sodium bicarbonate, a yield of 13 g. (35%) of *dl*-β-methylhydrocinnamaldehyde, b. p. 92–93° (14 mm.), $n^{30}D$ 1.5106, was obtained.

*Anal.* Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16. Found: C, 80.08; H, 8.56.

The 2,4-dinitrophenylhydrazone of *dl*-β-methylhydrocinnamaldehyde was prepared in the usual manner. The crude product was dissolved in ether and extracted with three portions of 1:1 hydrochloric acid. The ether layer was separated, the solvent removed and the residue recrystallized several times from ethanol; yellow crystals, m. p. 123–123.5°.

*Anal.* Calcd. for $C_{16}H_{16}O_4N_4$: C, 58.53; H, 4.91. Found: C, 58.35; H, 5.09.

***d*-α-Phenethylamine Bisulfite Addition Compound of *l*-β-Methylhydrocinnamaldehyde.**—The amine bisulfite was formed by the action of sulfur dioxide on 4.5 g. of *d*-α-phenethylamine, 1.0 g. of water and 15 ml. of ether. When bisulfite formation was complete, 6.0 g. of crude *dl*-β-methylhydrocinnamaldehyde was added in one portion. The solid addition product was isolated by filtration and washed with ether, m. p. 95–115°; yield 7.0 g. (54%).

All of the crude bisulfite addition compound of the *d*-amine and the *dl*-aldehyde was dissolved in 30 ml. of 95% ethanol at 45°. When the solution was allowed to stand at room temperature, 1.78 g. of glistening, white crystals were isolated, m. p. 131.5–132°.

*Anal.* Calcd. for $C_{18}H_{25}O_4NS$: S, 9.12. Found: S, 9.20. *Rotation.* 0.0870 g. made up to 5 ml. with ethanol at 32° gave $\alpha_D$ −0.36; *l*, 1; $[\alpha]^{32}D$ −20.7°.

**2,4-Dinitrophenylhydrazone of *l*-β-Methylhydrocinnamaldehyde.**—Approximately 0.5 g. of the first fraction of the *d*-amine bisulfite addition compound of *l*-β-methylhydrocinnamaldehyde was decomposed and converted to the 2,4-dinitrophenylhydrazone, which was purified in the same manner as the corresponding derivative of the *dl*-aldehyde. A yellow crystalline product was isolated, m. p. 97–97.5°.

*Rotation.* 0.0681 g. made up to 10 ml. with chloroform at 27° gave $\alpha_D$ −0.27°; *l*, 1; $[\alpha]^{27}D$ −39.6°.

***l*-α-Phenethylamine Bisulfite Addition Compound of *d*-β-Methylhydrocinnamaldehyde.**—Sulfur dioxide was passed into 4.8 g. of *l*-α-phenethylamine, 1.0 g. of water and 10 ml. of ether. To the resulting solution 5.0 g. of pure *dl*-β-methylhydrocinnamaldehyde, b. p. 93–94° (16 mm.), was introduced. The reaction mixture solidified when allowed to stand in the ice-box for a few hours and the product was filtered, m. p. 88–115°; yield, 7.2 g. When a mixture of 6 g. of the bisulfite addition compound of the *l*-amine and the *dl*-aldehyde in 20 ml. of absolute ethanol and 0.25 ml. of water at 45° was allowed to stand at room temperature, 1.03 g. of acicular crystals were formed, m. p. 130–131°.

*Anal.* Calcd. for $C_{18}H_{25}O_4NS$: S, 9.12. Found: S, 9.05. *Rotation.* 0.1411 g. made up to 10 ml. with ethanol at 32° gave $\alpha_D$ + 0.30; *l*, 1; $[\alpha]^{32}D$ +21.3°.

## Summary

1. Several primary amines were converted to their bisulfites and these were added to various aldehydes and ketones. The adducts were usually white crystalline products, melting in the range 100–160°, and readily purified from ethanol or ethanol–water mixtures.

2. The optically active forms of α-phenethylamine were converted to their bisulfites and when they reacted with *dl*-3-methylcyclohexanone or *dl*-β-methylhydrocinnamaldehyde yielded products from which pure salts were isolated. Upon decomposition, the optically active aldehyde or ketone resulted. Only partial resolution of *dl*-*p*-*s*-butylbenzaldehyde was affected in the same manner.

3. *d*-β-Naphthol phenylaminomethane and *l*-menthylamine bisulfites did not give satisfactory results in the resolution of the three aldehydes and ketones used.

4. *p*-*s*-Butylbenzaldehyde was prepared from the aryl lithium compound, resulting from the action of lithium on *p*-iodo-*s*-butylbenzene, and N-methylformanilide. A new synthesis of β-methylhydrocinnamaldehyde from the Grignard of β-bromoisopropylbenzene and N-methylformanilide appears to be an improvement over those previously used.

5. A satisfactory quantitative method for determination of sulfur in the adducts of amine bisulfites and aldehydes or ketones is described.

# The Synthesis of β-Carbolines. V. 1-Amino-β-carboline[1]

BY H. R. SNYDER, HOWARD G. WALKER[2] AND FRANK X. WERBER[3]

In preceding papers[1,4] syntheses of the isomeric 3- and 6-amino derivatives of harman were reported. These amines were prepared by the degradation of an acid (Curtius reaction) and the reduction of a nitro compound, respectively. Although the direct amination, by alkali amides, of higher heterocyclic bases containing the pyridine nucleus has been found to have only limited applicability,[5] it was of interest to test the possible use of the reaction in the β-carboline series. Accordingly, norharman (III) has been subjected to the action of sodium amide; reaction occurred readily, and the product has been shown to be 1-amino-β-carboline (IV).

The preparation of norharman (III) was carried out according to Harvey, Miller and Robson[6] in direct analogy to the synthesis of harman,[4] without isolation of the intermediate tetrahydrocarboxylic acid (II). *dl*-Tryptophan (I) was condensed with formaldehyde and the 1,2,3,4-tetrahydronorharman - 3 - carboxylic acid so formed (II) was converted directly to III by dehydrogenation and decarboxylation with aqueous potassium dichromate. Amination of III with sodium amide proceeded in 89% yield to give 1-amino-β-carboline (IV). Acetylation of IV with acetic anhydride in pyridine solution produced a diacetyl derivative, the detailed structure of which has not yet been elucidated.

Chichibabin and Oparina[7] have shown that 1-aminoisoquinoline is obtained by direct amination of isoquinoline. It thus seemed reasonable to assume that the β-carboline nucleus would be attacked at the 1-position. All approaches to the structure proof were based on this assumption. Diazotization followed by hydrolysis, or direct hydrolysis of the amine with acid or base, might be expected to lead to the 1-hydroxy-β-carboline prepared by Elderfield and Hageman.[8] All attempts in this direction were unsuccessful, however. 9 - Methyl - 1 - hydroxy - β - carboline[9] might be prepared by methylation and subsequent diazotization of the amine, but methylation with diazomethane failed, so that this approach was abandoned. Similarly, no identifiable products were obtained in attempts to replace the amino group with bromine, nor was it found possible to hydrolyze any of the resulting crude reaction products to the hydroxy compound.

An unequivocal synthesis of 1-amino-β-carboline has been carried out by the method shown in the accompanying diagram. Harman (V) was oxidized to β-carboline-1-carboxylic acid (VII) essentially by the method of Kermak, Perkin and Robinson,[9] who condensed harman with benzaldehyde and oxidized the condensation product (VI) with potassium permanganate. The acid (VII) could be degraded to 1-amino-β-carboline by application of the Curtius reaction.[10] Preliminary experiments indicated that the more direct route to the carbonylazide—treatment of the acid chloride with sodium azide—was not feasible because of the extreme insolubility of the acid, which made conversion to the acid chloride unsatisfactory. The acid was readily esterified, however, and the methyl ester reacted with hydrazine almost instantaneously, without application of heat. Although the hydrazide was very insoluble it was readily transformed into the azide by treatment with nitrous acid in a large

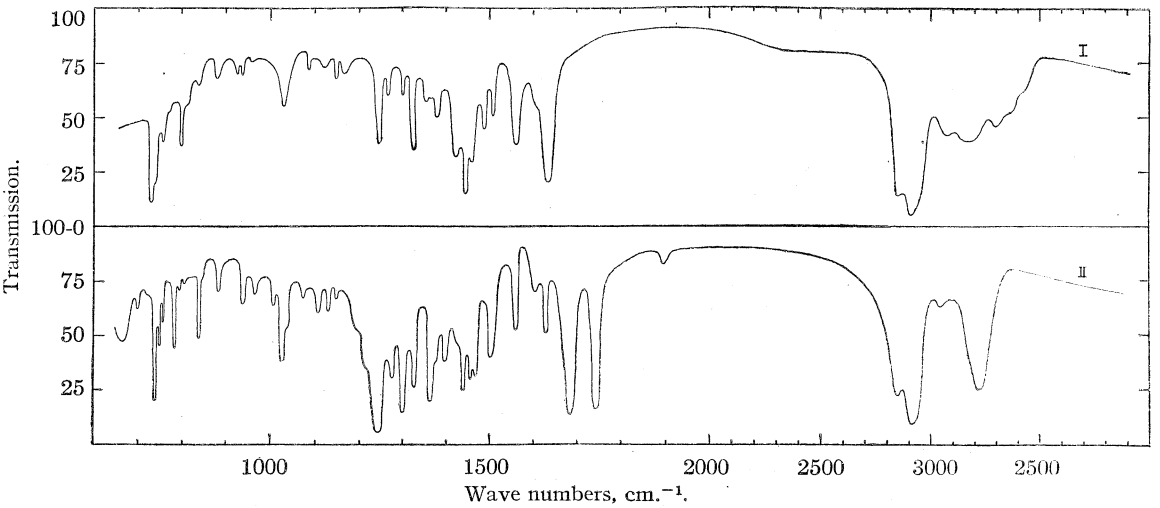

Fig. 1.—I, 1-Amino-β-carboline, suspended in mineral oil; II, diacetyl derivative of 1-amino-β-carboline, suspended in mineral oil.

volume of water. The azide was quite stable at room temperature. Attempted conversion to the amine in dilute acetic acid gave the *sym*-urea, which could be converted to the amine by hydrolysis with concentrated aqueous potassium hydroxide, but only in low yields. Conversion to the amine by preparation and hydrolysis of the ethyl carbamate was the most successful of the methods tried. The amine (IV) thus obtained melted two degrees lower than that formed by direct amination of norharman, but a mixture of the two samples melted at an intermediate temperature. Infrared absorption[11] spectra of the two amines were identical (see Fig. 1).

The diacetyl derivative of the amine obtained by the indirect route was also prepared; this substance and the compound derived from the direct-amination product melted at the same point, alone or mixed, and their infrared absorption curves were identical in every detail (Fig. 1).

## Experimental[12]

**Norharman.**—The general procedure of Harvey, Miller and Robson[6] was followed. Ten grams (0.049 mole) of *dl*-tryptophan was dissolved in 500 ml. of 0.1 *N* sodium hydroxide containing 5.6 ml. (0.07 mole) of aqueous formalin (40%). The solution was incubated at 37° for forty-six hours. It was neutralized with 4 ml. of glacial acetic acid, transferred to a 5-l. flask, and diluted with water to a volume of 2.5 l. The suspension was heated to boiling, and most of the 3-carboxy-1,2,3,4-tetrahydro-β-carboline dissolved. A mixture of 500 ml. of 10% aqueous potassium dichromate and 100 ml. of glacial acetic acid was added to the slowly boiling solution, with stirring, over a period of forty-five minutes. The solution darkened, carbon dioxide was evolved, and a brown precipitate appeared soon after the addition was started. Boiling was continued for two minutes after the addition was complete. The mixture was cooled and the excess dichromate was destroyed with sodium bisulfite. Sodium carbonate was added to definite alkalinity and the product was extracted exhaustively with about 2.5 l. of ether. The extracts were dried over magnesium sulfate and the solvent removed. After one recrystallization from aqueous methanol the slightly yellow, crystalline norharman weighed 2.80 g. (34%), m.p. 199–201°.

**1-Amino-β-carboline.**—Sodium amide was prepared according to the standard procedure,[5] from 1.81 g. (0.0788 mole) of sodium and 30 ml. of liquid ammonia in a 200-ml. three-necked flask fitted with mercury-sealed stirrer and reflux condenser. After the ammonia had evaporated, 3.31 g. (0.0197 mole) of norharman and 90 ml. of dimethylaniline were added, and the mixture was stirred and heated at 140–150° for twenty-four hours. The contents of the flask were allowed to cool, and 50 ml. of 5% sodium hydroxide solution and 100 ml. of water were added cautiously. Low-boiling petroleum ether was added to precipitate all material in the organic layer, the mixture was cooled in an ice-bath, and the crystalline product was collected. It was washed with low-boiling petroleum ether and dried in a vacuum desiccator; there was obtained 3.31 g. (89%) of material, m.p. 193–197°. Recrystallized from a methanol–water mixture it melted at 198–200°. A mixture of the crude reaction product and norharman melted at 142–159°. A sample of the product was recrystallized once more from methanol–water, yielding white platelets, m.p. 199.5–200.5° (dec.).

*Anal.* Calcd. for $C_{11}H_9N_3$: C, 72.11; H, 4.95. Found: C, 72.22; H, 4.79.

The diacetyl derivative was prepared according to a standard method of acetylation.[13] Recrystallized four times from benzene, it melted at 196–197.5°. A sample mixed with 1-amino-β-carboline melted at 135–150°.

*Anal.* Calcd. for $C_{15}H_{13}O_2N_3$: C, 67.40; H, 4.90; N, 15.72. Found: C, 67.56; H, 4.58; N, 15.59.

**Benzalharman.**[9,14]—Harman,[4] 9.94 g. (0.055 mole), and 55 ml. of distilled benzaldehyde were placed in a 500-ml. round-bottomed flask and the mixture was refluxed gently for four hours, with a condenser short enough to permit the slow evaporation of the water formed in the reaction. After cooling, the brown mixture was diluted with 200 ml. of ether, and dilute hydrochloric acid was added to precipitate the yellow hydrochloride of benzalharman. It was separated, washed with ether and water, and recrystallized from 95% ethanol. The hydrochloride

(12) All melting points are corrected. Microanalyses by Miss Theta Spoor and Mr. H. S. Clark.

(13) Shriner and Fuson, "Systematic Identification of Organic Compounds," 3rd ed., John Wiley and Sons, New York, N. Y., 1948, p. 165, Procedure B.

(14) Barger and Scholtz, *J. Chem. Soc.*, 614 (1933); Leonard and Elderfield, *J. Org. Chem.*, 7, 556 (1942).

was suspended in 40 ml. of 95% ethanol, neutralized with dilute aqueous ammonia (1:5 ammonium hydroxide–water), and the free base was collected. The yield of yellow crystalline benzalharman was 12.6 g. (84%), m.p. 197–199°.

**β-Carboline-1-carboxylic Acid.**—The permanganate oxidation method of Kermak, Perkin and Robinson[9] was used. Benzalharman, 12.7 g. (0.046 mole) was dissolved in 50 ml. of pyridine, the solution was cooled in ice and stirred during the dropwise addition of enough saturated aqueous potassium permanganate to leave a pink color for one hour (approx. 300 ml.). The exact amount added depends on rapidity of addition, temperature and other factors. Five ml. of 95% ethanol was added and the mixture was heated on the steam-bath to destroy excess permanganate. The dark suspension was filtered hot and the filtrate was concentrated to a volume of 100 ml. and acidified with dilute hydrochloric acid. The canary-yellow hydrochloride was collected. The manganese dioxide residue was suspended in 100 ml. of water and acidified with hydrochloric acid; the mixture was treated with sodium bisulfite to dissolve the manganese dioxide, and the additional hydrochloride precipitate was collected. (Direct treatment of the original mixture with sodium bisulfite, to circumvent the necessity for removal of the manganese dioxide by filtration, resulted in lower yields.) The combined hydrochloride precipitates were dissolved in 1500 ml. of hot 5% aqueous potassium hydroxide, the solution was filtered, cooled, and the free acid was precipitated with acetic acid. The material was collected, washed with water, and dried; it weighed 3.4 g., m. p. 235°. The acidic mother liquor yielded an additional 0.9 g. of product (total crude yield, 43%). β-Carboline-1-carboxylic acid is a bright yellow, crystalline powder whose insolubility in all solvents tried made recrystallization impossible.

**1-Carbomethoxy-β-carboline.**—β-Carboline-1-carboxylic acid, 3.9 g., was suspended in 300 ml. of anhydrous methanol saturated with hydrogen chloride. The mixture was refluxed for twenty hours and concentrated to a volume of 100 ml. under reduced pressure and at room temperature. It was diluted with an equal volume of ice water, made barely alkaline with sodium bicarbonate, and extracted with chloroform. The extract was dried over magnesium sulfate and the solvent was removed. The yield of crude ester was 1.50 g., m.p. 152–157°. A small sample was sublimed *in vacuo* and recrystallized three times from dilute methanol; m.p. 165.3–166.0°.

*Anal.* Calcd. for $C_{13}H_{10}O_2N_2$: C, 69.02; H, 4.46; N, 12.39. Found: C, 69.02; H, 4.18; N, 12.41.

The magnesium sulfate residue was combined with the extracted water solution, and the mixture was concentrated and acidified with acetic acid. One and one-half grams of β-carboline-1-carboxylic acid was recovered.

**β-Carboline-1-carbonyl Hydrazide.**—The remainder of the crude ester from the previous preparation, 1.35 g., was dissolved in a mixture of methanol and water and the solution was slowly added to 7 ml. of 85% hydrazine hydrate. Precipitation of the hydrazide started immediately and was allowed to go to completion in the refrigerator overnight. The product was collected, m.p. 215–236°. One recrystallization from dioxane gave 1.20 g. of hydrazide, m.p. 265–267°. A sample recrystallized repeatedly from dioxane melted at 268–269.5° (dec.).

*Anal.* Calcd. for $C_{12}H_{10}ON_4$: C, 63.71; H, 4.46. Found: C, 63.47; H, 4.30.

**β-Carboline-1-carbonyl Azide.**—β-Carboline-1-carbonyl hydrazide, 0.95 g., was added to 146.1 ml. of dilute hydrochloric acid (6.1 ml. of the concentrated acid in 140 ml. of water), and the suspension was filtered to remove the insoluble residue. The filtrate was cooled to 0° in an ice–salt-bath, and 0.33 g. of sodium nitrite in 5 ml. of water was added over a period of five minutes. The suspension of azide-hydrochloride was allowed to stand in the cooling bath for two hours, made definitely alkaline with saturated aqueous sodium carbonate, and the solid was collected and washed with water. After drying to constant weight in a vacuum desiccator the product weighed 0.86 g.; it was quite stable at room temperature, but slowly decomposed at temperatures of 70–100°.

**Ethyl β-Carboline-1-carbamate.**—The crude azide, 0.86 g., was refluxed for three hours in 13 ml. of absolute ethanol diluted with 4 ml. of dry xylene. The mixture was filtered hot and the residue was washed with hot 95% ethanol. The combined filtrate and washings were concentrated to a volume of 15 ml., and 0.38 g. of fluffy yellow needles was collected, m.p. 283–285° (dec.), with characteristic shrinking at 181–183°. Examination of the residue from the hot reaction mixture, weighing 0.16 g., revealed it to be a less soluble crystalline modification of the major reaction product. Its melting point and infrared-absorption curve were identical with those of the ethanol-soluble portion, and mixtures of the two samples showed no melting point depression. A small amount of the soluble modification, recrystallized repeatedly from ethanol, melted at 285–288° (dec.), shrinking at 184–186°.

*Anal.* Calcd. for $C_{14}H_{13}O_2N_3$: N, 16.46: Found: N, 16.36.

**1-Amino-β-carboline.**—A suspension of 0.33 g. of crude carbamate in 7 ml. of 20% aqueous potassium hydroxide was refluxed for two hours. The mixture was allowed to cool, and the crude amine was collected and washed with cold water. After one recrystallization from dilute ethanol (Norite) there was obtained 0.21 g. of colorless needles, m.p. 199–201 (dec.). A sample recrystallized to constant melting point melted at 196.5–198.5° (dec.). Mixed with the amine prepared by direct amination of norharman it melted at 198–200°.

*Anal.* Calcd. for $C_{11}H_9N_3$: C, 72.11; H, 4.95. Found: C, 72.32; H, 5.14.

The diacetyl derivative was prepared[13] and recrystallized repeatedly from benzene. It melted at 195.5–197.5°, alone or mixed with a sample derived from the amination product of norharman.

*Anal.* Calcd. for $C_{15}H_{13}O_2N_3$: N, 15.72. Found: N, 15.54.

## Summary

1-Amino-β-carboline has been prepared by direct amination of norharman, and the structure of the product has been proved by an independent synthesis.

# Preparation of N-Substituted 1-(3′,4′-Dihydroxyphenyl)-2-aminoethanols[1]

BY JOHN R. CORRIGAN,[2a] MARIE-JO LANGERMANN[2b] AND MAURICE L. MOORE[2c]

In a previous report[3] from these laboratories we have described the preparation of a series of N-substituted 1-(*p*-hydroxyphenyl)-2-aminoethanols. Our investigations were prompted by an observation of Konzett[4] that 1-(*p*-hydroxyphenyl)-2-isopropylaminoethanol was more active as a broncholdilator than the N-methyl analog (Synephrine). Konzett[4] also studied the broncholytic properties of several N-alkyl analogs of epinephrine and reported that 1-(3′,4′-dihydroxyphenyl)-2-isopropylaminoethanol possessed ten times the bronchodilator activity of its N-methyl analog (epinephrine) against pilocarpine-induced bronchial spasm in dogs. The chemical synthesis of these N-alkyl epinephrine analogs (alkyl = ethyl, propyl, isopropyl, butyl and isobutyl) has not been reported. We have, therefore, extended our investigations to include the preparation of a series of N-substituted 1-(3′,4′-dihydroxyphenyl)-2-aminoethanols.

All of the amino alcohols in this series were obtained from the corresponding amino ketone hydrochlorides by catalytic hydrogenation with palladium-on-charcoal in aqueous solution. By careful removal of the solvent from the reduction solutions most of the amino alcohol hydrochlorides were isolated in crystalline form. In certain cases where the hydrochlorides resisted crystallization it was found necessary to precipitate the relatively unstable amino alcohol bases from the reduction solutions with ammonia. These bases, which were filtered if solid or extracted with butanol or ether if gummy, were converted to the acetate salts with glacial acetic acid in alcohol–ether solution. The properties of these amino alcohol salts are shown in Table I.

[a] Acetate salt.

The amino ketones were prepared by condensing ω-chloro-3,4-dihydroxyacetophenone with various primary amines and were isolated as the hydrochloride salts. The reactions were usually carried out in ethanol or isopropanol. However it was found that ω-*t*-butylamino-3,4-dihydroxyacetophenone hydrochloride was isolated in higher yield when the condensation was run in dioxane instead of alcohol. The reaction temperatures were generally around 60–80° and the yields of amino ketone hydrochlorides varied between 15 and 55%. Properties of the aminoketone hydrochlorides are listed in Table II.

We are indebted to Dr. A. M. Lands and coworkers in the Pharmacological Research Laboratories for a preliminary report of the pharmacological activity of these compounds. The N-isopropyl, N-*s*-butyl, and N-*t*-butyl analogs of epinephrine are the most active vasodepressor and bronchodilator members of this series. In general the most potent vasodepressor compounds were also the most active bronchodilators. The N-*n*-butyl derivative, however, is a very effective bronchodilator although its depressor activity is only 1/20 that of the N-isopropyl analog.

An extensive pharmacological study of 1-(3′,4′-

dihydroxyphenyl)-2-isopropylaminoethanol has shown it to be 1.5 to 2 times more active than epinephrine against histamine-induced asthma in guinea pigs and in addition its LD50 is approximately 450 mg./kg. by intraperitoneal administration in white mice as compared with 4 mg./kg. for epinephrine. This compound is a potent vasodepressor and also possesses marked antispasmodic properties.

## Experimental[5]

Most of the amines in this work were supplied through the courtesy of Commercial Solvents Corporation and Sharples Chemicals, Inc. *t*-Butylamine was prepared by catalytic hydrogenation of 2,2-dimethylethylenimine.[6] Cyclopentylamine, 3-amylamine, and 2-methyl-isobutylamine were obtained from the appropriate ketones by catalytic hydrogenation in ammoniacal alcohol solution.

**ω-Isopropylamino-3,4-dihydroxyacetophenone Hydrochloride** (I).—A mixture of 37.5 g. (0.2 mole) of ω-chloro-3,4-dihydroxyacetophenone, 39 g. (0.66 mole) of isopropylamine, and 125 ml. of isopropanol was heated with stirring to 65–70° at which point the heat was removed to allow the reaction to proceed spontaneously. The amino ketone base which separated after completion of the reaction was converted to the hydrochloride salt by the addition of concentrated hydrochloric acid to the reaction solution. After cooling overnight the amino ketone hydrochloride was filtered, washed with acetone, and dried; m. p. 239–242°, dec., yield 26.5 g. (54%).

(5) All melting points are uncorrected.

(6) Campbell, Sommers and Campbell, THIS JOURNAL, **68**, 140 (1946).

**1-(3′,4′-Dihydroxyphenyl)-2-isopropylaminoethanol Hydrochloride** (III).—Fifteen grams (0.06 mole) of (I) was dissolved in 150 ml. of hot water, 1 g. of 10% palladium-on-Nuchar catalyst added, and the warm solution hydrogenated under 50 pounds pressure. After filtering the catalyst, the water was carefully removed by distillation under reduced pressure. Acetone was distilled from the concentrate to remove residual water. The residue which solidified was recrystallized from alcohol–ether or 90% isopropyl alcohol to give a white crystalline product which melted at 170–172° dec., yield 11.5 g. (78%).

## Summary

1. A number of ω-alkylamino-3,4-dihydroxyacetophenones have been prepared from ω-chloro-3,4-dihydroxyacetophenone and various primary amines in alcohol or dioxane.

2. A series of N-alkyl 1-(3′,4′-dihydroxyphenyl)-2-aminoethanols has been obtained by the catalytic hydrogenation of the corresponding ketones.

3. Most of these amino alcohols possess broncholytic and vasodepressor activity with the isopropyl, *t*-butyl and *s*-butyl derivatives being the most active on both counts. The *n*-butyl compound is one of the most active in the series as a bronchodilator although it is a relatively weak vasodepressor. One of these compounds, 1-(3′,4′-dihydroxyphenyl)-2-isopropylaminoethanol is now in clinical use.

# Dialkylaminoalkyl Esters of Trisubstituted Acetic Acids

BY A. A. LARSEN, A. WAYNE RUDDY, B. ELPERN AND MILDRED MACMULLIN

In connection with studies directed toward the synthesis of compounds possessing antispasmodic activity a series of dialkylaminoalkyl esters of 2,2-diphenylalkanoic acids, 2,2-diphenyl-4-pentenoic acid and 2-cyclohexyl-2-phenylbutanoic acid was prepared. The 2,2-diphenylalkanoic acids were prepared by the following sequence of reactions.

$C_6H_5CH_2CN \longrightarrow C_6H_5CHBrCN \longrightarrow$
$(C_6H_5)_2CHCN \longrightarrow (C_6H_5)_2CRCN \longrightarrow (C_6H_5)_2CRCO_2H$

Diphenylacetonitrile was obtained in about 80% yield from phenylacetonitrile. Subsequent alkylation with sodamide gave upward of 80% of the tertiary nitriles. Hydrolysis of these nitriles was best accomplished by refluxing with 70% sulfuric acid for about sixty hours.[1] Increased concentrations of sulfuric acid led to the formation of water soluble products, probably sulfonated material. Use of less concentrated acid and shorter periods of heating gave an increased amount of the corresponding amides. Wieland and Dorrer[2] employed 75% sulfuric acid for the hydrolysis of 2,2-diphenylpropanenitrile; however, their period of heating was short and the principal product isolated was the amide. Hydrolysis with alkali and water or alcohols was attended with little success, resulting in low yields of the amides. Hydrolysis of the nitriles in a sealed tube with hydrochloric and sulfuric acids gave the desired product, but was less convenient than the method employed.

2-Cyclohexyl-2-phenylbutanoic acid was readily obtained by alkylation of cyclohexylphenylacetonitrile followed by hydrolysis of the tertiary nitrile to the acid. 2,2-Diphenyl-4-pentenoic acid was prepared from allyl diphenylacetate by rearrangement with sodamide.[3] The unsaturated acid obtained in this manner had the same melting ing point as that reported by Ramart,[4] which was prepared by allylation of benzyl diphenylacetate followed by hydrolysis to the acid.

The various acids were converted to the corresponding acyl chlorides upon treatment with thionyl chloride and then allowed to react with an excess of the appropriate amino alcohol to give the desired esters (Table I).

## Experimental

**Preparation of the 2,2-Diphenylalkanoic Acids.**—The general procedure employed here is suitably illustrated by the preparation of 2,2-diphenylbutanoic acid.

A well-stirred mixture of 193 g. (1 mole) of diphenylacetonitrile[5] and 48 g. (1.2 moles) of sodamide in 600 ml. of dry benzene was refluxed for two hours. The deep red-colored mixture was cooled to 60° and 312 g. (2 moles) of ethyl iodide was added as rapidly as possible. The reaction mixture was then refluxed for several hours. Upon working up there was obtained 196 g. (88%) of 2,2-diphenylbutanenitrile, b. p. 145–147° (0.3 mm.), $n^{25}D$ 1.5660.

A mixture of 111 g. (0.5 mole) of the above nitrile and 686 g. of 70% (d. 1.61) sulfuric acid was heated with stirring at 150° until a test portion remained clear when diluted with water and made alkaline. The reaction mixture was cooled to 100° and poured onto ice and water with vigorous stirring. The solid material was filtered off by means of a large fluted filter paper and washed repeatedly with water to leave a practically colorless product. The crude acid was taken up in 2% sodium hydroxide, filtered and slowly reprecipitated with dilute sulfuric acid. The white 2,2-diphenylbutanoic acid after drying weighed 86 g. (71%) and melted from 170–173°. A small portion when recrystallized from benzene melted at 174–175°.[6]

In a similar manner, 2,2-diphenylpropanenitrile[2] (95% yield, b. p. 127–130° (1.5 mm.), $n^{25}D$ 1.5713), 2,2-diphenylpropanoic acid[2,4] (66% yield, m. p. 173–175°), 2,2-diphenylpentanenitrile[5] (81% yield, b. p. 126–130° (0.2 mm.), $n^{25}D$ 1.5634), and 2,2-diphenylpentanoic acid[7] (56% yield, m. p. 156–157°) were also prepared.

**2-Cyclohexyl-2-phenylbutanoic Acid.**—Cyclohexylphenylacetonitrile[8] was alkylated with ethyl bromide and sodamide in the same manner as that employed for the alkylation of diphenylacetonitrile to give 2-cyclohexyl-2-phenylbutanenitrile (94%), b. p. 120–126° (1 mm.), $n^{25}D$ 1.5264.

*Anal.* Calcd. for $C_{16}H_{21}N$: C, 84.53; H, 9.31; N, 6.16. Found: C, 84.47; H, 9.44; N, 6.20.

After this nitrile was refluxed with 70% sulfuric acid the reaction mixture was poured onto ice and water, the layers separated and the acid extracted with dilute alkali. Upon acidification the alkali extracts gave the desired acid which when recrystallized from dilute methanol melted at 121–123° (64% based on unrecovered nitrile).

*Anal.* Calcd. for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00; neut. equiv., 246. Found: C, 77.94; H, 9.10; neut. equiv., 246.

When this acid was refluxed for two hours with excess thionyl chloride there was obtained a 90% yield of 2-cyclohexyl-2-phenylbutanoyl chloride, b. p. 119–120° (1 mm.), $n^{25}D$ 1.5418.

*Anal.* Calcd. for $C_{16}H_{21}ClO$: Cl, 13.39. Found: Cl, 13.28.

**2,2-Diphenyl-4-pentenoic Acid.**[4]—A mixture of 10 g. (0.04 mole) of allyl diphenylacetate and 1.5 g. (0.04 mole) of sodamide in 75 ml. of dry benzene was refluxed for thirty hours. After the reaction mixture was diluted with water, extracted with benzene, and the alkaline layer acidified, an oil separated out which soon solidified. The crude acid weighed 7.7 g. and melted from 120–130°. After two recrystallizations from methanol it melted at 142–143°.

*Anal.* Calcd. for $C_{17}H_{16}O_2$: neut. equiv., 252. Found: neut. equiv., 249.

**Preparation of the Basic Esters.**—The same general procedure outlined below was used to prepare all the esters listed in Table I except that the acid chloride from 2-cyclohexyl-2-phenylbutanoic acid was prepared in one lot and distilled before using. Yields of the basic esters varied from 40–70%.

[d] *Anal.* Calcd. for $C_{21}H_{25}NO_2\cdot HCl$: bromine uptake, 1 mole. Found: bromine uptake, 0.98 mole.

A solution of 10 g. (0.04 mole) of 2,2-diphenylbutanoic acid in 25 ml. of thionyl chloride was refluxed for three hours. The solution was concentrated and then reconcentrated several times with benzene to remove the excess thionyl chloride. The residue was finally taken up in 40 ml. of dry benzene, decolorized with charcoal and refluxed for ten hours with 7.4 g. (0.08 mole) of dimethylaminoethanol. The reaction mixture was made alkaline with 10% sodium hydroxide, extracted with benzene and the benzene extracts washed well with water and finally concentrated at the water pump. The residue was taken up in dry ether and the hydrochloride of the basic ester precipitated with alcoholic hydrogen chloride. After washing with ether, the hydrochloride was recrystallized twice from ethyl acetate to give 8.3 g. (57%) of product, m. p. 164–165°.

## Summary

A number of basically substituted esters of 2,2-diphenylalkanoic acids, 2,2-diphenyl-4-pentenoic acid and 2-cyclohexyl-2-phenylbutanoic acid have been prepared.

Procedures for the hydrolysis of certain tertiary nitriles to the corresponding acids have been investigated.

# A Synthesis of Adenine. The Incorporation of Isotopes of Nitrogen and Carbon[1]

BY LIEBE F. CAVALIERI, JOHN F. TINKER AND AARON BENDICH

The earlier procedure[2] used for the synthesis of adenine labeled with isotopic nitrogen in the 1 and 3 positions[3] suffered from the disadvantage that the yields in certain steps were variable. This procedure as well as others[4,5] has been re-investigated and the synthesis now developed (Fig. 1) provides uniformly reproducible and satisfactory yields. This synthesis has been used for the incorporation of isotopes of carbon and of nitrogen into adenine.

Formamidine hydrochloride was prepared in nearly quantitative yield according to the reactions shown in Fig. 1. It will be noted that the atom per cent. excess of $N^{15}$ in the formamidine hydrochloride is one half of that in the ammonia used, and that the isotope is distributed equally between the two nitrogen atoms. The condensation of formamidine hydrochloride and phenylazomalononitrile, to give I was carried out in *n*-butanol in the presence of sodium butoxide. In our hands, the yield of I was consistently lower when the condensation was carried out in ethanol containing sodium ethoxide.[2]

The previously described catalytic hydrogenation of 4,6-diamino-5-phenylazopyrimidine (I) to 4,5,6-triaminopyrimidine (II)[2] was found to be sensitive to impurities and variable yields were obtained. Upon investigation of other methods it was found that reduction with zinc and water proceeded smoothly with crude I.

A two-step cyclization of 4,5,6-triaminopyrimidine (II) to adenine (IV) was accomplished by

(1) The authors gratefully acknowledge the assistance of the James Foundation of New York, Inc., the National Cancer Institute of the U. S. Public Health Service, the United States Office of Naval Research and the Barker Welfare Foundation.

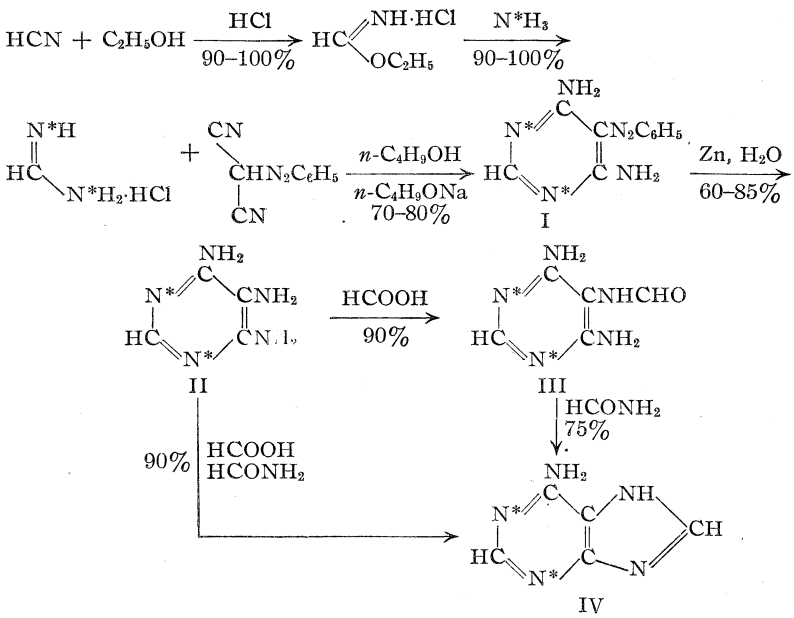

Fig. 1.—N* is $N^{15}$.

Baddiley, Lythgoe and Todd.[2] These investigators prepared the sulfur analog of III, 4,6-diamino-5-thioformylaminopyrimidine, by the reaction of II with potassium dithioformate and this derivative was cyclized to adenine by refluxing with either water or pyridine. In this Laboratory the product which resulted when the cyclization was carried out in water[3] revealed the presence of adenine and of 4,6-diamino-5-formylaminopyrimidine, when investigated by counter-current distribution. Cyclization with pyridine yielded, in addition to adenine, a small amount of 4,6-diamino-5-formylaminopyrimidine and unchanged starting material. The cyclization of 4,5,6-triaminopyrimidine (II) directly to adenine (IV) with formic acid[4] gave, in our hands, maximum yields of 35–40%. The conversion to adenine was most readily accomplished by heating II with a dilute solution of formic acid in anhydrous formamide.[6] Alternatively, the reaction could also be carried out in two steps. 4,6-Diamino-5-formylaminopyrimidine (III) was formed in quantitative yield when II was warmed gently with 98% formic acid. III was then cyclized to adenine in the presence of anhydrous formamide.

In hydrolysis experiments it was noted that when 4,6-diamino-5-formylaminopyrimidine (III) was heated with 1 *N* hydrochloric acid some adenine was produced together with a larger quantity of the hydrolysis product, 4,5,6-triaminopyrimidine. However, in the presence of concentrated hydrochloric acid, III was converted completely to 4,5,6-triaminopyrimidine.

Still another synthetic route which was investigated was based upon the condensation of malononitrile and thiourea to give 2-thio-4,6-diaminopyrimidine which was then nitrosated to 2-thio-4,6-diamino-5-nitrosopyrimidine.[4,6] The treatment of the latter compound with Raney nickel resulted in simultaneous desulfurization and the reduction of the nitroso group to yield 47% of 4,5,6-triaminopyrimidine (II). When 2-thio-4,5,6-triaminopyrimidine, prepared from the nitroso derivative by hydrosulfite reduction,[6] was desulfurized by Raney nickel treatment, a 78% yield of triaminopyrimidine (II) was obtained. The preparation of thiourea from isotopic ammonia is readily carried out but, although this synthesis could be useful for the incorporation of isotopic ammonia, the over-all yields based on malononitrile are less than for the method described in the experimental section.

The incorporation of isotopic carbon into malononitrile and thence into phenylazomalononitrile has also been accomplished (Fig. 2) and the incorporation of either $C^{13}$ or $C^{14}$ into the 4 and 6 carbons of the adenine molecule has been carried out by this synthesis.

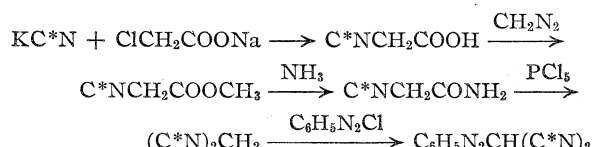

Fig. 2.—C* is $C^{13}$, $C^{14}$.

## Experimental

**Ethyl Formimino Ether Hydrochloride.**—A four-necked flask was equipped with a mercury-sealed stirrer, a sintered glass gas-dispersion tube, a calcium chloride drying tube, and an inlet tube for the introduction of hydrogen cyanide. The flask was surrounded by a bath (alcohol–Dry Ice) kept at −10 to −20°. A mixture of one pound of commercial anhydrous ether and 225 cc. (3.86 moles) of absolute ethyl alcohol was placed in the flask. The stirrer was set in motion and the generation of hydrogen cyanide from 4 moles of sodium cyanide was begun.[7] When approximately 3.5 moles of the hydrogen cyanide was collected, a vigorous stream of anhydrous hydrogen chloride was passed in and continued for ten minutes after the first appearance of turbidity (total time, thirty to forty-five minutes). The mixture was then allowed to warm overnight, without stirring, during which time the bath temperature reached 10°. The bath was cooled to −20° and the solvent was removed through the gas dispersion tube by suction. The residual solid was washed with two one-half pound portions of ether, and the ether removed as before. The white crystalline product (285 g., 90% based on hydrogen cyanide, in an experiment where it was measured accurately) was dried briefly in air and stored in a tightly stoppered bottle. The compound slowly loses weight on exposure to air.

(7) "Organic Synthesis," Coll. Vol. I, John Wiley & Sons, Inc. New York, N. Y., 1932, p. 307.

*Anal.* Calcd. for $C_3H_7ON \cdot HCl$: Cl, 38.0. Found: Cl, 38.9.

**Formamidine Hydrochloride.**—Ethyl formimino ether hydrochloride (17.0 g., 0.18 mole) and 35 cc. of commercial absolute ethanol were placed in a dry Carius tube equipped with an inlet tube reaching an inch below the surface of the ethanol. The inlet tube was arranged so as to be easily detached. The tube was immersed in a Dry Ice-bath and connected to an ammonia generator. The generator consisted of a flask provided with a condenser and an inlet tube for the introduction of air. A drying tower filled with pellets of potassium hydroxide was placed on top of the condenser. Ammonium nitrate (8.8 g., 0.11 mole containing *ca.* 25 atom per cent. excess $N^{15}$ in the ammonium group) which had been dried over calcium chloride was dissolved in 5–10 cc. of water and decomposed carefully by the addition of 11 cc. of 12 *N* potassium hydroxide. A brisk stream of air was drawn through the apparatus into an acid trap containing 5% aqueous boric acid and methyl violet indicator. Fifteen minutes after the addition of the potassium hydroxide, a water-bath was placed around the generating flask, the rate of air-sweep was decreased somewhat and the bath was warmed gradually to boiling in twenty minutes. After the bath had boiled for fifteen minutes, it was removed and the solution was boiled over a direct flame for fifteen minutes. Little or no ammonia remained in the generator.

The bomb tube, with its inlet tube detached and included, was sealed and heated for two hours at 100°, during which time the tube was shaken occasionally. The tube was cooled, opened and any excess ammonia was collected in the aqueous boric acid trap by drawing a stream of dry air through the inlet tube for thirty minutes while the tube was surrounded by a bath at 55–60°. Usually with this ratio of reactants no excess ammonia was collected. Ammonia which was not recoverable varied from 0 to 8%. The hot ethanolic solution was filtered (the residue is 99% pure ammonium chloride), the alcohol was evaporated by means of a stream of dry air, and the residual formamidine hydrochloride was dried *in vacuo* over phosphorus pentoxide and sulfuric acid.

*Anal.* Calcd. for $CH_4N_2 \cdot HCl$: Cl, 44.1. Found: Cl, 43.8. (The analysis was carried out on material containing no excess $N^{15}$.)

**4,6-Diamino-5-phenylazopyrimidine (I).**—In a one-liter erlenmeyer flask was placed 29 cc. (46.5 g., 0.15 mole) of aniline and 85 cc. (1.02 moles) of concentrated hydrochloric acid. Ice was added to the mixture to maintain a temperature of 0 to 5°. Sodium nitrite (29.0 g., 0.50 mole, assay 97%) in 50 cc. of water was added in small portions, while stirring. After ten minutes, 51 g. (0.63 mole) of anhydrous sodium acetate in 100 cc. of water was added, followed by 33 g. (0.50 mole) of malononitrile[8] in 25 cc. of ethanol. After thirty minutes the phenylazomalononitrile[9] was collected by filtration, washed with cold water and dried in air. The material may be recrystallized from benzene (5 cc. per g.) although the crude material could be used for the following reaction. The yield of recrystallized material was 48–52 g., 55–60%. A three-necked flask was provided with a Hershberg stirrer, a reflux condenser (protected with a drying tube) and two separatory funnels (one on top of the other). Formamidine hydrochloride prepared from 0.11 mole of ammonia was placed in the flask. To this was added 20 g. (0.118 mole) of phenylazomalononitrile in 30 cc. of *n*-butanol (dried by distillation). In the bottom separatory funnel (connected to a drying tube) was placed 2.9 g. (0.13 mole) of sodium. Dry *n*-butanol (100–150 cc.) from the upper funnel was added to the sodium in small portions. The sodium butoxide solution was added to the reaction mixture in several portions, and the mixture refluxed gently for four hours. The mixture was cooled to 5° and the solid collected by filtration. The cake was washed alternately with water and alcohol and dried for a short time at 110°; yield, 15–18 g., 70–80%. This material was used in the next step without further purification, since the compound was difficult to recrystallize. When carefully dried ethanol was used as a solvent for the reaction[2] the yield was frequently as low as 30%.

**4,5,6-Triaminopyrimidine Sulfate (II).**—4,6-Diamino-5-phenylazopyrimidine (4.0 g., 0.0186 mole) was added to a boiling solution of 40 cc. of water and 6 cc. of ethyl cellosolve containing 4 g. of zinc dust. The mixture was boiled for 60–90 seconds while stirring. Sulfuric acid (6 cc. of 18 *N*) was added to the hot solution as rapidly as possible and the mixture decolorized with norite and filtered immediately. A lower yield resulted when the material was left in contact with acid. Upon cooling 2.4–3.4 g. (55–78%) of precipitate was collected. The 4,5,6-triaminopyrimidine sulfate thus obtained was used for the next step. The material could be recrystallized from 2 *N* sulfuric acid (20 cc. per g.) with an 85% recovery.

*Anal.* Calcd. for $C_4H_7N_5 \cdot H_2SO_4 \cdot H_2O$: N, 28.8. Found: N, 28.7.

**4,6-Diamino-5-formylaminopyrimidine.**—4,5,6-Triaminopyrimidine (1.0 g., 0.008 mole) was warmed gently with 2 cc. of 98% formic acid until all the solid had gone into solution. The excess formic acid was removed by evaporation at room temperature and the residue recrystallized from ethanol; yield, 1.15 g., 95%. The distribution constant in *n*-butanol–1 *N* phosphate, *p*H 6.5, for this material was 0.16.[3,10]

*Anal.* Calcd. for $C_5H_6ON_5$: C, 39.09; H, 4.51; N, 45.68. Found: C, 39.21; H, 4.61; N, 45.73.

**4,6-Diamino-5-thioformylaminopyrimidine.**—This compound was prepared according to the procedure of Baddiley, Lythgoe and Todd.[2] The distribution constant was 0.96.[10]

*Anal.* Calcd. for $C_5H_6N_5S$: C, 35.68; H, 3.99; N, 41.49; S, 18.79. Found: C, 35.49; H, 4.17; N, 41.39; S, 18.95.

**Adenine Sulfate (IV).**—(a) 4,5,6-Triaminopyrimidine sulfate (II) (0.78 g.) and 9 cc. of anhydrous formamide containing 0.3 cc. of 98% formic acid was heated in a bomb tube at 160–165° for two and one-half hours. The contents of the tube were chilled and the insoluble portion united with the residue on concentration of the filtrate *in vacuo* at *ca.* 150°. The residues were recrystallized from *ca.* 12 cc. of 2 *N* $H_2SO_4$; yield, 0.62 g. (95%).

(b) 4,5,6-Triaminopyrimidine sulfate (II) (5.0 g., 0.0207 mole) was dissolved in 25 cc. of anhydrous formic acid while warming the mixture gently. The solution was evaporated to dryness by warming gently in a stream of air. The 4,6-diamino-5-formylaminopyrimidine was transferred to a Carius tube and 20 cc. of formamide added. The tube was sealed and heated at 170° for two and one-half hours. The contents of the tube were cooled and the mixture filtered. The filtrate was evaporated to dryness and the two solid residues were recrystallized from 2 *N* sulfuric acid; yield, 3.1–3.5 g. (77–87%). The yield was lowered when the 4,5,6-triaminopyrimidine sulfate was boiled with formic acid or when the heating period in the formamide was greater than two and one-half hours.

*Anal.* Calcd. for $(C_5H_5N_5)_2 \cdot H_2SO_4 \cdot H_2O$: N, 36.3; S, 8.28. Found: N, 36.3; S, 8.50.

Atom per cent. excess $N^{15}$, 4.82. Counter-current distribution revealed that the adenine sulfate was 98–100% homogeneous with respect to ultraviolet absorbing impurities.[10]

**Cyanoacetamide.**[12]—In a 50-cc. flask was placed 590 mg. of sodium cyanide (90%) and approximately 2.7 millicuries of $C^{14}$ in the form of sodium cyanide (147 mg.) containing about 80 mg. of sodium hydroxide. Five cc. of a 3.2 *N* solution of chloroacetic acid (neutralized with sodium carbonate) was added and the mixture was boiled

gently for five minutes. The solution was allowed to cool somewhat and 2 cc. of concentrated hydrochloric acid was added. The mixture was evaporated to dryness *in vacuo* at 60–70°. The solid was extracted twenty times with 5-cc. portions of ether and the ether solution was added gradually to an ethereal solution of diazomethane (prepared from 4.5 g. of nitrosomethylurea). The solution was allowed to evaporate while standing overnight at room temperature. The residual oil was treated with 2 cc. of concentrated ammonia and warmed gently. An additional 2 cc. of ammonia was added and the solution was allowed to remain at room temperature overnight. The reaction mixture was evaporated to dryness *in vacuo* at room temperature and dried over phosphorus pentoxide for forty-eight hours; yield 400 mg., 42% over-all yield, based on the cyanide used.

**Malononitrile.**[8]—The cyanoacetamide was placed in a sublimation apparatus together with 400 mg. of phosphorus pentachloride. The system was evacuated by means of a water pump and the apparatus was immersed in a boiling water-bath. After the reaction had subsided, chloroform (cooled to −5° by means of a chloroform–Dry Ice-bath) was circulated through the cold finger. With the aid of an oil-bath the reaction mixture was heated to 160° and maintained there until the sublimation was complete (ten minutes).

**Phenylazomalononitrile.**—The malononitrile was allowed to melt from the cold finger into a 50-cc. glass-stoppered erlenmeyer and rinsed with a few cc. of methanol. Five cc. of 1 *M* phenyldiazonium acetate solution was added and the flask kept in an ice-bath overnight. The product was collected by filtration, washed with cold water and dried in the air; yield, 200 mg., 20% based on the cyanoacetamide used.

**Adenine Sulfate.**—The phenylazomalononitrile thus prepared was utilized in the preparation of adenine according to the directions described above. The final yield of adenine sulfate was 75[13] mg., which represents an over-all yield of 3.8% based upon the cyanide used. The product possessed an activity of approximately 7000 counts/min./milligram when a film of 1.93 micrograms/cm.$^2$ was prepared by evaporation of an aqueous solution on an aluminum planchet and counted with a thin window (1.9 mg./cm.$^2$) Geiger–Müller counter.

**Acknowledgment.**—The authors wish to acknowledge the advice of Dr. George Bosworth Brown, the coöperation of Dr. Harold Beyer in the isotope determinations, and the assistance of Alice Angelos, Rosco Funk, Jr., and Thelma Kaplan.

## Summary

Various syntheses of adenine have been investigated and a satisfactory procedure for the introduction of isotopes of nitrogen and carbon has been developed.

The preparation from isotopic carbon of cyanoacetamide and malononitrile is described.

(13) Of this amount, 32 mg. was obtained from the filtrate by washout dilution with 450 mg. of non-radioactive adenine.

# The Hydration, Size and Shape of Tobacco Mosaic Virus[2a,2b]

BY H. K. SCHACHMAN[3] AND MAX A. LAUFFER

## Introduction

On the basis of indirect evidence, several investigators have speculated about the degree of hydration of tobacco mosaic virus,[4a,b,c] but there has been no direct experimental attack on this problem. The ultracentrifuge furnishes a possible means for the direct determination of the density of the virus in solution by a study of the effect of varying solvent density on the change of sedimentation rate.[5a,b] The combination of this solution density with the apparent partial specific volume permits an evaluation of the hydration of the virus.

A certain amount of ambiguity arises in a precise evaluation of the size and shape of any molecule because of the difficulty in determining the relative contributions of hydration and anisometry to the physical chemical properties of the material in question. In the case of tobacco mosaic virus, the application of several physical technics, including ultracentrifugation, X-ray diffraction, viscosity, birefringence of flow and diffusion, has led to the evaluations of size and shape which were largely substantiated by direct observation in the electron microscope.[6] These computations, however, were predicated upon the assumption of little or no hydration of the virus particles, an assumption made because X-ray measurements could be interpreted to mean that the particles did not swell when placed in solution.[7]

In view of the apparent success of the centrifugation method of determining the hydration of viruses, it seemed worthwhile to determine the hydration of tobacco mosaic virus and then to re-examine the other physical chemical properties in the light of this result.

## Materials and Methods

Tobacco mosaic virus freshly isolated by differential centrifugation, according to the method of Stanley,[8] was examined in the ultracentrifuge at a concentration of 3.0 mg. per cc. in solvents of varying density. Different concentrations of crystalline bovine serum albumin in *p*H 4.7, 0.2 *M* acetate buffer, were used as solvents. Some of the bovine serum albumin was obtained through the courtesy of Dr. Hans Neurath of Duke University Medical School, and some of it was purchased directly from Armour and Company, Chicago, Illinois. Experiments on two other samples of tobacco mosaic virus, isolated in similar fashion, were conducted at *p*H 7.0 in 0.01 *M* phosphate buffer containing sucrose in varying concentrations. One of these samples, A, was also examined in several concentrations of bovine serum albumin at *p*H 7.0 in 0.01 *M* phosphate buffer. The studies were carried out in an air driven ultracentrifuge of the Bauer–Pickels type, equipped with the Svensson optical system. Specific gravities of the solutions were obtained by the use of a 2-cc. pyknometer, and viscosities were determined in an Ostwald type viscometer.

## Experimental Results

Figure 1 shows the relation of sedimentation rate to the density of the suspending medium for the studies on tobacco mosaic virus suspended in serum albumin solutions of various concentrations.

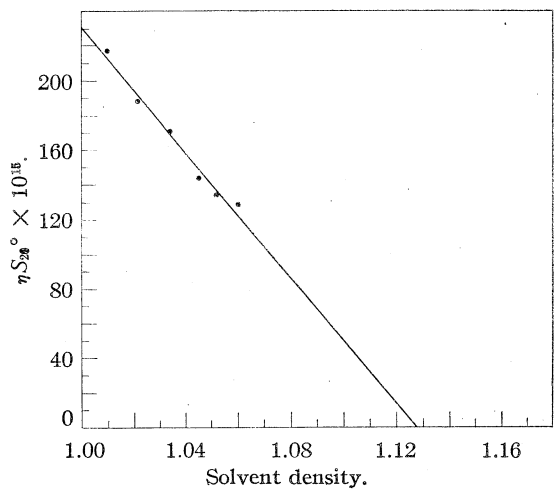

Fig. 1.—Sedimentation constants corrected for solution viscosity of tobacco mosaic virus in serum albumin solutions plotted as a function of solution density. The *p*H was maintained at 4.7 by means of 0.2 *M* acetate buffer. Straight line was fitted by method of least squares.

In Fig. 2 are plotted the results for tobacco mosaic virus in a medium containing sucrose at different concentrations. The ordinate in these graphs is the sedimentation constant corrected for the viscosity to correspond to a value in a solvent with the viscosity of water at 20°. The abscissa is the density of the suspending medium at 20°.

The rate at which particles suspended in a strictly homogeneous medium sediment in a centrifugal field should be directly proportional to the difference between the densities of the particles and of the medium. If the medium causes no alteration in size, shape and density of the particles,

(8) W. M. Stanley, THIS JOURNAL, **64**, 1804 (1942).

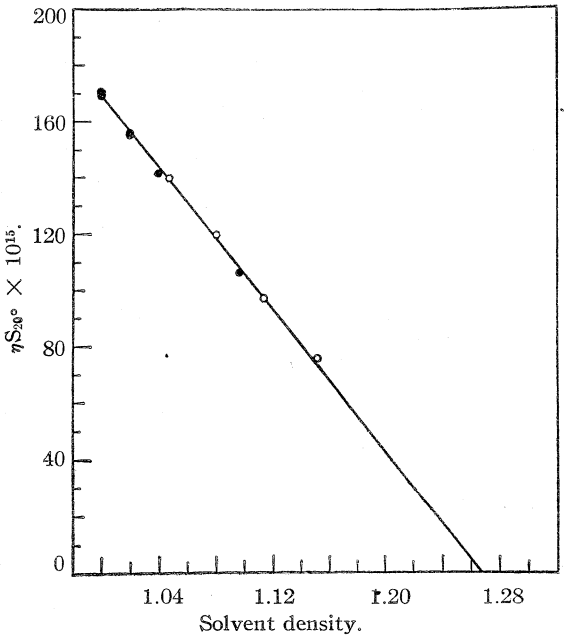

Fig. 2.—Sedimentation constants corrected for solution viscosity of tobacco mosaic virus in sucrose solutions plotted as a function of solution density. The *p*H was maintained at 7.0 with 0.01 *M* phosphate buffer. Straight line was fitted by method of least squares.

then the decrease in sedimentation constant, $S$, multiplied by viscosity, $\eta$, is directly proportional to the increase in density of the solution, $\rho_s$. In general, it can be shown that eqn. 1

$$\eta S = \frac{M(\rho - \rho_s)}{6\pi N \left(\frac{3VM}{4\pi N}\right)^{1/3} \left(\frac{f}{f_0}\right) \rho} \qquad (1)$$

where $M$ is the anhydrous molecular weight of the sedimenting particles, $V$ is the partial specific volume of the material, $\rho$ is the density of the particles, $N$ is the Avogadro number, and $(f/f_0)$ is the friction ratio, which is a function of the anisometry and hydration of the particles, describes the relationship. Equation 1 can be used to evaluate the hydrated molecular weight, if $V$ and $\rho$ are the specific volume and density of the hydrated particles. In this case the friction ratio is only a function of anisometry. If the sedimenting particles are unaltered by the medium, a plot of $\eta S$ *vs.* $\rho_s$ according to eqn. 1 should yield a straight line. The slope of the line is a function of size, shape and the density of the particles, and the intercept at $\eta S = 0$ is dependent only on the density of the particles.

That the curve in Fig. 1 shows this linear dependence of $\eta S$ on $\rho_s$ suggests that the medium has little or no effect on the size, shape, and density of the particles. It cannot be said with complete certainty, however, that the physical characteristics of the virus were not altered by the serum albumin. A complex precipitates at *p*H values between about 4 and 5 when the ionic strength is

considerably lower than in the present experiments. Also the virus is precipitated by serum albumin at *p*H values above 5 when the ionic strength is about 0.1.[9]

Similarly, the linearity of the curve in figure 2 suggests that the medium has not altered the virus. Smadel, Pickels and Shedlovsky[4] obtained a non-linear dependence of sedimentation rate on the density of the medium when they studied the sedimentation of the elementary bodies of vaccinia in sucrose solutions. They suggested as one explanation of their results that the sucrose solutions caused an osmotic withdrawal of water from the particles with a consequent increase in particle density. Studies[10,11] on the influenza viruses showed similar behavior. It was this concept of osmotic influence of the medium on the virus particles that prompted Sharp, *et al.*,[5] to use serum albumin rather than sucrose as a means of obtaining solvents of different densities. Because of the higher molecular weight of serum albumin as compared to sucrose, it was expected that such an osmotic withdrawal of water, if real, would be considerably reduced. The resultant straight lines in plots of $\eta S$ *vs.* $\rho_s$ for the sedimentation of the influenza viruses in serum albumin solutions[5,11] lend support to the suggestion of Smadel, Pickels and Shedlovsky.

Extrapolation of the curve in Fig. 1 yields a value of $\rho_s = 1.13$ g./cc. for the density of solution in which virus particles do not sediment. If no alteration of the virus has occurred, the density of the virus in aqueous solution can be considered as equal to 1.13 g./cc. Similarly, extrapolation of the results presented in Fig. 2 indicates that the density of the virus in aqueous solution is about 1.27 g./cc. Preparation A, which also appeared to have a density of 1.27 g./cc. in solutions containing sucrose, was studied in serum albumin solutions of low ionic strength at *p*H 7.0, and a value about 1.1 was obtained by extrapolation. This result is in reasonable agreement with that obtained at *p*H 4.7 and presented in Fig. 1.

For the case of non-linear dependence of corrected sedimentation constant on density, Smadel, Pickels and Shedlovsky suggested the construction of a tangent to the curve at the point corresponding to the density of dilute buffer. The value of $\rho_s$ at which this tangent intercepts the abscissa can then be taken as the density of the virus particles in a solvent devoid of sucrose.[12] Sharp, *et al.*, demonstrated a discrepancy between the two methods for influenza virus and concluded that the lower value obtained in serum albumin was more reliable.

The data of Fig. 1 show a value of about 230 $S$[14] for the sedimentation constant of tobacco mosaic virus in the absence of serum albumin. In a previous study[6] a value of 185$S$ was found for the sedimentation constant of tobacco mosaic virus in the unaggregated state, and it was shown that boundaries corresponding to higher sedimentation constants could be attributed to dimers and trimers. The high value obtained for the tobacco mosaic virus indicates that the virus particles are in a polymerized state. Inasmuch as the aggregation is predominantly end-to-end, the hydrodynamic density of the polymerized virus probably would not differ from that of the virus in the monomeric state. The data of Fig. 2 indicate that the virus studied at *p*H 7.0 is unaggregated.

If no contraction occurs on the combination of a strictly homogeneous medium and the dry virus, the degree of hydration can be calculated from the partial specific volume of the virus and the density obtained from the sedimentation experiments. Inherent in these calculations is the assumption that the bound water is not unlike the body of water acting as solvent. If a volume, $v$, of anhydrous virus with density $\rho$ becomes associated with a volume $\Delta v$ of water with density $\rho_w$ to form a hydrated particle of density $\rho_s$, the total volume of the hydrated virus particle will be $(v + \Delta v)$ and its mass will be $(v\rho + \Delta v\rho_w)$. The data of sedimentation rate in serum albumin solutions lead to a hydration value of about 1.9 ml. of water per ml. of dry virus or 66% by volume on a wet basis. Similar calculations for the sedimentation in sucrose solutions lead to the value of about 0.37 ml. of water per ml. of dry virus or 27% water by volume on a wet basis.

## Discussion

**The Hydration of Tobacco Mosaic Virus.**—The vastly different hydrodynamic densities obtained in the sucrose and in the serum albumin solutions indicate a marked difference in the apparent hydration of tobacco mosaic virus in the two media. The following considerations, which were proposed in a private communication by Kauzmann,[15] show that this difference can possibly be attributed to a region in the medium surrounding a virus particle which, for purely geo-

(12) In the studies in serum albumin solutions a correction was made for the sedimentation of the serum albumin. This correction was made according to the suggestion of Sharp, Taylor and Beard[13] by subtracting the sedimentation constant of serum albumin from the measured sedimentation constant of the virus before multiplying by the viscosity. This correction seems reasonable at high concentrations of serum albumin where the virus is sedimenting very slowly, but such a correction does not seem valid when the virus is sedimenting in a very dilute serum albumin solution. If the correction were not made, the points at high serum albumin concentrations would no longer fall on a straight line, and a tangent to the curve at the density of the buffer would be necessary. In that case, a result not significantly different from the 1.13 g./cc. obtained in Fig. 1 would still be obtained.

(14) The symbol $S$ represents the Svedberg unit defined as $10^{-13}$ cm. per sec. per cg. unit of centrifugal field.

(15) The authors wish to acknowledge their indebtedness to Dr. W. Kauzmann of Princeton University and to express their appreciation to him for his contributions to this problem.

metrical reasons, cannot be penetrated by serum albumin or sucrose molecules. In other words, the assumption that sucrose and serum albumin solutions are homogeneous media may not be appropriate for the present purpose. In that event, computation based upon the assumption of a homogeneous medium would not be valid.

If serum albumin molecules are considered to be rigid, uncharged spheres of radius $a$, it is clear that the center of a serum albumin molecule will not be able to come closer than a distance $a$ from the surface of a virus particle suspended in a serum albumin solution. This will lead to a region of thickness $2a$ in which the density changes gradually from that of water to that of the serum albumin solution. It can be shown by a statistical procedure that this is equivalent to having each virus particle surrounded by a layer of thickness $a$ of liquid with the density of the medium exclusive of serum albumin. In the case of a virus particle suspended in a sucrose solution, a similar but much thinner equivalent layer of sucrose-free fluid will surround the virus particle. As will be seen in the subsequent more quantitative treatment, this equivalent layer of fluid affects the force operating on a virus particle in a centrifugal field.

If $v$ is defined as the volume of a virus particle, $\Delta v$ as the volume of a shell of thickness $a$ corresponding to the equivalent layer of albumin-free medium as described above, $a$ as the radius of a serum albumin molecule, $\rho$ as the average density of the virus particle including any water of hydration really part of the virus particle, $\rho_s$ as the density of the serum albumin solution, $\rho_w$ as the density of the medium exclusive of serum albumin, $W$ as the mass of a volume $V$ of serum albumin solution, and $W'$ as the mass of the same volume of solution containing a single virus particle, the following considerations apply. The effective force acting on the virus particle in the centrifuge should be proportional to $(W' - W)$, and, when this difference vanishes, the particle should not sediment. For purposes of these considerations, the excess mass of a serum albumin molecule over that of an equal volume of water can be considered to be concentrated at a point in the center of the molecule. Thus, the shell of volume, $\Delta v$, which can contain no centers of serum albumin molecules, must have density $\rho_w$. On the other hand, the density of the solution outside $\Delta v$ is $\rho_s$. Therefore

$$W = V\rho_s \qquad W' = v\rho + \Delta v\rho_w + (V - v - \Delta v)\rho_s$$

The particle will not sediment when $W' - W$ is equal to zero, that is, when the effective weight of the virus particle is $W' - W$ or $v\rho + \Delta v\rho_w - (v + \Delta v)\rho_s$. This equation is identical with that used for the calculation of the hydration per unit volume of dry virus. The apparent hydration in this case, however, is entirely a property of the medium in which the virus is suspended.

Physical studies carried out on serum albumin[16] indicate that the molecule is not spherical but is a rod about 150 Å. long and 38 Å. in diameter.[16] This can be approximated by a cylinder capped by hemispheres, with a diameter, $2a$, of 38 Å. and a total length, $2b$, of 150 Å. Obviously, a virus particle will be surrounded by a layer of medium of thickness, $a$, in which no serum albumin molecule centers can exist and by an additional layer of thickness, $(b - a)$, in which centers of only serum albumin particles oriented in certain ways can be found. It can be shown by a statistical procedure that this amounts to the equivalent of a layer of medium with a thickness of $^1/_2\ (a + b)$ from which serum albumin is excluded entirely. These calculations apply only in those cases in which the radius of curvature of the virus particle is substantially greater than the thickness of the surrounding serum albumin-free medium. Calculations carried out by the method of Schultz[17] show that the thickness of this layer surrounding a cylinder with the diameter of a tobacco mosaic virus particle should still be approximately $^1/_2(a + b)$. Thus, a tobacco mosaic virus particle should be surrounded by the equivalent of a zone of albumin-free medium 47 Å. thick.

Similar effects should also be expected to occur in sucrose solutions. The sucrose molecule is equivalent in size to a sphere of about 4 Å. in radius, but undoubtedly the molecule is somewhat asymmetric, so that perhaps the effective radius is 5 or 6 Å. Thus, in a sucrose solution a tobacco mosaic virus particle should be surrounded by the equivalent of a layer of sucrose-free medium 5 or 6 Å. in thickness because of the inability of sucrose particles to get any closer to the surface.

The apparent water associated with the virus particle in serum albumin solution and in sucrose solution is, of course, a property dependent primarily upon the medium in which the virus finds itself and is not an intrinsic property of the virus particle itself. If there is any intrinsic water of hydration, regardless of the means by which that water is attached to the virus particle, it must be the total water indicated by the sedimentation experiments in sucrose or in serum albumin solution minus that which is to be attributed to the inability of the sucrose or the serum albumin particle centers to approach the virus surface. The apparent hydration of tobacco mosaic virus in serum albumin solution is the equivalent of a layer of water 53 Å. thick surrounding a rod-like particle with an anhydrous diameter of 152 Å. Since a layer approximately 47 Å. thick must be attributed to the inability of the serum albumin molecule centers to touch the surface of a tobacco mosaic virus particle, this leaves only about a 6 Å. shell attributable to the intrinsic hydration of the tobacco mosaic virus particle. Similarly, the results obtained when tobacco mosaic virus was sedimented in a sucrose solution indicate that the virus particle has an apparent hydration equiva-

(16) E. J. Cohn, J. L. Oncley, L. E. Strong and S. Armstrong, Jr., *J. Clin. Invest.*, **23**, 417 (1944).

(17) G. V. Schultz, *Z. Naturforsch.*, **2**, 348 (1947).

lent to a shell 13 Å. thick surrounding the virus rod. However, when the 6 Å. figure corresponding to the probably effective radius of a sucrose molecule is subtracted, a value of only 7 Å. remains as an estimate of the thickness of the layer corresponding to the intrinsic hydration of a tobacco mosaic virus particle. It is apparent that the same order of magnitude is obtained for the intrinsic hydration from the two series of experiments when interpreted in this manner. Thus, the best estimate of the intrinsic hydration of tobacco mosaic virus is about 15% by volume on a wet basis.

X-Ray diffraction measurements have been of value in determining the ultimate virus particle size and the role of associated water. The investigation of tobacco mosaic virus by X-ray scattering has followed two paths. One, the intramolecular structure resulting from large angle scattering and corresponding to small spacings, demonstrated that certain intraparticle spacings were not altered by a change in concentration of the virus from a dry gel to moderately concentrated solutions. Because of the constancy of the internal spacings over a broad concentration region, Bernal and Fankuchen[7] suggested that the particles do not swell appreciably when placed in aqueous solution.

The second problem attacked by Bernal and Fankuchen was a study of the intermolecular pattern as exhibited by small angle scattering. They found that the distance between the particles is inversely proportional to the square root of the concentration by volume. This requires that the particles separate appreciably only in a lateral direction. Despite the large separation distances involved, of the order of 500 Å., there was a regular lattice arrangement in the form of an hexagonal pattern. Thus, the virus particles can exist in solutions and in gels in a regular pattern where the particles are separated by water layers several times the diameter of the particles. The degree of association of the water cannot be determined from X-ray measurements. Centrifuge studies in serum albumin solutions and in sucrose solutions, when interpreted in the manner described above, indicate that the hydrodynamic unit contains an intrinsic hydration equivalent to a shell of water 6 or 7 Å. thick. If one accepts the interpretation of Bernal and Fankuchen of the meaning of the wide angle scattering, most of this water would actually be found in a shell surrounding the virus particle. It is not difficult to conceive of a water layer of such thickness being held to the outside of a virus particle.

**Hydrodynamic Complications.**—The existence of this shell of diluted albumin solution about the sedimenting virus particles causes complications in connection with the viscosity correction to the sedimentation constant. Evidently the virus moves in an environment of somewhat lower viscosity than that of the bulk solution. Therefore it is not correct to multiply the observed sedimentation constant by the over-all relative viscosity of the solution in order to obtain the equivalent sedimentation constant in water. The difference between the over-all viscosity and this effective viscosity is probably considerable, especially in concentrated albumin solutions, but it does not seem to be easy to compute.[18] This consideration contributes an element of uncertainty to the extrapolated value of the solution density corresponding to zero sedimentation rate, and thus casts some doubt upon the reliability of the extent of hydration indicated above.

Finally, the question might be raised whether such a layer of low density will be able to maintain itself as the virus particle moves in the centrifuge. Thus it might seem reasonable to expect that the virus particle would act as a plow in moving through the albumin solution, with albumin molecules piling up in front of the virus and being swept clear at the back. In the centrifuge, a tobacco mosaic virus particle moves at the rate of about $^1/_5 \times 10^{-3}$ cm./sec. Serum albumin has a diffusion constant of about $6 \times 10^{-7}$ sq. cm./sec. This corresponds to a root mean squared displacement of serum albumin molecules, due to kinetic energy, of $\sqrt{12 \times 10^{-7}}$ or $1.1 \times 10^{-3}$ cm. in one second. Thus, in the usual experiment, most of the serum albumin molecules should have time to move out of the path and into the wake of an advancing virus particle.

**The Size and Shape of Tobacco Mosaic Virus.**—The study of macromolecules has invoked such a varied number of physical tools that it has become possible to validate partially certain of them by their combined use on one substance. Tobacco mosaic virus, because of its characteristic shape and large size, serves as an excellent model for study. It was shown that the predictions of the size and shape of the virus particles from viscosity, sedimentation and diffusion data were in substantial agreement with the results obtained from electron microscopy and X-ray diffraction.[6] The generally accepted value, 15.2 mμ, for the diameter of the rod-like particle resulted from small angle scattering of X-rays. Studies in the electron microscope on purified and unpurified tobacco mosaic virus lend support to the concept of a rod-like particle 280 mμ in length by 15.2 mμ in diameter. On the basis of a partial specific volume of 0.73 cc./g., the molecular weight of the anhydrous particle is $41.9 \times 10^6$.

Detailed accounts of the available methods for determining molecular size and shape have been presented elsewhere,[6,19,20] but these are complicated, as mentioned above, by the difficulty in evaluating the relative contributions of hydration and anisometry to the friction ratio. If the value 0.15 ml. of water per ml. of wet virus is used in

(18) J. M. Burgers, *Proc. Acad. Sci., Amsterdam*, **45**, 10 (1942).
(19) M. A. Lauffer and W. M. Stanley, *Chem. Revs.*, **24**, 303 (1939).
(20) J. L. Oncley, *Ann. N. Y. Acad. Sci.*, **41**, 121 (1941).

conjunction with the intrinsic viscosity,[21] ($\eta$), 39 ml./ml.,[6] an axial ratio of 18.3 results for the hydrated particle. This value of the axial ratio can be used in the Perrin equation to yield a friction ratio due to asymmetry of 1.92. Allowing for the fact that a hydrated particle has a frictional resistance greater than that of an anhydrated particle produces a value, 2.01, for the over-all friction ratio. Combination of this ($f/f_0$) value with the sedimentation constant, 185 *S*, leads to $34 \times 10^6$ for the anhydrous molecular weight. This corresponds to a rod about 270 by 14 m$\mu$.[22]

Diffusion and sedimentation data can also be used to predict the size of the anhydrous particles. The calculation of molecular weight by this method is independent of hydration and the value, $31 \times 10^6$, previously reported still obtains. This corresponds to a rod-like particle 250 by 14 m$\mu$ for the case in which 15% by volume of water on a wet basis are associated with the virus.

The size and shape of the particle can be calculated, also, by a combination of viscosity and diffusion data. Results obtained in this manner correspond to a rod-shaped particle 250 by 13 m$\mu$ and a molecular weight of $27 \times 10^6$ when 15% of volume hydration is assumed.

(21) Intrinsic viscosity is defined as the ratio, as the volume fraction approaches zero, of specific viscosity to volume fraction.

(22) This calculation was made on the assumption that hydration increases the thickness but not the length of a virus particle.

## Summary

The hydrodynamic density of tobacco mosaic virus was determined by centrifugation in bovine serum albumin and sucrose solutions of various densities. In both sets of experiments, straight lines could be used to express the dependence of sedimentation rate upon density of the medium. A hydrodynamic density of 1.13 was obtained for the experiments carried out in serum albumin solutions, and a value of 1.27 was obtained for experiments carried out in sucrose solutions. It was shown that this great discrepancy can be attributed to the effect upon the buoyancy of a virus particle produced by a disturbance of the homogeneous distribution of solute molecules in the immediate neighborhood of a virus particle. This effect depends upon the radius of the solute molecule and is therefore greater for serum albumin than for sucrose. When this effect is taken into account, the data can be interpreted to indicate that tobacco mosaic virus has an intrinsic hydration of approximately 15% by volume on a wet basis. The size and shape of the virus particle were calculated by several methods on the basis of this new hydrated model. Excellent agreement was obtained when the calculations from viscosity and sedimentation data were compared with direct measurements obtained by electron microscopy and X-ray diffraction. Calculations involving the diffusion constant gave less satisfactory agreement.

# The Separation of the Antibodies, Isoagglutinins, Prothrombin, Plasminogen and $\beta_1$-Lipoprotein into Subfractions of Human Plasma[1a,b]

BY J. L. ONCLEY, M. MELIN, D. A. RICHERT,[1c] J. W. CAMERON[1d] AND P. M. GROSS, JR.[1e]

The separation of the protein and lipoprotein components of human plasma into a series of fractions by the use of a five-variable system, as well as the principles involved in this fractionation, have been described in a previous paper.[2] The procedure developed depends upon the use of organic precipitants (ethanol in this case), low temperatures (0 to $-8°$), low ionic strengths of electrolytes (below 0.16 mole per liter), and accurate control of the *p*H and protein concentration. In this work the albumins were concentrated in Fraction V, fibrinogen in Fraction I, most of the $\alpha$-globulins in Fraction IV-1 and IV-4. Fraction II + III contained isoagglutinins, prothrombin, plasminogen, certain lipoproteins with properties ascribed to the X-protein of plasma, as well as antibodies.[3]

The aim of this study was to devise methods

(1a) This work was originally supported by grants from the Rockefeller Foundation and from funds of Harvard University. It was aided early in 1941 by grants from the Committee on Medicine of the National Research Council, which included a grant from the American College of Physicians. From August, 1941, to July, 1946, it was carried out under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University. Since then it has been aided by a grant recommended by the Panel on Hematology of the National Institute of Health.

(1b) This paper is Number 73 in the series "Studies on the Plasma Proteins" from the Harvard Medical School, Boston, Massachusetts, on products developed by the Department of Physical Chemistry from blood collected by the American Red Cross, and Number XIX in the series "Preparation and Properties of Serum and Plasma Proteins" from the same laboratory.

(3) The importance of these methods for the concentration of antibodies was pointed out in an earlier paper of this series: E. J. Cohn, J. A. Luetscher, Jr., J. L. Oncley, S. H. Armstrong, Jr., and B. D. Davis, *ibid.*, **62**, 3396 (1940).

for large scale subfractionation of as many constituents of Fraction II + III as possible into useful and stable concentrates which could then be made available for more extensive chemical and clinical work.

## I. Isolation of Lipoproteins

Approximately three-quarters of the lipoproteins of plasma were concentrated in Fraction II + III. Measurements at low ionic strengths (0.005 to 0.02) indicated that both the carotenoid-bearing[4] and cholesterol-bearing proteins in this fraction had a minimum solubility at about *p*H 5.9. Isolated lipoprotein fractions, however, were usually isoionic near *p*H 5.5 (Table I).[5] The lipoprotein of Fraction II + III has the peculiar property of sedimenting in the ultracentrifuge with a rate that was very sensitive to the density of the solution. This behavior is characteristic of the so-called "X-protein" of plasma, first described by McFarlane,[6] and later by Pedersen.[7,8]

Processing of Fraction II + III, as of whole plasma, was made difficult by the presence of this lipoprotein. The total fraction could not be dried, or even frozen and thawed, without some denaturation.[10] Ammonium sulfate fractionation had yielded precipitates which either centrifuged poorly[7] or rose to the surface.[11] Separation of the lipoproteins from Fraction II + III thus became of the utmost importance.

This lipoprotein fraction, bearing the carotenoid pigment, cholesterol and most other lipids found in Fraction II + III, was extracted almost quantitatively from the residue of plasminogen, prothrombin, isoagglutinins and γ-globulins at 0.07 mole fraction (20%)[12] ethanol if the *p*H were about 7.6 and the ionic strength about 0.005. This ionic strength was readily achieved by resuspending Fraction II + III in a volume of this solvent equal to or twice that of the plasma from which it was obtained. The resulting precipitate (Fraction II + IIIW) contained considerable cholesterol if the extraction was carried out below *p*H 7, but almost none if at *p*H 7.6 or above, and could then be frozen and dried with little or no denaturation of the protein. The lipoprotein fraction separated was designated Fraction III-0. The advantages of this procedure, which yielded both a lipoprotein concentrate soluble in aqueous solutions and a lipid-poor precipitate, were so great that it became the first step in our subfractionation of Fraction II + III (globulin methods 8 and 9).

The extracted lipoproteins were precipitated at 0.09 mole fraction ethanol, *p*H 5.6 to 5.9. Because of its very low density, quantitative separation of lipoprotein from the suspension was somewhat difficult,[13] but was more complete in the presence of traces of calcium ion. The resulting lipoprotein precipitate contained a large percentage of β-globulin, and 60 to 70% of the fraction behaved as X-protein in the ultracentrifuge. Analyses revealed about 35% total lipid, about half of which was cholesterol and cholesterol esters. Materials with the properties usually ascribed to "plasmin inhibitor" and "antithrombin" were found in this fraction.[14]

Fraction III-0, like Fraction II + III, could not be dried from the frozen state without denaturation. Most of the lipoprotein was, however, precipitated as euglobulin by resuspension in a large volume of water at an ionic strength below 0.002 and at a *p*H between 5.4 and 5.9. The remaining protein (Fraction II + IIIW) could then be precipitated with ethanol, dried from the frozen state, and reconstituted to give a satisfactory solution.

## II. Isolation of γ-Globulin Antibodies

Many antibody molecules fall into the γ-globulin class when studied by electrophoresis.[15] Proteins of this group have the most alkaline isoelectric points and the smallest electrical charges at neutral *p*H values of any of the major components of plasma. The γ-pseudoglobulins from horse serum[16] have an isoelectric point near *p*H 6.4. Human γ-globulin of this isoelectric point appears to be largely euglobulin,

(4) We are indebted to J. W. Mehl of the Department of Biochemistry, University of Southern California School of Medicine, for these observations, which were carried out at the Harvard Plasma Fractionation Laboratory during the summer of 1944.

(5) Euglobulins isoelectric in this range were reported early by W. B. Hardy (*J. Physiol.*, **33**, 251 (1905)), J. Mellanby (*ibid.*, **33**, 338 (1905)), H. Chick, (*Biochem. J.*, **8**, 261 (1914)), and E. J. Cohn (*J. Gen. Physiol.*, **4**, 697 (1922)), and more recently by A. A. Green (THIS JOURNAL, **60**, 1108 (1938)). The β-globulins as a whole were reported by A. Tiselius (*Biochem. J.*, **31**, 313, 1464 (1937)); (*Trans. Faraday Soc.*, **33**, 524 (1937)) to be isoelectric near *p*H 5.1.

(8) Solutions containing 86% of X-protein in the ultracentrifuge have been obtained in some of the euglobulin lipoprotein fractions, which were found by electrophoresis to consist largely of $\beta_1$-globulin. Further purification in the air-driven preparative ultracentrifuge has given fractions still having the sechmentation behavior of X-protein and containing as much as 97% $\beta_1$-globulin.[9]

[a] Determined by measuring the *p*H of the pseudoglobulin and euglobulin solutions after exhaustive dialysis, and hence representing the isoionic points of these proteins, rather than the isoelectric points. *Cf.* E. J. Cohn and J. T. Edsall, "Proteins, Amino Acids and Peptides as Ions and Dipolar Ions," Reinhold Publishing Corporation, New York, N. Y., 1943, p. 446.

Solubility studies have indicated that although γ-globulin was readily precipitated by 0.09 mole fraction (25%) ethanol at neutral reaction, its solubility at *p*H 5 was considerably higher than that of albumin.[17] Sodium acetate was found to dissolve considerably more γ-globulin than sodium chloride of equal ionic strength, and both electrolytes decreased solubility with increasing ionic strength; results similar to those described for the influence of neutral salts on casein and edestin at reactions acid to their isoelectric points.[18] Great dependence of solubility upon the amount of saturating body in the system, as was earlier described for serum globulin[19,20,21] has also been observed and assumed to demonstrate the molecular heterogeneity of the γ-globulin precipitate.

The lipid-poor, readily dried, antibody-rich Fraction II + IIIW has formed an ideal starting material for the separation of γ-globulin (Fraction II) from other components (Fraction III). The γ-globulins have been extracted from these components at *p*H values of 5.8 and lower, usually 5.2. This was desirable because the γ-globulins are more soluble under these conditions than at reactions nearer neutrality, and the other components less, since they have isoelectric points in this *p*H range (5.9 to 4.8).

At any given *p*H an ethanol concentration was chosen which would permit solution of at least 3 g. of γ-globulin per liter, and in which only traces of contaminating substances were soluble.[22] Because of possible instability of various antibody molecules at acid *p*H, most efforts at isolation were carried out above *p*H 5. Reactions acid to *p*H 4.7 led to appreciably increased solubility of β-globulin, unless the ethanol concentration was greater than mole fraction 0.059 (17%). A *p*H value of about 5.2, 0.015 ionic strength, and an ethanol concentration of 0.059 mole fraction (17%) gave a very satisfactory solubility differential between the γ-globulin and the other components. A *p*H of 5.4, 0.005 ionic strength in 0.024 mole fraction ethanol (7.5%) was also satisfactory for this separation. A total Fraction II was precipitated from the supernatant by increasing the ethanol to 0.09 mole fraction and the *p*H to 7.2.

Attempts were made to separate the γ-globulins in Fraction II into subfractions. Addition of 0.05 mole/l. of sodium chloride to the γ-globulin solution at *p*H 5.2, mole fraction ethanol 0.059 (17%), and ionic strength of 0.015,[23] led to the separation of a fraction designated Fraction II-3. After Fraction II-3 had been removed, the solution was adjusted to *p*H 7.2, holding the ethanol and ionic strength constant. The precipitate formed under these conditions was called Fraction II-1. The γ-globulin remaining in solution precipitated at 0.09 mole fraction (25%) ethanol, and was called Fraction II-2.

Some physical–chemical,[9] chemical[25] and immunological[26] properties of these γ-globulin fractions have already been recorded. Clinical studies have indicated the usefulness of Fractions II-1 and II-2 in prophylaxis against measles and

(17) We are indebted to Mrs. M. H. Blanchard of this Laboratory for these studies.

(22) The γ-globulin fractions obtained by these methods have often been found to contain substances which cause a blood pressure lowering effect upon the blood pressure of certain test animals, especially cats. A number of experiments suggested that the temperature coefficient of solubility of the depressor causing substance was of a larger magnitude than that of the γ-globulin, and made it desirable to use as low a temperature as possible for the separation. L. H. Woodruff, C. A. Janeway and W. Berenberg made the earlier assays of depressor activity. More recently O. Krayer and his associates in the Department of Pharmacology, Harvard Medical School, have investigated these effects. Some studies have also been made by E. Shorr and B. W. Zweifach of the New York Hospital.

(23) The precipitation of γ-globulin under these conditions was predicted from solubility studies,[17] and by work simultaneously carried out at the University of Wisconsin.[24] Fraction II-3 was not extracted from Fraction II + III by the earlier methods, which had been carried out in the presence of the lipoprotein now concentrated in Fraction III-0 and at higher ionic strengths.

epidemic jaundice.[27] Fraction II-3 has been shown effective in measles prophylaxis,[28] but studies in prophylaxis against epidemic jaundice have not yet been completed. Although differences among these γ-globulin fractions were observed in the above-mentioned studies, further fractionation of purified γ-globulin must be undertaken to explore more fully the possibility of separating the γ-globulin antibodies from one another.

## III. Separation of Isoagglutinins, Prothrombin and Plasminogen

Solubility studies of anti-A, anti-B and anti-Rh isoagglutinins indicated a minimum solubility near 6.3, and a strong solvent action of neutral salts in water or in ethanol–water mixtures at that *p*H, and at reactions acid to the isoelectric point[29,30] Under most conditions employed, the solubility of the fractions containing the isoagglutinins was considerably lower than that of other γ-globulins. Quantitative measurements indicate, however, that less than 1% of even the most highly purified fractions were agglutinating antibody.[31]

Highly purified human prothrombin has thus far not been prepared. However, as Mellanby's important observations suggested, it appears to be a euglobulin with a minimum solubility near *p*H 4.8, dissolved by most electrolytes in aqueous solutions when the ionic strength was 0.08 mole per liter or greater.[32,33] Most investigators have reported inactivation of prothrombin at reactions acid to *p*H 4.8 and alkaline to *p*H 10. If it is assumed that human prothrombin has the same activity as the bovine prothrombin highly purified by Seegers and reported to be 1500 u./mg,[33] then fractions with activities of less than 30 u./mg., routinely prepared in the course of this work, contained less than 2% prothrombin.[34] Although there was no need to purify this component further, when it is prepared to yield human thrombin for clinical purposes[35] the fractions containing prothrombin which have been obtained must be considered only as starting material for further chemical investigations.

Plasma, or a fraction of plasma, has been rendered proteolytic by the use of certain reagents[36]; the activated enzyme termed plasmin (fibrinolysin), and the inactive enzyme (or precursor), plasminogen.[37] Under most conditions investigated, plasminogen precipitated with prothrombin. The observation that plasminogen was adsorbed by fibrin made possible its separation from prothrombin.

The separation of the isoagglutinins from prothrombin and plasminogen was made possible by utilizing the different isoelectric points of these materials. At *p*H 5.4 there were large differences in solubility, and the solubilities of the two components to be separated can be adjusted to suitable values by the variation of the ionic strength of an aqueous solution. Since it has been observed that prothrombin was considerably less soluble in sodium acetate buffers[38] than in sodium chloride solution with *p*H adjusted to the same value, and since a specific effect of the acetate ion upon the solubility of the isoagglutinins was not noted, it was found advantageous to use acetate buffers for this step. This separation was effected by completely dissolving Fraction III in a small volume of acetate buffer of about 0.2 ionic strength, and then precipitating the prothrombin and plasminogen (Fraction III-2,3) together with most of the remaining fibrinogen and a part of the other proteins present by diluting this solution

(28) C. A. Janeway, personal communication.

(29) The presence of anti-A and anti-B isoagglutinins in Fraction II + III was noted by W. C. Boyd, and reported in some detail by J. F. Enders, *J. Clin. Invest.*, **23**, 510 (1944), (*cf.* table on p. 515, compiled by W. C. Boyd), and by L. Pillemer, J. L. Oncley, M. Melin, J. Elliott and M. C. Hutchinson, *J. Clin. Invest.*, **23**, 550 (1944).

(30) Studies of the anti-Rh isoagglutinins have been carried out in collaboration with L. K. Diamond, Department of Pediatrics, Children's Hospital, Boston, Mass.

(31) E. A. Kabat, private communication. See also E. A. Kabat and A. E. Bezer, *J. Exptl. Med.*, **82**, 207 (1945).

(32) For a discussion of the earlier literature see J. T. Edsall, R. M. Ferry and S. H. Armstrong, Jr., *J. Clin. Invest.*, **23**, 557 (1944).

(33) A recent survey of the properties of prothrombin has been made by W. H. Seegers, E. C. Loomis and J. M. Vandenbelt, *Proc. Soc. Exptl. Biol. and Med.*, **56**, 70 (1944); and *Arch. Biochem.*, **6**, 85 (1945).

(34) The assay of thrombin and prothrombin was briefly described by Edsall, Ferry and Armstrong.[32] More recently, it has been defined in terms of a standard thrombin reference preparation, whose activity is fixed by definition. This new thrombin unit is identical within the limits of experimental error with the thrombin unit described by Seegers,[33] and has been officially adopted by the National Institute of Health (defined in detail in Minimum Requirements for Dried Thrombin, National Institute of Health, August 28, 1945). See the reports on the determination of prothrombin in "Blood Clotting and Allied Problems," Josiah Macy, Jr., Foundation New York, 1948.

(35) E. A. Bering, Jr., *J. Clin. Invest.*, **23**, 586 (1944); O. T. Bailey and F. D. Ingraham, *ibid.*, **23**, 591 (1944); F. D. Ingraham and O. T. Bailey, *J. Neurosurg.*, **1**, 23 (1944); F. D. Ingraham, O. T. Bailey and F. E. Nulsen, *ibid.*, **1**, 171 (1944); O. T. Bailey, F. D. Ingraham, O. Swenson, J. J. Lowrey and E. A. Bering, Jr., *Surgery*, **18**, 347 (1945).

(36) In Fraction III-3, the separation of which is described below, D. A. Richert found a slow spontaneous activation of plasminogen to plasmin, even in sterile solution, without the addition of chloroform, streptokinase, or any other activator. The final concentration of plasmin obtained in this way was about one-third of the maximum obtainable on complete activation with streptokinase. Chloroform treatment of Fraction III-3 did not give any increase in the rate or in the final amount of activation, as compared with the control sample without added activator. This is perhaps explainable by the fact that the lipids present in Fraction II + III were previously separated in Fraction III-O. The function of the chloroform in whole plasma or crude plasma fractions may well be due to its extraction of fat soluble inhibitors which normally prevent the spontaneous conversion of plasminogen to plasmin. For further discussion of the proteolytic enzyme system of plasma, see J. T. Edsall, "Advances in Protein Chemistry," **3**, 449–51 (1947).

(37) In order to describe the protease system the revised terminology suggested by L. R. Christensen and C. M. MacLeod, *J. Gen. Physiol.*, **28**, 559 (1945), has been followed.

(38) These observations were made by L. Pillemer, D. J. Mulford, J. T. Edsall, S. G. Miller and D. A. Richert.

with water to an ionic strength of about 0.08.[39]

The recovery of isoagglutinin in the supernatant solution from Fraction III-2,3 was accomplished by raising the *p*H to 6.3 (minimum solubility of the isoagglutinins), and adding a small amount of ethanol. The recovery of the isoagglutinins was quite satisfactory, and the precipitate so obtained (Fraction III-1) was dried from the frozen state without deterioration.

Prothrombin and plasminogen were separated by dissolving Fraction III-2,3 in about 0.1 ionic strength sodium chloride and sufficient buffer to bring the *p*H to about 6.9. Under proper conditions a fibrin clot[40] formed and was removed by centrifugation. This clot lysed in a few hours at room temperature, or after standing overnight in the cold room, and contained a large part of the plasminogen.[41]

The supernatant solution from the clot contained most of the prothrombin, which could be reprecipitated by lowering the *p*H and adding a small amount of ethanol, or could be dried from the frozen state. Prothrombin was not stable indefinitely, but could be readily converted to thrombin by suitable agents.[32,42]

## IV. Procedures for the Subfractionation of Fraction II + III[43]

Studies of the subfractionation of Fraction II + III involving isoelectric precipitation at various ionic strengths, but without the use of ethanol, yielded fairly active prothrombin fractions, but failed to yield concentrated antibody-containing fractions which were free of lipid. Various methods involving precipitation with ethanol, with careful control of the *p*H, ionic strength and temperature, were then introduced. Only the last methods have led to the separation of all protein components in conditions approximating the native state. For this reason it has not seemed desirable to describe in detail earlier attempts at complete fractionation. Since they may be useful for specific purposes, however, they have been briefly outlined.[44] Although developed for the fractionation of normal human plasma, they have also been applied with some success to certain types of convalescent human plasma and to the plasma of certain animals. Modifications of these methods may lead to more satisfactory separations of the comparable proteins of different species, because of their somewhat different concentrations and solubilities.

**Method 1** for preparing the total Fraction II + III for immunological studies was introduced in 1942. The precipitated Fraction II + III, removed and stored at a temperature of −5°, contained approximately 35% protein by weight, 0.062 mole fraction (18%) ethanol, and 0.06 ionic strength of salts (largely sodium chloride with some citrate and bicarbonate). This material was suspended in about an equal volume of 0.1 *M* sodium chloride solution previously chilled to 0°, and dialyzed against 0.1 *M* sodium chloride at 0° for two or three days with frequent changes of dialysate to remove the ethanol present in the precipitated material. During dialysis a clot of fibrin usually formed and was removed by filtration and centrifugation. The precipitate was then washed with cold 0.5 *M* sodium chloride solution, recentrifuged, and the supernatant solution was added to the dialyzed material. The resulting protein solution, containing only traces of ethanol, was adjusted to 0.15 *M* sodium chloride, approximately 15% of protein by dry weight. It could be sterilized by filtration through Seitz type filter pads. Thrombin was largely removed during clotting, and prothrombin was removed by the filtration.

**Method 2** made available γ-globulin and thrombin. Fraction II + III was suspended in cold sodium chloride solution, allowed to clot, and clarified. Prothrombin (Fraction III-2) was removed by adjusting to *p*H 4.7–5.3 and an ionic strength of about 0.08. The remaining α- and β-globulin (Fraction III-1) was removed at 0° by adjusting the *p*H to 5.7, the ionic strength to 0.015 or 0.03 and the ethanol concentration to about 0.051 mole fraction (15%). The volume used was about twice that of the original plasma. The γ-globulin (Fraction II) was then precipitated by increasing the ethanol concentration to mole fraction 0.091 (25%), which precipitated Fraction II-2. By then adjusting the *p*H to 7.0, Fraction II-1 was precipitated.

**Method 3** involved suspension of Fraction II + III paste, clotting of fibrinogen, and removal of thrombin by methods similar to those used in Method 2. Fraction III-1 was then removed at more acid *p*H (5.2 to 4.5), lower volume (approximately equal to the volume of original plasma), and ethanol concentrations from 0.04 to 0.07 mole fraction (12 to 20%) (Table II). The total γ-globulin was usually precipitated in one fraction, but in some cases Fractions II-1 and II-2 were removed separately.

**Method 4** involved suspension of Fraction II + III in a volume of water twice that of the original plasma at *p*H 5.9, 0.005 ionic strength, 0°. The resulting euglobulin precipitate represented about half the total protein, and contained considerable γ-globulin. The supernatant solution, precipitated by bringing the ethanol concentration to 0.1 mole fraction (30%), contained large amounts of γ-globulin and lipoprotein.

**Method 5** was developed to make isoagglutinins available in good yield. Suspension, clotting of fibrinogen, and removal of prothrombin were accomplished as in Methods 2 and 3, except that Fraction III-2 was precipitated at a slightly lower ionic strength (0.06). Fraction III-1, containing β-globulin, lipoprotein and isoagglutinin, was precipitated in a volume 1.8 times that of the plasma represented, at *p*H 6.3, 0.015 ionic strength, 0.026 mole fraction (8%) ethanol, 0°. The ethanol was removed by suspending the precipitate in about 20 volumes of water at 0°, *p*H 6.3, and ionic strength less than 0.001. The resulting lipoprotein-rich precipitate could not be dried without denaturation, but the paste could be suspended in 0.15 *M* sodium chloride and adjusted to *p*H 7.2. The γ-globulin was precipitated as in Method 3.

(39) These conditions are very nearly those used in the original Mellanby procedure.[20] A similar procedure, using somewhat lower ionic strengths, was used in the isolation of the C'1 component of complement from guinea pig serum, L. Pillemer, E. E. Ecker, J. L. Oncley and E. J. Cohn, *J. Expll. Med.*, **74**, 297 (1941).

(40) If sufficient thrombin had been formed by converting agents in the plasma, spontaneous clotting occurred. If insufficient thrombin were present, a small amount was added at this point.

(41) The products of the lysis of the fibrin clot have been studied by W. H. Seegers, M. L. Nieft and J. M. Vandenbelt, *Arch. Biochem.*, **7**, 15 (1945), who found two main components called α- and β-fibrin. The α-fibrin, *pI* = 5.5, has an electrophoretic behavior similar to fibrinogen; the β-fibrin, *pI* = 4.2, is somewhat more like α-globulin or albumin.

(42) See L. E. Strong, Encyclopedia of Chemical Technology, Vol. II, p. 571–572. The Interscience Encyclopedia, Inc., New York, N. Y., 1948.

(43) The materials and method used for these subfractionations are completely described in ref. 2.

(44) Detailed procedures for carrying out most of these methods have been published in the Bulletin of the Blood Substitutes Committee, Committee on Medical Research, Office of Scientific Research and Development. They will be made available upon request.

TABLE II

CONDITIONS FOR THE SEPARATION OF FRACTION III-1 FROM γ-GLOBULIN

| Method | pH | Ionic strength, moles/l. | Ethanol concn. Mole fraction | Ethanol concn. Vol. %(25°) | Temperature, °C. | Volume compared to plasma |
|---|---|---|---|---|---|---|
| 2 | 5.7 | 0.015–0.03 | 0.051 | 15 | 0 | 2.0 |
| 3A | 5.1 | .040 | .048 | 14 | −3 | 1.0 |
| 3B[a] | 5.2 | .059 | .040 | 12 | −3 | 1.0 |
| 3C | 5.2 | .036 | .051 | 15 | −5 | 0.9 |
| 3D | 5.2 | .036 | .059 | 17 | −3 | .9 |
| 3E | 5.2 | .036 | .059 | 17 | −5 | .9 |
| 3F | 5.2 | .036 | .059 | 17 | −6 | .9 |
| 3G | 4.8 | .036 | .070 | 20 | −7 | .9 |
| 3H[a] | 4.5 | .036 | .070 | 20 | −7 | .9 |
| 5 | 6.3 | .015 | .026 | 8 | 0 | 1.8 |
| 8 | 5.4 | .005 | .024 | 7.5 | −2 | 0.7 |
| 9 | 5.2 | .015 | .059 | 17 | −6 | 0.7 |

[a] The γ-globulin fraction obtained from these conditions was found to contain considerable β-globulin as impurity.

**Method 6** was used to obtain a satisfactory isoagglutinin fraction when other fractions were not desired. Fraction II + III was suspended and taken to *p*H 6.3, 0.01 ionic strength, 0.024 mole fraction (7.5%) ethanol, 0°, and a volume about 0.6 times that of the original plasma. Isoagglutinins were precipitated along with lipoprotein. The resuspended precipitate was adjusted to *p*H 7.2 in water at 0°, 0.005 ionic strength, and a volume 0.7 times that of plasma. Much of the lipoprotein and γ-globulin were soluble under these conditions, but the isoagglutinins remained in the precipitate. This precipitate was dissolved in 0.1 *M* sodium chloride, and thrombin was added to remove fibrinogen as a fibrin clot.

**Method 7** recovered only the isoagglutinin fraction. Fraction II + III was suspended at 0° or 25° in a volume of water eight times that of the plasma, *p*H 6.3, and an ionic strength of 0.005. The water was saturated with toluene. The isoagglutinin fraction settled in about twenty-four hours. Resuspension under the same conditions was sometimes desirable. Fibrinogen and most of the γ-globulin and lipoprotein were removed by this procedure.

**Method 8** was similar to method 9, except that Fraction III was removed at *p*H 5.4, 0.005 ionic strength, 0.024 mole fraction (7.5%) ethanol, −2°, and a volume 0.7 times the volume of plasma represented.

**Method 9** evolved from the combination of method 8 with the modification of method 3 to a lower ionic strength developed at the University of Wisconsin[24] for the separation of Fraction III from γ-globulin. This method is given in detail in the remainder of this section.

**Precipitate II + III** from standard preparations of normal serum albumin (human) is used as the starting material for this preparation.[45] Each kilogram of this precipitate is suspended in 2 kg. of water containing ice (about one-quarter of the water should be frozen, in the form of very fine ice crystals). When the suspension is fairly uniform, add 3 kg. of water (cooled to 0°) to which 112 cc. of 0.5 *M* disodium phosphate (*p*H 9.2) has been added.[46] The suspension should be stirred slowly and kept at a temperature of 0° until all lumps are dissolved and a nearly complete solution is obtained. After the suspension is complete, add it to 20 kg. of water (cooled to 0°), and stir slowly at 0° for thirty to sixty minutes. The *p*H of this suspension[47] should be 7.6 ± 0.2. Then bring to 20% ethanol by adding 15 liters of 53.3% ethanol keeping the temperature as low as possible until −5° is reached. This suspension should stand at −5° with a slow stirring for several hours before centrifuging. Centrifuge at a rate of about 30 liters per hour.

**Precipitate III-O** is precipitated from the supernatant from precipitate II + IIIW by bringing the *p*H to about 5.7, with *p*H 4 calcium acetate buffer,[48] and the ethanol concentration to 25%. This suspension should be allowed to stand for about forty-eight hours at −5° before centrifugation, and then centrifuged at a rate of about 20 liters per hour. The supernatant solution still contains appreciable protein, a large part of which is precipitated by adjusting the *p*H to 4.8, and the ethanol concentration to 35%.

**Precipitate II + IIIW** is resuspended in acetate buffer[49] and taken to *p*H 5.2, 0.015 ionic strength and 17% ethanol. This can be done by suspending each kilogram of precipitate II + IIIW in 2 kilograms of water and ice, as before, and then adding 2 kg. of cold water to which 0.35 mole of sodium acetate has been added. When this suspension is complete, add sufficient *p*H 4 acetate buffer,[51] diluted with one liter of cold water per kilogram of precipitate II + IIIW, to lower the *p*H of the suspension to 5.0 ± 0.1 and stir for several hours. Then add 13.5 liters of cold water and then 8.66 liters of 53.3% ethanol per kilogram of precipitate II + IIIW, raising the ethanol concentration to 17%. The temperature should be lowered during the addition of the ethanol, keeping the suspension near the freezing point until it is cooled to −6°. The precipitate is re-

(45) This method can also be applied to precipitate II + III or I + II + III from special lots of plasma or serum, such as convalescent serum or plasma, or to various similar fractions obtained by these methods. Occasionally, where materials have been stored in the frozen or dry state, the original suspension will yield a considerable quantity of insoluble material consisting of denatured protein and lipid. In these cases, material can be centrifuged and clarified with filtration through Seitz-type pads in a solution of 1 or 2 per cent. protein and 0.15 *M* sodium chloride at *p*H about 7. The clarified solution can then be taken to −5°, *p*H 6.8, 25% ethanol, ionic strength 0.1 just as plasma would be treated (but omitting the removal of Fraction I), and the precipitate corresponding to the usual Fraction II + III can then be used in this preparation.

(46) A sodium glycinate buffer solution was also used for this *p*H adjustment. See ref. 53.

(47) Because of the low ionic strength of this suspension, the *p*H value obtained depends considerably upon the method of reading in the glass electrode. We have used the value obtained by dilution of the suspension just before the alcohol addition with an equal volume of 0.02 *M* sodium chloride solution. Dilution with an equal volume of 0.15 *M* sodium chloride solution will give a *p*H nearer 7.2

(48) The *p*H 4 calcium acetate buffer is that used in the fractionation of plasma except that the sodium acetate is replaced by calcium acetate. It consists of 4.0 *M* acetic acid and 0.4 *M* calcium acetate, and is diluted before use.

(49) When we are dealing with plasma collected so that it contains a high titer of the various anti-Rh isoagglutinins[50] it is often advantageous to process the Fraction II + IIIW by a modification of Method 7. The procedure which has been used follows:

Precipitate II + IIIW is resuspended in water and taken to *p*H 6.3, 0.005 ionic strength, using acetate buffer. This can be done by suspending each kilogram of precipitate II + IIIW in two liters of cold water and ice. When this suspension is complete, pour it with good stirring into 90 liters of 0.005 ionic strength *p*H 6.3 acetate buffer per liter of starting II + IIIW paste. This resulting suspension may be held at either 0° or 25°. It is usually carried out at 0°, but where there is a large amount of fibrinogen present in the precipitate II + IIIW the 25° extraction procedure is advantageous. When the extraction is carried out at room temperature, the buffer is saturated with toluene as a bacteriostatic agent (approximately 0.5 cc. per liter). The dilute suspension is then stirred for about an hour, and then allowed to settle overnight. The precipitate is suspended in a small amount of *p*H 6.3 buffer of 0.005 ionic strength (sodium acetate), frozen and dried in vacuum.

This method can also be applied to precipitate III as obtained from method 9 for the subfractionation of Fraction II + III.

The use of this material as a reagent for blood typing has been discussed in an earlier paper.[50]

(50) J. L. Oncley, M. Melin, J. W. Cameron, D. A. Richert and L. K. Diamond, *Ann. N. Y. Acad. Sci.*, **47**, 899 (1946).

(51) The *p*H 4.0 sodium acetate buffer is that used in the fractionation of plasma.[3] It consists of 4.0 *M* acetic acid and 0.8 *M* sodium acetate.

moved by centrifugation at a rate of about 30 liters per hour and at a temperature of −6.0 ± 0.5°. The effluent from this centrifugation should then be clarified by filtration[52] at a temperature of −6.0 ± 0.5°.

Each kilogram of precipitate III is suspended in 2 kg. of water and ice, and then diluted with 2 kg. of 0.5 ionic strength *p*H 5.4 acetate buffer cooled to 0°. The suspension is stirred until uniform, and then diluted with 7.5 kg. of 0° water. This suspension should be at *p*H 5.4, ionic strength 0.08, and 0 to +1°, and should be stirred for several hours. The precipitate is removed by centrifugation at a relatively slow rate of speed and at 0 to +1°.

**Precipitate III-2,3** should be suspended as soon as possible in 1 liter of 0° water per kilogram of precipitate and the *p*H adjusted to 6.8 to 7.0 with sodium glycinate buffer.[53] Then add 1 liter of 0° water containing enough sodium chloride to give a total ionic strength of 0.1. After one to two hours of stirring, test the solution for preformed thrombin and remove a sample to see if the fibrinogen has clotted. To do this, centrifuge a small sample and then add thrombin to the supernatant solution to see whether more fibrin is formed. If all the fibrinogen has clotted, do not add additional thrombin. If there is fibrinogen still left in solution, then add enough thrombin to give a total amount (including that already present) of 10,000 units per kilogram of Fraction III-2,3. Stir this suspension for an additional hour and centrifuge at 0° for about an hour, or at a very slow rate if continuous centrifugation is required. The supernatant containing Fraction III-2 can either be dried directly if prothrombin is desired, or immediately converted to thrombin before drying. To accomplish the conversion of prothrombin to thrombin, calcium chloride and thromboplastin are added, according to the directions given elsewhere,[42] and the temperature is raised to 20–25°. This solution is then clarified, sterilized and dried.

**Precipitate III-3** should be suspended[54] in sodium chloride and bicarbonate solution to give an ionic strength of 0.15 and a *p*H of 7.1 ± 0.1, and allowed to stand at 0° until all of the fibrin has been lysed. After clarification and sterilization, this material can be dried from the frozen state.

Each kilogram of the supernatant from precipitate III-2 is adjusted to *p*H 6.3 by the addition of sodium bicarbonate (approximately 20 cc. of 1 *M* sodium bicarbonate should be required), and then the ethanol is adjusted to 15% by the addition of an equal volume of 30% ethanol, keeping the temperature at or near the freezing point until lowered to −5°, where it should be maintained. The precipitate can then be removed by centrifugation at −5°, and at a speed of about 80 liters per hour.

**Precipitate III-1** can be dried from the frozen state, and reconstituted to about 5% protein in isotonic saline at *p*H 7 for a blood grouping solution if the pool were group specific and of sufficiently high titer.[50,55]

Each kilogram of filtrate from precipitate III is taken to about 0.06 ionic strength by the addition of 50 millimoles of sodium chloride, holding the *p*H at 5.2, the ethanol concentration at 17%, and the temperature at −6°.

**Precipitate II-3** can be removed by centrifugation of the above suspension at a rate of about 50 liters per hour and at a temperature of −5°. It may be dried from the frozen state[56] preferably without the addition of sodium chloride or glycine.

Each kilogram of filtrate from precipitate II-3 is taken to *p*H 7.4 ± 0.2 by addition of about 15 millimoles of sodium bicarbonate, and to 20–25% ethanol by the addition of 40–114 cc. of 95% ethanol. The temperature is maintained at −5°.

**Precipitate II-1,2**[57] can be removed by centrifugation of the above suspension at a rate of about 50 liters per hour, and at a temperature of −5°. It may be dried from the frozen state preferably without the addition of sodium chloride or glycine.

**Precipitate II.**—A total Fraction II, rather than the Fractions II-1,2 and II-3, can be prepared from the filtered effluent from precipitate III by increasing the *p*H to 7.4 ± 0.2 with sodium bicarbonate solution, and the ethanol concentration to 25% with 95% ethanol. The temperature should be maintained at −5°. The precipitate may be removed by centrifugation at the same rate as recommended for Fractions II-1,2 and II-3.

## V. Distribution of Proteins in the II + III Subfractions

Analyses of the various steps in the fractionation procedure have been carried out by the same methods already reported in a previous study of this series (2). The results obtained during the fractionation of a large lot of Fraction II + III prepared by method 6 for the fractionation of citrated plasma (2) are recorded in Table III. Nitrogen determinations and volume measurements were made on all suspensions and supernatant solutions obtained during subfractionation, and of all resuspended precipitates. Values for the protein in the precipitates are calculated from the analyses of the resuspended precipitates, and the protein lost in centrifugation or filtration, and the protein remaining in the supernatant solutions at the end of the process were calculated from the analyses of the suspensions or supernatant solutions. These results are tabulated as the percentage of total protein nitrogen in the fraction referred to the protein nitrogen in the Fraction II + III used for subfractionation. To convert these values to the amount of protein by nitrogen (N × 6.25) which would have been obtained from a liter of plasma, we have used the value of 15.1 g. of Fraction II + III per liter of plasma previously reported.[58] The nitrogen factors estimated from nitrogen and dry weight determinations of each resuspended precipitate are also recorded in Table IV. Using these nitrogen factors, instead of 6.25 as used in Table III, we obtain the values recorded in the last column of Table

(52) We have used Seitz S-1 pads and 0.5% 505 filter aid and sometimes K-5 pads and 1% Hyflow filter aid for this filtration. The filter pad should be washed with 0.30 *M* sodium chloride and then with 0.01 *M* acetic acid, and finally with 0.05 ionic strength *p*H 5.2 acetate buffer in 17% ethanol. The *p*H of the final washings should be checked to see that it is 5.2 after filtration (this can be easily done with a spot-plate and suitable indicator solution). This washing procedure is essential because the low ionic strength of the solution and changes in *p*H at this point can substantially lower the recovery of γ-globulin.

(53) Sodium glycinate buffer is prepared by half-neutralizing a glycine solution with sodium hydroxide. The solution we have used contains 1 mole of glycine and 0.5 mole sodium hydroxide per liter. It has a *p*H of about 9.5 and has the advantage of causing less of a drift in *p*H upon aeration than is observed when sodium bicarbonate is used to increase the alkalinity.

(54) The suspension of this material is conveniently carried out using a Waring blendor to break up the fibrin clot.

(55) M. Melin, *J. Clin. Invest.*, **24**, 662 (1945).

(56) We have found it helpful to suspend precipitate II-3 and II-1,2 in 1.5 volumes of water–ice mixture (1.3 of water frozen). If this mixture is kept cold during the suspension, most of the globulin remains undissolved, and does not "lump up" upon freezing.

(57) Fraction II-1,2 represents the more soluble part of the γ-globulin and is taken off at conditions used for preparation of Fraction II by earlier methods. Such material has been used clinically in both measles and epidemic jaundice. This fraction should be dissolved to make solutions containing 16.5 g. of γ-globulin per 100 cc. and sterilized by Seitz filtration.

(58) See Ref. 2, Table VII.

TABLE III

DISTRIBUTION OF PROTEINS IN SUBFRACTIONS OF FRACTION II + III

| Experiment | Per cent. of total protein nitrogen in fraction 1 | 2 | 3 | 4 | Mean | G. N × 6.25 per liter of plasma |
|---|---|---|---|---|---|---|

V(b) for the grams of protein per liter of plasma recovered in fractions.

We have recorded the electrophoretic analyses of the various II + III sub-fractions in Table V(a). In some cases the separations between these components is incomplete, especially in the case of the $\beta_1$-globulin and the $\beta_2$-globulin + fibrinogen components. The protein distributions in Tables V(b) and V(c) have been corrected for the nitrogen factor, but not for the refractive index increment of the components. Recent papers in this series[59] have indicated that these refractive index corrections would be small, and they can properly be neglected at this time. The unusually high mobilities assigned to the $\beta_1$ component in the lipid-rich fractions has also been discussed.[59]

TABLE IV

ESTIMATES OF NITROGEN AND CHOLESTEROL IN SUBFRACTIONS OF FRACTION II + III OF HUMAN PLASMA

| Fraction | Grams protein/gram nitrogen (1) | (2) | (3) | (4) | Mean | Wt. per cent. Nitrogen | Cholesterol |
|---|---|---|---|---|---|---|---|
| II + III | 7.9 | 7.8 | 7.8 | 7.8 | 7.8 | 12.8 | 6.0 |

[a] Including β-fibrin.[61] [b] Including α-fibrin.[61]

In order to estimate the composition of plasma from these data, we have also calculated the amounts of each of these subfractions present in a liter of plasma (Table V(c)), using the data in Table III to estimate the losses. Although the lost material probably does not have the same electrophoretic composition as the isolated subfractions, we have calculated the distribution of proteins using this assumption, and the total found in the corrected subfractions is near to that observed for the Fraction II + III.

The distribution of the lipoprotein components has been followed by cholesterol determinations in most of these fractions, as recorded in Table IV. These values, when combined with the yield of the fractions from Table V(c), indicate that about 85% of the cholesterol of II + III, or about two-thirds of the cholesterol of plasma, is concentrated into Fraction III-0. The purified $\gamma$-globulin fractions (II-1,2 and II-3) contain less than one-fourth molecule of cholesterol per molecule of $\gamma$-globulin.

## VII. Distribution of Antibodies and Physiologically Active Components

Studies of the antibody content of the various fractions have been reported by Enders.[26] More extensive studies are now available.[60] Nearly all antibodies which have been studied are found concentrated into Fractions II-1,2, II-3 or III-1, and Fractions I, III-0, III-2, III-3, IV-1, IV-4 and V are found to contain only traces of antibody. Table VI gives the results obtained on two preparations which were carefully studied. The results are first compared with a reference solution containing the same concentration of protein Table VI (a) and (b), and then with the plasma (or Fraction II + III for preparation S362) from which it was fractionated. The totals recorded in Table VI (c) and (d) represent the amount of antibody accounted for in the various fractions. Deviations from 100% represent destruction of activity, loss into other fractions, and the collected errors of these tests. The latter cause probably is the most significant. Errors in antibody assay are most serious when the activity is low, such as is found in plasma, and Fractions III-0, III-2 and III-3.

Table VII summarizes a much larger number of tests made on Fractions II-1,2, II-3 and III-1. The antibody content of the fraction, compared

TABLE VII

AVERAGE ANTIBODY CONTENT OF FRACTIONS II-1,2, II-3 AND III-1

Comparison with equal weights of plasma protein[a]

| | II-1,2 | II-3 | III-1 |

| Diphtheria antitoxin | 10 | 7 | 4 |
| Streptococcal antitoxin | 9 | 9 | .. |

[a] Antibody concentration of solutions of Fractions II-1,2 or II-3 containing 165 mg. protein/ml., compared with plasma, will be 2.5 times these values. Values for Fraction II-1,2 compared with plasma from Enders[6] and additional data obtained more recently (about 30 preparations). Values for Fraction II-3 were obtained largely by comparison of Fraction II-3 with II-1,2 (about 13 preparations). Values for Fraction III-1 compared with plasma or Fraction II-1,2 and II-3 obtained in about 4 preparations.

(60) We wish to thank Professor John F. Enders and his group in the Department of Bacteriology and Immunology at the Harvard Medical School—Miss Julia C. Sullivan, Miss Bettie Griffith, and Miss Jeanne E. Beauchamp—for making most of these studies. Studies of anti-A, anti-B, anti-Rh$_0$, anti-Rh', and anti-Rh'' isoagglutinins were made by Dr. L. K. Diamond, Children's Hospital, Boston, Dr. W. C. Boyd, Boston University School of Medicine, Boston, and some of us (M. Melin, J. W. Cameron, and D. A. Richert). The distribution of the following antibodies has been studied: (a) On most preparations: agglutinins against typhoid O antigen; agglutinins against typhoid H antigen; antibody causing inhibition of the hemagglutinin of influenza A virus, strain PR8; mouse protection (neutralizing) antibody against influenza A virus, strain PR8; diphtheria antitoxin (interdermal neutralization test on rabbits). (b) On many preparations: complement-fixing antibody against the virus of mumps; complement-fixing antibody against influenza A virus, strain PR8; (c) on selected preparations: agglutinins against H pertussis, phase 1, strain 484, Philadelphia; streptococcal antitoxin (interdermal neutralization test on rabbits); antibody against streptococcal hemolysin; isoagglutinins against cells of human blood groups A and B; isoagglutinins against cells of human blood groups Rh$_0$, Rh' and Rh''.

with the content of the same weight of plasma protein has been recorded.

TABLE VIII

ASSAY FOR PROTHROMBIN AND PLASMINOGEN ACTIVITY

Values are in units/cc. plasma

| Run | Plasma | (II + III) | II + III Susp. | II + IIIW | III | III-2 | III-3 |
|---|---|---|---|---|---|---|---|
| | | | Prothombin | | | | |
| 171 | 82 | 63 | 75 | 70 | 46 | .. | .. |
| 173 | 100 | 54 | 91 | 60 | .. | .. | .. |
| 175 | ... | 95 | 89 | 50 | 41 | .. | .. |
| 176 | 58 | 83 | 86 | 60 | 37 | .. | .. |
| 177 | 72 | 61 | 38 | 17 | .. | .. | .. |
| 178–179 | 88 | 58 | 18 | 190 | 35 | .. | .. |
| 180–181 | 56 | 68 | 32 | 55 | 37 | 34 | .. |
| 182–183–184 | 68 | 73 | 24 | 18 | 27 | .. | .. |
| 185–186 | 63 | 78 | 53 | 31 | 21 | .. | .. |
| S362-1,2 | ... | .. | 62 | 73 | 81 | 78 | .. |
| | | | Plasminogen | | | | |
| S-362-1,2 | ... | .. | 32 | 27 | 30 | (21) | 14 |

Typical assays for prothrombin and plasminogen activity are recorded for the various fractions in Table VIII.[61] Assays for both of these substances are somewhat uncertain, probably due largely to the presence of inhibitors which make it difficult to completely convert prothrombin to thrombin and plasminogen to plasmin without decomposition. Little or no prothrombin and plasminogen is found in any fraction other than III-2 and III-3.

(61) These studies have been made by Miss S. G. Miller and one of us (D. A. Richert), under the supervision of Professor J. T. Edsall. The methods used are recorded elsewhere.[34,36]

## Summary

1. The properties of various protein components of Fraction II + III of normal human plasma are reviewed.

2. Methods are outlined for the separation of Fraction II + III into a series of subfractions by low-temperature ethanol precipitation, in which careful control of the *p*H, temperature, and concentration of ethanol, salt and protein have been achieved. The subfractions so obtained have led to satisfactory separation and concentration of the following components: γ-globulin antibodies in Fraction II, isoagglutinins in Fraction III-1, prothrombin in Fraction III-2, plasminogen in Fraction III-3 and $\beta_1$-lipoprotein in Fraction III-0.

3. Studies of the distribution of components into these subfractions are tabulated. They have involved measurements of protein nitrogen, dry weight of protein, cholesterol, prothrombin activity, plasminogen activity and various antibody activities.

# Filter Paper Chromatography

BY HENRY B. BULL, J. WILFRID HAHN AND VICTOR H. BAPTIST

Consden, Gordon and Martin[1] reported a very ingenious method for the separation of amino acids by filter paper chromatography in which phenol or some other appropriate organic solvent sweeps the applied amino acids along the filter paper, capillarity causing the organic solvent to move. The positions of the amino acids are located by spraying the filter paper with a solution of ninhydrin and heating the filter paper strips. The amino acids develop colors, the intensity and tint of which depend upon a number of factors. A review of filter paper chromatography has recently appeared.[2]

The present paper reports an attempt to make filter paper chromatography of amino acids quantitative. The percentage light intermission along the chromatogram is measured and this transmission has been plotted on semi-log graph paper against the distance along the filter paper strips, and the areas of the segments above the plotted curve measured with a planimeter. It has been found that the areas so determined are over a limited concentration range a simple function of the concentration of the amino acids. The various factors which influence the reliability of this method are reported.

## Experimental

Carl Schleicher and Schuell quantitative filter paper number 507 was cut against the machine direction into strips 7.20 mm. wide and 60 cm. long. One end of the filter paper strip was placed in the bottom of an oblong butter dish and a thick glass strip placed on top of the paper to hold it in position. It was found convenient to use 5 such strips hanging at about 2 cm. intervals over each side of the butter dish. The lower ends of the filter paper strips were attached to small metal clamps affixed to a metal rod. 0.0135 cc. of the amino acid solution adjusted to a *p*H 5 to 7 was placed on a marked spot on the filter paper strip with a Blodgett pipet about 4 cm. from the edge of the butter dish. The filter strips were in a horizontal position during this operation. The amino acid solutions were air dried on the filter paper and the butter dish, with the filter paper strips hanging vertically, was placed on a stage in a tall glass jar. The jar had a layer of 80% aqueous solution of Merck reagent grade of phenol on the bottom. Eighty per cent. aqueous solution of phenol was poured into the butter dish to cover the ends of the filter paper strips. A second glass jar was inverted over this jar and the joint between the jars sealed with vaseline.

After about forty-eight hours, the phenol solution had nearly reached the ends of the filter paper strips. The strips were removed and the flow distance of the phenol marked with a pencil. The strips were allowed to air dry until they were no longer "wet" with phenol. They were then placed in an oven provided with a circulating fan for two minutes at 90°. The filter paper strips were removed and stretched in a horizontal position and sprayed with a solution containing 0.40 g. of ninhydrin, 10 g. of phenol and 90 g. of *n*-butyl alcohol. After the "wet" appearance of the strips had disappeared, they were sprayed on the reverse side and allowed to dry until the "wet" appearance had disappeared. The strips were then placed in an oven at 90° for ten minutes. They were then placed over an enclosed steam-bath for five minutes. The color had now reached its maximum.

The filter paper strips were mounted on a glass slide 4 cm. wide, 0.5 cm. thick and 70 cm. long blacked out except for a groove 7.2 mm. wide in which the filter paper strip was placed and fastened at both ends with Scotch tape. The glass strip was then passed between an illuminated slit 6 mm. high and 5 mm. wide and the phototube. An electronic photometer model 512 and photometer tube "D" of the Photovolt Corporation of New York was used in this work. The Photovolt Corporation has since generously placed at our disposal a densitometer specially constructed for this type of measurement, the details of which can be obtained from this Corporation.

The percentage light transmission was read every 5 mm. along the filter paper; thus the entire filter paper strip was scanned except for 0.6 mm. along each edge. A light filter whose maximum transmission was at 570 mμ was placed in front of the slit.

The light transmission through the filter paper was then expressed in per cent. of the light transmitted through a "blank" filter paper strip which had been carried through the entire procedure except that no amino acid had been applied to it. The per cent. transmission was then plotted on semi-log graph paper against the distance along the filter paper strips. The areas above the plotted curve and 100% transmission were measured with a planimeter and this area multiplied by the standard color-area of the particular amino acid to obtain the concentration of the amino acid. The amino acid was identified by its $R_F$ value as defined by Consden, *et al.*[1]. In case there remained doubt as to the identity of a color band on the chromatogram, known amino acids were added to the amino acid mixture and the position of the increase in areas of the light transmission against distance plot noted.

## Discussion

The various factors which influence the success of this method and which have been investigated by us are as follows:

**Filter Paper.**—About 15 brands of filter paper were studied. The suitability of these filter papers varied widely. As a result of this investigation we concluded that the ideal paper must be dense so that the rate of flow of phenol would be slow, otherwise the resolution of the amino acids on the strip will not be sharp. Further, the filter paper must be uniform with a good light transmission. And lastly, the filter paper must be free of impurities which give rise to extraneous colors. The filter paper which was found to fulfill these conditions best is the Carl Schleicher and Schuell quantitative filter paper number 507 cut against the machine direction.

**Resolving Solvent.**—We have confined our studies entirely to freshly made aqueous phenol solutions using Merck reagent grade. In the beginning part of this research, we employed phenol saturated with water in the butter dish and water saturated with phenol in the bottom jar. This arrangement was abandoned for several reasons but principally because the $R_F$ values of the amino acids were too erratic, and the system was much too sensitive to minor temperature changes. As noted in the experimental part of this paper, 80% aqueous phenol, both in the butter dish and in the bottom of the jar, seemed to yield the best results.

Various phenol concentrations were investigated, using identical concentrations in the butter dish as well as in the bottom of the jar. The $R_F$ values of the various amino acids are shown in Table I as a function of the phenol concentration, the *p*H of the applied amino acid solutions being 5.0.

TABLE I

$R_F$ VALUES AS A FUNCTION OF THE PHENOL CONCENTRATION EXPRESSED IN GRAMS OF PHENOL PER 100 G. OF AQUEOUS SOLUTION

| Amino acid | Phenol concentration 60 | 65 | 70 | 75 | 80 | 85 |
|---|---|---|---|---|---|---|
| Serine | 0.73 | 0.33 | 0.34 | 0.31 | 0.30 | 0.32 |
| Glycine | .73 | .38 | .40 | .35 | .36 | .38 |
| Methionine | .92 | .73 | .74 | .70 | .70 | .72 |
| Phenylalanine | .92 | .80 | .80 | .75 | .76 | .78 |
| Lysine | .63 | .37 | .30 | .25 | .23 | .19 |
| Arginine | .63 | .45 | .41 | .35 | .33 | .28 |
| Alanine | .74 | .53 | .53 | .53 | .52 | .52 |
| Leucine | .94 | .77 | .78 | .75 | .74 | .73 |
| Glutamic | .63 | .36 | .35 | .31 | .32 | .23 |
| Theonine | .70 | .48 | .47 | .44 | .44 | .38 |
| Aspartic | .63 | .18 | .18 | .13 | .14 | .077 |
| Valine | .88 | .72 | .70 | .69 | .69 | .67 |

The amino acids most sensitive to changes in phenol concentration are aspartic, glutamic, lysine and arginine. Indeed, these are the amino acids whose $R_F$ values are the most variable under all conditions.

*p*H.—The *p*H of the amino acid solutions was adjusted with the addition of sodium hydroxide or with hydrochloric acid, and the $R_F$ values determined using 80% aqueous phenol. These results are shown in Table II.

TABLE II

$R_F$ VALUES AS A FUNCTION OF THE *p*H OF THE AMINO ACID SOLUTIONS APPLIED TO THE FILTER STRIPS

| Amino acid | $R_F$ values at *p*H 3.30 | 5.00 | 8.60 |
|---|---|---|---|
| Aspartic | 0.17 | 0.14 | 0.15 |
| Lysine | .28 | .23 | .32 |
| Serine | .35 | .30 | .33 |
| Glutamic | .33 | .32 | .30 |
| Arginine | .37 | .33 | .40 |
| Glycine | .40 | .36 | .38 |
| Threonine | .47 | .44 | .48 |
| Alanine | .55 | .52 | .55 |
| Valine | .70 | .69 | .72 |
| Methionine | .74 | .70 | .70 |
| Leucine | .76 | .74 | .75 |
| Phenylalanine | .78 | .76 | .74 |

As will be noted from Table II, the $R_F$ values of the amino acids are largely independent of the *p*H of the amino acid solutions. The color developed was also independent of the *p*H from values of 4 to about 7.5. More alkaline *p*H values changed the blue purple color characteristic of all amino acids tested to a red purple, and at *p*H values of about 9 the color became a brick red. At *p*H values acid to about 4, a red color was also obtained.

**Developing Solution.**—Various developing solutions were studied and the solution which appeared to give the maximum color intensity and which was most reliable in performance had a small amount of phenol added to it; the composition of this solution is given in the experimental part. This solution must be freshly prepared to obtain uniform colors.

**Color Development.**—It has been our objective to develop the maximum color intensity possible for a given amino acid concentration. When the filter-paper strips are heated at 90° in the oven, they reach a constant level of color intensity in about five minutes, and this intensity remains essentially unchanged for at least thirty-five minutes of heating. However, when the strips are removed from the oven after the constant level of intensity has been attained and the color intensity measured in the densitometer after successive intervals, it is found that the color intensity increases with time at room temperature. This increase in optical density of the filter strips amounted to about 30% after twenty-four hours. The increase in optical density with time was finally recognized as probably being due to moisture uptake by the paper from the atmosphere. It was then found that a five-minute treatment in the steam oven after the dry oven brought the strips to their final color intensity. This final color was stable within experimental error for at least forty-eight hours provided the strips were protected from light.

**Color Developed.**—Contrary to some reports in the literature, the tint of the color developed with ninhydrin was as near as could be determined exactly the same for all the amino acids investigated, provided the *p*H of the amino acid solution was within the range of 4 to 7.5. Figure 1 shows the per cent. transmission for colors developed by alanine and by aspartic acid on the filter paper as a function of the wave length of the light. The colors developed by a number of other amino acids were investigated, and were found to be practically identical with the two shown in Fig. 1.

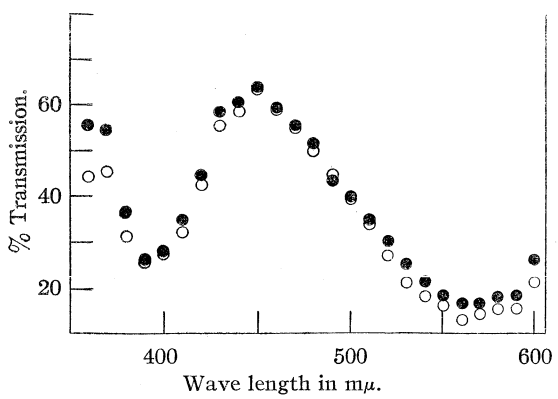

Fig. 1.—Per cent. light transmission through the color bands of alanine (open circles) and of aspartic acid (solid circles) on the filter paper as a function of the wave length of light.

There is a broad minimum in the optical transmission in the neighborhood of 570 mμ and this is the reason for using a light filter of this wave length in the densitometer.

**Amino Acid Concentration.**—As noted above, the per cent. light transmission was plotted on semi-log graph paper (Keuffel and Esser No. 358-51) against the distance along the filter paper strip allowing the space between each line on the graph paper to equal 2 mm. The areas between the plotted curve and 100% transmission were measured with a planimeter in square inches. These areas were then divided by the amount of amino acid in micromoles and this ratio was plotted against the area in square inches. It was found that the points for arginine, serine, valine, glutamic acid, leucine, threonine, alanine and lysine fell about a line whose least square equation is

$$A/C = 380.4 - 9.10A \qquad (1)$$

where $A$ is the area in square inches and $C$ is the amount of the amino acid in micromoles. The probable per cent. error for 68 determinations extending from 0.67 to 13.5 micrograms of the above acids was ±8.82. The per cent. errors were more or less independent of concentration.

The results for aspartic acid, phenylalanine, methionine and glycine did not follow equation 1. All of these acids developed less color than the first group of amino acids although when $A/C$ was plotted against $A$, linear relations were obtained. The equations for these amino acids are

| | | |
|---|---|---|
| Aspartic | $A/C = 340 - 10.0A$ | (2) |
| Phenylalanine | $A/C = 210 - 6.5A$ | (3) |
| Methionine | $A/C = 160 - 0.5A$ | (4) |
| Glycine | $A/C = 275 - 12.3A$ | (5) |

We did not attempt to evaluate the errors associated with equations 2, 3, 4 and 5. Since these acids did not develop the maximum color, the amount of color which is developed is probably very much dependent on how the reaction is carried out.

The addition of sodium chloride up to 0.1 $N$ had no significant influence on the color developed by alanine, but 0.2 $N$ sodium chloride produced a reddening of the color and reduced the area about 10%. The $R_F$ values for all the amino acids were independent of the amounts of the amino acids present.

**Mixtures of Amino Acids.**—The greatest utility of paper chromatography is in the study of mixtures of amino acids such as are obtained in protein hydrolysates. Shown in Fig. 2 is a

light transmission curve plotted on a semi-log scale against the distance in cm. along the filter paper strip. The mixture consisted of 3.38 micrograms each of arginine hydrochloride, valine, leucine, threonine, alanine and lysine hydrochloride.

There was too much overlapping of the arginine and the threonine for separate resolutions, but the sum of the micromoles of these two acids was 0.048 and the same calculated by the use of equation 1 is 0.043 micromole. The amounts of the other amino acids in micrograms were lysine hydrochloride 3.78, alanine 2.84, valine 3.51, and leucine 3.32. Where there was overlapping of the amino acid curves as shown in Fig. 2, a vertical line is drawn between the two overlapping amino acids from the peak transmission to the 100% transmission line and the respective areas assigned on the basis of this line. Providing there is not excessive overlapping, this treatment yielded good results.

All resolutions of amino acids on filter paper strips were done at room temperature and no thermostating was attempted. We have been unable to detect any important influence of temperature using 80% aqueous phenol except that the phenol moved faster at higher temperatures, and if this rate became too high the separation of the amino acids was not sharp. The rate we have tried to maintain was about 40 cm. or less in forty-four hours. If temperature gradients exist, the filter paper strips should be arranged so that they face the gradient; otherwise, the amino acid bands will be distorted.

**Acknowledgments.**—We are grateful to Corn Products Refining Company for the support of J. Wilfrid Hahn and to Swift and Company for the support of Victor H. Baptist. We wish to thank Dr. K. K. Jones for the loan of a photospectrometer, and Drs. L. S. Fosdick and C. O. Rupe for gifts of pure amino acids. The Carl Schleicher and Schuell Company and the Photovolt Corporation have been most helpful.

## Summary

1. A new arrangement of the filter paper chromatography of Consden, Gordon and Martin is described.

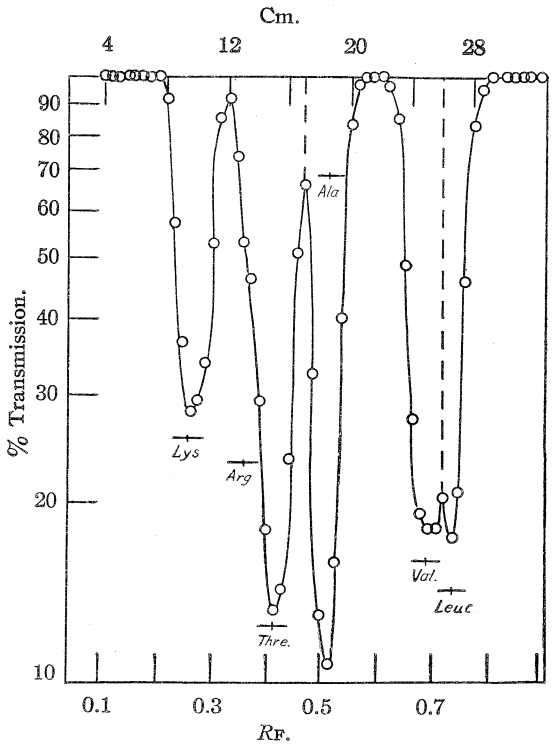

Fig. 2.—Optical transmission curve for a mixture of 3.38 micrograms each of lysine hydrochloride, arginine hydrochloride, threonine, alanine, valine and leucine.

2. The main features of this new approach consist in the use of a superior grade of filter paper, of 80% aqueous phenol, and attention to the details of color development.

3. It appears that arginine, serine, valine, glutamic acid, leucine, threonine, alanine and lysine give the same micromolar color values, and by the technique described it is possible to estimate these acids in the range of 0.67 to 13.5 micrograms with a probable per cent. error of a single determination of ±8.82. Aspartic acid, phenylalanine, methionine and glycine yield lower micromolar color values.

4. The application of this method to amino acid mixtures is described.

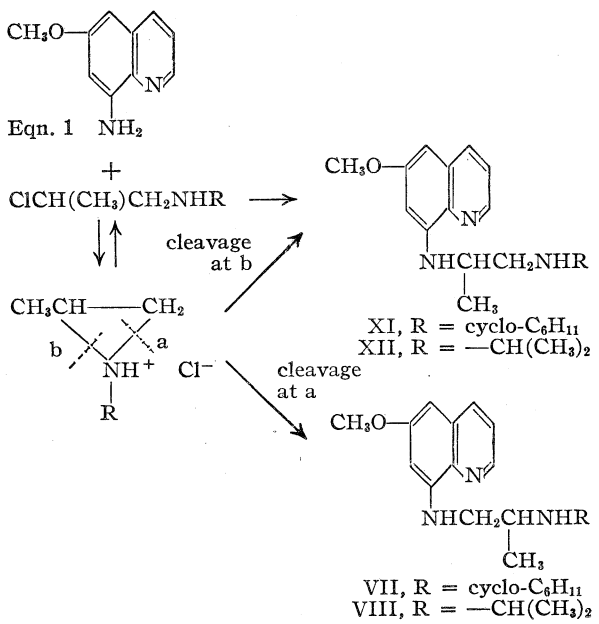
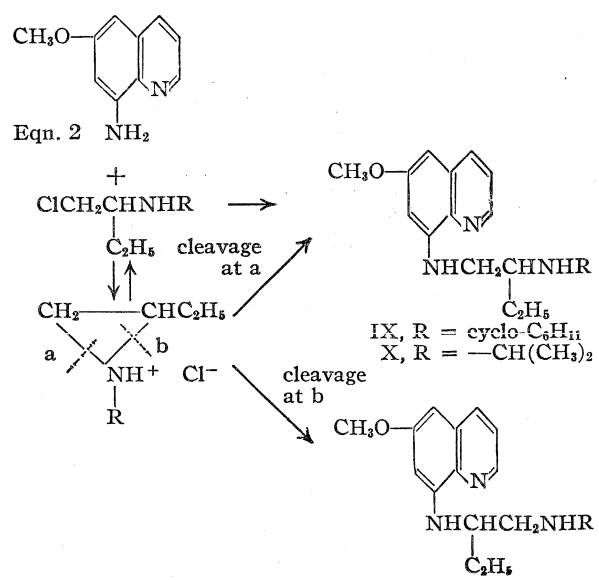
# Synthesis of 6-Methoxy-8-aminoquinoline Derivatives; Ethyleneimine Rearrangements in Attachment of Monoalkylaminoalkyl Side Chains[1]

BY ARTHUR C. COPE, HAROLD R. NACE,[2] WILLIAM R. HATCHARD, W. H. JONES, MARK A. STAHMANN AND RICHARD B. TURNER



This paper describes the synthesis of a number of 6-methoxy-8-aminoquinoline derivatives[3] related to Plasmochin (I) but containing *primary* aminoalkyl (II and III) or *secondary* aminoalkyl side chains (IV-X) attached to the 8-amino group. Rearrangement is possible in the alkylation reactions through which VII, VIII, IX and X were prepared if ethyleneimines are formed as intermediates, as was proved to have occurred in two of the four cases by unequivocal syntheses of each of these compounds.



The *primary* aminoalkyl side chains in II and III were introduced by alkylation of 6-methoxy-8-aminoquinoline with phthalimidoalkyl halides, followed by removal of the phthalyl group as phthalhydrazide by treatment first with hydrazine hydrate then hydrochloric acid.[4] The primary amino group in II was converted to the isopropylamino group in the synthesis of IV by reductive alkylation with acetone in the presence of Adams platinum catalyst.

I, R = $-CH(CH_3)(CH_2)_3N(C_2H_5)_2$
II, R = $-(CH_2)_4NH_2$
III, R = $-CH_2CH(OH)CH_2NH_2$
IV, R = $-(CH_2)_4NHCH(CH_3)_2$
V, R = $-(CH_2)_2NHC_6H_{11}$-(cyclo)
VI, R = $-(CH_2)_2NHCH(CH_3)_2$

Secondary aminoalkyl side chains in V-X (Table II) were introduced by the alkylation of 6-methoxy-8-aminoquinoline with secondary aminoalkyl chloride hydrochlorides.[5] It is evident from the following equations that the alkylation reactions could proceed by direct displacement of the chlorine of the aminoalkyl chloride, as in an alkylation by a simple alkyl halide, or that an ethyleneimine might be formed as an intermediate. Either course would lead to the same product from an alkylaminoethyl chloride, as in the syntheses of V and VI by alkylation of 6-methoxy-8-aminoquinoline with cyclohexylaminoethyl chloride hydrochloride and isopropylaminoethyl chloride hydrochloride, respectively. The two paths could lead to the same or different products in cases where an intermediate ethyleneimine would have an unsymmetrical structure, ac-

[a] Survey number SN 15,288; see ref. 3 for significance. [b] Of material with the melting point tabulated unless otherwise noted. [c] Thionyl chloride added during two hours and the mixture heated under reflux for two hours. [d] M. p. 212–212.5° (uncor.). [e] Recrystallized from ethanol. [f] Heated under reflux for one and one-half hours. [g] M. p. 176–177° (uncor.). [h] The mixture was allowed to stand overnight at room temperature after the thionyl chloride was added. [i] Recrystallized from ethanol and from chloroform. [j] Heated under reflux for half an hour. [k] Recrystallized from ethanol–ether and from carbon tetrachloride–petroleum ether. The m. p. tabulated was observed on rapid heating. Slow heating produced softening at this temperature and decomposition at 238–240°. [l] Recrystallized from ethanol–ethyl acetate and from ethyl acetate. [m] Described by Hancock, Hardy, Heyl, Wright and Cope, THIS JOURNAL, **66**, 1751 (1944). [n] Heated under reflux for one and one-half hours. [o] Recrystallized from ethanol; m. p. uncor.

cording to the point at which it opened in the alkylation.[6]

Displacement reactions of tertiary aminoethyl halides have been established as proceeding through intermediate quaternary ethyleneimmonium salts in a number of instances.[7] Ross[8] has shown that one unsymmetrical quaternary ethyleneimmonium salt reacted by cleavage under basic conditions between the nitrogen and the least substituted carbon atom (corresponding to cleavage at point *a* in the tertiary ethyleneimines represented as intermediates in equations 1 and 2). In other cases intermediate quaternary ethyleneimmonium salts apparently cleaved between the nitrogen and the most highly substituted carbon atom (as at point *b* in equations 1 and 2),[9] while in still other cases similar unsymmetrical quaternary ethyleneimmonium intermediates cleaved at both positions to give mixtures of isomeric products.[10] More recently secondary ethyleneimines have been shown to rupture preferentially but not exclusively at the primary carbon atom in reactions with amines, catalyzed by ammonium chloride.[11]

The alkylation reactions in which VII-X were prepared differ from others studied earlier in that the alkylating agents are secondary aminoalkyl chlorides, and the possible intermediates would be tertiary ethyleneimines or their hydrochlorides. Independent syntheses of VII-X by methods noted below established their structures, which correspond to cleavage of the ethyleneimines between the nitrogen and the least substituted carbon atom (point *a*, equations 1 and 2). Another possibility in the synthesis of IX and X, in which rearrangement did not occur, is direct displacement of the chlorine without intervention of a cyclic intermediate. It should be noted that yields of VII-X were not high, and the presence of isomers (derivable by cleavage of the intermediates at point *b*) in the solutions from which they were isolated is not excluded.

The secondary aminoalkyl chloride hydrochlorides with which 6-methoxy-8-aminoquinoline was alkylated in the syntheses of V-X were prepared from the corresponding aminoalcohol hydrochlorides and thionyl chloride (Table I). Evidence that rearrangement did not occur in the preparation of the chlorides was obtained for the last four compounds in Table I, which could have isomeric structures if the ethyleneimmonium chlorides formulated in equations 1 and 2 were formed as intermediates. These four compounds were heated with an excess of aqueous silver nitrate, which converted them to nitric acid salts of alkylaminoalcohols (any intermediate nitric acid esters which may have been formed were hydrolyzed under the reaction conditions). The alkylaminoalcohols which were obtained when the solutions were made basic were proved to be identical with the original alkylaminoalcohols from which the chlorides were prepared by a direct comparison of physical properties and of the hydrochlorides, which were prepared as solid derivatives. Rearrangement under the acidic conditions of these transformations is unlikely, and formation of the original alkylaminoalcohols of two structural types (two primary and two secondary alcohols) makes it very improbable that ethyleneimmonium salts were intermediates in the reaction with silver nitrate, for the cyclic imines which would be of the same structural type in all four cases would have to undergo

(6) The alkylaminoalkyl chlorides were used as hydrochlorides, which would be less susceptible to the rearrangement than the corresponding bases. In alcohol solution containing 6-methoxy-8-aminoquinoline, however, an equilibrium would be set up in which all of the basic species present would be present as bases and salts in amounts dependent upon their concentrations, basic strengths and solubilities of their hydrochlorides. Presence of the hydrogen chloride is not shown in the equations except in the ethyleneimmonium salts, which would be formed as a first step in self alkylation regardless of whether subsequent cleavage at a or b occurred in the salt or the corresponding base.

two different types of cleavage to lead to these products.

Two of the possible alkylation products of equation 1 were prepared by first adding 6-methoxy-8-aminoquinoline to 1-nitro-1-propene to give 6-methoxy-8-(2-nitroisopropylamino)-quinoline (XIII).[12] XIII was reductively al-

kylated with cyclohexanone and with acetone in the presence of Adams platinum catalyst[13] to give XI and XII, which were isolated as the dihydrochlorides. The dihydrochlorides and dipicrates of XI and XII differed in m.p. and showed depressions in mixed m.p. with the corresponding derivatives prepared from the alkylation products (equation 1), which accordingly could be assumed to be the isomers VII and VIII. Attempts to prepare known samples of VII and VIII by a similar procedure beginning with the addition of 6-methoxy-8-aminoquinoline to 2-nitro-1-propene were unsuccessful, for a pure crystalline addition product could not be isolated. Attempts to utilize 6-methoxy-8-(2-hydroxypropylamino)-quinoline (XIV) or 6-methoxy-8-acetonylaminoquinoline (XV) as intermediates in the synthesis of VII and VIII also were unsuccessful. XIV was prepared from 6-methoxy-8-aminoquinoline and propylene oxide, but could not be oxidized to XV under the conditions which were investigated. XV was obtained in very low yield by alkylation of 6-methoxy-8-aminoquinoline with bromoacetone, and could be converted to a crystalline semicarbazone and phenylhydrazone, which by reduction might have been converted to 6-methoxy-8-(2-aminopropylamino)-quinoline (XVII). The low yield in the preparation of XV led to abandonment of this route in favor of successful syntheses of VII and VIII through XVII as an intermediate which began with 2-phthalimido-1-propanol, prepared from phthalic anhydride and 2-amino-1-propanol. Reaction of this compound with phosphorus pentabromide yielded 2-phthalimido-1-bromopropane, which with 6-methoxy-8-aminoquinoline gave 6-methoxy-8-(2-phthalimidopropylamino)-quinoline (XVI). Removal of the phthalyl group in XVI[14] yielded 6-methoxy-8-(2-aminopropylamino)-quinoline (XVII). Reductive alkylation of XVII with cyclohexanone and with acetone gave samples of VII and VIII of known structure, which were proved to be identical with the alkylation products (equation 1) by comparison of the m.p. and mixed m.p. of the dihydrochlorides and dipicrates, and of the free base in the case of VII (a crystalline solid).

Similar syntheses which gave samples of IX and of X of known structure utilized as intermediates 2-amino-1-butanol, 2-phthalimido-1-butanol and 2-phthalimido-1-bromobutane, which with 6-methoxy-8-aminoquinoline yielded 6-methoxy-8-(2-phthalimidobutylamino)-quinoline (XVIII). Removal of the phthalyl group in XVIII gave 6-methoxy-8-(2-aminobutylamino)-quinoline XIX, which was reductively alkylated with cyclohexanone and with acetone to give IX and X. These samples of IX and X yielded dihydrochlorides and dipicrates which were identical (m.p. and mixed m.p.) with corresponding derivatives prepared from the products obtained from alkylation according to equation 2, and the crystalline samples of IX from the two sources were identical.

Difficulty was encountered in some instances in obtaining hydrochlorides with constant melting or decomposition points in this series (VII-X) and although their mixed melting points indicated the identities noted, comparison of the crystalline bases (VII and IX) and the picrates of VII-X obtained by the two methods of synthesis furnished more satisfactory proofs of identity.

## Experimental[14]

**6-Methoxy-8-(4-aminobutylamino)-quinoline Dihydrochloride Hemihydrate (II, SN 3, 883).**—4-Bromobutylphthalimide[15] was prepared from tetramethylene dibromide[16] and potassium phthalimide[17] and recrystallized from ligroin; yield 48%, m.p. 78–79°. A mixture of 60.0 g. of 6-methoxy-8-aminoquinoline and 97.0 g. of 4-bromobutylphthalimide was heated in a bath at 120–125° for six hours. The temperature of the reaction mixture was observed and heating was discontinued in the early stages if necessary to avoid a rapid spontaneous rise in temperature. After cooling, the mixture was heated under reflux with 350 ml. of ethanol to dissolve oily material, cooled and filtered. The orange hydrobromide was converted to the free base by shaking with methylene chloride and a dilute solution of potassium carbonate. The extract was washed with sodium chloride solution, filtered through sodium sulfate and concentrated. Crystallization of the residue from ethanol gave 55.0 g. (43%) of light yellow prisms, m.p. 92–94°. Several recrystalliza-

tions from ethanol gave an analytical sample of 6-methoxy-8-(4-phthalimidobutylamino)-quinoline, m.p. 94–94.5°.

*Anal.* Calcd. for $C_{22}H_{21}O_3N_3$: C, 70.38; H, 5.64; N, 11.19. Found: C, 70.2; H, 5.73; N, 11.1.

The hydrobromide of 6-methoxy-8-(4-phthalimidobutylamino)-quinoline melted at 210–211° (dec.) after several crystallizations from ethanol. Robinson and Tomlinson[18] report m.p. 196–198° (dec.).

*Anal.* Calcd. for $C_{22}H_{21}O_3N_3 \cdot HBr$: N, 9.21; Br, 17.51. Found: N, 9.08; Br. 17.6.

A solution of 55.0 g. of 6-methoxy-8-(4-phthalimidobutylamino)-quinoline and 10.0 g. of 85% hydrazine hydrate in 500 ml. of ethanol was heated under reflux for two hours. The solvent was removed under reduced pressure and the residue was heated on a steam-bath with 200 ml. of 4.0 *N* hydrochloric acid for one hour. The mixture was cooled, filtered to remove phthalhydrazide, and the filtrate was concentrated under reduced pressure. Crystallization of the residue from ethanol yielded 41.9 g. (87%) of II, m.p. 209–211° (dec.). An analytical sample purified by several crystallizations from ethanol had m.p. 213–214° (dec.) (ref. 18 reports m.p. 208° (dec.)).

*Anal.* Calcd. for $C_{14}H_{19}ON_3 \cdot 2HCl \cdot 0.5H_2O$: C, 51.38; H, 6.78; N, 12.84; Cl, 21.66; $H_2O$, 2.75. Found: C, 51.2; H, 6.48; N, 12.7; Cl, 21.6; $H_2O$, 2.59 (by loss in weight on drying at 1 mm. and 110°).

**6-Methoxy-8-(4-isopropylaminobutylamino)-quinoline Dihydrochloride (IV, SN 13,275).**—The above dihydrochloride hemihydrate (II) (19.6 g.) was converted to the free base by shaking with ether and a dilute solution of potassium carbonate. The ether solution was dried over sodium sulfate, the ether was distilled and the residual oil was dissolved in 60 ml. of ethanol. Acetone (5 ml.) was added and the solution was added to the platinum catalyst prepared by hydrogenating 1.5 g. of platinum oxide in ethanol. Hydrogenation began rapidly at atmospheric pressure and became very slow after about thirty minutes; 78% of the theoretical amount of hydrogen was absorbed. The catalyst was removed by filtration and 70 ml. of 1.96 *N* ethanolic hydrogen chloride was added to the filtrate. After concentration, the filtrate was diluted with ether and yielded 15.5 g. (72%) of IV, m.p. 185–187° (dec.). An analytical sample was crystallized several times from ethanol–ether; m.p. 189–190° (dec.).

*Anal.* Calcd. for $C_{17}H_{25}ON_3 \cdot 2HCl$: C, 56.66; H, 7.55; N, 11.66; Cl, 19.68. Found: C, 56.6; H, 7.62; N, 11.6; Cl, 19.7.

**6-Methoxy-8-(3-amino-2-hydroxypropylamino)-quinoline (III, SN 12,943).**—A mixture of 174 g. of 6-methoxy-8-aminoquinoline, 120 g. of 3-chloro-2-hydroxypropylphthalimide[19] and 300 ml. of *n*-butanol was heated under reflux for sixty-eight hours. The mixture was cooled and poured into 800 ml. of water containing 1.2 moles of hydrochloric acid, with stirring. The suspension was stirred with 500 ml. of benzene for thirty minutes, the benzene was decanted, and the process was repeated with 200 ml. of benzene. The mixed hydrochlorides were collected by filtering the aqueous suspension, dried, and converted to the free bases by dissolving in 1200 ml. of boiling ethanol and 130 ml. of pyridine. After cooling overnight the solids were separated by filtration and redissolved in 500 ml. of boiling ethanol and 100 ml. of pyridine. The hot solution was filtered and 400 ml. of hot water was added slowly. On cooling, 54 g. (29%) of 6-methoxy-8-(3-phthalimido-2-hydroxypropylamino)-quinoline separated, m.p. after recrystallization from 700 ml. of ethanol 142–143°.

*Anal.* Calcd. for $C_{21}H_{19}O_4N_3$: C, 66.83; H, 5.07; N, 11.13. Found: C, 66.8; H, 5.1; N, 11.1.

A solution of 46 g. of 6-methoxy-(3-phthalimido-2-hydroxypropylamino)-quinoline and 8.5 ml. of hydrazine hydrate in 460 ml. of ethanol was heated under reflux for ninety minutes. The ethanol was removed under reduced pressure and the residue heated under reflux for fifteen minutes with 420 ml. of water containing 0.3 mole of hydrochloric acid. After cooling and separating phthalhydrazide by filtration, 400 ml. of 1.0 *N* sodium hydroxide was added. After cooling for one hour the crystalline product was separated; yield of III 29 g. (92%), m.p. after recrystallization from 750 ml. of boiling ethanol 157–158°.

*Anal.* Calcd. for $C_{13}H_{17}O_2N_3$: C, 63.13; H, 6.93; N, 16.99. Found: C, 62.9; H, 6.9; N, 17.1.

The hydrochloride was prepared from III and after recrystallization from ethanol–ether had m.p. 189–190°.

*Anal.* Calcd. for $C_{13}H_{17}O_2N_3 \cdot 2HCl$: C, 48.76; H, 5.98. Found: C, 48.5; H, 6.4.

**Alkylaminoalkyl Chloride Hydrochlorides.**—The following general procedure was used in preparing the compounds listed in Table I. The aminoalcohol[20] (0.3–1.0 mole) was dissolved in dry alcohol-free chloroform (750 ml. per mole) and placed in a three-necked flask fitted with a stirrer, reflux condenser and gas delivery tube dipping beneath the surface of the liquid. The solution was stirred and saturated with dry hydrogen chloride. The gas delivery tube was replaced with a dropping funnel and thionyl chloride (2.0 to 3.0 molar equivalents) was added with stirring and cooling. The solution was heated under reflux or allowed to stand as stated in the footnotes, the solvent and excess thionyl chloride were removed under reduced pressure, and the residue was crystallized to constant melting point from the solvent noted.

Evidence confirming the structures of the last four alkylaminoalkyl chloride hydrochlorides listed in Table I was obtained by converting them into the corresponding aminoalcohols in the following manner. 1-Isopropylamino-2-chloropropane hydrochloride (9.3 g., 0.056 mole), 39.2 g. (0.23 mole) of silver nitrate and 100 ml. of water were heated under reflux for eighteen hours. The mixture was filtered and the silver chloride (15.6 g., 97.5%) was washed with water. Saturated sodium chloride solution was added to the combined filtrate and washings until no more silver chloride precipitated. After filtering and washing the silver chloride with water, the combined filtrate and washings were made basic with sodium hydroxide and extracted with ether. The extracts were dried over magnesium sulfate and treated with dry hydrogen chloride in acetone to convert the aminoalcohol into its hydrochloride. On concentration 4.8 g. of 1-isopropylamino-2-propanol hydrochloride separated, m.p. 143.5–145°. The m.p. of this sample was not depressed on mixture with a known sample prepared from the aminoalcohol[20b] and hydrogen chloride in acetone and purified by crystallization to constant m.p. from acetone and acetone–methylene chloride; m.p. 144.5–146.5°.

*Anal.* Calcd. for $C_6H_{16}ONCl$: C, 46.90; H, 10.50; N, 9.12; Cl, 23.08. Found: C, 46.80; H, 10.57; N, 8.81; Cl, 23.2.

By a similar procedure 1-cyclohexylamino-2-chloropropane hydrochloride (20 g.) was converted to 1-cyclohexylamino-2-propanol (11.4 g., 77%), b.p. 125° (20 mm.), which solidified on cooling and was identified as the hydrochloride, m.p. and mixed m.p. with a known sample[20b] 162.5–164°. Likewise 2-isopropylamino-1-chlorobutane hydrochloride (20.6 g.) yielded 10.3 g. (68%) of 2-isopropylamino-1-butanol, b.p. 88° (20 mm.), m.p. 43–46°. This aminoalcohol was converted to the hydrochloride as a solid derivative, m.p. 99.5–101°. Its m.p. was not depressed on mixture with a known sample prepared from 2-isopropylamino-1-butanol[20c] and hydrogen chloride in acetone and recrystallized from acetone; m.p. 100–101.5°.

*Anal.* Calcd. for $C_7H_{18}ONCl$: C, 50.14; H, 10.82; N, 8.35; Cl, 21.15. Found: C, 50.28; H, 10.58; N, 8.29; Cl, 21.2.

On treatment with silver nitrate under similar conditions 2-cyclohexylamino-1-chlorobutane hydrochloride

[a] Identified by these numbers in column 1, Table I. [b] Number by which the compound is designated in ref. 3. [c] Designated as XI in ref. 3 but the correct structure is VII. [d] Designated as XII in ref. 3 but the correct structure is VIII. [e] Yield of analytically pure material crystallized to constant m. p. Yields of fairly pure products were considerably higher. [f] Yield of the free base, distilled at 0.03 mm. and a bath temperature of 180–200° and recrystallized from ethanol–water; m. p. 93–94°. *Anal.* Calcd. for $C_{19}H_{27}ON_3$: C, 72.81; H, 8.69; N, 13.41. Found: C, 73.15; H, 8.66; N, 13.3. [g] Eight per cent. was isolated as the free base, distilled at 0.03–0.04 mm. and a bath temperature of 170–185° and recrystallized from ethanol–water; m. p. 62–63°. *Anal.* Calcd. for $C_{20}H_{29}ON_3$: C, 73.35; H, 8.93; N, 12.83. Found: C, 73.50; H, 8.89; N, 12.7. The remainder (6%) was isolated as the dihydrochloride. [h] Recrystallized from absolute ethanol. [i] Recrystallized from absolute ethanol–ether. [j] Dried at 60° and 1 mm. overnight. Analysis indicated that the salt was a hemihydrate. Drying at 118° and 1 mm. caused partial loss of hydrogen chloride. [k] The reactants were heated in 40 ml. of refluxing *n*-butanol for sixty-eight hours. [l] The period of reflux was forty-seven hours.

(13.35 g.) yielded 7.4 g. (73%) of 2-cyclohexylamino-1-butanol, b.p. 128–129° (25 mm.). The hydrochloride was prepared as a derivative, m.p. 158.5-160.5°. The m.p. of this sample was not depressed on mixture with a known sample prepared from 2-cyclohexylamino-1-butanol[20c] and hydrogen chloride in acetone–ethanol and recrystallized from methylene chloride–acetone and ethanol–ether; m.p. 161–162°.

*Anal.* Calcd. for $C_{10}H_{22}ONCl$: C, 57.81; H, 10.68; N, 6.75; Cl, 17.07. Found: C, 57.97; H, 10.49; N, 6.57; Cl, 17.0.

**Alkylation of 6-Methoxy-8-aminoquinoline with Alkylaminoalkyl Chloride Hydrochlorides.**—The 6-methoxy-8-aminoquinoline derivatives V-X listed in Table II were prepared by the procedure described by Rohrmann and Shonle,[5] modified as described below and in the foot notes. Absolute ethanol solutions of the reactants were heated under reflux for sixty to sixty-seven hours, after which the ethanol was removed under reduced pressure. Water was added to the residue, which was made strongly basic with 20% sodium hydroxide, in some cases saturated with potassium carbonate,[21] and extracted with ether or methylene chloride.[22] The extracts were dried over magnesium sulfate, concentrated, and the residue was distilled in a short-path modified Hickmann molecular-type pot still. In each case 6-methoxy-8-aminoquinoline was separated as a low boiling fraction. V, VII and IX distilled as higher boiling fractions, VII and IX under conditions noted in the footnotes and V at 0.015 mm. and a bath temperature of 155–180°. V was converted to the dihydrochloride and purified by recrystallization, while VII and IX were purified by the methods described in the footnotes. In the distillation of VI, VIII and X, decomposition began after removal of the 6-methoxy-8-aminoquinoline, so the undistilled residues were dissolved in ethanol and hydrochloric acid was added to convert the products to dihydrochlorides, which were purified by recrystallization.

Dipicrates (Table III) were prepared from VII, VIII, IX and X prepared by alkylation (Table II) in order to obtain additional crystalline derivatives for comparison with dipicrates of these compounds obtained from the unequivocal syntheses described below. The bases and picric acid (2.2 molar equivalents) in absolute ethanol were heated to the reflux temperature. The dipicrates separated on cooling, and were purified by recrystallization to constant m.p. from the solvents noted in Table III.

(21) There was some evidence that the bases were partially converted to carbonates in the presence of potassium carbonate, which was omitted in later preparations.

(22) In the preparation of V, 6-methoxy-8-aminoquinoline was separated from the more basic product by preparing a solution of the crude product in 500 ml. of water and 200 ml. of ethanol, adding concd. hydrochloric acid until the solution was acid to congo red, then sodium acetate until the solution was slightly basic to congo red, and extracting with eight 100-ml. portions of ether. See Elderfield, *et al.* THIS JOURNAL, **68**, 1521 (1946).

### Synthetic Proofs of Structure

**6-Methoxy-8-(2-nitroisopropylamino)-quinoline (XIII).**—A solution of 3.5 g. of freshly distilled 1-nitro-1-propene[23] in 50 ml. of ether was added to 7 g. of 6-methoxy-8-aminoquinoline dissolved in 50 ml. of ether, and the solution was heated under reflux for twenty-four hours. The ether was removed under reduced pressure; the residue crystallized on cooling and scratching. Crystallization from 40 ml. of absolute ethanol gave 7.5 g. (72%) of light yellow needles, m.p. 84–85°.

*Anal.* Calcd. for $C_{13}H_{15}O_3N_3$: C, 59.76; H, 5.79; N, 16.08. Found: C, 60.03; H, 6.01; N, 16.15.

**6-Methoxy-8-(2-cyclohexylaminoisopropylamino)-quinoline Dihydrochloride (XI).**—A solution of 1 g. of XIII and 0.75 g. of cyclohexanone in 15 ml. of ethanol was added to the platinum catalyst prepared by reducing 0.1 g. of platinum oxide in 5 ml. of ethanol, and the mixture was shaken with hydrogen. After twenty-two hours hydrogen absorption stopped at 98% of the theoretical value. The catalyst was separated and ethanolic hydrogen chloride added to the filtrate, which was concentrated and diluted with ether. One recrystallization of the yellow product from absolute ethanol gave 0.6 g. (40%) of XI; m.p. 207.5–208.5° (dec.), which was raised to a constant m.p. of 210–211° (dec.) by two recrystallizations from absolute ethanol.

*Anal.* Calcd. for $C_{19}H_{27}ON_3 \cdot 2HCl$: C, 59.06; H, 7.57; N, 10.88; Cl, 18.35. Found: C, 59.19; H, 7.44; N, 11.09; Cl, 18.35.

A mixed m.p. of XI with the product of alkylation (VII, equation 1; Table II, m.p. 226–228° (dec.)) was depressed to 196–200° (dec.).

XI was heated with 2.2 equivalents of picric acid in ethanol and converted to the dipicrate, which was recrystallized from 95% ethanol to a constant m.p. of 171.5–172.5° (dec.).

*Anal.* Calcd. for $C_{31}H_{33}O_{15}N_9$: N, 16.34. Found: N, 16.38.

A mixed m.p. of XI dipicrate with the dipicrate of the

TABLE III

DIPICRATES OF 6-METHOXY-8-AMINOQUINOLINE DERIVATIVES PREPARED BY ALKYLATION

| Dipicrate of: | M. p., °C. | Formula | Analyses, % Carbon Calcd. | Carbon Found | Hydrogen Calcd. | Hydrogen Found |
|---|---|---|---|---|---|---|
| VII | 186–186.5 (dec.)[a] | $C_{31}H_{33}O_{16}N_9$ | 48.25 | 48.16 | 4.31 | 4.36 |
| VIII | 188.5–189 (dec.)[a] | $C_{28}H_{29}O_{15}N_9$ | 45.97 | 45.86 | 4.00 | 4.31 |
| IX | 164.5–165[a] | $C_{32}H_{35}O_{15}N_9$ | 48.92 | 48.63 | 4.49 | 4.49 |
| X | 140.5–141[b] | $C_{29}H_{31}O_{15}N_9$ | 46.71 | 46.71 | 4.19 | 4.46 |

[a] Recrystallized from a mixture of two parts of absolute ethanol and one part of acetone. [b] Recrystallized from a mixture of four parts of absolute ethanol and one part of acetone.

alkylation product (VII, equation 1; Table III, m.p. 186–186.5° (dec.)) was depressed to 162–162.5° (dec.).

**6-Methoxy-8-(2-isopropylaminoisopropylamino)-quinoline Dihydrochloride (XII).**—Hydrogenation of a solution of 1 g. of XIII and 0.45 g. of acetone in 15 ml. of ethanol in the presence of 100 mg. of prereduced platinum oxide required twenty-two hours, and 96.5% of hydrogen was absorbed. The product was isolated in the same manner as XI and recrystallized from ethanol; yield 0.45 g. (35%), m.p. 217.5–218.5° (dec.).

*Anal.* Calcd. for $C_{16}H_{23}ON_3 \cdot 2HCl$: C, 55.48; H, 7.28; N, 12.13; Cl, 20.48. Found: C, 55.56; H, 7.41; N, 12.10; Cl, 20.60.

A mixed m.p. of XII with the product obtained by alkylation (VIII, equation 1; Table II, m.p. 239–240° (dec.)) was depressed to 207–207.5° (dec.).

XII was converted to the dipicrate, which was recrystallized from 2:1 ethanol–acetone; m.p. 184–185° (dec.).

*Anal.* Calcd. for $C_{28}H_{29}O_{15}N_9$: C, 45.97; H, 4.00. Found: C, 46.09; H, 4.12.

A mixed m.p. of XII dipicrate with the dipicrate of the alkylation product (VIII, equation 1; Table III, m.p. 188.5–189° (dec.)) was depressed to 169–170° (dec.).

**6-Methoxy-8-(2-hydroxypropylamino)-quinoline (XIV).**—Propylene oxide (7 g.) was added to a solution of 17.4 g. of 6-methoxy-8-aminoquinoline in 50 ml. of dioxane and 10 ml. of water. The solution was heated under reflux for twenty-four hours, concentrated under reduced pressure, and the residue distilled from a Hickmann molecular-type pot still. 6-Methoxy-8-aminoquinoline (12.5 g.) distilled at a bath temperature of 110–130° (0.02–0.025 mm.), followed by XIV as a very viscous orange oil (6.8 g., 29%) at a bath temperature of 130–145° (0.02–0.025 mm.).

*Anal.* Calcd. for $C_{12}H_{16}O_2N_2$: C, 67.22; H, 6.94; N, 12.06. Found: C, 67.21; H, 6.97; N, 12.01.

Attempts to oxidize XIV to XV with chromic acid in acetic acid, potassium permanganate in acetone, cyclohexanone and aluminum isopropoxide in benzene, and benzophenone and potassium *t*-butoxide in benzene were unsuccessful.

**6-Methoxy-8-acetonylaminoquinoline (XV).**—A solution of 34.8 g. of 6-methoxy-8-aminoquinoline and 13.7 g. of bromoacetone in 250 ml. of ether was heated under reflux for a total of forty-four hours and filtered at intervals to remove insoluble salts (principally 6-methoxy-8-aminoquinoline hydrobromide). The ether filtrate was concentrated under reduced pressure. Semicarbazide hydrochloride (5 g.) and sodium acetate (10 g.) were added to a solution of the residue in 75 ml. of ethanol, followed by water to the point of turbidity (50 ml.). The mixture was boiled for ten minutes, cooled, and the solid which separated was recrystallized to constant melting point from benzene–petroleum ether to yield 3.0 g. of XV semicarbazone, m.p. 171.5–173.5°.

*Anal.* Calcd. for $C_{14}H_{17}O_2N_5$: C, 58.52; H, 5.97; N, 24.38. Found: C, 58.65; H, 5.99; N, 24.09.

XV semicarbazone (1 g.) was hydrolyzed by heating on a steam-bath with 20 ml. of 3 *N* hydrochloric acid for thirty minutes. The solution was cooled, made alkaline with potassium carbonate, and extracted with methylene chloride. The XV in the extract was purified by crystallization from methylene chloride–ether and ether; m.p. 92.5–93.5°.

*Anal.* Calcd. for $C_{13}H_{14}O_2N_2$: C, 67.81; H, 6.13; N, 12.17. Found: C, 67.85; H, 6.16; N, 12.23.

XV (0.1 g.) was converted to the phenylhydrazone as an additional derivative, which was purified by four crystallizations from ethanol–water; yield 0.055 g., m.p. 133.5–135°.

*Anal.* Calcd. for $C_{19}H_{20}ON_4$: C, 71.23; H, 6.29; N, 17.49. Found: C, 71.40; H, 6.50; N, 17.54.

**6-Methoxy-8-(2-phthalimidopropylamino)-quinoline (XVI).**—XVI was prepared and isolated by the procedure described for 6-methoxy-8-(4-phthalimidobutylamino)-quinoline, from 19 g. of 2-phthalimido-1-bromopropane[24] and 13.6 g. of 6-methoxy-8-aminoquinoline, which were heated in a nitrogen atmosphere at 145–150° for six hours. The product crystallized from ethanol as light yellow needles; yield 5.35 g. (21%), m.p. 142–144°. An analytical sample recrystallized twice from ethanol had a constant m.p. of 145–145.5°.

*Anal.* Calcd. for $C_{21}H_{19}O_3N_2$: C, 69.79; H, 5.30; N, 11.63. Found: C, 69.48; H, 5.33; N, 11.76.

**6-Methoxy-8-(2-aminopropylamino)-quinoline Dihydrochloride (XVII).**—A solution of 7 g. of XVI and 1.4 g. of 85% hydrazine hydrate in 150 ml. of absolute ethanol was heated under reflux for two hours and then concentrated under reduced pressure. The residue was heated on a steam-bath for one hour with 200 ml. of 2 *N* hydrochloric acid, cooled, and filtered to remove the phthalhydrazide, which was washed with water. The filtrate and washings were concentrated under reduced pressure, treated with dilute sodium hydroxide to liberate XVII as the free base, and extracted with methylene chloride. The extracts were washed with sodium chloride solution, dried over sodium sulfate, and concentrated. A solution of the residue in ethanol was made acid to congo red with hydrogen chloride in ethanol. XVII separated as bright orange crystals on cooling; yield 4.0 g. (68%), m.p. 230.5–233° (dec.). Two recrystallizations from absolute ethanol gave an analytical sample with a constant m.p. of 230.5–231.5° (dec.).

(24) Gabriel and Ohle, *Ber.*, **50**, 812 (1917).

*Anal.* Calcd. for $C_{13}H_{17}ON_3 \cdot 2HCl$: C, 51.32; H, 6.30; N, 13.81; Cl, 23.31. Found: C, 51.34; H, 6.41; N, 13.89; Cl, 22.85.

**6-Methoxy-8-(2-cyclohexylaminopropylamino)-quinoline (VII).**—One gram of XVII was converted to the free base by shaking with dilute sodium hydroxide and methylene chloride. The extract was dried, the solvent removed, and a solution of the residue and 1 ml. of cyclohexanone in 15 ml. of ethanol was shaken with hydrogen and 100 mg. of prereduced platinum oxide. The theoretical amount of hydrogen was absorbed in ten minutes, and then the rate decreased sharply. The catalyst was removed, the filtrate concentrated to a volume of 15 ml., and water was added slowly. VII separated as light brown needles; yield 0.66 g. (65%), m.p. 92–93°. Crystallization from ethanol–water after treatment with Darco gave 0.62 g. of VII as white needles, m.p. 93–93.5°, which was not depressed on mixture with a sample of VII melting at 93–94° prepared by alkylation (equation 1, Table II).

*Anal.* Calcd. for $C_{19}H_{27}ON_3$: C, 72.81; H, 8.69; N, 13.41. Found: C, 72.43; H, 8.41; N, 13.60.

The dihydrochloride of VII prepared in this way was recrystallized twice from absolute ethanol and dried to constant weight at 40° and 1 mm.; m.p. 229–230°; mixed m.p. with VII dihydrochloride prepared by the alkylation reaction (equation 1, m.p. 229–230° (dec.), Table II) was not depressed. A mixed m.p. with XI dihydrochloride (m.p. 210–211° (dec.)) was depressed to 200–201° (dec.). Analysis indicated that VII dihydrochloride was a hemihydrate.

*Anal.* Calcd. for $C_{19}H_{27}ON_3 \cdot 2HCl \cdot 0.5H_2O$: C, 57.72; H, 7.65. Found: C, 57.80; H, 7.61.

The dipicrate of VII from this source was recrystallized from 2:1 ethanol–acetone as bright orange crystals, m.p. 186–186.5° (dec.); mixed m.p. with the dipicrate of VII prepared by alkylation (equation 1; m.p.186–186.5° (dec.), Table III) was unchanged; mixed m.p. with XI dipicrate (m.p. 171.5–172.5° (dec.)) was depressed to 162–168.5° (dec.).

*Anal.* Calcd. for $C_{31}H_{33}O_{15}N_9$: C, 48.25; H, 4.31; N, 16.34. Found: C, 48.39; H, 4.52; N, 16.10.

**6-Methoxy-8-(2-isopropylaminopropylamino)-quinoline Dihydrochloride (VIII).**—One gram of XVII dihydrochloride was converted to the free base and reductively alkylated with acetone (1 ml.) in 15 ml. of absolute ethanol by the procedure described for VII. The theoretical amount of hydrogen was absorbed in one hundred minutes. VIII was isolated as the dihydrochloride in yellow needles, m.p. 234.5–235° (dec.); yield 0.9 g. (79%). A mixed m.p. with VIII dihydrochloride prepared by alkylation (equation 1; m.p. 232.5–233.5° (dec.), Table II) was 233–233.5° (dec.). A mixed m.p. with the isomeric XII dihydrochloride (m.p. 217.5–218.5° (dec.) was depressed to 205–207° (dec.)).

*Anal.* Calcd. for $C_{16}H_{23}ON_3 \cdot 2HCl$: C, 55.48; H, 7.28; N, 12.13; Cl, 20.48. Found: C, 55.11; H, 7.46; N, 12.37; Cl, 20.45.

The dipicrate prepared from this sample of VIII was recrystallized from 2:1 absolute ethanol–acetone and dried to constant weight at 40° and 1 mm.; m.p. and mixed m.p. with the dipicrate of VIII prepared by alkylation (equation 1; m.p. 188.5–189° (dec.), Table III) 188.5–189°.

*Anal.* Calcd. for $C_{28}H_{29}O_{15}N_9$: C, 45.97; H, 4.00; N, 17.23. Found: C, 46.23; H, 4.44; N, 17.04.

**2-Phthalimido-1-hydroxybutane.**—Phthalic anhydride (41.5 g.) was added in portions with cooling to a solution of 25 g. of 2-amino-1-butanol in 100 ml. of methanol. The methanol was removed by distillation and the residue was heated at 20 mm. in a bath at 180–200° until no more water distilled. Distillation of the residue gave 37 g. (60%) of 2-phthalimido-1-hydroxybutane as a very viscous straw-colored liquid, b.p. 155–159° (1 mm.); $n^{25}D$ 1.5613; $d^{25}_4$ 1.2107. $MD$ calcd. 57.18, found 58.66. A redistilled sample was analyzed; b.p. 180° (4 mm.); $n^{25}D$ 1.5617.

*Anal.* Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.39. Found: C, 65.78; H, 5.99; N, 6.48.

**2-Phthalimido-1-bromobutane.**—2-Phthalimido-1-hydroxybutane (45 g.) was added dropwise to 88.4 g. of phosphorus pentabromide, and after the addition the mixture was heated on a steam-bath until it became homogeneous. After cooling, 200 ml. of water was added, followed by potassium carbonate until the mixture was alkaline. The product was extracted with ether, dried over magnesium sulfate and distilled; yield 37 g. (64%), b.p. 159–162° (2 mm.). A redistilled sample of the viscous straw-colored liquid had b.p. 159–160° (2 mm.); $n^{25}D$ 1.5736.

*Anal.* Calcd. for $C_{12}H_{12}O_2NBr$: C, 51.08; H, 4.29; N, 4.97; Br, 28.33. Found: C, 51.05; H, 4.36; N, 4.97; Br, 28.16.

**6-Methoxy-8-(2-phthalimidobutylamino)-quinoline (XVIII).**—A mixture of 25 g. of 2-phthalimido-1-bromobutane and 17 g. of 6-methoxy-8-aminoquinoline was heated in a nitrogen atmosphere at 145–155° for twelve hours. The mixture was heated under reflux with 50 ml. of absolute ethanol, cooled, and filtered to remove 6-methoxy-8-aminoquinoline hydrobromide (11.3 g.). The filtrate was made acid to congo red with concd. hydrochloric acid and yielded a yellow crystalline salt (9.6 g.) which was converted to the free base (XVIII). After crystallization the yield of the yellow product was 6.9 g. (21%), m. p. 112–113°. Three recrystallizations from absolute ethanol gave an analytical sample with a constant m. p. of 113.5–114° (with previous softening).

*Anal.* Calcd. for $C_{22}H_{21}O_3N_3$: C, 70.38; H, 5.64; N, 11.19. Found: C, 70.31; H, 5.70; N, 11.25.

**6-Methoxy-8-(2-aminobutylamino)-quinoline Dihydrochloride (XIX).**—The procedure described for preparing XVII was used to convert 7.5 g. of XVIII to XIX; yield 5.0 g. (78%), m. p. 231–232° (dec.). After one recrystallization from absolute ethanol an analytical sample had a constant m. p. of 235–235.5° (dec.).

*Anal.* Calcd. for $C_{14}H_{19}ON_3 \cdot 2HCl$: C, 52.84; H, 6.65; N, 13.20; Cl, 22.28. Found: C, 52.86; H, 6.94; N, 13.39; Cl, 22.13.

**6-Methoxy-8-(2-cyclohexylaminobutylamino)-quinoline (IX).**—The reductive alkylation procedure described for preparing VII was applied to XIX (1 g.) and 1 ml. of cyclohexanone; hydrogenation was complete in fifteen minutes. IX was isolated as silky-white needles by crystallization from ethanol–water; yield 0.6 g. (58%), m. p. 61–61.5°. Recrystallization from ethanol–water raised the m. p. to 62–62.5°; mixed m. p. with IX prepared by alkylation (equation 2; Table II, m. p. 62–63°) was not depressed.

*Anal.* Calcd. for $C_{20}H_{29}ON_3$: C, 73.35; H, 8.93; N, 12.83. Found: C, 73.41; H, 8.95; N, 13.22.

The dihydrochloride of this sample of IX, recrystallized from absolute ethanol and dried to constant weight at 70° and 1 mm. had a constant m. p. and mixed m. p. with IX dihydrochloride prepared by alkylation (equation 2; Table II, m. p. 208–209° (dec.)) of 208–209° (dec.).

*Anal.* Calcd. for $C_{20}H_{29}ON_3 \cdot 2HCl$: C, 59.99; H, 7.81; N, 10.50. Found: C, 59.78; H, 7.92; N, 10.52.

The dipicrate of this sample of IX had a constant m. p. of 165–166° after one recrystallization from 2:1 ethanol–acetone and a mixed m. p. with IX dipicrate derived from the alkylation product (equation 2; m. p. 164–165°, Table III) was not depressed.

*Anal.* Calcd. for $C_{32}H_{35}O_{15}N_9$: C, 48.92; H, 4.49. Found: C, 48.63; H, 4.46.

**6-Methoxy-8-(2-isopropylaminobutylamino)-quinoline Dihydrochloride (X).**—One gram of XIX was reductively alkylated with acetone during two hours by the procedure described for preparing VIII. X was obtained in a yield of 0.8 g. (70%), m. p. 161.5–166° (with previous softening). Three recrystallizations from ethanol gave an analytical sample with a constant m. p. of 171–171.5° (with previous softening). The salt lost weight on drying

and appeared to be a hydrate; a sample dried at 40° and 1 mm. analyzed correctly for a hemihydrate.

*Anal.* Calcd. for $C_{17}H_{25}ON_3 \cdot 2HCl \cdot 0.5H_2O$: C, 55.28; H, 7.64; N, 11.38; Cl, 19.20. Found: C, 55.76; H, 7.36; N, 11.66; Cl, 19.12.

A mixed m. p. of this sample of X with X prepared by alkylation (equation 2; Table II, m. p. 177–179°) was 172–173°.

The dipicrate prepared from this sample of X, recrystallized from 4:1 ethanol–acetone and dried at 70° and 1 mm. had a m. p. of 137–138° (with previous softening) and was not depressed on mixture with X dipicrate prepared from the alkylation product (equation 2; Table III, m. p. 140.5–141°).

*Anal.* Calcd. for $C_{29}H_{31}O_{15}N_9$: C, 46.71; H, 4.19. Found: C, 46.76; H, 4.44.

## Summary

A number of derivatives of 6-methoxy-8-aminoquinoline have been prepared which are substituted on the 8-amino group by primary or secondary aminoalkyl side chains. A rearrangement proceeding through a tertiary ethyleneimine intermediate has been observed to occur in the alkylation of 6-methoxy-8-aminoquinoline with 1-alkylamino-2-chloropropane hydrochlorides (equation 1). 6-Methoxy-8-(alkylaminoalkylamino)-quinolines of known structure have been synthesized by first attaching primary aminoalkyl side chains to the 8-amino group through intermediate phthalimido compounds, and then reductively alkylating the primary aliphatic amino group with acetone and with cyclohexanone in the presence of Adams platinum catalyst and hydrogen. A 6-methoxy-8-(nitroalkylamino)-quinoline also has been reductively alkylated with these ketones under the same conditions.

# The Adsorption of Water Vapor on Activated Charcoal

BY EDWIN O. WIIG AND A. J. JUHOLA[1]

There will be presented in the papers that follow a method for measuring pore size distribution of charcoal which assumes that water on charcoal is held by capillary condensation. The main support for this assumption is that the pronounced hysteresis in the adsorption isotherm can best be accounted for by explanations based on the capillary condensation theory.[2,3,4,5] The results reported in this paper of studies of the changes in the density of adsorbed water with change in relative pressure and of the changes in the dimensions of an activated charcoal during adsorption and desorption lend further support to this theory.

## I. Linear Expansion of Charcoal

The change in length of charcoal rods as water and also various other vapors are adsorbed has been studied by numerous investigators.[6] In most of these investigations, which will be discussed later, relatively large carbon rods were employed whereas in the present work an activated gas mask adsorbent was used.

This charcoal, N-19, was prepared from hardwood sawdust, zinc chloride activated, extruded as rods 1/16 inch diameter, calcined at 600°, washed and calcined at 850°. It had an ash content of 0.2%, an apparent density of 0.48, a particle density of 0.80, a carbon density (by helium) of 2.09 and a surface area of 1300–1700 sq. m./g.

**Determination of Linear Expansion of Charcoal.**—The principal part of the apparatus for measuring the linear expansion of charcoal during adsorption and desorption is shown in Fig. 1. The inner tube A is filled with the extruded charcoal rods, 2–5 mm. long and 1.6 mm. diameter, placed end to end. The ends of each granule were squared off with emery cloth before being placed in the tube. B is a short piece of wire with squared-off ends placed on top of the charcoal column. Changes in length of the column during adsorption and desorption were observed by following with a cathetometer the movement of the upper edge of the wire with respect to a reference mark on the inner tube. The length of the charcoal column was 960 mm. and its weight was 0.920 g.

The tube assembly, which was weighed at intervals to determine the water content, was attached to an apparatus similar to that shown in Fig. 4 for the necessary evacuation of the sample, adsorption, desorption, measurement of the relative vapor pressure, etc. The charcoal column was thermostated at 24.4° with a water-cooled jacket.

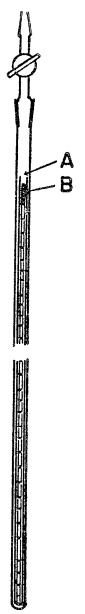

Fig. 1.—Apparatus for measuring linear expansion of charcoal.

## Results

The per cent. change in length of the charcoal column as a function of the relative pressure is shown in Fig. 2. It will be observed that, starting with dry char, as the humidity is increased the charcoal first contracts and then at $p/p_0 \sim 0.68$ begins to expand

until at $p/p_0 \sim 1$ it is 0.2% longer than at the start. Determinations on the adsorption wave were repeated to make certain the contraction was real. Contraction was again observed but the second set of determinations (broken line curve) did not quite coincide with the first. This displacement of the curve to the left may be due to the same cause as the displacement to the left of the second and subsequent adsorption curves of isotherms as in Fig. 5. On desorption a much greater contraction is obtained.

Except for the results of Haines and McIntosh,[6] which appeared while this work was in progress and with which the present observations are in essential agreement, the contraction obtained here would seem to disagree with the expansion noted by earlier workers. The experimental conditions are quite different, however, and appear to account for the differences in behavior. Most of the charcoals were not as highly activated as are modern chars. Meehan's[5] charcoal was prepared from three-inch cubes of yellow pine which were slowly dried and then heated uniformly for approximately four hours in a charcoal packed cylinder having small gas vents in its ends. After gradual cooling the charcoal so obtained was trimmed to approximately two-inch cubes. Some of the experiments of Bangham,[6] *et al.*, were carried out with rods cut from this charcoal. It would appear doubtful that such cubes could be completely carbonized near the center. Any oxygen structure remaining in the charcoal might easily produce immediate swelling as in wood itself. The oft quoted observation of Bangham and Fakhoury[6] that the first traces of water admitted to their char caused a marked expansion was made on an 80 × 8 × 8 mm. rod of German willow charcoal of pre-World War I manufacture. Again there is no way of knowing how thoroughly carbonized such charcoal might be. This charcoal was untreated except that between experiments it was "submitted to prolonged vacuum-heating at 220°" in the extensometer. On heating one of Meehan's charcoals to 1000° Bangham observed on adsorbing methanol at 20° that no measurable expansion occurred until 0.059 g. of methanol per g. of carbon had been adsorbed, then marked expansion set in at 0.07 g. per g., followed by a steady increase thereafter. This is in contrast with greater expansion on less rigorously treated samples.

McBain, Porter and Sessions[6] report only expansion for a rod (60 mm. long × 25 mm. diameter) of activated sugar charcoal. However, in the lower relative pressure range, where contraction was observed in the present investigation, these workers chose to hold the water vapor pressure constant and heated the charcoal to 37–61° to reduce the relative humidity. Since the surface tension changes with temperature, any contraction that might have occurred at lower temperatures may have been missed. Bangham observed no expansion by water vapor absorbed at 100° and a decrease in expansion by methanol at 50° compared to 0°. Also, Haines and McIntosh[6] found an expansion with dimehtyl ether at 20° but an initial contraction with a more sensitive extensometer at 6.5°. Using relatively large rods of a zinc chloride activated charcoal similar to that employed here, Haines and McIntosh observed no change in length with increase in water vapor pressure until $p/p_0 = 0.75$ was reached, after which expansion increased regularly. On subsequent desorption contraction below the original length and then expansion to the original length occurred as reported here. However, in a footnote they report that with their more sensitive electrical condenser arrangement for measuring the change in length of the charcoal rod a slight initial *contraction* was observed in the lower relative pressure range, analogous to the larger contraction in the present work.

The thermal effects which Haines and McIntosh observed on admitting vapors to charcoal might also contribute to the difference in behavior of the large rods of other investigators and the very small rods used here. With long relatively thick rods the vapor penetration must advance crosswise radially. The thermal effects should consequently be lengthwise. If the temperature is lower toward the center of the rod then perhaps contraction sets in crosswise and expansion, due to the higher temperature, lengthwise. Eventually the rod should reach equilibrium but the at-

tainment of equilibrium between a radial contraction and a lengthwise expansion might be slow, especially when one considers that charcoal is, as X-ray data indicate,[7] probably composed of small graphite platelets. At any rate, in the second condenser arrangement of Haines and McIntosh, where the thermal effect was smaller, a slight contraction rather than expansion was observed with water.

## II. The Density of Adsorbed Water

The density of water adsorbed on silica gel has been reported by Ewing and Spurway[8] to vary from 0.5408 for larger amounts of water to 1.0285 for smaller quantities. Danforth and DeVries[9] found densities for carbon tetrachloride adsorbed on activated charcoal which began at about 1.9, fell to a minimum of 1.36 and then rose to 1.58 as the vapor pressure was increased. Similar results were obtained with acetone. Morrison and McIntosh[10] have recently reported the density of water adsorbed on several activated charcoals. Their values, however, are quite different from those reported here.

Two charcoals were used in the present work: N-19, on which the linear expansion measurements were made; N-291-AY-1, a zinc chloride activated wood charcoal which was extruded through a seven-inch die in one step of its preparation and later crushed to small particles. The pore size distribution, etc., of this char are reported in detail in the following paper.

**Determination of the Density of Adsorbed Water.**—In principle the determination consisted of measuring by helium displacement the volume of a known weight of dry charcoal followed by similar volume measurements with varying amounts of adsorbed water.

The charcoal (16–20 mesh) contained in adsorption tube T, Fig. 3, was degassed at 360° for several hours, stopcock A closed and the thermostat water jacket J placed around T. In the case of charcoal N-291-AY-1 the adsorption tube had a volume of about 32 cc. and held 7.380 g. char. To obtain much greater accuracy the sample was increased tenfold for N-19. Gas buret B, with the mercury level at one of the constrictions between the bulbs, and the system to A were filled with helium to nearly atmospheric pressure, usually about 740 mm. as measured by mercury manometers 1 and 3. The pressure on both sides of the dibutyl phthalate null manometer 5 was adjusted to that of B. Stopcock A was opened to admit helium to the charcoal and the mercury level in B raised to increase the helium pressure to the initial pressure as determined by the null manometer. After equilibrium was reached, mercury was drained from B until the initial level was obtained and the mercury weighed. The volume of the weighed mercury was the volume of T, with or without charcoal as the case might be.

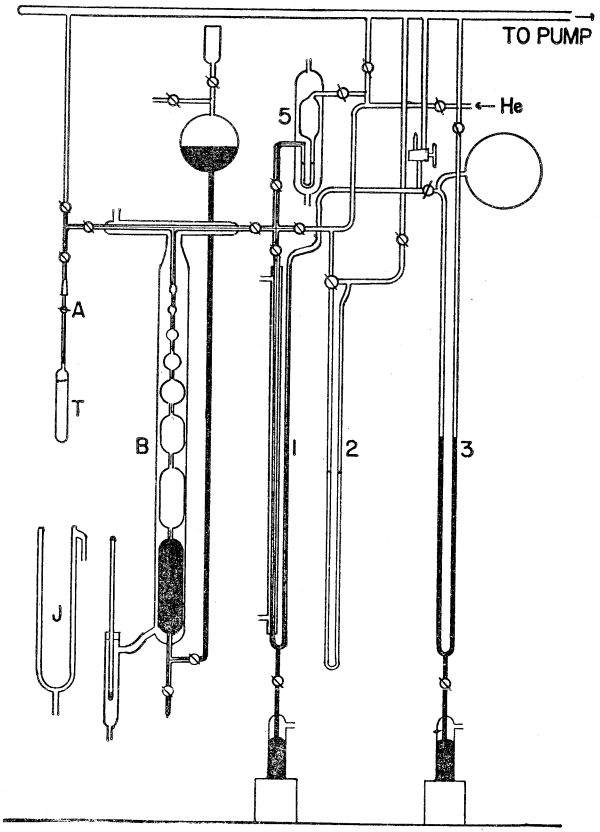

Fig. 3.—Apparatus for measuring apparent volume of adsorbed water.

When the charcoal contains adsorbed water a slightly different procedure was followed since a vapor pressure correction was necessary in the calculations. The water vapor was allowed to expand from T into B and over to dibutyl phthalate manometer 2, where its pressure was measured after attainment of equilibrium. Dead space corrections were negligible. The buret system to stopcock A was evacuated and from this point on the determination was the same as for dry char. Tube T contained a fine capillary below A which prevented diffusion of water vapor through the helium into B. The vapor pressure correction was introduced into the calculations through the relationship

$$V_t = \frac{P}{P - p} V_h$$

where $P$ is the helium pressure, $p$ the vapor pressure of the adsorbed water, $V_h$ the volume of weighed mercury, and $V_t$ the volume of tube T. An indication of the accuracy of the measurements is given by two sets of experiments with smaller than 16 mesh Pyrex glass particles in place of charcoal in tube T. The volume by helium displacement of, *e. g.*, 2.5 and 5.0 g. water on the glass

gave 0.997 for the density of water at 24° as compared to the accepted value of 0.9973.

**Determination of Water Adsorption Isotherms.**—The apparatus for determining the isotherms, which are needed in connection with both the density of adsorbed water and the linear expansion of charcoal, is shown in Fig. 4. Manometers M and N contained dibutyl phthalate, M measured $P$, the vapor pressure of adsorbed water, and N measured $P_0$, the saturation vapor pressure of water. A and C were three-way stopcocks with one of the outlets sealed to a capillary tube as shown in the diagram. During evacuation the stopcocks were turned so that gases passed through the larger outlets while during adsorption or desorption the stopcocks were turned so the water vapor passed through the capillaries. The purpose of the capillaries was to slow down the adsorption or desorption process sufficiently so that the pressure of the vapor surrounding the charcoal was not greatly different from the equilibrium pressure. The amount of water adsorbed was determined by weighing tube T. Flask B, containing water, and T were submerged in a water-bath maintained at about 24°, slightly below room temperature. While precautions were taken to prevent rapid changes in temperature, no effort was made to keep the bath at exactly constant temperature, since Coolidge[11] has shown that the water adsorption isotherm is not affected by temperature changes near room temperature.

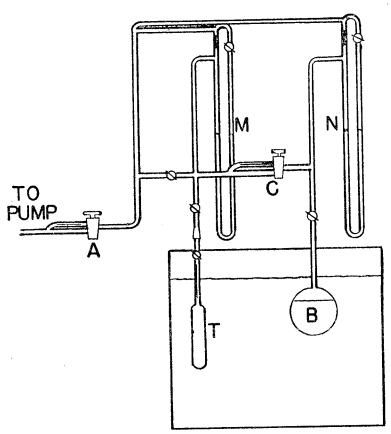

Fig. 4.—Apparatus for measuring water adsorption.

## Results

For the two charcoals studied the water adsorption isotherm is presented in Figs. 5 and 6, the apparent volume of adsorbed water in Figs. 7 and 8 and the density of adsorbed water in Table I. The latter, consistently less than unity, is in disagreement with the values 1.01 to 1.16, 0.95 to 1.04, 0.99 to 1.15 and 0.98 to 1.17 obtained by Morrison and McIntosh on four different charcoals but in line with their values of 0.95, 0.94 and 0.93 at 100% relative humidity. The present data would appear to be reliable; the high results

mentioned could be caused by either or both of two possible sources of error.[12] At first sight it might appear strange that the volume (or density) of adsorbed water does not reach the normal

TABLE I

(12) Small amounts of acid spray from the sulfuric acid solutions (stirred to hasten equilibrium) which were used to control the water vapor pressure might, as suggested by Emmett (private communication) have contaminated the water adsorbed on the charcoal. A more likely source of error is to be found in the method used to determine the volume of the adsorbed water by helium displacement. In making this determination helium, at high pressure and mixed with water vapor of the same partial pressure as that over the charcoal, was admitted to the charcoal tube. This has the effect of yielding a total water vapor pressure in the charcoal tube greater than the original partial pressure. Some of this extra water vapor should be adsorbed, resulting in a somewhat greater pressure drop, hence a smaller volume for the adsorbed water and an increased density. Though the system was open for twenty-four hours to allow attainment of equilibrium, the back diffusion of water vapor through two stopcocks and tubing filled with helium at relatively high pressure would be very slow. As the water content of a given char increases the effect of the extra pressure decrease will be smaller and the density will decrease, as was observed in general. *Cf.* Tuck, McIntosh and Maass, *Canadian J. Res.*, **26**, 20 (1948).

liquid state. Since these chars have a large volume of small pores, the voids prevent the attainment of the normal density.

## Discussion

The results of the measurements of the linear expansion of charcoal suggest that the expansion is a function of the relative vapor pressure and the weight of adsorbed water. It was found that the experimental data approximately obey the equation

$$L = kw(\ln p/P_0 - B) \qquad (1)$$

where $L$ is the per cent. linear expansion, $B$ is $\ln p_a/P_0$ where $p_a$ is the vapor pressure when $L = 0$ (*i. e.*, where $L$ changes from negative to positive), $w$ is the weight of adsorbed water per cc. of charcoal and $k$ is a constant. When the quantity $w(\ln p/P_0 - B)$ is plotted against $L$ as shown in Fig. 9, an essentially straight line is obtained, the slope of which gives $k$ a value of 2.8. The greatest deviation from this equation, indicated by the dotted line curve, occurs during contraction on adsorption at low partial pressures; the rest of the experimental points obey the equation quite well.

The contraction of the carbon structure can readily be accounted for by the capillary condensation theory which requires a contraction pressure or tension on the adsorbent. When the latter predominates—as in the intermediate pressure

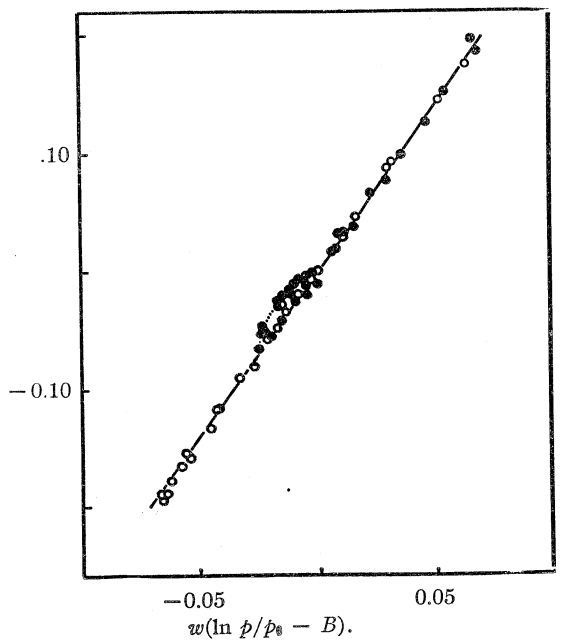

Fig. 9.—Percentage linear expansion $L$ of charcoal as function of logarithm of relative vapor pressure and weight of adsorbed water $w$ per cc. of charcoal: $B$ constant; ●, adsorption points; O, desorption points.

range, in which the pores are filled but in which the curvature of the menisci is still appreciable—contraction results but, as the tension is reduced, owing to decreased curvature of the menisci, the swelling pressure predominates and a net expansion results which increases to $P_0$. The constant $B$ may then be considered due to the swelling pressure similar to the swelling of any solid by a liquid.

A helpful picture which fits in with the data in the succeeding papers is as follows. The water molecules in pores behave as rigid spheres and due to the relative size of the pores as compared to the water molecules, there are larger voids between the molecules than exist in the normal liquid phase. Owing to their mutual attraction (hydrogen bonding), the molecules tend to squeeze into these voids and the result is an outward pressure exerted against the pore wall which appears as expansion of the charcoal. When the meniscus of the condensed water is in small pores, the meniscus exerts a negative pressure on the liquid which partially balances the mutual attraction between the molecules and, therefore, they do not tend to squeeze into the voids. The result is that the charcoal does not expand but rather contracts. As more water is adsorbed, the meniscus moves to larger pores, thereby decreasing the negative pressure (or increasing the hydrogen bonding since the molecules approach each other closer), and as a result the charcoal expands. It follows that if there were no voids between the water molecules there would be no expansion of the charcoal at the higher relative pressures. The length of the charcoal column during adsorption would pass through a minimum and come to its normal length at saturation.

According to the capillary rise equation a liquid is under a tension or negative pressure $P$ which varies inversely with the pore diameter $D$

$$P = -\frac{4\sigma \cos\theta}{D} \qquad (2)$$

where $\sigma$ is the surface tension and $\theta$ the contact angle of the liquid with the wall. Assuming adsorption of water by capillary condensation and the validity of the Kelvin equation

$$D = \frac{4V\sigma \cos\theta}{RT \ln P_0/p} \qquad (3)$$

where $V$ is the molar volume of adsorbed water, and substituting for $D$ in equation (2) one obtains

$$P = \frac{RT}{V} \ln p/P_0 \qquad (4)$$

During the contraction of charcoal the pressure on the carbon is equal to the pressure on the adsorbed liquid, equation (4), with the sign changed. If the per cent. linear expansion, $L$, is directly proportional to this negative pressure and to the amount of water adsorbed, then at constant temperature

$$L = k'\frac{w}{V} \ln p/P_0 \qquad (5)$$

This differs from equation (1) in that it contains the variable $V$ and constant $B$ is lacking. In the adsorbed water density studies it was observed that the maximum variation of $V$ was less than 5%, hence for approximate calculations $V$ may be considered constant. If then constant $B$ is attributed to the void effect mentioned earlier, equation (1) has some theoretical foundation.

If the water adsorption isotherms of the two charcoals in Figs. 5 and 6 are compared with the volume curves of adsorbed water on the same char in Figs. 7 and 8, it is evident that over nearly the complete range the volume (or density) is some function of the relative pressure. According to equation (4) any change in the relative pressure produces a change in pressure $P$ on the adsorbed liquid. The change in volume per unit volume of adsorbed water depends on this change in pressure on the liquid and the coefficient of compressibility $\beta$

$$\beta(P_2 - P_1) = -\frac{v_2 - v_1}{v_1} \qquad (6)$$

By proper combination of equations (4) and (6) one obtains

$$\beta RT\left(\frac{1}{V_2}\ln\frac{p_2}{P_0} - \frac{1}{V_1}\ln\frac{p_1}{P_0}\right) = -\frac{v_2 - v_1}{v_1} \qquad (7)$$

Values of $\beta$ are available only for positive pressures. Since $\beta$ increases with increasing tension or negative pressure, this change in $\beta$ was estimated from calculations based on the van der Waals equation, using $a = 7003$ and $b = 0.811$, and on equation (6). In making these calculations it was

assumed that the van der Waal's $P-V$ relationship would be an extension into the negative pressure range of its known behavior in the positive pressure range.

To test the relationship in (7) on charcoal N-291-AY-1 the value of the right side of the equation was calculated from the curves in Fig. 7. For a given weight of adsorbed water the volume on the desorption curve was taken as $v_2$ and on the adsorption curve as $v_1$. This gave the change in volume per unit volume when the relative vapor pressure was decreased from $p_1/P_0$ on the adsorption side of the isotherm to $p_2/P_0$ on the desorption side. The molar volumes $V_1$ and $V_2$ were calculated from $v_1$ and $v_2$, respectively.

In Fig. 10 the calculated values of the right side of equation (7) are presented graphically by the lower curve and the left side of the equation by the upper curve. Although the experimental accuracy of the volume measurements, shown by the vertical lines through the experimental points, does not warrant a quantitative comparison, the similarity in shape of the two curves does give a qualitative indication that equation (7) may be essentially correct.

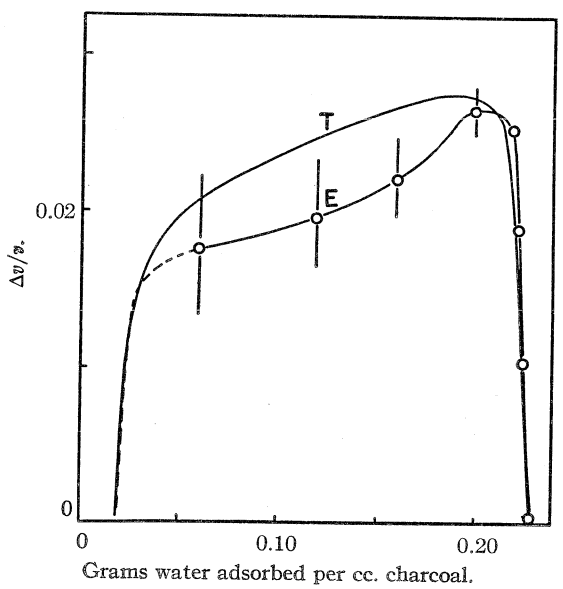

Fig. 10.—Change in volume per unit volume $\Delta v/v$ of the apparent volume of adsorbed water as observed experimentally and calculated from the isotherm: E, experimental; T, calculated; charcoal N291-AY-1.

The water density data obtained on N-19 were treated in a somewhat different manner. Figure 11 shows the molar volume of adsorbed water in equilibrium with relative water vapor pressures on the main desorption branch and the two scanning curves of the isotherm (Fig. 6) as a function of weight of water adsorbed. In Fig. 12 the solid line curves are the accumulated change in volume per unit volume of adsorbed water, starting at saturation in Fig. 11 and proceeding to lower moisture contents along the desorption and scanning curves 1 and 2. The broken line curves were calculated from the left side of equation (7) as for

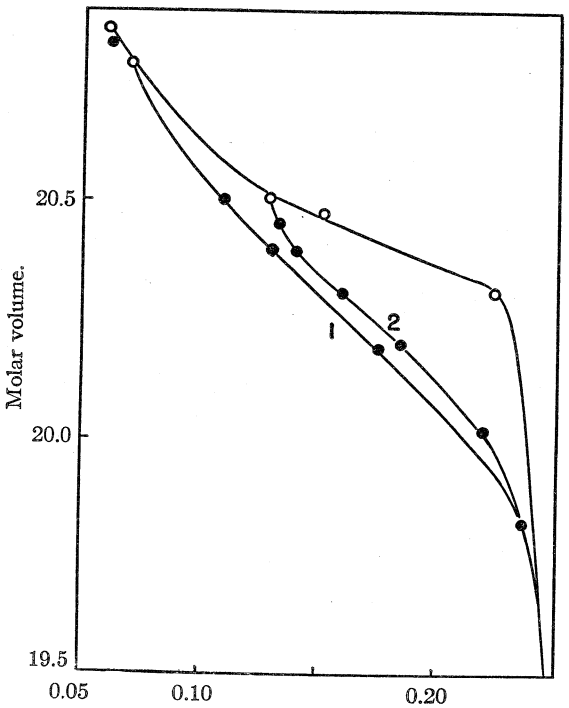

Fig. 11.—Molar volume of adsorbed water in equilibrium with relative vapor pressures on the main desorption and two scanning curves of the isotherm: ●, adsorption; ○, desorption; charcoal N-19.

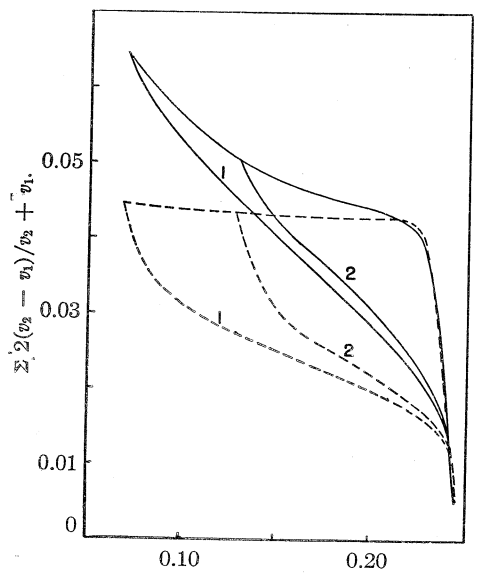

Fig. 12.—Change in volume per unit volume of adsorbed water in equilibrium with the desorption side and scanning curves of the isotherm: solid curves, experimental; broken line curves, theoretical; charcoal N-19.

charcoal N-291-AY-1. The agreement is good between the theoretical and experimental volume change in the range 0.21 to 0.25 g. water adsorbed per cc. charcoal but at lower moisture contents the experimental and theoretical curves begin to diverge.

The choice of N-19 for this study may have been an unfortunate one since an extra variable, which apparently did not exist in N-291-AY-1, appears to influence the molar volume of adsorbed water on this charcoal. For N-291-AY-1 the molar volume on the desorption side for a given weight of adsorbed water was always found to be greater than on the adsorption side. On N-19, however, the molar volume on adsorption at moisture contents below 0.13 g. was found to be greater than on the desorption side, as shown by the curves in Fig. 8. This crossing of the two curves may be attributed to the water adsorbed below 0.01 g. of moisture content, desorption side, having a very low molar volume. It appears that on adsorption, as more and more water is adsorbed, the previously adsorbed water molecules rearrange themselves into a closer packed state which is retained on desorption.

In order to avoid the complicating effects due to this rearrangement of the water molecules in the determination of the effect of the relative pressure on the molar volume, calculations were made only with data from the main desorption branch of the hysteresis loop and the two scanning curves. In Fig. 13 the differences between the curves in Fig. 12 were plotted against weight of water adsorbed in an attempt to cancel out the

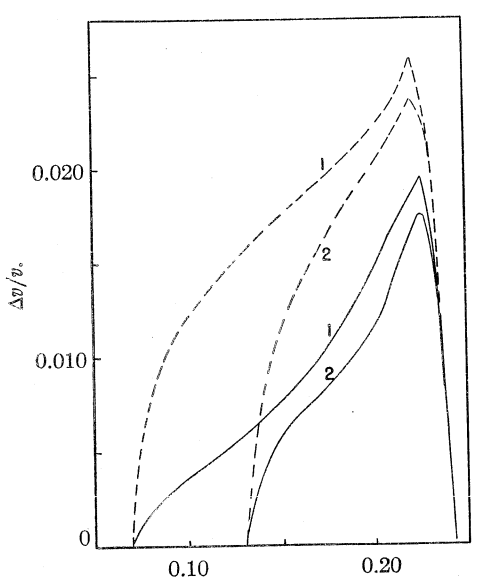

Fig. 13.—Change in volume per unit volume of the adsorbed water when the relative vapor pressure is decreased from the adsorption to the desorption side of the isotherm: solid curves, experimental; broken line curves, theoretical, charcoal N-19.

contribution of the submicro volume (which is apparently the volume of voids between water molecules in small pores) to the molar volume. Curve 1 in Fig. 13 was obtained by plotting the difference between scanning curve 1 and its desorption curve in Fig. 12 against the weight of water adsorbed. The other curves were obtained similarly. These curves represent the change in volume per unit volume for a given weight of adsorbed water when the relative pressure is increased from points on the desorption branch of the isotherm to points on the scanning curves. For N-19, Fig. 13, as for N-291-AY-1 in Fig. 10, a similarity exists between the theoretical and experimental curves, and again the magnitudes of the theoretical values are greater. These studies would appear to show that a definite relationship does exist between the relative vapor pressure and the molar volume of adsorbed water but the exact quantitative relation is complicated by the factors discussed above.

The evidence presented in this paper for the initial contraction of charcoal on exposure to water vapor, for a density of adsorbed water close to that of liquid water and for the similarity of experimental adsorbed water volume relationships with those calculated on the basis of capillary condensation would seem to constitute rather strong support for the capillary condensation theory. Additional support for the theory has recently been claimed by Broad and Foster[13] through their observation that isotherms of water and deuterium oxide on charcoal are identical (within 3%).

## Summary

Charcoal exposed to water vapor has been found to undergo an initial contraction followed by a subsequent expansion as the vapor pressure is increased. The per cent. linear expansion of the charcoal has been shown to be a function of the relative vapor pressure and the amount of water adsorbed. This relationship is expressed approximately by the equation

$$L = k'w\ (\ln p/P_0 - B)$$

which was partially justified on theoretical grounds by the capillary condensation theory.

The change in the volume per unit volume of adsorbed water was found to vary with the relative vapor pressure qualitatively according to a relationship derived from theoretical considerations based on the capillary condensation theory. For the density of water adsorbed on charcoal a value slightly less than unity was obtained.

# An X-Ray Diffraction Study of the Copper Chromites and of the "Copper-Chromium Oxide" Catalyst[1]

BY JAMES D. STROUPE

The "copper–chromium oxide" hydrogenation catalyst, effective for the liquid phase hydrogenation of some types of organic compounds,[2,3] is normally prepared by decomposing a copper ammonium chromate at low temperatures to give a material reported as "copper–chromium oxide," "copper chromite," "copper oxide–chromite," etc.[2] Of the descriptive names for the catalyst "copper–chromium oxide" appears to be the most generally accepted and will be used to designate the normal catalyst in the following discussions. In order to determine its real composition and to investigate its behavior by means of X-ray diffraction a similar study of the pure copper chromites has been necessary.

It is the primary purpose of this paper to report the characteristic powder diffraction data for cupric and cuprous chromites, to clarify the composition of the normal catalyst by means of positive identification of its components through their powder diffraction patterns and to further apply these data to the study of catalyst transformations during use and reclamation. All diffraction work was carried out on G.E. and Norelco apparatus using CuK$\alpha$ radiation.

## Cupric Chromite and Cuprous Chromite

Following the Groger[4] method for preparing the copper chromites, separate samples of precipitated chromate were given ignition treatments ranging from one hour at 700° to several hours at 1100°. After each ignition the crystalline product was leached with hot, concentrated hydrochloric acid until cupric ion no longer appeared in the filtrate and the diffraction pattern of cupric oxide could no longer be detected in that of the solid residue.

The washed products which had received the extremes of ignition treatment were found to be single, structurally different, crystalline compounds whose chemical analyses very closely checked those calculated for cupric chromite ($CuCr_2O_4$-low temperature) and cuprous chromite ($Cu_2Cr_2O_4$[5] high temperature), respectively. Tables IB and IC list the diffraction data for these compounds.

From their characteristic diffraction patterns, both chromites were identified in samples which had received intermediate ignition treatment, the cuprous salt systematically replacing the cupric chromite at higher temperatures. Since the unwashed products contained only cupric oxide in addition to the chromites, high temperature interaction of cupric oxide with cupric chromite to give cuprous chromite was indicated. Behavior of this system was determined by an extensive series of ignitions made in air. The three most important typical reactions, determined through positive diffraction identification of all solid components, are discussed below.

(1) Pure cupric chromite prepared by the Groger method was ignited at temperatures increasing from 700 to 1100°. The material was found to be relatively stable at low temperatures but to break down to give cuprous chromite and chromic oxide at high temperatures according to the simplified reaction

$$2CuCr_2O_4 \xrightarrow{>900^\circ} Cu_2Cr_2O_4 + Cr_2O_3 + [O]$$

(2) An intimate equimolar mixture of cupric chromite and cupric oxide behaved quite differently under the above ignition conditions. At temperatures below 900° these components were observed to combine slowly to form only cuprous chromite and oxygen; above 900°, this reaction could readily be driven to completion

$$CuCr_2O_4 + CuO \xrightarrow{>900^\circ} Cu_2Cr_2O_4 + [O]$$

(3) Though the cuprous chromite obtained in the above fashion was found to be entirely stable at room conditions it was completely reoxidized to the original components by "annealing" in air for several hours at temperatures between 600 and 700°. Thus

$$[O] + Cu_2Cr_2O_4 \xrightarrow{600\text{–}700^\circ} CuO + CuCr_2O_4$$

From the second observation the mechanism of formation of cuprous chromite at high temperatures in the Groger synthesis is apparent. Together with the final one these direct diffraction results verify the high temperature equilibrium claimed by L. and P. Wohler[6] from oxygen pressure measurements on a closed system originally containing an equi-molar mixture of cupric oxide and cupric chromite.

$$CuO + CuCr_2O_4 \underset{\text{"red heat"}}{\rightleftharpoons} Cu_2Cr_2O_4 + [O]$$

## The "Copper-Chromium Oxide" Catalyst

Preparation of the "copper–chromium oxide" catalyst by thermal decomposition of copper am-

(5) The double formula $Cu_2Cr_2O_4$ will be used instead of $CuCrO_2$ to more directly indicate the oxide composition ($Cu_2O \cdot Cr_2O_3$).

(6) L. and P. Wohler, *Z. physik. Chem.*, **62**, 445–453 (1908).

monium chromate was first described by Adkins and Connor[7] and by Lazier.[8] Many other ways of combining the oxides of copper and chromium have since been tried with varied success in catalytic application[2,3] but the most efficient catalysts have usually been obtained by some modification of the method originally suggested and blocked out below

$$\underset{\text{(Reactants)}}{Cu(NO_3)_2 \text{ soln.} + (NH_4)_2CrO_4 \text{ soln.}} \longrightarrow \underset{\text{(Intermediate precipitate)}}{\text{Complex chromates}} \xrightarrow[\text{decomposition}]{\text{low temperature}} \underset{\text{(Catalyst)}}{\text{"Copper–chromium oxide"}}$$

Connor, Folkers and Adkins[9] early suggested the partial replacement of copper by barium, and Calingaert and Edgar[10] claimed the following near quantitative reactions to describe the two step process.

$$2CuSO_4 + Na_2Cr_2O_7 + 4NH_3 + 3H_2O \longrightarrow 2Cu(OH)NH_4CrO_4 + Na_2SO_4 + (NH_4)_2SO_4 \quad (1)$$

$$2Cu(OH)NH_4CrO_4 \xrightarrow[\text{decomposition}]{\text{Low temp.}} \underset{\text{(Catalyst)}}{Cr_2O_3 \cdot 2CuO} + N_2 + 5H_2O \quad (2)$$

It is possible to carry out the decomposition step under sufficiently controlled low temperatures (350°) to secure "copper–chromium oxide" catalysts which are amorphous. At slightly higher ignition temperatures the presence of a fraction of very small crystallites is indicated by weak and broad diffraction bands. Ordinarily, however, the exothermic nature of the decomposition reaction makes its temperature control difficult and the normal ignited catalyst batch usually is a mixture of completely crystallized components.

Though one cannot determine the composition of amorphous catalysts by X-ray diffraction, it appears significant that only very slight differences in absolute chemical composition between amorphous and crystalline "copper–chromium oxide" catalysts can be detected and that a constant Cu:Cr ratio is maintained. Accordingly it seems reasonable to assume that the component composition of amorphous catalysts may be very similar to that of the crystalline catalysts normally prepared for production applications. Typical behavior of both the simple catalyst prepared according to the directions of Calingaert and Edgar and of the similarly obtained barium-modified catalyst has been determined by X-ray diffraction.

**Intermediate Precipitate.**—The barium-free intermediate was found to be a single, crystalline material having a chemical composition closely approximating the formula $Cu(OH)NH_4CrO_4$.[10] Partial (10%) replacement of copper by barium caused precipitation of crystalline barium chromate which appeared to remain substantially unchanged during catalyst decomposition, use and reclamation and therefore has been omitted from the discussion of the subsequent steps.

**Normal Catalyst.**—Decomposition of the above precipitate and ignition at 500° for two hours produced the finely divided, black, crystalline normal catalyst. From its diffraction data cupric oxide and cupric chromite were readily identified and their relative line intensities found to indicate an equimolar ratio. This latter result was closely checked by chemical analyses and is further substantiated by those reported by Calingaert and Edgar in their previous analytical study. Without claiming any such real compound they indicated the catalyst composition to be $Cr_2O_3 \cdot 2CuO$. The true mode of combination determined by the diffraction data is $CuCr_2O_4 + CuO$. Catalyst batches ignited above 600° were found already to show the expected partial combination of cupric oxide with cupric chromite to form cuprous chromite and at very high temperatures (1100°) this conversion was completed.

**Used Catalyst.**—X-Ray data from catalysts which had been used in a typical liquid phase hydrogenation below 300° often showed crystalline cupric chromite to have been largely reduced to the cuprous chromite in a reaction with cupric oxide competing with the reduction of this oxide to crystalline, metallic copper. The red color of such used catalysts has long been claimed—and is proved by the identifiable diffraction pattern of metallic copper—to be due to the finely divided metal and many empirical attempts have been made to prevent this reduction. The very low temperature reaction of cupric oxide with cupric chromite to produce the cuprous salt has not previously been considered and should be taken into account in further efforts to develop the catalyst and explain its behavior.

**Reclaimed Catalyst.**—It has been economically feasible to reclaim used "copper–chromium oxide" catalyst by burning off the residual organic materials with alcohol in open pans and reigniting the catalyst for two hours at 600°. Diffraction data from samples taken at various stages of the reclamation process show that the copper is readily reoxidized but that the cuprous chromite remains unchanged. From the previous study of the copper chromites it was apparent that, to obtain a catalyst composition identical with that of new material, a relatively long, low temperature "annealing" treatment would be necessary. A four to six hour annealing at 650° in air was found sufficient to reoxidize the cuprous chromite of the used catalyst to the cupric salt giving a material chemically and structurally identical with the original catalyst.

## Summary

The reactions involved in the copper chromite

system may be summarized in a sketch of the following type

## The Copper Chromite "Spinel"[11]

Cupric chromite has often been spoken of as a likely spinel-former though a careful check of the diffraction literature has failed to turn up data to prove the point. Among the most recent of such assertions are those of Selwood[12] who discussed the "spinel" obtained by high temperature ignition of an oxide mixture and of the "copper–chromium oxide" catalyst. Samples kindly provided by him and thought to be representative of the treatment given his samples no. 16 and no. 17 have been carefully re-examined in this Laboratory by X-ray diffraction methods. The "spinel" prepared by high temperature vacuum ignition of a 1:1 mechanical mixture of copper oxide and chromic oxide is heterogeneous containing free chromic oxide and cuprous chromite; that prepared by high temperature vacuum ignition of the normal copper chromite catalyst is identical in chemical composition and crystalline structure with the cuprous chromite obtained by our similar ignitions in air. These high temperature catalysts do not have the typical spinel composition; furthermore there is strong indication that the cuprous chromite really formed crystallizes on an hexagonal lattice instead of the cubic one required by the spinel structure.

Thin, single crystal plates of the cuprous chromite prepared in this laboratory by high temperature ignition of an equimolar mixture of cupric oxide and cupric chromite are optically isotropic in the plate view, anisotropic in the edge view, show a typical uniaxial interference figure and are characterized by angles of 60 and 120° between bounding edges. Laue data secured from plates mounted perpendicular to the X-ray beam show perfect hexagonal symmetry and axial lengths of the indicated hexagonal cell $a_0 = 2.975$ Å., $c_0 = 17.096$ Å. have been calculated from single crystal oscillation and powder back reflection data. A rough density measurement of 7.0 g./cc. by carbon tetrachloride displacement indicates two $Cu_2Cr_2O_4$ per unit cell. All lines of the CuK$\alpha$ powder diffraction pattern of this compound have been successfully indexed on the basis of the hexagonal cell and further work on the single crystal data is in progress.

(11) The "Spinel" structure is based upon a face-centered cubic unit cell containing eight $R_2MX_4$($Cr_2CuO_4$ in this case).

(12) P. W. Selwood, F. N. Hill and Harold Boardman, THIS JOURNAL, **68**, 2055 (1946).

In the following table are listed the interplanar spacings ("d") and estimated line intensities (I) found to be characteristic of (A) $Cu(OH)NH_4CrO_4$, (B) $CuCr_2O_4$ and (C) $Cu_2Cr_2O_4$, respectively. Line spacings have been approximately corrected for sample absorption and line intensities relate only to the strongest line of each pattern and do not permit direct intercomponent comparison.

## Summary

Cupric chromite and cuprous chromite have been prepared, chemically analyzed, characterized by their X-ray powder diffraction data and found to be related in the following way.

$$CuO + CuCr_2O_4 \underset{600\text{–}700^\circ}{\overset{900^\circ}{\rightleftharpoons}} Cu_2Cr_2O_4 + [O]$$

Crystalline $Cu(OH)NH_4CrO_4$ precipitated in the first step of the preparation of "copper–chromium oxide" catalyst, is decomposed at relatively low temperatures to produce an equimolar mixture of cupric oxide and cupric chromite, the normal catalyst. Very high temperature ignition of the catalyst causes their complete combination to form cuprous chromite. Microscopic and X-ray data indicate the latter substance to crystallize in the hexagonal system with two $Cu_2Cr_2O_4$ per unit cell, $a_0 = 2.975$ Å., $c_0 = 17.096$ Å.

Normal "copper–chromium oxide" catalysts used in typical low temperature hydrogenations show partial or complete reduction to metallic copper and cuprous chromite. Ordinary reclamation processes succeed only in removing organic matter and re-oxidizing the copper but complete return to the chemical composition of the original catalyst can be accomplished by a relatively long, low temperature "annealing" treatment.

# The Equilibrium $CaCO_{3(melt)} = CaO_{(s)} + CO_2$. The Activity Coefficients of Calcium Carbonate in Alkali Carbonate Melts

BY H. FLOOD, T. FÖRLAND AND B. ROALD

## Experimental

The equilibrium diagram of the system calcium carbonate–sodium carbonate–carbon dioxide ($p_{CO_2}$ = 1 atm.) has been examined by P. Niggli,[1] and later by W. Eitel.[2] A sketch of the diagram is shown in Fig. 1a. Only the right-hand side of the diagram is of interest in connection with the questions to be treated here. At the composition ratio 1:1, a compound ($CaCO_3 \cdot Na_2CO_3$) appears which is decomposed at temperatures above 817°. Solid calcium carbonate does not dissolve appreciable amounts of sodium carbonate. The solubility of calcium carbonate in the melt increases with the temperature (compare the curve DA). At about 900° the carbon dioxide tension of solid calcium carbonate exceeds 1 atm. Above this temperature only calcium oxide, not calcium carbonate, can exist in equilibrium with the melt. The composition of the melt in equilibrium with calcium oxide at 1 atm. carbon dioxide pressure is given by the curve AB. The curve AB has been only roughly estimated in the previous publications. Thus in the diagram of W. Eitel it is drawn with the curvature the wrong way.

By assuming calcium oxide insoluble[3] in the melt, however, the curve AB can be determined by a simple gravimetric procedure.

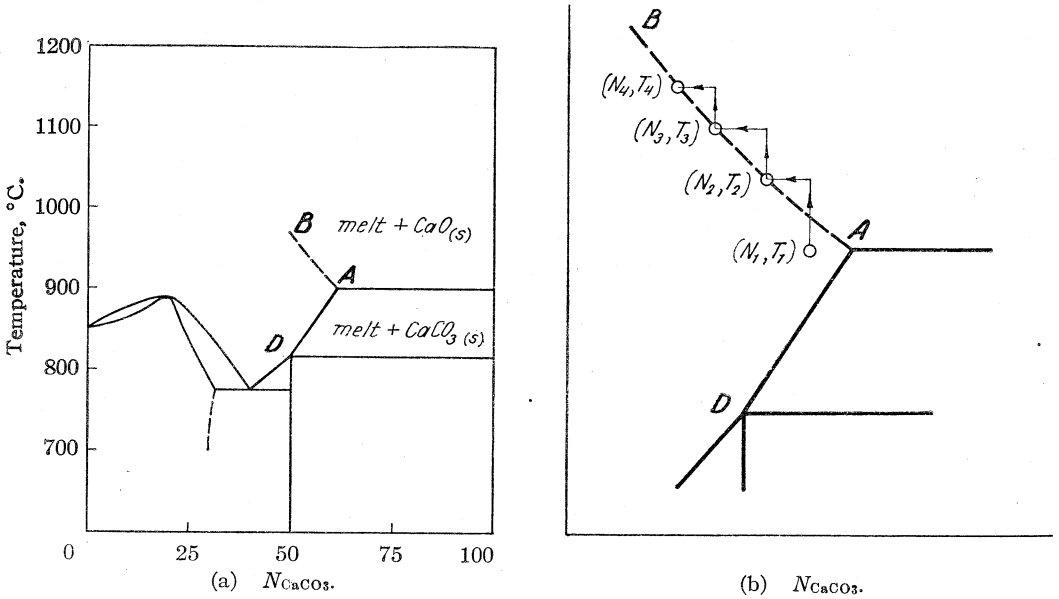
Starting with a melt, for instance, of composition and temperature corresponding to the point $N_1$, $T_1$ (compare Fig. 1b), and raising the temperature to $T_2$, calcium oxide will be precipitated and carbon dioxide expelled until the composition of the melt corresponds to $N_2$. This composition is given by the amount of carbon dioxide expelled, which is determined by weighing. By further raising of the temperature to $T_3$ another composition corresponding to $N_3$ will be found after adjustment of the equilibrium, etc. In this way the curve AB may be determined.

The experiments were carried out in an apparatus previously used in the investigation on the reactions of polyacids with alkali carbonate[4] (compare also ref. 1). As precipitated calcium oxide proved to re-dissolve very slowly in the melts, the experiments were always carried out at rising temperatures.

The platinum crucible with the weighed charge was placed in the heating zone of the furnace and kept there at a constant temperature about twenty minutes. Then it was quickly as possible removed, cooled in a desiccator and weighed (in a weighing bottle).

In addition to the system mentioned, the system with potassium carbonate was examined. Also a few experiments with lithium carbonate were carried out. The results are given in Table I and a graphical representation is shown in Fig. 2. The potassium and sodium systems give results with smaller limits of error than the lithium system. It seems that basic lithium melts may cause an attack on the platinum crucible.

TABLE I



| Experiment | Temperature, °C. | Mol. $10^{-3}$ CaO precip.-$CO_2$ expelled | $CaCO_3$ | $K_2CO_3$ | $N_{CaCO_3}$ |

Figs. 1a and b.—The equilibrium diagram of the system calcium carbonate–sodium carbonate when $p_{CO_2}$ = 1 atm.

## Discussion

The data given in Table I and Fig. 2 can be used for a discussion of the deviations of the melts from ideal solutions. We denote by $p'_{CO_2}$ the carbon dioxide pressure above a molten mixture of calcium carbonate and alkali carbonate in presence of solid calcium oxide according to the equilibrium

$$CaCO_3(m) = CaO(s) + CO_2(g)$$

On the other hand, the carbon dioxide pressure $p_{CO_2}$ according to the equilibrium

$$CaCO_3(s) = CaO(s) + CO_2(g)$$

is fairly well investigated. K. K. Kelley and C. T. Anderson[5] give the following formula for $p_{CO_2} = K$

$$RT \ln K = 42.500 + 1.52T \log T + 2.155.10^{-3}T^2 - 0.0205.10^5T^{-1} - 34.58T$$

In the following we denote the activities of calcium carbonate in the solid state by $a_s$, in the liquid state by $a_l$ and in molten mixtures by $a_m$. Then

$$a_m/a_s = p'_{CO_2}/K \qquad (1)$$

and when the carbon dioxide pressure above the melt is 1 atm.

$$a_m/a_s = 1/K \qquad (2)$$

Introducing $a_l$ in numerator and denominator we have

$$\frac{a_m}{a_l}\frac{a_l}{a_s} = \frac{1}{K} \qquad (3)$$

and

$$RT \ln \frac{a_m}{a_l} + RT \ln \frac{a_l}{a_s} + RT \ln K = 0$$

(5) K. Kelley and C. T. Anderson, Bull. 384, Bureau of Mines (1935).

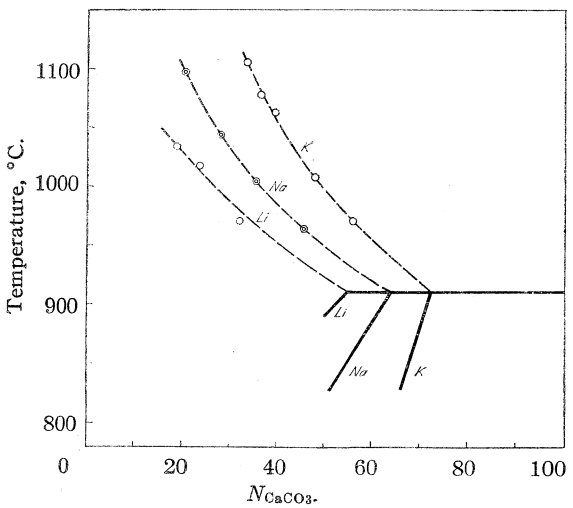

Fig. 2.—The equilibrium diagrams of the systems calcium carbonate–potassium carbonate, calcium carbonate–sodium carbonate and calcium carbonate–lithium carbonate when $p_{CO_2}$ = 1 atm.

The term $RT \ln \frac{a_l}{a_s}$ is the change in free energy for the process

$$CaCO_3(s) \longrightarrow CaCO_{3(\text{pure liquid})}$$

at the same temperature. If we denote the heat absorbed in the melting process by $\Delta H$, and $T_0$ is the melting point for calcium carbonate, we have

$$RT \ln \frac{a_m}{a_l} + RT \ln K + \Delta H \left(1 - \frac{T}{T_0}\right) = 0 \qquad (4)$$

neglecting the variation of $\Delta H$ with the temperature.

Now we will choose $CaCO_{3\,(\text{pure liquid})}$ as stand-

ard state. Introducing $f_1$ for the activity coefficient and $N_1$ for the mole fraction of calcium carbonate in the molten mixture, we get $a_1 = 1$ and

$$RT \ln f_1 = -RT \ln N_1 - RT \ln K - \Delta H \left(1 - \frac{T}{T_0}\right) \quad (5)$$

This equation contains two unknown $f_1$ and $\Delta H$. $T_0$ has been found by Smyth and Adams to be 1340°.[6] J. H. Hildebrand and E. J. Salstrom[7] have investigated mixtures of silver bromide–alkali bromide by aid of e. m. f. measurements. They find that the melts behave as "regular solutions"; this means that the entropy of mixing is the same as for an ideal mixture. This is expressed by the equation

$$RT \ln f_{AgBr} = bN^2_{Alk.\ Br.}$$

where $f$ is the activity coefficient, $N$, the mole fraction and $b$ a constant individual for each alkali metal. In the rubidium and potassium systems $b$ is positive, but in the sodium and lithium systems $b$ is negative. Hildebrand and Salstrom connect this with the fact that the ionic radii of the two former are larger than the radii of the two latter alkali metal ions.

We will now examine if similar simple rules are valid in the molten carbonate mixtures. From eqn. 5 we have

$$\frac{RT \ln N_1K}{1 - \frac{T}{T_0}} + \frac{RT \ln f_1}{1 - \frac{T}{T_0}} + \Delta H = 0$$

If the melt behaves as a "regular solution," we should get a straight line by plotting $-RT \ln N_1K/1 - (T/T_0)$ against $N_2^2/1 - (T/T_0)$ ($N_2$ is the mole fraction of alkali carbonate). Compare Fig. 3. It appears from the diagram that the experimental values, at least in the case of potassium and the sodium systems, are well represented by straight lines, with a mutual intercept for $N_2^2 = 0$, giving

$$\Delta H = 3.400 \pm 600 \text{ cal.}$$

We may therefore write

$$RT \ln f_1 = bN_2^2$$

where $b$ is an individual constant for each alkali carbonate system. The melts in fact seem to behave as regular solutions.

(The principal error in this calculation is caused by inaccuracies in the estimation of the temperature. The temperature in the heating zone was constant during the adjustment of the equilibrium with an accuracy of ±1°. This leads to an uncertainty in the computation of $K$ corresponding to d log $K$/d$T$ = 0.01. At 1000° this corresponds to ±70 cal.)

The slopes of the straight lines give values of $b$. The $b$-values of Hildebrand and Salstrom for the bromide systems, which also are given in Table II, show that the deviations from ideal solution are distinctly smaller in the bromide mixtures where the mixing cations are of equal electric charge than in the carbonate mixtures where the electric charges are different.

TABLE II

| | $CaCO_3 + (Alk.)_2CO_3$, cal. | $AgBr + Alk.\ Br$, cal. |
|---|---|---|
| K | −11500 | −1480 |
| Na | − 5500 | +1050 |
| Li | − 2400 | +1880 |

Having found the values of $\Delta H$ and $b$, we are able to give the formula for the calculation of the curve AB (Fig. 1) at any carbon dioxide pressure. For a carbon dioxide pressure ($p'_{CO_2}$) above the melt different from 1 atm., eqn. 3 will have the form

$$\frac{a_m}{a_1} \cdot \frac{a_1}{a_s} = \frac{p'_{CO_2}}{K}$$

and eqn. 5 will have the form

$$RT \ln p'_{CO_2} = RT \ln K + RT \ln N_1 + RT \ln f_1 + \Delta H \left(1 - \frac{T}{T_0}\right)$$

substituting for $RT \ln f_1$ we get

$$RT \ln p'_{CO_2} = RT \ln K + RT \ln N_1 + bN_2^2 + \Delta H \left(1 - \frac{T}{T_0}\right)$$

which is the equation for the curve AB at any carbon dioxide pressure. The limit $p'_{CO_2} = K$ corresponds to the co-existence of $CaCO_3$(s), (CaO(s)) and $CaCO_3$–$(Alk)_2CO_3$ melt. This gives the equation

$$RT \ln N_1 + b(1 - N_1)^2 + \Delta H(1 - T/T_0) = 0$$

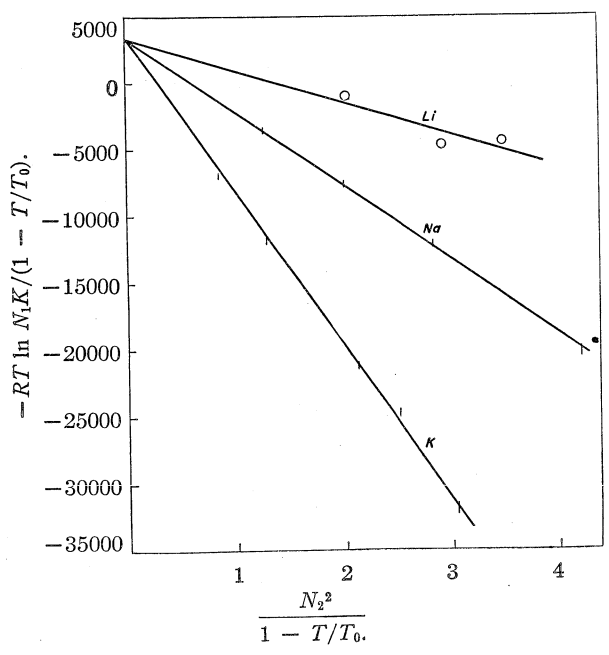

Fig. 3.

(7) J. H. Hildebrand and E. J. Salstrom, THIS JOURNAL, **54**, 4257 (1932).

(This result may also be derived from the Clausius–Clapeyron formula considering the melt as a regular solution.) The calculated curve checks only fairly with W. Eitel's measurements of the same phase diagram. However, there is also quite a difference in decomposition temperature for $CaCO_3(s)$ at $p_{CO_2} = 1$ atm. given by W. Eitel (900°) and given by K. Kelley (884°). Our calculations are based upon K. Kelley's data.

The authors express their thanks to Det Videnskapelige Forskningsfond av 1919 and Norges tekniske høgskoles Fond for grants.

## Summary

1. By means of a simple gravimetric procedure the composition of calcium carbonate–alkali carbonate melts in equilibrium with solid calcium oxide at a carbon dioxide pressure of 1 atm. has been determined.

2. On the basis of these results calculation of the activity coefficient of calcium carbonate in the melt is discussed. It follows that the carbonate mixtures behave as regular solutions.

3. The heat of fusion of calcium carbonate is calculated to 3400 cal.

# Reactions of the Silver Salts of Carboxylic Acids with Iodine in the Presence of Some Tertiary Amines

BY RALPH A. ZINGARO, JUDSON E. GOODRICH, JACOB KLEINBERG AND CALVIN A. VANDERWERF

Recent reports[1,2] that monopyridine iodine (I) *p*-nitrobenzoate is toxic *in vitro* to certain fungi have reawakened interest in base stabilized iodine salts of organic acids.[3]

The purpose of the present work was the preparation of a series of positive iodine salts of organic acids, using pyridine or α- or β-picoline as the coördinating agents, with the intent of finding new compounds which may be effective against bacteria and fungi. Thirty-one of these salts have been prepared and pertinent data concerning them are collected in the tables. The percentage yields are based on the silver salt used and not on the amount of iodine which reacted.

In those cases where pyridine was the coördinating agent, the aromatic acids used were selected in such a way as to permit comparisons of the effects on the yield of desired product of various substituents at different positions on the aromatic acid ring.

In many of the reactions where the yield of iodine salt was low, recovery of appreciable free acid was realized even under rigorously anhydrous conditions. For example, in the attempt to prepare α-picoline iodine (I) *p*-bromobenzoate, *p*-bromobenzoic acid was recovered in over 70% yield. This may mean that the formation of the iodine compound and the formation of the free acid are competing reactions.

## Experimental

**Preparation of Reagents.**—Since positive iodine compounds decompose in the presence of water, anhydrous conditions must be maintained throughout in their preparation. The chloroform and Skellysolve A were dried over calcium chloride and distilled; the commercial absolute ether was dried over sodium and distilled. The pyridine and α- and β-picoline were dried over sodium hydroxide pellets for two weeks and distilled, the distillates boiling at 114.5 and 128.1° at 740 mm. and 141.7° at 735 mm., respectively, being collected.

**Preparation of Silver Salts of the Acids.**—The organic acid was dissolved in hot alcohol and a hot aqueous solu-

[a] The success of the reaction for the synthesis of the iodine salt appears to decrease with decreasing electron withdrawing power of the ring substituents. Moreover, the yield of the desired product seems to depend upon the position of the substituent, decreasing in the order $p > m > o$. The reaction is unsuccessful when applied to acids which contain *o*-substituents exhibiting weak +I or +T effects, and to acids substituted in any position by groups, such as hydroxy and amino, which exhibit strong +T effects. [b] Decomposes over a wide range. [c] These compounds were prepared by treating the silver salts with a large excess of pyridine and less than the theoretical amount of iodine. If treated under ordinary conditions, a residue was obtained from which the acid could be isolated by extracting with Skellysolve A and removing the excess iodine with mercury. [d] This compound could not be salted out of solution, but the residue remaining after evaporation of the chloroform gave the compound after continuous washing with Skellysolve A and ether. These washings on evaporation yielded crystals identified as the acid. [e] This compound salted out of solution as a heavy, viscous liquid which crystallized on standing in the cold.

tion of sodium carbonate was added until the solution tested basic to litmus. Nitric acid was then added dropwise until the solution tested acid to litmus. Any solid present was filtered off and a hot aqueous solution of an equivalent amount of silver nitrate was added. The silver salt was removed by filtration, washed with distilled water and alcohol, and dried at 70°.

**Preparation of Positive Iodine Compounds.**—To a suspension of a few grams of the silver salt of the acid in dry chloroform, iodine was added with shaking until the solution remained light orange in color. A slight excess of the coördinating base was then added and the addition of iodine was continued until the solution again remained colored after shaking. The silver iodide was filtered and a volume of Skellysolve A from one to four times the volume of the solution, depending upon the solubility of the compound being prepared, was added. The solution was allowed to stand overnight in the dark and the solid which had precipitated was filtered, washed with ether (or with Skellysolve if the compound was soluble in ether), and dried *in vacuo* over sulfuric acid. The positive iodine compounds are white or pale yellow crystalline solids.

**Analysis of Positive Iodine Compounds.**—To a 0.05-g. sample of the iodine compound, an excess of potassium iodide solution was added. Five ml. of carbon tetrachloride was then added and the solution acidified with a few drops of acetic acid. The organic acid which separated was retained in the carbon tetrachloride layer and did not interfere with the analysis. Finally, the free iodine in the solution was titrated with a 0.01 *N* sodium thiosulfate solution.

**Acknowledgment.**—The authors wish to thank the Upjohn Company for their grant during the time this work was carried out.

## Summary

Thirty-one new compounds of positive univalent iodine coördinated with pyridine or α- or β-picoline have been prepared.

# Transference Numbers of Zinc and Cadmium Sulfates at 25°, as Functions of the Concentration

BY GERARD M. WOLTEN AND CECIL V. KING

The method of determining transference numbers by means of the ratio of the electromotive forces of concentration cells with transference to those without[1] is thought by some[2] to be capable of great accuracy.

To throw further light on this method and to provide additional data on transference numbers, we have applied this method to solutions of zinc sulfate and cadmium sulfate at 25°.

## Experimental

To measure the e. m. f.'s of zinc and cadmium sulfate concentration cells with transference, of the type MHg, $MSO_4(m')$, $MSO_4(m'')$, MHg, where MHg indicates an amalgam, we used a cell of the same design as used by Stokes and Levien.[3] A Leeds and Northrup type K-1 potentiometer and a no. 2500B galvanometer, with 8000 to 10,000 ohms in series for suitable damping, were used. To shield against electric leakage and stray currents, the equipotential shielding method of White[4] was used. The thermostat was kept at 25.00 ± 0.02°. All cells reached equilibrium within one hour and stayed constant for at least several hours. Duplicate cells were reproducible within 0.05 mv., each cell being constant within 0.03 mv. or better.

### Materials

Zinc, zinc sulfate, and cadmium sulfate were the "C. P. Analysed" reagent grade of the J. T. Baker Chemical Co. C. P. triply distilled mercury was obtained from F. W. Berk & Co. Cadmium was obtained from the Udylite Corp. and by spectrographic analysis shown to be 99.95%

pure. Distilled water was redistilled from a quartz vessel and swept with nitrogen. The concentrations of the zinc sulfate solutions were determined by titration with potassium ferrocyanide, using diphenylamine as internal indicator.[5] The titrations were performed upon weighed samples of the solutions, so that the molalities followed immediately. The solutions of concentrations lower than 0.5 molal were made by weight dilution from the more concentrated ones. The solutions of cadmium sulfate were made by dissolving the required amounts of anhydrous salt in known weights of water, since it is a standard analytical procedure to determine cadmium quantitatively by weighing it as the sulfate.[6] From the works of Puschin,[7] Bijl,[8] Henderson and Stegeman,[9] Bray,[10] Cowperthwaite and LaMer,[11] and LaMer and Parks,[12] it is evident that all of the amalgams used in this work exhibit an unvarying e. m. f. over a wide range of concentrations of the metal in mercury, including the concentrations used here. Since it was thus unnecessary to reproduce the amalgam concentrations exactly for each run, it was found most convenient to prepare the amalgams in small batches, using a fresh one for each determination. This eliminated any problems of proper storage of these materials. The amalgams were made by heating about 35 g. of mercury and enough zinc or cadmium to make 6 or 8% amalgams, respectively. The heating was done in a stream of nitrogen.

The corresponding concentration cells without transference are of the type

$$MHg, MSO_4(m'), PbSO_4(s), PbHg, PbSO_4(s), MSO_4(m''), MHg$$

The e. m. f. of such a cell is the difference between the e. m. f.'s of two cells of the type

$$MHg, MSO_4(m), PbSO_4(s), HgPb$$

where $m$ first assumes the value $m'$ and then $m''$. Bray[10] investigated such cells for M = Zn, and LaMer and Parks[12] for M = Cd. From these data, the e. m. f.'s of zinc sulfate and cadmium sulfate concentration cells without transference have been calculated. If one chooses identical concentrations for the reference electrodes of both types of cells, one can then use the well-known relationship $dE_t/dE = t$, to calculate the transference number ($t$) of the ion with respect to which the terminal electrodes are not reversible, the sulfate ion in this case. $E_t$ denotes the e. m. f. of a cell with and $E$ the e. m. f. of a cell without transference. For the computation of the differential coefficient, we used the method of Rutledge,[13] following the example of Stokes and Levien.[3,14] Unlike graphical methods of differentiating, the method of Rutledge enables one to utilize the full degree of accuracy of the original data. In this case, the gain is slight, but we like to draw attention to the method, which is an intriguing one.

## Discussion

The anionic transference numbers of zinc sulfate and of cadmium sulfate are shown graphically in Figs. 1 and 2, where they are compared with the values obtained by Hittorf, Jahn and co-workers.[15]

We have no explanation to offer for the discrepancy. We can, however, point out that the presence of complex-formation, which our results indicate, is strongly supported by the low values of the activity coefficients. According to Masaki and Ikkatai,[16] Bray,[10] and LaMer and Parks,[12] the activity coefficients of both zinc and cadmium sulfate are about 0.08 in a 0.3 molal solution. This is approximately the concentration above which our results indicate negative cationic transference numbers. It has also been shown by McBain and Van Rysselberghe[17] that the cations in solutions of magnesium, zinc and cadmium sulfates form negatively charged complexes in the presence of excess alkali sulfate. The cationic and the anionic transference numbers must necessarily add up to unity. We have determined the anionic transference number. The cationic transference number can be determined in a quite similar manner, by means of the cell

$PbHg, PbSO_4(s), MSO_4(m'), MSO_4(m''), PbSO_4(s), PbHg$

The use of lead amalgam requires the rigid exclusion of air,[10] and a cell must be used which makes this possible. Such a cell vessel differs from the one used in the present investigation. For this reason, measurements on the above cell have not been included in this work, but it is hoped to make such a report in a future communication from this department.

## Summary

The transference numbers of zinc and cadmium sulfate have been investigated at 25° by the method of electromotive forces.

# The Salts of Perrhenic Acid. II. The Iron Family and Manganese[1]

BY WILLIAM T. SMITH, JR., AND GROVER E. MAXWELL

The perrhenates of cobalt, nickel and manganese have been previously prepared and the colors and compositions of these salts reported.[2,3,4]

This paper deals with a more extensive examination of the composition and properties of the perrhenates of these metals in the divalent state as well as the perrhenates of iron in both di- and trivalent states.

**Preparation of the Salts.**—The carbonate or hydroxide of the metal was treated with a solution of perrhenic acid[5] and the hydrated salt was crystallized from the solution by evaporation at room temperature. All of these salts are deliquescent at the prevailing humidity in Knoxville during summer and were consequently crystallized by evaporation in a vacuum. In winter the crystallizations take place spontaneously in contact with the ambient air. The preparation of ferrous perrhenate was first attempted in an atmosphere of hydrogen. In spite of the precautions, approximately 10% of the iron present was oxidized to the ferric state, and the perrhenate so obtained suddenly became very viscous and black on evaporation at room temperature in a vacuum. This black semi-solid was very soluble in water giving a brown solution which on repeated evaporation gave the black semi-solid again. This solid was very soluble in ether although tests showed that neither the pure ferrous nor ferric perrhenate was

[a] Briscoe and co-workers[2] reported these compounds and also the pentahydrates of cobalt and nickel perrhenates. [b] This compound has been previously reported.[3] The trihydrate of manganese perrhenate was also reported by the same investigator but was not found in this investigation. [c] One sample of ferric perrhenate on rapid evaporation yielded a brown hydrate. On dehydration the product was also brown. [d] Solubilities of the lower hydrates and anhydrous salts were calculated from these measurements on the actual equilibrium system.

very soluble in this solvent. The possibility of this product being a covalent complex is being investigated. A more satisfactory method for producing ferrous perrhenate was the reduction of ferric perrhenate in solution with powdered electrolytic iron. The reduction, decantation and crystallization were carried out in a vacuum. On one such preparation of ferrous perrhenate the concentrated solution separated into two immiscible liquid phases. Both phases produced crystals of the same appearance and composition.

The anhydrous salts and lower hydrates were produced by dehydration of the salts which crystallized from water solution.

**Analysis of the Salts.**—The analyses were all duplicated and good checks were obtained. The method used for rhenium was a modification[5] of the method of Willard and Smith.[6] The iron was determined gravimetrically as ferric oxide.[7] The method used in determining cobalt as the pyrophosphate and oxide was one described by Schoeller.[8] The standard dimethylglyoxime method[9] was used for nickel. The pyrophosphate method[10] was used for manganese.

The determination of water in the different hydrates was made by dehydration. Ferrous perrhenate tetrahydrate was dehydrated over calcium chloride at room temperature. No inflection points in the dehydration curves were observed. No further significant loss in weight occurred in an oven at 105°. Ferric perrhenate tetrahydrate lost water over calcium chloride at room temperature. There is a decided break in the curve at a loss in weight corresponding to the conversion to the dihydrate. The rate at which water was lost from the dihydrate was approximately one-fiftieth of the rate observed for the tetrahydrate. The dihydrate becomes anhydrous on heating in an oven at 105°. Cobalt perrhenate tetrahydrate on drying over calcium chloride yields the trihydrate. The trihydrate loses water very slowly over fresh calcium chloride and was found to maintain a constant weight over somewhat spent calcium chloride. The anhydrous salt is obtained on heating in an oven at 105°. Although six samples were dehydrated under varying conditions the previously reported pentahydrate[2] was not observed. The tetrahydrate of nickel perrhenate is the most stable of the tetrahydrates of the perrhenates of the iron family. Some samples of this hydrate remained over calcium chloride for several months with only slight visible evidence of efflorescence on the corners of some crystals. This hydrate has been reported to be stable[2] at 100° but it was found in this study that heating to 100° yields the anhydrous salt and heating at 80° to constant weight yields the dihydrate. The pentahydrate which has been previously reported[2] was not found. Manganous perrhenate crystallizes

water solutions as the dihydrate. The dehydration curve for this salt over calcium chloride gave no indication of a lower hydrate. After dehydrating the salt to constant weight over calcium chloride no further loss in weight was observed at 105° in an oven. The results of the analyses are presented in Table I.

**Density Determination.**—The densities of the solid salts were determined by displacement of benzene at 25°. The pycnometer, containing the salt and benzene, was placed in a desiccator and the system evacuated until the benzene boiled for a few minutes. After the removal of dissolved and adherent bubbles of gas in this manner, the temperature of the system was allowed to rise to 25° before weighings were made. The method was checked using salts of known density. Results indicate that the method is good to about 0.5%. The densities for the hydrates which crystallized from water and anhydrous salts which had been fused were determined.

**Solubility Determinations.**—The solubility was determined by evaporation of water from weighed quantities of the saturated solutions. Since all of the salts are very soluble (see Table I) the solubility was determined at only one temperature, approximately 27°. The solubilities of the salts other than those which exist in equilibrium with the saturated solution were calculated from the data on those that do exist in the equilibrium mixture. While the solubilities are all of the same order there is a distinct increase in solubility of the salts in the following order: ferrous, ferric, cobalt, nickel and manganese.

**Freezing Points.**—None of the hydrates listed in Table I are stable at the melting point. In fact, all of them decompose to form anhydrous salts at or below 105°. Three of the anhydrous salts decomposed without melting. The decompositions resulted in the volatilization of the rhenium as heptoxide. Ferrous perrhenate, the least stable, decomposed rapidly in a low bunsen flame. A full bunsen flame was necessary to rapidly decompose ferric perrhenate while nickel perrhenate required an oxygen flame for rapid decomposition. The anhydrous cobalt and manganese perrhenates can be melted, although some decomposition occurs at the temperatures required. Despite the decomposition excellent checks on the freezing points were obtained (see Table I). The decomposition products apparently are insoluble in the molten perrhenates. The method used for determining the freezing points has been previously described.[5] The thermocouple gave standard Chromel–Alumel voltages at the freezing point of sodium chloride, 800.4 ± 0.5°.[11]

**Microscopic Examination of Crystals.**—All of the salts which were obtained by primary crystallization either from water solution or from the fused substance were examined in polarized light with a microscope. These crystals are all anisotropic.

**Magnetic Susceptibility Measurements.**—The unusual colors of the ferrous and ferric perrhenates indicate some different type of structure from that in most salts of iron. Magnetic susceptibility measurements were made in an attempt to throw some light on the structure. The molar magnetic susceptibility of ferric perrhenate in a saturated solution was found to be $14{,}000 \times 10^{-6}$ and for the solid tetrahydrate $15{,}200 \times 10^{-6}$. This gives 5.83 and 6.08, respectively, as the magnetic moments. The molar susceptibility for the ferrous perrhenate tetrahydrate was measured as $11{,}300 \times 10^{-6}$ which gives a magnetic moment of 5.21. According to Selwood[12] a moment of 4.90 corresponds to four unpaired electrons per molecule and 5.92 to five unpaired electrons. Thus, within the limits of experimental error, the iron apears to be in the states normally found in simple salts. The magnetic susceptibility measurements were made using a modification of the Curie–Cheneveau balance.[13,14] The modification consisted principally in having the magnet stationary and measuring the torsion on a wire necessary to pull a sample of given volume and shape from the field between the poles of the magnet. Solid ferrous ammonium sulfate which has about the same susceptibility as the perrhenates measured was used in standardizing the apparatus.

## Summary

The perrhenates of the iron family and manganese have been prepared and the formulas verified by analysis. The solids which crystallize from solution at room temperature are the tetrahydrates of ferrous, ferric, cobalt and nickel perrhenates and the dihydrate of manganese perrhenate. The dihydrates of nickel and ferric perrhenates and the trihydrate of cobalt perrhenate were also isolated. All of these salts are deliquescent at high summer humidities. All of the hydrates produced anhydrous salts at 105° or below. The densities of those substances obtained by primary crystallization were determined. The solubilities have been measured at room temperature. Freezing points have been obtained for the salts which could be melted under atmospheric pressure. Microscopic examinations of all primary crystals revealed they are optically anisotropic. The unusual colors of the perrhenates of iron are indicative of complex formation, although magnetic susceptibility measurements indicate that if complex linkages do exist in these compounds they have an ionic rather than a covalent nature.

# Quantitative Determination of Cobaltammine Ammonia. Application to the Determination of Ferrocyanide Ion

BY HAROLD A. HORAN AND HENRY J. EPPIG[1]

A modification of the analytical method ingeniously employed by Brönsted[2] for solubility measurements with the cobaltic ammines, can be adapted advantageously to the volumetric determination of anionic constituents which form quantitatively insoluble, filterable precipitates with common ammines such as hexammine cobalt (III) chloride. The determination of ferrocyanide ion by this adaptation is presented in the experimental part of this paper. Although the cobaltic ammines have been used for the gravimetric determination of anions,[3] the thermal instability of the precipitated ammines generally precludes weighing of the compounds as such. The necessary conversion to a suitable weighing form sacrifices time and an advantageous ratio of compound weight found per unit weight of constituent sought. The proposed volumetric procedure has the advantages of speed and accuracy. In essence the method is that commonly used for the determination of combined ammonia in ammonium salts, the presence of the many ammonia groups in the ammine compound serving to increase the accuracy of the calculated anion. The latter is simply precipitated with a cobaltic ammine cation. After filtering and washing, the precipitated ammine is decomposed with alkali under conditions such that its ammonia is quantitatively evolved and determined by the standard alkalimetric procedure. The anion is then calculated from the known ratio of ammonia to anion in the compound. As pointed out by Horan,[3d] the hexammines are more reliable as precipitants than the substituted complex ions such as $Co(NH_3)_nX_m$, X = Cl, $NO_3$, etc., and $n + m = 6$. The proposed methods are accordingly limited to hexammine precipitants.

In the initial stages of this work the quantitative evolution and determination of cobaltammine ammonia presented a problem which has been recognized by many, including those who first investigated the compounds nearly a century ago. Although Genth[4] originally employed simple alkaline decomposition of the ammine and absorption of the evolved ammonia in hydrochloric acid, Gibbs and Genth[5] later reported difficulty with this method. They indicated a loss of ammonia in the course of the decomposition, due to oxidation by tervalent cobalt. Even after prior reduction by agents such as sulfurous acid, this method was found to be unsatisfactory. Krok[6] and Jörgensen[7] experienced low ammonia analyses by this method, and Jörgensen showed that alkaline decomposition in the presence of the reducing agent stannous chloride did not obviate the difficulty; nitrogen results were at best 1% low. It seems paradoxical that Brönsted in his earlier works[2,8] used simple alkaline decomposition for the evolution of ammonia, and without a reducing agent. Later, Brönsted[9] claimed, contrary to Jörgensen,[7] that "accurate ammonia determinations for all compounds of this type can be carried out by decomposing with alkali, with or without addition of reducing agents such as stannous chloride." Neusser[10] referred to "incomplete decomposition" into ammonia when certain cobaltic ammines were decomposed by means of alkali. Recently Lamb and Mysels[11] mentioned a method developed by Lamb and Damon.[12] It involves a preliminary reduction of the cobalt in hot acid solution by means of stannous chloride, after which the solution is made alkaline and the ammonia quantitatively evolved. This modification, however, requires an extra step as compared with the direct alkaline decomposition which is the basis of the methods suggested in the present paper.

Repeated experiments in this Laboratory with several types of carefully purified cobaltic ammines, using varied concentrations of alkali and observing proper experimental and mechanical precautions,[13] confirm the conclusions of Gibbs and Genth,[5] namely, that accurate and precise ammonia values cannot be obtained when the compounds are decomposed by means of alkali alone. This is the case with solid samples or solutions of the compounds; it is characteristic of the cobaltic ammines in general, and can be ascribed to oxidation of ammonia by tervalent cobalt.[14] We have found, however, that alkaline

(14) This effect of tervalent cobalt on ammonia in alkaline solution can be readily observed by treating a solution of an ammonium salt and a tervalent cobalt compound, for instance potassium cobalt (III) oxalate $[K_3Co(C_2O_4)_3]$, with sodium hydroxide.

decomposition of stable hexammine and pentammine cobaltic salts in the presence of the soluble, alkaline-stable reductant, arsenious oxide, proceeds with the quantitative evolution of ammonia. Volumetric determinations of the latter, when the compounds are decomposed in this manner, are highly accurate and reproducible. The adaptation to determinations of cobaltammine precipitated anions is simple and direct, and the results obtained are excellent. The procedure is presently described for the determination of ferrocyanide. The precipitate which forms upon addition of hexammine cobalt (III) ion to ferrocyanide ion has the composition indicated by the formula $[Co(NH_3)_6]_4[Fe(CN)_6]_3 \cdot H_2O$.[15] Eight moles of ammonia are equivalent to one of ferrocyanide.

## Experimental

**Materials.**—The following ammines were prepared and carefully purified: hexammine cobalt(III) chloride,[16] hexammine cobalt(III) nitrate,[17] bromopentammine cobalt(III) bromide,[18] chloropentammine cobalt(III) chloride[19] and carbonatotetrammine cobalt(III) chloride.[20] The compounds were analyzed for cobalt and anion. *Anal.* Calcd. for $Co(NH_3)_6Cl_3$: Co, 22.03; Cl, 39.78. Found: Co, 22.05, 22.05; Cl, 39.74, 39.77. Calcd. for $Co(NH_3)_6(NO_3)_3$: Co, 16.98; $NH_3$ + $NO_3$ as N, 36.32. Found: Co, 16.98, 17.00; N, 36.23, 36.28. Calcd. for $[Co(NH_3)_5Br]Br_2$: Co, 15.36; Br (total), 62.46. Found: Co, 15.39, 15.37; Br (total), 62.42, 62.49. Calcd. for $[Co(NH_3)_5Cl]Cl_2$: Co, 23.53; Cl (ionized), 42.47. Found: Co, 23.59, 23.52; Cl (ionized), 42.42, 42.43. Calcd. for $[Co(NH_3)_4CO_3]Cl$: Co, 26.49; Cl, 15.93. Found: Co, 26.53, 26.44; Cl, 15.88, 15.89.

An aqueous solution of hexammine cobalt(III) chloride, containing 4.0 g. of the solid in 96 ml. of water, was prepared for use in the determination of ferrocyanide.

**Apparatus.**—For determination of ammonia, weighed samples were decomposed with sodium hydroxide solution in a 500-ml. Kjeldahl flask which was connected through a Davisson scrubber trap[13a] to a water condenser; the latter was fitted with an improved adapter[13c] at its outlet. The entire apparatus was made of Pyrex glass, in order to avoid rubber connections: 250 ml. of redistilled water, free of ammonia and ammonium salts, together with a suitable amount of sodium hydroxide was present in the flask at the outset. Most of the air within the apparatus was expelled[13c] before the sample was allowed to enter the alkaline solution. The distillate was received under standard sulfuric acid.

Typical results which were obtained with hexammine cobalt(III) chloride, when the decomposition was effected with different amounts of sodium hydroxide, are given in Table I. Similar results were obtained with other hexammines and also with the substituted ammines listed above.

**Potassium Ferrocyanide.**—Merck reagent potassium ferrocyanide was first purified by recrystallization from water between 25 and 0°, and then treated according to Loftfield and Swift[21] for final purification. The salt was dried to constant weight at 95° in an atmosphere of pure dry nitrogen. An exact weight of the salt was dissolved in sufficient water to make a solution of known total weight. The solution was measured from a weight buret, and the weight of potassium ferrocyanide taken was then calculated. Several different solutions were used in the course of this work; a typical composition was 1.3900 g. of the salt in 98.0355 g. of aqueous solution.

Table I

Ammonia Analyses; Samples Decomposed with Alkali Alone

Calcd. for $Co(NH_3)_6Cl_3$: $NH_3$, 38.20

| Sodium hydroxide present in flask | $NH_3$, found, % | |
|---|---|---|
| 5 ml. of 50% NaOH solution | 37.50 | 37.66 |
| 10 ml. of 50% NaOH solution | 37.85 | 37.78 |
| 25 ml. of 50% NaOH solution | 37.84 | 37.90 |
| 200 g. NaOH, solid | 37.95 | 37.90 |

**Arsenious Oxide.**—Merck reagent was used without further purification.

Blanks containing the redistilled water, sodium hydroxide and arsenious oxide (7.0 g.) were distilled into standard acid, and the amounts of the latter which were consumed were estimated by back titration. These were less than 0.03 ml. of 0.1 *N* acid.

**Standard Sulfuric Acid and Sodium Hydroxide Solutions.**—Solutions of these were prepared in 0.1 *N* and in 0.05 *N* concentrations, and were standardized by the usual methods. Methyl red was used as the indicator in ammonia determinations.

**Accurate Ammonia Analyses of the Cobaltic Ammines.** The failure to recover completely the ammonia of these compounds when the decomposition was effected by alkali alone (Table I), was the result of a reaction between tervalent cobalt and ammonia; no detectable nitrogen remained in the residues from such decompositions.

Preliminary experiments demonstrated that the stable, alkaline soluble reductant, arsenious oxide, reacted with many of the cobaltic ammines forming a clear, deep-purple colored solution. The evolution of ammonia in these cases was quantitative. The following procedure was finally adopted for accurate ammonia analyses. The Kjeldahl flask of the previously described apparatus was charged with 250 ml. of redistilled water, 15 g. of sodium hydroxide and 7 g. of arsenious oxide. A weighed sample (*ca.* 0.2 g.) of the ammine was suspended in the neck of the flask while most of the air within the apparatus was displaced[13c] by rapidly bringing the solution to the boiling point. The sample was released; reduction took place rapidly. Distillation was continued until about 80% of the solution was distilled over into the standard acid. The condenser was briefly steamed, rinsed and the titration of the remaining acid performed. Results are given in Table II.

Table II

Accurate Cobaltammine Ammonia Analyses in the Presence of Arsenious Oxide

| Ammine used | $NH_3$, % Calcd. | $NH_3$, % Found | |
|---|---|---|---|
| $Co(NH_3)_6Cl_3$ | 38.20 | 38.17 | 38.21 |
| $Co(NH_3)_6(NO_3)_3$ | 29.44 | 29.45 | 29.47 |
| $[Co(NH_3)_5Br]Br_2$ | 22.19 | 22.18 | 22.20 |
| $[Co(NH_3)_5Cl]Cl_2$ | 33.99 | 33.93 | 33.95 |
| $[Co(NH_3)_4CO_3]Cl$[a] | 30.61 | 30.43 | 30.48 |

[a] In connection with the low results obtained with this relatively unstable tetrammine, it should be noted that decomposition proceeded with the immediate formation of a small amount of dark brown precipitate, instead of the immediate formation of a homogeneous purple mixture.

**Determination of Ferrocyanide by the Cobaltammine–Ammonia Method.**—A suitable amount of potassium ferrocyanide solution (containing no more than 0.2 g. of the

salt) was discharged from a weight buret into a 50-ml. beaker and this solution, which contained a known amount of the salt, was diluted to 20 ml. with water. Hexammine cobalt(III) chloride solution was added dropwise with stirring, sufficient to provide an excess of 20–30% over that required to form $[Co(NH_3)_6]_4[Fe(CN)_6]_3$. The beaker was placed in cold water (about 4°) for twenty minutes, and the precipitate allowed to settle. The latter was quantitatively filtered on a dense filter paper (Whatman No. 5) and washed thoroughly with approximately 45 ml. of cold water. The filter paper containing the precipitate was folded carefully, tied with a thin wire and suspended in the neck of the Kjeldahl flask of the apparatus described above. The flask contained 250 ml. of redistilled water, 15 g. of sodium hydroxide and 7 g. of arsenious oxide. After rapidly bringing the contents of the flask to the boiling point in order to expel most of the air,[13c] the filter paper was released. The liberated ammonia was distilled rapidly into the standard acid in the receiver. The final steps were as described above under accurate ammonia analyses: 0.1 *N* acid was used for the larger amounts of ferrocyanide; 0.05 *N* acid was used for amounts less than 0.1 g.

Blank determinations with ferrocyanide included were not measurably different from those mentioned above under arsenious oxide. Results are given in Table III. They were calculated from the ammonia analyses found, on the basis of eight moles of ammonia equivalent to one mole of potassium ferrocyanide.

## Discussion

The results in Table III show that the proposed method for the determination of ferrocyanide is very reliable even when semi-micro quantities of this anion are under consideration. In such instances no special equipment is required, and it is unnecessary to use standard solutions of extreme dilution. These are decided advantages over the usual oxidation–reduction methods generally used for this constituent, since the oxidimetric gram-equivalent weight of potassium ferrocyanide is very high, 368.34; in determinations of quantities of the order of 0.025 g. one must use 0.01 *N* oxidizing agent and a micro buret. Furthermore, the cobaltammine–ammonia method permits results of higher precision and accuracy than the corresponding gravimetric method[3b] which uses hexammine cobalt(III) ion as the precipitant for ferrocyanide. This follows since the present method takes advantage of a found/sought mole ratio of $8NH_3/1K_4Fe(CN)_6$, in comparison to the unfavorable 0.503/1.00 (wt. ignited oxides found/wt. potassium ferrocyanide taken) factor of the gravimetric procedure. An additional disadvantage of the latter is the adverse influence caused by small, uncontrollable variations in the composition of the ignited residues.

The reliability of the weighing forms used in most gravimetric cobaltammine methods is questionable. Since the precipitates are generally unstable on drying at 100° the compounds are either dried at room temperature after the final removal of the aqueous phase with volatile organic solvents, or they are converted to mixed oxides of cobalt by ignition. In the first instance loosely bound or lattice water[22] may be removed to an indefinite degree; in the second, the existence of several oxides of cobalt, *viz.*, CoO, $Co_2O_3$, $Co_3O_4$, with uncertain ranges of thermal stability[23] is a source of indeterminate error.

In view of the large number of ammonia groups present, it is suggested that adaptations similar to that suggested for ferrocyanide ion should make it possible to determine accurately several other anions, which are quantitatively precipitated by hexammine cobalt(III) chloride.

## Summary

A direct, accurate, volumetric method for the quantitative evolution and determination of ammonia in the stabile hexammine and pentammine cobalt(III) salts is presented.

Use of this method for ammonia present in hexammine cobalt(III) ferrocyanide which has been quantitatively precipitated from a solution containing ferrocyanide ion, serves as a convenient and accurate means of estimating this anion.

Suggestions are made relative to similar modifications of cobaltammine methods for the determination of other anions.

# Low Temperature Thermal Data on Eight $C_8H_{16}$ Alkylcyclohexanes

BY HUGH M. HUFFMAN, SAMUEL S. TODD AND GEORGE D. OLIVER[1]

In continuation of the program of the Bureau of Mines,[2] to investigate the thermodynamic properties of petroleum hydrocarbons and related substances, low-temperature thermal studies have been made on eight $C_8H_{16}$ alkylcyclohexanes over the temperature range 12 to 300°K. This investigation of a group of isomers represents one of the most comprehensive studies of isomers yet made in the field of low temperature calorimetry. A number of interesting and unusual phenomena were observed which will be discussed. Insofar as the authors are aware this is the first published work on the low temperature heat capacity of these substances.

## Experimental

**The Materials.**—The materials used in this investigation were API–NBS "best" samples prepared by the A.P.I. Research Project 6 at the National Bureau of Standards[3] and certified by them in regard to their purity.

**The Apparatus.**—The measurements were made in the apparatus described by Ruehrwein and Huffman.[4] Very briefly, the method is as follows: About 0.4 mole of the material under investigation was contained in a sealed copper calorimeter, which was mounted in the adiabatic calorimetric system. A measured amount of electrical energy was supplied to the calorimeter, and at all times the temperature of the environment was maintained at that of the calorimeter to prevent heat interchange. The initial and final temperatures of the calorimeter were measured by means of a platinum resistance thermometer. The electrical measurements required for determining the resistance of the thermometer and for the electrical energy were made on a "White" double potentiometer in conjunction with a high-sensitivity galvanometer and accurately calibrated resistances. The potential was in terms of a bank of six saturated cadmium cells, which had been certified by the National Bureau of Standards. Time measurements were made with an electric stopclock driven by alternating current, the frequency of which was controlled with an accuracy of 0.001%. The precision of the measurements was, in general, better than 0.1%; and above 30°K., it is believed that the accuracy uncertainty, unless otherwise stated, should not be greater than 0.2%. The energy measurements were made in terms of the international joule and were converted to calories by dividing by 4.1833.

Melting-point studies were made on all of these compounds as a part of the routine measurements and the results are summarized in Table I. It should be borne in mind that the equilibrium temperatures given correspond to triple points since the material in all cases was sealed in the calorimeter under its own vapor pressure. Three of these

(1) Present address: Carbide and Carbon Chemical Corporation, Oak Ridge, Tennessee.

(2) Knowlton and Huffman, THIS JOURNAL, **66**, 1492 (1944).

(3) These samples of API–NBS hydrocarbons have been made available by the American Petroleum Institute and the National Bureau of Standards through the A. P. I. Research Project 44 on the "Collection, analysis, and calculation of data on the properties of hydrocarbons." The samples were purified at the National Bureau of Standards by the A. P. I. Research Project 6 on the "Analysis, purification and properties of hydrocarbons," under the supervision of Frederick D. Rossini, from material supplied by the following laboratories:

*Ethylcyclohexane, cis-1,3-dimethylcyclohexane, trans-1,3-dimethylcyclohexane, 1,1-dimethylcyclohexane, cis-1,2-dimethylcyclohexane* and *trans-1,2-dimethylcyclohexane*, by the A. P. I. Research Project 45 on the "Synthesis and properties of hydrocarbons of low molecular weight" at the Ohio State University, under supervision of Cecil E. Boord.

*cis-1,4-Dimethylcyclohexane* and *trans-1,4-dimethylcyclohexane*, by the Standard Oil Development Co., Elizabeth, N. J. through the courtesy of W. J. Sweeney.

(4) Ruehrwein and Huffman, THIS JOURNAL, **65**, 1620 (1943).

[a] Calculations based on these experimental points.

compounds have small cryoscopic constants, and consequently the triple points may be expected to differ significantly from the melting points which are observed when the liquid materials are saturated with air at atmospheric pressure.

In the case of ethylcyclohexane, which has a low cryoscopic constant, the melting point study was repeated several times to test the precision of the measurements. The results of this study are shown in Fig. 1 which is a plot of $T$ against $1/F$, where $T$ is the absolute temperature and $F$ is the fraction melted. The extreme experimental difference is seen to be slightly greater than 0.002° but in any single series of measurements the precision of measurement is much better than this. In addition to the melting point measurements a single freezing-point[5] measurement was made. This point was approximately 0.015° below the melting-point curves. These data tend to confirm the hypotheses that equilibrium temperatures may be a resultant of the way the material is treated and not necessarily a true equilibrium.

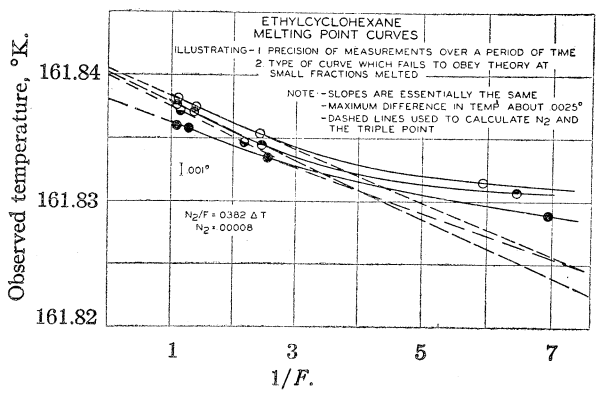

Fig. 1.—Melting point curves for ethylcyclohexane.

In the case of *trans*-1,2-, *trans*-1,3- and *trans*-1,4-dimethylcyclohexane there is some uncertainty in the melting points for pure material and for the mole fraction of impurity in the sample because in none of these materials was it possible to obtain an unambiguous value for the heat of fusion. The uncertainty due to this factor will not be very great in the absolute sense.

## Results

The experimentally determined heat capacities are given in Table II. In Table III are listed specific heat data at integral temperatures as selected from a smooth curve drawn through all of the data. The specific heat data for crystalline *trans*-1,3-dimethylcyclohexane may be less accurate than that of the other compounds for reasons which will be discussed later.

The molal heats of fusion of these compounds are given in Table IV. The uncertainties given are in all cases precision uncertain-

(5) Freezing point means the equilibrium was approached after crystallizing a portion of the material rather than melting.

TABLE II

THE MOLAL HEAT CAPACITY OF THE $C_8H_{16}$ ALKYLCYCLOHEXANES

0°C. = 273.16°K., mol. wt. = 112.208

ties. The accuracy uncertainty may be considerably greater because of premelting and other effects.

Two of these compounds, 1,1-dimethylcyclohexane and *cis*-1,2-dimethylcyclohexane, had isothermal transitions of considerable magnitude. The transition temperature was studied in the usual way by observing the equilibrium temperatures corresponding to various fractions transposed. The transition temperatures are 153.15 ± 0.05°K. and 172.5 ± 0.1°K., respectively. Duplicate measurements were made of the heats of transition and these values are given in Table V.

The thermal data obtained over the temperature range 12 to 298.16°K. were used to calculate the entropies of these compounds in the liquid state. The results of these calculations are summarized in Table VI.

In order to compare the experimental values with those obtained from theoretical considerations it is necessary to convert the experimental values to the hypothetical gaseous standard state of one atmosphere and 298.16°K. This has been done using the data from the A.P.I. Research Project 44 tables[6] and the results are given in

(6) Selected Values of Properties of Hydrocarbons, Circular of the National Bureau of Standards C461, p. 172.

Table VII. The entropies calculated by Pitzer, *et al.*,[7] have been included for comparison.

## Discussion

A number of interesting phenomena were noted in studying these compounds and will be discussed in the following section. As mentioned previously, *cis*-1,2-dimethylcyclohexane undergoes an isothermal transition at 172.5°K. The rate of transition from the high temperature form (crystals II) of *cis*-1,2-dimethylcyclohexane to the low temperature form (crystals I) was extremely slow. The maximum rate of transition occurred at a temperature 10 to 15° below the transition temperature. Even at this temperature, approximately one week was required to complete the transformation. Because of the slowness of the transition it was readily possible to supercool crystals II without any significant formation of crystals I. Consequently, heat capacity measurements were made on both crystalline forms from liquid hydrogen temperature up to the transition temperature, 172.5°K.

A plot of the molal heat capacity of both crystalline forms is shown in Fig. 2. The most interesting part of the plot is the rapid rise in the heat capacity of crystals II at about 95°K. This rapid change in the heat capacity over a short tempera-

ture interval is very similar to that behavior which is characteristic of organic glasses. A similar case was observed by Kelly[8] in his investigation of cyclohexanol, *i. e.*, the unstable crystals II could be easily supercooled to liquid hydrogen temperature and showed the glassy bump.

Since crystals II have a low heat of fusion, 393 cal. per mole, and a high heat capacity, about 6% less than that of the liquid at the melting point, it seems reasonable to postulate that the molecules are free to rotate in the lattice. However, as the material is cooled it is possible that the restrictions to rotation become greater and a major part of the rotation is frozen in a short temperature interval, thereby causing the rapid change in the

(8) K. K. Kelley, THIS JOURNAL, 51, 1400 (1929).

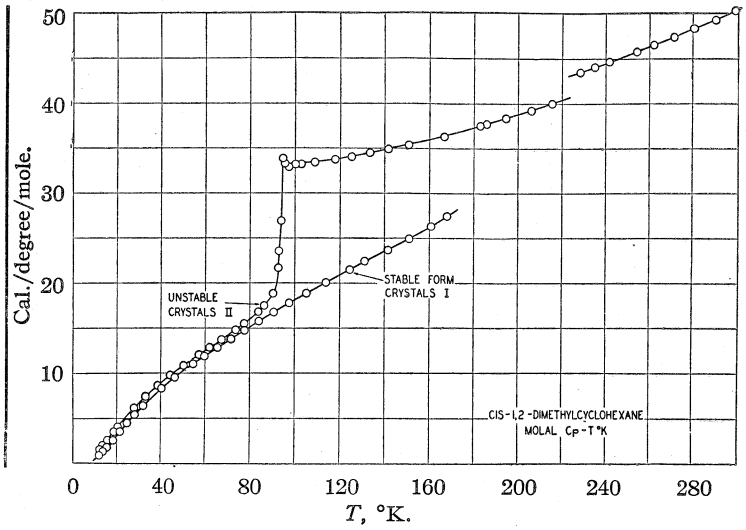

Fig. 2.—Heat capacity curves for the two different forms of *cis*-1,2-dimethylcyclohexane.

heat capacity. When crystals II were rapidly cooled and maintained under adiabatic conditions for a long period of time at a temperature about 10° below that of the rapid rise in heat-capacity curve, heat was evolved. This liberation of energy could be associated with the decrease in the energy of the crystals as the molecules reorient themselves toward equilibrium positions in the crystal lattice.

Since heat-capacity measurements were made on both crystalline forms from liquid-hydrogen temperature, the entropy of crystals II was calculated graphically at 172.5°K. over two different paths. These calculations showed the super-cooled crystals II to have a residual entropy of 2.06 E.U. at 0°K. Since *cis*-1,2-dimethylcyclohexane is a mixture of *d* and *l* forms, a part of this residual entropy can be explained if it is assumed that crystals II is a solid solution of the *d* and *l* forms that persist to 0°K. Thus the value for the entropy of mixing, 50-50 mixture, which is $R$ ln 2 would account for 1.38 E.U. of the observed residual entropy. This leaves approximately 0.6 E.U. unaccounted for and it is possible that imperfect orientation of the molecules is responsible for this difference. However, since there is no positive evidence that a solid solution is formed, it is possible that all of the residual entropy is due to the randomness or disorder of the rapidly cooled crystals.

The *trans*-1,4-dimethylcyclohexane heat-capacity curve, as shown in Fig. 3, has an unusually rapid rise in the temperature region below the melting point. The highest experimental heat-capacity point has an approximate value of 300 cal./mole at 236.0°K. It was first thought that this rapid rise in the curve was due to premelting. However, from the melting point studies, the amount of impurity was calculated to be 0.007 mole per cent. on the assumption that the system obeys Raoult's law. The premelting effect due to this amount of impurity would change the molal heat capacity only 0.1 or 0.2 cal./deg. at 236.0°K., which is insignificant as compared to the magnitude of the experimental value observed. Hence, the unusually steep slope of the curve cannot be due to premelting.

It appears unlikely that the observed behavior is associated with an impurity and hence it is believed that it is characteristic of the material and may be explained as follows. Since the shape of the curve is similar to the low temperature side of a *lambda* point we can assume that a second order transition started but melting took place before the transition was completed.

Egan and Kemp[9] observed a similar effect in the heat-capacity curve of ethylene and explained it in a like manner.

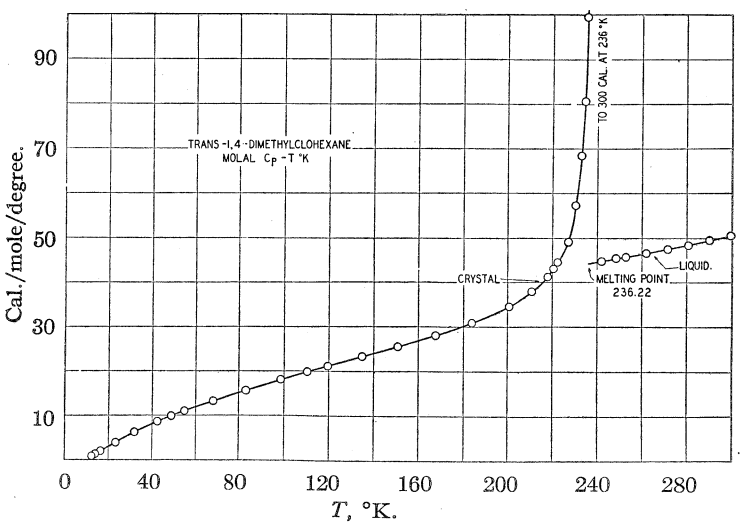

Fig. 3.—Heat capacity curve for *trans*-1,4-dimethylcyclohexane showing high heat capacity of crystals below the melting temperature.

Because of this rapid rise, it was impossible to extrapolate the heat-capacity curve to the melting point with any great reliability. Consequently, it was impossible to calculate an accurate value for the heat of fusion by the usual methods. This uncertainty will be reflected to some extent in the accuracy of the calculated melting point and the amount of impurity; but fortunately, the amount of impurity is probably small so that the accuracy

(9) C. J. Egan and J. D. Kemp, THIS JOURNAL, **59** 1264 (1937).

will not be greatly affected in the absolute sense and the reliability of the results will depend principally on how closely the system obeys Raoult's law.

In the study of *trans*-1,2-dimethylcyclohexane four measurements of the heat of fusion and two melting-point determinations were made. The heats of fusion fell into two internally consistent groups which appeared to be related to the manner in which crystallization was initiated. If the liquid material was cooled rapidly to about 85°K. and crystallization was initiated by slowly heating the undercooled liquid, crystals were obtained which gave the high heat of fusion. However, if crystallization was initiated by allowing the liquid to cool slowly across the vacuum and crystallization to take place spontaneously, crystals were obtained which gave the lower value for the heat of fusion. Melting-point studies were made on crystals obtained by both of these methods. These data gave melting points (for pure material) which differed by only 0.006° which is not a very large difference but greater than the expected error of the measurements. The higher melting point was associated with the material having the lower heat of fusion. If it is assumed that there are two crystalline forms of this material, the above data show that the high melting form, although the stable form at its melting point, will have to become the unstable modification at some lower temperature. Furthermore, if both forms obey the third law, the high-melting form, with the low heat of fusion, will have to have a higher heat capacity in some portion of the temperature range or will have to undergo a transition in order to gain the necessary entropy. Our measurements show that above 90°K. the high melting form does have the higher heat capacity by a small but significant amount. In the temperature range 50 to 90° the heat capacity of the two forms are identical within the experimental error. Assuming the postulate of two crystalline forms is correct, the entropy was calculated over the two paths and found to differ by only 0.04 cal./degree which is within the experimental error.

This explanation is substantiated further by an unpublished investigation made in this Laboratory on ethylcyclopentane in which were found, very definitely, two crystalline forms with melting points differing by 0.7°, the stable high-melting form having the lower heat of fusion by approximately 170 cal./mole. The high-temperature form has the higher heat capacity over the entire temperature range from 12° to the m. p. and the entropies over the two paths are identical.

In the case of *trans*-1,3-dimethylcyclohexane it was found impossible to obtain a satisfactorily reproducible value for the heat of fusion. A great many experiments were tried in which the method of crystallizing was varied as widely as was experimentally convenient. At this time it is not possible to explain the reason for the observed behavior of this material. However, the authors are inclined to believe that it is probably due to a very slow rate of crystallization as the crystallization approaches completion. Because of the above effect, the thermal data on this compound are much less reliable than is characteristic of data from this Laboratory. The value for the heat of fusion given in Table IV is the highest value observed but not necessarily the correct value. The value of the entropy calculated from these data will also be less reliable than usual.

Table VII shows that the experimental and calculated values[6] of the entropies are in excellent agreement when the old labels on *cis* and *trans*-1,3-dimethylcyclohexane are interchanged as proposed by Pitzer and Beckett.[10]

## Summary

The heat capacities of eight $C_8H_{16}$ alkyl cyclohexanes have been given over the temperature range 12 to 300°K.

Melting points, transition temperatures, heats of fusion, and heats of transition for these compounds have been given.

Entropy values have been calculated for the liquid and gaseous state at 298.16°K.

RECEIVED AUGUST 30, 1948

# Thermal Cracking of Higher Paraffins

BY H. H. VOGE AND G. M. GOOD

The decomposition of paraffins with two to eight carbon atoms has been quite well explained as being predominantly a chain reaction involving free radicals. The radical theory accounts for the products,[1,2] the inhibition of cracking by nitric oxide[3,4] and olefins,[4] and the initiation of cracking by mercury dimethyl[5] and other materials that readily produce radicals.[6] In addition, alkyl radicals have been detected in hydrocarbon systems undergoing decomposition at reduced pressures.[2,7] The cracking of paraffins containing more than eight carbon atoms has not been adequately tested against the theory, yet such materials offer a more stringent test of predicted products of reaction. Although a few examples of the cracking of higher hydrocarbons are to be found in the literature, such as the fine early studies of Gault and Hessel[8] and Gault and Sigwalt,[9] they are not adequate for detailed comparison. The data given in the present paper enable comparisons to be made between predicted and observed products of cracking and also furnish rates of cracking that lead to a general equation for the cracking velocities of normal paraffins. The experiments were made in connection with a study of catalytic cracking,[10] and supplied data on *n*-dodecane, an isododecane, and *n*-hexadecane. The results are compared with those predicted by the radical chain theory and by the alternative theory of Burk.[11]

## Experimental

All experiments were made in a system for flowing reactants. The equipment and procedure were essentially as described previously.[10a,12] The reactor tubes were of 18–8 chromium–nickel steel (A.I.S.I. type 302) of $^1/_2$, 1, or 1$^1/_2$-inch iron pipe size. Temperature control in the center of the tube was within ±3° of the specified value. The reactor tubes were vertical, and were filled with clean, dense quartz chips of 6–14 mesh (inch) size to aid heat transfer and prevent laminar flow. In the run at elevated pressure, the system was initially pressured with nitrogen, and at the end of the experiment, the pressure was reduced to atmospheric before the commencement of the usual nitrogen flush.

Analysis of gases was by low temperature distillation followed by sulfuric-acid absorption for olefins or infrared spectrophotometry for isomeric olefins and paraffins. Liquid products were distilled in a column of 14 mm. i.d. and 76 cm. length, packed with $^3/_{16}$ inch diameter helices. The fractions were analyzed for olefins by bromine number (bromine in carbon tetrachloride method), and for aromatics by ultraviolet absorption, or in some cases by acid absorption corrected for olefins or by refractive dispersion.

Although the cracking experiments were made in "stainless steel" tubes, there was no evidence of catalysis by the tube walls, which were maintained in an oxidized condition by treatment with air at 500–600° in the regenerations following each run of two to ten hours' duration. In other experiments not reported here, it has been noted that when stainless steel tubes develop catalytic activity, usually at 550° or above, they do so quite suddenly, and produce large amounts of hydrogen and carbon. No such effects were observed in the present experiments. The non-catalytic properties of oxidized stainless steel tubes have also been mentioned by Marschner,[13] who showed that they gave the same results as Pyrex in the cracking of *n*-octane. Nevertheless, we are uncertain whether all the coke and hydrogen arose from uncatalyzed reactions, and have not attached significance to the quantities of these materials.

**Results of Cracking *n*-Hexadecane.**—The *n*-hexadecane (cetane) was from du Pont, with $n^{20}D$ 1.4346, $d^{20}_4$ 0.7741, m.p. 17.0°, and b.p. 287.7° at 761.3 mm. Results from two cracking runs at atmospheric pressure, and one at a pressure of 21 atmospheres absolute, are shown in Table I, while Table II gives the products as moles from each 100 moles of hexadecane cracked. Conversions were computed from the amount of material in the range $C_1$ through $C_{14}$, together with hydrogen and coke. The $C_{15}$ material was not included because the amount was not always determined; actually the $C_{15}$ fraction was 0.9% of the charge in the run at 21 atmospheres, and should be less in the other runs at lower conversions. Material other than hexadecane in the products boiling above 273° was also quite small, as judged by the refractive index of that fraction from the run at 31.5% conversion, which was $n^{20}D$ 1.4360 (hexadecane feed 1.4346).

Reaction velocity constants were computed for a first order reaction, since the first order law, $kt = \ln 100/100 - C$, where $C$ is the percentage conversion, is known to hold approximately for the thermal decomposition of paraffins at a given pressure. The residence time, $t$, is not directly measurable in a flow system, and therefore the proper equation for a flow system, first given by Benton,[14] was used. This is

$$kG/V = N \ln (100/100 - C) - (N - 1)\, C/100$$

where $k$ is the rate constant in sec.$^{-1}$, $G$ is the void hot volume of the reactor in cc., $V$ is the influx gaseous flow rate in cc. per sec. at reaction temperature and pressure, $N$ is the moles of product per mole of hexadecane cracked, and $C$ is the percentage conversion. The void volume of the quartz chips was 45% of the gross volume. In computing the volume G, correction was made for the temperature profile, by weighting small sections of the tube in accordance with relative reaction velocities at the observed temperatures, to get an equivalent volume at 500°. This was done by assuming an activation energy of 60 kcal. per mole. Actually, about 95% of the equivalent volume was between 495 and 503°. After $k$

had been computed from the above equation, the residence time, $t$, was obtained from the usual first order law. Since the first order law probably does not hold exactly, $k$ and $t$ are approximations. The values of $k$ in the two experiments at atmospheric pressure, 0.0026 and 0.0032 sec.$^{-1}$ agree moderately well, and are also in approximate agreement with an earlier rough value of 0.004[10a] at 4% conversion. The experiment at 21 atmospheres led to a higher value of 0.0078, but since this has not been checked, it is not now taken as indicating that cracking rate increases with pressure. The primary interest in the experiment at 21 atmospheres lies in the nature of the products.

The products from thermal cracking of hexadecane, listed in Table II, cover the full range from methane upward, but methane, ethylene, ethane and propylene are especially prominent at atmospheric pressure. The elevated pressure of 21 atmospheres causes an increased saturation of the fractions, and a general shift of products toward higher molecular weights. Analyses of a few of the liquid fractions, included in Table I, indicate that olefin contents were very high for the atmospheric pressure runs. In the run at 21 atmospheres, olefin contents were lower and aromatic and paraffin contents were higher.

## Radical Theory of Cracking

Rice and Rice[2] noted that the products from the cracking of *n*-hexadecane as observed by Gault and co-workers[8,9] were in general agreement with the predictions of the radical chain theory. The present data permit a much more detailed comparison, and show that while the simple theory of Rice and Rice[2] overemphasizes certain products, the

improved theory of Kossiakoff and Rice[15] gives better agreement.

According to the radical chain theory, small alkyl radicals accumulate to a steady state concentration. These radicals remove hydrogen atoms from paraffin molecules, leaving a large radical which will decompose rapidly in definite ways, ultimately regenerating a small radical which continues the chain. Reasonable values for the parameters determining products were set forth by Kossiakoff and Rice,[15] and almost the same values have been adopted here. The rate of removal of secondary hydrogen is taken to be greater than that of primary hydrogen by a factor of 3.66 at 500° (exp $(2000/RT)$). The total rate of removal of each type is proportional to the number of such atoms multiplied by this factor. The relative rate of removal of a tertiary hydrogen at 500° is 13.4 (exp $(4000/RT)$).

Radicals formed by removal of hydrogen atoms rupture at a carbon–carbon bond that is removed by one carbon atom from the hydrogen-deficient carbon (that is, at a beta bond). There are good reasons why the rupture occurs only at the beta bonds.[16] No carbon–hydrogen bonds are made or broken when rupture occurs, and the products are always an olefin and a smaller radical. When alternative beta bonds are available, the relative rates of cracking are determined by the resonance

(15) A. Kossiakoff and F. O. Rice, THIS JOURNAL, **65**, 590 (1943).

(16) C. E. H. Bawn, *Trans. Faraday Soc.*, **34**, 598 (1938); F. O. Rice and E. Teller, *J. Chem. Phys.*, **6**, 489 (1938); **7**, 199 (1939).

stabilizations of the radicals that crack off. For simplicity in view of lack of accurate knowledge, the relative rates of cracking have been taken as follows, corresponding to $\exp(1700/RT)$, and powers thereof.

| Radical cracked off | Relative rate |
|---|---|
| Methyl | 1 |
| Ethyl and higher primary | 3 |
| Secondary | 9 |
| Tertiary | 27 |

The theory described so far may be called the simple chain theory. It is compared with experimental results in Table III. The amount of ethylene predicted is much too great. Most of this ethylene arises from the breakdown of large primary alkyl radicals, which, according to the simple theory, continue to split off ethylene until they are reduced to the methyl or ethyl radicals that appear in the final products as methane or ethane. An amplification of the theory introduced by Kossiakoff and Rice[15] overcomes this difficulty by assuming that the large radicals, although too short-lived to be converted to paraffins, are sufficiently long-lived to undergo isomerization prior to rupture. In the present work it is assumed as by Kossiakoff and Rice, that the radical position can only shift by a coiling mechanism to a carbon atom separated by three or more carbon atoms from the original position. Therefore, $C_3$, $C_4$ and $C_5$ radicals do not isomerize; among the hexyl radicals only the 1- and 2-forms are taken to be interconvertible; for the heptyl, the 1-, 2- and 3-; and for the higher radicals, all possible isomers obtainable by a shift of a hydrogen atom. Branched chain radicals are not formed from straight chains by these isomerizations. In computing the equilibrium among the radicals immediately prior to their cracking, the secondary are estimated to be 4,000 cal. per mole more stable than the primary, and the tertiary another 4,000 cal. per mole more stable than the secondary. Thus the relative weights at 500° are 1, 13.4 and 47.7 for primary, secondary and tertiary, and of course these weights have to be multiplied by the appropriate statistical factor.[15]

In computing the predicted products from the cracking of $n$-hexadecane by the amplified radical theory of Kossiakoff and Rice, every radical formed in the process of decomposition was taken to isomerize to equilibrium before cracking further, except for the $C_7$ and smaller, as noted above. The restriction on the degree of isomerization of the smaller radicals is rather arbitrary, since it is conceivable that isomerization may occur by a simple shift of a hydrogen atom rather than by a coiling mechanism. In the case of $n$-hexadecane, however, this restriction makes little difference because of the relatively small number of isomerizations excluded. Table III shows that the products predicted by the chain theory with radical isomerization agree well with those observed in cracking at atmospheric pressure. Comparison has been made with the run of 31.5% conversion, but the other run agrees about as well. It would be more desirable to compare experimental cracking at very low conversions, since the theory is for the initial cracking and does not take into account secondary decomposition of initial products. However, secondary cracking reactions will change the theoretical values of Table III less than 15% at conversions below 30% according to some unpublished calculations made with the simple radical theory by Drs. R. S. Rasmussen and D. P. Stevenson of these laboratories.

The agreement obtained using radical isomerization is suggestive, but is not a full proof of this step for alternative, more complex, explanations of the products are conceivable.

A graphical comparison of theoretical and experimental results from hexadecane is given in Fig. 1, in which products are grouped by carbon number. As noted above, agreement is quite good. The more detailed data of Table III show a few discrepancies. For example, the theoretical amount of ethylene is somewhat high, even with radical isomerization. Likewise some propane is obtained, indicating that the theoretical assumption that all propyl radicals decompose is not correct. Other deviations are minor, such as the failure to predict traces of butadiene and isobutylene, present in the experimental products in amounts scarcely greater than the error of analysis. One of the most important predictions of the theory is the absence of paraffins above ethane.

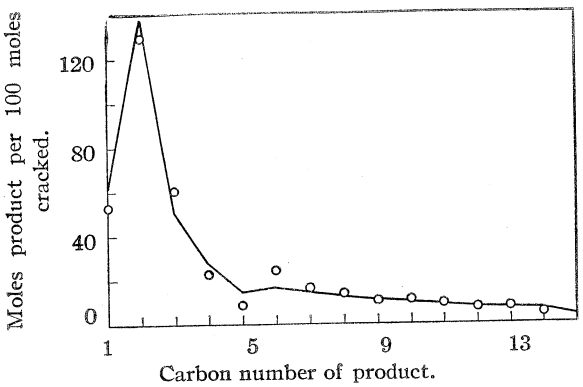

Fig. 1.—Experimental and theoretical product distributions from hexadecane at 500°: circles, experimental, 31.5% conversion; line, theoretical, with radical isomerization.

With the exception of propane, this is well borne out. Very small amounts of paraffins are found in the $C_4$, $C_5$, and liquid fractions. Similar results have been observed for the thermal cracking of paraffin wax at low pressures and in the presence of steam diluent.[17] The wax consists primarily of normal paraffins, $C_{20}$ to $C_{28}$, and liquid products from cracking are 90% olefinic, or more.

No attempt was made to compute the products from cracking at elevated pressure. Certain qualitative aspects are in good agreement with the principles of the radical chain theory, such as the presence of paraffins above ethane, and the higher average molecular weight. At 21 atmospheres it is thought that some of the higher radicals are converted to paraffins before they can decompose. This also accounts for the lesser amount of ethylene.

## Cracking of Dodecanes

Products from the thermal cracking of an isododecane were given in a previous paper.[10a] The isododecane was made by hydrogenation of the trimer of isobutene obtained in the polymerization with cold sulfuric acid, and there are valid reasons for believing that the predominant structure present was 2,2,4,6,6-pentamethylheptane. Calculations of the products theoretically expected from this structure were made under the same assumptions employed above. The experimental and theoretical products are compared in Table IV. The agreement is a little better without radical isomerization, but there is not a large difference between the two cases as there was with *n*-hexadecane. The correspondence of calculated and experimental products is considered fairly good. It is of interest that no $C_2$ is predicted and very little is found. Also, butane is predicted in the observed quantity, in contrast with normal paraffins where no paraffinic products above ethane are theoretically expected.

Experimental results from thermal cracking of *n*-dodecane at 550°, previously published,[10a] are in qualitative agreement with the results from *n*-hexadecane and with the amplified radical chain theory.

## Direct Fission Theory and Rates of Cracking

Before the development of the chain theory, Burk[11] suggested that cracking might occur by direct fission of a paraffin into a smaller paraffin and an olefin. He also proposed[11,18] a general equation for the rate of cracking of normal paraffins, namely, $k = (n - 1)v \exp(-E/RT)$, where $k$ is the first order rate constant, $n$ is the number of carbon atoms, and $v$ and $E$ are constants for the homologous series. It is now clear that the direct fission theory does not explain the products of cracking, for it predicts only two moles of product per mole cracked, and a mixture of olefins and paraffins for all carbon numbers two or more below that of the paraffin cracked (except, of course, for $C_1$). The rate equation was tested by Burk, Laskowski and Lankelma[18] with available data by computing values of $E$ from the known values of the reaction rates, $k$, and a constant value of $v$. They obtained $E$'s varying from 59 to 65 kcal. From the approximate constancy of $E$, they concluded that the data supported the equation and mechanism of Burk.

The rate constant obtained in this work for hexadecane has been combined with a few other values from the literature in another test of the above equation. The present test has been made by plotting values of $k/(n - 1)$ against $n$ for a single temperature. According to the Burk equation for the rate of cracking, a horizontal line should result. Data for the plot are given in Table V, and Fig. 2 shows the result. It is seen

(17) For example, A. J. van Peski, U. S. Patent 2,172,228 (1939).

(18) R. E. Burk, L. Laskowski, and H. P. Lankelma, THIS JOURNAL, 63, 3248 (1941).

that $k/(n-1)$ increases in a regular fashion with increasing $n$. It is concluded that the equation is not a very good approximation. Instead, the following empirical relationship, taken from the straight line drawn in Fig. 2, may be written for the rate of cracking of normal paraffins at 500°

$$k\ (\text{sec.}^{-1}) = (n-1)(1.57\,n - 3.9) \times 10^{-5}$$

and atmospheric pressure, for $4 \leq n \leq 16$. Actually the agreement of the experimental points with this line in Fig. 2 is better than can be expected, considering the variations in $k$ normally met. It is not thought that the above empirical equation represents the true relationship for $n$-paraffins, but simply that it is a useful approximation. It should also be stressed that expression of the rates by means of first order constants in itself is an approximation, because the most careful work shows first order rate constants usually decrease somewhat with increasing depths of cracking.

TABLE V

THERMAL CRACKING RATES FOR $n$-PARAFFINS, $C_nH_{2n+2}$

| $n$ | Ref. | First order rate const., sec.$^{-1}$: $k$ at temp., °C. | $k$ at 500° | $k \times 10^5/(n-1)$ |
|---|---|---|---|---|
| 4 | 4 | $2.06 \times 10^{-4}$, 520 | $0.80 \times 10^{-4}$ | 2.7 |
| 4 | 19 | $1.32 \times 10^{-4}$, 513 | $0.66 \times 10^{-4}$ | 2.2 |
| 7 | 1 | $5.5 \times 10^{-3}$, 552 | $3.8 \times 10^{-4}$ | 6.3 |
| 8 | 13 | $3.9 \times 10^{-3}$, 538 | $6.0 \times 10^{-4}$ | 8.6 |
| 12 | 10a | $1.8 \times 10^{-2}$, 550 | $16.8 \times 10^{-4}$ | 15.3 |
| 16 | 20 | $3.2 \times 10^{-3}$, 500 | $32 \times 10^{-4}$ | 21.3 |

The rate constants given in Table V are from experiments in which conversion lay between 10 and 32% (except for dodecane at 41%) and the pressure was atmospheric or very close to atmospheric. If rates at 500° were not given, they were converted from the nearest available temperature, using the activation energy given by the same author, or 60 kcal. if no other was stated. Although this procedure is not as satisfactory as would be measurements on a number of homologs in one apparatus at one temperature, it is considered sufficiently accurate for the test presented here.

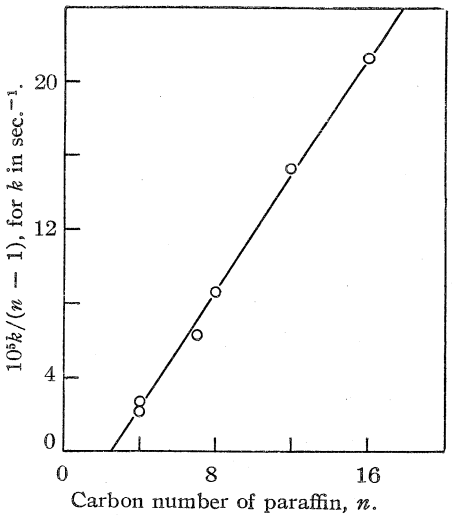

Fig. 2.—Variation of cracking rate constant with carbon number for $n$-paraffins at 500°.

**Acknowledgment.**—Dr. B. S. Greensfelder gave valuable encouragement. Mrs. S. S. Tornbom assisted in the performance of the experiments.

## Summary

The thermal cracking of $n$-hexadecane was observed in a system for flowing reactants at 500° and pressures of one and 21 atmospheres absolute. Detailed analyses of the products are given, and those at one atmosphere are shown to be in good agreement with the predictions of the Rice radical chain theory as amplified by Kossiakoff and Rice. Earlier data for the products from an isododecane are also shown to agree with the theory. Rates of cracking for homologous normal paraffins are approximately represented by first order rate constants, which do not fit an equation proposed by Burk, but lead to the empirical relationship $k$ (sec.$^{-1}$) $= (n-1)(1.57\,n - 3.9) \times 10^{-5}$ for rates at 500°.

# The Thermal Polymerization of Hexafluorobutadiene[1]

BY MAURICE PROBER[2] AND WILLIAM T. MILLER, JR.

The unsaturated fluorocarbons have been of especial interest in this Laboratory because of their high order of reactivity, and consequent suitability for study and for use as synthetic intermediates, in marked contrast to corresponding chloro compounds. Hexafluoro-1,3-butadiene, the first fluorocarbon diolefin prepared[3] and investigated, was found to exhibit a chemical reactivity in many ways rivaling its hydrogen analog. It underwent radical chain type and thermal polymerization and was readily halogenated and attacked by neutral permanganate in contrast to the comparatively inert hexachloro-1,3-butadiene.[4] The present paper reports on the thermal reactions of hexafluoro-1,3-butadiene and of its dimer and trimer.

The thermal polymerization of conjugated hydrocarbons has already been studied in the case of a number of dienes.[5-17] At elevated temperatures there was appreciable formation of dimers and in some cases trimers. High molecular weight products were also formed in the liquid phase thermal reactions unless special precautions were taken to remove peroxides and oxygen. Dimerization may be generally represented by 1,4-addition of one molecule of a diene to a double bond of a second molecule and the dimers of butadiene, isoprene and 2,3-dimethylbutadiene, and the trimer of butadiene all have been reported to have cyclohexene structures.[5,8,12,15,18] However, 1-phenyl-1,3-butadiene appears to be an exceptional case and a cyclopentene structure has been assigned to its thermal dimer.[17,18a] Kinetic studies of vapor phase thermal diene dimerizations have indicated a homogeneous second order reaction.[6,7,9]

**Thermal Reactions of Hexafluorobutadiene.**—On the basis of preliminary work, the thermal reactions of hexafluoro-1,3-butadiene have now been investigated over the temperature range of 150 to 180°. The reactions were carried out by heating the diene in steel bombs with not more than trace amounts of water or oxygen normally present. The reaction products were hexafluorocyclobutene, dimers which distilled at 98 to 100°, trimers which distilled at 64 to 66° at 10 mm., and some higher boiling material. The higher boiling fractions were viscous liquids which indicated that the degree of polymerization was low. In the higher temperature runs small amounts of a compound boiling below the dimer fraction but with the empirical formula $C_8F_{12}$ was isolated as well. The reaction product was readily separated into its major components, which differed by four carbon units, by fractional distillation. The recovered butadiene fraction was analyzed by chlorination and separation of the resulting dichloride and tetrachloride by fractional distillation. Experimental data are summarized in Table I.

These data indicated that the yields of the different products were strongly influenced by reaction temperature. Similar observations have been made for the thermal dimerization of butadiene,[10] but a comparison of the reactivity of the two dienes is complicated by the side reactions in the case of hexafluorobutadiene to form cyclobutene and trimer. Intramolecular cyclization became more pronounced as the reaction temperature was increased, and at 500° and atmospheric pressure, hexafluorobutadiene was quantitatively converted to hexafluorocyclobutene when passed through a heated tube with a five to fifteen second contact time.[19] Under comparable conditions, butadiene undergoes dimerization.[20] Although a trimer has been obtained by heating vinylcyclohexene and butadiene, the yield was very poor.[18] Formation of a trimer proceeded more rapidly with hexafluorobutadiene, and as shown above this fraction constituted a considerable portion of the reaction product. As might be expected

[a] Conversions are calculated on the basis of all reaction products recovered including intermediate fractions. [b] Yields expressed as weight per cent. of hexafluorobutadiene converted. [c] Charged under nitrogen. [d] Charged under air. [e] Catechol, 0.3 g., added. [f] Dissolved gases removed by distillation. [g] Complete reaction; the conversion is less than 100% because of losses in handling.

on the basis of a stepwise reaction mechanism, heating hexafluorobutadiene with excess dimer yielded considerably more trimer than was obtained directly.

The presence of oxygen or an anti-oxidant such as catechol did not affect the composition of the products as shown in Table I by the results of reactions 1, 2 and 3 further supporting a molecular type thermal reaction and in all cases the residues were indicated as very low polymers. These results differ considerably from those observed with the hydrocarbon dienes where the presence of oxygen generally leads to appreciable yields of high polymer.

With the exception of hexafluorocyclobutene, the structures of the thermal reaction products of hexafluorobutadiene have not been proved. The lack of related compounds was a major handicap to this work. However, some progress was made toward assigning structures to the dimer products. Analyses and molecular weight determinations confirmed the molecular formula, $C_8F_{12}$, and the presence of more than one isomer was indicated by the absence of a sharp boiling point and failure to obtain a plateau in the cooling curve. Chlorination confirmed this conclusion, and yielded tetrachloride, and hexachloride in approximately 2.5 to 1 molar ratio. Both chlorides were saturated to permanganate in acetone. The presence of structural isomeric chlorides was not excluded.

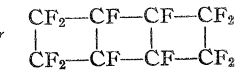
The dimer skeletons derivable from hexafluorobutadiene without carbon–carbon or carbon–fluorine bond rearrangements, which are capable of yielding tetrachlorides are listed below.

Little direct evidence was available to indicate a preferred structure. All of the hydrocarbon dimers formed from dienes which have been examined[5,8,13,14,15] with the exception of the dimer from 1-phenylbutadiene[17] have been indicated as cyclohexene ring compounds. By analogy, hexafluorobutadiene would undergo a similar reaction to form structure I. However, one of the interesting differences between fluorocarbon and hydrocarbon chemistry is the more ready formation of cyclobutane structures with the highly fluorinated systems. Examples are the cyclobutane dimer formed by heating tetrafluoroethylene,[21] chlorotrifluoroethylene,[21,22] or unsym.-dichlorodifluoroethylene,[21,22] and the cyclization of hexafluorobutadiene to hexafluorocyclobutene described above. In addition, the thermal reactions of the dimer fraction could be best explained by assuming a cyclobutane structure for at least one of the isomers.

No data were collected with specific reference to the non-planar cycloöctadiene structure III. It is planned to continue work on the hexafluorobutadiene dimer structures by oxidation. Different acids should be obtained from I, II and III.

The preparation of the hexachloride, $C_8Cl_6F_{12}$, from the dimer fraction indicated the presence of a dimer with a structure formed by rearrangement as well as condensation. Formation of hexachloride by ring cleavage of tetrachloride was unlikely because chlorination at 0 and 100° yielded the same tetrachloride: hexachloride ratios and because of the observed difficulty of cleaving known fluorinated cyclobutane compounds with chlorine.

The absence of a sharp boiling point also indicated the presence of more than one isomeric trimer.



**Thermal Reactions of Hexafluorobutadiene Dimers.**—When the hexafluorobutadiene dimer fraction was heated in a glass bomb at 200° for one hundred and sixty-four hours, 40% was converted into a remarkable isomeric compound,

(21) Harmon, U. S. Patent 2,404,374, July 23, 1946.

(22) Henne and Ruh, THIS JOURNAL, **69**, 279 (1947). The thermal dimerization of tetrafluoro- and of the chlorofluoroethylenes to form cyclobutanes was also carried out independently by Miller and his associates as a part of the fluorocarbon war research program.

$C_8F_{12}$, which boiled at 80° and melted at 40°. Reheating the recovered high boiling $C_8F_{12}$ yielded a total conversion for the two cycles of about 65% of the original fraction to the low boiling isomer. The purified low boiling compound was entirely stable to permanganate and to chlorination. Its formula was checked by molecular weight determinations and by analysis. These facts require a fused tricyclic structure such as IV. Such a compound could be formed by

IV

intramolecular condensation of *cis*-dodecafluoro-1,2-divinylcyclobutane, IIa, or dodecafluoro-1,5-cycloöctadiene, III, without rearrangement of groups. Evidence for the ready formation of cyclobutane rings in fluorinated systems has been presented above. The stability of a simple cyclobutane ring was also demonstrated by passing 1,2-dichlorohexafluorocyclobutane and excess chlorine through a heated glass tube. No reaction occurred until pyrolysis temperatures approaching 500° were reached. The relatively high melting point of 40° of the saturated $C_8F_{12}$ suggested a symmetrical structure, but no other direct chemical evidence was available to support the structure postulated for this unusual material. However, preliminary X-ray diffraction studies on the crystalline $C_8F_{12}$ compound by Professor J. L. Hoard and Mr. R. W. Broge of this Laboratory have yielded results which are consistent with the tricyclic structure proposed above.

In addition to the low boiling isomer, a white infusible polymer was isolated in low yield from the bomb reactions of hexafluorobutadiene dimer. This polymer was insoluble in acetone, pentane, ethyl alcohol, carbon tetrachloride, benzene, $C_8F_{16}$, and 1,1,2-trichlorotrifluoroethane and decomposed on heating above 300°.

A 60% yield of the low boiling saturated $C_8F_{12}$ isomer was obtained by passing the dimer fraction through a hot tube at 500°. The recovered dimer fraction was recycled, but did not yield additional low boiling $C_8F_{12}$. The recovered material was chlorinated and yielded only tetrachloride, indicating the absence of triene, and it was considered significant that the physical properties of this tetrachloride fraction were not identical with those of the tetrachloride fraction isolated by direct chlorination of hexafluorobutadiene dimer as described above. Approximately five per cent of the dimer fraction underwent depolymerization in the hot tube reaction. The $C_4F_6$ product isolated was hexafluorocyclobutene which, under the conditions of the experiment would have been formed from hexafluorobutadiene. No products boiling higher than $C_8F_{12}$ were obtained from the hot tube reactions.

**Thermal Reactions of the Hexafluorobutadiene Trimer.**—The trimer was found to undergo polymerization when heated at 300° in a sealed tube. After one hundred and sixteen hours, approximately 35% $C_{12}F_{18}$ fraction was recovered, 30% boiled from 175 to 200° at 10 mm., probably $C_{24}$ fractions, and the remainder did not distil at a bath temperature of 300° under 1.5 mm. pressure. Less than 5% low boiling material was formed and the recovered $C_{12}F_{18}$ was indicated as approximately equivalent in unsaturation to the starting material by permanganate titration. Partial depolymerization occurred when the trimer was passed through a hot tube at 520°.

## Experimental

**Hexafluorobutadiene.**—Hexafluorobutadiene was prepared by dechlorination of 1,2,3,4-tetrachlorohexafluorobutane. The tetrachloride was gradually added to a hot stirred suspension of zinc dust in absolute alcohol and the diene fractionally distilled out as formed utilizing a partial condenser topped by a short packed column. The product was refluxed over phosphorus pentoxide to remove alcohol and then redistilled through a 70 × 1.2 cm. glass helix packed low temperature column. The fraction b. p. 6.5 to 7.5° (uncor.) was taken for polymerization studies.

**Thermal Reactions.**—The polymerization bombs were steel "lecture" cylinders[23] in which the conventional valve was replaced by a plug bearing inlet and outlet tubes equipped with brass needle valves. The bombs were thoroughly washed and dried before each run, but the walls were coated with iron oxide. The diene was distilled through a drying tube packed with "Drierite" directly into the bombs under dry oxygen-free nitrogen. The nitrogen was purified by passing it through a series of wash bottles containing Fieser solution,[24] lead acetate solution, and concentrated sulfuric acid, followed by a phosphorus pentoxide tube. In those experiments where the effect of oxygen was tested, a slow stream of dry air was passed through the bomb after it had been charged with diene. The vapor phase was about 200 cc. After the first three experiments this procedure was discarded in favor of charging the bomb under dry air and distilling out 10 to 20 g. of diene to sweep out dissolved gases. The polymerization bombs were heated in a constant temperature oven controlled to ±0.5°, and the reaction times include the time necessary for the bomb to warm up from room temperature. At the conclusion of a run, the bombs were cooled rapidly to room temperature and the contents transferred to a cold still pot under a carbon dioxide atmosphere. It was preferable to carry out the transfer and distillations under an inert atmosphere to avoid oxidation since perfluoro olefins in general undergo ready oxidation to yield acid halide type products in air. The reaction product was distilled through a 75 × 1.0 helix packed column with Dry Ice trap in series. The Dry Ice trap condensate consisted of recovered hexafluorobutadiene and hexafluorocyclobutene, b. p. 0.0°.[25] This mixture was analyzed by chlorination under a Dry Ice reflux condenser with illumination from a quartz mercury vapor lamp. The 1,2-dichlorohexafluorocyclobutane, b. p. 60.4,[26] resulting from the cyclobutene and the 1,2,3,4-tetrachlorohexafluorobutane, b. p. 134.1°,[27] resulting from the diene were readily separated by fractional distillation. The dimer fraction, $C_8F_{12}$, was collected from 96 to 100° with most of it distilling from 98 to 100°.

*Anal.* Calcd. for $C_8F_{12}$: C, 29.56; mol. wt., 324. Found: C, 29.3, 29.6; mol. wt., 326, 331.

In the higher temperature runs, a lower boiling dimer was

(27) Determined by J. M. Phelan.

collected over the boiling range 80 to 85°. The behavior of this compound is described below. In the first five runs, the trimer fraction was too small for convenient fractional distillation, and was separated from the higher boiling residue by simple distillation. It was collected over the boiling range 165 to 185° and distilled largely from 175 to 180°. In subsequent runs the residue from the $C_8F_{12}$ distillation was fractionally distilled at 10 mm. and the trimer, $C_{12}F_{18}$, collected, b. p. 62 to 68°, largely b. p. 64 to 66°.

*Anal.* Calcd. for $C_{12}F_{18}$: C, 29.65. Found: C, 29.7, 29.8.

The quantitative results for the hexafluorobutadiene polymerizations are given in Table I. The amounts of hexafluorobutadiene charged for the eight reactions for which data are given was as follows: Reaction (1), 305 g.; (2), 253 g.; (3), 196 g.; (4), 328 g.; (5), 327 g.; (6), 350 g.; (7), 390 g.; (8), 418 g.

**Hexafluorobutadiene Dimer.**—The dimer fraction of b. p. 96 to 100°, as indicated above, was utilized for the following experiments.

**Chlorination.**[28]—Chlorine, 41 g., was passed into 81.7 g. $C_8F_{12}$ while the reaction mixture was illuminated by a mercury vapor lamp. The light source was placed about one foot away to minimize heating effects and the chlorination flask was maintained at 0 to 5° by circulating ice water through a cold finger. The reaction product was washed with 5% sodium hydroxide solution, dried, and fractionally distilled at 20 mm. pressure to yield the following fractions: 6.5 g., Dry Ice-trap condensate; 2.6 g., b. p. 55 to 90.5°; 59.7 g., b. p. 90.5 to 94.0°; 4.3 g., b. p. 94.0 to 138.0°; 27.0 g. b. p. 138.0 to 139.5°; 3.1 g., residue.

The same general procedure as above was carried out with 81.5 g. of $C_8F_{12}$. However, the liquid was maintained at reflux during the chlorination and varied in temperature from 100° at the beginning to over 200° at the end of the run. The reaction product was washed with 5% sodium hydroxide solution, dried, and refractionally distilled at 20 mm. pressure to yield the following fractions: 7.1 g. Dry Ice-trap condensate; 4.9 g., b. p. 91 to 94°; 68.0 g., b. p. 94 to 127° but principally at 94 to 97°; 1.7 g., b. p. 127 to 138°; 25.8 g., b. p. 138 to 140°.

A heart cut from redistillation of the combined fractions of b. p. 90 to 97° at 20 mm. was found to be saturated to potassium permanganate in acetone; b. p. 203°, 90.5 to 91.5° at 20 mm., $n^{20}D$, 1.3870.

*Anal.* Calcd. for $C_8Cl_4F_{12}$: C, 20.62. Found: C, 20.6, 20.7.

A heart cut from redistillation of the fraction of b. p. 138 to 140° at 20 mm. was also saturated to permanganate in acetone; b. p. 261°, 139 to 140° at 20 mm.; $n^{20}D$ 1.4040.

*Anal.* Calcd. for $C_8Cl_6F_{12}$: C, 17.88; Cl, 39.63. Found: C, 18.0, 18.1; Cl, 39.6, 39.3.

The molar ratio of tetrachloride to hexachloride was estimated as 2.5 to 1.0 for the low temperature reaction and 2.8 to 1.0 for the high temperature chlorination; agreement within experimental error.

**Thermal Reactions.**—Hexafluorobutadiene and its unsaturated dimer, $C_8F_{12}$, reacted as follows.[29] A steel bomb was charged with 40 g. of $C_8F_{12}$ and 10 g. $C_4F_6$ and heated for twelve hours at 170°. No unreacted hexafluorobutadiene remained, and 39.8 g. of $C_8F_{12}$ and 7.5 g. of $C_{12}F_{18}$ were obtained. The yield of $C_{12}F_{18}$ was considerably higher than that derived solely from $C_4F_6$ under comparable conditions and indicated that formation of $C_{12}F_{18}$ proceeded through interaction of $C_8F_{12}$ and $C_4F_6$.

The unsaturated dimer of hexafluorobutadiene was partially converted by heating into an isomeric saturated compound.

A sealed glass bomb tube containing 56.7 g. of $C_8F_{12}$, b. p. 96 to 100° was heated at 200° for one hundred and sixty-four hours. The volatile reaction products were distilled out of the bomb to leave 2 g. of white solid residue. Upon slow heating the solid began to darken at 300° and underwent slow decomposition at 400° without melting. The solid was insoluble in acetone, pentane, ethyl alcohol, carbon tetrachloride, $C_8F_{16}$ (satd.), 1,1,2-trichlorotrifluoroethane and benzene. The liquid product was separated into the following fractions by distillation through a small Vigreux column: 19.0 g., b. p. 82 to 86° (solid at room temperature); 6.7 g., b. p. 86 to 96°; 15.3 g., b. p. 96 to 100°; 3.7 g. residue. The 98 to 100° portion of the recovered $C_8F_{12}$ was reheated under the same conditions to yield additional low boiling $C_8F_{12}$. However, no infusible solid was formed in this reaction.

The isomerization of hexafluorobutadiene dimer was also carried out in the vapor phase. The 30-cm. middle section of a 60 × 3 cm. glass tube was heated by an electric combustion tube furnace and the midpoint temperature maintained at 500 ± 10° while 187.7 g. of $C_8F_{12}$, b. p. 96 to 100°, was passed through the tube at a rate of 11.7 ± 1.8 g. per hour. No carbonization and only slight etching of the tube was observed. The reaction product, 184 g., was collected at room temperature. Only 0.2 g. was recovered from a Dry Ice trap and nothing condensed in a liquid oxygen trap arranged in series. Distillation yielded the following fractions: 12.1 g. Dry Ice trap-condensate; 114.3 g., b. p. 78 to 83°; 7.7 g., b. p. 83 to 95°; 44.0 g., b. p. 95 to 101°; 3.1 g. residue. The fraction of b. p. 78 to 83° was chlorinated but very little chlorine absorption was observed. The chlorination product was fractionally distilled and neglecting a small forerun and residue boiled sharply at 80°. This fraction had a freezing point of 40.1° (cooling curve) and was saturated to permanganate in acetone.

*Anal.* Calcd. for $C_8F_{12}$: C, 29.65; mol. wt., 324.1. Found (80° b. p. fraction): C, 29.8, 29.9; mol. wt., 321, 323.

The Dry Ice trap condensate was shown to consist of hexafluorocyclobutene and low boiling $C_8F_{12}$.

The fraction of b. p. 95 to 101° was recycled through the hot tube at 500° and the product fractionally distilled to yield: 0.2 g. of Dry Ice trap condensate; 3.7 g., b. p. 89 to 95°; 36.4 g., b. p. 95 to 100°; 2.0 g. residue. No low boiling $C_8F_{12}$ was recovered. The fraction of b. p. 95 to 100° was chlorinated and distilled at 20 mm. pressure to yield: 1.2 g. Dry Ice trap condensate; 37.0 g., b. p. 96 to 100°; 0.7 g. residue. The composition of the fraction b. p. 96 to 100° at 20 mm., $n^{20}D$ 1.3952, was shown to be $C_8Cl_4F_{12}$.

*Anal.* Calcd. for $C_8Cl_4F_{12}$: C, 20.62; Cl, 30.44. Found: C, 20.5; Cl, 30.7.

**Hexafluorobutadiene Trimer.**—The trimer of hexafluorobutadiene underwent polymerization on heating. A 50.0-g. sample of $C_{12}F_{18}$, b. p. 65 to 66° at 10 mm. was heated at 300° for one hundred and sixteen hours in a sealed glass tube. Distillation of 48.6 g. of the product through a short Vigreux column at 10 mm. yielded the following fractions: 4.2 g., Dry Ice trap condensate; 16.8 g., b. p. 62 to 68°; 26.3 g., residue. The unsaturation of the recovered $C_{12}F_{18}$ fraction, b. p. 62 to 68° at 10 mm., and the starting material were compared by measuring the volume of potassium permanganate solution required to produce a lasting pink color under identical conditions. No difference in unsaturation was detected. Distillation of 24.0 g. of the residue from a Claisen flask yielded 7.1 g., b. p. 175 to 200° at 10 mm., and a residue which did not distill with a final bath temperature of 320° and 1.5 mm. pressure. By comparison with the boiling points reported for fluorocarbons,[30] the distillate was indicated as probably a $C_{24}$ fraction. When the trimer was passed through a nickel tube at 520° with a contact time of ten seconds, depolymerization occurred. Approximately 15% was converted into hexafluorocyclobutene and 20% into the low boiling $C_8F_{12}$ isomer.

(28) The chlorination experiments were carried out by R. L. Ehrenfeld.

(29) This experiment was carried out by Oscar Blum.

**Acknowledgment.**—We are greatly indebted to Mr. Oscar Blum, Mr. R. L. Ehrenfeld, and Dr. F. H. Winslow for permission to quote from their experimental work and to Miss Pearl Foster, Dr. Frank McKenna, Mr. J. M. Phelan, and Mrs. Rebecca Teston for analytical determinations.

## Summary

Hexafluorobutadiene has been shown to be a highly reactive compound resembling in general butadiene rather than the relatively inert hexachlorobutadiene.

The thermal reactions of hexafluorobutadiene were investigated over the temperature range 150 to 180° and hexafluorocyclobutene, dimers, which were formed in largest amount, and trimers isolated as the principal products.

Hexafluorobutadiene dimer and trimer fractions were shown to be mixtures of isomers. On heating, the dimer was partially converted into a remarkable lower-boiling saturated and highly stable isomer for which a fused tricyclic structure was proposed. Hexafluorobutadiene trimer polymerized slowly on heating. Both dimer and trimer were partially depolymerized by passing through a hot tube.

# Disproportionation of Aromatic Stiboso Compounds. I. Mechanism[1]

BY H. H. JAFFE[2] AND G. O. DOAK[2]

Stibosobenzene and its derivatives are known to disproportionate in the solid state at moderately elevated temperatures according to the equation[3]

$$4ArSbO \longrightarrow (Ar_2Sb)_2O + Sb_2O_3$$

In order to determine the mechanism of this reaction and possibly to elucidate the effect of structure on the stability of the carbon–antimony bond we have chosen to investigate the rate of the above reaction. The present paper is concerned with stibosobenzene alone: the effect of substitution will be presented in a later paper.

## Experimental

Benzenestibonic acid, prepared by a method described previously,[4] was reduced in concentrated hydrochloric acid and ethyl alcohol with sulfur dioxide in the presence of a trace of hydriodic acid. The resulting solution of phenyldichlorostibine was hydrolyzed by dilute aqueous ammonia or sodium hydroxide.[3] The precipitated stibosobenzene was washed with 10 to 12 liters of water, alcohol and ether, and dried *in vacuo*.

Stibosobenzene, prepared in this manner, was obtained as an amorphous colorless solid, soluble in formic and acetic acids, but insoluble in other common organic solvents and in water. So far it has not been possible to prepare it in a crystalline state. The compound does not possess a well-defined melting point, but sinters at approximately 154°, although this temperature varies somewhat with the rate of heating. The molecular weight is unknown. Cryoscopic measurements in formic and acetic acids gave anomalously large depressions, probably due to reaction with the solvents. By analogy with antimony trioxide which exists in a bimolecular and a polymolecular form,[5] and with aromatic arsenoso compounds, which have molecular weights four times the formula weight,[6] stibosobenzene is probably not monomolecular.

In preliminary experiments it was demonstrated that the disproportionation of stibosobenzene at 100° yielded bis-(diphenylantimony)-oxide in quantitative yield. The product was identified by melting point and analysis. In an atmosphere of nitrogen no side reaction could be detected. It was further shown that extraction of a mixture of stibosobenzene, antimony trioxide and bis-(diphenylantimony)-oxide with five portions of ether (40 ml. each) permitted quantitative recovery of the bis-(diphenylantimony)-oxide, without contamination with stibosobenzene or antimony trioxide.

To determine the rate of disproportionation, samples of stibosobenzene (0.25 to 0.75 g.) were permitted to rearrange in large test-tubes in an atmosphere of nitrogen in a constant temperature bath maintained at fixed temperatures between 75 and 100°. Samples were withdrawn at accurately measured intervals, chilled in ice and extracted with ether. The extracts were evaporated *in vacuo* at room temperature and dried to constant weight. The bis-(diphenylantimony)-oxide was weighed and analyzed and the fraction of the original material that had rearranged was obtained from these data. The rate constants, $k_2$, were calculated from equation (1) below by the method of least squares using from 6 to 14 experimental points.

## Results and Discussion

**Kinetics.**—The rearranged fraction $(1 - x)$ plotted against time $(t)$ resulted in an S-shaped curve. This could be reduced to a linear relationship by plotting $\ln(1/x - 1)$ against $t$ (except for the first portion of the curve) (Figs. 1a and b), corresponding to a rate law

$$-dx/dt = k_2(x)(1 - x) \qquad (1)$$

or in the integrated form

$$\ln\left(\frac{1 - x}{x}\right) = k_2(t - t_{1/2}) \qquad (1a)$$

where $t_{1/2}$ is the time required for one half of the original material to rearrange. The early portion of the curve deviated from the expected straight line in different directions depending on whether sodium hydroxide or ammonia was used in the synthesis. An explanation of this phenomenon will be suggested below.

The rate constants determined from equation (1) in a series of experiments using a single preparation of stibosobenzene were constant within the limits of experimental error (Table I). The constants obtained with different preparations varied over a wide range (Table II). In spite of this variation, the same rate law was found to apply in more than fifty experiments with eleven separate preparations.

TABLE I

THE RATE OF DISPROPORTIONATION OF A SINGLE PREPARATION OF STIBOSOBENZENE AT 78°

| $10^4k_2$ sec.$^{-1}$ | Standard error |
|---|---|
| 3.11 | 0.20 |
| 3.16 | .20 |
| 2.96 | .20 |

TABLE II

THE RATE OF DISPROPORTIONATION OF VARIOUS PREPARATIONS OF STIBOSOBENZENE AT 78°

| $10^4k_2$ sec.$^{-1}$ | Standard error | $10^4k_2$ sec.$^{-1}$ | Standard error |
|---|---|---|---|
| a. Hydrolyzed with Aqueous Ammonia | | b. Hydrolyzed with Sodium Hydroxide | |
| 4.73 | 0.29 | 0.514 | 0.15 |
| 3.08 | .09 | .651 | .059 |
| 1.24 | .27 | .254 | .011 |
| 3.52 | .17 | 1.44 | .04 |
| 5.21 | .11 | 2.06 | .09 |
| 4.63 | .14 | | |

The variation of the rate constants in different preparations is probably due to small amounts of impurities which could not be removed since stibosobenzene could not be purified. Tables III and IV show the effect of the addition of various substances to the rate of the reaction. It is seen that bases and bis-(diphenylantimony)-oxide are effective catalysts. The effect of hydrogen chloride and other strong acids could not be investigated because stibosobenzene reacts with acids to form ether soluble compounds.

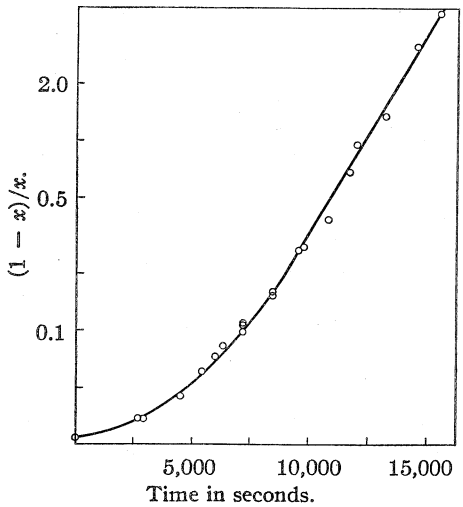

Fig. 1a.—The disproportionation of stibosobenzene at 78°: preparations hydrolyzed with aqueous ammonia.

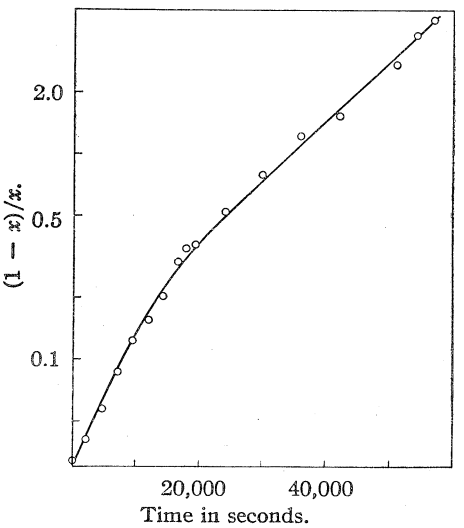

Fig. 1b.—The disproportionation of stibosobenzene at 78°: preparations hydrolyzed by sodium hydroxide.

The rate constant of one preparation of stibosobenzene was determined at three temperatures (Table V). The plot of ln $k_2$ against $1/T$ (Fig. 2) permits calculation of the apparent energy of activation, $E$, which was 23.5 ± 1.5 kcal./mole.

TABLE III

THE EFFECT OF VARIOUS SUBSTANCES ON THE RATE OF DISPROPORTIONATION OF STIBOSOBENZENE AT 78°

| Nature of substance | Amount: weight fraction of stibosobenzene | $10^4k_2$ sec.$^{-1}$ | $10^4k_2(0)$[a] sec.$^{-1}$ |

TABLE V

THE EFFECT OF TEMPERATURE ON THE RATE OF DISPROPORTIONATION OF STIBOSOBENZENE

| $T$, °K. | $10^4 k_2$, sec.$^{-1}$ | Standard error |
|---|---|---|
| 350.6 | 5.21 | 0.11 |
| 362.1 | 12.8 | 1.0 |
| 373.2 | 33.4 | 1.5 |

can be suggested. The simplest interpretation of rate law (1) is a bimolecular, autocatalytic reaction. However no plausible reaction between stibosobenzene and bis-(diphenylantimony)-oxide to form more of the latter product can be written. The fact that most of the effective catalysts for the reaction are liquids at the experimental temperatures (pyridine, sodium acetate and bis-(diphenylantimony)-oxide) suggests that the reaction occurs in solution, the supposed catalyst functioning by virtue of its solvent power for stibosobenzene. The catalysis by dry ammonia and sodium hydroxide is an argument against such a mechanism. Further, the kinetics of such a reaction would be expected to be first order with respect to the solvent, to give a break

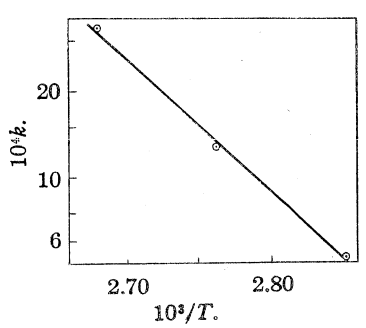

Fig. 2.—The effect of temperature on the rate of disproportionation of stibosobenzene.

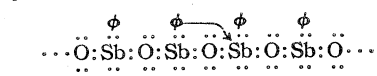
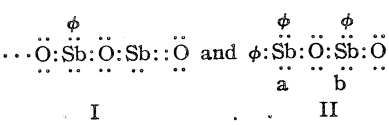
when the solvent is no longer saturated with stibosobenzene, and thereafter to be first order with respect to stibosobenzene. No such break has been observed in following the reaction to completion.[7]

Reactions occurring in the solid phase have usually been interpreted as interface reactions,[8] which follow the rate law



$$-\frac{dx}{dt} = \frac{d(1-x)}{dt} = k(1-x)^{2/3}$$

in the early portion of the reaction, and later approach the rate law

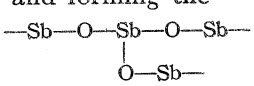


$$-dx/dt = k'x^{2/3}$$

The rate of disproportionation of stibosobenzene did not conform with these kinetics. Also as an interface reaction catalysis by both products would be expected, while it was shown (Table IV) that antimony trioxide was not a catalyst, although bis-(diphenylantimony)-oxide was. Further the reaction obeyed the same rate law whether the catalytic product, the bis-(diarylantimony)-oxide, was liquid at experimental temperatures (stibosobenzene), or solid (the *p*-chloro and *p*-methyl derivatives).

Another possible mechanism, which seems to afford the best interpretation of the experimental facts, is a chain reaction; the initiating step of which is the transfer of a phenyl group ($\phi$) from one antimony atom to an adjacent one

followed by splitting at the oxygen atom to yield fragments I and II.



I II

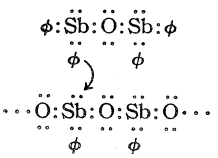
The fragment I then attacks an adjacent antimony atom of stibosobenzene:

causing the shift of a phenyl group, thus propagating the chain, and forming the

grouping characteristic of antimony trioxide.[5]

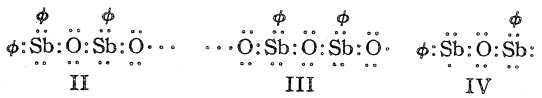
Resonance with two phenyl groups lowers the electron density on antimony atom a in fragment II, compared with the antimony atoms in stibosobenzene. By an inductive effect the electron

(7) The disproportionations of the *p*-Cl- and *p*-$CH_3$- derivatives of stibosobenzene (to be reported in a later paper) obey the same rate law, although the corresponding bis-(diarylantimony)-oxides are solid at the experimental temperature. This is a further argument against the above mechanism.



(8) *Cf.* G. M. Schwab, H. S. Taylor and R. Spence, "Catalysis" D. Van Nostrand Company, New York, N. Y., 1937, p. 324 ff.

density on antimony atom b is also lowered. This makes it less likely for this atom to lose a phenyl group than to gain one, thus forming bis-(diphenylantimony)-oxide.



The chain breaking reaction may be the recombination of a phenyl group with an antimony atom of fragment I, or the attack of the oxygen atom of fragment I on an antimony atom of another such fragment, or both.

The proposed mechanism considers the shift of a phenyl group as the first step in the reaction. It is not known at the present time whether this phenyl group shifts with or without its electron pair, or with only one electron. The formation of fragments I and II would result in any case.

The autocatalysis by the product, bis-(diphenylantimony)-oxide, may be interpreted in terms of the following mechanism. A phenyl group migrates from a molecule of bis-(diphenylantimony)-oxide to an adjacent one of stibosobenzene.

followed by a break at the antimony–oxygen bond. This process results in fragments II, III and IV.

II III IV

Fragment III has a reactive oxygen atom which can propagate the chain in the same manner as fragment I above, while fragment IV may act as a chain breaker. The reaction according to the above mechanisms would be expected to obey the rate law

$$-dx/dt = k'x[k_1'x + k_2'(1 - x)] \qquad (2)$$

where $k'$ is the resultant rate constant of the chain propagating and chain breaking reactions, and $k_1'$ and $k_2'$ are the rate constants of the chain initiating steps (the thermal dissociations of stibosobenzene and bis-(diphenylantimony)-oxide respectively). Using $k_1 = k'k_1'$ and $k_2 = k'k_2'$ equation (2) can be written

$$-dx/dt = k_1x^2 + k_2x(1 - x) \qquad (2a)$$

If $k_2 \gg k_1$ equation (2a) will reduce to equation (1) except when $(1 - x) \ll x$, *i. e.*, for the first portion of the reaction.

The rate curves for all the preparations of stibosobenzene hydrolyzed with aqueous ammonia followed equation (2a) throughout (Fig. 1a). Equation (2a) can be integrated to give

$$\ln (k_2/x - k_2 + k_1) = k_2(t - C) \qquad (2b)$$

It is easily seen that this reduces to (1a) if $k_2 \gg k_1$, and that as a good approximation

$$C = t_{1/2} - (\ln k_2)/k_2$$

Substitution of this value for $C$ and solving for $k_1$ leads to the expression

$$k_1 = k_2\left[1 - \frac{1}{x} + e^{-k_2(t_{1/2} - t)}\right] \qquad (2c)$$

which permits calculation of $k_1$. Six experimental points (Fig. 1a) give $k_1 = 0.102 \pm 0.008 \times 10^{-4}$ sec.$^{-1}$. For the same preparation of stibosobenzene $k_2$ was found to be $4.68 \pm 0.14 \times 10^{-4}$ sec.$^{-1}$, and therefore $k_1 = 0.02\ k_2$, which bears out the assumption that $k_2 \gg k_1$. Since all experimental curves for stibosobenzene preparations hydrolyzed by ammonia gave the same characteristic curvature it seems probable that the ratio $k_1/k_2$ remains approximately constant regardless of the amount of catalyst present.

The early portion of the rate curves obtained with preparations hydrolyzed with sodium hydroxide showed a rapid initial rate, an effect opposite to that obtained with preparations hydrolyzed with aqueous ammonia (Fig. 1b). In spite of this the rate constants $k_2$ calculated from equation (1) from the main portion of the curve, but neglecting the early portion, were slower than those from the products hydrolyzed with ammonia (Table II). This may be explained by the assumption that sodium hydroxide molecules, while actually catalyzing the reaction more than ammonia molecules, cannot freely diffuse through the reaction mixture, and are thus effectively prevented from catalyzing more than the initial phase of the reaction. It might be possible to remove all traces of catalyst by partially rearranging samples of stibosobenzene, and extracting the bis-(diphenylantimony)-oxide together with the entrapped catalyst. The rate constant of the resulting product might then approximate that of pure stibosobenzene, free from catalyst.

To test this postulate large samples of stibosobenzene (10–15 g.) prepared by hydrolysis with sodium hydroxide were permitted to rearrange partially, extracted with ether and dried. The amount of stibosobenzene in the resulting mixture was determined by antimony analysis. The rate of disproportionation of the stibosobenzene in these mixtures containing antimony trioxide was then determined in the usual manner. A definite reduction of the rate constant was observed, which was not due to negative catalysis by antimony trioxide, since increasing amounts of the latter did not further retard the reaction. Nevertheless, the rate constants obtained from two different mixtures prepared in this manner were not in agreement (Table VI). It appears that the deter-

## Summary

1. The kinetics of the disproportionation of stibosobenzene were determined. From 20 to 100% completion the reaction was shown to obey a rate law: $-dx/dt = k_2x(1 - x)$, where $x$ is the fraction of stibosobenzene remaining at time $t$.

2. Preparations of stibosobenzene hydrolyzed with aqueous ammonia obeyed a rate law: $-dx/dt = k_1x^2 + k_2x(1 - x)$ over the entire course of the reaction, and the ratio $k_1/k_2$ was found to be 0.02.

3. The reaction was shown to be catalyzed by the product, bis-(diphenylantimony)-oxide, and by bases such as sodium hydroxide, ammonia and pyridine.

4. Rate constants were reproducible for each preparation, but varied widely with different preparations, an effect which is probably due to traces of impurities.

5. The apparent energy of activation was found to be 23.5 kcal./mole.

6. As mechanism of the reaction a chain reaction is proposed which is initiated by the thermal dissociation of phenyl groups from stibosobenzene and bis-(diphenylantimony)-oxide.

# On the Constitution of the Active Principles Isolated from the Matured Bark of *Aegle marmelos*, Correâ

BY ASIMA CHATTERJEE AND SUDHANGSU SEKHAR MITRA

The tree *Aegle marmelos*, Correâ (*Rutaceae*) commonly known as Bael, is indigeneous to India and found wild all over the Sub-Himalayan forests, in Central and South India. Its wood is yellowish-white with a strong aromatic scent. It is reputed to be a valuable Ayurvedic medicine for dysentery and various intestinal complaints. The bark as well as the fruits are used for this purpose. An examination of the fruits by various workers has revealed the occurrence of a coumarin[1] termed "marmelosin" which is identical with imperatorin,[2] a furocoumarin isolated from *Imperatoria ostruthium*[3] and *Angelica archangelica*.[4] The isolation of three crystalline constituents of the *Aegle marmelos* bark was described earlier.[5] We wish to report that one is an alkaloid identical[6] with γ-fagarine[7]; the second compound is marmesin, a coumarin which has not been isolated so far from other natural sources; and the third compound is umbelliferone.

Hydrochloric acid washing of ethereal bark extracts yielded a basic portion from which an alkaloid, m. p. 142.5–143°, was separated in 0.3% yield, which has been shown by Chakravarty[6] to be identical with γ-fagarine[7] (I).

I

The remaining ether extract upon concentration and standing in the refrigerator deposited crystals of marmesin, m. p. 189.5°, in a 0.6% yield. The mother liquor, after alkali washings and steam distillation, deposited umbelliferone m. p. 230° (yield, 0.06%).

The molecular formula of marmesin appeared to be $C_{14}H_{14}O_4$ which was confirmed by Rast's method and also by titration. Marmesin is optically active, $[\alpha]^{34}D$ +26.8° (in chloroform). This compound does not contain methoxy or methylenedioxy groups. It yields a monoacetyl derivative and readily undergoes dehydration producing anhydromarmesin. These facts indicate the presence of an hydroxyl group. Since the compound does not react with ferric chloride or diazomethane, it must contain an alcoholic group. Marmesin is neutral to litmus and is insoluble in aqueous alkali but readily dissolves in alcoholic alkali with a stable yellow color. This solution precipitated, on acidification, the original substance indicating a lactone structure. Marmesin dissolves in concentrated sulfuric acid with a yellow color and a deep violet fluorescence. When refluxed with aqueous alkali and a little mercuric oxide, marmesin passed into solution and, on acidification with hydrochloric acid, yielded an acid which did not undergo ring closure to give the

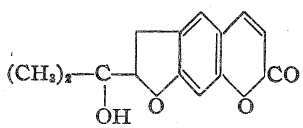
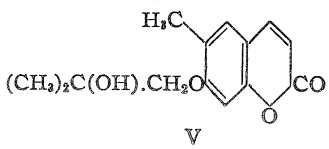
original substance. Consequently, a corresponding *trans* coumaric (*trans*-marmesic acid) acid, $C_{14}H_{16}O_5$, must have been formed under the influence of mercuric oxide. All these reactions are indicative of a coumarin ring which was secured by the oxidation of marmesin with chromic acid to umbelliferone-6-carboxylic acid (II).



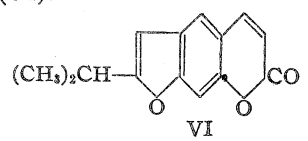
II

Consequently, the partial structure for marmesin can now be represented by (III).



III

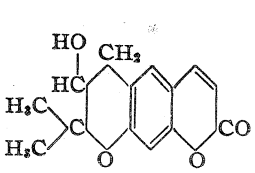
When fused with alkali, marmesin yields resorcinol, and, upon mild oxidation with chromic acid, acetone. The latter indicates that the group, $(CH_3)_2C(OH)$–, might be a part of the $C_4H_{10}O$-residue. The presence of a dimethylhydroxymethyl radical would also explain the easy dehydration of marmesin. One of the two phenolic hydroxyl groups which appears in resorcinol and umbelliferone-6-carboxylic acid is apparently involved in an ether linkage which in all probability leads to structure (IV) for marmesin.



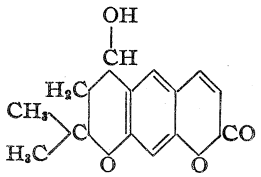
IV

By catalytic hydrogenation marmesin yields dihydromarmesin ($C_{14}H_{16}O_4$); however, anhydromarmesin adds four atoms of hydrogen ($C_{14}H_{16}O_3$). This observation eliminates structure (V).

V



Formula (IV) represents a substituted dihydrofurocoumarin where the $(CH_3)_2C(OH)$-group is attached to the $\beta$-carbon atom in the dihydrofuran ring which has been also confirmed by the established identity of anhydromarmesin with desoxyoreoselone[8] (VI).



VI

(8) E. Späth, K. Klager and C. Schlösser, *Ber.*, **64**, 270 (1931); E. Späth and K. Klager, *ibid.*, **66**, 749 (1933).

The possibility of an alternate structure (VII) or (VIII) involving a chroman ring can be ruled out since anhydromarmesin is not identical with xanthyletin.[9] From the study of marmesin it appeared that it might be an optical isomer of L-nodakenetin,[10] the degradation product of the glucoside nodakenin, isolated from *Peucedanum decursivum*.[11] Therefore, our marmesin sample was compared with authentic nodakenetin obtained from Dr. W. Grüber (Vienna) to whom our thanks are due. Although the two compounds and their corresponding derivatives are very similar, they show a large melting point depression (35°). The mixture of the two samples in equal amounts shows no optical activity. It should be mentioned that free nodakenetin has not yet been found in nature but only as the glucoside mentioned[11]; however, its D-isomer, marmesin, occurs in the free state.

VII

VIII

An interesting observation was made in connection with umbelliferone, *viz.*, that the latter was not present as such in the residual oil but could be obtained from it by steam distillation or saponification.[12] It is, therefore, probable that the bark of *Aegle marmelos* contains another as yet not isolated coumarin which can be readily hydrolyzed to umbelliferone.

## Experimental

**Extraction of the Matured Bark of Aegle Marmelos.**—Two kg. of air-dried, powdered bark was extracted with ether for forty-eight hours in a Soxhlet apparatus. The deep-brown extract was shaken with 0.1% hydrochloric acid (300 ml.) to remove $\gamma$-fagarine. This was repeated (about 5 times) until the acid digest gave only an insignificant precipitate with Dragendorff's reagent. Then the brown ether solution (P) was washed with water, dried over sodium sulfate, concentrated to 500 ml. and kept in a refrigerator for four weeks.

**Isolation of Marmesin.**—The brown ethereal solution (P) deposited 12 g. of marmesin which was filtered off, and the mother liquor (Q) was kept for further investigation. Marmesin was purified by successive crystallizations from acetone, ethyl alcohol, benzene, and ethyl acetate when rhombic plates of a constant m. p. 189.5° were obtained. It sublimes unchanged in a 0.1 mm. vacuum at 150–160°. It is freely soluble in chloroform, fairly in acetone or alcohol, sparingly in benzene, ethyl acetate, ether, and is insoluble in petroleum ether or water; $[\alpha]^{34}D$ +26.8° (in chloroform).

*Anal.* Calcd. for $C_{14}H_{14}O_4$: C, 68.30; H, 5.69; mol. wt., 246. Found: C, 68.42; H, 5.74; mol. wt. (Rast), 252, 250.

**Molecular Weight by Titration.**—Marmesin (0.15 g.) was dissolved in 5 ml. of alcohol and refluxed for half an hour

(9) E. Späth, P. K. Bose, E. Dobrovolny and A. Chatterjee (née Mookerjee), *ibid.*, **72**, 1452 (1939).

(10) E. Späth and P. Kainrath, *ibid.*, **69**, 2062 (1936).

(11) J. Arima, *Bull. Chem. Soc. Japan*, **4**, 16 (1929).

(12) E. Späth and L. Socias, *Ber.*, **67**, 59 (1934).

with 25 ml. of 1 *N* aqueous potassium hydroxide. The pale yellow solution was cooled and the excess of alkali was back titrated with sulfuric acid (phenolphthalein). Found: mol. wt., 250, 253.

**Action of Dilute Alkali on Marmesin.**—Marmesin (0.25 g.) in 5 ml. of methyl alcohol was mixed with 40 ml. of 1% aqueous potassium hydroxide and refluxed for half an hour. The substance passed into solution and gradually became yellow. It was acidified with hydrochloric acid (congo red), allowed to stand overnight, and extracted with ether. The dry residue of this extract crystallized from acetone in colorless, rhombic plates which melted at 189–189.5°, alone or when mixed with a pure specimen of marmesin.

**Acetylation of Marmesin.**—A mixture of marmesin (0.25 g.), 5 ml. of acetic anhydride and 0.5 g. of freshly fused sodium acetate was refluxed for five hours. The mixture was poured into ice-cold water and stirred. The separated solids were collected, washed with ice-cold water and crystallized from hot water. The colorless flakes (0.25 g.), m. p. 130°, were washed with cold water and dried.

*Anal.* Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.55. Found: C, 66.91, H, 5.42.

**Dehydration of Marmesin.**—Marmesin (0.25 g.) dissolved in 50 ml. of dry benzene was refluxed with 2.5 g. of phosphorus pentoxide for five hours. The decanted, clear solution was concentrated to 5 ml. Transparent plates of anhydromarmesin separated which were filtered and washed with cold benzene; constant m. p., 138–140°.

*Anal.* Calcd. for $C_{14}H_{12}O_3$: C, 73.69; H, 5.26. Found: C, 73.80; H, 5.60.

**Catalytic Hydrogenation of Marmesin.**—Marmesin (0.3 g.), dissolved in glacial acetic acid (10 ml.), was treated with hydrogen and Adams platinum oxide catalyst (0.1 g.) which had been saturated previously with hydrogen. The absorption of hydrogen (30.0 ml. at 30°, 760 mm.) corresponded almost exactly to 1 $H_2$. The solution was filtered, diluted with water and extracted with ether. The ethereal solution was washed successively with sodium bicarbonate and water, dried over sodium sulfate, concentrated to 5 ml., diluted with 1 volume of petroleum ether, and kept overnight. Colorless, rhombic plates separated, m. p. 135°.

*Anal.* Calcd. for $C_{14}H_{16}O_4$: C, 67.75; H, 6.45. Found: C, 68.34; H, 6.20.

**Catalytic Hydrogenation of Anhydromarmesin.**—Anhydromarmesin (0.450 g.) in 10 ml. of glacial acetic acid was treated as above in the presence of 0.15 g. of catalyst. Within a few minutes 98.0 ml. of hydrogen was absorbed (30°, 760 mm.) corresponding to 4 gram atoms of hydrogen. The solution was treated as described in the previous section. The product crystallized from a mixture of benzene and petroleum ether in colorless flakes, m. p. 116–117°.

*Anal.* Calcd. for $C_{14}H_{16}O_3$: C, 72.40; H, 6.90. Found: C, 72.70, H, 7.07.

***trans*-Coumaric Acid Derivative of Marmesin (*trans*-marmesic acid).**—A mixture of marmesin (0.39 g.), 30 ml. of aqueous 2 *N* sodium hydroxide and a little mercuric oxide was refluxed for two hours and filtered. The yellow filtrate was acidified with hydrochloric acid (congo red) and kept overnight. The precipitated yellowish-green flakes were recrystallized from dilute methyl alcohol and melted at 204° (dec.).

*Anal.* Calcd. for $C_{14}H_{16}O_5$: C, 63.63; H, 6.02. Found: C, 63.95; H, 6.31.

**Fusion of Marmesin with Potassium Hydroxide; Isolation of Resorcinol.**—Marmesin (1.00 g.) was fused with potassium hydroxide (5.00 g.) in a nickel crucible and heated to 250° on a metal-bath for one hour. The product was cooled and digested with water. The brown solution was acidified with hydrochloric acid and extracted with ether. The ethereal solution was washed with 10% aqueous sodium bicarbonate and then with water, dried and concentrated. The separated crystals were recrystallized from alcohol and petroleum ether (b. p. 60°) and then from ethyl acetate (m. p. 109°). They gave a violet color with ferric chloride and reduced ammoniacal silver nitrate. The sample gave no melting point depression with resorcinol.

*Anal.* Calcd. for $C_6H_6O_2$: C, 65.45; H, 5.45. Found: C, 65.50; H, 5.61.

**Oxidation of Marmesin with Chromic Acid.**—A solution of marmesin (0.5 g.) in glacial acetic acid (8 ml.) was added to chromic acid (0.25 g. in 10 ml. of 50% acetic acid) and kept at room temperature for sixty hours in a closed flask. The mixture was cooled in ice and was slowly almost neutralized with strong sodium hydroxide. The solution was distilled until 15 ml. was collected in a receiver containing 4 drops of freshly distilled benzaldehyde and 4 drops of 10% sodium hydroxide. On keeping the mixture overnight in the refrigerator, a semi-solid separated that was extracted with ether. The dried extract was evaporated. The oily residue was treated with 2 drops of benzaldehyde (in dilute, acetone-free methyl alcohol) and cooled in ice when immediately glistening needles separated which were recrystallized from dilute methanol (acetone-free); pale yellow, shining needles, m.p. 112°. The substance was identified as dibenzal acetone by the mixed melting point test.

**Isolation of Umbelliferone-6-carboxylic Acid by Oxidation of Marmesin.**—Marmesin (1.5 g.) was treated with 300 ml. of 3% sulfuric acid and the mixture was heated. To the boiling mass, 5 g. of potassium bichromate (in 60 ml. of water) was slowly added and the brown-red solution was refluxed for six hours. Then the dark-green solution was cooled and shaken with ether to remove unchanged marmesin. The green aqueous filtrate was concentrated on a water-bath to 100 ml. and kept overnight at 0°. The separated pale yellow solid (0.5 g.) was washed with cold water. It crystallized from methyl alcohol in colorless needles, m.p. 260° (dec.). It gave a violet color with ferric chloride and dissolved readily in aqueous alkali or alkali bicarbonate (with effervescence) with a stable yellow color. The compound was identified as umbelliferone-6-carboxylic acid by m.p. and mixed m.p. tests.[13]

*Anal.* Calcd. for $C_{10}H_6O_5$: C, 58.27; H, 2.95. Found: C, 58.52; H, 3.23.

**Methylation of Umbelliferone-6-carboxylic Acid.**—The compound (0.05 g.) in methanol was treated with excess diazomethane (in ether). After two days, the solvent was removed, and the residue crystallized from a mixture of ether and methyl alcohol. The pale yellow needles melted at 165–166° and gave no depression with dimethyl-7-hydroxy-coumarincarboxylic acid (m.p. 168°).

**Decarboxylation of 7-Hydroxy-coumarin-6-carboxylic Acid.**—Umbelliferone 6-carboxylic acid (0.2 g.) isolated from chromic acid oxidation products of marmesin, was heated above its m.p. to 265–270° for thirty minutes. From the brown mass a colorless solid distilled at 150–160° (0.1 mm.). It crystallized from dilute methyl alcohol in needles, m.p. 230°. It had the same melting point when mixed with synthetic umbelliferone.

*Anal.* Calcd. for $C_9H_6O_3$: C, 66.64; H, 3.74. Found: C, 66.21; H, 3.98.

The methyl derivative of the decarboxylation product, prepared by the action of diazomethane, melted at 118–119° and showed no change when mixed with synthetic methyl-umbelliferone.

**Isolation of Umbelliferone from the Fraction (Q).**—The mother liquor, Q, left after removal of marmesin, was freed from the solvent, and the oil (R) obtained weighed 300 g. Two hundred grams of this oil was steam-distilled for twelve hours when an oil (6 ml.) was collected, having a bitter taste, and a pleasant smell, resembling that of a mixture of eucalyptus and lemon oil. After removal of this essential oil, the residue was cooled and a crystalline substance (0.80 g.) obtained. It was purified by crystallizations from methyl alcohol, ethyl acetate and

(13) H. von Pechmann, *Ber.*, **17**, 932 (1884).

water, yielding shining needles of umbelliferone, m.p. 230°.

**Isolation of Umbelliferone from Oil (R) by Saponification.**—To the oil (100 g.) (15°), 200 ml. of 20% methanolic potassium hydroxide was added with constant shaking. The mixture was allowed to stand for forty-five minutes, poured into 1.5 liters of ice-water and extracted five times with ether to remove unsaponifiable matter. The alkaline aqueous portion was acidified with hydrochloric acid (congo red) and distilled *in vacuo* to remove the greater portion of methyl alcohol. The next day the separated oil was extracted with ether and the extract was washed with 2 × 100 ml. of 25% potassium carbonate (W). The ethereal extract was washed with water, dried and distilled. Only a very small, gummy residue was left.

**Isolation of Umbelliferone from Fraction (W).**—The brown potassium carbonate washings (W) were acidified with hydrochloric acid (congo red) whereby the solution became turbid. It was extracted with 100 ml. of ether; the extract was twice washed with water, dried and distilled. A brownish, solid residue of umbelliferone (0.4 g.), mixed with a little viscous oil, was left, which crystallized from dilute methanol in silky, colorless needles; m.p. 230°.

**Acknowledgment.**—It is a pleasure to thank Professor L. M. Parks for suggestions and the laboratory facilities granted, and Professor A. H. Uhl, Professor S. N. Bose, Professor P. C. Mitter, and Dr. P. K. Bose for their interest in this investigation.

## Summary

From the matured bark of *Aegle marmelos*, Correâ, three crystalline compounds have been isolated in pure state: 1, The alkaloid γ-fagarine; 2, A coumarin which had not been observed before in the free state in nature. It is an optical isomer of nodakenetin; and 3, Umbelliferone.

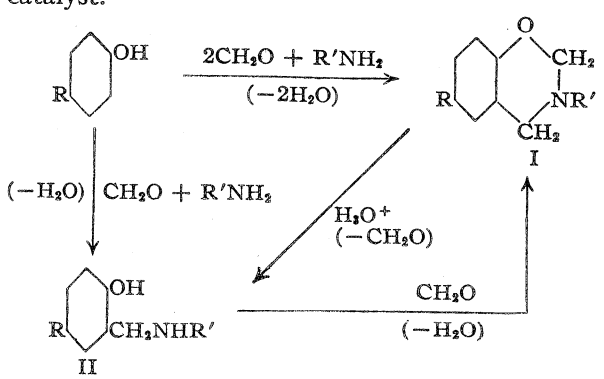
# 3,4-Dihydro-1,3,2H-Benzoxazines. Reaction of *p*-Substituted Phenols with N,N-Dimethylolamines

BY W. J. BURKE

Major attention in reactions involving phenol and formaldehyde has quite naturally been directed toward polymeric products in view of their wide industrial application. The marked reactivity of the intermediates involved, however, indicates the desirability of investigating further the possibility of isolating well defined monomeric compounds from such systems.

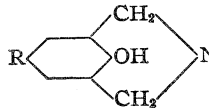


Interaction of secondary aliphatic amines and formaldehyde with phenols has been shown by Caldwell and Thompson,[1] and by Bruson and MacMullen[2] to result in the introduction of one or more dialkylaminomethyl substituents in positions ortho or para to the hydroxyl group. The reaction involved is shown as

$$C_6H_5OH + CH_2O + R_2NH \longrightarrow HOC_6H_4CH_2NR_2$$

Although generally considered to be a Mannich type of condensation, this and similar reactions involving the interaction of a secondary amine and formaldehyde with a compound containing active hydrogen were studied by others[3,4] several years before the initial related work of Mannich.[5]

Analogous studies involving primary rather than secondary aliphatic amines appear to have been limited to the use of 2-aminoethanol.[6] Reaction of equimolar quantities of this amine with formaldehyde and certain *o*- or *p*-substituted phenols resulted in crystalline compounds having *o*- or *p*-beta-hydroxyethylaminomethyl groups. Other phenols, such as the three cresols, gave resins containing nitrogen or sirups which could not be purified. The condensation of selected phenols and formaldehyde with sodium sulfanilate and related aminoaromatic sulfonic acid salts has also been reported[7] but the exact composition of the products was not determined.



The present work has been concerned with the reaction of *p*-substituted phenols with formaldehyde and primary amines in a molar ratio of 1:2:1, respectively. This procedure led to the formation in good yield of 3,4-dihydro-3,6-disubstituted-1,3-2H-benzoxazines (I), a new series of compounds.[8] In an alternate method, equimolar quantities of the *p*-substituted phenol, formaldehyde, and primary amine reacted to give as an intermediate an *o*-alkylaminomethyl-*p*-substituted phenol (II). Conversion of II to I took place readily by treatment with formaldehyde in the presence of a basic catalyst.

(8) The nomenclature employed in this paper follows that kindly suggested by Dr. Leonard T. Capell of *Chemical Abstracts*.

For values for R and R′, see Table I.

Inasmuch as N-methylolamines are capable of attacking *p*-substituted phenols at the free ortho positions[1,2] the possibility of the alternate structure III

III

isomeric with I, might be considered. Study of the hydrolysis of the products in the presence of aqueous acid showed that one mole of formaldehyde was readily eliminated with the formation of a compound identical with the corresponding *p*-substituted-*o*-alkylaminomethylphenol II, prepared by an independent synthesis. This behavior is in accord with a 3,4-dihydro-1,3-2H-benzoxazine structure, which contains the labile —O—$CH_2$—N< group capable of releasing formaldehyde under the mild hydrolytic conditions used. Essentially complete recovery (95%) of starting material when 3,4-dihydro-3-cyclohexyl-6-*t*-butyl-1,3,2H-benzoxazine was treated with acetic anhydride in pyridine is also compatible with the formula assigned.

In the synthesis of 3,4-dihydro-3,6-disubstituted-1,3,2H-benzoxazines, the primary amine and formaldehyde were first condensed to the N,N-dimethylolamine, which was then allowed to react with the *p*-substituted phenol. As a means of obtaining homogeneous reaction media it was found convenient to employ dioxane as solvent. When the reagents were heated under gentle reflux the condensation took place readily and was essentially complete within fifteen minutes in certain instances. Methyl-, cyclohexyl- and benzylamines were used as examples of aliphatic, alicyclic and aralkyl primary amines in condensations with formaldehyde and a variety of *p*-substituted phenols. A summary of the products prepared is given in Table I. Both aqueous formaldehyde and paraformaldehyde were employed satisfactorily. The 3,4-dihydro-1,3,2H-benzoxazines were quite stable toward hot aqueous alkali and formed hydrochlorides readily.

Condensation of benzylamine with 2,6-dimethylol-4-methylphenol might be expected to lead to a compound of the type III. When these two reagents were heated together, however, little or no monomeric condensate appeared to have formed since the major portion (86%) of the dimethylolphenol was recovered. This behavior is in contrast to the related reactions in which a combination of either dimethylolurea and a primary amine or urea and a dimethylolamine readily resulted in the formation of a tetrahydro-5-substituted-2(1)*s*-triazone.[9]

[a] Uncorrected. [b] Recrystallized from methanol. [c] Recrystallized from 95% ethanol. [d] Recrystallized from ethyl acetate–methanol (1:1, by vol.). [e] Recrystallized from ethyl acetate–ethanol (95:5, by vol.). [f] This compound was prepared by Mr. Carl Weatherbee.

With a view to obtaining additional information regarding structure, 2,4-dimethylphenol was treated with formaldehyde and cyclohexylamine in a 1:2:1 molar ratio, respectively. The condensation resulted in the elimination of two molecules of water indicating the formation of 3,4-dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine (IV), since only a single ortho position was available for reaction. Upon hydrolysis of IV in aqueous acid, formaldehyde was evolved with the formation of V, which was also synthesized by the condensation of equimolar quantities of 2,4-dimethylphenol, formaldehyde, and cyclohexylamine.

IV

V

The heterocyclic products from *p*-substituted phenols accordingly behave as 3,4-dihydro-1,3,-2H-benzoxazines upon hydrolysis.

**Acknowledgment.**—The assistance given by the Research Corporation in the form of a Frederick Gardener Cottrell Research Grant is gratefully acknowledged.

## Experimental

**3,4-Dihydro-3-cyclohexyl-6-*t*-butyl-1,3,2H-benzoxazine.**—The preparation of this compound by the two procedures given below indicates the general methods used in the synthesis of the 3,4-dihydro-1,3,2H-benzoxazines.

**Procedure A.**—Cyclohexylamine (39.6 g., 0.4 mole) was added portionwise with cooling to 200 ml. of dioxane containing 60 ml. of aqueous 37% formaldehyde (0.8 mole). After addition of 60 g. of *p*-*t*-butylphenol (0.4 mole), the mixture was heated under reflux for two hours. Upon cooling to room temperature, a crystalline solid (85 g.) separated. The product was recrystallized

(9) Burke, THIS JOURNAL, 69, 2136 (1947).

from 95% ethanol; m.p. 94°, yield 78%. The product was insoluble in water, 10% aqueous hydrochloric acid, and 10% aqueous potassium hydroxide but was soluble in acetic acid, benzene, and chloroform.

*Anal.* Calcd. for $C_{18}H_{27}NO$; C, 79.07; H, 9.96; N, 5.12. Found: C, 79.11; H, 9.70; N, 5.06.

**Procedure B.**—Paraformaldehyde (6 g., 0.2 mole) was dissolved in 8 ml. of warm methanol containing 0.1 g. of potassium hydroxide. The solution was cooled during the portionwise addition of 9.9 g. of cyclohexylamine (0.1 mole). After addition of 15 g. *p-t*-butylphenol (0.1 mole), the resulting solution was heated under reflux for fifteen minutes. Upon cooling the reaction mixture solidified. Recrystallization from 95% ethanol yielded 23 g. of product; m.p., 94°. An additional 2 g. was obtained from the mother liquor; yield 92%. A mixed m.p. determination with the product prepared by procedure A showed no depression.

In order to determine the effect of acetylating conditions on the product, the following experiment was carried out. A solution of 2.73 g. of the product (0.01 mole) in 10 ml. of pyridine and 6.1 g. of acetic anhydride (0.06 mole) was heated on a boiling water-bath for one and a half hours. The reaction mixture was poured into crushed ice and the resulting solid (2.6 g. or 95% recovery) removed by filtration. The product was recrystallized from ethanol; m.p. 94°. A mixed m.p. determination with starting material showed no depression.

**2-Cyclohexylaminomethyl-4-*t*-butylphenol.**—To 30 ml. of dioxane containing 7.5 ml. of 37% aqueous formaldehyde (0.1 mole) was added 9.9 g. of cyclohexylamine (0.1 mole) with sufficient cooling to keep the temperature below 25°. After addition of 15 g. of *p-t*-butylphenol (0.1 mole) in 20 ml. dioxane with agitation, the resulting solution was heated under gentle reflux for one hour. A sticky mass of crystals was obtained upon removal of dioxane and water at room temperature. The product was recrystallized from ethanol; m.p. 112°; yield, 17 g. (65%).

*Anal.* Calcd. for $C_{17}H_{27}NO$: C, 78.11; H, 10.41. Found: C, 78.00; H, 10.01.

**Hydrolysis of 3,4-Dihydro-3-cyclohexyl-6-*t*-butyl-1,3,-2H-benzoxazine.**—To 2.73 g. of 3,4-dihydro-3-cyclohexyl-6-*t*-butyl-1,3,2H-benzoxazine (0.01 mole) was added 10 ml. of 95% ethanol and 5 ml. of aqueous hydrochloric acid (0.11 mole). The resulting solution was heated in a 50 ml. modified Claisen flask and 20 ml. of ethanol–water (1:1, by vol.) added during the course of the distillation. The distillate was collected in 25 ml. of water. The distillation was interrupted after a solid began to precipitate out and the volume of the residue was about 10 ml. Ethanol (20 ml.) was added and the resulting solution was removed from the flask. Addition of 6.1 ml. of 10% alcoholic potassium hydroxide (0.11 mole) to the solution resulted in the immediate formation of a precipitate. The product was washed thoroughly with water and recrystallized from ethanol; m.p. 112°; yield 2.2 g. (84%). A mixed melting point determination with 2-cyclohexylaminomethyl-4-*t*-butylphenol showed no depression.

Treatment of a portion of the distillate with 2,4-dinitrophenylhydrazine gave a yellow crystalline product, which was recrystallized from ethanol; m.p. 166°. A mixed m.p. determination with a specimen of the 2,4-dinitrophenylhydrazone of formaldehyde showed no depression.

**Reaction of 2-Cyclohexylaminomethyl-4-*t*-butylphenol with Formaldehyde.**—To 0.6 g. of paraformaldehyde (0.02 mole) dissolved in 10 ml. of methanol containing 0.05 g. of potassium hydroxide was added 2.61 g. of 2-cyclohexylaminomethyl-4-*t*-butylphenol (0.01 mole). Most of the phenol went into solution but within a minute the reaction mixture became a solid mass. Methanol (35 ml.) was added and the resulting solution heated under reflux for one and a half hours. Upon addition of 4 ml. of water and cooling, a white crystalline product (2.6 g.) separated out. The product was recrystallized from ethanol; m.p., 94°; yield 95%. A mixed m.p. determination with 3,4-dihydro-3-cyclohexyl-6-*t*-butyl-1,3,2H-benzoxazine, prepared as described above, showed no depression.

**3,4-Dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine.**—To 19.8 g. of cyclohexylamine (0.2 mole) in 100 ml. of dioxane was added 30 ml. of 37% aqueous formaldehyde (0.4 mole) with cooling. After addition of 22.4 g. of 2,4-dimethylphenol (0.2 mole), the resulting solution was heated under reflux for one and a half hours. A light brown liquid (46 g.) was obtained by removal of solvent under reduced pressure. Distillation of the product gave a light-yellow oil; b.p. 140–142° at 0.3 mm., yield 81%.

*Anal.* Calcd. for $C_{16}H_{23}NO$: C, 78.32; H, 9.45. Found: C, 78.01; H, 9.22.

In another run carried out under analogous conditions, the crude oil was dissolved in ethanol and an equivalent quantity of concentrated aqueous hydrochloric acid added with cooling. The product was isolated as the white crystalline hydrochloride; m.p. 192–195° (dec.); yield 80%.

*Anal.* Calcd. for $C_{16}H_{24}NOCl$: neut. equiv., 282. Found: neut. equiv., 280.

A mixed m.p. determination with the hydrochloride prepared from the distilled oil showed no depression. Treatment of the hydrochloride with an equivalent quantity of 10% alcoholic potassium hydroxide yielded the free base as a light-yellow oil. The free base was insoluble in water and aqueous 10% potassium hydroxide and was readily soluble in benzene, acetic acid, and chloroform.

**Hydrolysis of 3,4-Dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine Hydrochloride.**—A solution of 2.82 g. of 3,4-dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine hydrochloride in 25 ml. of water was heated in a distilling flask. An additional 25 ml. of water was added during the course of the distillation, which was continued until about 10 ml. of liquid remained. Removal of water yielded 2.6 g. of a crystalline product, which was recrystallized from water and then from ethanol; m.p. 214–215°, yield 96%.

*Anal.* Calcd. for $C_{15}H_{24}NOCl$; neut. equiv., 270. Found: neut. equiv., 268.

The presence of formaldehyde in the distillate was confirmed by the preparation of a 2,4-dinitrophenylhydrazone; m.p., 166°. A mixed melting point determination with the 2,4-dinitrophenylhydrazone of formaldehyde showed no depression.

To 1.0 g. (0.037 mole) of the above 2-cyclohexylaminomethyl-4,6-dimethylphenol hydrochloride in 15 ml. of ethanol was added 2.1 ml. of 10% alcoholic potassium hydroxide (0.037 mole). The precipitate of potassium chloride was removed by filtration and water added to the filtrate to incipient opalescence. Upon cooling, the crystalline free base (0.65 g.) was obtained; m.p. 51°, yield 68%.

*Anal.* Calcd. for: $C_{15}H_{23}NO$: C, 77.20; H, 9.93. Found: C, 77.36; H, 9.98.

**Direct Synthesis of 2-Cyclohexylaminomethyl-4,6-dimethylphenol.**—To 40 ml. of dioxane containing 7.5 ml. of 37% aqueous formaldehyde (0.1 mole) and 9.9 g. of cyclohexylamine (0.1 mole) was added 11.2 g. of 2,4-dimethylphenol (0.1 mole). The reaction mixture was heated under reflux for two hours. The solvent was removed under reduced pressure and the resulting solid recrystallized from ethanol; m.p. 51°, yield 8.5 g. (36%). A mixed m.p. determination with the free base obtained indirectly through hydrolysis of 3,4-dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine hydrochloride showed no depression.

**Reaction of 2-Cyclohexylaminomethyl-4,6-dimethylphenol with Formaldehyde.**—To a solution of 0.6 g. of paraformaldehyde (0.02 mole) in 16 ml. of methanol containing 0.05 g. of potassium hydroxide was added 2.33 g. (0.01 mole) of 2-cyclohexylaminomethyl-4,6-dimethylphenol. The reaction mixture was refluxed for one and a half hours and then cooled in ice and water. Addition of 0.87 ml. of concentrated hydrochloric acid (0.01 mole) in 3 ml. of methanol resulted in the formation of a white crystalline product (1.8 g.) which was removed by filtra-

tion, and washed with cold water and then acetone; m.p. 192–195° (dec.). An additional 0.4 g. was obtained from the mother liquor: yield, 78%. A mixed m.p. determination with 3,4-dihydro-3-cyclohexyl-6,8-dimethyl-1,3,2H-benzoxazine hydrochloride showed no depression.

**Treatment of 2,6-Dimethylol-4-methylphenol with Benzylamine.**—A solution containing 3.36 g. of 2,6-dimethylol-4-methylphenol[10] (0.02 mole), 2.14 g. of benzylamine (0.02 mole) and 5 ml. of benzene was heated under reflux for three hours. Upon cooling and filtering 2.4 g. of solid was obtained, which after crystallization from ethanol melted at 131–132°. Admixture of 2,6-dimethylol-4-methylphenol with either the crude or recrystallized product did not result in a depression of the m. p. of the latter products. An additional 0.4 g. of the same material was obtained from the filtrate; recovery, 86%.

(10) This compound (m. p. 132–133°) was prepared by the procedure of Ullman and Brittner, *Ber.*, **42**, 2539 (1909). These authors recorded a m. p. of 135°.

## Summary

1. Reaction of *p*-substituted phenols with formaldehyde and primary aliphatic amines in a molar ratio 1:2:1, respectively, resulted in the formation of a new series of compounds, the 3,4-dihydro-3,6-disubstituted-1,3,2H-benzoxazines.

2. An alternate synthesis for the above compounds involving condensation of formaldehyde with *o*-alkylaminomethylphenols was reported.

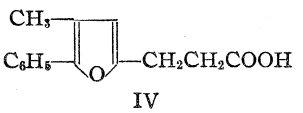
# Some Aryl Substituted Cyclopentenones: A New Synthesis of the Cyclopentenophenanthrene Structure

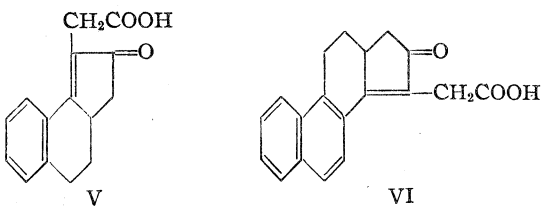


BY D. L. TURNER

The 3-(β-naphthyl)-2-cyclopenten-1-one-2-acetic acid of Robinson[1] has been found to produce myeloid hyperplasia when injected into guinea-pigs in large doses (100 mg.).[2] This observation led us to prepare a series of similar compounds for biological testing.

The desired compounds were made by the general methods of Robinson, and Kehrer and Igler,[3] from the furfurylidene ketones I (Table I) by way of the phenacyl levulinic acids II (Table II). The cyclopentenones III are formed by the alkaline catalyzed ring closure of the diketo-acids (Table III).

Anomalous behavior was shown by furfurylidene propiophenone; on acid hydrolysis, this substance took up the elements of one molecule of water only, and the product contained no carbonyl group. This substance is evidently 3-methyl-2-phenylfuran-5-propionic acid IV; its



IV

absorption spectrum coincides almost exactly with that of 2-phenylfuran-5-propionic acid[4a] (Fig. 1). Robinson[1] has suggested that an intermediate naphthylfuranpropionic acid was formed in the hydrolysis of furfurylidene-2-acetylnaphthalene.

A similar furan had been isolated previously by Blicke[4b] from the hydrolysis of furfurylideneacetophenone.

The present work provides an easy preparation for the ring systems V and VI, available from α-tetralone and 1-keto-1,2,3,4-tetrahydrophenanthrene, respectively. Similar compounds, lacking

V VI

the acetic acid side-chains, have been made by Wilds,[5,6] who has studed their absorption spectra.[7] The absorption spectrum of the methyl ester of VI was found to be almost identical with that of Wilds' analogous substance (Fig. 2); slight discrepancies were found at low wave lengths where carboxyl group absorption might be expected to make a difference.

[a] By hydrolysis of ester. [b] 7-*p*-Methoxyphenyl-4,7-diketoheptanoic acid has been made by Robinson. Furfurylidene *p*-methoxyacetophenone is described by Maxim and Angelesco, *Bull. soc. chim.*, [5] 1, 1128 (1934), as well as by Robinson.[4] [c] By esterification with diazomethane. [d] M. p. rose from 153–155° after drying *in vacuo* at 100°. [e] Semicarbazone from ethanol, m. p. 204° (dec). *Anal.* Calcd. for $C_{19}H_{25}N_3O_3$: C, 66.4; H, 7.3. Found: C, 66.7; H, 7.5. [f] Semicarbazone from ethanol, m. p. 217° (dec). *Anal.* Calcd. for $C_{19}H_{19}N_3O_4$: C, 64.6; H, 5.4. Found: C, 64.4; H, 5.7.

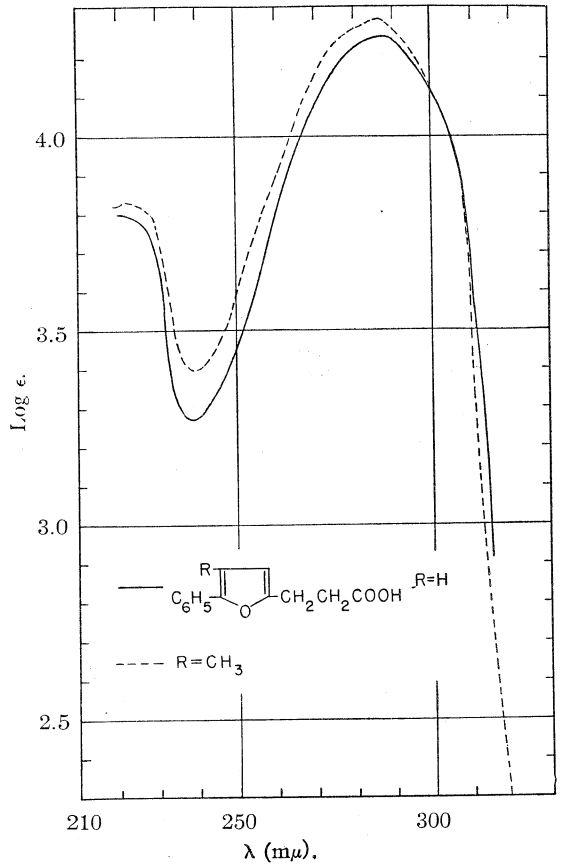

Fig. 1.—Spectra of phenylfurans.

Finally, we describe the preparation of 1-keto-1,-2,3,4,9,10-hexahydrophenanthrene by the method devised by Bachmann, Kushner and Stevenson[8] for the 7-methoxy derivative of this ketone. Since the yield was poor, we did not attempt to convert this ketone to the cyclopentenone. The 7-methoxy group facilitates the two ring closures of this synthetic method. Bachmann and Wendler,[9] and Johnson, Johnson and Petersen[10] have described alternative routes to 1-keto-1,2,3,4,9,10-hexahydrophenanthrene.

This investigation was aided by a grant from the American Cancer Society.

## Experimental[11]

The substituted acetophenones, not commercially available, were made by the general method of "Organic Syntheses."[12] Their properties agreed with those described in the literature.[13] The 1-keto-1,2,3,4-tetrahydrophenanthrene was prepared by the usual methods[14] from β-(1-naphthoyl)-propionic acid. However, the initial acid was made by the method of Lontz,[15] which does not seem to be widely known.

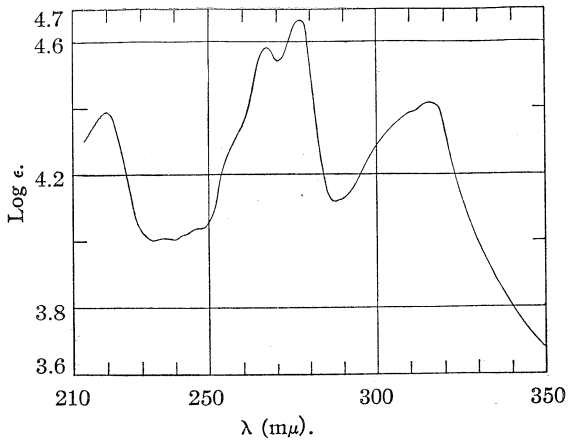

Fig. 2.—Spectrum of methyl 11,12,13,17-tetrahydro-16H-cyclopentaphenanthren-16-one-15-acetate.

**4-Methoxy-1-acetylnaphthalene.**—The methyl ether of α-naphthol (0.5 mole), acetic anhydride (0.5 mole), and iodine (10 g.) were heated together in an oil-bath at 160° for two hours, under a reflux condenser. The mixture was diluted with water and extracted with benzene. The benzene solution was washed with 5% sodium hydroxide, and then with 10% sodium bisulfite solution, then dried and distilled.[16] The product had b.p. 165° (2 mm.). Recrystallization from ether gave 47 g. (53% yield), m.p. 69–71°.[17]

**Furfurylidene Ketones.**—An equimolecular quantity of freshly distilled furfural was added to a solution of 100 g. of ketone in 100 ml. of ethanol. To the mixture was added 10 ml. 45% (by weight) of potassium hydroxide. The quantity of solvent was increased when the ketone was insoluble. The furfurylidene derivatives from *p*-ethyl- and *p*-isopropylacetophenone, and that from propiophenone, were obtained crystalline by diluting the reaction product with water and extracting with chloroform. The chloroform solution was washed with water, dried, and distilled. The residue could then be crystallized from *n*-pentane. Like chalcones, the furfurylidene ketones undergo photochemical alteration on standing.

**Diketo Acids.**—The Robinson[1] method indicated in Table II differs from that of Kehrer and Igler[3] by the addition of acetic acid to the hydrolysis mixture.[18]

**3-Methyl-2-phenylfuran-5-propionic Acid.**—The usual acid hydrolysis method of Robinson applied to furfurylidene propiophenone gave a 10% yield of this material in three extractions. The only other product was the usual residue of black tar. Recrystallized from benzene, the crystalline product from the acid hydrolysis mixture had m.p. 139–140°. Treated with boiling potassium hydroxide solution, under the conditions[1] for the preparation of the cyclopentenones (Table III), it was unaltered. It did not react with reagents for the carbonyl group.

*Anal.* Calcd. for $C_{14}H_{14}O_3$: C, 73.0; H, 6.1. Found: C, 72.7; H, 6.3.

**Cyclopentenones.**—These were obtained by the method of Robinson,[1] except as noted below.

(13) *p-s*-Amylacetophenone is described by Hennion, THIS JOURNAL, **64**, 2421 (1942); *p*-cyclohexylacetophenone by Mayes and Turner, *J. Chem. Soc.*, 500 (1929). The others can be found in "Beilstein."

(14) Drake and McVey, *J. Org. Chem.*, **4**, 464 (1939).

(15) Lontz, U. S. Patent 2,339,789 (1944).

(16) This preparation is based on a method described by Kosak and Hartough, THIS JOURNAL, **68**, 2639 (1946), and by Chodroff and Klein, *ibid.*, **70**, 1647 (1948).

(17) Gattermann, Erhardt and Maisch, *Ber.*, **23**, 1199 (1890), give m. p. 71–72°.

(18) The yields reported in Table II might be increased by more complete extraction of the diketo-acids.

**3-*p*-*s*-Amylphenyl-2-cyclopenten-1-one-2-acetic Acid.**—To 50 g. of furfurylidene *p*-*s*-amylacetophenone was added 500 ml. of ethanol and 125 ml. of concentrated hydrochloric acid. After refluxing for ten hours, the solvent was distilled and the residual tar was refluxed with a mixture of 250 ml. of acetic acid, 250 ml. of concentrated hydrochloric acid and 500 ml. of water for two hours. The mixture was cooled, diluted with water, and extracted with ether. The ethereal solution was washed with water until the acetic acid was removed, and then the acidic hydrolysis products were removed with 9% sodium bicarbonate solution. The alkaline solution was acidified and extracted with carbon tetrachloride. Evaporation of the solvent gave 31 g. of oil. This was heated to 95° for one hour in 3 liters of 2% potassium hydroxide solution. The solution was treated with "Nuchar," filtered, and acidified. The resulting oil was taken up in ether; evaporation of the ether and rubbing the residue in carbon tetrachloride–*n*-pentane induced crystallization. The crystalline product weighed 12 g.

**3-(4-Methoxy-1-naphthyl)-2-cyclopenten-1-one-2-acetic Acid.**—The diketo-acid intermediate was again an oil, obtained as described for the preceding preparation. This oil (from 140 g. of furfurylidene ketone) was remethylated by dissolving in a slight excess of 10% sodium hydroxide and stirring with dimethyl sulfate for three hours without heating. The product was diluted with 1500 ml. water and 100 ml. 45% potassium hydroxide was added; it was boiled for one hour, treated with "Nuchar" and acidified. The acid precipitated as an oil, which crystallized on standing overnight; yield 21 g. The yield in this preparation, and in the preceding, could be increased by repeating the original acid extraction from the hydrolysis of the furfurylidene ketones several times.

**γ-(2,2-Dicarboxy-1,2,3,4-tetrahydronaphthylidene-1)-butyric Acid.**—Ethyl β-phenethylmalonate[19,20] (b. p. 148–150° (3 mm.)) was converted to the sodium derivative and caused to react with the acid chloride of ethyl hydrogen glutarate as described by Bachmann, Kushner and Stevenson[8] in their preparation of ethyl 5-keto-6,6-dicarbethoxy-8-*m*-anisyloctanoate, quantities being altered in accordance with the difference in molecular weights. Volatile material was removed from the product up to 180° (2–3 mm.). The residue was not distilled but was used in crude form for cyclization.[21] To 7 g. residue was added 50 ml. commercial 66° Be. sulfuric acid, previously cooled to 0°. The temperature rose to 7°. The mixture was then allowed to stand in a refrigerator at −22° for twenty hours. It was poured into ice-water and extracted with ether. The ether was dried and distilled. The residue was refluxed for three hours with 30 ml. of 45% aqueous potassium hydroxide and 20 ml. methanol. The methanol was distilled and the residue was diluted with water, and extracted with ether. Evaporation of the ether gave an oil that crystallized on adding chloroform. The crystalline product, 710 mg., was recrystallized from chloroform; the substance decomposed at 182–183°.

*Anal.* Calcd. for $C_{16}H_{16}O_6$: C, 63.2; H, 5.3. Found: C, 63.4; H, 5.2.

This ring closure could not be effected with 100% phosphoric acid.[8]

Bachmann's procedure for converting γ-(6-methoxy-2,2-dicarboxy-1,2,3,4-tetrahydronaphthylidene-1)-butyric acid to 7-methoxy-1-keto-1,2,3,4,9,10-hexahydrophenanthrene,[8] involving refluxing for one hour with hydrochloric acid in acetic acid, was applied to 2.6 g. of the above tricarboxylic acid. Instead of the expected hexahydrophenanthrene ketone, there was obtained only a trace of neutral material and 1.0 g. of an acid, m.p. 87–88°, which is evidently the γ-(3,4-dihydro-1-naphthyl)-butyric acid of Bachmann and Wendler.[9] The acid was crystallized from dilute acetic acid and then from carbon tetrachloride.

*Anal.* Calcd. for $C_{14}H_{16}O_2$: C, 77.7; H, 7.5. Found: C, 77.5; H, 7.3.

This monocarboxylic acid (0.8 g.) was converted to 1-keto-1,2,3,4,9,10-hexahydrophenanthrene by the method used by Stork[22] for the corresponding methoxy acid. The semicarbazone, previously described by Johnson, Johnson and Petersen,[10] was obtained in a yield of 0.5 g. It decomposed at 253–254°.[23]

*Anal.* Calcd. for $C_{15}H_{17}N_3O$: C, 70.6; H, 6.7. Found: C, 70.5; H, 6.7.

**Absorption Spectra.**—Measurements were made with a Beckmann quartz spectrophotometer. Absolute ethanol was used as solvent for the cyclopentaphenanthrene compound and 95% ethanol for the furans. The three substances were crystallized three times from ether–pentane to remove possible benzene of crystallization; they were dried *in vacuo*. Measurements were taken at intervals of 1 mμ about the maxima and minima, and at intervals of 2 mμ at other places. The results are shown in Table IV and in Figs. 1 and 2.

TABLE IV

ULTRAVIOLET ABSORPTION SPECTRA

| Compound | Maxima λ (mμ) | Maxima log ε | Minima λ (mμ) | Minima log ε |
|---|---|---|---|---|
| Methyl-11,12,13,17-tetrahydro-16H-cyclopentaphenanthren-16-one-15-acetate | 220 | 4.39 | 228 | 4.08 |

**Biological Activity.**—Most of the substances described here were tested by Dr. F. R. Miller of this Laboratory and found to be inactive. The 3-*p*-tolyl-cyclopentenone-acetic acid is the only one that produces myeloid hyperplasia comparable to that produced by myelokentric acid.[24] This work will be reported elsewhere.

## Summary

1. A series of 3-substituted 2-cyclopenten-1-2-acetic acids has been prepared by the method of Robinson.

2. The method has been extended to cyclic ketones. This provides an easy synthesis of 11,12,13,17-tetrahydro-16H-cyclopentaphenanthren-16-one-15-acetic acid.

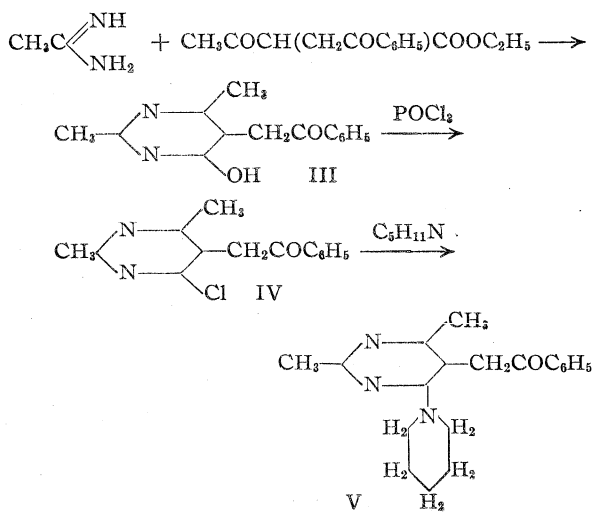
# Phenacylpyrimidines

BY BARBARA ROTH AND JAMES M. SMITH, JR.

A preceding paper[1] described a series of phenacylpyridines and -quinolines and their $\alpha$-amino derivatives, some of which showed moderate analgesic activity in preliminary tests on animals. It seemed of interest to investigate the corresponding phenacylpyrimidines, and therefore certain 2- and 5-phenacylpyrimidines have been prepared using benzoylacetamidine and $\alpha$-phenacylacetoacetic ester as intermediates. Phenacylpyrimidines previously reported in the literature include 1- and 5-derivatives obtained by treatment of a barbituric acid derivative with phenacyl bromide[2a] or alloxan with ethyl benzoylacetate.[2b]

Benzoylacetamidine (I) was prepared from benzoylacetonitrile through the imino ester hydrochloride. Haller[3] described the latter, which was treated with ammonia to obtain the free imino ester, but apparently no attempt was made to convert it to an amidine. Due to the presence of the benzoyl group, this amidine is unusual in regard to its stability and lack of strongly basic properties. The free amidine (I), rather than a hydrochloride, is the product isolated from the reaction of the imino ester hydrochloride with alcoholic ammonia. This can be recrystallized from water without decomposition.

To prepare 2-phenacylpyrimidine (II), benzoylacetamidine was condensed with $\beta$-ethoxyacrolein acetal. Condensation of I with acetylacetone



gave 4,6-dimethyl-2-phenacylpyrimidine, and with ethyl acetoacetate, 4-hydroxy-6-methyl-2-phenacylpyrimidine. These condensations were carried out by the method of Tuey[4] for the preparation of sulfadiazine from sulfaguanidine and $\beta$-ethoxyacrolein acetal.

Since it was found that phenacylpyridines and -quinolines brominated very readily on the methylene group, yielding $\alpha$-bromo derivatives which reacted readily with amines,[1] similar bromination reactions were carried out with 2-phenacylpyrimidine. A monobromo derivative was thereby formed which was very stable and had the properties expected for 5-bromo-2-phenacylpyrimidine, rather than an $\alpha$-bromo derivative. For example, it was unattacked by heating several hours with sodium hydroxide solution. It is not surprising that apparently a 5-bromopyrimidine was formed, since pyrimidines as a rule brominate very readily in this position. However, attempts to introduce a second atom of bromine in boiling glacial acetic acid were unsuccessful, even with the addition of acetic anhydride and benzoyl peroxide as catalysts, and in the presence of ultraviolet light.

As further evidence of the unreactivity of the methylene group of 2-phenacylpyrimidine, a Mannich condensation with formaldehyde and piperidine was attempted, to obtain 2-[$\alpha$-benzoyl-$\beta$-(1-piperidyl)-ethyl]-pyrimidine. However, under all conditions tried the starting material was recovered unchanged. Likewise, attempted nitrosation of the methylene group with butyl nitrite in alcoholic sodium methylate solution[5] was unsuccessful. Unreactivity of the keto group was also evidenced by lack of oxime formation by the usual methods.

For synthesizing 5-phenacylpyrimidines, $\alpha$-phenacylacetoacetic ester[6] was employed. Reaction with acetamidine in aqueous or alcoholic medium produced 2,4-dimethyl-6-hydroxy-5-phenacylpyrimidine (III). Chlorination of the latter proceeded in normal fashion with phosphorus oxychloride to yield the 6-chloro derivative (IV), which reacted readily with piperidine, giving 2,4-dimethyl-5-phenacyl-6-(1-piperidyl)-pyrimidine (V). Compound III brominated readily in glacial acetic acid at 70°, but a mixture of products was obtained. These included the hydrobromide of the starting material and a dibrominated pyrimi-

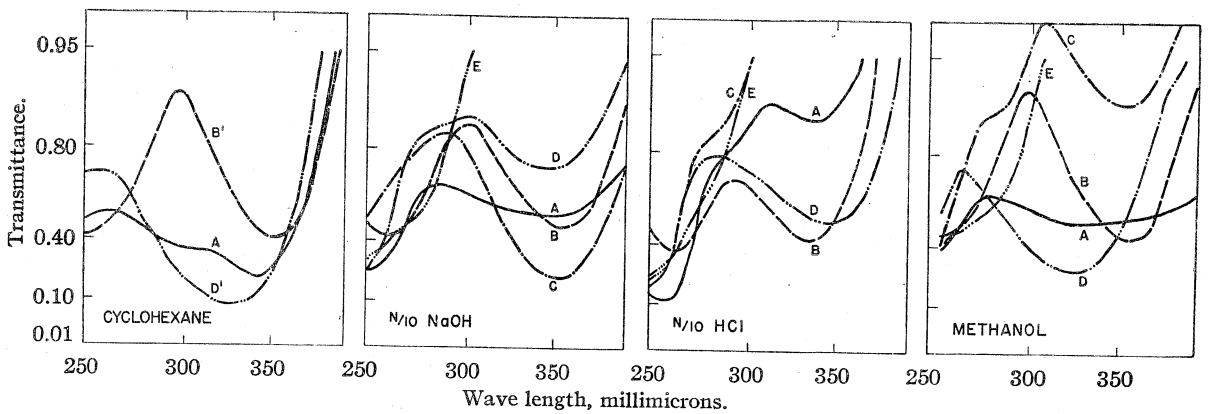

Fig. 1.—Ultraviolet absorption spectra[a] of 10 mg./l. solutions: A—, 2-phenacylpyridine; B– –, 2-phenacylpyrimidine hydrochloride; B'– –, 2-phenacylpyrimidine; C–·–, 4-phenacylpyridine hydrochloride; D–···–, 2-phenacyl-4,6-dimethylpyrimidine hydrochloride; D'–···–, 2-phenacyl-4,6-dimethylpyrimidine; E–···–, 2,4-dimethyl-5-phenacyl-6-hydroxypyrimidine hydrochloride.

[a] Data were obtained on a Beckman quartz spectrophotometer using 1-cm. cells. Readings were made at 5 mμ intervals except at points of inflection where they were made at 1 mμ intervals.

dine base. No monobrominated derivative was isolated from the mixture.

Pharmacological data on these compounds will be reported elsewhere.

In an effort to explain the difference in behavior of the 2-phenacylpyrimidines from the 2- and 4-phenacylpyridines and quinolines in regard to reactivity of the methylene group, a spectrophotometric study was carried out by Miss Ruth Abbott of this Laboratory on samples of 2- and 4-phenacylpyridine, 2-phenacylpyrimidine and its 4,6-dimethyl derivative, and 2,4-dimethyl-6-hydroxy-5-phenacylpyrimidine to see whether any differences in type of structure were indicated. While the data obtained do not definitely prove the structures of the phenacylpyrimidines, there is no indication that these structures are incorrect.

## Experimental[7,8]

**Benzoylacetamidine.**—Ten grams (0.069 mole) of benzoylacetonitrile[9] was dissolved in 50 ml. of dry benzene and 12.1 ml. (0.207 mole) of absolute alcohol added. The mixture was cooled to 0° and dry hydrogen chloride gas bubbled in until the mixture was saturated. It was kept at 0° over-night and then allowed to warm to room temperature, at which time only a small amount of crystalline material was present in the liquor. After two hours at room temperature, it had practically solidified. The product was filtered, washed with benzene, and dried in the vacuum desiccator; weight, 11.9 g. This was then mixed with 50 ml. of alcoholic ammonia, which had been saturated at 0°. The mixture stood for three days at room temperature, and was then filtered from ammonium chloride. The alcohol was distilled off, and ether added to the sirupy residue, resulting in the precipitation of 7 g. of benzoylacetamidine as a white solid. After two recrystallizations from water (1 g./20 ml.) the substance melted at 188–189°. It contained no halogen, and the *p*H of a saturated aqueous solution was 8.3. Upon warming with sodium hydroxide solution, ammonia was evolved.

*Anal.* Calcd. for $C_9H_{10}N_2O$: C, 66.6; H, 6.22; N, 17.3. Found: C, 66.1; H, 6.2; N, 16.7.

**2-Phenacylpyrimidine.**—A mixture of 16 g. (0.099 mole) of benzoylacetamidine, 17.8 g. (0.102 mole) of β-ethoxyacrolein acetal,[10] 38 ml. of amyl alcohol (b.p. 124–128°, from Pentasol) and 10 ml. of glacial acetic acid was refluxed for ten hours, and the ethyl acetate and amyl alcohol were then distilled off at atmospheric pressure. Upon cooling the residue, 10 g. of tan oily solid crystallized. After distillation of the mother liquor under vacuum to remove remaining solvents, and recrystallization of the dark residue from isopropyl acetate, an additional 2.1 g. of product was obtained. The resultant 12.1 g. was recrystallized from 65 ml. of isopropyl acetate, yielding 7.2 g. (49%) of yellow solid melting at 146–148°. Upon further recrystallization for analysis, the melting point was raised to 147.8–148.5°.

*Anal.* Calcd. for $C_{12}H_{10}N_2O$: C, 72.69; H, 5.09; N, 14.14. Found: C, 73.0; H, 5.3; N, 13.9.

An attempt to prepare an oxime by the usual method was unsuccessful.

**5-Bromo-2-phenacylpyrimidine.**—To 1.00 g. (0.005 mole) of 2-phenacylpyrimidine in 5 ml. of glacial acetic acid was added dropwise a solution of 0.808 g. (0.005 mole) of bromine in 2 ml. of glacial acetic acid at 20°. The bromine was taken up immediately. The mixture was poured into water, resulting in the precipitation of a yellow solid, which, upon recrystallization from alcohol, melted at 144.8–145.6°.

*Anal.* Calcd. for $C_{12}H_9BrN_2O$: C, 52.0; H, 3.28; Br, 28.9; N, 10.1. Found: C, 51.9; H, 3.4; Br, 28.8; N, 10.0.

The above reaction proceeded equally well in chloroform. The product was isolated by evaporating off the solvent and slurrying the resultant sirup in water, which resulted in the precipitation of the above-described 5-bromo-2-phenacylpyrimidine as a yellow solid. When the chloroform solution stood for some time, a small amount of light tan crystalline material separated which melted with decomposition at 246.5–249.0°. This was apparently the hydrobromide salt of the 5-bromo derivative, which completely hydrolyzed in water to the pyrimidine base.

When the above product was heated on the steam-bath for several hours in 5 *N* sodium hydroxide solution containing a little alcohol, the original material was recovered unchanged. Similarly, the bromo compound did not react with piperidine.

(7) All melting points are corrected.

(8) We are indebted to Mr. O. Sundberg and assistants for the microanalyses.

(9) Dorsch and McElvain, THIS JOURNAL, **54**, 2960 (1932); Long, *ibid.*, **69** 990 (1947).

(10) Claisen, *Ber.*, **36**, 3670 (1903); Price and Moos, THIS JOURNAL, **67**, 207 (1945).

**Addition of Two Moles of Bromine to 2-Phenacylpyrimidine.**—A solution of 3.23 g. (0.02 mole) of bromine in 4 ml. of glacial acetic acid was added dropwise to a refluxing solution of 2 g. (0.01 mole) of 2-phenacylpyrimidine in 10 ml. of glacial acetic acid. At first the bromine was rapidly taken up, but the solution turned a dark red after approximately half had been added, and no more reaction appeared to take place. The mixture was refluxed for two hours after the addition was complete. The product was then cooled and poured into water. A quantitative yield of 5-bromo-2-phenacylpyrimidine was obtained. The reaction was repeated with the addition of 1 ml. of acetic anhydride and a few crystals of benzoyl peroxide. The same results were obtained, except for some darkening of the product in this case.

In another experiment, 1.2 g. (0.004 mole) of 5-bromo-2-phenacylpyrimidine was dissolved in 8 ml. of glacial acetic acid, and 0.5 ml. of acetic anhydride and a few crystals of benzoyl peroxide added. To this refluxing mixture was added dropwise a solution of 0.69 g. (0.004 mole) of bromine in 2 ml. of glacial acetic acid, in the presence of light from an ultraviolet lamp. The mixture became almost black, and some hydrogen bromide was given off. The only product which could be isolated from the black mixture was the original 5-bromo-2-phenacylpyrimidine.

**Attempted Mannich Reaction with 2-Phenacylpyrimidine.**—A mixture of 4.95 g. (0.025 mole) of 2-phenacylpyrimidine, 3.04 g. (0.025 mole) of piperidine hydrochloride, 1.13 g. (0.0375 mole) of paraformaldehyde, and 20 ml. of absolute alcohol was heated to refluxing for five hours. After the initial two hours an additional 0.75 g. of paraformaldehyde was added. Complete solution occurred. The mixture stood overnight at room temperature, and a precipitate of long yellow needles appeared. This proved to be 2-phenacylpyrimidine. Alcoholic hydrogen chloride was added to the solution until it was acid to congo red test paper. Another 0.75 g. of paraformaldehyde was added and the mixture refluxed for another twenty-six hours, small portions of additional paraformaldehyde being added from time to time. At the end of this time, the mixture was cooled and ether added, precipitating an oil which was taken up in water and neutralized with dilute sodium hydroxide solution. A yellow solid formed which after recrystallization from isopropyl acetate melted at 145.5–147.0° and showed no depression of the melting point with 2-phenacylpyrimidine.

**Attempted Nitrosation of 2-Phenacylpyrimidine.**—2-Phenacylpyrimidine (4.95 g., 0.025 mole) was slurried in 25 ml. of absolute alcohol, and a solution of 1.5 g. (0.028 mole) of sodium methylate in 10 ml. of absolute alcohol added. The solution was cooled to 0°, and 2.58 g. (0.025 mole) of freshly prepared butyl nitrite added dropwise. No change occurred in the appearance of the mixture, and no exothermic reaction took place. The mixture was stoppered and allowed to stand at room temperature for two days. The mixture was then cooled and the solid filtered off, washed with water and dried. The substance weighed 4.6 g., melted at 147.0–148.8° and showed no depression of melting point with 2-phenacylpyrimidine.

**4,6-Dimethyl-2-phenacylpyrimidine.**—A mixture of 10 g. (0.062 mole) of benzoylacetamidine, 6.2 g. (0.062 mole) of acetylacetone, 20 ml. of mixed amyl alcohols, and 6 ml. of glacial acetic acid was heated under reflux for twelve hours. The solvents were distilled off under vacuum, and the sirupy residue was washed with dilute sodium hydroxide solution and cold water, after which it slowly crystallized. Approximately 12.5 g. of crude 4,6-dimethyl-2-phenacylpyrimidine was obtained. This was purified by dissolving in hot 5 *N* hydrochloric acid, from which a yellow hydrochloride precipitated on cooling. Upon recrystallizing twice more from 5 *N* hydrochloric acid and twice from alcohol, with the aid of decolorizing charcoal, 8 g. of light yellow crystals was obtained which melted between 202–210°.

*Anal.* Calcd. for $C_{14}H_{14}N_2O \cdot HCl$: C, 64.0; H, 5.75; N, 10.7; Cl, 13.5. Found: C, 64.2; H, 5.64; N, 10.7; 13.6.

From the aqueous solution of the hydrochloride a light yellow base was precipitated on adding dilute sodium hydroxide solution. After drying in the vacuum desiccator, this melted at 74.0–75.5°.

*Anal.* Calcd. for $C_{14}H_{14}N_2O$: C, 74.3; H, 6.24; N, 12.4. Found: C, 74.4; H, 6.32; N, 12.3.

**4-Hydroxy-6-methyl-2-phenacylpyrimidine.**—This was prepared from benzoylacetamidine and ethyl acetoacetate in a fashion similar to the above, the product being purified by repeated reprecipitation from dilute sodium hydroxide solution. A white product was obtained which melted at 248.5–250.0°.

*Anal.* Calcd. for $C_{13}H_{12}N_2O_2$: C, 68.4; H, 5.30; N, 12.3. Found: C, 68.6; H, 5.36; N, 12.2.

**2,4-Dimethyl-6-hydroxy-5-phenacylpyrimidine.**—A mixture of 515 g. (2.08 moles) of α-phenacylacetoacetic ester,[6] 197 g. (2.08 moles) of acetamidine hydrochloride, 84 g. (2.08 moles) of sodium hydroxide pellets dissolved in 830 ml. of water, and 100 ml. of 95% alcohol was stirred at room temperature for one-half hour, after which it was allowed to stand without stirring for two days. A thick crystalline mass formed, which was filtered off and washed well with water. This material, after drying at 50°, weighed 302 g., and contained considerable oily material. Upon recrystallization from 1100 ml. of 95% alcohol, a white crystalline product weighing 80 g. was obtained. This could be further purified by recrystallization from alcohol, benzene or isopropyl acetate, and then melted at 211–212°.

*Anal.* Calcd. for $C_{14}H_{14}N_2O_2$: C, 69.4; H, 5.83; N, 11.6. Found: C, 69.2; H, 5.8; N, 11.7.

The original mother liquor, upon standing two more days, deposited an additional 50 g. of somewhat oily crystalline product. After drying, this was dissolved in 250 ml. of absolute alcohol, and an excess of alcoholic hydrogen chloride added. Upon cooling, the hydrochloride precipitated as an almost white solid weighing 30 g. Upon two recrystallizations from 98% alcohol, with charcoal, the hydrochloride gradually sintered and melted with decomposition at 267–268°.

**4-Chloro-2,6-dimethyl-5-phenacylpyrimidine.**—A mixture of 106 g. of 2,4-dimethyl-6-hydroxy-5-phenacylpyrimidine and 265 ml. of phosphorus oxychloride was heated for one hour on the steam-bath. The excess phosphorus oxychloride was distilled off under vacuum, and the residue poured on ice and neutralized with sodium bicarbonate. The substance, which appeared tarry at first, solidified to a tan solid. After drying at 55°, the weight was 111 g. Upon recrystallization from 600 ml. of V.M. and P. naphtha, which served to separate it from some insoluble impurities, the yield was 82 g. or 72%. After two further recrystallizations with the aid of charcoal the melting point of the white product was 103.5–104.5°.

*Anal.* Calcd. for $C_{14}H_{13}ClN_2O$: C, 64.5; H, 5.03; Cl, 13.6; N, 10.8. Found: C, 64.2; H, 5.0; Cl, 13.7; N, 10.8.

**2,4-Dimethyl-5-phenacyl-6-(1-piperidyl)-pyrimidine.**—A mixture of 60 g. (0.23 mole) of 4-chloro-2,6-dimethyl-5-phenacylpyrimidine and 60 g. (0.70 mole) of piperidine was warmed on the steam-bath until an exothermic reaction commenced. Cooling was then necessary for a few minutes to keep the reaction under control, after which it was heated for an additional fifteen minutes on the steam-bath to complete the reaction. The mixture was then cooled, and sufficient benzene added to make a workable slurry. It was filtered from piperidine hydrochloride, and the benzene solution extracted with an excess of dilute hydrochloric acid, followed by clarification of the acid extracts and neutralization with ammonia. A gummy precipitate was formed which soon solidified. This was filtered off and dried at 45°; weight, 68.6 g. Upon recrystallization from 350 ml. of V.M. and P. naphtha with the aid of charcoal the white product weighed 55 g. (78% yield) and melted at 87–89°.

*Anal.* Calcd. for $C_{19}H_{23}N_3O$: C, 73.7; H, 7.50; N, 13.4. Found: C, 73.9; H, 7.7; N, 13.7.

The product was converted to the **hydrochloride** in absolute ether and recrystallized from alcohol–ether mixture. It then melted at 200–201°.

**Bromination of 2,4-Dimethyl-6-hydroxy-5-phenacylpyrimidine.**—2,4-Dimethyl-6-hydroxy-5-phenacylpyrimidine (1.00 g., 0.004 mole) was dissolved in 10 ml. of glacial acetic acid and a solution of 0.663 g. (0.004 m.) of bromine in 2 ml. of glacial acetic acid was added dropwise. No reaction occurred until the mixture was heated to 60–70°, when rapid decolorization took place. When a little more than half of the bromine had been added, white crystals began to separate, which redissolved for the most part by the time the remaining bromine had been added. The mixture was allowed to stand and cool for two hours, resulting in the slow formation of a white precipitate again. This was filtered, washed with ether, and dried; weight, 0.4 g. This proved to be a mixture consisting mainly of the hydrobromide of the starting material. On dissolving in water a small amount of insoluble material remained, which was removed by filtration. On neutralization of the filtrate with sodium bicarbonate, a white precipitate formed which, upon drying, melted at 207–209°, contained no halogen, and showed no depression of the melting point with the starting material. The acetic acid liquor yielded a white precipitate upon the addition of ether, but this became sirupy on all attempts at isolation. Upon pouring the acetic acid solution into water, a small amount of white precipitate formed; dry weight, 0.3 g. After purification by recrystallization from alcohol, the substance melted at 167–169°. Analysis indicated it to be a dibrominated base, which was not further identified.

*Anal.* Calcd. for $C_{14}H_{12}Br_2N_2O$: C, 42.0; H, 3.02; Br, 40.0; N, 7.01. Found C, 42.3; H, 2.97; Br, 40.1; N, 7.31.

## Summary

A series of 2- and 5-phenacylpyrimidines has been prepared for pharmacological testing purposes. Condensations of benzoylacetamidine, a new compound, with β-ethoxyacrolein acetal, acetylacetone and ethyl acetoacetate yielded 2-phenacylpyrimidine, 4,6-dimethyl-2-phenacylpyrimidine and 4-hydroxy-6-methyl-2-phenacylpyrimidine, respectively. Condensation of α-phenacylacetoacetic ester with acetamidine yielded 2,4-dimethyl-6-hydroxy-5-phenacylpyrimidine.

The methylene group of 2-phenacylpyrimidine has been shown to be unusually unreactive. Bromination of 2-phenacylpyrimidine produced the 5-bromo derivative only. Mannich and nitrosation reactions failed. The ketone did not yield an oxime.

2,4-Dimethyl-6-hydroxy-5-phenacylpyrimidine was chlorinated to yield the 6-chloro derivative, which reacted with piperidine to form 2,4-dimethyl-5-phenacyl-6-(1-piperidyl)-pyrimidine. Bromination reactions with the 6-hydroxy compound yielded mixtures, from which no monobrominated product was isolated.

# Analogs of Pteroylglutamic Acid. II. 9-Methylpteroylglutamic Acid and Derivatives

BY MARTIN E. HULTQUIST, JAMES M. SMITH, JR., DORIS R. SEEGER, DONNA B. COSULICH AND ERWIN KUH

Pteroylglutamic acid (I) was synthesized by Waller, *et al.*,[1] by the simultaneous reaction of 2,4,5-triamino-6-hydroxypyrimidine,[2] 2,3-dibromopropionaldehyde, and *p*-aminobenzoyl-*l*(+)-glutamic acid[3] in aqueous solution at *p*H 4.

I

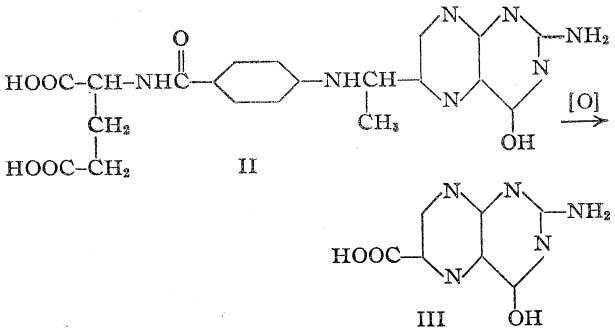
(2) Traube, *Ber.*, **33**, 1371 (1900).

(3) Van der Scheer and Landsteiner, *J. Immunology*, **29**, 373 (1935).

This reaction has proved to be of wide application and a number of derivatives of I have been prepared by varying one or more of the three components.[4] Previous communications from this Laboratory have described $N^{10}$-alkyl[5] and 4-amino[6] analogs of pteroylglutamic acid. The present paper deals with a series of analogs in which a methyl group has been introduced on the methylene bridge in the 9-position.



When 2,2,3-trichlorobutyraldehyde ("butyl chloral")[7] was reacted with 2,4,5-triamino-6-hydroxypyrimidine and *p*-aminobenzoylglutamic acid, there was formed N-[4-{[1-(2-amino-4-hydroxy-6-pteridyl)-ethyl]-amino}-benzoyl]-glutamic acid (II), hereafter designated as 9-methylpteroylglutamic acid.

Purification was accomplished by methods similar to those reported for pteroylglutamic acid.[1,4b,d,e,5] Also, it was found that recrystallization of the cyclohexylamine salt of II from aqueous butanol afforded a convenient method of obtaining an analytically pure material. Oxidation of II with hot alkaline permanganate gave solely 2-amino-4-hydroxypteridine-6-carboxylic acid (III).[8] This shows that the point of attachment of the side chain is in the 6-position on the pteridine ring.

9,10-Dimethylpteroic acid (IV) was prepared similarly, using *p*-methylaminobenzoic acid. Other variations in the starting materials resulted in 9,-

[a] See footnote to Fig. 1. [b] An arbitrary value of 100 is assigned for the antagonist activity of $N^{10}$-methylpteroylglutamic acid, for half-maximum inhibition of the growth of *Streptococcus faecalis* R. The inhibition ratio for this compound is 2.0 at a concentration of pteroylglutamic acid of 0.1 microgram per 10 ml. (ref. 5). Values for other compounds are reported in terms of the standard. [c] Crude material.

10-dimethylpteroylglutamic acid (V), and 4-amino-9,10-dimethylpteroylglutamic acid (VI).

The biological properties of these compounds have been examined by Dr. E. L. R. Stokstad and Dr. B. L. Hutchings of the Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York. The 9-methyl analogs are antagonists for pteroylglutamic acid in the growth of *Streptococcus faecalis* R., and also in certain animals. Details of this work will be reported elsewhere. The inhibition ratio of 9-methylpteroylglutamic acid for half-maximum growth of *S. faecalis* R is 2000 at a concentration of 0.01 microgram of pteroylglutamic acid per ml.

Table I summarizes the ultraviolet absorption data and relative antagonist activity of these analogs.

## Experimental

**9-Methylpteroylglutamic Acid (II).**—This compound was prepared from 2,4,5-triamino-6-hydroxypyrimidine hydrochloride,[2] 2,2,3-trichlorobutyraldehyde[7] and *p*-aminobenzoylglutamic acid,[3] under the conditions described by Waller, *et al.*, for the synthesis of pteroylglutamic acid[1]. A slurry of 20 g. of crude 9-methylpteroylglutamic acid and 8 g. of lime in 2000 ml. of water was heated at 80° for thirty minutes, clarified and washed with hot water. The filtrate was adjusted to *p*H 10.8 with aqueous zinc chloride, clarified, acidified to *p*H 3 and filtered. This cake was slurried in 2000 ml. of water, made alkaline with sodium hydroxide solution at 80° and then adjusted to *p*H 7 while cooling to 20°. After clarification, the filtrate was acidified to *p*H 3. The product was filtered and dissolved in 1000 ml. of water as the magnesium salt, treated with Darco G-60, clarified and reprecipitated at *p*H 3. The dry product weighed 2.2 g.; purity, 82.5%.

Further purification was accomplished by dissolving 1 g. of this material in 8 ml. of butanol, 2 ml. of water and 1 ml. of cyclohexylamine at 95°, and clarifying to remove some insoluble matter. After boiling to remove part of the water, there was gradually added 7.5 ml. of butanol and 3.5 ml. of cyclohexylamine. On stirring, there crystallized out the cyclohexylamine salt, which was filtered off at 20°. This was recrystallized again, using the above procedure, to give a light yellow, crystalline product.

*Anal.* Calcd. for $C_{32}H_{47}O_6N_9 \cdot 3H_2O$: C, 54.30; H, 7.55; N, 17.81. Found: C, 54.8; H, 7.55; N, 17.8.

The free acid was recovered from the cyclohexylamine salt by dissolving in water and acidifying to *p*H 3. It was dried at 100° (1 mm.) for seven hours.

*Anal.* Calcd. for $C_{20}H_{21}O_6N_7$: C, 52.74; H, 4.65; N, 21.53. Found: C, 52.9; H, 4.77; N, 21.5.

**Oxidation of II with Alkaline Permanganate.**—A solution of 0.2 g. of II in 60 ml. of *N* sodium hydroxide solution was treated with excess potassium permanganate for one and one-half hours at 95°. The permanganate color was then destroyed with a little sodium sulfite. The mixture was clarified, acidified to *p*H 3, cooled and filtered, yielding 0.075 g. of product which was identified as 2-amino-4-hydroxypteridine-6-carboxylic acid (III) by comparison with an authentic sample.[8]

Oxidation of the cyclohexylamine salt of II gave the same product in approximately the same yield.

**9,10-Dimethylpteroylglutamic Acid (V).**—This compound was synthesized by the method of Waller, *et al.*[1] using 2,4,5-triamino-6-hydroxypyrimidine, 2,2,3-trichlorobutyraldehyde, and *p*-methylaminobenzoylglutamic acid.[5] A mixture of 30 g. of the crude material, 9 g. of lime, and 2 l. of water was heated at 60° for forty minutes. After filtration with Hyflo-Supercel, the cake was washed with 750 ml. of water at 60°. The filtrate and wash were adjusted to *p*H 10.8–11.0 with 10% zinc chloride and then filtered free of precipitated material. The liquor was adjusted to *p*H 3–3.5 with dilute hydrochloric acid, cooled to 10°, and filtered. The cake was washed with water and then slurried in 1500 ml. of water and enough sodium hydroxide to give *p*H 11–12. After heating at 80° for ten minutes, the solution was adjusted to *p*H 7 while cooling to 20°, and filtered. The filtrate was treated with dilute hydrochloric acid to *p*H 3–3.5. The precipitate was filtered, reslurried in 1 l. of water containing enough magnesium carbonate to obtain about *p*H 9 at 80°, and filtered hot with 2 g. of charcoal. The filtrate at 80° was adjusted to *p*H 3–3.5 with hydrochloric acid and cooled to 10°. Orange microcrystalline material separated which was purified for analysis by repeating (at 1 g./l.) the last step twice more. On cooling to 10° after the second treatment, analytically pure yellow-orange microcrystalline material was isolated (see Table I for biological and ultraviolet absorption data). The analytical sample was dried at 100° and 2 mm. for five hours.

*Anal.* Calcd. for $C_{21}H_{27}N_7O_6 \cdot H_2O$: C, 51.7; H, 5.13; N, 20.13. Found: C, 51.4; H, 5.22; N, 19.8.

**Permanganate Oxidation of 9,10-Dimethylpteroylglutamic Acid (V).**—A solution of 0.5 g. of 9,10-dimethylpteroylglutamic acid in 166 ml. of N sodium hydroxide was treated at 80–90° with 5% potassium permanganate solution until the solution maintained a purple color. After adding sodium sulfite to destroy this color, manganese dioxide was filtered off and the filtrate adjusted to *p*H 3–3.5 with dilute hydrochloric acid. The precipitate,

isolated by filtering, washing with water and then acetone, and drying, was shown to be 2-amino-4-hydroxypteridine-6-carboxylic acid (III) by comparison of the ultraviolet absorption curve with that of an authentic sample.[8]

**9,10-Dimethylpteroic Acid (IV).**—This was prepared similarly to V above, except that *p*-methylaminobenzoic acid[6] was used (see Table I for ultraviolet absorption and biological data).

*Anal.* Calcd. for $C_{16}H_{16}N_6O_3 \cdot 0.5H_2O$: C, 55.1; H, 4.91; N, 24.1. Found: C, 54.7; H, 4.99; N, 24.0.

**N-[{N-[1-(2,4-Diamino-6-pteridyl)-ethyl]-N-methylamino}-benzoyl]-glutamic Acid, ("4-Amino-9,10-dimethylpteroylglutamic Acid") (VI).**—This compound was prepared by the method of Waller, *et al.*,[1] using 2,4,5,6-tetraminopyrimidine sulfate,[9] 2,2,3-trichlorobutyraldehyde and *p*-methylaminobenzoylglutamic acid.[5] A mixture of 31.6 g. of the crude, 9 g. of lime, and 2 l. of water was heated at 60° for forty minutes. After filtration, the cake was washed with 600 ml. of water at 60°. The combined filtrate and wash liquors were adjusted to *p*H 10.8–11.0 with 10% aqueous zinc chloride. The mixture was filtered, and the filtrate was adjusted to *p*H 3.5–4.0 with hydrochloric acid. After cooling to 5°, the precipitate was filtered, washed with water and slurried in 1500 ml. of water containing sodium hydroxide to give *p*H 11–11.5. After heating it at 60° for ten minutes, the *p*H of the solution was reduced to 7, while cooling the mixture to 20°, and filtered. The filtrate was adjusted to *p*H 3.5–4.0 with hydrochloric acid and cooled to 5°. After filtration, the cake was slurried in 1 l. of water containing enough lime to obtain *p*H 8.5–9 at 60° and filtered hot with 1.5 g. of charcoal. The filtrate was adjusted to *p*H 3.5–4.0 with hydrochloric acid and cooled to 0–5° overnight. The yellow-orange microcrystalline material which separated was isolated by filtration and was analytically pure. The biological and ultraviolet absorption data are shown in Table I.

*Anal.* Calcd. for $C_{21}H_{24}N_8O_5 \cdot 2H_2O$: C, 50.0; H, 5.55; N, 22.2. Found: C, 50.4; H, 5.42; N, 21.5.

**Acknowledgment.**—We are indebted to Mr. Richard L. Shepard for technical assistance in the preparation of certain of these substances, to Miss Ruth Abbott for the ultraviolet absorption data, and to Mr. O. Sundberg and coworkers for the microanalyses.

## Summary

N-[4-{[1-(2-Amino-4-hydroxy-6-pteridyl)-ethyl]-amino}-benzoyl]-glutamic acid (II), designated herein as 9-methylpteroylglutamic acid, has been synthesized and isolated in pure form. Corresponding analogs which have also been prepared are 9,10-dimethylpteroylglutamic acid (V), 4-amino-9,10-dimethylpteroylglutamic acid (VI), and 9,10-dimethylpteroic acid (IV).

These compounds exhibit antagonism for pteroylglutamic acid in the growth of *S. faecalis* R.

# Mechanical Properties of Substances of High Molecular Weight. V. Rigidities of Polyisobutylene Solutions in Various Solvents[1]

BY J. N. ASHWORTH[2] AND JOHN D. FERRY

Many concentrated solutions of linear polymers behave as highly viscous liquids in steady flow, but possess solid-like rigidity in small oscillating deformations; transverse waves can be propagated in them at audio frequencies. From the wave length of these waves the rigidity can be calculated, and from the damping the mechanical loss, or the dynamic viscosity, can be derived. Measurements of this sort on solutions of polystyrene in xylene have been reported previously.[3]

In seeking to understand the mechanism of rigidity in polymer solutions, it is desirable to study a variety of molecular types. In this paper, measurements are reported for a non-polar polymer for which complications due to intermolecular forces should be at a minimum: polyisobutylene. As in the earlier work on polystyrene, the dependence of rigidity on frequency, concentration, and temperature has been studied. Also, four different solvents have been employed.

## Materials

The polyisobutylene was kindly furnished by Dr. John Rehner, Jr., of the Esso Laboratories. It was designated 303-92-1. From measurements of viscosities of dilute solutions in di-isobutylene, the intrinsic viscosity in this solvent at 20° was found to be 2.85 $(g./100\ cc.)^{-1}$, corresponding to a viscosity-average molecular weight of 1,200,000 on the basis of the interpolation equation of Flory.[4] Intrinsic viscosities in the solvents used for the rigidity studies were also determined at 20° and 30°; these are given in Table IV below. The details of the intrinsic viscosity measurements are presented elsewhere.[5]

In most cases, the polymer was used without purification. However, it contained a small amount of tiny fibrous foreign particles which, though negligible in quantity, were optically anisotropic and interfered somewhat with optical measurements of waves. Accordingly, a portion of the polymer was dissolved in toluene at a concentration of about five per cent., clarified by filtration through Whatman No. 4 filter paper on a

Buchner funnel, completely precipitated by methyl alcohol, and dried *in vacuo* at room temperature for twelve hours and at 60° for four hours. This preparation, hereafter referred to as clarified polymer, afforded the best measurements of damping.

The *n*-heptane was "99 mole per cent." sold by the Phillips Petroleum Corp. Xylene was obtained from Mallinckrodt and Merck, and chlorobenzene and isoöctane (2,2,4-trimethylpentane) from the Eastman Kodak Company. The solvents were used without further purification.

Preparation of concentrated solutions was expedited by rotating bottles containing polymer and solvent at about 12 revolutions per hour. Concentrations were determined by dry weight after heating samples *in vacuo* for twenty-four hours at 110°. Concentrations were expressed both as weight per cent. and as g./cc. The latter values were calculated assuming additivity of the volumes of polymer and solvent, taking the density of polymer as 0.91 and those of the solvents from the "International Critical Tables," and assuming that the thermal expansion coefficients of solutions were the same as those of the respective solvents.[3]

## Method

The apparatus and procedure were the same as previously described,[3,6] with some minor modifications. The Strobotron was mounted outside the air thermostat, and its illumination of the cell was improved by a reflector and a condensing lens. Photographic recording of the wave pattern was substituted for the former method of visual observation with horizontal and vertical micrometer adjustments. The rather faint pattern was satisfactorily photographed on Eastman Kodak Co. CTC plates or Contrast Process Panchromatic cut film, the latter affording a contrast between light and dark Babinet bands which was an improvement over visual observation.

The photographs of wave patterns were projected by an enlarger on cross-section paper, and the contours of the wavy Babinet bands were traced in pencil. An example is shown in Fig. 1. Similar projections of photographs of the undeviated Babinet bands, when superimposed, permitted measurements of the displacements from which damping data were calculated. The wave length was taken as the average of ten or more measured distances between successive maxima or minima on each photograph. There was no perceptible change in wave length with distance from the vibration source.

As in the previous studies on polystyrene, the damping was within experimental error exponential; a plot of ln $\delta$ ($\delta$ being the double refraction in the solution observed at the maxima and minima of the stroboscopically immobilized wave) against $x$, the distance from the vibrator plate, was a straight line.[7] The reciprocal slope of the line is $x_0$, the critical damping distance. Values of $\delta$ can be calculated from the equation[6] $\tan \delta = \tan \Delta \sin 2\alpha$, where $\Delta$ is the relative retardation corresponding the Babinet line displacement, and $\alpha$ is the angle between the axes of the Babinet and the polarizer. However, a simpler procedure was followed; since $\sin 2\alpha$ is small (in our case $\alpha = 2°14'$), $\tan \delta$ is nearly equal to $\delta$, and $\tan \Delta$ is proportional to $\delta$; it follows that the reciprocal slope of a plot of ln $\tan \Delta$ against $x$ is $x_0$, and the critical damping distance is obtained without calculating $\delta$ directly.

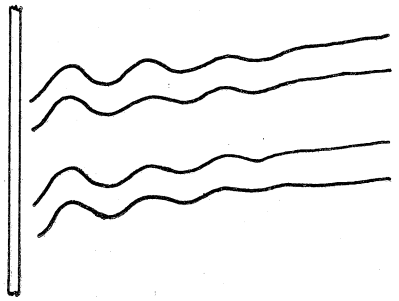

Fig. 1.—Tracing of wave pattern in 15.7% polyisobutylene in chlorobenzene, 17.1°, 400 cycles/sec. The vibrator plate is indicated at left.

The wave rigidity,[1] $\tilde{G}$, was calculated as $\lambda^2\nu^2\rho$, where $\lambda$ is the measured wave length, $\nu$ the frequency, and $\rho$ the density. The latter value was calculated assuming additivity of the volumes of polymer and solvent. The dimensionless damping index,[9] $\lambda/x_0$, was used to characterize the severity of the damping.

Different sizes of cells and vibrator plates were used in four combinations (Fig. 2). Comparisons of the same solutions with different cells and plates

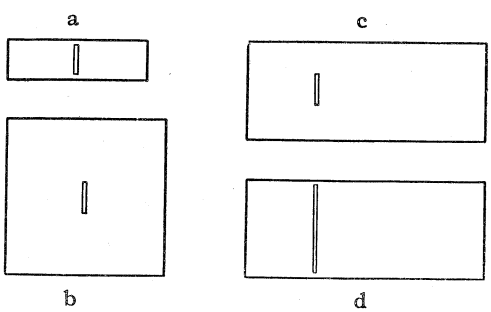

Fig. 2.—Cell-plate combinations (top view). Cell sizes: a, 1.0 × 3.5 cm.: b, 4.0 × 4.0 cm.; c and d, 2.5 × 6.0 cm. Plate widths: a, b, and c, 0.8 cm.; d, 2.5 cm.

(7) The first maximum or minimum often deviated materially. This is to be expected from theoretical calculations[8] of wave propagation in which the finite dimensions of the cell are taken into account. The calculations show that the value of $x_0$ determined as outlined here is within a few per cent., and hence well within experimental error, of the value which would characterize the damping of a plane wave in a medium of infinite extent.[9]

(9) J. D. Ferry, W. M. Sawyer and J. N. Ashworth, *J. Polymer Sci.*, **2**, 593 (1947).

revealed no differences in $\tilde{G}$ and $\lambda/x_0$ exceeding experimental scatter. Most measurements were made with combinations (c) and (d), which provided room for longer wave trains. The widest frequency range was achieved with combination (d). The cell used in (c) and (d) was of aluminum with glass windows cemented with litharge and glycerol.

In some cases the dynamic rigidity $G'$ and the dynamic viscosity $\eta'$, which are useful for comparison with results of other experimental methods and for theoretical interpretation, were calculated by the equations[9]

$$G' = \tilde{G}\frac{4\pi^2[4\pi^2 - (\lambda/x_0)^2]}{[4\pi^2 + (\lambda/x_0)^2]^2} \quad (1)$$

$$\eta' = \frac{\tilde{G}}{\omega}\frac{16\pi^3\lambda/x_0}{[4\pi^2 + (\lambda/x_0)^2]^2} \quad (2)$$

where $\omega$ is $2\pi$ times the frequency.

## Results

**Dispersion of Rigidity.**—In experiments where a frequency range of five or sixfold was achieved, a small increase in $\tilde{G}$ with increasing frequency was observed. Representative data for clarified polymer in chlorobenzene solutions are given in Table I (concentrations expressed in weight per cent). The dependence of $\tilde{G}$ on the frequency can be approximated by straight lines of equal slope (Fig. 3).

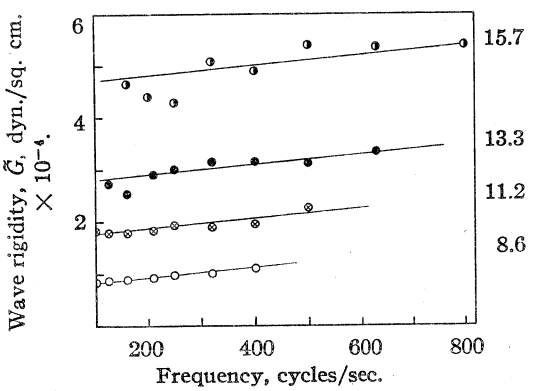

Fig. 3.—$\tilde{G}$ plotted against frequency for chlorobenzene solutions at 25°. Figures opposite the lines denote concentrations in weight per cent.

In other experiments, where the frequency range was limited to three or fourfold, the dispersion of $\tilde{G}$ was within experimental scatter (5 to 10%). It was, in any case, so small that the dispersion function appears to be essentially a plateau in the range from 100 to 1000 cycles/sec. for our solutions. Accordingly, to determine the dependence of $\tilde{G}$ on concentration and temperature, values measured at different frequencies were simply averaged.

**Dependence of Rigidity on Concentration and Temperature.**—Average values of $\tilde{G}$, together with the frequency range covered in each case, are given for solutions in *n*-heptane at different concentrations and temperatures in Table II. At constant weight concentration, the rigidity decreases somewhat with increasing temperature,

about 0.3% per degree. In the case of polystyrene–xylene solutions, where a somewhat more pronounced decrease was observed,[3] the temperature dependence of $\tilde{G}$ could be described by the relation $\tilde{G} = A_G e^{Q_G/RT}$, with $Q_G = 1500$ cal. The results of Table II can also be fitted by this relation, with $Q_G = 550$ cal. However, for polyisobutylene, the temperature dependence at constant weight concentration can be entirely attributed to the change in volume concentration due to thermal expansion; when rigidities are compared at constant *volume* concentration, the temperature dependence vanishes.

Proportionality of $\tilde{G}$ to the third power of $c$, the volume concentration (g./cc.) was anticipated from the behavior of polystyrene.[10] The last column of Table II shows that for polyisobutylene in *n*-heptane $\tilde{G}/c^3$ is constant for each solution over a temperature range from about −7 to 35°. The average values of $\tilde{G}/c^3$ for each solution are also close together, and no trend with increasing concentration is apparent.[12]

TABLE III

VALUES OF $\tilde{G}/c^3$ FOR SOLUTIONS IN XYLENE, ISOÖCTANE, AND CHLOROBENZENE

| Solvent | Concn., wt. % | $\tilde{G}/c^3 \times 10^{-6}$ | Av. |
|---|---|---|---|
| Xylene | 10.3[e] | 8.9 | |

[a] Cell-plate combination a. [b] Cell-plate combination b. [c] Cell-plate combination c. [d] Cell-plate combination d. [e] Clarified polymer. [f] Measured at 25° only.

(10) Proportionality to $c^3$ was shown for the rigidity of polystyrene solutions after a calculated low-frequency component of rigidity had been subtracted from the measured values.[11] However, the low-frequency component was so small that the relation holds also for the total rigidity (see Fig. 7).

(11) J. D. Ferry, THIS JOURNAL, **64**, 1330 (1942).

(12) Since the frequency range represented by the average $\tilde{G}$ changes somewhat with concentration (Table II), this does not quite represent a test of the third power relation at constant frequency. Values interpolated from Fig. 3 at constant frequency and plotted logarithmically against log $c$ give slopes ranging from 2.7 to 3.0. However, these small differences are too close to experimental error to attempt to describe at present.

Data for the other solvents are given in detail in the thesis[5] on which this paper is based. In each case $\tilde{G}$ decreased about 0.3% per degree at constant weight concentration, but $\tilde{G}/c^3$ was independent of temperature and concentration.[13] The values of $\tilde{G}/c^3$ averaged at different temperatures for each solution are given in Table III.

In Table IV, the over-all averages of $\tilde{G}/c^3$ for the four solvents are correlated with the respective intrinsic viscosities at 20 and 30°. The intrinsic viscosities show that the solvents are arranged in the order of decreasing solvent power; the temperature dependence, which is probably significant only for chlorobenzene, also indicates that this is a somewhat poorer solvent than the others. The differences are on the whole slight, but it is clear that the order of decreasing intrinsic viscosity is the order of increasing rigidity.

TABLE IV

AVERAGE VALUES OF $\tilde{G}/c^3$ AND INTRINSIC VISCOSITIES

| Solvent | $\tilde{G}/c^3$, (dyn./sq. cm.) (g./cc.)$^{-3}$ $\times 10^{-6}$ | $[\eta]$, 20° | $[\eta]$, 30° |
|---|---|---|---|
| *n*-Heptane | 8.1 | 2.68 | 2.60 |
| Xylene | 9.4 | 2.63 | 2.67 |
| Isoöctane | 10.1 | 2.45 | 2.36 |
| Chlorobenzene | 10.9 | 2.15 | 2.35 |

**Damping.**—In almost all cases, the damping index, $\lambda/x_0$, varied within the rather narrow range from 0.6 to 1.2. Except in a few cases, the experimental scatter did not permit a reliable study of the dependence of damping index on concentration, temperature, or nature of solvent; as a first approximation, it was independent of all these variables.

With increasing frequency, $\lambda/x_0$ generally decreased. The best measurements, on chlorobenzene solutions, are given in Table V and plotted against the logarithm of the frequency in Fig. 4.

**Dynamic Rigidity and Viscosity.**—From the data in Tables I and V, the dynamic rigidity $G'$ and the dynamic viscosity $\eta'$ of the chlorobenzene

TABLE V

DAMPING INDICES IN CHLOROBENZENE AT 25°

| Frequency, cycles/sec. | Damping index, $\lambda/x_0$ Concn. = 11.2% | 13.3% | 15.7% |
|---|---|---|---|
| 125 | 1.14 | .. | .. |
| 160 | 0.97 | .. | .. |
| 200 | .. | .. | 1.20 |

| 630 | .. | .70 | .74 |
| 800 | .. | .. | .64 |

(13) Since the thermal expansion coefficients of the solvents are all very nearly one-tenth per cent. per degree, $c^3$ decreases three-tenths per cent. per degree, accounting exactly for the observed decrease in rigidity.

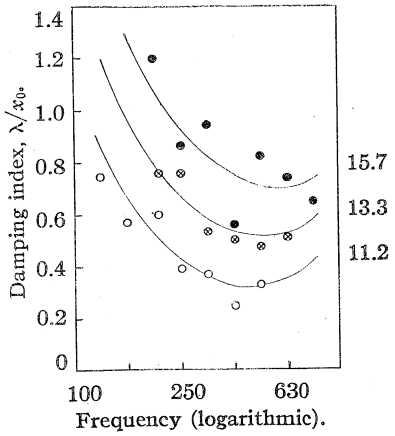

Fig. 4.—Damping indices for chlorobenzene solutions, plotted against the logarithm of the frequency. Figures opposite the curves denote concentrations in weight per cent. The ordinate scale refers to the 15.7% curve; the curves for 13.3% and 11.2% have been shifted downward 0.2 and 0.4 unit, respectively. The curves are calculated for retarded Maxwell elements, using the constants of Table VI.

solutions were calculated by equations (1) and (2), and they are plotted against the logarithm of the frequency in Figs. 5 and 6. The rigidity $G'$ is from three to ten per cent. smaller than $\tilde{G}$. The viscosity $\eta'$ is of the order of a few poises and falls off rapidly with increasing frequency; this is the usual behavior found for concentrated polymer solutions by direct measurements with transducer methods.[14] By contrast, the viscosity in steady flow of these solutions is of the order of hundreds to thousands of poises.

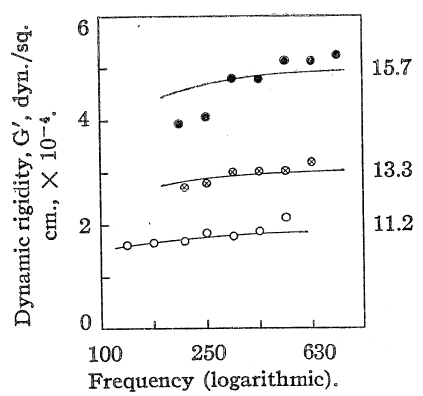

Fig. 5.—Dynamic rigidities of chlorobenzene solutions, plotted against the logarithm of the frequency. Figures opposite the curves denote concentrations in weight per cent. The curves are calculated for retarded Maxwell elements, using the constants of Table VI.

Since $G'$ never differs from $\tilde{G}$ by more than 10% in our experiments, the two rigidities can be taken as equivalent for some purposes, as in Fig. 7,

(14) T. L. Smith, J. D. Ferry and F. W. Schremp, *J. Appl. Physics*, in press.

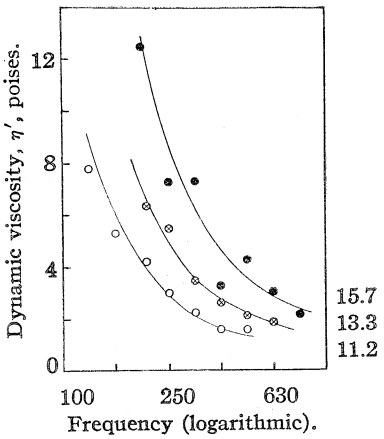

Fig. 6.—Dynamic viscosities of chlorobenzene solutions, plotted against the logarithm of the frequency. Figures opposite the curves denote concentrations in weight per cent. The curves are calculated for retarded Maxwell elements, using the constants of Table VI.

where $\tilde{G}$ values for solutions are compared with $G'$ for the undiluted polymer. In most cases the accuracy of $\lambda/x_0$ is insufficient for an adequate calculation of $\eta'$, although its order of magnitude can always be estimated from Eq. 2, since $\lambda/x_0$ almost never exceeds the range 0.6–1.2.

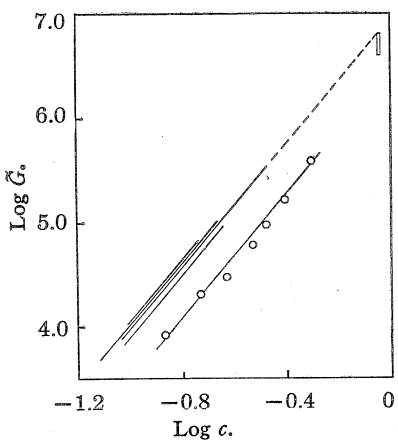

Fig. 7.—Log $\tilde{G}$ plotted against log $c$. Solid lines (drawn with slope of 3), in descending order: polyisobutylene in chlorobenzene, isoöctane, xylene, and heptane; polystyrene in xylene (points from ref. 3). Rectangle: $G'$ of pure polyisobutylene (ref. 16).

## Discussion

**Representation of Frequency Dependence by a Mechanical Model.**—A simple model which can imitate approximately the frequency dependence of mechanical properties of concentrated polymer solutions in the audio frequency range is a retarded Maxwell element,[9] with a viscous dashpot ($\eta_S$) in series with a parallel combination of spring ($G$) and dashpot ($\eta_P$). The three model constants are frequency-independent. In the range where $\omega\eta_S/G \sim 10$, when $\eta_P \ll \eta_S$, the

model gives the following dispersion behavior: both $\tilde{G}$ and $G'$ are represented by plateaus, almost equal to $G$, with a drop at lower frequencies, while the former rises at higher frequencies; $\eta'$ decreases with increasing frequency; and $\lambda/x_0$ goes through a minimum. The equations are given elsewhere,[9,15] together with illustrative graphs.

This behavior is qualitatively similar to the experimental dispersion shown in Figs. 3–6; and, for these chlorobenzene solutions, a fairly good quantitative fit is obtained, taking $\eta_P/\eta_S = 0.013$. The model constants chosen are given in Table VI, and the calculated curves are drawn in Figs. 4–6.

As would be expected from the fact that $G \cong G' \cong \tilde{G}$ in this frequency range, the frequency-independent rigidity $G$ is proportional to $c^3$. Both viscosities are proportional to $c^2$ in this case, so that the two relaxation times, $\tau_S = \eta_S/G$ and $\tau_P = \eta_P/G$, are inversely proportional to $c$. It should be noted that $\eta_S$ is smaller than the steady flow viscosity by a factor of about 0.03, so the utility of the model does not extend to zero frequency.

For most of the other solutions, experimental scatter does not permit model fitting. However, from the magnitudes of $\lambda/x_0$, it is clear that any application of a retarded Maxwell element would be restricted to $\eta_P/\eta_S$ ratios of the order of 0.01. For the xylene solutions, $\tau_S$ appeared to increase with increasing concentration.

TABLE VI

CONSTANTS OF RETARDED MAXWELL ELEMENTS DESCRIBING DISPERSION IN CHLOROBENZENE SOLUTIONS AT 25°

| Concn., g./cc. | $G \times 10^{-6}$, dyn/sq. cm. | $\eta_S$ poise | $\eta_P$ poise | $G/c^3 \times 10^{-6}$ | $\eta_S/c^2 \times 10^{-5}$ |
|---|---|---|---|---|---|
| 0.120 | 1.9 | 61 | 0.79 | 10.9 | 4.1 |
| .143 | 3.1 | 90 | 1.1 | 10.6 | 4.3 |
| .167 | 5.1 | 128 | 1.6 | 10.9 | 4.5 |

It is evident that important frequency-dependent phenomena must exist at lower frequencies than those employed here, since the rigidity must drop from the plateau exhibited in our frequency range to zero under constant stress.

**Dependence of Rigidity on Concentration.**—Pending measurements of dynamic rigidity at higher concentrations, which will require a different experimental method, it is of interest to extrapolate the $c^3$ relation to the pure polymer ($c$ = 0.91 g./cc.). Of course, the four solvents do not extrapolate into the same point, but the differences are small, as shown in Fig. 7; the value obtained is about $6 \times 10^6$ dyn./sq. cm. at 25°. This agrees quite well with measurements of $G'$ on the same sample of polymer by a twin transducer method,[16] which gave a range from 4 to $6 \times 10^6$ in the frequency range from 50 to 250 cycles/sec.

(15) J. D. Ferry, *J. Res. Nat. Bureau Standards*, **41**, 53 (1948).

(16) R. S. Marvin, E. R. Fitzgerald and J. D. Ferry, reported at the Los Angeles meeting of the Rubber Division of the American Chemical Society, July 22, 1948.

As a first approximation, apparently, all the solutions can be regarded as dilutions of the solid polymer, differing from it only in concentration and not fundamentally in structure.

The earlier data for polystyrene–xylene solutions[3] at 25° are also plotted in Fig. 7. In the concentration range studied, up to 52% polymer, the proportionality of $\tilde{G}$ to $c^3$ also holds; the rigidities are smaller than those of the polyisobutylene solutions by about a factor of three. The polystyrene rigidities, however, do not extrapolate into the rigidity of the pure polymer (about $5 \times 10^9$). This difference is undoubtedly associated with the fact that at 25° polyisobutylene is above, and polystyrene below, its brittle point. In the polystyrene–xylene system, the brittle transition must occur somewhere between 50 and 100% polymer at 25°.

**Origin of Rigidity.**—The rigidity observed in concentrated solutions of polyisobutylene and other polymers is no doubt due to storage of elastic energy in the deformation of long chain molecules. This could be accomplished by bending and stretching of bonds, or orientation entropy (rubber-like elasticity), or twist against the hindering potential opposing free rotation around bonds. For tension applied to the ends of an isolated contorted molecule, Kuhn[17] has shown that the contributions to deformation from bond bending and stretching are extremely small. In an analysis of the other two mechanisms, he finds that the molecular spring constant (force per unit extension) is inversely proportional to the number of bonds for orientation entropy, and inversely proportional to the square of this number for twist against the hindering potential.

To apply these considerations to a concentrated solution, we suppose the presence of a transitory network structure, whose net points are entanglements where two chains happen to be tightly kinked around each other. Then the molecular spring is not the entire molecule but the average strand between two points of entanglement. The number of entanglements should be proportional to the square of the volume concentration; if the strands are sufficiently short compared with the total molecular length so that free ends are negligible, the number of strands should also be proportional to the square of the concentration and their average length should be inversely proportional to the first power.

It follows[15] that the network rigidity should be proportional to the square of the volume concentration for rubber-like elasticity, but to the cube of the concentration for twisting against hindered rotation. The experimental concentration dependence thus corresponds to the latter mechanism.

On the basis of the network hypothesis, the temperature independence of $G/c^3$ would mean that in the polyisobutylene solutions the entangle-

(17) W. Kuhn, *Helv. Chim. Acta*, **29**, 609, 830, 1095 (1946).

ments are purely statistical, and not influenced by any perceptible energy differences. The similarity of the values in different solvents would have the same significance. The small differences which are observed could be attributed to differences in the entropy of entanglement, entanglements being slightly more probable in chlorobenzene, for example. A lower intrinsic viscosity, reflecting a greater tendency for the polymer chain to coil back on itself, should be associated with a greater entanglement probability[18] and hence a higher rigidity, in agreement with Table IV.

The network hypothesis predicts that the rigidity should be independent of molecular weight, provided the latter is high enough so that free ends outside entanglements can be neglected. Data are not yet available to test this conclusion.

From mechanical measurements at much higher frequencies on undiluted polyisobutylenes of low molecular weight, Mason and Baker[19] have also postulated an elastic mechanism involving twisting of the polymer chains.

**Interpretation of Model Constants.**—If $\tilde{G}$ (Table VI) represents the hindered rotation elasticity mechanism, $\eta_S$ could represent relaxation by rotation over the barriers or by slippage at entanglement points. Probably both mechanisms should occur, in different frequency ranges. According to Kuhn,[17] the former should be represented by a single relaxation time, directly proportional to the number of bonds involved; for the network, then, the relaxation time should be inversely proportional to concentration, and $\eta_S$ should be proportional to $c^2$. This appears to be the case for the chlorobenzene solutions. However, measurements should be extended to a broader frequency range before a detailed interpretation is attempted.

(18) A lower intrinsic viscosity means that in very dilute solution a smaller volume is pervaded by the average polymer coil. In concentrated solution, also, the volume pervaded is probably smaller. In concentrated solution, however, the domain of each coil is thoroughly interlaced by other molecules. The number of entanglements per cc. should be practically independent of the size of coil domain; but it should be markedly influenced by local chain configuration, back kinking giving rise to "snagging," and hence higher entanglement probability.

## Summary

1. The propagation of transverse waves in solutions of polyisobutylene ($\bar{M}_\eta$ = 1,200,000) in *n*-heptane, xylene, isoöctane, and chlorobenzene has been studied as a function of frequency, temperature, and concentration.

2. The rigidity $\tilde{G}$ increases only slightly with frequency in the range from 100 to 1000 cycles/sec.

3. At constant weight concentration, $\tilde{G}$ decreases slightly with increasing temperature; at constant volume concentration ($c$), $\tilde{G}$ is independent of temperature.

4. The rigidity is proportional to $c^3$; in the different solvents, the ratio $\tilde{G}/c^3$ increases slightly in the order named above, which is also the order of decreasing intrinsic viscosities (at 20°).

5. The damping index, $\lambda/x_0$, decreases with increasing frequency or passes through a minimum.

6. The dispersion of rigidity and damping in chlorobenzene solutions can be fitted by a retarded Maxwell element with a ratio of parallel to series viscosity of 0.013.

7. The concentration dependence of $\tilde{G}$ can be interpreted in terms of a transient network structure with storage of elastic energy by twist against potentials opposing free rotation about bonds in the chains.

# Variation of Monomer Pressure with Degree of Conversion in Emulsion Polymerization of Butadiene and of Butadiene–Styrene[1]

BY E. J. MEEHAN

## Introduction

During a polymerization reaction the pressure of the unpolymerized monomer decreases as the reaction proceeds to completion. The way in which the pressure changes with the degree of conversion of monomer to polymer depends upon the monomer and upon the nature of the polymerization system. Different relations between pressure and conversion are observed in a homogeneous system (solution or bulk polymerization) and in a heterogeneous system (emulsion polymerization).

Pressure measurements can yield certain information about the nature of the polymerization system. Thus in a homogeneous system pressure measurements gave directly the value of the monomer activity in the thermal polymerization of pure styrene.[1a] In the emulsion polymerization of a monomer which is only slightly soluble in water, the unreacted monomer is present as a separate (oil) phase during the earlier part of the reaction; in the latter part of the reaction the unre-

(1) This Investigation was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program.

(1a) Walling, Briggs and Mayo, THIS JOURNAL, **68**, 1145 (1946).

acted monomer is entirely dissolved in the polymer particles. The pressure of the system evidently indicates the exact point at which the separate monomer phase disappears. It was shown by W. B. Reynolds[2] that the pressure of butadiene remains constant and equal to the vapor pressure of pure butadiene during more than the first half of the emulsion polymerization of butadiene, corresponding to the presence of a separate phase of butadiene. The disappearance of this phase is made evident by an abrupt decrease of the pressure from that of pure butadiene. As another example the application to copolymerization studies may be mentioned. The pressure of a copolymerizing system is related to the composition of the copolymer which is formed. The pressure may increase, remain unchanged, or decrease during the first part of the reaction, depending on whether the copolymer contains less than, the same amount as, or more than, the relative amount of the more volatile monomer present at the beginning of the reaction.

It is possible to give a simple interpretation of the data of a copolymerizing system only so long as the oil phase is present. After this phase has disappeared one is dealing with a solution of excess of monomers in a suspension of polymer. If the monomer–polymer system were ideal in the sense that the partial pressure of the monomer would be proportional to the mole fraction of the monomer, there would be no significant decrease in pressure until the consumption of monomer had become substantially complete. Thus in the conversion of a monomer of molecular weight 100 into a polymer of number-average molecular weight 40,000, the mole fraction of unreacted monomer in the monomer–polymer system is 0.99 at 80% conversion and is 0.80 at 99% conversion. Actually a marked decrease in pressure occurs at conversions smaller than 80%, because polymer–solvent systems do not follow Raoult's law; the entropy of mixing is very different from the entropy of mixing given by classical thermodynamics.

In this paper data are given showing the dependence of pressure upon conversion in the emulsion polymerization of butadiene and of butadiene–styrene mixtures. The points of principal interest were the disappearance of the monomer phase in both cases and the connection with copolymer composition in the latter case. A discussion of data obtained after the disappearance of the oil phase is not given at the present time.

## Experimental

### A. Preparation of Polymerization Charges

The following formula was used in the preparation of the charges: temperature, 50 or 30°

| Ingredient | Parts by weight |
|---|---|
| Monomer(s)[a] | 100 |
| Water | 180 |
| Soap | Variable[b] |
| Potassium persulfate | 0.3 |
| *n*-Dodecylmercaptan | 0.5 |

[a] Either butadiene or butadiene (75)–styrene (25). [b] Usually 5; otherwise varied from 10 to 5/8.

The sources and purities of the various ingredients were the same as in previous investigations.[3] The charges were prepared either in 4-ounce glass bottles with metal screwcaps lined with self-sealing gasket material obtained from Dr. E. A. Willson of the B. F. Goodrich Company, or in a special metal reaction vessel described in a later section.

### B. Pressure Measurements

1. **Use of Pressure Gages.**—Some measurements were made using ordinary pressure gages by the method described by Harrison and Meincke.[4] The charges were prepared in glass bottles, and the pressure was measured by removing the bottle from the 50° thermostat and inserting through the self-sealing gasket a pressure gage equipped with a hypodermic needle. To minimize loss of butadiene from the bottle during this operation, the gage was maintained at a temperature of about 51° and the pressure in the gage was maintained at a pressure approximately equal to or greater than that expected in the bottle. The precision of these pressure measurements is about 2 pounds per square inch.

2. **Manometric Measurements.**—Houston and Briggs at Goodrich[5] constructed a mercury manometer of sufficient height to permit measurement on butadiene-containing systems at 50°, and determined pressure–conversion relations for a number of comonomer systems. A mercury manometer of similar dimensions was constructed in this Laboratory and used in connection with a completely closed polymerization system. The polymerizations were carried out in a chromium plated vessel with a capacity of about 100 ml. The vessel, subjected to horizontal agitation, was connected to the manometer system by means of a flexible brass helix leading to an iron vessel which served as mercury reservoir for the open-end manometer. Both helix and reservoir were immersed in the thermostat; this prevented the distillation of butadiene from the reaction vessel at 50° into the manometer. Since the mercury well was about one meter above the lowest point of the manometer it was possible to read pressures lower than atmospheric pressure.

In use, the polymerization vessel was filled with the ingredients of the charge and sealed. It was connected to the helix after the helix and the air space in the mercury well had been pumped out and flushed with butadiene several times to remove the last trace of oxygen. The pressure was read to the nearest millimeter during the desired period of time. At the end of the experiment hydroquinone was injected and the conversion was determined by the usual method of total solids. The pressures reported correspond to mm. at room temperature rather than at 0°. The over-all accuracy of the measurements was estimated to be better than 0.5%.

## Results

A. **Monomers and Monomer Mixtures.**—Accurate values of the vapor pressure and other thermal properties of pure 1,3-butadiene have been given by the Bureau of Standards.[6] The vapor pressure found at 50° was 4264 mm. (corrected to a column of mercury at 0°), and the rate of change of vapor pressure with temperature at 50° was 112 mm. per degree (calculated from the empirical pressure–temperature equation).

(6) R. B. Scott, C. H. Meyers, R. D. Rands, Jr., F. G. Brickwedde and N. Bekkedahl, *J. Res. Nat. Bur. Standards*, **35**, 39 (1945).

The vapor pressure of butadiene at 50° was found in this research to be 4.27 meters with an average deviation of about 0.01 meter. This value agrees well with that of the Bureau of Standards; the precision of 0.01 meter indicates that the temperature was controlled within about 0.1°. Accurate values of the vapor pressure of styrene have been given by Pitzer, Guttman and Westrum[7] who found the vapor pressure at 50° to be 24.23 mm. mercury. The vapor pressure of styrene has been measured also by Patnode and Schreiber.[8] From the empirical equation given by these authors, one calculates that at 50°, $p = 24.4$ mm.

Known mixtures of butadiene and styrene of mole fraction of butadiene ranging from 1.000 to 0.278 were prepared in the metal vessel by adding a known amount of styrene by pipet, followed by the addition of slightly more than the desired weight of butadiene, which had been liquefied in Dry Ice–acetone. The excess of butadiene was allowed to evaporate until the desired weight was present, and the vessel was then quickly sealed. (The amount of styrene which evaporates with the excess of butadiene is negligibly small.) The observed pressures of the mixtures were found to agree within experimental error with the values calculated from the pressures of the pure monomers on the assumption that they form an ideal solution.

## B. Vapor Pressure of Polymerizing Systems

**1. Pressure Variation During the Emulsion Polymerization of Butadiene.**—It was shown already by Reynolds[2] that the pressure remained constant during the first (approximately) 60% conversion in the emulsion polymerization of butadiene. The experiments described now were directed to establish whether or not the conversion at which the butadiene pressure first becomes less than the pressure of pure butadiene depends on the amount of soap initially present in the charge. Charges were prepared according to the previously quoted recipe with the amount of soap varied from 10 ("2 soap") to $^5/_8$ ("$^1/_8$ soap"). The results of the pressure and conversion determinations are given in Table I.

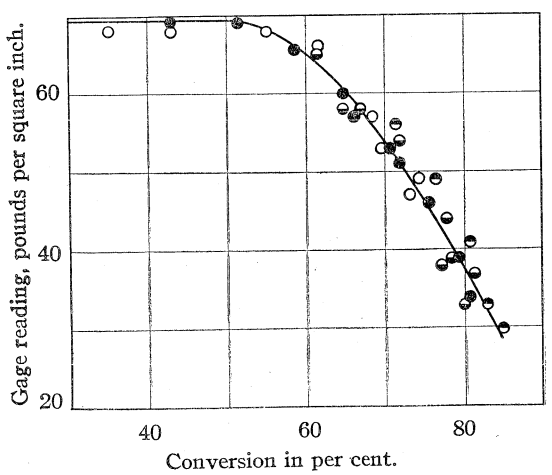

Fig. 1.—Emulsion polymerization of butadiene at 50°: ●, 2X soap; ◒, 1X soap; ◓, $^1/_4$X soap; ○, $^1/_8$X soap.

TABLE I

RELATION BETWEEN PRESSURE AND CONVERSION IN THE EMULSION POLYMERIZATION OF BUTADIENE AT 50°: 100 BUTADIENE, 180 WATER, 0.5 DDM, 0.3 PERSULFATE, AND S. F. FLAKES AS INDICATED

| 33 | 66 | 61.5 | | |
| 35 | 57 | 68.3 | | |
| 37 | 49 | 74.2 | | |

The data of Table I are plotted as Fig. 1. It appears that the butadiene pressure first decreases at about 52% conversion, regardless of the amount of soap (from 2× to $^5/_8$×) initially present in the charge. The size of the polymer particles in the latex is changed greatly as the soap content is varied sixteen-fold. Thus it appears that the amount of butadiene which can dissolve in the polymer particles is determined only by the amount

(7) K. S. Pitzer, L. Guttman and E. F. Westrum, Jr., THIS JOURNAL, **68**, 2209 (1946).

(8) W. Patnode and W. J. Schreiber, *ibid.*, **61**, 3449 (1939).

of polymer and not by the size of the polymer particles.

This conclusion depends upon the assumption that an equilibrium value of the solubility is attained and maintained during the reaction. This was proved to be so in the following way. In several experiments the polymerization was halted (short-stopped) at various conversions greater and smaller than 52%, by the injection of hydroquinone. The pressure subsequently did not change upon continued rotation at 50° for twenty-four hours.

In a similar way (pressure gage technique) the pressure was determined during the emulsion polymerization of butadiene at 30°. It was found that the pressure drop occurred at the same conversion (52%) as at 50°, thus indicating that the solubility of butadiene in polybutadiene is not markedly temperature-dependent.

A few experiments were made with the accurate manometric technique with polybutadiene at 50° to verify the conclusions reached above on the basis of the gage measurements. In polymerizations with 1× and with 1/4× the ordinary amount of soap (5 parts per 100 parts monomers), it was found that the pressure drop occurred between 51–52% conversion.

**2. Variation of Pressure in the Emulsion Copolymerization of Butadiene–Styrene.**—The composition of the copolymer formed in the emulsion copolymerization of butadiene–styrene varies during the reaction.[9] The polymer initially formed contains relatively more butadiene than is present in the charge, so that the proportion of butadiene in the residual monomers decreases during the reaction. This causes a continual decrease in the pressure of the system apart from the relatively abrupt decrease which is observed when the separate phase of residual monomers disappears.

The variation of pressure with conversion up to about 60% conversion was determined accurately in two separate experiments for the previously-quoted mixture with 75 parts of butadiene, 25 parts of styrene and 5 parts of soap. The experiments were made by observing the pressure as a a function of time, and determining the conversion at the end of the experiment. The conversion at a given time could be calculated since it had been established that the rate of conversion in this recipe is constant up to more than 60% conversion. It was not attempted to adjust the weight of butadiene added to the reaction vessel to exactly the correct figure; moreover, some butadiene is lost in the operation of flushing out the manometer system to remove air. For these reasons the initial pressures observed in the experiments did not correspond exactly to that expected for a mixture containing 75.0% butadiene. Therefore all the observed pressures (after subtraction of 92 mm., corresponding to the vapor pressure of water at 50°) were corrected to an initial butadiene content of 75.0%, by multiplying all the values by the ratio of the theoretical initial pressure to the observed initial pressure. The data, corrected as described above, are given in Table II and Fig. 2.

[a] Adjusted to the theoretical initial pressure of 3650 mm. Hg.

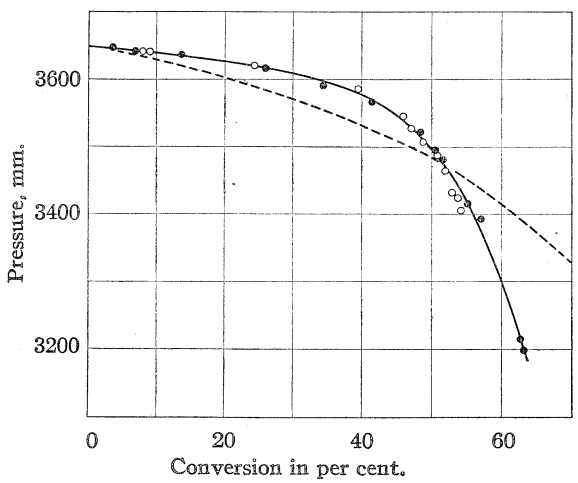

Fig. 2.—Pressure–conversion curve: emulsion polymerization of butadiene (75)–styrene (25), 50°.

Since the composition of the copolymer is known as a function of conversion[9] it is possible to calculate the composition of the total residual monomers at any conversion. Thus if a copolymer containing 19.2% styrene is formed at 50% conversion from a mixture which contained originally 75% butadiene, the residual monomers evidently contain 69.2% butadiene. This calculation does not give any information about the composition of the oil phase, since the residual monomers are in part dissolved in the polymer. So if the two monomers are dissolved to different extents in the

polymer, the distribution would result in a difference in the composition of the monomer mixture in the two phases.

If it is assumed (the correctness of the assumption can be checked immediately) that the composition of the free monomer phase is the same as that of the total monomer mixture, the dependence of pressure upon conversion can be calculated solely from the copolymer composition and the vapor pressures of the pure monomers, since the monomers form an ideal solution. The values so calculated are compared with the observed values in Fig. 2.

From Fig. 2 it is seen that up to about 50% conversion the observed and calculated pressures are in excellent agreement, the maximum deviation being less than 1.3%. The observed pressure becomes markedly less than the calculated value around 52% conversion, which indicates that it is at, or somewhere before, this conversion that the monomer phase disappears by solution in the polymer.

The point at which the monomer phase disappears also was determined approximately by visual examination of non-polymerizing systems. A quantity of "stripped" GR-S latex (*i. e.*, latex from which nearly all the unreacted monomers had been removed) of 69.3% conversion was obtained through the courtesy of Mr. W. K. Taft of the Government Rubber Pilot Plant in Akron, Ohio. To a definite amount of this latex of known polymer content, was added, in an ordinary polymerization bottle, such an amount of butadiene and styrene that the mixture polymer—monomer would correspond to 45, 50, 55 or 60% conversion. (For example, to prepare a latex corresponding to 55% conversion, 45 g. of mixed monomers was added to a quantity of latex which contained 55 g. of polymer.) The composition of the monomer mixture added to the latex was calculated by stoichiometry from the composition of the copolymer.[9] These polymer–monomer mixtures were then shaken at 50° and examined carefully and independently by a number of observers. A layer or droplets of residual monomers could be seen in the charges corresponding to 45 and 50% conversion, but not in those of 55 and 60% conversion. This is in agreement with the inference from the pressure measurements. It is of interest to note also, that there appeared to be a pronounced decrease in the viscosity of the latex upon the complete solution of the residual monomers. The charges corresponding to 45 and 50% conversion were noticeably more viscous than those of 55 and 60% conversion.

The agreement of observed and calculated values below 52% conversion shows that the assumption made in the calculation is essentially correct, which means that the monomers dissolve in the polymer particles in almost the same proportions that they are present in the total monomer mixture.

The conclusion that the composition of the monomer layer is not changed much by distribution with the polymer particles could be checked by direct experiments on non-polymerizing systems. (The measurements were not made with the accurate manometric method, but with the pressure gage-injection method.) To the stripped latex previously referred to, were added various amounts of different monomer mixtures, the amounts being chosen so that some undissolved monomer was present (*i. e.*, equivalent conversion less than 50%). It was found that the pressure of the monomer–polymer mixture was the same (within the limits of experimental uncertainty, 1–2%) as the pressure of the monomer mixture alone. This proves in a direct way, that there is little change in the composition of a butadiene–styrene mixture on dissolving in polymer.

Measurements of precision greater than 1% reveal a difference in the composition as a result of the distribution of the monomers between the phases. Consider the situation at exactly 40% conversion. The copolymer contains 18.7% styrene,[9] which corresponds to 70.8% butadiene in the total residual monomers. If the free monomer phase had this composition the hydrocarbon pressure would be 3527 mm. The actual pressure is 3576 mm. which corresponds to 72.5% butadiene in the monomer phase. Therefore the oil phase is slightly richer in butadiene than would correspond to the composition of the entire mixture, which means that relatively more styrene than butadiene is dissolved in the polymer particles.

If the solubility of butadiene in the copolymer were known, the amount of each monomer which is dissolved in the copolymer could be calculated since the compositions of the total monomer mixture and of the separate monomer phase are known. As an approximation, the solubility of butadiene in the copolymer may be taken equal to the solubility in polybutadiene, which is known from the observed pressure drop to be about 48/52 or 0.92 g. of monomer per g. of polymer. With this assumption, it may be calculated that at 40% conversion, 87% of the residual butadiene and 88% of the residual styrene are dissolved in the polymer, and at 20% conversion, about 32% of the residual butadiene and 37% of the residual styrene are dissolved. It should be emphasized that these calculated values are of only an approximate nature.

I wish to thank Dr. I. M. Kolthoff for many discussions and suggestions.

## Summary

The pressure of the residual monomer(s) has been measured during the emulsion polymerization of butadiene and of butadiene–styrene mixtures. During the emulsion polymerization of butadiene the monomer pressure is constant and equal to that of pure butadiene as long as a separate phase of undissolved butadiene is present.

The first drop in pressure corresponds to the disappearance of the phase of residual monomer by solution in the polymer. This occurs at about 52% conversion corresponding to a "solubility" of 0.92 g. of butadiene per g. of polybutadiene. This solubility is approximately the same at 30 and at 50°, and is unaffected by a sixteen-fold variation in the amount of soap used in preparing the emulsion charges. Equilibrium as regards distribution of monomer between the oil phase and the polymer phase appears to be maintained during the polymerization at 50°.

During the emulsion copolymerization of butadiene–styrene, the pressure changes continuously from the start of the reaction because of the change in the composition of the copolymer which is formed. At about 50–52% conversion a fairly abrupt drop in pressure occurs corresponding to the solution of excess monomers. The composition of the oil phase corresponds closely to the composition of the total residual monomers, which indicates that only a small change in composition of a butadiene–styrene mixture results from its distribution between the polymer and the oil phase.

# Absorption Spectra of Azines and Dianils[1]

BY LLOYD N. FERGUSON AND THOMAS C. GOODWIN[2]

The order of increasing chromophoric power of the common chromophores was early recognized to be

C=C C=N C=O N=N C=S

This order has been attributed by several persons[3,4,5,6,6a] to the relative amounts of strain[7] within the double bonds. Other factors being equal, with increasing strain within the bond there results a less stable ground state, causing a smaller difference in the potential energies of the ground and first excited states and, hence, an absorption of light of longer wave length.

What appears to be at first glance an anomaly to this generalization is the fact that azines, which contain two stronger chromophores than a polyene hydrocarbon containing the same number of double bonds, absorb light of shorter wave length than the latter compounds. For instance, Lewis and Calvin[3] have pointed out that benzalazine, $C_6H_5CH{=}N{-}N{=}CHC_6H_5$, ($\lambda_{max.}$ = 301 mμ) absorbs light at shorter wave lengths than does 1,4-diphenylbutadiene, $C_6H_5CH{=}CH{-}CH{=}CHC_6H_5$ ($\lambda_{max.}$ = 334 mμ), and Blout and Fields[8] have reported that polyene azines of the generic formula $CH_3(CH{=}CH)_nCH{=}N{-}N{=}CH(CH{=}CH)_nCH_3$ have maximum absorption bands at shorter wave lengths than do the corresponding aliphatic polyene hydrocarbons with the same number of double bonds.

Lewis and Calvin have explained this on the basis of the "strain" theory by saying that due to the highly strained N=N bond in one of the predominant excited states of benzalazine

the potential energy of the excited state is raised. Although the ground state of the azine may lie above that of the diene, there is a larger difference between the energies of the first excited state and the ground state for the azine to the extent that it absorbs at shorter wave lengths. Blout and Fields have offered a different explanation. Their concept is to place greater emphasis on the contribution of forms Ib and Ic than on Ia to the resonance of the azines which, they believe, favors absorption at shorter wave lengths.[9]

$CH_3{-}CH{=}CH{-}CH{=}N{-}N{=}CH{-}CH{=}CH{-}CH_3$ I

$CH_3{-}\overset{\mp}{C}H{-}CH{=}CH{-}N{=}N{-}CH{=}CH{-}\overset{\pm}{C}H{-}CH_3$ Ia

$CH_3{-}\overset{+}{C}H{-}CH{=}CH{-}\overset{-}{N}{-}N{=}CH{-}CH{=}CH{-}CH_3$ Ib

$CH_3{-}CH{=}CH{-}CH{=}\overset{-}{N}{-}\overset{+}{N}{-}CH{=}CH{-}CH_3$ Ic

When the three compounds, glyoxaldianil ($C_6H_5N{=}CH{-}CH{=}NC_6H_5$), diphenylbutadiene and benzalazine are considered from Lewis' and Calvin's viewpoint, one may expect the dianil to absorb at longer wave lengths than the diene because, first, the dianil possesses two stronger chromophores and, second, the resonance of structures IIa, IIb and IIc for the dianil makes a greater contribution to the excited state than does the resonance of the corresponding ionic forms of the hydrocarbon.

(7) The word "Strain" is used as a mechanical way of referring to the relative potential energy of a particular structure.

(8) E. R. Blout and M. Fields, THIS JOURNAL, **70** 189 (1948).

(9) The author is of the opinion that due to the greater electronegativity of nitrogen over carbon, the forms Ib and Ic do make a contribution to the resonance of the azines but this only tends to lower the potential energy of the excited states and would lead to absorption at longer wave lengths than the azines might have if these ionic forms were not possible contributors. This contribution, however, is too small to outweigh the opposite effect caused by the strain in the N=N bond.

Hence, one may anticipate the decreasing order of the chromophoric power of these three classes of compounds to be dianil, butadiene, azine. To verify this hypothesis, a number of dianils and azines were prepared and studied spectroscopically. These compounds are listed in Table I, together with their $\lambda_{max.}$ and $\epsilon_{max.}$, and their spectra are drawn in Figs. one to seven.

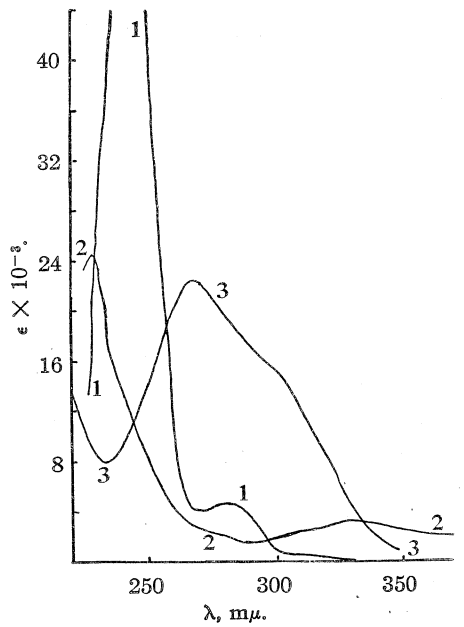

Fig. 1.—Absorption spectra of: di-(acetophenonal)-ethylenediamine, 1; diacetyldianil, 2; acetophenonazine, 3.

From the spectra it can be seen that the decreasing order of the longest wave length of absorption for compounds 10, 10a and 10b is in the order dianil, diene, azine. In addition, the dianils 5a and 6a have maximum absorption bands at longer wave lengths than do the corresponding azines 5 and 6. The hypsochromic shift in going from 8 to 8a cannot be explained satisfactorily. Unfortunately, all attempts to isolate the parent compound glyoxal dianil, $C_6H_5N{=}CH{-}CH{=}NC_6H_5$, were unsuccessful.

Upon looking at compounds 7 with 7a, 2 with 2a and 9 with 9a it is noted that there results a large difference between the maxima of the dianils and the azines when the hydrogen atoms on the methine carbon atoms have been replaced by

methyl groups. This perhaps is due to three factors: 1, the absence of the highly strained N=N bond in the excited state; 2, a hypsochromic effect in the ketazines due to steric hindrance,[10] and 3,

(10) Spacial interference of the methyl groups prevent the coplanarity of the molecule such as is required for the resonant forms

This has been pointed out by Blout, Eager and Gofstein (THIS JOURNAL, **68**, 1983 (1946)) for a number of ketazines and is further observed for the pairs of compounds 6 with 7 and 8 with 9.

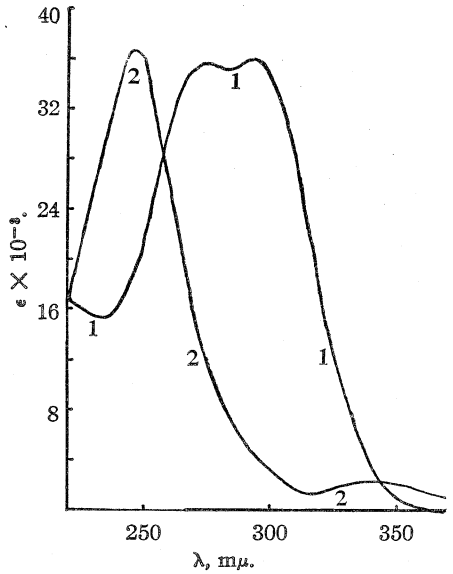

Fig. 4.—Absorption spectra of: *m*-nitrobenzalazine, 1 (from unpublished work by Ferguson and Branch); glyoxaldi-(-*m*-nitroanil), 2.

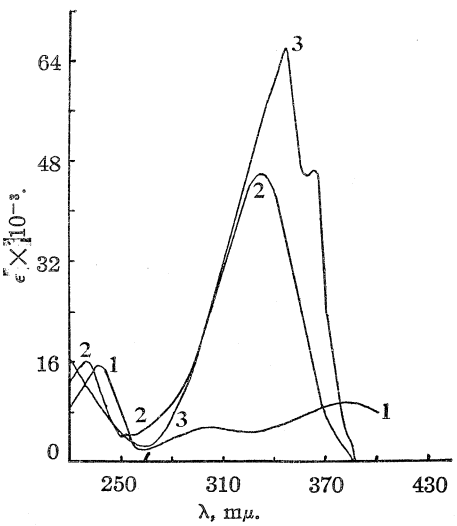

Fig. 7.—Absorption of: 1, glyoxaldi-(*p*-methoxyanil); 2, *p*-methoxybenzalazine; 3, 1,4-di-(*p*-methoxyphenyl)-butadiene-1.

a bathochromic effect by the methyl groups on the N=C—C=N system as observed when comparing the compounds 8a with 9a and 6a with 7a. This is the usual bathochromic effect of alkyl groups on a conjugated double bond which has been attributed to hyperconjugation.[11] This auxochromic effect by methyl groups is also revealed by the pair of compounds 3 and 4 where the steric factor, found in ketazines is absent.

Other points to be noted about the spectra are: 1, the large decrease in $\epsilon_{max.}$ in going from the C=N—N=C to the N=C—C=N system, 2, the close similarity of the absorption bands for the pairs of compounds 5 with 10 and 5a with 10a indicates the absence of association of the hydroxy compounds through hydrogen bonds, 3, the "insulation" effect, illustrated by comparing compound 1 and 3, is masked when comparing compound 2 with 4 because of the hypsochromic steric effect of the methyl groups in 2.

## Experimental

The compounds studied were prepared by one of four general procedures, which were: A, Mix the amine and carbonyl compound in 50 to 70% alcohol, warm a short period on the steam-bath and cool over a period of several hours. B, Identical to A except that 2 *N* acetic acid was the solvent. C, Identical to A except that $H_2O$ was the solvent. D, Dissolve glyoxal bisulfite in 2 *N* acetic acid

and the amine in an equal volume of alcohol, mix and heat on the steam-bath for about half an hour and cool over a period of several hours. Ninety-five per cent. ethanol was always the solvent for recrystallization unless otherwise specified.

The absorption measurements were made using a Beckman Photoelectric Quartz Spectrophotometer, Model DU, with 1-cm. square, fused silica absorption cells. Ninety-five per cent. ethanol served as the solvent. The absorption by compounds 2a, 5a, and 10a was found to slowly increase during the measurement of their spectra, this increase being more marked in the regions of maximum absorption.

**Acknowledgment.**—The authors are indebted to Mr. Theodore Austin, instructor of chemistry in Howard University, for drawing the spectra.

## Summary

The order of chromophoric power for the systems dianil, diene, and azine is discussed and illustrated to be decreasing in the order named. A bathochromic effect by substituting methyl groups upon the methine carbon atoms of the dianil system is noted.

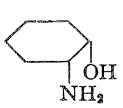
# Stereochemistry of Cyclic Amino-alcohols. Inversion, Retention and Participation[1]

BY G. E. MCCASLAND,[2] R. K. CLARK, JR.,[3] AND HERBERT E. CARTER



The isolation of streptamine (I),[4] one of the three major degradation products of streptomycin, has stimulated interest in the stereochemistry of polysubstituted alicyclic compounds, and of cyclic aminoalcohols in particular. Streptamine is one of the twenty possible diastereoisomeric forms of 1,3-diamino-2,4,5,6-tetrahydroxycyclohexane. Of these forms, eight are *meso* and twelve racemic, and the recent synthesis[5] of streptamine from glucosamine indicates that "natural" streptamine is the all-*trans*, *meso* form. In support of stereochemical studies on streptamine, model compounds of simpler structure were investigated.

I

II

III

For this purpose the 2-aminocyclohexanols were selected.

Both the *cis* and *trans* forms of 2-aminocyclohexanol lack a plane of symmetry and hence are theoretically resolvable. Thus the configurations cannot be established by resolution of the *trans* isomer, as with the diol or diamine. Experimentally, two racemic forms of 2-aminocyclohexanol are known. The first, isomer "A," melts at 68°; the second, isomer "B," melts at 72°. The melting points of a number of derivatives of "A" and "B" are given in Table I.

Isomer "A" was first prepared in 1905 by Brunel[6a] by the amination of cyclohexene oxide, and also can be obtained by the amination of cyclohexene halohydrin,[6b] or by the reduction of 2-hydroxycyclohexanone oxime.[6c] The preparation of the "B" isomer was first described in a 1936 patent,[7] and few details regarding it have been published. An alternate preparation of the "B" isomer (N-benzoyl), by the tosylation and detosylation of the "A" N-benzoyl derivative, is described below.

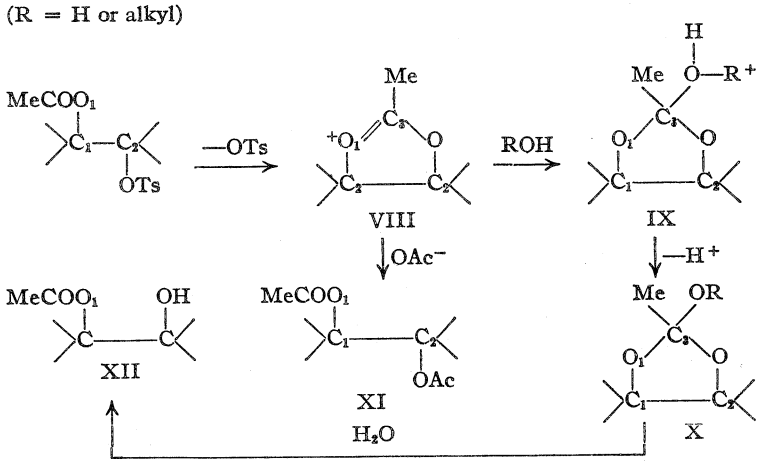
| N-Benzylidene | 90–92[a,b] | ... |



[a] Not previously reported. [b] To be described in a subsequent publication.

Isomer "A" is listed as "*cis*" in Beilstein,[8] on the basis of Brunel's designation. Certain later authors[9] favored the *trans* configuration for "A." It is now known that the oxide ring normally is opened in the *trans* manner. For this reason, and on the basis of the results described below, the "A" isomer will be designated as *trans*.

Chart I

Mechanism of Detosylations

(R = H or alkyl)

For benzamidotosylate, replace —O—by —NH— and Me by phenyl

Although direct physical methods, such as X-ray diffraction and dipole moment, may be the most powerful approach to such questions of molecular geometry, their application at present involves well-known difficulties, which need not be considered here. An alternate approach involves a study of the inversions or retentions at each step in the formation or reactions of the aminocyclohexanols. A functional group on a neighboring carbon atom can alter the normal steric result of a displacement on carbon from inversion to retention, or *vice versa*, and the extensive recent development[10] of theories to explain this "participation" furnishes an indispensable guide to such steric studies.

The formation of *trans*-2-aminocyclohexanol by amination of either cyclohexene oxide or the *trans* halohydrin in aqueous or alcoholic ammonia is to be expected on the basis of present knowledge concerning the formation and opening of oxide rings. Supporting evidence on this point was afforded by the reaction of cyclohexene oxide with potassium amide in anhydrous liquid ammonia. In this case the high concentration of the powerfully nucleophilic amide ion should make a *trans* ring-opening more certain. From this reaction only the "A" isomer (*trans*) was obtained; the yield, however, was small.[11]

## Tosylation and Detosylation

In 1942 Winstein, Hess and Buckles[12] conducted a series of experiments on the detosylation of *d,l-trans*-2-acetoxycyclohexyl-*p*-toluenesulfonate. The results obtained by these authors, and the mechanism proposed by them are shown in Chart I. Departure of tosylate ion yields the charged cyclic intermediate VIII, with inversion. In *dry* acetic acid–sodium acetate, the acetate ion attacks carbon atom $C_2$, with inversion, giving *trans*-diacetate XI (over-all *retention*). In *wet* acetic acid–sodium acetate, or in dry ethanol, the water or ethanol reacts more rapidly than acetate ion, to give the conjugate acid IX of the ortho ester X, which opens with retention to give the *cis*-acetoxyalcohol XII (over-all *inversion*).

It seemed probable to us that a *trans* acylamino group would participate in such detosylation reactions in the same manner as an acyloxy group. A comparison of the stereochemical behavior of the acylamino and acyloxy compounds might then provide evidence testing the validity of the *trans* assignment of configuration to "A" 2-aminocyclohexanol.

Accordingly, we prepared the N-benzoyl-O-*p*-toluenesulfonyl derivative of the "A" form of *d,l*-2-aminocyclohexanol, and solvolyzed it under Winstein's three conditions: (1) sodium acetate in dry acetic acid, (2) sodium acetate in acetic acid with a small amount of added water, (3) sodium acetate in absolute ethanol.

The results were completely analogous with those obtained by Winstein, *et al.*, for their *trans*-acyloxytosylate. In dry acetic acid the product we obtained was the "A" benzamidoacetate with

*cis*, m. p. 147°. *trans*, m. p. 127°.

Fig. 1.—X-Ray powder spectra of *d,l*-2-acetaminocyclohexanols.

retention. In wet acetic acid, or in (dry) ethanol, the product was the "B" benzamidoalcohol with inversion.

The mechanism as modified by us for the benzamido compound is also given by Chart I if Me is replaced by phenyl and —$O_1$— by —NH—. Intermediate (X) in the acyloxy detosylation would be an ortho-ester; in the acylamino detosylation it would be a 2-hydroxy-2-phenyloxazolidine. While we have no direct evidence on the formation of the postulated intermediates, the striking parallelism between the results on acylamino- and acyloxytosylates strongly suggests a common mechanism. And it indicates that the "A" amino-alcohol, like the diol, has the *trans* configuration.[13]

## Chlorination and Dechlorination

The treatment of a secondary alcohol with phosphorus pentachloride commonly gives the alkyl chloride with inversion. In the case of *trans*-2-aminocyclohexanol hydrochloride the normal displacement of hydroxyl by chlorine might be expected to result, since participation by the neighboring positively charge ammonium ion seems improbable.

Experimentally the reaction of *trans*-2-aminocyclohexanol hydrochloride with phosphorus pentachloride gives a high yield of a 2-chlorocyclohexylamine hydrochloride which there is good reason to regard as *cis*. Attempts to dechlorinate this compound with silver oxide were unsuccessful; only starting material could be isolated (as the N-benzoyl derivative) from the reaction mixture. The chloride and its N-benzoyl derivative failed to react appreciably even when boiled for twenty-one hours with an acetic acid solution of silver acetate.

These results are quite in accord with the findings of Winstein and co-workers[13] who reported that *cis* isomers of 2-substituted cyclohexyl chlorides show a remarkable inertness. Likewise, Leffler and Adams[14] reported that *cis*-2-*p*-nitrobenzoylaminocyclohexyl chloride was highly inert (to alkali).

**X-Ray Powder Spectra.**—The X-ray spectra were observed on powdered samples of *trans* and *cis*-*d,l*-2-acetaminocyclohexanol. The results are shown in Fig. 1 and are presented merely for purposes of identification.

## Experimental[15,16]

**Preparation of *trans*-2-Aminocyclohexanol Derivatives** *d,l-trans*-**2-Aminocyclohexanol.**—(a) The amination pro-

(13) *dl-cis*-2-Acetoxycyclohexyltosylate reacts with dry acetic acid–acetate with inversion (Winstein, *et al.* THIS JOURNAL, **70**, 816 (1948)).

(14) Leffler and Adams, *ibid.*, **59**, 2256 (1937).

(15) Microanalyses by Clark Microanalytical Laboratory, Urbana, unless otherwise credited. Semi-micro Kjeldahl analyses by Dr. Robert S. Pogrund.

(16) All melting and boiling points are corrected.

cedure of Wilson and Read[6c] was found most convenient. Redistilled, colorless *d,l-trans*-2-chlorocyclohexanol (du Pont), b.p. 92–97° (33 mm.) was used. The product, colorless stout needles, m.p. 68°, b.p. 102–107° (9 mm.), darkens on prolonged standing in air, and is best stored *in vacuo*, or in the form of its hydrochloride. Solubility of the free aminoalcohol in benzene is about 8 g./100 ml. solvent.

*Anal.* Calcd. for $C_6H_{13}NO$ (115.17): N, 12.17. Found: N, 12.22.

(b) To regenerate the aminoalcohol from its hydrochloride, the latter was neutralized with an equivalent amount of 0.3 *N* ethanolic sodium hydroxide. After one-half hour at 0°, sodium chloride was filtered off, and the filtrate vacuum distilled to dryness, giving colorless needles, m. p. 68–69°.

*d,l-trans*-2-**Aminocyclohexanol Hydrochloride.**—Evaporation of a solution of the aminoalcohol in excess hydrochloric acid gave the hydrochloride,[6a] colorless prisms, m. p. 176–177° (without decomposition). The hydrochloride can be recrystallized from absolute alcohol–benzene (1:2).

**Amination with Potassium Amide–Liquid Ammonia.**—To a solution of one gram of potassium metal in 100 ml. of anhydrous liquid ammonia was added 5.0 g. of cyclohexene oxide,[17] and an iron nail as catalyst. This mixture was kept overnight at −33°. Ethanol was then added to destroy potassium amide, most of the ammonia was boiled off and the residual solution neutralized with hydrochloric acid. Inorganic matter was filtered off, and the filtrate vacuum distilled to dryness. The residue was again taken up in a little ethanol, filtered and distilled. Finally, the residue was taken up in aqueous 6 *N* hydrochloric acid, and the solution distilled to dryness, giving 0.14 g. of colorless crystals, m.p. 176–178°. A mixed m. p. with the *trans* hydrochloride was not depressed.

*Anal.* Calcd. for $C_6H_{14}NOCl$ (151.64): N, 9.24. Found: N, 9.30 (Kjeldahl).

Liquid ammonia alone failed to react with the oxide.

*d,l-trans*-2-**Acetaminocyclohexyl Acetate.**—The procedure of Raiford and Mortensen[18] was used. Recrystallization of the product from benzene–ligroin (1:1) yielded long, colorless needles, m. p. 117–119°.

*Anal.* Calcd. for $C_{10}H_{17}NO_3$ (199.25): N, 7.03. Found: N, 7.05 (Kjeldahl).

*d,l-trans*-2-**Acetaminocyclohexanol.**—This compound[18] is best prepared by hydrolysis of the diacetyl derivative. Titrations of samples from the reaction mixture with standard acid showed that the hydrolysis in 1 *N* sodium hydroxide at 25° is complete in thirty minutes or less. Recrystallization of the product from benzene gives short colorless needles, m. p. 126–127°.

*Anal.* Calcd. for $C_8H_{15}NO_2$ (157.21): N, 8.91. Found: N, 8.78 (Kjeldahl).

*d,l-trans*-2-**Benzoylaminocyclohexanol.**—The general method of Leffler and Adams[14] gave a 95% yield of crude product, colorless needles, m. p. 175–176°, which did not need recrystallization.

*d,l-trans*-2-**Benzoylaminocyclohexyl Benzoate.**—The procedure of Raiford[18] and Mortensen was used. The product melted at 215–216°.

*Anal.* Calcd. for $C_{20}H_{21}O_3N$ (323.38). N, 4.33; sapon. equiv., 323.4. Found: N, 4.69; sapon. equiv. 313.

## Preparation of *cis*-2-Aminocyclohexanol Derivatives

**2-Acetaminophenol.**—The method of Lumière and Barbier[19] was used. The alkaline solution of 2-aminophenol should be filtered (Super-Cel) to remove insoluble impurities. Recrystallization of the product from ethanol (Norit) gives colorless leaflets, m. p. 206–207°.

**2-Acetaminophenyl Acetate.**—The method of Meldola, *et al.*,[20] was found more satisfactory than others. The product was recrystallized from water, giving colorless needles, m. p. 74–77°. Further recrystallizations from either water or benzene–ligroin gave a maximum m. p. of 75–77°, which is that reported for the sesquihydrate.[20]

*d,l-cis*-2-**Acetaminocyclohexanol.**—A 22-g. portion of 2-acetaminophenol in 150 ml. of absolute ethanol was hydrogenated with Raney nickel catalyst at 100 atm. and 180°. The theoretical uptake of hydrogen was reached in four to six hours. The catalyst was removed by filtration, and the colorless or red filtrate concentrated in vacuum to a thick sirup, which crystallized on mixing with 100 ml. of acetone. Filtration and drying gave 2.5 g. (11%) of *d,l-cis*-2-acetaminocyclohexanol,[7] as colorless prisms, m. p. 146–147°. On recrystallization from acetone the m. p. was unchanged.

Fractional crystallization of the mother liquor, using various solvents, failed to yield any additional *cis* product, nor was it possible to isolate in a pure form any of the *trans* isomer, which is presumably present.

With the specially active nickel catalyst of Pavlic and Adkins,[21] the hydrogenation proceeded at 150°, but the yield was even lower.

When (dry, acid-free) ethyl acetate was used as hydrogenation solvent (to prevent alcoholysis), the yield was only 5%.

When diacetyl-2-aminophenol was hydrogenated, in ethanol, extensive alcoholysis occurred, and a very small yield of *cis*-2-acetaminocyclohexanol was obtained.

Hydrogenation of 2-acetaminophenol with platinum oxide catalyst gave an unpurifiable product.

*d,l-cis*-2-**Aminocyclohexanol Hydrochloride.**—A solution of 1.0 g. of the acetamino compound in excess of 6 *N* hydrochloric acid was refluxed for two hours, and distilled in vacuum to dryness. The residue was washed with a little acetone, giving 0.9 g. (94%) of colorless crystals,[7] m. p. 189–190°, with decomposition.

**Attempted Preparation of** *d,l-cis*-2-**Acetaminocyclohexyl Acetate.**—Application of the method used for the *trans* compound, and of other methods, failed to yield any crystalline product, possibly due to oxazoline formation.

*d,l-cis*-2-**Aminocyclohexanol.**—Treatment of the *cis* hydrochloride by the same procedure described for the *trans* isomer gives the free aminoalcohol,[7] colorless crystals, m. p. 72–73°.

*d,l-cis*-2-**Benzoylaminocyclohexanol.**—(a) Treatment of the aminoalcohol hydrochloride by the general procedure of Leffler and Adams[14] gave an 86% yield of crude product, colorless leaflets melting sharply at 189–190°, which did not need recrystallization. (b) This compound can be obtained by detosylation of the *trans* tosylate (see below).

*d,l-cis*-2-**Benzoylaminocyclohexyl Benzoate.**—Treatment of 150 mg. of the aminoalcohol hydrochloride by the Schotten–Baumann procedure, followed by benzoylation in hot pyridine, gave a product which crystallized from ethanol as colorless crystals, m. p. 152–154°.

*Anal.* Calcd. for $C_{20}H_{21}NO_3$ (323.38): N, 4.33; sapon. equiv. (O-benzoyl), 323.4. Found: N, 4.42 (Kjeldahl); sapon. equiv., 342.

## Inversion and Retention in Detosylation Reactions

**Preparation of** *d,l-trans*-2-**Benzoylaminocyclohexyl-***p*-**toluenesulfonate.**—To the benzamidoalcohol (4.4 g.) suspended in 10 ml. dry pyridine at 0° was added 4.3 g. of *p*-toluenesylfonyl chloride, and the clear yellow solution allowed to stand at 25° for twenty-four hours. The mixture was chilled to 0° and 10 ml. of 6 *N* hydrochloric acid and 20 ml. of water (both ice-cold) were successively added. The precipitate was filtered off, washed repeatedly with water and dried. The crude product (3.5 g.) was recrystallized from 15 ml. of 60–70% ethanol, giving 1.3 g. (18%) of colorless needles, m. p. 111–112°. A sample recrystallized again, for analysis, melted at 113–114°.

(17) "Organic Syntheses," Coll. Vol. I, 2nd ed., p. 185.

(18) Raiford and Mortensen, This Journal, **50**, 1201 (1928). (The m. p. of *d,l-trans*-2-acetaminocyclohexanol was incorrectly reported as 315° instead of 127°.)

(19) Lumière and Barbier, *Bull. soc. chim.*, [3] **33**, 784 (1905).

(20) Meldola, *et al.*, *J. Chem. Soc.*, **69**, 1323 (1896).

(21) Pavlic and Adkins, This Journal, **68**, 1471 (1946).

*Anal.* Calcd. for $C_{20}H_{23}O_4NS$ (373.45): C, 64.32; H, 6.21; N, 3.75. Found: C, 64.23; H, 5.91; N, 3.75.

The use of ethanol probably lowers the yield by detosylation, but no other satisfactory method of purification has been found.

**Inversion of Configuration with Wet Acetic Acid–Sodium Acetate: Formation of *d,l-cis*-2-Benzoylaminocyclohexanol.**—A mixture of 0.95 ml. of acetic acid (m. p. 16°), 0.05 ml. of water, 0.1 g. of fused sodium acetate, and 300 mg. of the *trans*-benzamidotosylate was refluxed four hours. After cooling, 10 ml. of water was added, and solid sodium carbonate added gradually until *p*H 8. The mixture was extracted with two 20-ml. portions of ether. The dried ether extract on evaporation gave an oily solid residue, which was washed with benzene–ligroin, yielding 25 mg. of colorless crystals, m. p. 179–182°. From the benzene–ligroin filtrate was obtained 15 mg. more material, of m. p. 186–188°; total yield[22] 40 mg. (22%). The product was recrystallized for analysis from benzene–ligroin, giving colorless plates, m. p. 192–193°.

*Anal.* Calcd. for $C_{12}H_{17}O_2N$ (219.28): N, 6.39. Found: N, 6.44.

**Retention of Configuration with Dry Acetic Acid–Sodium Acetate: Formation of *d,l-trans*-2-Benzoylaminocyclohexyl Acetate.**—An anhydrous acetic acid solution was prepared by refluxing 9.5 ml. of glacial acetic acid (m. p. 16°) with 0.53 ml. of acetic anhydride and 1.0 g. of fused sodium acetate. A 1.0-ml. aliquot of the resulting solution was added to 300 mg. of the *trans*-benzamidotosylate, and the mixture refluxed for four hours, with exclusion of moisture. After cooling, the reaction mixture was diluted with 4 ml. of water, causing the separation of 170 mg. (dry weight) of precipitate, m. p. 115–130°. The material was recrystallized from 50% ethanol, giving 80 mg. (38%)[22] of *trans*-2-benzoylaminocyclohexyl acetate,[18] colorless plates, m. p. 135–139°. A final recrystallization raised the m. p. to 143–144°.

**Inversion of Configuration with (Dry) Ethanol–Sodium Acetate: Formation of *d,l-cis*-2-Benzoylaminocyclohexanol.**—A mixture of 300 mg. of *trans*-benzamidotosylate, 280 mg. of fused sodium acetate, and 4.3 ml. of absolute ethanol was refluxed for forty-nine hours. After a few hours, crystals (sodium *p*-toluenesulfonate?) separated from the solution. After cooling, the filtered solution was evaporated to dryness, 1–2 ml. of water added, and the precipitate filtered off and washed with 2–3 ml. of water. The residue, after drying, was a crystalline powder, weight 157 mg., m. p. about 175°. Recrystallization from ethyl acetate gave 95 mg. (54%)[22] of *d,l-cis*-2-benzoylaminocyclohexanol, colorless plates, m. p. 184–186°.

**Preparation of *d,l-cis*-2-Benzoylaminocyclohexyl *p*-Toluenesulfonate.**—A 373-mg. portion of the *cis*-benzamidoalcohol was suspended in 1.0 ml. of dry pyridine. With ice-cooling, 350 mg. of *p*-toluenesulfonyl chloride was added, and the mixture left at 25° for fifty hours. At 0° there was successively added 2–3 ml. of water, 1.0 ml. of 6 *N* hydrochloric acid, and again 2–3 ml. of water. The precipitate was filtered off, washed well with water, and dried *in vacuo*. The colorless crystalline solid so obtained weighed 339 mg. and melted at 145–175°.

Between crossed Nicol prisms the crystals appeared as colorless needles, with a smaller amount of colored leaflets. By successive crystallizations from dilute ethanol or absolute methanol, an analytic sample of m. p. 163–165° was obtained which appeared nearly homogeneous (needles) under the polarizing microscope. The yield at this stage was very small, however, and has not yet been improved.

*Anal.* Calcd. for $C_{20}H_{23}O_4NS$ (373.45): C, 64.32; H, 6.21; N, 3.75. Found: C, 64.36; H, 6.20; N, 3.66.

### Chlorination and Dechlorination

***d,l-cis*-2-Chlorocyclohexylamine Hydrochloride.**—A 6.0-g. portion of the *trans* aminoalcohol hydrochloride was treated with 11.9 g. of finely powdered phosphorus pentachloride in 100 ml. of dry benzene at 10°, and the mixture stirred for two hours at 25°. The product was collected on a sintered glass filter and washed repeatedly with dry carbon tetrachloride. After drying, the product[6b] weighed 5.0 g., m. p. 179–181°, with decomposition. The product was recrystallized from benzene–alcohol (5:1) yielding 3.5 g. of colorless needles, m. p. 185–186°, with decomposition. A mixed m. p. with the starting material was depressed to 143–153°.

The free chloro-amine was obtained by neutralizing the hydrochloride with concentrated aqueous alkali at 0° in the presence of ether. The crude liquid chloro-amine obtained by evaporating the dried ether extract was used directly for further operations.

***d,l-cis*-2-Benzoylaminocyclohexyl Chloride.**—A 0.4-g. portion of the chloro-amine hydrochloride was treated by the Schotten–Baumann procedure at 0–10° with 2.0 equivalents of benzoyl chloride, and 4.0 equivalents of 1 *N* aqueous sodium hydroxide. The precipitate was washed with water, and recrystallized from ethanol, yielding 0.3 g. of colorless rectangular leaflets, m. p. 153–154°. A sample recrystallized again, for analysis, showed no change in m. p.

*Anal.* Calcd. for $C_{13}H_{16}NOCl$ (237.73): C, 65.68; H, 6.79; Cl, 14.92. Found: C, 66.27; H, 7.15; Cl, 15.12.

A mixed m. p. with the dibenzoyl derivative (m. p. 153°) was depressed. The compound gave a positive Beilstein test for halogen, but was totally inert to hot alcoholic silver nitrate, and when it was boiled for twenty-one hours with silver acetate–acetic acid, hardly any silver chloride was formed.

**Reaction of the *cis*-Chloro-amine with Silver Oxide or Carbonate.**—Silver nitrate solution was treated with excess sodium carbonate solution, and the precipitate was washed, and suspended in water. To an excess of the resulting suspension the *d,l*-chloro-amine (or its hydrochloride) was added in portions. (If added all at once, a gummy ball forms.) The mixture was stirred at 40° for two hours. The product was mainly unchanged starting material, even when the temperature was increased from 40 to 70°, or the reaction time increased, or sodium hydroxide used in place of sodium carbonate. This was verified by benzoylation of the product, giving a 54% yield of *d,l-cis*-2-benzoylaminocyclohexyl chloride, m. p. 150–153°; mixed m. p. with an authentic sample not depressed. (A mixed m. p. with the dibenzoyl derivative was depressed.) These results indicate that the *d,l*-chloro-amine very largely fails to react under these conditions.

### X-Ray Power Spectra

Patterns on powdered samples of *trans*- and *cis*-*d,l*-2-acetaminocyclohexanol were obtained using a flat cassette at 5 cm. from the sample and copper K$\alpha$ radiation. The results are shown as positive prints in Fig. 1.[23]

## Summary

1. Detosylation of *d,l-trans*-2-benzoylaminocyclohexyl-*p*-toluenesulfonate in dry acetic acid–sodium acetate gives the benzamidoacetate with retention. The reaction in wet acetic acid or (dry) ethanol gives the benzamidoalcohol with inversion. Thus, a neighboring acylamino group can participate in the same manner as a neighboring acyloxy group to determine the steric result of a detosylation reaction.

2. The steric results are consistent with the viewpoint that the 2-aminocyclohexanol of m. p. 68°, originally designated as *cis*, is actually the *trans* isomer.

3. The *cis* and *trans* forms of *d,l*-2-aminoc

(22) It is reasonable to expect that the amount of each detosylation product actually present in its reaction mixture may be considerably greater than the reported yield based on material actually isolated and purified.

(23) We are indebted to Dr. R. T. Miller and Dr. N. N. J of the Northern Regional Research Laboratory, Peoria, f observations.

hexanol have been characterized by the preparation of various new derivatives and by X-ray powder spectra.

4. The chloro-amine obtained by phosphorus pentachloride treatment of *d,l-trans*-2-aminocyclohexanol hydrochloride has a very inert halogen characteristic of its *cis* structure.

# Sulfur-containing Amines. VI.[1] Antispasmodics

BY GEORGE M. FOHLEN,[2] WOLFGANG HUBER,[3] S. C. LASKOWSKI AND R. O. CLINTON

In previous communications[4,5] from these laboratories there have been described a number of sulfur-containing amines, which are of pharmacological interest as ester and amide precursors in local anesthetic types[1] and as side chains in antimalarial types.[6] In the present work we have extended the investigation to include derivatives of the sulfur-containing amines with a number of disubstituted acetic acid types, with the expectation that the sulfide linkage might provide favorable toxicity indices.[1]

The acids used were of the type which previous investigators have shown to form spasmolytically active esters, *viz.*: diphenylacetic, benzilic, fluorene-9-carboxylic, dibenzylacetic, α-cyclohexylphenylacetic and 9,10-dihydroanthracene-9-carboxylic acids.

The esters were prepared by either of two general methods. The first of these, reaction of an acid chloride with the alcohol or amine in cold benzene, is the preferable method. As has been previously indicated,[1] the reaction of the sulfur-containing amines with an acid chloride must be carefully controlled to avoid decomposition of the heat-labile sulfur compound. Only in two cases were satisfactorily stable hydrochlorides isolated; in general it was found preferable to isolate the free bases and convert them to the citrate salts.

The second method of preparing the basic esters utilized transesterification, in the presence of sodium alkoxide as catalyst. This method gave excellent results with both methyl benzilate[7] and methyl fluorene-9-carboxylate.

In Table I there are listed the esters prepared from straight and branched chain sulfur-containing amino alcohols. In addition, there was prepared one ester of an alcohol containing two sulfide linkages and a single example of an amide. These compounds, with other examples, are described in the experimental section.

This series of compounds has been tested for antispasmodic activity *in vitro* against barium chloride and acetylcholine-induced spasms on rabbit intestinal strips and against histamine-induced spasms on strips of guinea pig ileum.[8] None of the compounds exhibited a high degree of activity against the acetylcholine-induced spasms. The activity against histamine-induced spasms was considerably less than that of papaverine, with the exception of 3-(3-(1-piperidyl)propylmercapto)-2-propyl fluorene-9-carboxylate citrate which was of the same order of magnitude. The compounds did not differ greatly in their musculotropic activity, *i. e.*, against barium chloride-induced spasms, all being equal to or slightly more active than papaverine.

## Experimental[9]

The following examples will serve to illustrate the various procedures used. The yields of the compounds varied from 24 to 87%, the lower yields being chiefly ascribable to isolation difficulties.

**2-(2-Diethylaminoethylmercapto)-ethyl Diphenylacetate Hydrochloride.**—To an ice-cooled solution of 13.0 g. of diphenylacetyl chloride in 100 ml. of dry benzene was added during a five-minute period, with shaking, a cold solution of 10.0 g. of 2-(2-diethylaminoethylmercapto)-ethanol[4] in 50 ml. of dry benzene. The clear solution was warmed for fifteen minutes on the steam-bath and then cooled. Five hundred milliliters of Skellysolve A was then added; the precipitated oil crystallized on cooling and scratching. After three recrystallizations from ethyl acetate there was obtained 15.8 g. (67%) of large white prisms.

With the other sulfur-containing amines it was necessary to convert the oily or low-melting hydrochlorides to the free bases by means of ethyl acetate–ammonia, and thence to the citrate through the use of citric acid monohydrate in acetone or absolute alcohol solution.

**3-(2-Diethylaminoethylmercapto)-propyl Benzilate Citrate.**—A mixture of 5 g. of methyl benzilate, 4 g. of 3-(2-diethylaminoethylmercapto)-propanol,[4] and 0.15 g. of sodium metal in 50 ml. of Skellysolve E was refluxed under a pressure of about 30 mm. for four hours. An equal volume of benzene was then added and the mixture was washed several times with water and dried. The oily residue remaining after removal of the solvents *in vacuo* was taken up in dry acetone and treated with a solution of 4.2 g. of citric acid monohydrate in acetone. The white crystalline product was then repeatedly recrystallized from acetone.

(8) We are indebted to Dr. T. J. Becker (deceased) and his staff for the pharmacological testing of these compounds. A more detailed report of these tests will be published elsewhere.

(9) All melting points are uncorrected. We are indebted to Mr. Morris E. Auerbach and his staff for the analyses.

TABLE I

BASIC ESTERS OF DISUBSTITUTED ACETIC ACIDS[a]

| Acid, RCOO– | *m* | *n* | R′ | Yield, % | M. p., °C.[b] | Formula | Analyses, % Nitrogen Calcd. | Nitrogen Found | Sulfur Calcd. | Sulfur Found |

[a] The esters are listed as the citrate salts, unless otherwise specified. [b] The melting points are uncorrected. The citrate salts melted in all cases with effervescence. [c] Hydrochloride. [d] Calcd.: C, 64.76; H, 7.41. Found: C, 64.55; H, 7.73. [e] Calcd.: C, 60.29; H, 6.80. Found: C, 60.22; H, 6.93. [f] Calcd.: C, 58.67; H, 6.62. Found: C, 58.62; H, 7.19. [g] Calcd.: C, 60.89; H, 6.98. Found: C, 60.84; H, 6.59. [h] 1-Piperidyl.

**2-(2-(2-Diethylaminoethylmercapto)-ethylmercapto)-ethyl Diphenylacetate Citrate.**—The condensation of 2-(2-(2-diethylaminoethylmercapto)-ethylmercapto)-ethanol[4] with diphenylacetyl chloride, and conversion of the isolated free base to the citrate was carried out as described previously. The **citrate monohydrate** formed waxy white crystals from acetone, m.p. 87–89°.

*Anal.* Calcd. for $C_{24}H_{33}NO_2S_2.C_6H_8O_7.H_2O$: C, 56.13; H, 6.75; N, 2.19. Found: C, 55.80; H, 6.46; N, 2.30.

**N-(2-(2-Diethylaminoethylmercapto)-ethyl) Diphenylacetamide.**—To a mixture of 17.6 g. of 2-(2-diethylaminoethylmercapto)-ethylamine,[4] 12.6 g. of sodium bicarbonate, and 80 ml. of water was added a solution of 27.6 g. of diphenylacetyl chloride in 100 ml. of chloroform, with vigorous stirring, during a period of forty-five minutes. The mixture was stirred for an additional hour; the chloroform layer was separated, washed with dilute sodium hydroxide solution and water and dried over anhydrous potassium carbonate. Concentration of the chloroform solution *in vacuo* yielded a viscous colorless oil which readily crystallized. Two recrystallizations from ethyl acetate–Skellysolve A gave 24.5 g. (62%) of product as white leaflets, m.p. 55.8–57.0°.

*Anal.* Calcd. for $C_{22}H_{30}N_2OS$: C, 71.31; H, 8.16. Found: C, 71.55; H, 7.64.

The **citrate** was prepared in absolute alcohol–ethyl acetate mixture: white rosettes, m.p. 80°.

*Anal.* Calcd. for $C_{22}H_{30}N_2OS.C_6H_8O_7$: citric acid, 34. Found: citric acid, 33.

## Summary

Fifteen esters of certain sulfur-containing amines with disubstituted acetic acids have been prepared for testing as antispasmodics. One related amide and an ester of a basic alcohol containing two sulfide linkages have also been prepared. No high degree of spasmolytic activity has been found in this series.

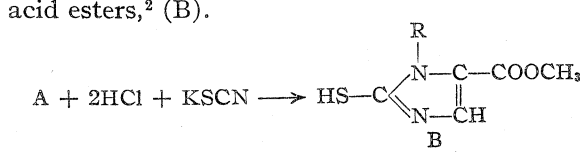
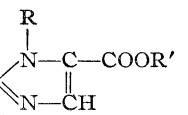
# Studies on Imidazoles. II. The Synthesis of 5-Imidazolecarboxylates from Glycine and Substituted Glycine Esters



BY REUBEN G. JONES

A number of biologically important derivatives of imidazole including histamine, histidine, methylhistidine and pilocarpine have substituents attached to the 4- or 5-position of the imidazole ring. Although methods of synthesizing these compounds have been rather thoroughly investigated, the methods generally involve many tedious steps and low yields. Therefore, it was of interest to investigate more simple and direct ways of preparing imidazoles with suitable substituents in the 4(or 5)- and 1,5-positions.

This paper describes the synthesis of 5-imidazolecarboxylates from glycine and N-substituted glycine derivatives. It is known that N-acylated glycine esters may be formylated by the Claisen method to give the sodium enolate salts of N-acyl-C-formylglycine esters,[1] [A].



It has now been found that the sodium enolate salts (A) may be treated with acid and thiocyanate to yield 2-mercapto-5-imidazolecarboxylic acid esters,[2] (B).

This reaction takes place smoothly when the acyl group (—COR′) of A is formyl or acetyl but not when the acyl group is benzoyl. It was surprising to find that a pre-hydrolysis of A to form the intermediate, $RNHCH(CHO)COOCH_3$, was unnecessary. The reactions were best carried out by adding acid and thiocyanate simultaneously to a water or water–alcohol solution of A and heating. Under these conditions the N-acyl group appeared to be rapidly cleaved. A number of 2-mercapto-5-imidazolecarboxylates prepared in this way are presented in Table I.

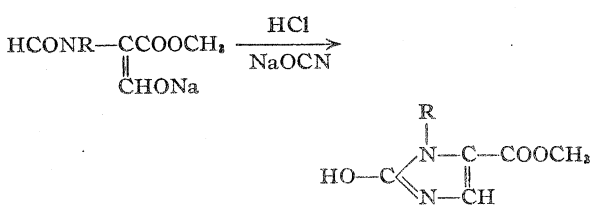
(1) Erlenmeyer and Stoop, *Ann.*, **337**, 236 (1904).

(2) When the substituent, R, is hydrogen the compound must be designated as a 4(or 5)-imidazolecarboxylate.



(3) Marckwald, *Ber.* **25**, 2354 (1892); Pyman, *J. Chem. Soc.*, **99**, 668 (1911).

tures and more concentrated nitric acid were used. It was observed that the oxidation of mercaptoimidazoles even in hot nitric acid did not take place unless oxides of nitrogen were present. However, by adding a little sodium nitrite to initiate the oxidation, it was possible to carry out the reaction at 25 or 30°, and under these conditions there was no significant hydrolysis of the ester groups.

Starting with the readily available glycine ethyl ester hydrochloride, the present imidazole synthesis constitutes an excellent method for the preparation of imidazole itself. By the following sequence of reactions, imidazole has been obtained in over-all yields of 35 to 40%

The condensation of the sodium enolate salts A with cyanate took place less satisfactorily than with thiocyanate, and only moderate yields of 1-substituted-2-hydroxy-5-imidazolecarboxylates were obtained.

It has been found that the carbalkoxy groups in imidazoles such as those of Table II can be readily converted to aldehyde, ketone, hydroxymethyl and other groups valuable for the synthesis of important imidazole derivatives. This work will be the subject of a separate publication.

**Acknowledgment.**—The writer expresses his appreciation to William L. Brown and Howard L. Hunter for the microanalyses reported herein, and to Keith C. McLaughlin for valuable assistance.

## Experimental

**N-Formyl-N-substituted-glycine Esters.**—These compounds, listed in Table III, were prepared from the appropriate amine hydrochlorides by the method[4] illustrated in the following typical example.

A mixture of 272 g. (2.0 moles) of cyclohexylamine hydrochloride, 250 ml. of 40% formalin, and 100 ml. of water, in a flask provided with a stirrer, was cooled in an ice-bath, and with continuous stirring a cold concentrated, aqueous solution of 130 g. (2.0 moles) of potassium cyanide was added in portions over a period of two hours. The temperature was held below 10°, and a little solid carbon dioxide was added from time to time to maintain a carbon dioxide atmosphere. The mixture was stirred for one additional hour and then extracted with two 500-ml. portions of ether. After drying the solution over calcium oxide, the ether was removed by gentle warming, finally under vacuum. The crude cyclohexylaminoacetonitrile was dissolved in 2.5 l. of dry methanol which had been saturated in the cold with hydrogen chloride. This solution was allowed to stand overnight at room temperature and then heated under reflux for four hours. The ammonium chloride which had separated was removed by filtration. The filtrate was evaporated on the steam-bath under vacuum to a volume of about 800 ml. and again filtered through a pad of filter cell. Evaporation of this filtrate under vacuum left a residue of 340 g. of crude N-cyclohexylglycine methyl ester hydrochloride.

The crude ester hydrochloride was dissolved by warming in 250 ml. of 98% formic acid. To this solution was added a hot solution of 150 g. of sodium formate in 200 ml. of 98% formic acid. After the mixture had stood for one hour, the precipitated sodium chloride was removed by filtration through a layer of filter-cel, and 450 ml. of acetic anhydride was added in portions. When the vigorous reaction had subsided the mixture was heated on the steam-bath for one-half hour and then evaporated under vacuum to remove the formic and acetic acids. The residual liquid was taken into 1 l. of acetone whereupon a quantity of sodium chloride separated. The solution was filtered, the acetone distilled and, finally, the residual material was distilled under vacuum to yield pure N-formyl-N-cyclohexylglycine methyl ester as a colorless somewhat viscous liquid.

In the same way, N-formylglycine ethyl ester and methyl ester were prepared from glycine ethyl ester and methyl ester hydrochlorides respectively; and the N-formyl-N-

TABLE III

[a] Yields are for the over-all process and are based on the amine hydrochloride used. [b] This yield is based on glycine methyl ester hydrochloride. The corresponding N-formylglycine ethyl ester, b. p. 110° (1 mm.) was prepared in 92% yield from glycine ethyl ester hydrochloride. [c] This boiling point is at 4 mm. pressure. The compound was first prepared by Dr. Q. F. Soper. [d] Cyclohexyl. [e] This yield is based on N-phenylglycine methyl ester hydrochloride. The corresponding N-formyl-N-phenylglycine ethyl ester,[5] b. p. 157–159° (7 mm.), was obtained in 90% yield from N-phenylglycine ethyl ester.

(4) The preparation of the substituted glycine ester hydrochlorides from amine hydrochlorides, formaldehyde and cyanide reported here is a modification of Staudt's method for the synthesis of sarcosine: see Staudt, *Z. physiol. Chem.*, **146**, 286 (1925).

phenylglycine ethyl and methyl esters[5] were prepared from the corresponding ethyl and methyl ester hydrochlorides of N-phenylglycine.

**Condensation of N-Formylglycine Esters with Methyl Formate.**—One example will suffice to illustrate the method by which the N-formylglycine esters of Table III were condensed with methyl formate.

In a three-necked flask provided with a stirrer and thermometer was placed 106 g. (0.67 mole) of N-formyl-N-isopropylglycine methyl ester and 120 g. (2.0 mole) of dry methyl formate. The flask was surrounded with an ice-bath and, with continuous stirring, a suspension of 40 g. (0.74 mole) of sodium methoxide[6] in 150 ml. of dry benzene was added in five portions during a period of one-half to one hour. The temperature of the reaction mixture was maintained below 15°, and stirring was continued for one hour after all of the sodium methoxide had been added. The mixture was then placed in the refrigerator and allowed to stand for twenty-four hours.

If it was desired to isolate the sodium enolate salt, dry ether was added to the reaction mixture, and the solid was collected on a filter, washed with dry ether and dried in vacuum.

**2-Mercapto-5-imidazolecarboxylates.**—The following example of the preparation of ethyl 2-mercapto 4(or 5)-imidazolecarboxylate shows the method by which the compounds of Table I were prepared.

The reaction mixture of 411 g. (3.12 moles) of N-formylglycine ethyl ester, 700 g. of ethyl formate, 700 ml. of benzene and 183 g. (3.4 moles) of sodium methoxide, carried out as described above, was shaken with 1 l. of water. When all solid had dissolved, the aqueous solution was separated, cooled in an ice-bath and stirred while 565 ml. (6.8 moles) of 12 *N* hydrochloric acid was added slowly. To the resulting solution was added 350 g. (3.6 moles) of crystalline potassium thiocyanate. The mixture was warmed on the steam-bath at 50–70° for two hours, allowed to stand overnight and finally cooled in an ice-bath. The crystalline ethyl 2-mercapto-4(or 5)-imidazolecarboxylate was collected on a filter, washed with a little water and air dried. The yield was 304 g. Yields for a number of experiments varied from 50 to 60% based on N-formylglycine ethyl ester.

N-Acetylglycine ethyl ester[7] (58 g., 0.4 mole) was condensed with 100 ml. of ethyl formate and 24 g. (0.44 mole) of sodium methoxide in 115 ml. of benzene by the procedure described above. The mixture was extracted with 200 ml. of water, 42 g. of potassium thiocyanate and 75 ml. of 12 *N* hydrochloric acid were added to the aqueous solution, and it was heated on the steam-bath for two hours. There was thus obtained 31 g. (43% yield) of ethyl 2-mercapto-4(or 5)-imidazolecarboxylate, identified by melting point and mixed melting point.

N-Benzoyl-C-formylglycine ethyl ester, when treated with thiocyanate under the same conditions as described above for the formyl and acetyl analogs, gave no imidazole compound.

The reactions of thiocyanate with the formyl-N-cyclohexyl, N-benzyl and N-phenylglycine derivatives were carried out in 50% alcohol. In most cases, after acidifying the sodium enolate solutions with two equivalents of hydrochloric acid it was not necessary to immediately add the thiocyanate. For example, 25.7 g. (0.10 mole) of the dry sodium enolate salt of N-formyl-N-benzyl-C-formylglycine methyl ester was dissolved in 100 ml. of 50% alcohol and 19 ml. (0.23 mole) of 12 *N* hydrochloric acid was added. After standing for twenty hours at room temperature, 15 g. (0.155 mole) of potassium thiocyanate was added and the mixture was heated on the steam-bath until most of the alcohol had evaporated. The methyl 1-benzyl-2-mercapto-5-imidazolecarboxylate was collected by filtration, washed with water and air dried. The yield was 24.0 g. (97%). A similar experiment, in which the thiocyanate was added immediately after the hydrochloric acid, yielded 90% of the desired imidazole.

In the case of N-formyl-N-phenyl-C-formylglycine esters it was necessary to add the thiocyanate simultaneously with the acid in order to get a good yield of the mercaptoimidazole. When acidified solutions were allowed to stand without the addition of thiocyanate a sparingly soluble crystalline substance was deposited, the nature of which has not as yet been determined. For example, from 24.3 g. (0.10 mole) of the sodium enolate salt of N-formyl-N-phenyl-C-formylglycine methyl ester and 19 ml. of 12 *N* hydrochloric acid in 100 ml. of 50% alcohol, there was obtained, after twelve hours, 12 g. of crystalline precipitate, m. p. 145–146° (from alcohol).

*Anal.* Found: C, 66.53; H, 5.79; N, 5.79.

**Oxidation of 2-Mercapto-5-imidazolecarboxylates. 5-Imidazolecarboxylates.**—A solution of 330 ml. of concentrated nitric acid in 950 ml. of water in a large beaker was mechanically stirred, and 2 g. of sodium nitrite was added. The beaker was then surrounded with an ice-bath, and with continuous stirring 300 g. (1.75 mole) of crude methyl 1-methyl-2-mercapto-5-imidazolecarboxylate was added portionwise at such a rate that the temperature of the mixture remained at about 25–35°. After all material had been added the solution was stirred for about ten minutes or until the evolution of nitrogen oxides had completely stopped. An excess of solid sodium carbonate was added carefully and with stirring. The mixture was extracted with four 200-ml. portions of chloroform; the extract was dried, the chloroform removed and the residual liquid distilled in vacuum. The distillate immediately crystallized.

By the same method the other compounds listed in Table II were prepared from the corresponding 2-mercapto compounds. The 1-isopropyl compound was purified by distillation. The 1-cyclohexyl and 1-phenyl compounds separated as crystalline solids and were purified by recrystallization from chloroform–petroleum ether.

Methyl 1-benzyl-5-imidazolecarboxylate separated from the oxidation mixture as the nitrate which did not decompose in the presence of cold excess sodium carbonate. A sample was recrystallized from alcohol; m. p. 170–171°.

*Anal.* Calcd. for $C_{12}H_{12}N_2O_2 \cdot HNO_3$: C, 51.60; H, 4.76; N, 15.04. Found: C, 51.72; H, 4.52; N, 14.89.

The nitrate was boiled with sodium carbonate solution to liberate methyl 1-benzyl-5-imidazolecarboxylate.

The solution resulting from the oxidation of ethyl 2-mercapto-4(or 5)-imidazolecarboxylate was made basic with ammonium hydroxide (instead of sodium carbonate), chilled to 10° and the precipitated product collected and air dried.

**Imidazole-4(or 5)-carboxylic Acid.**[8]—Into 500 ml. of 6 *N* sodium hydroxide solution was stirred 250 g. (1.78 moles) of ethyl 4(or 5)-imidazolecarboxylate. The resulting solution was heated on the steam-bath for three hours and then cooled and acidified to *p*H 2.0 with concentrated hydrochloric acid. After standing for two hours the mixture was chilled to 0° and the white crystalline solid was collected on a filter. The product was stirred to a paste with 250 ml. of cold distilled water, filtered and washed on the filter with 200 ml. of alcohol followed by 200 ml. of ether. The yield of air dried product was 180 g. (84%); m.p. 271° (dec.) (lit.[8] 275°).

*Anal.* Calcd. for $C_4H_4N_2O_2$: N, 25.00. Found: N, 24.75.

**Imidazole.**—In a 200-ml. round-bottom flask carrying an eighteen-inch Vigreux column and a condenser set for distillation was placed 50 g. (0.45 mole) of 4(or 5)-imidazolecarboxylic acid. The flask was heated with a small flame and decarboxylation took place smoothly. The product was distilled under vacuum to yield 28.5 g. (94%) of pure imidazole, m.p. 90°.

**1-Phenyl-2-mercapto-5-imidazolecarboxylic Acid.**—A solution of 5 g. (0.02 mole) of ethyl 1-phenyl-2-mer-

(5) Paal and Otten, *Ber.*, **23**, 2587 (1890).

(6) Commercial sodium methoxide of good quality was satisfactory.

(7) Curtius, *Ber.*, **17**, 1663 (1884); *J. prakt. Chem.*, [2] **94**, 116 (1915).

(8) Pyman, *J. Chem. Soc.*, **109**, 186 (1916).

capto-5-imidazolecarboxylate in 12 ml. of 6 *N* sodium hydroxide solution was allowed to stand for forty-eight hours. The solution was acidified with acetic acid but nothing precipitated; therefore, hydrochloric acid was added whereupon a white precipitate of the desired acid seperated. The yield was 4.2 g. (95%). A sample was recrystallized from water for analysis; m.p. 198–200° (dec.).

*Anal.* Calcd. for $C_{10}H_8N_2O_2S$: N, 12.72. Found: N, 12.71.

**1-Methyl-2-mercapto-5-imidazolecarboxylic Acid.**—This was prepared from the methyl ester in the same way as described above for the corresponding phenyl compound m.p. 207–208°.

*Anal.* Calcd. for $C_5H_6N_2O_2S$: N, 17.71. Found: N, 17.55.

**N-Formyl-C-formylglycine Ethyl Ester.**—The dry sodium enolate salt from the condensation of 1.5 mole of N-formylglycine ethyl ester with ethyl formate was ground to a fine powder and added in one portion with stirring to a freshly prepared mixture of 135 ml. of 12 *N* hydrochloric acid and 200 g. of cracked-ice. As soon as all the salt had dissolved the solution was extracted with twenty 100-ml. portions of chloroform. The chloroform solution was dried with magnesium sulfate and evaporated in vacuum leaving 177 g. of crystalline residue. This was taken up in 1500 ml. of dry ether. The solution was decanted from a little insoluble gum, dried with magnesium sulfate, filtered and evaporated leaving 147 g. (62% yield) of white crystalline solid; m.p. 68–69°.

*Anal.* Calcd. for $C_6H_9NO_4$: C, 45.27; H, 5.70; N, 8.80. Found: C, 45.38; H, 6.32; N, 9.07.

The compound appeared to be somewhat hygroscopic; it was very soluble in alcohol or water, and slowly underwent decomposition at room temperature but could be kept for reasonably long periods of time at ice-box temperatures.

The corresponding methyl ester was also isolated but in lower yield because it was more water soluble and consequently more difficult to extract with chloroform. It was stable and not hygroscopic; m.p. 108–109°.

*Anal.* Calcd. for $C_5H_7NO_4$: N, 9.65. Found: N, 9.78.

**1-Substituted-2-hydroxy-5-imidazolecarboxylates.**—A solution of 20.9 g. (0.10 mole) of the sodium enolate salt of N-formyl-N-isopropyl-C-formylglycine methyl ester in 100 ml. of water was treated with 19 ml. of 12 *N* hydrochloric acid. The solution was allowed to stand for four hours then 9 g. of sodium cyanate was added. Effervescence took place. Gradually, a white crystalline precipitate of methyl 1-isopropyl-2-hydroxy-5-imidazolecarboxylate separated. After seven days the yield was 6.0 g. (32%). An analytical sample was recrystallized from alcohol; m.p. 174–175°.

*Anal.* Calcd. for $C_8H_{12}N_2O_3$: N, 15.21. Found: N, 14.87.

Methyl 1-cyclohexyl-2-hydroxy-5-imidazolecarboxylate was obtained in 22% yield from the sodium enolate salt of N-formyl-N-cyclohexyl-C-formylglycine methyl ester. It melted at 230–232°.

*Anal.* Calcd. for $C_{11}H_{16}N_2O_3$: N, 12.50. Found: N, 12.61.

Methyl 1-benzyl-2-hydroxy-5-imidazolecarboxylate was obtained in 8.6% yield from the sodium enolate salt of N-formyl-N-benzyl-C-formyglycine methyl ester. It melted at 160–161°.

*Anal.* Calcd. for $C_{12}H_{12}N_2O_3$: N, 12.07. Found: N, 12.20.

Ethyl 2-hydroxy-4-(or 5)-imidazolecarboxylate, obtained in 14% yield from the sodium enolate salt of N-formyl-C-formylglycine ethyl ester melted at 243–245°.

*Anal.* Calcd. for $C_6H_8N_2O_3$: N, 17.95. Found: N, 18.46.

## Summary

A method for the preparation of 1-substituted-5-imidazolecarboxylates and 4(or 5)-imidazolecarboxylates from glycine derivatives is described. This method has also been shown to be a convenient synthesis of imidazole.

# Preparation of N-Alkyl Acrylamides and Methacrylamides by Pyrolysis of the Corresponding Acetoxy Amides

BY WILLIAM P. RATCHFORD, J. H. LENGEL AND C. H. FISHER

In a previous paper[2] it was shown that N,N-dimethylacrylamide (II) and acetic acid are obtained in high yields in the thermal decomposition of N,N-dimethyl-α-acetoxypropionamide (I). The present paper describes the preparation of certain acrylamides and methacrylamides (IV) by pyrolysis of appropriate acetoxy amides, and outlines some of the limitations of this method of making unsaturated amides.

$$\underset{\text{I}}{CH_3COOCH(CH_3)CON(CH_3)_2} \xrightarrow{520^\circ} \underset{\text{II}}{CH_2{=}CHCON(CH_3)_2} + CH_3COOH \quad (1)$$

$$\underset{\text{III}}{CH_3COOC(CH_3)_2CONHCH_3} \longrightarrow \underset{\text{IV}}{CH_2{=}C(CH_3)CONHCH_3} + CH_3COOH \quad (2)$$

N-Methyllactamide and N-methyl-α-hydroxyisobutyramide were made conveniently by allowing methyl lactate and methyl-α-hydroxyisobutyrate, respectively, to stand with methylamine at room temperature. N,N-Diethyllactamide, N,N-dibutyllactamide, and N,N-dimethylhydroxyisobutyramide could not be prepared satisfactorily by this method because of excessively low reaction rates. Diethylamine reacted slowly with polyactic acid[3] and with the methyl ester of polyactic acid, a moderate yield of N,N-diethyllactamide being obtained.

Probably the low reactivity of diethylamine (and the moderately high reactivities[4] of both piperidine and morpholine) toward methyl lactate can be explained on the basis of steric effects of the type discussed by Brown.[5] In a study of the addition compounds of reference acids and diethylamine,[5] Brown concluded that the configuration of diethylamine limits association with a highly hindered reference acid. If the plausible assumption is made that aminolysis occurs *via* the same mechanism as ammonolysis,[6] it is possible to consider the amide ion (or amine) the base and methyl lactate the reference acid (with association occurring between the carbonyl carbon atom and the nitrogen atom), and apply the steric theory of Brown to explain the observed phenomena.

N-Methylacetoxypropionamide, N-methylacetoxyisobutyramide (III) and N,N-diethylacetoxypropionamide were prepared by treatment of the corresponding lactamide or hydroxyisobutyramide with acetic anhydride. N,N-Diethylacetoxypropionamide, N,N-dibutylacetoxypropionamide and N,N-dimethylacetoxyisobutyramide (Table I) were made by the reaction of the proper dialkylamine with α-acetoxypropionyl chloride or α-acetoxyisobutyryl chloride.

The lower acetoxy amides of the present work were similar to N,N-dimethylacetoxypropionamide,[2] in that the amide, but not the acetoxy groups, were resistant to saponification (Table I).

N,N-Diethylacrylamide and acetic acid were the principal products of the thermal decomposition (500 to 550°) of N,N-diethylacetoxypropionamide, and therefore the pyrolysis method is suitable for the preparation of both N,N-dimethyl- and N,N-diethylacrylamide. A brief study of the pyrolysis of N-methyl- and N,N-dibutylacetoxypropionamide, however, indicated that the pyrolysis of α-acetoxy-propionamides is less satisfactory for producing N-monoalkylacrylamides or the higher N,N-dialkylacrylamides.

As pointed out earlier,[2] the pyrolysis behavior of N,N-dimethylacetoxypropionamide resembles that of its oxygen analog, methyl acetoxypropionate, in that acetic acid and an acrylic acid derivative are the principal products. The thermal decomposition of the N,N-diethyl amide, however, was distinctly different from that of ethyl acetoxypropionate, which yielded ethylene instead of ethyl acrylate as a major decomposition product.[7]

The pyrolysis behavior of N-methylacetoxypropionamide was similar to that of alkyl lactates[8] and α-acetoxypropionic acid[8] in that acrylic acid or its derivatives were formed in low yield. The common feature of alkyl lactates, acetoxypropionic acid, and N-methylacetoxypropionamide is the presence of hydrogen attached to oxygen or nitrogen, and therefore it appears that lactic acid derivatives having an O- or N-hydrogen (and perhaps S-hydrogen) are unsuitable for pyrolytic conversion into the corresponding acrylic acid derivatives.

It has been postulated[9] that the normal thermal decomposition of acetates (equation 3, X = H or alkyl) involves the transient formation and subsequent decomposition of a ring such as V into an olefinic product (VI) and acetic acid. When the acetate (or other ester) contains —COOH or —CONHR as substituents (that is, X = carboxyl or amide groups), the formation of rings[10] such

as VIII, IX, or X might take preference over that of the usual or normal intermediate (V). Scission of the bonds as shown in equation 4 might be responsible for decomposition into acetic acid, acetaldehyde and carbon monoxide, the products actually formed when α-acetoxypropionic acid is pyrolyzed.[8]

Both N-methyl-(IV) and N,N-dimethylmethacrylamide were obtained satisfactorily by pyrolyzing the corresponding α-acetoxyisobutyramides. These results suggest that α-acetoxyisobutyramides generally decompose more readily than α-acetoxypropionamides into the corresponding unsaturated amides. It has been demonstrated[11] that α-acetoxyisobutyrates decompose more readily than the corresponding α-acetoxypropionates into methacrylic or acrylic esters.

The success of the pyrolytic method for preparing these acrylamides and methacrylamides suggests that it may be useful in preparing certain crotonamides and amides of other unsaturated acids.

The pyrolysis of alkyl acetoxypropionates, which contain two ester groups, affords a comparison of the thermal stability of esters of acetic and α-acetoxypropionic acids.[7] Since N,N-diethylacetoxypropionamide contains both ester and amide groups, results obtained by pyrolyzing this compound may be used as a measure of the relative thermal stability of ester and amide groups; the formation of the acrylamide as the principal product indicates that the amide group is more stable.

**Acknowledgment.**—The authors gratefully acknowledge the assistance of C. O. Willits, Ruth W. Brand, Betty B. Linker and Pauline McDowell, who supplied most of the analytical data, and the interest and helpful suggestions of Allan R. Day.

## Experimental

**N,N-Diethyllactamide (Table I).**—When it was found that this lactamide was not obtained by the usual preparative method for lactamides,[2] other methods were tried. In the most successful experiment, 2 equivalents of polylactic acid (equiv. wt. 79) and excess diethylamine were circulated counter-currently through a heated tower[12] maintained at 175° and packed with 1/4-inch porcelain Berl saddles for five six-hour periods (1 pass per period). At the end of each period, the product from the tower was distilled to recover N,N-diethyllactamide; all other fractions, including the residue, were returned to the tower, and the process was repeated. At the end of successive periods, the total conversions to diethyllactamide were 18, 38, 53, 61 and finally 72%.

**N-Methyllactamide (Table I)** was obtained in 91% yield by distilling a mixture of 2 moles of methyl lactate, 2 moles of methylamine and 0.2 ml. of concentrated sulfuric acid that had been stored at room temperature for three weeks. The catalyst was neutralized with sodium acetate before distillation.

**N-Methyl-α-hydroxyisobutyramide** was obtained in 97% yield by distilling a mixture of 2 moles methyl hydroxyisobutyrate, 2 moles methylamine and 0.2 ml. concentrated sulfuric acid that had been stored at room temperature for two months (catalyst neutralized before distillation).

**Acetylation of N-Alkyllactamides.**—N-Methyllactamide and N,N-diethyllactamide were acetylated with acetic anhydride by the method used previously with N,N-dimethyllactamide,[2] high yields (98 and 95%) of the corresponding α-acetoxypropionamides being obtained.

**Reaction of α-Acetoxypropionyl Chloride with Amines.**—Acetoxypropionyl chloride (2.2 moles) was allowed to react with 2 moles of diethylamine. N,N-Diethyl-α-acetoxypropionamide was obtained in 66% yield by distillation of the reaction mixture. N,N-Dibutyl-α-acetoxypropionamide (69% yield) and N,N-dimethyl-α-acetoxyisobutyramide (78% yield) were made similarly from the appropriate acid chlorides and amines.

**N-Methyl-α-acetoxyisobutyramide** was prepared in 50% yield from N-methylhydroxyisobutyramide and 10% excess acetic anhydride, concentrated sulfuric acid being used as catalyst. After the catalyst had been neutralized and the acetic acid distilled, the acetoxy amide was collected at 118° (0.3 mm.). The low yield was due to the formation of viscous tacky fractions.

In determining the saponification equivalents[13] of Table I, a weighed sample was dissolved in 25 ml. of neutral ethanol cooled in ice-water, and titrated to determine free acidity, if any. Then 25 ml. of 0.2 *N* sodium hydroxide in ethanol was added. The weight of the sample was taken so that the alkali would be present in 50% excess of the ester group. The solution was refluxed on a steam-bath for one hour (air condenser), 50 ml. of distilled water was added, and refluxing was continued for another hour. At this point the condenser was rinsed, and excess alkali was back-titrated with 0.1 *N* hydrochloric acid, cresol red–thymol blue mixed indicator being used.

**Pyrolysis Experiments.**—Essentially the equipment and method described previously[14] were used. In some instances the acetoxy amide was dissolved in benzene prior to pyrolysis. The pyrolyzates were distilled (after a small amount of hydroquinone was added to prevent polymerization) to determine the nature and amounts of the products.

A solution consisting of 185.5 g. of N-methylacetoxypropionamide and 138.5 g. of benzene was pyrolyzed at 524° at a rate of 0.6 mole per hour of the amide (contact time, 2.9 sec., for the tube within 15° of 524°). The recovery of liquid products (1 g. of which neutralized 3.59 ml. *N* NaOH) was 97.2%. The following products were obtained on distillation (yields are expressed as per cent. of moles of acetoxy amide pyrolyzed): acetic acid, 87%,

[a] Corrected for acidic material, principally acetic acid, present. [b] Acid-free material. [c] Not definitely identified. [d] Crude, but polymerizable, material. [e] A solution of 95 g. of amide and 81 g. of benzene was pyrolyzed. [f] A solution of 71 g. of amide and 81 g. of benzene was pyrolyzed.

and water, 30–44%. A fraction of impure N-methylacrylamide was obtained (approximately 30% yield). The contents of the trap (cooled with solid carbon dioxide) had an aldehyde odor; treatment with 2,4-dinitrophenylhydrazine gave a compound identified as the acetaldehyde derivative: m.p., 165.5–166, mixed m. p., 165°.

*Anal.* Calcd. for $C_8H_8O_4N_4$: N, 25.0; C, 42.9; H, 3.6. Found: N, 24.6; C, 42.9; H, 3.8. The results of other pyrolysis experiments are given in Table II.

When the pyrolyzates of N,N-diethylacetoxypropionamide were distilled, it was found that the acrylamide fractions contained acetic acid (compare yields of acetic acid in Table II found by titration and distillation). In experiment 3 the crude acrylamide fractions were treated with aqueous sodium carbonate and extracted with ether. The ether extract was distilled, yielding an acid-free distillate having physical constants identical with those of the acrylamide made from acrylyl chloride and diethylamine. In experiment 4 the crude acrylamide fractions (containing 6% acetic acid) were redistilled, yielding the acrylamide containing 2.4% acid. In experiment 2 the crude diethylacrylamide fractions (with 7% acid) were redistilled to give the acrylamide with 0.9% acid; the yield of this material was 54% (based on acetoxy amide destroyed). In this experiment analysis of the gaseous products showed yields of 12, 5 and 2% for carbon monoxide, unsaturates and saturates, respectively.

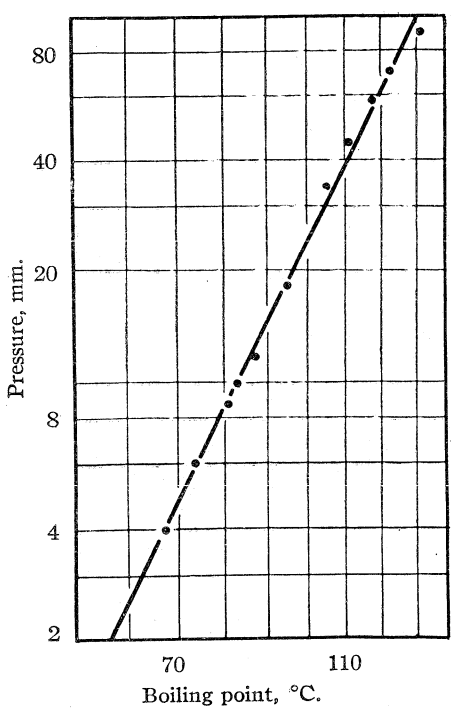

Fig. 1.—Boiling points of N,N-diethyl acrylamide.

Figure 1 shows a boiling point curve for N,N-diethylacrylamide.

When the pyrolyzate of N,N-dimethylacetoxyisobutyramide was distilled, 96% of all the acid charged was recovered in the distillate fractions; of the acid distilled, 24% was collected in the "N,N-dimethylmethacrylamide fractions." The latter distilled at 69–71° (10 mm.), but the acid content ranged from 18 to 6%, and $n^{20}D$ from 1.4481 to 1.4558. The acid content of the combined fractions was 13%. When heptane (in excess of that required for the reported heptane–acetic acid azeotrope[15]) was added to the combined fractions and the mixture carefully distilled, 96% of the acid charged was recovered; of this, 67% appeared in the "methacrylamide fractions," which distilled at 70° (10 mm.). The individual fractions showed acid contents from 15.6 to 5.2%; $n^{20}D$ ranged from 1.4498 to 1.4568.

Thus N,N-dimethylmethacrylamide strongly resembles N,N-dimethacrylamide in distilling with acetic acid.[2] Other N,N-disubstituted amides have been reported to form maximum boiling azeotropes with acetic acid.[16] The relatively large affinity of the N,N-dialkyl amides for acetic acid might be due to the increased electron density around the nitrogen caused by the presence of two electron-releasing alkyl groups. Possibly steric factors[5] are responsible for the fact that the N,N-diethyl amides have less attraction for acetic acid than the N,N-dimethyl amides. The N-methylacrylamide and N-methylmethacrylamide fractions were essentially acid-free.

**Polymeric Acrylamides.**—N,N-diethylacrylamide was polymerized in mass and in water solution, benzoyl peroxide and ammonium persulfate, respectively, being used as initiators.

Polymeric N,N-diethylacrylamide was moderately hard and transparent. It resembled polymeric N,N-dimethylacrylamide in appearance, but was much different in solubility characteristics. The polymeric N,N-diethylamide dissolved readily in benzene, toluene and acetone, and swelled in water, chloroform and carbon tetrachloride. A polymer prepared by polymerizing an aqueous solution of N,N-diethylacrylamide was more soluble in cold water than in hot water. It precipitated from hot water as a soft tacky mass.

A sample of impure N-methylacrylamide on storage in a refrigerator at about 5° darkened and polymerized slowly to a viscous tacky mass that was soluble in water but insoluble in chloroform, benzene, toluene, carbon tetrachloride, acetone, ethyl acetate and heptane.

## Summary

The pyrolysis method used previously to transform the acetyl derivatives of N,N-dimethyllactamide into N,N-dimethylacrylamide was applied to the preparation of other N-alkyl acrylamides and methacrylamides. N,N-Diethylacrylamide was obtained in good yield by the thermal decomposition of N,N-diethyl-α-acetoxypropionamide, but pyrolysis of N-methyl- and N,N-di-*n*-butyl-acetoxypropionamide was less satisfactory for the preparation of the corresponding acrylamides.

N-Methyl- and N,N-dimethylmethacrylamides were made successfully by pyrolyzing the corresponding N-alkyl α-acetoxyisobutyramides. Apparently methacrylamides can be made more readily than acrylamides by the pyrolysis method.

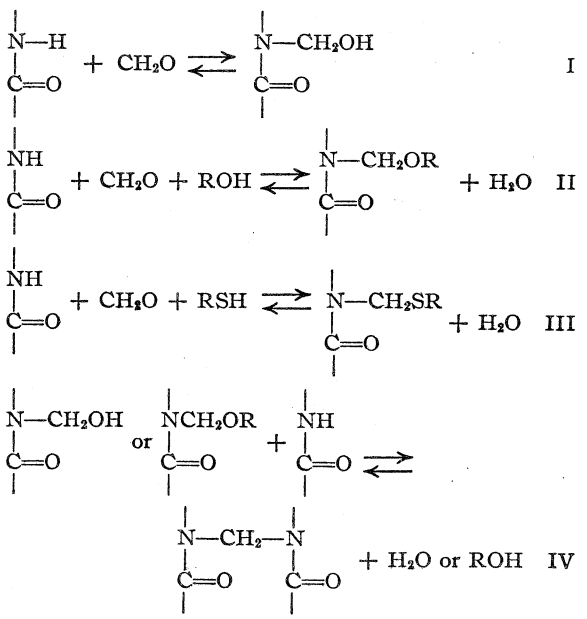
# Preparation and Properties of N-Methylol, N-Alkoxymethyl and N-Alkylthiomethyl Polyamides



BY THEODORE L. CAIRNS, HENRY D. FOSTER, ARTHUR W. LARCHAR, ALLAN K. SCHNEIDER AND RICHARD S. SCHREIBER

The preparation and properties of high molecular weight, linear polyamides derived from amino acids and from diamine-dibasic acid salts have been studied in detail by Carothers.[1] There has, however, been no report of the chemical reactions which these polymers undergo. Other workers refer to the treatment of polyamides with formaldehyde to give slight modification[2,4] but the preparation of well-defined chemical entities is not described. This work was undertaken to explore the possible reactions of the high molecular weight polyamides and to study the properties of the derivatives obtained.

The starting materials for this investigation were polyhexamethyleneadipamide and polyhexamethylenesebacamide.[3] Both of these polymers are high melting solids which show appreciable solubility, without degradation of molecular weight, only in formic acid, phenol, sulfuric acid and solutions of salts such as calcium chloride in methanol. These two polymers are both sensitive to degradation by hydrolysis, alcoholysis, and ammonolysis at elevated temperatures. From consideration of these facts it is evident that the variety of experimental conditions which may be imposed upon these polyamides during a study of their chemical reactions is severely limited.

## Preparation

It has been found that these polyamides react with formaldehyde to yield an N-methylol derivative or with formaldehyde in the presence of alcohols or mercaptans to yield N-alkoxymethyl (II), and N-alkylthiomethyl (III) derivatives. In addition, a fourth product, probably having the crosslinked methylene structure (IV) has been obtained.[4,5] These reactions are represented in the following equations where the polyamide chain is indicated simply by the amide group.

The formation of the N-methylol polyamides (I) is brought about in the presence of acids or bases while the formation of II, III and IV is catalyzed by acids but not by bases. The same situation holds also for the reverse reaction: the methylol groups are readily removed by acids or bases

(5) The following U. S. Patents are related to the work described here: Cairns, 2,393,972 (1946); Cairns, 2,430,860, (1947); Charch, 2,430,910 (1947); Foster and Larchar, 2,430,923 (1947).

while the alkoxymethyl and alkylthiomethyl groups and the methylene crosslinks are stable to bases but hydrolyzed easily in the presence of acids. Such behavior is also found with comparable derivatives of monomeric amides and with the formals which are analogs of the substituted amides under consideration here. It is also of interest that mild heat alone causes reversal of eqn. I but not of II or IV.

The N-methylol polyamides (I) may be prepared by the action of aqueous formaldehyde on solutions of 66 in formic acid at temperatures around 60°. In this case the conditions of reaction must be very carefully controlled in order to prevent the formation of the crosslinked structure (IV). This cross-linking manifests itself by a very rapid increase in the viscosity of the solution. In many cases the reaction mixture may change from a smooth solution of moderate viscosity to a tough, intractable, rubbery gel in a few seconds. A more controllable and satisfactory method for the preparation of N-methylol polyamides consists in treatment with formaldehyde in the presence of an inert medium (such as chloroform, dimethylformamide, dioxane or toluene) and a basic catalyst (potassium carbonate) at 120 to 150°. The use of pyridine as an inert medium is advantageous since it also serves as a basic catalyst.

The N-alkoxymethyl and N-alkylthiomethyl polyamides are prepared readily by the action of a solution of formaldehyde in an alcohol or mercaptan on a polyamide dissolved in formic acid at 60°. Prevention of cross-linking is, in these cases, accomplished by using an excess of alcohol or mercaptan. A second method for the preparation of N-alkoxymethyl derivatives involves the treatment of a solid polyamide with an alcohol–formaldehyde solution at temperatures up to 150° in the presence of catalytic quantities of acid. It has been demonstrated that the use of this method at elevated temperatures brings about some reduction in the average molecular weight of the polymer. The products obtained by this method are still true high polymers and exhibit the properties of high strength, elongation and flexibility, and show viscosity effects common to all soluble, high molecular weight, linear polymers.

## Degree of Substitution

The parent polyamides used in this study ranged in molecular weight up to perhaps 50,000 and were usually about 15,000 to 25,000. For 66 a molecular weight of 22,600 corresponds to a chain having 200 amide groups or 100 repeating units. In the preparation of the derivatives described here it was found possible to effect reaction with practically all of the amide groups under special conditions but major attention has been devoted to products having up to 50% amide substitution. Large excesses of formaldehyde and other reagents are usually required to bring about high degrees of substitution. Thus alkoxymethyl polyamides are prepared using about 7.5 moles of formaldehyde and 10 to 15 moles of alcohol per unit molecular weight of polyamide,[6] and of these quantities only about 0.5 to 1 mole of formaldehyde and alcohol appear as part of the final product. All the reactions under consideration here, with the possible exception of the formation of I, involve water as one of the products and it is therefore not surprising that addition of water to any reaction mixture results in a lowering of the degree of substitution. For example, under certain conditions a reaction mixture based on 1 unit mole of 66, 7.5 moles of paraformaldehyde, 11 moles of methanol and 0.4 mole of water yields a N-methoxymethyl-66 of about 45% amide substitution, and a similar mixture containing 4.0 moles of water gives a product of about 31% substitution. The second important factor governing the degree of substitution is the relative amounts of formaldehyde and polyamide used. Increasing the amount of formaldehyde increases the degree of substitution.

## Proof of Structure

The structure assigned to these derivatives is based first of all on the method of formation. Further it has been found that acid hydrolysis of a N-methoxymethyl-66 gives rise to formaldehyde in quantities which roughly balance the calculated values based on the methoxyl content of the same polymer as determined by the standard Zeisel method. The differences found between formaldehyde and methoxyl content usually indicate excess of formaldehyde over the calculated quantities. These observations point strongly toward the existence of groups of the structure $\begin{matrix} \\ \text{N}\text{–}(\text{CH}_2\text{O})_x\text{R} \\ \\ \text{C}{=}\text{O} \\ \end{matrix}$. Additional evidence supporting the N-alkoxymethyl structure is found in the fact that polyamides prepared from dibasic acids and N,N′-dialkylated diamines (such as N,N′-dimethylhexamethylenediamine) are apparently unaffected by treatment with formaldehyde. Finally, comparison of the infrared absorption spectra of 66 and N-methoxymethyl-66 indicates a definite reduction in the intensity of certain NH absorption bands in the case of the substituted derivative.[7] Unequivocal evidence to show that these products are not oxygen alkylated derivatives of the structure $\begin{matrix} \text{N} \\ \| \\ \text{C}\text{—}\text{OCH}_2\text{OR} \end{matrix}$ has not been obtained.

## Physical Properties

The parent polymers from which the alkoxymethyl derivatives are obtained by chemical reaction are hard, high-melting materials of consid-

(6) "Unit molecular weight" is the molecular weight of the recurring unit in the polymer. In the case of 66 this unit is $\text{HN}(\text{CH}_2)_6\text{NH}\text{—}\overset{\overset{\text{O}}{\|}}{\text{C}}\text{—}(\text{CH}_2)_4\text{—}\overset{\overset{\text{O}}{\|}}{\text{C}}\text{—}$.

(7) We are indebted to Dr. J. R. Downing for this observation.

erable strength and are capable of being oriented by the process of "drawing." These polymers are also "crystalline" as evidenced by their opacity when allowed to cool slowly from the melt and the typical sharp patterns obtained by X-ray diffraction of unoriented materials as well as the well-defined fiber pattern shown by oriented products. Most of these properties are almost certainly the manifestation of two structural features of these polyamides: first, they have uniform chains which can pack well into a crystal unit; and second, there is abundant opportunity for the formation of hydrogen bonds between chains which would result in very high interchain forces. The conversion of 66 into a N-alkoxymethyl-66 involves the replacement of some of the amide hydrogens by the $CH_2OR$ group. The removal of the amide hydrogens reduces the opportunity for interchain hydrogen bonds, and the introduction of the large $-CH_2OR$ group makes it less probable that the polymer chains can pack well into a crystal unit. The properties of the alkoxymethyl polyamides in comparison with the unsubstituted polymers from which they are derived are best interpreted in the light of these two structural characteristics.

The properties of 66 and the corresponding N-alkoxymethyl derivatives of two different degrees of substitution are listed in Table I.

TABLE I

PHYSICAL PROPERTIES OF POLYAMIDES

| | 66 | N-Methoxymethyl-66 35% Amide subst. | N-Methoxymethyl-66 50% Amide subst. |
|---|---|---|---|
| Max. concn. in hot 80% ethanol | None | About 40% | >60% |
| Melting point, °C. | 264 | 150–160° | 100–110 |
| Modulus of stiffness in 1000's lb./sq. in. | 290 | 14.2 | 3.0 |
| Recovery from 100% stretch, % | 30–35 | 70–80 | 90–95 |
| Tensile strength, lb./sq. in. | 8000–10,000 | 4500–6000 | 2000–3000 |

The solubility of the parent 66 and 610 is limited to mineral acids, strong organic acids, phenols and solutions of calcium chloride in methanol. The alkoxymethyl derivatives are soluble in all these solvents and also dissolve readily in the lower alcohols and mixtures of these alcohols with water or chloroform. Methanol and ethanol containing 15 to 30% water are excellent solvents for these polyamides and are much better than the alcohols alone. As the degree of amide substitution increases the solubility in alcohol increases and the stability of solutions toward gelation also increases. The stability of solutions of N-methoxymethyl-66 in aqueous alcohol shows a sharp increase around 30–35% amide substitution. It is interesting to note that Baker and Fuller[8] found that the related N-methyl polyamides also showed greatly increased solubility at about the same point. Most of these alkoxymethyl polyamides are insoluble in hydrocarbons, chlorinated hydrocarbons, esters and ketones. Certain unusual effects were noted in connection with the precipitation of N-methoxymethyl-66 from its alcohol solutions. Addition of acetone causes separation of the polymer from its alcohol solution, and the amount of acetone required to cause precipitation is directly related to the amide subsitution. The amount of acetone required, however, is independent of the *concentration* of polymer in the alcohol solution. In effect, a given polymer shows solubility in a critical acetone/alcohol ratio which is a function of the amide substitution. Addition of water to an alcohol solution of these polymers also causes precipitation but in this case the amount of water is independent of the *degree of amide substitution* and depends solely on the chemical structure of the base polyamide and the substituent group.[9] Thus, each of these polymer derivatives may be characterized by a simple test which has roughly the same utility as the melting point of a monomeric compound. These relationships, particularly the acetone precipitation, are also affected to a minor extent by the degree of polymerization. Specific examples of these data are shown in Table II.

TABLE II

PRECIPITATION OF N-ALKOXYMETHYL POLYAMIDES FROM SOLUTION

| Polymer | % Methoxyl | Volume of solvent to initiate precipitation, ml. (a) Acetone | (b) Water |
|---|---|---|---|
| N-Methoxymethyl-66 | 7.21 | 48 | 23.5 |
| | 9.72 | 66 | 22.8 |
| | 9.94 | 81 | 23.3 |
| N-Methoxymethyl-610 | 7.86 | 43 | 7.0 |
| | 8.03 | 53 | 7.1 |
| | 9.23 | 96 | 7.4 |
| | 9.81 | 128 | 7.5 |
| N-*n*-Propoxymethyl-66 | .. | 140 | 13.4 |
| N-Isobutoxymethyl-66 | .. | 105 | 11.0 |
| N-Isobutoxymethyl-610 | .. | 350 | 1.0 |

[a] Acetone added to refluxing, stirred solution of 1.0 g. of polymer in 20 ml. 80% ethanol in case of N-isobutoxymethyl-610 and products based on 66. The other polymers from 610 were measured at concentration of 0.5 g. in 12 ml. of 80% ethanol. [b] Water added to refluxing, stirred solution of 0.5 g. of polymer in 25 ml. of methanol in all cases.

The melting points of the N-substituted polymers decrease as the degree of substitution increases. In the case of N-methoxymethyl-66 the melting point changes from 264° for zero substitution to about 100° at 50% and finally to room temperature and lower at 70 to 80% substitution. The lowering of melting point as the amide hydrogen is replaced has been noted with other series of polyamides.[8,10]

The modulus of stiffness and of stretching also decreases rapidly as amide substitution increases. At about 50% substitution, products approaching

(10) Salisbury, U. S. Patent 2,351,074 (1944).

rubber and synthetic elastomers in this respect are obtained. The tensile strength decreases as substitution increases while the total elongation at break remains roughly constant.

One of the most striking changes in physical properties which accompanies substitution on the amide nitrogen is the increase in recovery from stretching. Unsubstituted 66 or 610 when stretched undergoes a deformation ("drawing" orientation—see ref. 1) which is not recovered when the stress is released unless the temperature is raised to a very high value. In the case of the alkoxymethyl polyamides the tendency to recover from stretching at room temperature is pronounced and at 45 to 50% substitution, rapid recoveries of 90–95% from elongations up to 500% of the original length are realized.

## Experimental[11]

**N-Methylol-66 (I).—(a) In Acidic Medium.**—A solution of 60 g. of 66 (0.265 unit mole) in 210 g. of 90% formic acid (sp. gr. 1.20) was prepared by stirring the mixture at 60° for one to two hours. Prolonged exposure of the polyamide to warm formic acid should be avoided since gradual hydrolysis of amide linkages occurs under these conditions. To this solution was added a solution of 60 g. (2 moles) paraformaldehyde in 110 ml. of water, also at about 60°, over a period of eight minutes. Care must be taken at the beginning of the addition since a too rapid rate at first will cause separation of the 66. Twelve minutes later 50 ml. of 60° water was added and after a total time, from the beginning of the aldehyde addition, of thirty-five minutes, the solution was poured into a mixture of 500 ml. of water and 500 ml. of acetone. To the resulting slightly turbid solution, 1500 ml. of water was added over a period of forty minutes causing the N-methylol-66 to separate as a granular powder. This product was washed by reslurrying several times with water, then with aqueous ammonia, water and finally acetone.

*Anal.*[12] Found $CH_2O$, 5.9. This corresponds to substitution of 23% of the amide groups with $CH_2OH$ groups.

Use of commercial formalin in the above procedure yields an N-methylol polyamide which also contains a few per cent. of methoxymethyl groups derived from the methanol present in the commercial product.

**(b) In Basic Medium.**—A mixture of 100 g. of 66 (pulverized to about 20-mesh size) 100 g. of paraformaldehyde and 300 g. of pyridine was charged into a 1-liter stainless steel tube which was mounted in a device for rocking and heating the tube. The mixture was heated to 130–135°, held at this temperature for thirty minutes and then cooled rapidly to room temperature. The resulting sirupy solution was filtered to remove a small amount of unchanged 66 and foreign material and then poured into a large volume of water. The polymer separated as a soft slime and was freed of solvent and formaldehyde by mechanical working (rubber rolls or dough mixer) in a stream of cold water. The product was air dried in the form of thin sheets. *Anal.* Found $CH_2O$, 12.6. This corresponds to substitution of 55% of the amide groups with methylol groups.

**N-Methoxymethyl-66 (II). (a) Preparation by Solution Method.**—A solution of 60 g. of 66 in 180 g. of 90% formic acid was prepared by stirring at 60°. To this was added a solution of 60 g. paraformaldehyde in 60 g. methanol[13] also heated to 60°. The rate of addition was very slow during the first minute in order not to precipitate any of the 66 and then was increased so that it was complete at the end of three minutes. Ten minutes after the aldehyde addition was begun,[14] 60 g. of methanol was added rapidly and the reaction allowed to proceed for a total of thirty minutes. The solution was then poured into 1700 ml. of equal parts (by volume) of acetone–water, and aqueous ammonia was added gradually. The addition of the ammonia caused the N-methoxymethyl-66 to separate as fine white granules. *Anal.* Found: $CH_3O$ (Zeisel), 7.13; $CH_2O$ by sulfite method,[12] 1.4. These values correspond to a total amide substitution of methoxymethyl and methylol groups of 36%.[15]

A procedure analogous to that described above but using an anhydrous formic acid/acetic acid mixture (prepared by addition of sufficient acetic anhydride to 90% formic acid to combine with the water present) yielded a higher substituted product. *Anal.* Found: $CH_3O$ (Zeisel), 9.94; $CH_2O$ by sulfite method, 0.30. The combined total amide substitution corresponding to these analyses is 46%.

**(b) Preparation by "Direct" Method.**—In a 1-gallon nickel-lined autoclave equipped with an efficient anchor type agitator and an overhead discharge line was placed 1000 g. of 66 (pulverized to pass a 16-mesh screen), 1000 g. of paraformaldehyde, 30 g. of water and 1500 g. of methanol. This mixture was heated to 139°, and a solution of 20 ml. of 85% phosphoric acid in 50 g. of methanol was forced in by means of nitrogen pressure. The reaction mixture was maintained between 139 and 140° for eight minutes and then discharged very rapidly (forty to fifty seconds) through the overhead pipe into a solution of 1600 ml. of methanol, 400 ml. of water and sufficient ammonia to neutralize the phosphoric acid catalyst. The resulting solution was freed of foreign material and a trace of unchanged 66 granules by filtration using a diatomaceous earth filter-aid, and the clear filtrate poured into water. The polymer was freed of solvent and aldehyde by working in a stream of water in a mixer. Finally treatment with 1% sodium hydroxide at 40° for fifteen minutes served to remove N-methylol substitution, and also caused the polymer to break up into fine granules. In most runs about 980 g. of polymer was obtained but there were, of course, high losses involved in the use of an autoclave with an overhead discharge line. *Anal.* Found $CH_3O$ (Zeisel), 10.53; amide substitution based on $CH_3O$, 45%. A procedure analogous to the above, using 300 g. of water in the reaction mixture, yielded a *lower substituted product*. *Anal.* Found $CH_3O$, 7.8; amide substitution based on $CH_3O$, 31%.

This direct synthesis of N-alkoxymethyl polyamides has been found to be of wide applicability. The optimum temperature generally varies for each polyamide–alcohol combination. For example, N-methoxymethyl-610 is best prepared at 130–133°, while a copolymer such as 66/610/

(11) We are indebted to Drs. J. W. Stillman and A. H. Halè of these Laboratories under whose supervision many of the analyses reported here were carried out.

(12) The analysis for $CH_2O$ derived from N-methylol groups was carried out by treating a solution of the polyamide in 70% aqueous alcohol with sodium sulfite and titrating the liberated alkali with standard acid.

(13) Such solutions are best prepared by warming a suspension of paraformaldehyde in methanol to 60° and then adding a trace of solid sodium or potassium hydroxide. Under these conditions most samples of paraformaldehyde dissolve very rapidly to give perfectly clear solutions. Such a solution undoubtedly contains a large proportion of the aldehyde and methanol in the form of the hemiacetal, $CH_3OCH_2OH$.

(14) The time at which this second quantity of methanol is added is an important factor in determining the total degree of substitution. The longer this time interval, the higher will be the degree of substitution. This is believed to be due to the effect of the water formed by the esterification of the formic acid by the methanol.

(15) Calculation of degree of amide substitution.—Equations have been derived which permit analyses to be simply converted to the per cent. of amide groups substituted. For N-methoxymethyl-66

$$Z - 0.014\,ZP = 3.65\,P$$

Where $Z$ = % of amide groups substituted, and
$P$ = % methoxyl

Similar relationships may be derived for any combination of substituent groups and kinds of analyses.

6,[16] which is soluble in methanol, may be converted to an alkoxymethyl derivative at temperatures around 50°. Higher alcohols require higher temperatures than does methanol; *n*-butyl alcohol reacts smoothly at 150°.

**N-Ethylthiomethyl-66.**—A solution of 60 g. of 66 (0.265 unit mole) in 150 ml. of 90% formic acid was prepared at room temperature. A solution of formaldehyde in ethyl mercaptan was prepared by the gradual addition of paraformaldehyde (60 g., 2 moles) to 120 g. (1.93 moles) of well cooled ethyl mercaptan containing a trace of sodium hydroxide. This solution was added to the 66 solution at room temperature. After one hour, during which time the temperature rose to 40° and the solution separated into two phases, 1200 ml. of acetone was added slowly to yield a homogeneous solution. Addition of aqueous ammonia to this solution caused the polymer to separate as white granules. This product was found to dissolve readily in warm ethanol. *Anal.* Found: S, 7.39; amide substitution based on sulfur content, 31%.

(16) This copolymer is prepared from 40 parts hexamethylenediammonium adipate, 40 parts hexamethylenediammonium sebacate, and 30 parts caprolactam. For details see Brubaker, Hanford and Wiley, U. S. Patent 2,285,009 (1942).

## Summary

The preparation and properties of representative examples of N-methylol, N-alkoxymethyl and N-alkylthiomethyl polyamides by the treatment of linear polyamides with formaldehyde in the presence of acids of bases, or with formaldehyde and alcohols or mercaptans in the presence of acids, respectively, have been described.

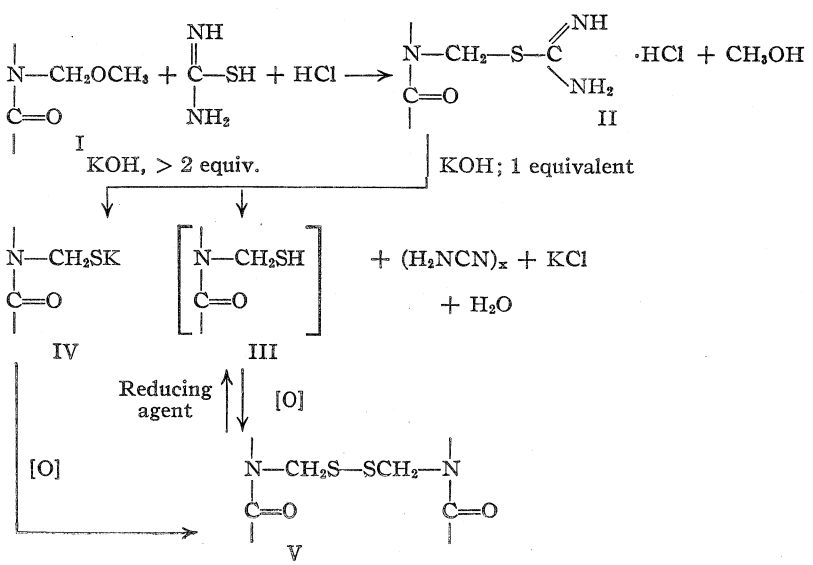
# The Reactions of N-Alkoxymethyl Polyamides

BY THEODORE L. CAIRNS, HUGH W. GRAY, ALLAN K. SCHNEIDER AND RICHARD S. SCHREIBER

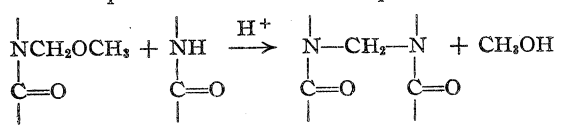


The previous paper has described the preparation and properties of the N-alkoxymethyl polyamides.[1] This report[2] is concerned with the chemical changes which these polymers undergo.

It has been found that the N-alkoxymethyl polyamides condense with compounds containing the thiol group to yield the corresponding N-alkylthiomethyl polyamides according to the equation

The reaction proceeds at room temperature in the presence of strong acids, such as hydrochloric acid, without the necessity of using large excesses of the mercaptan. In this respect it is greatly superior to the method for the preparation of these sulfur derivatives which was described earlier,[1] and permits the preparation of polyamide derivatives from difficultly available mercaptans such as octadecylmercaptan, 1-thiosorbitol and N,N′-diethyl-β-mercaptoethylamine.

An analogous product may be derived by condensation with thiourea. If one equivalent of concentrated hydrochloric acid is added to a methanol solution of N-methoxymethyl-66 and thiourea (1 mole thiourea per mole of methoxymethyl group) the polymer is very rapidly converted to a water-soluble form. The addition of sufficient alkali to neutralize the hydrochloric acid causes the solution to be converted into a rubbery gel, while the addition of about 2.2 equivalents of alkali for each equivalent of acid produces no apparent change in viscosity and the polymer remains water-soluble. Addition of oxidizing agents (*e. g.*, hydrogen peroxide) to this alkaline solution results in immediate gelation or, in the case of very dilute solutions, precipitation of the polymer. These observations may be explained as the result of a series of reactions represented by the following equations.

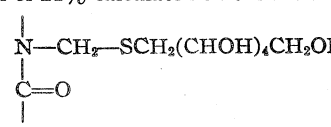


(1) Cairns, Foster, Larchar, Schneider and Schreiber, THIS JOURNAL, 71, 651 (1949).

(2) Cairns, U. S. Patent 2,430,859 (1947), and 2,430,860 (1947), are related to this work.

Treatment of I with thiourea and acid yields first, the S-alkyl isothiourea salt II, which is water-soluble. Action of an equivalent amount of alkali on this salt results in the formation of the N-mercaptomethyl polyamide III. This first step has an analogy in the reaction of monomeric N-methylol amides[3] while the formation of II is analogous to the well-known method for the preparation of mercaptans from the S-alkyl isothioureas.[4] The N-mercaptomethyl polyamide is very sensitive to oxidation and in the presence of atmospheric oxygen yields the cross-linked polymeric structure V which causes gelation of the solution. Addition of excess alkali to II forms the potassium salt of the mercaptomethyl polyamide (IV). This product is water soluble and is much less readily oxidized by air than is the free mercaptan III but yields the same product (V) when treated with oxidizing agents such as hydrogen peroxide or iodine. The potassium salt (IV) may be isolated as such and, if stored under nitrogen, remains water soluble for several days at least. Neutralization of a solution of II with sodium acetate results in the formation of an insoluble, sulfur-free product, which is probably the original unsubstituted polyamide. This series of reactions presents a useful route for the preparation of high polymers having a controllable number of cross-linkages between chains.

The action of aqueous acid on the alkoxymethyl polyamides results in hydrolysis of the substituent group with the regeneration of the unsubstituted amide group and is, in fact, the reversal of the synthetic method used for the preparation of these polymers. When heated with acid, in the absence of water or any solvent, an interchain condensation takes place as shown in the equation



The evidence in support of this reaction is a decrease in methoxyl content and conversion of the original alkoxymethyl polyamide into an insoluble and infusible form. Insolubility and infusibility are the prime criteria of a three-dimensional, cross-linked polymer. Conditions under which the hydrolytic regeneration of the polyamide and the acid catalyzed cross-linking may be carried out are given in the experimental section.

## Experimental[5]

**N-Alkylthiomethyl Polyamides. (a) Reaction with Octadecyl Mercaptan.**—A solution of 20 g. of N-methoxymethyl-66 (% $CH_3O$ = 9.72) and 19 g. of crude octadecyl mercaptan in 100 ml. of absolute alcohol was prepared at 60–65°. The mercaptan mixture contained about 85% octadecyl mercaptan (0.066 mole). A solution of 1 ml. of concentrated hydrochloric acid in a few milliliters of absolute alcohol was added and after two hours at 60° the polymer was precipitated as a granular powder by the addition of acetone. After thorough washing with acetone the polymer was dried in air and finally over phosphorus pentoxide. *Anal.* Found: S, 3.72, 3.87; $CH_3O$, 1.20, 1.16. This octadecylthiomethyl derivative was found to have greatly reduced affinity for water as evidenced by the fact that it was not completely soluble in 80% aqueous ethanol but was readily soluble in absolute alcohol, whereas the original N-methoxymethyl-66 was more soluble in 80% alcohol than in absolute alcohol.

**(b) Reaction with 1-Thiosorbitol.**—A solution of 25 g. of N-methoxymethyl-66 (% $CH_3O$ = 11.5) and 32 g. of 1-thiosorbitol (0.16 mole) was prepared in 100 ml. of 80% aqueous methanol at 50°. A mixture of 1 ml. concentrated hydrochloric acid in about 5 ml. of methanol was added and the solution heated at 50° for two hours and then allowed to stand at room temperature for sixteen hours. Alcoholic alkali was added to neutralize the acid, and the polymer was precipitated as a soft plastic mass by pouring the solution into a large volume of water. The polymer was freed of impurities by working with water and was dried in the form of a thin film. *Anal.* Found: S, 6.42. The sulfur content corresponded to an amide substitution of 21% calculated on the basis of the formula

The introduction of large amounts of the hydrophilic thiosorbityl radical resulted in a polymer of greatly increased affinity for water. The product described above was found to be completely soluble in 30% ethanol–70% water (by volume) while the original N-methoxymethyl-66 did not dissolve in any alcohol–water mixture containing more than 50% water.

**N-Mercaptomethyl-66. (a) Reaction of N-Methoxymethyl-66 with Thiourea.**—A solution of 30 g. of N-methoxymethyl-66 (% $CH_3O$ = 9.72) and 6.0 g. of thiourea (0.079 mole) was prepared by stirring with 70 g. of aqueous methanol (80% methanol by volume) at 55–60° for about one hour. This solution was cooled to 30–35° and 6.35 ml. of concentrated hydrochloric acid (0.079 mole) in 15 ml. methanol was added. After about one minute a drop of this solution added to water gave no precipitate. After three minutes a solution of 0.84 g. potassium hydroxide (0.158 mole) in 10 ml. of water and 25 ml. of methanol was added. During the next few seconds the solution changed in color from pale yellow to pink and set to a transparent tough rubbery gel (V).

If the neutralization with potassium hydroxide was carried out in the presence of hydrogen sulfide, gelation did not take place. Further, addition of more than 2.0 moles of alkali per mole of acid used did not cause gelation of the solution, while any quantity less than 2.0 moles resulted in immediate gelation.

**(b) Isolation of the Disulfide of N-Mercaptomethyl-66 (V).**—A solution of 120 g. of N-methoxymethyl-66 (% $CH_3O$ = 6.46) and 36 g. of thiourea (0.47 mole) was prepared in 500 ml. of aqueous methanol (80% methanol by volume) at 60° and then cooled to room temperature. To this was added 36 ml. of concentrated hydrochloric acid (0.40 mole) in 50 ml. of methanol. After fifteen minutes this solution was poured into a mixture of 60 g. of potassium hydroxide (1.06 moles) dissolved in 25 ml. of water and 150 ml. of methanol with vigorous agitation. The precipitate which formed was separated by pressure filtration and the clear yellow, viscous filtrate was stored in an atmosphere of nitrogen.

A portion of this filtrate was diluted with a large volume of water and an excess of 3% hydrogen peroxide added. This caused the precipitation of a white curdy product—the disulfide of N-mercaptomethyl-66 (V). This polymer was washed free of all traces of alkali with water, finally

washed with acetone and dried first in air and then in vacuum over phosphorus pentoxide. *Anal.* Found: S, 4.90; $CH_3O$, 3.08; ash (calcd. as $K_2SO_4$), 0.31. This disulfide was insoluble in hot aqueous ethanol and treatment with an excess of a mercaptan caused reduction to a soluble form. Addition of lead acetate to an aqueous solution of the potassium salt of N-mercaptomethyl-66 described above caused formation of a yellow precipitate.

**Hydrolysis of N-Methoxymethyl-66 by Aqueous Acid.**—The hydrolysis of the methoxymethyl group to $CH_3OH$, $CH_2O$ and the unsubstituted amide group may be carried out in a controllable fashion and thus is an additional method for obtaining any given degree of methoxyl content.

Small strips of film (0.002″ thick) of N-methoxymethyl-66 were suspended in a solution of 10 ml. of concentrated hydrochloric acid in one liter of water at 50° for various lengths of time. The strips were removed, washed thoroughly in water, soaked in aqueous ammonia, washed in water and finally dried in vacuum over phosphorus pentoxide.

| Time in acid solution, minutes | $CH_3O$, % |
|---|---|
| 0 | 7.13 |
| 1 | 6.61 |
| 2 | 5.41 |
| 3 | 4.57 |
| 4 | 2.77 |

**Acid Cross-linking of N-Methoxymethyl-66.**—A 20% solution of N-methoxymethyl-66 in methanol–water (80% methanol by weight) was prepared by stirring under reflux at 60°. To this was added maleic acid (1% based on the polymer) and the mixture stirred for thirty minutes to dissolve the acid. This solution was filtered under pressure, allowed to stand two hours at 60° to permit the air bubbles to rise out of the solution and was then cast into films on glass plates. The solvent was allowed to evaporate at room temperature for about twenty hours.

The pliable, transparent film prepared in this manner analyzed for 8.53% methoxyl. Baking this film (on the glass plate) for six hours at 60° gave a product of 6.94% methoxyl content; one hour at 100° gave a product of 6.31% methoxyl content. Both these baked films were found to be insoluble (although highly swollen) in hot 80% methanol, and they did not melt at any temperature but charred gradually about 295°. A film of the same N-methoxymethyl-66 prepared in a similar manner but without added acid melted at about 155° and was readily soluble in hot aqueous methanol even after baking for one hour at 100°.

## Summary

The conversion of N-alkoxymethyl polyamides to alkylthiomethyl and mercaptomethyl polyamides by treatment with mercaptans or thiourea in the presence of strong acids has been described.

# Perylene, a By-product from Some 1-Naphthyl-metallic Compounds

BY HENRY GILMAN AND CECIL G. BRANNEN

Incidental to the preparation of some substituted silanes using 1-naphthyllithium, perylene was isolated from several different mixtures. Mr. L. Miller[1] isolated this hydrocarbon from the reaction between 1-naphthyllithium and silicon tetrachloride, while we have found it in some reactions of 1-naphthyllithium with ethyl silicate and hexachlorodisilane, as well as with silicon tetrachloride.

In order to determine if a silicon compound is essential for the formation of perylene, 1-naphthyllithium was made from 1-bromonaphthalene of the highest purity available, hydrolyzed, and the residue examined chromatographically. Pure perylene in a yield of 3% was isolated from the mixture.

There is no evidence in the literature that 1,8-dibromonaphthalene is formed during the bromination of naphthalene and even if traces are formed, it is improbable that perylene in the yield of 3% could have come from that source. To reduce further the possibility that perylene might have resulted from a dibromo isomer, 1-naphthyllithium was prepared from the halide obtained from a Sandmeyer reaction and the mixture examined as before. A 2.8% yield of perylene was found.

Among the mechanisms by which perylene might be produced in this reaction are: (1) the formation and disproportionation of free radicals, followed by coupling; and (2) a ring closure, by dehydrogenation, of an intermediary biaryl, 1,1′-binaphthyl. Free radical formation and disproportionation have been advanced by several investigators,[2] and in this case the mechanism may be as shown by the following set of reactions

$$1\text{-}C_{10}H_7Br + Li \longrightarrow 1\text{-}C_{10}H_7^- + LiBr \quad (1)$$

$$2\ 1\text{-}C_{10}H_7^- \longrightarrow 1,1'\text{-}C_{10}H_7\text{-}C_{10}H_7 \quad (2)$$

$$2\ 1\text{-}C_{10}H_7^- \longrightarrow \text{(I)} + C_{10}H_8 \quad (3)$$

(I)

$$2\ (I) \longrightarrow \text{(II)} \quad (4)$$

(II)

Some organometallic compounds are known to effect dehydrogenation[3] and such dehydrogenation

may lead to cyclization.[4] This may be represented by the equation

$$1,1'\text{-}C_{10}H_7\text{-}C_{10}H_7 \xrightarrow{1\text{-}C_{10}H_7Li} \text{(II)} \quad (5)$$

To check the validity of equation (5), pure 1,1'-binaphthyl was refluxed for several days with phenyllithium and the mixture was examined for perylene. The fluorescent material was separated from the bulk of binaphthyl by chromatographic purification and was shown to contain perylene by the characteristic absorption bands at 410 and 435 mμ. Similar results were obtained using *p*-dimethylaminophenyllithium instead of phenyllithium.

The formation of perylene is not peculiar to the lithium compound since traces were found in the products resulting from the hydrolysis of the Grignard reagent, 1-naphthylmagnesium bromide.

**Acknowledgment.**—The authors thank William Meikle for assistance.

## Experimental

All identifications (other than those by absorption curves) were made by mixed m.p. The petroleum ether used as solvent had a b.p. of 90–115°. The perylene used was made by three methods: (1) from naphthalene[5a]; (2) from 1-bromonaphthalene[5b]; and (3) from β-dinaphthol.[5c] The m.p.'s and mixed m.p.'s of all combinations of the samples were 268–269° (cor.).

**Perylene from the Hydrolysis of 1-Naphthyllithium.**—One hundred grams (0.48 mole) of 1-bromonaphthalene ($n^{20}D$ 1.6578, sp. gr. $1.481^{20}/_{20}$) was added with stirring to 7.0 g. (1.0 g. atom) of lithium in 500 ml. of ether in an atmosphere of nitrogen, and refluxed one hour. The yield,

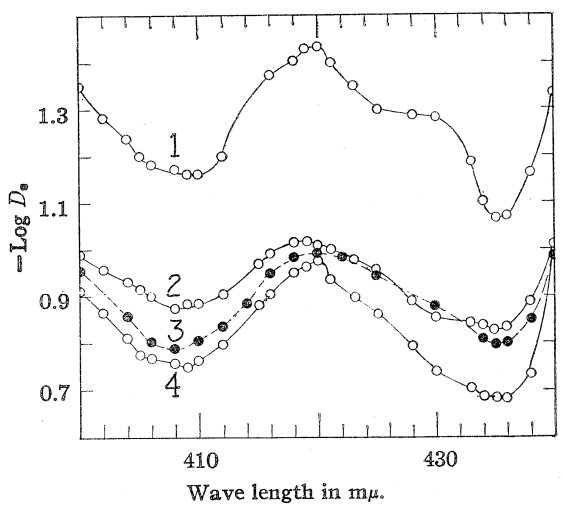

Fig. 1.—Ultraviolet absorption spectra in alcohol: (1) perylene ($1.4 \times 10^{-8}$ *M*); fluorescent material from (2) reaction of 1,1'-binaphthyl with *p*-dimethylaminophenyllithium, (3) prepn. of 1-naphthylmagnesium bromide, and (4) reaction of 1,1'-binaphthyl with phenyllithium. Measurements were made with a Beckman Spectrophotometer (Model DU).

as determined by acid titration,[6] was 96%. The ether solution was hydrolyzed with cracked ice, washed with water, steam distilled, and the resulting dark red solid residue, 11.8 g., dried *in vacuo* for forty-eight hours. After extraction in a Soxhlet for three days with petroleum ether, the 0.9 g. of insoluble residue, m.p. 190–260°, was discarded and the solution was diluted to 1 l. with pure solvent and examined chromatographically.

A 40-ml. portion of the petroleum ether extract was diluted to 250 ml., poured through a 15 × 150 cm. column of alumina[7] and observed with ultraviolet light. After development with, first, 1 l. of pure solvent and, second, 1 l. of 10% benzene–petroleum ether, the solvents were separately evaporated, giving 79 mg. (3.1%) of crude perylene, m.p. 261–264°, from the first filtrate, and a few crystals (not weighed) of 1,1'-binaphthyl, m.p. 155–156°, from the benzene–petroleum ether filtrate. Several other zones developed in the column, but they were not investigated.

The same procedure was followed using 1-bromonaphthalene prepared[8] by a Sandmeyer reaction from purified 1-naphthylamine. The yield of perylene in this experiment was 2.8%.

Perylene (mixed m.p.) was also obtained by the action of lithium metal on 1,1'-binaphthyl.

**1,1'-Binaphthyl and Phenyllithium.**—Ten grams of 1,1'-binaphthyl,[9] m.p. 155–156°, and 0.3 mole of phenyllithium in ether were refluxed under nitrogen for fifty-two hours and then poured onto cracked ice. The ether layer was washed with water and the solvent removed. The residue was dissolved in dry petroleum ether and the resulting yellow solution poured through an alumina column. The blue fluorescent zone was cut off, eluted, dried overnight at 130° and the adsorbed material was dissolved in 200 ml. of 95% ethanol. The absorption curve of the solution is shown in Fig. 1.

The authors are grateful to Dr. Robert R. Sealock for assistance.

**1,1'-Binaphthyl and *p*-Dimethylaminophenyllithium.**—Five grams (0.02 mole) of 1,1'-binaphthyl, m.p. 156°, added to 0.2 mole of *p*-dimethylaminophenyllithium in 250 ml. of ether, was refluxed for fourteen hours and then poured onto cracked ice. The ether solution was thoroughly washed with hydrochloric acid and water, dried with sodium sulfate, and concentrated. The residue was dissolved in 1 l. of petroleum ether and chromatographed. After two passes through a 15 × 150 cm. alumina column, 4.8 g. (96%) of the 1,1'-binaphthyl was recovered from the filtrate, while a bright blue fluorescent zone developed on the column. The blue zone was eluted with ether, the solvent removed, and the residue was dried and dissolved in 200 ml. of 95% ethanol. The absorption spectrum is shown in Fig. 1.

**Perylene from the Hydrolysis of 1-Naphthylmagnesium Bromide.**—Forty-one and four-tenths grams (0.2 mole) of 1-bromonaphthalene was added to 5.0 g. (0.21 g. atom) of magnesium in ether under the usual conditions to give a 96% yield of the Grignard reagent. The ether solution was carbonated by pouring upon crushed Dry Ice, extracted with 20% sodium hydroxide, washed with water and the solvent removed. The residue was dissolved in petroleum ether and chromatographed. The filtrate contained 2.1 g. (0.008 mole) of 1,1'-binaphthyl, m.p. 156°, while the column contained a blue fluorescent zone. The blue zone was cut off and eluted with ether, the solvent removed, and the residue dried. Substantial evidence that the residue contained perylene was obtained by comparison of the ultraviolet spectrum of the ethanol solution of this residue with that of an authentic sample of perylene in ethanol; see Fig. 1.

(8) Prepared by Mr. R. Brennan of this Laboratory.

(9) Prepared by the method of Krizewsky and Turner, *J. Chem. Soc.*, **115**, 559 (1919), from the Grignard reagent and cupric chloride and purified chromatographically on alumina from petroleum ether.

**1-Naphthyllithium and Silicon Compounds.**—Perylene was isolated from several mixtures resulting from the separate treatment of silicon tetrachloride, ethyl silicate and hexachlorodisilane with 1-naphthyllithium. In all cases the 1-napthyllithium was made in the conventional manner from the bromide and lithium.

A typical run is described. 1-Naphthyllithium (0.26 mole) in 400 ml. of ether was added to 17.9 g. (0.086 mole) of ethyl silicate and refluxed overnight. The ether was replaced with benzene, the solution filtered and the filtrate was concentrated to about 50 ml. and allowed to crystallize. The yellow solid, m.p. 190–210°, after two crystallizations from benzene melted at 268–269° and showed no depression of m.p. when mixed with perylene. The yield from this run was 2.1%.

Similar runs using silicon tetrachloride gave yields of perylene from 1.2 to 2.6%, and with hexachlorodisilane, 2.2 and 2.4%. The evidence is, therefore, that the silicon compounds play no significant part in the formation of perylene.

## Summary

The hydrocarbon, perylene, has been isolated from several reaction mixtures involving 1-naphthyllithium and 1-naphthylmagnesium bromide. The formation of perylene from the 1-naphthyl-metallic compounds may be due in part to a free radical mechanism and also to a cyclodehydrogenation of 1,1′-binaphthyl by means of organolithium compounds. Experiments are presented in support of this latter mechanism.

# Characterization of Sulfonic, Sulfinic, Phosphonic and Some Other Acids as Thallous Salts

BY HENRY GILMAN AND R. K. ABBOTT, JR.[1]

It has been suggested[2] that thallous sulfonates may be reagents of choice in the characterization of some sulfonic acids. Several advantages of the thallous salts as derivatives of the sulfonic acids were detailed in a previous contribution.[2] The present report extends the scope of the reaction to other types of acids, and also further defines certain limitations in the usefulness of the reaction.

Although the thallous arylsulfonates meet the requirements for good derivatives, the thallous alkylsulfonates appear to be less satisfactory derivatives.

The arylsulfinic acids appear to be conveniently characterized as thallous salts.

The aromatic thiols give excellent derivatives, but the aliphatic thiols give salts having insufficiently sharp melting points. Moreover, the thallous mercaptides are evidently unstable, decomposing on standing in the dark in tightly stoppered vials. However, the quantitative formation of the highly colored thallous mercaptides suggests their use as extremely sensitive qualitative tests for the detection of mercaptans.

Both arylphosphonic acids and arylphosphinic acids are readily characterized by this method. Either the mono- or the di-thallous salts of the phosphonic acids provide derivatives with good melting points.

Nitromethane and nitroethane readily form monothallous salts, but only the latter has a definite decomposition point.

2,4,6-Trinitrobenzoic acid gives a crystalline monothallous salt, melting with decomposition at 160–163°, which decarboxylates smoothly in boiling pyridine solution giving 1,3,5-trinitrobenzene and thallous oxalate. Thallous 2,4,6-trinitrobenzoate reacts further with a second equivalent of thallous hydroxide giving a blood-red complex of uncertain composition. 1,3,5-Trinitrobenzene was found likewise to react with one, two and three equivalents of thallous hydroxide giving complexes of rather indefinite composition which explode on heating.

Thallium trichloride reacts with sodium *p*-toluenesulfinate and with *p*-toluenesulfinic acid to give thallium dichloride *p*-toluenesulfinate.

$$p\text{-}CH_3C_6H_4SO_2Na + TlCl_3 \longrightarrow p\text{-}CH_3C_6H_4SO_2TlCl_2 + NaCl$$

However, the interesting observation was made that this compound did not eliminate sulfur dioxide with the formation of a carbon–metal linkage, as has been observed with some related mercury compounds.[3]

## Experimental

Two general procedures have been mentioned[2] for the preparation of thallous sulfonates. These procedures were used for the thallous salts described in Table I. The most important point in their preparation is the recrystallization solvent. In most cases it was desirable to evaporate the solution of salt almost to dryness and then recrystallize the salt from ethanol–water mixtures since most of them are very soluble in water and much less soluble in ethanol.

**Thallium Dichloride *p*-Toluenesulfinate.**—On mixing 0.1 mole each of sodium *p*-toluenesulfinate and thallium trichloride dissolved in a minimum of water, there was an immediate precipitate accompanied by an odor of *p*-toluenesulfonyl chloride. The precipitate was filtered, washed, and dried giving 36 g. (84%) of the salt, which melted at 203–205° (dec.).

*Anal.* Calcd. for $C_7H_7O_2Cl_2STl$: Tl, 47.4. Found: Tl, 47.6.

**2,4,6-Trinitrobenzoic Acid and Two Equivalents of Thallous Hydroxide.**—In order to determine whether the red precipitate transitorily encountered in the preparation

| Methylmercaptide[f] | 136–140 (dec.) | 100 | $CH_3STl$ | 80.9 | 80.5 |
| Ethylmercaptide | Dec. | 100 | $C_2H_5STl$ | 76.8 | 76.4 |
| *n*-Butylmercaptide | 84–90 | 100 | $C_4H_9STl$ | 69.4 | 69.1 |
| Thiophenolate | 258–260 | 99 | $C_6H_5STl$ | 65.2 | 65.0 |
| *p*-Thiocresolate | 178–180 | 99 | $C_7H_7STl$ | 62.3 | 62.0 |
| Thio-β-naphtholate | 165–168 | 97 | $C_{10}H_7STl$ | 56.2 | 55.9 |
| 2,4,6-Trinitrobenzoate | 160–163 | 93 | $C_7H_2O_8N_3Tl$ | 44.3 | 44.1 |

[a] All melting points were taken on a Fisher–Johns type block, uncorrected. [b] The melting point of this compound was not sharp. After two recrystallizations from 95% ethanol, the crystals sintered at 125° before melting at 143–145°. [c] This compound showed a transition point at 260° when examined under a hot-stage microscope, melting and immediately resolidifying. The compound then melted to a clear phase at 317–320°. [d] A mixed melting point with monothallous phenylphosphonate was depressed to 140–150°. [e] This salt appeared to be extremely resistant to detonation by mechanical shock. [f] The canary yellow precipitate of thallous mercaptide obtained with the volatile aliphatic mercaptans is so delicate a test that the vapor present in the air was sufficient to give a precipitate with solutions of thallous hydroxide three or four feet distant. The mercaptides and thiophenolates were obtained from absolute methanol or ethanol solutions.

of thallous 2,4,6-trinitrobenzoate actually contained more than one equivalent of thallium, 0.02 mole of 1.04 *N* thallous hydroxide[2] was added to 0.01 mole of 2,4,6-trinitrobenzoic acid in 75 ml. of methanol. A heavy red precipitate formed after the addition of the first equivalent of base. After prolonged shaking, filtering, and drying, 5.6 g. of product was obtained. The compound exploded on heating. Analysis showed that nearly two atoms of thallium were present in the molecule, but no satisfactory agreement for any definite compound was indicated.

*Anal.* Calcd. for $C_7H_2O_8N_3Tl_2$: Tl, 61.7. Found: Tl, 59.4.

**1,3,5-Trinitrobenzene and Thallous Hydroxide.**—Equivalent amounts of 1,3,5-trinitrobenzene and thallous hydroxide were reacted in a manner similar to the previous experiment. The red precipitate did not melt but exploded on heating.

*Anal.* Calcd. for $C_6H_4O_7N_3Tl$: Tl, 46.9. Found: Tl, 41.1.

The products of reaction of trinitrobenzene with two and three equivalents of thallous hydroxide, respectively, likewise showed approximate but not stoichiometric amounts of thallium to be present.

*Anal.* Calcd. for $C_6H_5O_8N_3Tl_2$: Tl, 62.5. Found: Tl, 56.8. Calcd. for $C_6H_6O_9N_3Tl_3$: Tl, 70.0. Found: Tl, 62.5.

**Decarboxylation of Thallous 2,4,6-Trinitrobenzoate.**—A suspension of 0.01 mole of this salt in 25 ml. of pyridine was boiled until a microcrystalline precipitate was deposited, during which time the color of the solution changed from an intense green to a pale brown. On filtering off the precipitate and diluting the clear filtrate, 1.4 g. (67%) of 1,3,5-trinitrobenzene was obtained melting at 120–122°.

The crystalline precipitate was found to contain all the thallium of the original thallous 2,4,6-trinitrobenzoate in the monovalent state. It was soluble in hot water, insoluble in cold water and hot pyridine, and nitrogen-free, melting at 320° with decomposition.

*Anal.* Calcd. for $C_2O_4Tl_2$: Tl, 82.5. Found: Tl, 82.7.

Although thallous oxalate has been reported,[4] no record could be found of its melting or decomposition point. An authentic sample was prepared. It was found to melt at 315–320° with decomposition and to be identical with that obtained on pyrolysis of thallous 2,4,6-trinitrobenzoate in solubility, analysis and pyrolytic behavior.

**Acknowledgment.**—The authors are grateful to Dr. H. Smith Broadbent for valuable assistance.

## Summary

The thallous salts have been found to be well crystallized and easily prepared derivatives of the arylsulfonic, sulfinic, phosphonic and phosphinic acids, as well as for the thiophenols. However, they are of limited use for alkylsulfonic acids and of little value for mercaptans and the simple nitroalkanes.

Thallous 2,4,6-trinitrobenzoate, which also melts sharply, is pyrolyzed smoothly to 1,3,5-trinitrobenzene and thallous oxalate.

2,4,6-Trinitrobenzoic acid and 1,3,5-trinitrobenzene unite with more than one equivalent of thallous hydroxide giving red insoluble complexes.

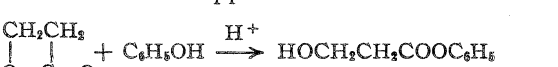
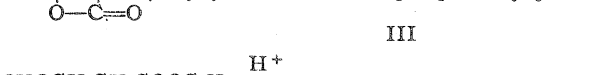
# β-Propiolactone. VI. Reactions with Phenols, Thiophenols and their Salts[1]

BY T. L. GRESHAM, J. E. JANSEN, F. W. SHAVER, R. A. BANKERT, W. L. BEEARS AND MARIE G. PRENDERGAST



β-Propiolactone (I) and phenol react slowly at room temperature to give β-phenoxypropionic acid (II) and a small amount of a polymer of I. At higher temperatures (above 150°) the polymerization[2] becomes the major reaction. Except for the rate these results are similar to those ob-



I II

served in the reaction between alcohols[3] and I. The polymers were separated from the phenoxy acids by alkaline saponification but it was necessary to avoid an excess of alkali; otherwise the phenoxy acids were cleaved to phenol and hydracrylic acid. Nuclear substituents had marked effects on the yields of β-phenoxypropionic acids (Table II). These products result from ring opening of I at the alkyl–oxygen link.

In the presence of catalytic amounts of sulfuric acid a striking change in the reaction of I with phenol occurs. Phenyl hydracrylate (III) is formed rapidly in high yield. This product must arise from ring opening of I at the acyl–oxygen linkage and it is somewhat surprising that none of II is formed. This appears to be in direct con-

III

IV

trast to the acid catalyzed reactions of I with alcohols[3] since the hydracrylate does not result from the polymers of I and phenol. The polymerization of I occurs to only a small extent.

The primary product (III) undergoes a self-alcoholysis to give phenyl β-(β-hydroxypropionoxy)-propionate (IV). This reaction continues at the expense of III beyond the few minutes required for complete reaction of I with phenol and it is possible to minimize it only to a small extent by increasing the excess of phenol or by reducing the acid catalyst concentration. The reaction also occurs to a similar extent with III and sulfuric acid in phenol solution.

Nuclear substituents have little or no effect on the yields of phenyl hydracrylates (Table I) as judged by the combined yields of phenyl hydracrylates and phenyl β-(β-hydroxypropionoxy)-propionates. The amount of self-alcoholysis tended to increase with increasing acid strength of the phenol.

The lactone and sodium phenoxide in water solution gave rise to sodium β-phenoxypropionate (V) in low yield. Hydrolysis to sodium hydracrylate (VI) accounts for most of I and variations in time, temperature, concentration and excess sodium phenoxide had only minor effects on the yields of V. In these reactions cleavage of the lactone ring occurred at the alkyl–oxygen link as in the salt reactions.[4]

Using the optimum conditions found for the reaction of I with sodium phenoxide, large variations in the yields of β-phenoxypropionates were observed with nuclear substituted phenols. The

V

VI

effects of substituents (Table II) differ from those reported for similar reactions of phenoxides with alkyl halides[5] and ethylene oxide.[6]

β-Propiolactone reacts much more rapidly with thiophenol than it does with phenol and the yield of β-thiophenoxypropionic acid is higher. With aqueous sodium thiophenoxide the yield of sodium β-thiophenoxypropionate is nearly quantitative.

## Experimental

**Materials.**—The phenols were Eastman Kodak Company chemicals or equivalent grade. They were redistilled before use. The β-propiolactone was similar to that described in the first paper[1] of this series.

**Reaction of β-Propiolactone with Phenol. A. Non-Catalyzed. β-Phenoxypropionic Acid. (II).**—A solution of one mole (72 g.) of β-propiolactone and three moles (282 g.) of phenol was kept at 100° for six hours with stirring. The unreacted lactone and most of the excess phenol was distilled at 20 mm. until the flask temperature was 140°. An ether solution of the distillation residue was extracted with three 300-ml. portions of saturated sodium bicarbonate solution. Evaporation of the extracted ether solution left a small residue of phenol. The combined sodium bicarbonate extract was boiled to hydrolyze the polymer until the volume was 500 ml. On cooling and acidifying with concentrated hydrochloric acid, pure β-phenoxypropionic acid was deposited. After standing overnight, the precipitate was filtered with suction, washed with water and dried at room temperature. The colorless product melted at 94–95°; yield 24.8 g., 14.8%; (18 hr. reaction time; yield 42.5 g., 24%).

[a] Recrystallized from carbon tetrachloride, m. p. 27–28°. [b] Saponification equivalents for some compounds are in poor agreement with that calculated due to instability and interference of colored decomposition products in determining end-points. [c] Analysis for carbon is in poor agreement with that calculated, except for the unsubstituted ester, due to impurities which appear to be mostly the phenyl β-(β-hydroxypropionoxy)-propionates. Repeated attempts to purify these compounds were not successful due to the great ease with which they underwent a self-alcoholysis under distillation conditions. [d] M. p. 42–43°. [e] The yield of polymer-free residue assumed to be dimeric self-alcoholysis products were: *o*-$CH_3$, 31.8; *m*-$CH_3$, 34.2; *p*-$CH_3$, 38.2; *o*-$OCH_3$, 38.0; *p*-$OCH_3$, 44.8; *o*-Cl, 59.4; *p*-Cl, 51.4.

*Anal.* Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.07; neut. equiv., 166. Found: C, 65.13; H, 6.14; neut. equiv., 169.5.

**Stability of β-Phenoxypropionic Acid in Alkaline Solution.**—A suspension of 10 g. (0.06 mole) of phenoxypropionic acid (m.p. 94–95°) in 200 ml. of water containing 2.48 g. (0.06 mole) of 97% sodium hydroxide was boiled under a reflux condenser for thirty minutes. Solution was complete at the boiling point. The solution was cooled, acidified with concentrated hydrochloric acid and after standing three hours was filtered from the β-phenoxypropionic acid. The solid acid was washed with water and dried at room temperature; wt. 9.5 g.; 95% recovery. The loss is mostly due to water solubility.

A similar experiment but using 4.96 g. (0.12 mole) of 97% sodium hydroxide gave a recovery of 7 g. (70%) of β-phenoxypropionic acid. Continued boiling of a similar solution for five hours resulted in the recovery of 0.5 g. (5%) of the phenoxy acid and 3.5 g. of phenol (62%).

**B. Acid Catalyzed. Phenyl Hydracrylate (III) and Phenyl β-(β-Hydroxypropionoxy)-propionate (IV).**—β-Propiolactone (one mole, 72 g.) was added over a period of fifteen minutes to phenol (3 moles, 282 g.) containing 0.5 g. of sulfuric acid. The reaction was stirred and held at 46–50° by means of an ice-bath. After twenty minutes the catalyst was neutralized with an equivalent of sodium methoxide and most of the excess phenol removed at reduced pressure until the flask temperature was 100° at 1 mm. The residue was taken up in 400 ml. of ether and the solution filtered from a small amount (7 g.) of polymer, extracted with 100 ml. of saturated sodium bicarbonate, washed twice with water, dried over anhydrous sodium sulfate and evaporated. The residue was distilled at 0.2 mm. and phenyl hydracrylate (66 g., 39.8%) was collected as a colorless oil at 90–92° leaving a residue (88 g., 37%) of phenyl β-(β-hydroxypropionoxy)-propionate. Acidification of the sodium bicarbonate extract with concentrated hydrochloric acid gave no insoluble material, showing no phenoxy acid was formed. Physical and analytical data are shown in Table I.

Increase in time of reaction to six hours gave a reduction (18%) of III and an increase (15%) of IV. Doubling the number of moles of phenol in the reaction mixture gave an increase (10%) of III and a decrease (4%) of IV.

**Phenyl β-(β-Hydroxypropionoxy)-propionate (IV).**—Distillation of combined residues (270 g.) from reactions carried out as in B above in a short-path still at 0.001 mm. gave 226 g. of product which was collected at a film temperature of 90–97°; $n^{20}D$ 1.5100; $d^{20}_4$ 1.2036.

*Anal.* Calcd. for $C_{12}H_{14}O_5$: C, 60.50; H, 5.88; sapon. equiv., 119; acetyl value, 7.2; mol. wt., 238. Found: C, 61.13; H, 6.13; sapon. equiv., 122; acetyl value, 7.3; mol. wt. (cryoscopic in benzene), 230. It appears from these data that the product contained phenyl hydracrylate as an impurity.

The phenyl urethan derivative was recrystallized from chloroform from which it separated as small prisms; m. p. 97–98°.

*Anal.* Calcd. for $C_{19}H_{19}O_6N$: N, 3.92. Found: N, 3.85.

**Self-Alcoholysis of Phenyl Hydracrylate. Phenyl β-(β-Hydroxypropionoxy)-propionate (IV).**—A solution of 166 g. (1 mole) of phenyl hydracrylate, 1 g. of sulfuric acid, and 470 g. (5 moles) of phenol was stirred and held at 46° for six hours. The reaction mixture, after treatment as in B above, gave 488 g. phenol, 70 g. (42% recovery) of phenyl hydracrylate, and 44 g. (37%) of phenyl β-(β-hydroxypropionoxy)-propionate, $n^{20}D$, 1.5070. The phenyl urethan derivative melted at 97–98° after recrystallization from chloroform. The mixture melting point with the phenyl urethan above was not depressed.

**The Reaction of β-Propiolactone (I) with Sodium Phenoxides. General Procedure.**—β-Propiolactone (0.5 mole) was added over an eight-minute period to a solution of 0.5 mole of sodium hydroxide and 0.5 mole of the phenol in 200 ml. of water at 100° with stirring. The heat of reaction held the temperature during the addition of I and heat was then supplied to maintain the temperature for a total time of fifteen minutes. The solution was cooled to 30° with an ice-bath, and acidified with 50 ml. of concentrated hydrochloric acid. The colorless oil which separated was extracted with three 200-ml. portions of ether. The combined ether extract was shaken twice with 300-ml. portions of saturated sodium bicarbonate. The solids, which precipitated on acidification of the alkaline solution, were filtered, washed with water, dried and recrystallized from benzene–hexane. The yields, physical and analytical data for the β-phenoxypropionic acids are given in Table II.

**β-Thiophenoxypropionic Acid.**[7]—One mole (72 g.) of I was added dropwise (fifteen minutes) to 110 g. (1 mole) of thiophenol at 100–110° with stirring. After an additional hour the mixture was distilled at 5 mm. to give a crude fraction, b.p. 145–175°, of β-thiophenoxypropionic acid which solidified on cooling. This was crystallized from ether–petroleum ether. It formed small flat plates, m.p. 57–58°; yield 89 g. (49%).

*Anal.* Calcd. for $C_9H_{10}O_2S$: C, 59.31; H, 5.53; S, 17.59. Found: C, 59.21; H, 5.56; S, 17.68.

**Sodium β-Thiophenoxypropionate.**—One mole (72 g.) of I was added slowly to a stirred mixture of 41.7 g. (1 mole) of 97% sodium hydroxide and 110 g. (1 mole) of thiophenol in 200 ml. of water. The temperature was held at 10° during the addition and at room temperature

[a] % yields are for purified products. [b] Less than 1 g. of β-phenoxypropionic acid was lost due to water solubility when it was carried through the work-up procedure. Other reaction conditions and results were: The yield was not changed with increased time. The yield was lower (7.8%) at 50° in one hour and with less time it was still lower. Greater dilution (300 ml. water) gave decreased yield (16.9%). Increase in the ratio of sodium phenoxide to lactone (2:1) did not change the yield. [c] *Anal.* Calcd. for $C_9H_9O_5N$: N, 6.63. Found: N, *o*-, 6.62; *m*-, 6.57; *p*-, 6.59. [d] *Anal.* Calcd. for $C_9H_9O_3Cl$: Cl, 17.67. Found: Cl, *o*-, 17.60; *m*-, 17.67; *p*-, 17.59. [e] *Anal.* Calcd. for $C_9H_9O_3Br$: Br, 32.61. Found: Br, *o*-, 32.58; *p*-, 32.73. [f] Sodium phenoxide reactions at lower temperatures (30°) for one hour gave the following % yields with the cresols: *o*-, 5.0%; *m*-, 7.0%; *p*-, 5.8%. Although the yields of β-cresoxypropionic acids are lower, the ratio of yields is similar to that at 100°. [g] A above; six hours, 100°.

for an additional hour. The crystals which separated after acidification with 100 ml. of concentrated hydrochloric acid were filtered, washed with water, dried and recrystallized from ether–petroleum ether, m.p. 57–58°; yield, 166 g. (91%). The mixture melting point with the above sample was not depressed.

## Summary

β-Propiolactone reacts with phenol to give β-phenoxypropionic acid. In the presence of acid catalysts phenyl hydracrylate is formed. It reacts with sodium phenoxide to give sodium β-phenoxypropionate. The effects of nuclear substituents on these reactions are described. Thiophenol and its sodium salt react more rapidly but give similar products in higher yields.

# Carbon Alkylations with 1-Methylgramine and its Methiodide[1]

BY H. R. SNYDER AND ERNEST L. ELIEL[2]

In previous papers,[3] alkylations of sodium cyanide and acetamidocyanoacetic ester with the methiodide (I) of 1-methylgramine (II) have been described. These alkylations, which proceed much more readily than corresponding reactions of quaternary salts of benzyldimethylamine,[4,5] undoubtedly occur by a substitution mechanism. However, their existence does not constitute proof that the Mannich base itself (II), as well as the quaternary ammonium salt (I), is capable of reacting by any mechanism other than the elimination-addition scheme[3a] proposed for gramine.

Further experiments have now been undertaken to elucidate this point. The alkylation reactions of the methiodide (I) have been extended to ethyl malonate, ethyl cyanoacetate, ethyl cyanomalonate, and tricarbethoxymethane, all of which were alkylated in the form of the sodium salts. The intermediate esters were not isolated but were hydrolyzed to the substituted malonic acid (III). Decarboxylation of this acid, either thermally or in refluxing pyridine,[6] yielded 1-methylindole-3(β)-propionic acid (IV). In view of the allylic rearrangement observed in the alkylation of sodium cyanide with the salt (I),[3b] an unequivocal proof of the structure of IV was considered necessary. The structure was proved by a Curtius degradation *via* the methyl ester, hydrazide, and azide of IV; the azide was subjected to rearrangement in dry xylene, and the resulting isocyanate was converted directly into N-phthalyl-1-methyltryptamine by baking it with phthalic anhydride. The phthalimide thus obtained was identical with an authentic specimen. The possibility still exists that in

the alkylations with ethyl malonate and ethyl cyanoacetate small amounts of rearrangement products accompanying the major product (III) may have escaped detection, but in the other two alkylations the crude product (III) had essentially the same melting point as an analytically pure specimen, indicating that it was quite homogeneous.

Alkylations by 1-methylgramine (II) itself were found to proceed with ethyl cyanoacetate, ethyl acetamidomalonate, and tricarbethoxymethane. From an attempted alkylation of sodium cyanide in refluxing aqueous alcohol no neutral products could be obtained; 92% of the base (II) was recovered. Gramine under the same conditions yields indole-3-acetamide and indole-3-acetic acid.[7] The alkylation products from ethyl cyanoacetate and tricarbethoxymethane were identified by hydrolysis to the malonic acid (III). The product from ethyl acetamidomalonate was identified by hydrolysis and decarboxylation to N-acetyl-1-methyltryptophan.[3c] Some of the alkylation reactions were carried out in the presence of a trace of the sodium salt of the active methylene compound, and some without any added base. In one case (cyanoacetic ester) in which the reaction was carried out both with and without the sodium salt, it was noted that the presence of the sodium salt retards the speed of the reaction considerably and seems to have no appreciable effect on the yield of the alkylation product. Thus there seems to be some indication that the alkylation reaction is acid-base catalyzed.

Even with tricarbethoxymethane, which gave the highest yield of alkylation product, the overall yield of IV was only about 25%, while in a comparison experiment with gramine, skatylmalonic acid (V) was obtained in a yield of 67%. The yields from the other two alkylations were of the order of 15% and compare very unfavorably with the yields of the corresponding alkylation products from gramine.[5,8] Any explanation of the mechanism of the alkylation reaction must take this difference into account, but the fact that 1-methylgramine does act as an alkylating agent suggests that the elimination-addition mechanism[3a] is not *necessarily* the path of alkylations with Mannich bases of the gramine type.

The reactions of ethyl cyanoacetate and ethyl acetamidomalonate with II produced as a by-product (12–15% yield) a crystalline substance, the analysis of which indicated that it might be 1,1′-dimethyl-3,3′-diindolylmethane (VI). That the by-product is VI was proved by an unequivocal synthesis from $\alpha,\alpha'$-diketopimelic acid and *unsym*-methylphenylhydrazine; treatment of the dihydrazone of the diketo acid with hydrochloric acid (Fischer synthesis) yielded the dicarboxylic acid (VII) which was decarboxylated to VI in refluxing quinoline. A simpler, but less unequivocal synthesis of VI consists in the condensation of methylindole and formalin in the presence of acetic acid, which yields over 90% of VI.[9] The formation of VI from 1-methylgramine (II) involves a reversal of the Mannich reaction. Similar reactions are known in the case of phenolic Mannich bases, which undergo self-alkylation when treated with boiling dilute sodium hydroxide.[10] The self-alkylation of 1-methylgramine, however, does not seem to be brought about by base alone. The base II was recovered to the extent of 70% or more after prolonged heating at 225° in the presence of sodium methoxide and metallic sodium with or without the addition of an equal weight of 1-methylindole, and none of the condensation product VI could be isolated from these reactions. However, methylgramine *acetate* yielded 66% of the coupling product (VI) when refluxed in aqueous solution for one hour. Thus the self-condensation of 1-methylgramine appears to be acid-base catalyzed. Similar self-alkylations of other indole derivatives of the Mannich base type have been reported in the literature.[11]

Methylgramine methiodide (I) also underwent self-alkylation to VI when refluxed with aqueous sodium hydroxide or sodium acetate. In this case the formation of formaldehyde was demonstrated by its odor and by conversion to its methone derivative. Two experiments were devised to obtain evidence as to whether self-alkylation consists in a reverse Mannich reaction of part of the methiodide

(9) 1-Methylindole reacts with benzaldehyde at 100° in the presence of catalytic amounts of zinc chloride; the product is assumed to be 1,1′-dimethyl-3,3′-diindolylphenylmethane, but its structure has not been proved [Fischer, *Ber.*, **19**, 2988 (1886); *Ann.*, **242**, 372 (1887)].

(10) Auwers and Dombrowski, *Ann.*, **344**, 280 (1906).

(11) Passerini, *et al.*, *Gazz. chim. ital.*, **63**, 138 (1933); **65**, 933 (1935); Neri, *ibid.*, **64**, 420 (1934).

(I) followed by alkylation of the methylindole so formed by more of the quaternary salt (I), or whether two molecules of the methiodide couple and subsequently lose the elements of formaldehyde and trimethylamine. In one experiment a mixture of the quaternary salt (I), water, and sodium hydroxide was steam distilled in the hope of removing methylindole before it had an opportunity to react. However, no methylindole was found in the steam distillate. In another experiment, the methiodide (I), methylindole, and sodium hydroxide were refluxed in aqueous alcohol. The high yield of the product VI (98% of practically pure material if calculated on the basis of the methiodide alone) and the low recovery of methylindole make it almost certain that part of the methylindole was alkylated, but the evidence is not quite conclusive.

When the methiodide or the hydrochloride of 1-methylgramine was refluxed with water alone, an oily product soon separated and solidified on cooling; the solution contained free formaldehyde, as shown by the methone test. However, no homogeneous indole derivative could be isolated from this reaction.

## Experimental[12,13]

**Reaction of Methylgramine Methiodide (I) with Sodiomalonic Ester.**—Sodium (0.23 g., 0.01 atom) was dissolved in 8 g. of ethyl malonate at 80° in a two-necked flask equipped with a stirrer and an air-cooled condenser protected by a soda-lime tube. Three and three-tenths grams of I (0.01 mole) was added, the temperature was raised to 130–140°, and the mixture was stirred for ten hours. Trimethylamine was given off. At the end of the reaction period gas evolution had practically ceased. Stirring was continued for two hours at 140–150°. A solution of 10 g. of potassium hydroxide in 100 ml. of 80% ethanol was then added and the solution was refluxed for four and one-half hours. Fifty milliliters of water was added and most of the alcohol was distilled. The residual solution was decanted from some resin, boiled with Norite, filtered, and acidified with hydrochloric acid. An oily precipitate, which solidified on standing in the ice box overnight, was obtained. It was collected and dissolved in sodium bicarbonate solution and the solution was boiled with Norite, filtered with suction, acidified, and chilled as before. The brown solid (III) was collected, washed with water and dried; wt. 0.55 g. (22%), m. p. 165.5–167.5° (dec.). Repeated washings with chloroform and recrystallization from ethyl acetate–petroleum ether (b. p. 30–60°) raised the melting point to 172.5–173° (dec.).

*Anal.* Calcd. for $C_{13}H_{13}O_4N$: C, 63.14; H, 5.30. Found: C, 63.29, 63.55; H, ——, 5.48.

When absolute ethanol was employed as a solvent in the alkylation, the yield of III was essentially the same but the product was less pure.

**Reaction of Methylgramine Methiodide (I) with Sodiocyanoacetic Ester.**—Sodium (0.34 g., 0.015 atom) was dissolved in 8.4 g. (0.075 mole) of ethyl cyanoacetate. Five grams (0.015 mole) of I was added and the suspension was stirred at 125° for twelve hours. A solution of 15 g. of potassium hydroxide in 75 ml. of 80% ethanol was added and the mixture was refluxed for eleven hours. It was worked up as described for the reaction with sodiomalonic ester. The product was partly crystalline and partly resinous. The crystals weighed 0.65 g. (17.5%) and melted at 159–160° (dec.); two recrystallizations raised the melting point to 170–171° (dec.) and the mixed melting point with the product from malonic ester was 172–172.5° (dec.). The resinous part crystallized after several weeks and melted at 135–145° (dec.), weight 1.7 g.

**Reaction of Methylgramine Methiodide (I) with Ethyl Cyanomalonate Sodium Salt.**—A solution of 3.3 g. of I (0.01 mole) and 2.1 g. (0.01 mole) of ethyl cyanomalonate sodium salt[14] in 20 ml. of water was refluxed for one hour. There was a vigorous evolution of trimethylamine, and a viscous oil separated. The aqueous layer was decanted, filtered from a little solid material, and extracted with ether. The ether extract, the solid collected and the oily residue were combined and the ether was removed in a current of air. The residue was refluxed for six hours with 25 ml. of 10% aqueous sodium hydroxide solution. The solution was cooled, decanted from some resinous material, boiled with Norite, filtered with suction and acidified with hydrochloric acid. A crystalline precipitate appeared. The solution was chilled, and the precipitate was collected, washed with ice water and dried. There was obtained 1.25 g. (51%) of a light pink powder of m. p. 172–173° (dec.); the mixed melting point with III was 172–173° (dec.).

The use of absolute alcohol as a solvent in this alkylation did not affect the yield and quality of the product.

**Reaction of Methylgramine Methiodide (I) with Tricarbethoxymethane Sodium Salt.**—To a solution of 0.23 g. (0.01 atom) of sodium in 30 ml. of absolute alcohol were added 4.65 g. (0.02 mole) of tricarbethoxymethane[15] and 3.3 g. (0.01 mole) of I. The mixture was refluxed for one and one-half hours while a current of nitrogen was passed over it. There was a vigorous evolution of trimethylamine. Ten milliliters of 40% aqueous sodium hydroxide was added, followed, after ten minutes, by 10 ml. of water, while refluxing was continued. Trimethylamine evolution resumed for a short time. After two and one-fourth hours heating was discontinued, and the solution was concentrated *in vacuo*, extracted twice with ether, acidified with concentrated hydrochloric acid and chilled. Brown crystals separated. They were collected and dissolved in 15 ml. of a saturated solution of sodium carbonate and 25 ml. of water. The solution was boiled with Norite, filtered with suction, acidified with concentrated hydrochloric acid, and chilled. After having been thoroughly washed with ice water and dried, the light pink crystals (III) weighed 1.55 g. (62.5%), m. p. and mixed m. p. 171–172° (dec.).

When the alkylation was carried out in aqueous medium, the yield was only 34.5%.

**Decarboxylation of III.**—(a) Thermal: Fairly pure III of m. p. 165.5–167.5 (0.550 g.) was heated in an oil-bath at 180–190° until gas evolution ceased (about five minutes). The product was distilled in a short-path apparatus at 0.4 mm., bath temperature 150°. The yield of IV was 0.300–0.325 g. (67–72%), m. p. 123–125°. Recrystallization from benzene gave white platelets, m. p. 125.5–126°.

*Anal.* Calcd. for $C_{12}H_{13}O_2N$: C, 70.92; H, 6.45; N, 6.89. Found: C, 71.28; H, 6.65; N, 6.95.

When impure III (melting point around 140°) was decarboxylated, pure IV was obtained by sublimation, but the yield dropped to 38%.

(b) In Pyridine: Two grams of pure III was refluxed for twenty minutes in 20 ml. of pyridine. The pyridine was distilled *in vacuo*, and 20 ml. of 1:4 hydrochloric acid was added to the residue, which then crystallized promptly. The crystals were collected, washed with water, and dried; weight 1.47–1.56 g. (89.5–94.5%), m. p. 120.5–123.5°. Recrystallization from benzene raised the melting point to 124–126°.

**Curtius Degradation of IV.**—(a) Methyl Ester of IV: To 0.624 g. of IV dissolved in 30 ml. of ether was added an

(12) All melting points are corrected.

ethereal solution of diazomethane prepared from 2 g. of nitrosomethylurea.[16] There was an immediate evolution of nitrogen. The solution was allowed to stand for two hours, then a solution of glacial acetic acid in ether was added dropwise until the excess diazomethane was destroyed, as shown by decolorization of the solution. The ethereal solution was extracted twice with small portions of 10% sodium carbonate solution, which were then extracted with about 50 ml. of ether in a second separatory funnel. The ethereal solutions were washed with water, combined, dried over sodium sulfate and distilled. A viscous oil resulted which would not crystallize. It was distilled in a two-bulb microdistillation apparatus at 0.25 mm., bath temperature 180–190°, to yield 0.58 g. (83.5%) of a light yellow oil.

The picrate crystallized in dark red needles from methanol, melting point 98–99°.

*Anal.* Calcd. for $C_{19}H_{18}O_9N_4$: C, 51.12; H, 4.06. Found: C, 51.25; H, 4.33.

(b) Hydrazide of IV: A solution of 0.40 g. of the above ester in 4 ml. of methanol was refluxed for twenty hours with 0.75 ml. of 85% hydrazine. On concentration of the solution the hydrazide crystallized. It was collected, washed with aqueous methanol and dried. The yield was 0.32 g. (80%), m. p. 135.5–136.5°. Recrystallization of a sample from benzene containing a little absolute ethanol yielded fine white needles of melting point 136.5–137.5°.

*Anal.* Calcd. for $C_{12}H_{15}N_3O$: C, 66.32; H, 6.97. Found: C, 66.28; H, 6.81.

**(c) N-Phthalyl-1-methyltryptamine.**—Two milliliters of a solution of 0.6 ml. of concentrated hydrochloric acid in 10 ml. of water was cooled to 10° and there was added to it, in succession, 0.175 g. of the above hydrazide, 2 ml. of ether, and 0.2 ml. of a 37.5% solution of sodium nitrite in water. After thorough shaking, the layers were separated, and the aqueous layer was twice more extracted with small portions of ether. The ether layers were washed with sodium bicarbonate solution followed by water; they were then combined and dried over calcium chloride. Five milliliters of xylene was added and the ether and part of the xylene were distilled *in vacuo*. The xylene solution was then refluxed for a short time, 0.2 g. of phthalic anhydride was added, and refluxing was continued for a total of two hours. The xylene was distilled and the residue was heated to 240°. It was then allowed to cool somewhat and 3 ml. of ethanol was added. The tan crystals which appeared when the solution was cooled weighed 0.050 g. After one recrystallization the derivative melted at 172–175°. Two further recrystallizations from the same solvent raised the melting point to 174.5–176.5°. The mixed melting point with an authentic sample of the phthalimide[3a] of melting point 176.5–177° was 176–176.5°. The two samples were indistinguishable under the microscope and their infrared spectra were essentially identical.[17]

**Reaction of 1-Methylgramine (II) with Cyanoacetic Ester.**—In the presence of sodium: To a solution of 3.8 g. (0.02 mole) of 1-methylgramine in 6.8 g. (0.06 mole) of ethyl cyanoacetate 25 mg. of sodium was added and the mixture was heated at 150° for twenty-four hours in a flask equipped with a short air condenser. Additional 25-mg. portions of sodium were added at the end of five and eighteen hours. A basic gas was evolved. When the gas evolution had ceased at the end of twenty-four hours, the reaction mixture was cooled and 50 ml. of 1 *N* hydrochloric acid was added. The mixture was extracted twice with 70-ml. portions of ether. No unchanged methylgramine was recovered when the aqueous layer was made alkaline. The ether layers were washed twice with water, combined, dried over sodium sulfate, and the solvent was distilled. The residue was hydrolyzed by refluxing overnight with a solution of 10 g. of potassium hydroxide in 50 ml. of 80% ethanol. Forty milliliters of water was then added and most of the ethanol was distilled. The residue was extracted with ether, boiled with Norite, filtered with suction, acidified with hydrochloric acid and chilled. The acid was partly resinous and partly crystalline. The crystals were collected, washed, and dried; weight 0.2 g., m. p. 164.5–165.5° (dec.). Three recrystallizations raised the melting point to 171.5–172° (dec.); the mixed melting point with III was 172–172.5 (dec.). Decarboxylation of the acid yielded IV, identified by melting point and mixed melting point. The resinous part crystallized after standing in the ice box for several weeks; weight 1.3 g., m. p. 139.5–147.5° (dec.). The over-all yield of very impure material was 1.5 g. (30%), which corresponds to about 15% of pure material, as shown by the fact that the low-melting material gave a 38% yield of IV upon decarboxylation.

The ether solution containing the unsaponifiable reaction products was distilled to give a brown residue, which recrystallized on standing. Recrystallization from 95% ethanol yielded 0.3 g. of crystals of melting point 92–96°. Four more recrystallizations from 95% ethanol (Norite was used in the second) gave pure 1,1′-dimethyl-3,3′-diindolylmethane (VI) melting at 109.5–111.5°.

*Anal.* Calcd. for $C_{19}H_{18}N_2$: C, 83.16; H, 6.61; N, 10.21. Found: C, 83.06, 83.06; H, 6.60, 6.75; N, 10.31, 10.19.

The dipicrate was obtained by dissolving the parent substance in benzene, adding an excess of a saturated solution of picric acid in benzene, allowing the solution to evaporate, and digesting the residue with absolute ethanol to remove excess picric acid. The material was recrystallized from benzene–petroleum ether (b. p. 30–60) as dark red crystals melting at 112–113°.

*Anal.* Calcd. for $C_{31}H_{24}N_8O_{14}$: C, 50.81; H, 3.30. Found: C, 51.05; H, 3.43.

Without sodium: A solution of 3.8 g. (0.02 mole) of II and 3 g. (0.03 mole) of methyl cyanoacetate was heated at 135–150° for two hours. There was a very vigorous evolution of a basic gas, which practically ceased at the end of one and one-half hours. The reaction product was hydrolyzed by refluxing it overnight with a solution of 6 g. of potassium hydroxide in 50 ml. of water. The solution was cooled, decanted from undissolved material, extracted with ether, boiled with Norite, filtered with suction and acidified. A dark oil separated which solidified on standing in the ice box for several days. It was collected, washed with water and dissolved in acetone (there was no acetone-insoluble material). The acetone was distilled and the residue was decarboxylated by heating it at 180–190° until no more gas was given off. The decarboxylated acid was evaporatively distilled at 0.1 mm., bath temperature 135–205°. There was obtained 1.24 g. of crystals of m. p. 101–115°. Recrystallization from benzene yielded 0.71 g. (17.5%) of IV, m. p. and mixed m. p. 124.5–126°. No further amount of pure material could be recovered from the mother liquors.

The neutral residue of the saponification was taken up in ethyl acetate and added to the ether extract of the alkaline saponification mixture. The combined solutions were dried over sodium sulfate and concentrated. The addition of alcohol to the concentrate yielded 0.225 g. of crystals (VI); m. p. 106.5–110.5°; there was no depression in melting point when the crystals were mixed with the analytical sample obtained as described above. The mother liquors yielded a second crop weighing 0.035 g. of m. p. 105.5–109°; total yield 0.260 g. (9.5%).

**Reaction of 1-Methylgramine (II) with Acetamidomalonic Ester.**—A solution of 3.8 g. (0.02 mole) of II, 8.7 g. (0.04 mole) of ethyl acetamidomalonate and *ca.* 25 mg. of sodium was heated under nitrogen for twenty-four hours at 115–120° and for fifteen hours at 140–145° in a flask equipped with a short air condenser. A basic gas was evolved. The solution was cooled and the resulting syrup was taken up in 60 ml. of ether and extracted with 1 *N* hydrochloric acid. When the aqueous extract was made alkaline, no methylgramine was liberated. The

(16) Arndt, "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 166.

(17) The authors are indebted to Mrs. Agatha Johnson for the absorption studies.

ether solution was washed with water, dried over sodium sulfate, and concentrated. The residual amber sirup could not be crystallized. It was hydrolyzed by refluxing for three hours with 7 g. of potassium hydroxide in 7 ml. of water and 63 ml. of 95% ethanol. Thirty-five milliliters of water was added and most of the ethanol was distilled. The aqueous solution was extracted twice with 50-ml. portions of ether, boiled with Norite, filtered with suction, acidified with hydrochloric acid and chilled. A partly crystalline and partly resinous precipitate resulted. The crystalline material (presumably the alkylated acetamidomalonic acid) was collected, washed, and dried; it weighed 0.23 g. (3.8%). It was recrystallized once from absolute ethanol–acetone–benzene–petroleum ether and melted at 110.5–111.5° (dec.); it was not further purified.

When 40 mg. of this material was refluxed with *ca.* 3 ml. of water for four hours, white crystals of melting point 171–172° separated on cooling. The mixed melting point with N-acetyl-1-methyltryptophan[30] was 171–172.5°.

The resinous part of the malonic acid was collected by decantation and washed with water. It was refluxed with water for three and one-half hours and filtered to remove some resin. On cooling, the filtrate deposited tan crystals which were collected and dried; weight 0.40 g. (7.7%), m. p. 166.5°. Recrystallization from acetone–benzene (Norite) raised the melting point to 169–171°; the mixed melting point with N-acetyl-1-methylptryptophan was 169.5–171°.

The ether solution containing the unsaponifiable reaction products was concentrated and the residue was crystallized from 95% ethanol (Norite) to yield 0.25 g. of crystals (VI) of melting point 107.5–111° and 0.15 g. of impure material. Recrystallization from petroleum ether (b. p. 60–90°) raised the melting point to 108.5–111°. The mixed melting point with the neutral material obtained from the ethyl cyanoacetate reaction was 108.5–111°.

An attempt was made to condense II with acetamidomalonic ester in boiling xylene in the presence of sodium hydroxide,[8] but no crystalline materials could be obtained from the condensation under these conditions.

**Reaction of 1-Methylgramine (II) with Tricarbethoxymethane.**—A solution of 3.8 g. (0.02 mole) of II in 10.8 g. (0.05 mole) of tricarbethoxymethane[14] was heated under nitrogen at 160–170° for three hours. A basic gas was evolved. A solution of 20 g. of potassium hydroxide in 20 ml. of water and 160 ml. of 95% ethanol was added and the mixture was refluxed for six hours. One hundred and sixty milliliters of water was added and most of the ethanol was distilled. The solution was cooled, extracted with ether, boiled with Norite, filtered with suction, acidified with concentrated hydrochloric acid, and allowed to stand in the ice box for five days. The precipitate was partly crystalline and partly resinous. The crystals were collected, washed and dried; weight 0.51 g., m. p. and mixed m. p. (with III) 165.5–168° (dec.). Much of the non-crystalline portion dissolved in acetone, leaving 0.30 g. of crystals, apparently the mono-potassium salt, which melted around 250° after darkening around 200°. The crystals were dissolved in water (in which they were readily soluble) and hydrochloric acid was added to the solution. There was obtained 0.22 g. of crystals of melting point 173–175° (dec.); mixed m. p. with III 171–172° (dec.). The total yield of III was 0.73 g. (15%).

The acetone wash was concentrated, and the resinous residue was decarboxylated at 180–190° and sublimed at 0.1 mm. The sublimate was dissolved in sodium carbonate solution; the solution was extracted twice with ether, boiled with Norite, filtered, acidified, and chilled. It yielded 0.34 g. (8.5%) of crystals of IV; melting point and mixed melting point 122.5–124.5°.

**Attempted Reaction of 1-Methylgramine (II) with Sodium Cyanide.**—A solution of 3.8 g. of II and 5 g. of sodium cyanide in 10 ml. of water and 40 ml. of 95% ethanol was refluxed for eighty-four hours. Part of the ethanol was distilled, 50 ml. of water was added, and the emulsion was twice extracted with 100-ml. portions of ether.

The aqueous portion was boiled with Norite, filtered, and acidified with concentrated hydrochloric acid (hood!). There was no separation of organic material.

The ether layers were washed once with water, extracted with three 25-ml. portions of 1 *N* hydrochloric acid, washed with water, dried, and distilled. The residue weighed less than 0.1 g.

The acid layer was made alkaline with 10% sodium hydroxide, and extracted twice with 50-ml. portions of ether. After having been dried, the ether was distilled from 3.5 g. of 1-methylgramine (92% recovery) identified by its picrate (melting point 145.5–146°, mixed melting point 145.5–146.5°).

**Reaction of Gramine with Tricarbethoxymethane.**—A solution of 3.5 g. (0.02 mole) of gramine in 10.8 g. (0.05 mole) of tricarbethoxymethane[14] was heated under nitrogen at 115–120° for an hour and at 125–130° for an hour. There was a vigorous evolution of a basic gas, which ceased at the end of the heating period. Hydrolysis was effected by refluxing the product for six hours with a solution of 20 g. of potassium hydroxide in 20 ml. of water and 160 ml. of 95% ethanol. One hundred and forty milliliters of water was added and most of the ethanol was distilled. The solution was filtered, extracted with ether, boiled with Norite, filtered with suction and acidified with concentrated hydrochloric acid. After one week in the ice box the solution had deposited crystals which were collected, washed with ice water and dried; weight 1.26 g., m. p. 165.5–167.5° (dec.). Concentration of the mother liquors in a current of air led to the separation of a second crop; weight 1.79 g., m. p. 160–163° (dec.). The total yield was 3.05 g. (67%). Recrystallization from water (Norite) raised the melting point to 175.5–177° (dec.) [(lit.[5] 178° (dec.); lit.[18] 188–189° (dec.)].

Decarboxylation in Pyridine: The above acid (V) (0.60 g.) was decarboxylated in exactly the same manner as described for the acid III. There was obtained 0.38 g. (78%) of indole-3($\beta$)-propionic acid, m. p. 129.5–132.5°. Recrystallization from water raised the melting point to 133–134° (lit.[5] 132–133°, lit.[18,19] 134°).

**1,1′-Dimethyl-2,2′-dicarboxy-3,3′-diindolylmethane (VII).**—Methylenebisoxalacetic ester was obtained from oxalacetic ester and formaldehyde by the method of Blaise and Gault.[20] To convert it into $\alpha,\alpha'$-diketopimelic acid, 28 g. of the hydrate of methylenebisoxalacetic ester, 28 ml. of water and 12 ml. of concentrated hydrochloric acid were refluxed until the solution had become homogeneous (one hour). The solution was neutralized with 10% aqueous sodium hydroxide and then acidified slightly with a few drops of glacial acetic acid. The addition of 6 ml. of *unsym*-methylphenylhydrazine in 25 ml. of water containing sufficient glacial acetic acid to make a homogeneous solution caused the separation of a dark oil. The mixture was allowed to stand for two hours, the aqueous phase was decanted, and the residue was washed once with water by decantation. The water layers were extracted with ether, and the ether layer was combined with the water-insoluble oil. The ether was removed in a current of air, and the residue was swirled on the steam-bath with 45 ml. of water and 15 ml. of concentrated hydrochloric acid until it had solidified and then for five minutes longer. The suspension was chilled and the solid was collected. It was then dissolved in a slight excess of 5% aqueous sodium hydroxide. The aqueous solution was extracted with ether, boiled with Norite, filtered with suction, acidified with concentrated hydrochloric acid and chilled. Slightly tan crystals separated. They were collected, washed with ice-water and dried; weight 2.5 g. (40%), m. p. 202–203.5° (dec.). Four recrystallizations from acetone–alcohol raised the melting point to 227–228° (dec.).

*Anal.* Calcd. for $C_{21}H_{18}N_2O_4$: C, 69.58; H, 5.01; N, 7.73. Found: C, 69.71; H, 5.30; N, 7.92.

**1,1′-Dimethyl-3,3′-diindolylmethane (VI).**—From VII: A solution of 0.250 g. of VII (m. p. 226–227°) in 2.5

(18) Maurer and Moser, *Z. physiol. Chem.*, **161**, 131 (1926).

(20) Blaise and Gault, *Bull. soc. chim.*, [4] **1**, 78 (1907).

ml. of distilled quinoline was refluxed for ten minutes. It was cooled and taken up in *ca.* 25 ml. of ether. The ether solution was washed five times with 10-ml. portions of 1 *N* hydrochloric acid, five times with 5-ml. portions of 2.5% sodium hydroxide and twice with water. It was dried over sodium sulfate, the solvent was distilled, and the residue was crystallized from 95% ethanol. There was obtained 0.045 g. (20%) of white crystals; melting point 107.5–110°. Recrystallization from 95% ethanol raised the melting point to 109.5–111.5°. The mixed melting point with the material obtained in the alkylation reactions (described above) was the same, and the two samples had the same crystalline aspect under the microscope.

1,1′-Dimethyl-3,3′-diindolylmethane is very sensitive to both air and acids. When exposed to the atmosphere it turns pink. Ordinary Darco could not be used to decolorize solutions of VI, as it turns them bright red. Ammonia washed Darco was found satisfactory for decolorization purposes.

**From Methylindole.**—To 1 ml. (1.07 g.) of methylindole dissolved in 2 ml. of glacial acetic acid, 1 ml. of 40% aqueous formalin was added, and the reagents were mixed by shaking. The mixture warmed up and after a few minutes became heterogeneous and crystallized in part. The crystals were collected, and the non-crystalline, viscous portion was treated with a mixture of 95% ethanol and ethyl acetate, whereupon it also crystallized. The combined crystals were washed with 95% ethanol and dried. By reworking the mother liquors a total yield of 1.05 g. (94%) of VI of melting point 100.5–108.5° was obtained. Two recrystallizations from 95% ethanol (with ammonia-washed Darco in the first) raised the melting point to 108.5–110.5°. The mixed melting point with samples obtained by other methods (see above) was the same.

**From I.**—(a) A solution of 3.3 g. of I and 5 g. of the trihydrate of sodium acetate in 25 ml. of water was refluxed for three hours. Trimethylamine was evolved. The emulsion was cooled and extracted with ether. The ether layer was dried and concentrated and the residual oil was crystallized from 95% ethanol containing a little ethyl acetate. The crystals were collected, washed with 95% ethanol and dried; weight 1.19 g. (87%), m. p. 93–105.5°. Recrystallization from ether–petroleum ether (b. p. 30–60°) followed by two recrystallizations from 95% ethanol raised the melting point to 108.5–111.5°. There was no depression of melting point on admixture with samples of VI obtained by other methods.

Formaldehyde was identified in the aqueous layer by its odor and by the melting point of its methone derivative obtained by adding an alcoholic solution of methone to the aqueous layer; melting point and mixed melting point 190.5–191.5°.

(b) A solution of 3.3 g. of I and 1.5 ml. of 40% aqueous sodium hydroxide in 18.5 ml. of water was steam distilled for one hour. The distillate did not have the odor of methylindole. It was extracted with ether, and the ether was dried over sodium sulfate and distilled. There was a small amount of viscous residue which had none of the properties of 1-methylindole.

The residue, which contained a water-insoluble oil, was extracted with ethyl acetate. The ethyl acetate solution was concentrated by evaporation until crystals began to form; 95% ethanol was then added, and the mixture was chilled. The crystals were collected, washed with cold 95% ethanol, and dried; weight 0.87 g. (63.5%), m. p. 107.5–110°.

(c) A solution of 3.30 g. (0.01 mole) of I, 1.31 g. (0.01 mole) of 1-methylindole and 1.5 ml. of 40% aqueous sodium hydroxide in 7.5 ml. of water and 17.5 ml. of 95% ethanol was refluxed for six hours. The mixture was then steam distilled until the odor of methylindole in the residue was very faint. The distillate was extracted with ether and the ether was dried and distilled. The residue, after brief drying at 100° and 15 mm. pressure, weighed 0.64 g. It was distilled at 15 mm., air-bath 140–160°. The distillate was somewhat impure 1-methylindole ($n^{20}D$ 1.6029, melting point of crude picrate[21] 135.5–138.5°) and weighed 0.53 g. (40.5% recovery). There was a distillation residue of 0.06 g.

The residue of the steam distillation was extracted with ethyl acetate and worked up as described before; yield 1.34 g. of VI (98% if based on I alone), m. p. 107–110°. When the experiment was repeated, the yield was 1.28 g. of material of melting point 108.5–110.5° and 0.08 g. of melting point 102.5–107.5°.

When the alcoholic mother liquor was evaporated to dryness, and the residue was dried *in vacuo* (15 mm.) at 100°, 0.81 g. of a viscous oil remained. This oil was only very slightly soluble in cold 95% ethanol and could therefore not have contained much 1-methylindole.

(d) A solution of 1.12 g. (0.005 mole) of methylgramine hydrochloride[22] and 0.68 g. (0.005 mole) of sodium acetate trihydrate in 10 ml. of water was refluxed for one hour. The resulting mixture had a strong formaldehyde odor and contained an oil which crystallized on cooling. The solid was extracted with ethyl acetate, and the ethyl acetate extract was dried over sodium sulfate and evaporated in a current of nitrogen. The concentrate crystallized. Ethanol was added to it and the crystals were collected, washed with 95% ethanol and dried; weight 0.45 g. (66%), melting point and mixed melting point with samples obtained by other routes, 110–112°.

When the aqueous layer of the reaction mixture was made alkaline, some unchanged methylgramine separated and a basic gas (presumably dimethylamine) was liberated.

When a solution of 0.6 g. of methylgramine and 0.44 g. of sodium acetate trihydrate in 10 ml. of 50% ethanol was refluxed for one hour, there was no noticeable evolution of formaldehyde or dimethylamine, and no neutral material was formed. Methylgramine (77%, isolated as the hydrochloride) was recovered.

**Behavior of Methylgramine Methiodide and of Methylgramine Hydrochloride in Boiling Water.**—One gram of I was refluxed for one hour with 10 ml. of water. An oil separated and solidified on cooling. It was collected and dried; weight 0.35 g., m. p. 77–99°. Attempts to obtain a homogeneous substance from this material failed. The water solution contained formaldehyde, identified by its methone derivative, melting point and mixed melting point 188.5–190.5°.

The hydrochloride of II under the same conditions yielded an intractable white solid of melting point 50–90°. The water solution contained formaldehyde, identified by its odor and methone derivative. When it was made alkaline, a basic gas of ammoniacal odor (presumably dimethylamine) was given off.

**Thermal Stability of Gramine and of 1-Methylgramine.** When gramine was heated above its melting point, dimethylamine was evolved copiously and a brown resin resulted.

Heating of 1-methylgramine (1 g.) in the presence of small amounts of sodium methoxide and metallic sodium at 150–155° for four hours, then at 215–225° for nine hours, and finally at 160° for twelve hours, yielded an oil which was almost entirely soluble in 1 *N* hydrochloric acid. Extraction of the acid solution with ether yielded only a trace of neutral material. When the acid solution was made alkaline and extracted with ether, there was recovered 0.7 g. (70%) of 1-methylgramine, identified by its picrate, melting point 138.5–143.5° and after recrystallization 144–145.5°.

**Attempted Reaction of 1-Methylgramine (II) with 1-Methylindole.**—One gram of II, 1 g. of 1-methylindole and a trace of sodium methoxide were heated for four hours at 150–155°, for nine hours at 215–225° and then for twelve hours at 160°. The oil was cooled and dissolved in ether. The ether solution was exhaustively ex-

(21) The melting point of the picrate of 1-methylindole recorded in the literature is 150°, but we have never obtained specimens melting higher than 143.5–144.5° from pure 1-methylindole.

(22) For details of the preparation of this hydrochloride see Snyder and Eliel, THIS JOURNAL, **70**, 4233 (1948).

tracted with 1 *N* hydrochloric acid. The neutral products, obtained by distillation of the ether, weighed 0.77 g., were entirely soluble in cold petroleum ether, and yielded a picrate of melting point 141.5–143.5°, indicating that the material was practically pure 1-methylindole. The alkaline fraction, recovered by making the acid extract alkaline and extracting with ether, weighed 0.90 g. (90% recovery) and yielded a picrate of melting point 135.5–137.5°. Two recrystallizations from 95% ethanol raised the melting point to 140–141.5°; mixed melting point with the picrate of II, 144–145.5°.

## Summary

The sodium salts of ethyl malonate, ethyl cyanoacetate, ethyl cyanomalonate and tricarbethoxymethane have been alkylated with 1-methylgramine methiodide. The highest yield (62.5%) of the substituted malonic acid was obtained by saponifying the alkylation product of tricarbethoxymethane. Decarboxylation of the substituted malonic acid in refluxing pyridine gave a 90% yield of 1-methylindole-3(β)-propionic acid, whose structure was proved by a Curtius degradation.

Ethyl cyanoacetate, ethyl acetamidomalonate, and tricarbethoxymethane have been alkylated with 1-methylgramine. The yields of alkylation products are consistently lower than in the case of corresponding alkylations with gramine.

As a by-product in the alkylations with 1-methylgramine, 1,1′-dimethyl-3,3′-diindolylmethane was obtained. The structure of this product has been proved by unequivocal synthesis. The same product was obtained from methylindole and formaldehyde in the presence of acetic acid, from 1-methylgramine methiodide and aqueous sodium hydroxide or sodium acetate, and from 1-methylgramine hydrochloride and aqueous sodium acetate.

1-Methylgramine was found to be much more stable to heat than gramine.

# The Preparation of 1-R-5-(2-Thienyl)-hydantoins

BY LOREN M. LONG, C. A. MILLER AND GRAHAM CHEN

We have reported the synthesis and pharmacological activity of a series of 1-R-5-R′-5-phenylhydantoins[1] which may be represented by formula I. As reported in that paper, the more effective compounds in regard to protection against electrically induced convulsions are those in which R represents a short chain hydrocarbon group while R′ represents hydrogen.

I

II

Although our evidence to date does not indicate that the mere substitution of the 2-thienyl group for the phenyl group in physiologically active compounds is likely to lead to derivatives of greatly increased activity, the comparison of such related series is of interest and is sometimes necessary for patent purposes. For these reasons we decided to prepare the 2-thienyl derivatives represented by formula II in which R represents an alkyl, alkenyl, cycloalkyl or aralkyl group.

The only series of thiophene-containing hydantoins previously reported was prepared by Spurlock.[2] This series consists of 5-R-5-(2-thienyl)-hydantoins where R may be an alkyl or a phenyl group. Careful studies[3] recently made employing the electroshock method with cats have indicated that at best these derivatives are equal in activity to the corresponding phenyl compounds and that as a rule they are inferior. Final proof of relative therapeutic effectiveness, however, must await clinical studies.

The compounds summarized in Table I were prepared by the general method outlined in the earlier paper.[1] 2-Thiophenealdehyde was treated with an amine and the resulting thenylidene R-amine was converted to the corresponding aminonitrile by the addition of hydrogen cyanide. Treatment with cyanic acid yields the desired hydantoin. The various intermediates were not isolated. As indicated in Table I, in most instances the yields were inferior to those obtained with benzaldehyde. No attempt was made to improve the method, as sufficient material for testing was obtained in each case.

**Pharmacology.**—Most of the compounds herein reported have been tested both for inhibition of electrically induced convulsions in cats and metrazol-induced convulsions in rats. The activities listed in Table I indicate that the lower members of the series are the more effective anticonvulsants. This is in accord with the results obtained with the corresponding phenyl derivatives reported in the earlier publication.[1]

In each case, those compounds exhibiting an activity of 4+ when administered to cats in doses of 100 mg./kg. showed a lower activity at 50 mg./kg. Thus, no member of the series is as active as Dilantin.[4]

(1) Long, Miller and Troutman, THIS JOURNAL, **70**, 900 (1948).

(2) Spurlock, U. S. Patent 2,366,221.

(3) Chen and Ensor, unpublished data.

(4) Dilantin, registered trade-mark of Parke, Davis & Co. for 5,5-diphenylhydantoin.

TABLE I

1-R-5-(2-THIENYL)-HYDANTOINS

| R | M. p., °C. | Yield, % | Formula | Nitrogen, % Calcd. | Found | Activity: Electro-shock[a] | Activity: Metrazol[b] |
|---|---|---|---|---|---|---|---|
| Methyl | 163–164 | 38 | $C_8H_8N_2O_2S$ | 14.28 | 14.29 | + | 4+/250 mg. |
| Ethyl | 163–165 | 49 | $C_9H_{10}N_2O_2S$ | 13.33 | 13.37 | 4+ | 3+/50 mg. |
| Propyl | 109–110 | 47 | $C_{10}H_{12}N_2O_2S$ | 12.49 | 12.68 | 4+ | 3+/125 mg. |
| Isopropyl | 173–174 | 28 | $C_{10}H_{12}N_2O_2S$ | 12.49 | 12.47 | 2+ | 4+/250 mg. |
| Allyl | 105–106 | 48 | $C_{10}H_{10}N_2O_2S$ | 12.61 | 12.38 | 4+ | 4+/125 mg. |
| Butyl | 123–125 | 47 | $C_{11}H_{14}N_2O_2S$ | 11.76 | 12.01 | + | 4+/250 mg. |
| *s*-Butyl | 148–150 | 7 | $C_{11}H_{14}N_2O_2S$ | 11.76 | 12.14 | | |
| 1-Methylbutyl | 136–137 | 14 | $C_{12}H_{16}N_2O_2S$ | 11.11 | 11.14 | | +/250 mg. |
| Cyclohexyl | 181–183 | 2 | $C_{13}H_{16}N_2O_2S$ | 10.60 | 10.60 | | |
| Benzyl | 191–193 | 35 | $C_{14}H_{12}N_2O_2S$ | 10.29 | 10.29 | + | 4+/500 mg. |
| Phenethyl | 156–157 | 61 | $C_{15}H_{14}N_2O_2S$ | 9.79 | 9.75 | + | 3+/250 mg. |

[a] These results were obtained with an oral dose of 100 mg. for each compound. For a discussion of the method see Putnam and Merritt, *Science*, 85, 525 (1937). [b] An activity of 4+ means that five out of five rats are completely protected against a convulsive dose of metrazol.

Although the activity against metrazol is obtained without evidence of depression, doses at higher levels than those given in Table I induce appreciable hypnosis. Such hypnotic activity is an undesirable characteristic when possessed by potential anticonvulsant compounds.

## Experimental

**Material.**—The 2-thiophenealdehyde employed in the preparation of all of the compounds listed in Table I was obtained from Arapahoe Chemicals, Inc. It was used without further purification. The various amines were supplied by Eastman Kodak Co. or by Sharples Chemicals Inc.

**1-Propyl-5-(2-thienyl)-hydantoin.**—Except for minor details the preparation of this compound is typical of the series. Aqueous solutions of methylamine and ethylamine were used in preparing the first two members of the series while anhydrous amines were added to aqueous mixtures of 2-thiophenealdehyde in all other preparations. The precipitation of 1-methyl-5-(2-thienyl)-hydantoin from aqueous alkali is best carried out by the addition of hydrochloric acid while carbon dioxide, either gaseous or solid, is completely satisfactory for precipitating the remaining members of the series.

To a mixture of 33.6 g. (0.3 mole) of 2-thiophenealdehyde and 30 ml. of water in a small flask fitted with a mechanical stirrer, a reflux condenser and a dropping funnel was added 18.9 g. (0.32 mole) of propylamine over a period of fifteen minutes. The mixture became quite warm. Stirring was continued for one hour and then the flask was immersed in an ice-bath.

In another flask, equipped with a stirrer and a thermometer, 125 ml. of 80% aqueous acetic acid was cooled to 0°. With slow stirring 22.8 g. (0.35 mole) of potassium cyanide was added in portions so that the temperature remained below 8°. When the addition was complete, stirring was continued until the temperature was 0°.

The cold solution was stirred while the mixture of thenylidene propylamine and water was added at a fairly rapid rate. The temperature remained below 5°. When the addition was complete, the mixture was allowed to cool to −5°. At this point 27 g. (0.32 mole) of potassium cyanate was added rapidly. There was a slight rise in temperature. The mixture was stirred for one-half hour while being cooled and then for an additional half hour at room temperature.

The mixture was again cooled to 0° and 100 ml. of concentrated hydrochloric acid was added dropwise, the temperature remaining below 15°. Stirring was continued for one-half hour followed by heating on a steam-bath for another half hour. The hot mixture was poured into 300 g. of chipped ice. A thick yellow liquid precipitated which solidified after several minutes. The solid product was filtered off and purified by solution in 300 ml. of 5% aqueous sodium hydroxide, charcoaling and reprecipitation with carbon dioxide. Recrystallization from benzene and ligroin resulted in only a slight increase in melting point.

**Acknowledgment.**—The authors wish to thank Mr. A. W. Spang for the analytical data recorded in Table I and Mr. Charles R. Ensor and Mrs. Isobel G. Clarke for technical assistance in determining the anti-convulsant activity of the compounds reported herein.

## Summary

A series of 1-R-5-(2-thienyl)-hydantoins has been prepared and tested for anticonvulsant activity. Those derivatives containing not more than three carbon atoms in the 1-substituent are the more active members of the series against electrically induced and metrazol-induced convulsions.

# The Influence of N-Methylation upon the Electrical Conductivity of Dodecylammonium Chloride

BY A. W. RALSTON, F. K. BROOME AND H. J. HARWOOD

The substitution of the hydrogens of ammonia by alkyl groups is attended by an increase in basicity,[1] and Hall and Sprinkle[2] have shown that the introduction of one alkyl group into ammonia brings about a decided increase in basicity, a second alkyl group results in only a slight, further increase, whereas a third alkyl group produces a slight drop in basicity. The ionization constants of the tertiary amines are therefore comparable to those of the primary amines and are appreciably lower than those of the secondary amines. The long-chain, symmetrical secondary amines have been reported[3] to have much higher ionization constants than the primary amines, the values observed being essentially independent of the lengths of the hydrocarbon chains. The introduction of a fourth alkyl, or other hydrocarbon radical, into the amine molecule, with the formation of the quaternary ammonium compounds is accompanied by a profound change in the chemical and physical properties.[4] Certain of the quaternary ammonium bases, for example, tetramethylammonium hydroxide, are among the strongest bases known. In view of these facts we have undertaken a critical study of the effects of methylation upon the physical properties of dodecylammonium chloride and have studied the solubilities in water and in a number of organic solvents and also the electrical conductivities of aqueous solutions of dodecyl-, methyldodecyl-, dimethyldodecyl-, and trimethyldodecylammonium chlorides. This present paper reports the electrical conductivities of aqueous solutions of these compounds and compares their tendency toward colloid formation as portrayed by their conductivities. To our knowledge, no such studies have been previously made upon a comparable series of compounds.

## Experimental

**Preparation of Methyldodecylammonium Chloride.**—Dodecyl chloride was prepared from dodecyl alcohol (f.p. 24.0°) by treatment with gaseous hydrogen chloride using zinc chloride as the catalyst. Methylamine was purified as the benzal derivative. The reaction of the dodecyl chloride (331 g., 1.62 moles) with 458 g. of an ethanol solution containing 218 g. (7.04 moles) of methylamine was accomplished by heating the reactants in an autoclave at 125° for eight hours. After addition of 60 g. of sodium hydroxide, the excess methylamine was removed by distillation and the methyldodecylamine extracted with Skellysolve B and dried over potassium carbonate. Distillation through a Vigreux column yielded 258 g. (80%) of methyldodecylamine, b.p. 80–85° (0.4 mm.) and 56 g. (19%) of methyldidodecylamine, b.p. 180–185° (0.4 mm.). Purification of the methyldodecylamine was accomplished by fractionation through a Stedman-packed column. A fraction of the methyldodecylamine (f. p. 16.5°) was converted to the hydrochloride by treating its benzene solution with gaseous hydrogen chloride. The salt was recrystallized from benzene containing a little methanol.

*Anal.* Calcd.: N, 5.94. Found: N, 5.99.

**Preparation of Dimethyldodecylammonium Chloride.**—Dimethyldodecylamine was prepared in the manner previously described.[5] A fraction was converted to the hydrochloride by treatment of its ether solution with gaseous hydrogen chloride. The salt was recrystallized from ethyl acetate.

*Anal.* Calcd.: N, 5.61. Found: N, 5.68.

The conductivities were determined in the manner and with the equipment previously described.[6]

## Results and Discussion

The equivalent conductivities at 30° plotted against $\sqrt{N_V}$ of aqueous solutions of dodecyl-, methyldodecyl-, dimethyldodecyl- and trimethyldodecylammonium chlorides are shown in Fig. 1. The values for dodecylammonium chloride have been taken from a recent publication.[7] The

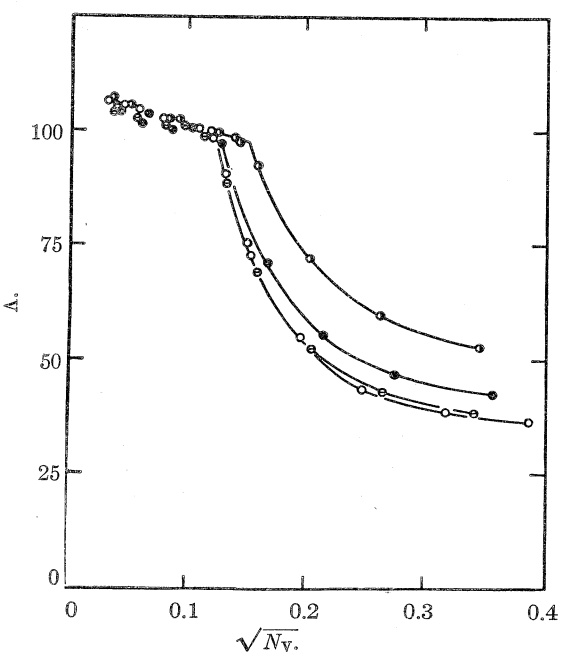

Fig. 1.—Equivalent conductivities of dodecylammonium chloride and N-methyl derivatives at 30°: ○, dodecylammonium chloride; ⊖, methyldodecylammonium chloride; ●, dimethyldodecylammonium chloride; ◑, trimethyldodecylammonium chloride.

(3) Hoerr, McCorkle and Ralston, *ibid.*, **63**, 328 (1943).
(4) Flürscheim, *J. Chem. Soc.*, **95**, 718 (1909).
(5) Reck, Harwood and Ralston, *J. Org. Chem.*, **12**, 517 (1947).
(6) Ralston, Hoerr and Hoffman, THIS JOURNAL, **64**, 97 (1942).
(7) Ralston and Eggenberger, *ibid.*, **70**, 436 (1948).

curves show that the conductivities of dodecyl- and methyldodecylammonium chlorides are almost identical, indicating that the transition from the primary to the secondary amine salt is not accompanied by a significant change in solution behavior. The tertiary amine salt, dimethyldodecylammonium chloride, has a somewhat higher concentration at the critical point and a higher equivalent conductivity at concentrations beyond the critical point. A much larger difference is encountered in going from the tertiary amine hydrochloride to the quaternary ammonium chloride. Trimethyldodecylammonium chloride has a significantly higher critical concentration and a much higher equivalent conductivity beyond this point. The values of $\Lambda_0$, $\Lambda_c$, $\sqrt{N_c}$, and $N_c$ for these four salts are shown in Table I.

TABLE I

| Compound, chloride | $\Lambda_0$ | $\Lambda_c$ | $\sqrt{N_c}$ | $N_c$ |
|---|---|---|---|---|
| Dodecylammonium | 108.5 | 100.0 | 0.121 | 0.0146 |
| Methyldodecylammonium | 107.9 | 99.1 | .121 | .0146 |
| Dimethyldodecylammonium | 109.2 | 98.1 | .127 | .0161 |
| Trimethyldodecylammonium | 109.8 | 97.8 | .151 | .0228 |

These values together with the curves in Fig. 1 show that for this series of salts the greatest change in conductivity behavior occurs in going from the tertiary amine salt to the quaternary ammonium salt. The colloidal state, as evidenced by the values of $N_c$, is assumed at the same concentration for the salts of the primary and secondary amines, at a somewhat higher concentration for the tertiary amine salt and at a materially higher concentration for the quaternary ammonium salt. The values of $\Lambda_c$ undergo a progressive, small decrease in going from the primary to the quaternary ammonium salt. The conductivities of these four salts at concentrations lower than the critical concentration are not significantly different as shown by the small differences in the values of $\Lambda_0$.

## Summary

1. The equivalent conductivities of aqueous solutions of dodecyl-, methyldodecyl-, dimethyldodecyl-, and trimethyldodecylammonium chlorides have been determined.

2. The greatest difference in these values is observed in going from dimethyldodecylammonium chloride to trimethyldodecylammonium chloride.

# The Electrical Conductivities of Tris-(hydroxyalkyl)-alkylammonium Chlorides

BY A. W. RALSTON, D. N. EGGENBERGER AND H. J. HARWOOD

The substitution of short-chain hydroxyalkyl groups for methyl groups in trimethylalkylammonium chlorides renders the long-chain cations more hydrophilic and should result in a modification of the colloidal properties portrayed by the electrical conductivities of aqueous solutions. In contrast to this expectation, it recently has been shown[1] that the progressive substitution of 2-hydroxyethyl groups for methyl groups in trimethylhexadecylammonium chloride does not bring about a significant change in either the equivalent conductivity or the concentration at the critical point. Substitution of one of the methyl groups in trimethylhexadecylammonium chloride by a 2,3-dihydroxypropyl group is likewise not attended by a noticeable change in the critical concentration. The critical concentration of trimethyldodecylammonium chloride is materially greater than that of trimethylhexadecylammonium chloride, thus manifesting that the colloidal state is not so readily assumed with the former salt as with the latter. As a consequence, the incorporation of hydroxyalkyl groups into a trimethyldodecylammonium salt should have a greater relative effect upon its colloidal properties than a similar incorporation into a trimethylhexadecylammonium salt. The present paper discusses the effect of the substitution of the methyl groups in trimethyldodecylammonium chloride by hydroxyethyl and 2,3-dihydroxypropyl groups and compares these effects with similar substitutions in the hexadecyl homolog.

(1) Ralston, Eggenberger, Harwood and Du Brow, THIS JOURNAL, **69**, 2095 (1947).

## Experimental

**Preparation of tris-(2,3-Dihydroxypropyl)-dodecylammonium Chloride.**—To a solution of 38 g. of sodium hydroxide in 400 cc. of ethanol was added 80 g. of dodecylamine (f. p. 28.2°). The solution was cooled to 15° and to it was added 120 g. of glycerol 1-chlorohydrin. The reaction which occurred was accompanied by an appreciable rise in temperature. After standing overnight the sodium chloride was filtered off and the ethanol distilled, the last traces of solvent being removed under reduced pressure. Without purification, the bis-(2,3-dihydroxypropyl)-dodecylamine was treated with 47.8 g. of glycerol 1-chlorohydrin and the mixture heated on the steam-bath at 100° for sixteen hours. Attempts to purify the product by crystallization from a number of solvents were unsuccessful. Some purification was achieved by dissolving the quaternary ammonium salt in ethyl acetate (700 cc.) containing methanol (35 cc.) and cooling the solution to −10°. The upper layer was decanted and the process repeated. After removal of the solvent under reduced pres-

sure the product was dried *in vacuo* over calcium chloride. The tris-(2,3-dihydroxypropyl)-dodecylammonium chloride was obtained as a sticky, plastic mass. A purity of 95% was indicated by titration with standard sodium dodecyl sulfate using dichlorofluorescein as indicator.

**Preparation of tris-(2,3-Dihydroxypropyl)-hexadecylammonium Chloride.**—This compound was prepared from hexadecylamine according to the above procedure. It was obtained as a plastic mass with an indicated purity of 100%.

**Preparation of tris-(2-Hydroxyethyl)-dodecylammonium Chloride.**—This was prepared from dodecylamine and ethylene chlorohydrin in a manner similar to that described above. The product was a white, crystalline solid which was somewhat hygroscopic. The indicated purity was 100%.

The electrical conductivities of solutions of the quaternary ammonium salts were determined in the manner and with the equipment previously described.[2]

## Results and Discussion

The equivalent conductivities plotted against $\sqrt{N_v}$ of dodecyltrimethylammonium chloride, tris-(2-hydroxyethyl)-dodecylammonium chloride, and tris-(2,3-dihydroxypropyl)-dodecylammonium chloride are shown in Fig. 1. Substitution of the three methyl groups of trimethyldodecylammonium chloride by hydroxyethyl groups enhances the colloidal properties as evidenced by the decrease in the critical concentration. The equivalent conductivity of tris-(2-hydroxyethyl)-dodecylammonium chloride is higher than that of trimethyldodecylammonium chloride at concentrations below the critical point; however, it is significantly lower at the higher concentrations. The difference in these curves may be explained on the basis of a greater tendency toward solubilization of the tris-(2-hydroxyethyl)-dodecylammonium chloride. Substitution of the three methyl groups by 2,3-dihydroxypropyl groups brings about a profound change in the nature of the conductance curve. Tris-(2,3-dihydroxypropyl)-dodecylammonium chloride shows a greatly decreased conductivity over the entire concentration range investigated, the curve having little similarity to those of typical colloidal electrolytes. The incorporation of the six hydroxyl groups into the molecule is therefore attended by a decided modification of the colloidal behavior as evidenced by the absence of a well-defined critical point.

Figure 2, which compares the equivalent conductivities of trimethylhexadecylammonium chloride and tris-(2,3-dihydroxypropyl)-hexadecylammonium chloride, shows that both these compounds function as typical cationic electrolytes. This behavior is in sharp contrast to that of the dodecyl homologs and indicates that the paraffin nature of the hexadecylammonium ion is not decidedly modified by the introduction of three 2,3-dihydroxypropyl groups.

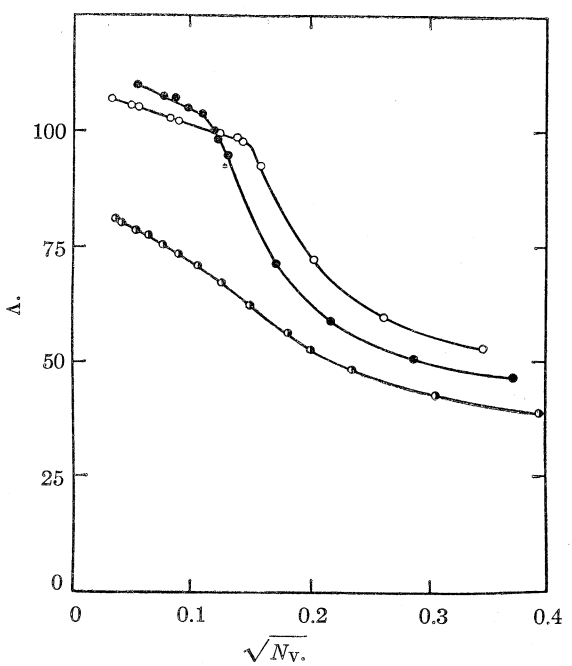

Fig. 1.—Equivalent conductivities of hydroxyalkyldodecylammonium chlorides at 30°: O, dodecyltrimethylammonium chloride; ●, tris-(2-hydroxyethyl)-dodecylammonium chloride; ◑, tris-(2,3-dihydroxypropyl)-dodecylammonium chloride.

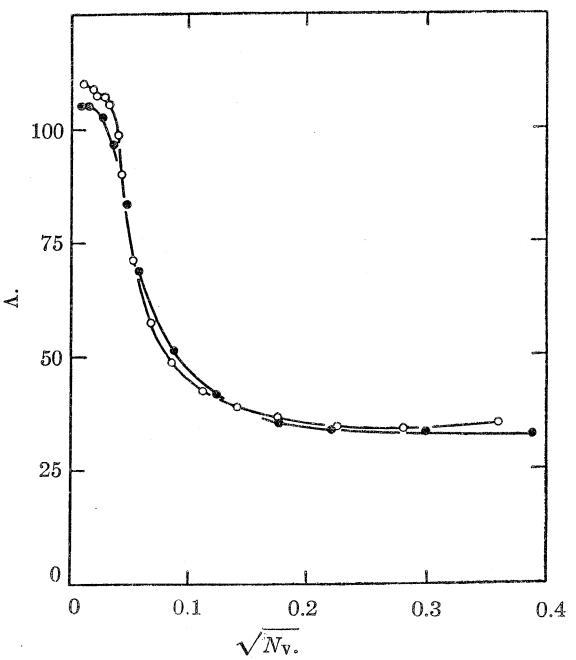

Fig. 2.—Equivalent conductivities of hexadecyltrimethylammonium chloride and tris-(2,3-dihydroxypropyl)-hexadecylammonium chloride at 30°: O, hexadecyltrimethylammonium chloride; ●, tris-(2,3-dihydroxypropyl)-hexadecylammonium chloride.

## Summary

1. The equivalent conductivities of trimethyldodecyl-, tris-(2-hydroxyethyl)-dodecyl-, tris-(2,3-dihydroxypropyl)-dodecyl-, trimethylhexadecyl-

(2) Ralston, Hoerr and Hoffman, *ibid.*, **64**, 97 (1942).

and tris-(2,3-dihydroxypropy)-hexadecylammonium chlorides have been compared.

2. The substitution of hydroxyethyl groups for methyl groups in trimethyldodecylammonium chloride does not greatly modify the colloidal properties; however, the substitution of 2,3-dihydroxypropyl groups results in a decided modification. A similar substitution in trimethylhexadecylammonium chloride is without a significant effect.

# The Dissociation Constants of Some Mono-substituted Benzeneseleninic Acids[1]

BY JAMES D. McCULLOUGH AND EDWIN S. GOULD

## Introduction

The benzeneseleninic acids are white crystalline solids analogous to benzenesulfinic acids in the sulfur series. They are weak acids of strengths comparable to that of acetic acid. A series of thirteen of these compounds has been prepared, six members of which have not been previously described in the literature. Acidic dissociation constants were determined by titration of approximately 0.005*F* solutions of the acids with standard (0.1*N*) carbonate-free sodium hydroxide using a model H Beckman *p*H meter. The dissociation constants thus obtained have been correlated with the Hammett $\rho$–$\sigma$ treatment[2] and a $\rho$ value for the ionic dissociation observed. The effects of small temperature changes on the dissociation constants have been noted for a number of the acids and have been found to be similarly small.

## Experimental

I. **Syntheses.**—The seleninic acids were prepared from the corresponding diselenides through oxidation with concentrated hydrogen peroxide.

$$R_2Se_2 + 3H_2O_2 = 2RSeO_2H + 2H_2O \qquad (1)$$

A. **Preparation of Diselenides.**—The diselenides were prepared by the two methods described by Campbell and McCullough.[3] The numbers in Table I refer to the numbering of the methods used by those authors.

B. **Oxidation of Diselenides.**—Two methods were employed depending on whether the diselenide was liquid or solid.

1. **Solid Diselenides.**—Ten grams of the diselenide was added to 10 ml. of 1,4-dioxane and the mixture warmed to about 60° to dissolve as much solid as possible. It was then cooled to below 5° and C. P. concentrated hydrogen peroxide (20–28%) was added dropwise, stirring the mixture and cooling externally to keep the temperature under 10°. After addition of a threefold excess of peroxide, fifteen grams of ice was added and the resulting solid (which was almost white) was filtered off and washed with 10 ml. of ice water.

2. **Liquid Diselenides.**—Ten grams of the diselenide was dissolved in 15 ml. of diethyl ether. Concentrated hydrogen peroxide was added dropwise; but after each five or six drops, the solution was swirled vigorously over a warm water-bath at 45° to ensure as complete a reaction as possible. If the temperature of the mixture rose above 38°, it was cooled to below 34°, ether being added from time to time to replace that lost by evaporation. After addition of a threefold excess of peroxide, the ether was stripped off at room temperature with a water pump, leaving a mixture of white seleninic acid and orange oil impurities.

If the amount of orange oil was excessive, 30 cc. of 6*N* ammonia was added to the residue, dissolving the acid. The solution was washed twice with 20-ml. portions of ether, removing a large part of the orange residue. The aqueous layer was acidified with dilute sulfuric acid, and an excess of potassium iodide was added along with an additional 15 ml. of ether to reduce the acid back to the original diselenide. The mixture was shaken thoroughly, and just enough sodium thiosulfate solution was added to reduce the $I_3^-$ formed. The ether layer, containing the diselenide, was separated, washed twice with dilute sodium hydroxide, twice with distilled water, and reoxidized with hydrogen peroxide as before.

C. **Purification Method.**—One of two methods was used, depending upon the solubility in water of the seleninic acid involved.

1. **Slightly Soluble Acids.**—A ten per cent. excess of 15*N* ammonia was added to the solid acid, and the solution was stirred until no white solid remained. The solution was filtered, decolorized twice with Norite, and the acid reprecipitated by slow addition of C. P. 6 *N* hydrochloric acid. The solid was washed with ice water, dissolved in a minimum volume of methanol, and the methanolic solution added dropwise to boiling water until cloudiness formed. At that point, 25% more boiling water was added, the solution filtered hot, decolorized if necessary, then cooled rapidly with scratching to 0°. After thirty minutes, the crystallized acid was filtered off and recrystallized as before, this time cooling very slowly. The crystals, usually needles, were filtered off, dried in a vacuum desiccator over calcium chloride for two days, and a preliminary melting point taken. If the melting point was above 120°, the acid was dried in an oven for an hour at 90°. If the melting point was below 120°, the solid was kept in the vacuum desiccator for three additional days. Difficulty was encountered in removing the last traces of water from the solid; for if it were dried too persistently, the product turned pink, indicating decomposition. For this reason, the equivalent weights of some of the acids were as much as 1% low while some were 3 or 4% high. This difficulty should not, however, affect the accuracy of the dissociation constants.

2. **Soluble Acids.**—If the acid was quite soluble in cool water, treatment with ammonia was omitted, the crude product dissolved directly in a minimum quantity of hot (but not boiling) water (80°), the solution filtered hot, decolorized with norite until a pale yellow, and the acid reprecipitated by cooling. A second recrystallization was then made. The drying procedure was that described above.

D. **Special Method.**—*m*-Nitrobenzeneseleninic acid was prepared by nitration of benzeneseleninic acid nitrate as described by Friend.[4] The procedure was modified by

reducing the heating time to thirty minutes and by diluting the starting material with an equal weight of concentrated nitric acid. The product is white, not yellow, as reported by Friend. (It is possible that the di-nitro compound is described.)

### II. Physical Measurements

A half-millimole sample of acid was weighed into a 250-ml. beaker and dissolved in 100 ml. of distilled water previously boiled twenty minutes to remove carbon dioxide. The titration was made with standard, approximately 0.1 *N* carbonate-free sodium hydroxide delivered from a 10-ml. buret. The solution was stirred and protected from carbon dioxide during the titration. Readings were taken with a Beckman Model H *p*H meter at the start and after each milliliter of base added. In the region of the end-point the *p*H value was read at each drop. The temperature of the solution was noted during each titration. The equivalence point was assumed to be at a *p*H value of 8.0 and the *p*H at half-neutralization was obtained either by interpolation or graphically. Complete titration curves were prepared for a number of the acids and with the remainder, readings were taken only in the vicinities of the half-neutralization and the equivalence points. In order to get an approximate evaluation of the temperature coefficients of the dissociation constants, the *p*H at half-neutralization was determined at both 25 and 35° for five of the acids.

## Results and Discussion

A typical titration curve, that for the *p*-methoxy acid, is shown in Fig. 1. A summary of results is shown in Table I. The melting points are in some cases rather sharp while in others a decomposition takes place which appears to involve a loss of water to give the anhydride. Further heating then causes the anhydride to melt. This behavior is noted for some acids in the table. The rather large discrepancies between the observed and theoretical equivalent weights is probably due to the difficulty of drying the acids without decomposition as previously noted. The tendency toward high experimental values is probably due to incomplete drying. This should not affect the accuracy of the *pK* values determined.

(5) McCullough, Campbell and Krilanovich, *Anal. Chem.*, **18**, 638 (1946).

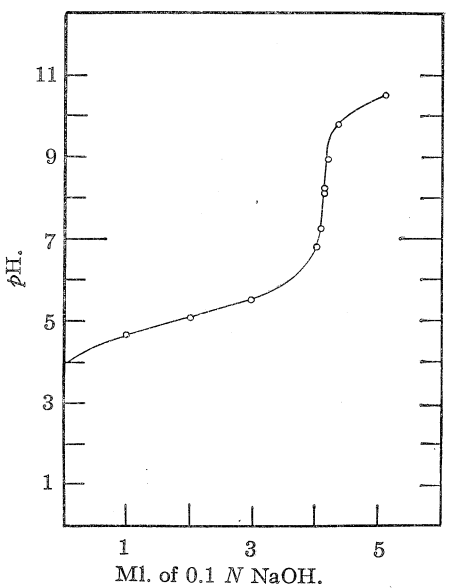

Fig. 1.—Titration curve for *p*-methoxybenzeneselenic acid.

In calculating the *pK* values from the *p*H at half-neutralization, correction was made for the activity coefficient of the acid anion. This was done as follows

$$K = \frac{a_{H^+}a_{X^-}}{a_{HX}} = \frac{a_{H^+}C_{X^-}\gamma_{\pm}}{C_{HX}\gamma_{HX}} \quad (1)$$

Since the activity coefficient of the un-ionized acid is practically unity, we have

$$-\log K = -\log a_{H^+} - \log \frac{C_{X^-}}{C_{HX}} - \log \gamma_{\pm} \quad (2)$$

or

$$pK = pH - \log \frac{C_{X^-}}{C_{HX}} - \log \gamma_{\pm} \quad (3)$$

At the half-neutralization point

$$C_{X^-} = C_{HX} \quad (4)$$

so that

$$pK = (p\mathrm{H})_{1/2} - \log \gamma_{\pm} \quad (5)$$

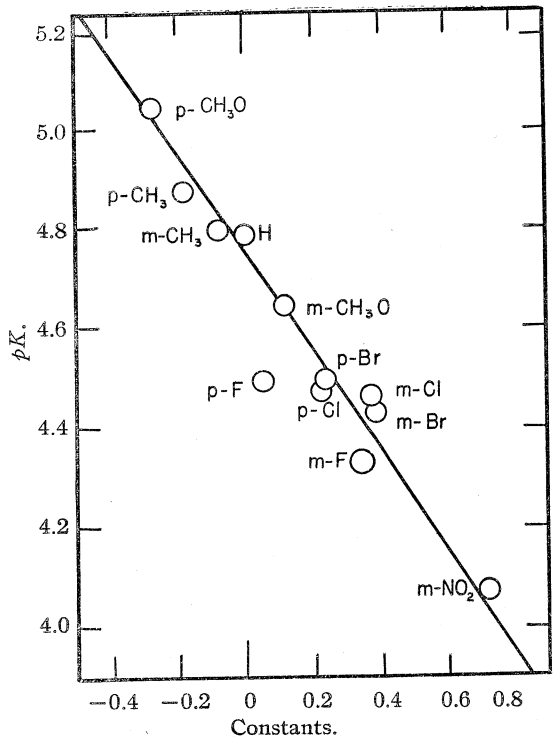

Fig. 2.—Plot of $pK$ *vs.* Hammett's substituent constants.

Since

$$-\log \gamma_{\pm} = 0.505 Z_a^2 \sqrt{\mu} \quad (6)$$

this term has the value 0.025 under our experimental conditions, which leads to

$$pK = (p\mathrm{H})_{1/2} + 0.025 \quad (7)$$

A plot of the $pK$ values at 25° is made against Hammett's substituent constants ($\sigma$ values) in Fig. 2 and it is seen that a good approximation to a straight line results. The best straight line through the points has a slope of 1.0 which indicates that the ionization constants of the benzeneseleninic acids have the same susceptibility toward substituents as do the benzoic acids which were the source of the $\sigma$ values.

The $pK$ values of the benzeneseleninic acids are rather insensitive to changes of temperature. The five acids investigated were the parent acid, *p*-$CH_3$, *m*-$CH_3$, *p*-Cl and *m*-Cl. In all cases the $pK$ increased approximately 0.02 unit per 10° rise in temperature in the range 25–40°.

## Summary

1. Thirteen benzeneseleninic acids have been prepared, six of which are new. Methods of preparation are described.

2. The ionization constants (as $pK$) of these acids have been determined by potentiometric titration using a Beckman $p$H meter. The $pK$ values thus found are a linear function of Hammett's $\sigma$ values.

3. Approximate temperature coefficients of the $pK$ values have been noted for five of the acids.

# The Surface Tension of Aqueous Sulfuric Acid Solutions at 25°

BY R. M. SUGGITT, P. M. AZIZ AND F. E. W. WETMORE

**Introduction.**—In this Laboratory we required values of the surface tension of sulfuric acid solutions at 25° up to the concentration corresponding to maximum conductivity. Morgan and Davis[1] reported values obtained by the drop-weight method; later Harkins and Brown[2] showed that certain corrections must be applied in using this method, but until now the corrected values have not been reported. More recently Sabinina and Terpugow[3] presented data obtained by the method of capillary rise, but gave no experimental details and reported no values for solutions less than 23% by weight acid.

The differential maximum bubble pressure technique described by Sugden[4] was chosen for our measurements, not only because it involves bubble formation which parallels the experimental arrangement for which we required the data, but also because choice of this technique would afford comparison of data obtained by three different methods.

## Experimental

The solutions were made from C. P. sulfuric acid and twice-distilled water. The individual solutions were standardized by precipitation of barium sulfate and by titration against freshly prepared sodium carbonate.

The apparatus, as shown in Fig. 1, consisted of a pressure generator G and reservoir R (20 liters) connected to the bubble-forming tubes immersed in the liquid, and a sensitive manometer M attached as closely as possible to the tubes. The pressure generator consisted simply of a fine oil stream admitted to a bottle at controlled rate; thus the head required to form bubbles could be maintained at any slow rate of air flow to the tubes. The reservoir minimized pressure fluctuations during the measurements. A connection C to the compressed air line served for setting the initial pressure roughly. The manometer was a water-filled 6 mm. i.d. U-tube enclosed in a thermally lagged box. A glass scale ruled at 0.5 mm.

intervals was set directly behind the U-tube; at the front a vertical square bar carried two vertically adjustable channels in which were set micrometer telescopes on ground slides for forward adjustment. The liquid level was determined by focussing a telescope on the meniscus and reading the micrometer graticule; the telescope was then run forward to bring the glass scale into focus and readings on the graticule taken for the nearest scale lines above and below the meniscus reading. By interpolation the meniscus level was referred to the glass scale. Readings of level difference could be made to 0.001 mm., an order of magnitude better than required.

Precision-bore Pyrex tubing was used for the bubble-forming tubes. The ends to be immersed were ground normal to the bore with very fine carborundum on a rotating linen disc; during this grinding the possibility of crushing or flaring of the bore was avoided by filling the end of the tube with deKhotinsky cement. The chipped edges left from the manufacturer's grinding were thus removed until microscopic examination showed a sharply circular bore. The outside diameter of both tubes was about 6 mm., the internal diameters, respectively, 0.227 and 0.454 mm., as measured with a microscope and graticule and with the ratio confirmed by the data obtained for water. The manufacture of precision-bore tubing in recent years has made possible the happy choice of tubes with bore ratio 2:1. The tubes were held in universally adjustable supports mounted in a framework which in turn was attached to a large cylindrical post with a clamping sleeve. By means of this arrangement the tubes were set vertically parallel; later they could be removed from liquid and reimmersed without change of slant or relative height. The small difference in level of the tips of the two tubes was determined with a micrometer telescope by measurement of the distance from each tip to the surface of a pool of mercury. The difference was confirmed during the runs. The liquid under test was maintained at 25.00 ± 0.02° with a conventional thermostat T. The temperature was determined with a thermometer calibrated by comparison with a platinum resistance thermometer.

With sufficiently slow formation of bubbles the maximum bubble pressure is independent of the rate of formation. Following preliminary tests the rate was set at one bubble every seven seconds (not critical). The pressure reading of the manometer slowly rose as the bubble nucleus expanded, dropping suddenly when the bubble exceeded the critical size; the maximum pressure was recorded. Every determination on a solution was preceded by one on water. Only with meticulously cleaned tubes could the readings be duplicated from one day to another.

## Experimental Results

In Table I are recorded duplicate readings of pressure differences found for the two tubes, in terms of the solution at 25° as the manometric liquid. With the exception of one number patently in error, no readings were found outside the limits of the duplicates shown. Values of the surface tension $\gamma$ were calculated through the method of successive approximation recommended by Sugden and the average value for each solution is recorded in Table 1. These values are based on

TABLE I

SURFACE TENSION OF AQUEOUS SULFURIC ACID AT 25°

| Acid, % | Press. diff. in mm. | | $\gamma$ | $\Delta$ |
|---|---|---|---|---|
| 4.11 | 63.24 | 63.24 | 72.21 | 0.24 |
| 8.26 | 61.85 | 61.83 | 72.55 | 0.58 |
| 12.18 | 60.48 | 60.46 | 72.80 | 0.83 |
| 17.66 | 58.86 | 58.84 | 73.36 | 1.39 |
| 21.88 | 57.66 | 57.66 | 73.91 | 1.94 |
| 29.07 | 55.66 | 55.65 | 74.80 | 2.83 |
| 33.63 | 54.42 | 54.43 | 75.29 | 3.32 |

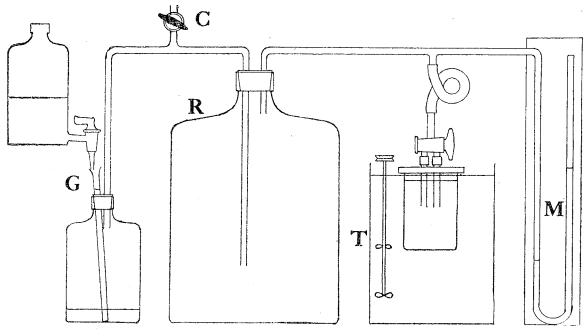

Fig. 1.—Experimental arrangement.

the assumption that the surface tension of water at 25°, $\gamma_0$, is 71.97 dynes/cm.[5] The increment of the surface tension of a solution over that of pure water, $\Delta = \gamma - \gamma_0$, is given as the more suitable recording of the data, since it is independent of small variations in $\gamma_0$ and will serve at any later time for calculating $\gamma$ by adding it to the then acceptable value of $\gamma_0$.

**Correction of the Data of Morgan and Davis.**—The values reported by Morgan and Davis were calculated from the formula $\gamma' = 936.0\ w$ (Eqn. 1), in which $\gamma'$ is the uncorrected surface tension, 936.0 a quantity dependent on the radius of their tube, but not, by their assumption, on the composition of the liquid, and $w$ is the average drop-weight in grams. Harkins and Brown suggested the form $\gamma = w\phi/r$ (Eqn. 2), in which $\gamma$ is the corrected surface tension, $r$ the radius of the tube, and $\phi$ is an empirical term depending on $r$ and the cube root of the volume, $v$, of one drop. The value of $v$ can be determined from the density of the liquid and the value of $w$ calculated through Eqn. 1. It so happens that $\phi$ can be expressed as a linear function of the variable $r/v^{1/3}$ over a range sufficient for the calculations here: $\phi = A + Br/v^{1/3}$ (Eqn. 3), *e. g.*, for $r/v^{1/3} = 0.61$ to 0.64, $A = 207.6$ and $B = 70$. Thus $r$ can be calculated by substituting in

TABLE II

SURFACE TENSION OF AQUEOUS SULFURIC ACID, CORRECTED DATA OF MORGAN AND DAVIS

| | $\Delta$ | | | |
|---|---|---|---|---|
| Acid, % | 0° | 30° | 50° | 25° (calcd.) |
| 4.67 | −0.23 | 0.24 | 0.45 | 0.17 |
| 8.93 | −0.17 | 0.49 | 0.83 | 0.39 |
| 16.40 | 0.42 | 1.21 | 1.67 | 1.09 |
| 22.73 | 0.98 | 2.08 | 2.63 | 1.92 |
| 28.18 | 1.60 | 2.68 | 3.45 | 2.49 |

(5) "International Critical Tables," Vol. IV, p. 447. In a recent private communication Professor F. E. Bartell of the University of Michigan has kindly offered the value 72.00 at 25° as part of a corrected series to be published by him shortly. This corrected value will be useful in obtaining $\gamma$ more accurately, but its use does not change the values of $\Delta$ cited here.

Eqn. 2 an acceptable value of $\gamma$ and in Eqn. 2 and 3 the values of $v$ and $w$ found as shown above. The data of Morgan and Davis for water and the more acceptable values of $\gamma_0$[5] give $r$ at 0, 30 and 50° as 0.2687, 0.2686 and 0.2685 cm., respectively; one would expect a small opposite thermal variation. The effective radius was taken as 0.2686 cm. and through Eqn. 1, 2 and 3 values of $\gamma$ were calculated from the data of Morgan and Davis. In Table II are shown the corrected values of $\Delta$, along with values for 25° obtained by parabolic interpolation of these data for 0, 30 and 50°.

**Comparison of Data.**—Table III shows the data of Sabinina and Terpugow for 10, 20, 30, 40 and 50°, as well as values for 25° obtained by graphical interpolation rather than the linear interpolation they used.

In Fig. 2 the data for 25° from the three experimental methods are compared. The line has been drawn to give a minimum square deviation of the points, without weighting. The circles have radius equal to 0.07 unit, or about 0.1% of $\gamma$. In Table IV are given the values of $\Delta$ corresponding to the mean curve of Fig. 2. Over the range 0 to 35% acid the points show an average vertical deviation of 0.07 unit, or 0.1% of $\gamma$. It is quite apparent that the data from the work of Morgan and Davis lie consistently below the other two sets; a part of this difference may have arisen in the parabolic interpolation, but undoubtedly a part is due to difference in the experimental method used.

## Summary

1. The surface tension of aqueous sulfuric acid at 25° has been determined over the range 0 to 33% acid by means of the differential maximum bubble pressure method.

2. The data of Morgan and Davis obtained by the drop-weight method have been recalculated in accordance with the corrections of Harkins and Brown.

3. Surface tension values obtained by three different methods have been compared.

# The Sodium Tungsten Bronzes. I. Chemical Properties and Structure

BY M. E. STRAUMANIS

## Introduction

The tungsten bronzes were discovered by F. Wöhler in 1824.[1] Since they have metallic properties, the name "tungsten bronzes" was applied, although they are neither alloys nor intermetallic compounds.

Later the "bronzes" were investigated by Brunner,[2] Spitzin[3] and others. W. F. de Jong found that the bronzes have the perovskite ($CaTiO_3$) type of structure and that the formula of the yellow bronze must be $NaWO_3$.[4] G. Hägg confirmed this statement and showed (1) that tungsten in the yellow bronze is pentavalent, (2) that sodium metatungstate and tungstic oxide form solid solutions with lattice contraction and change of color (from yellow through red and violet to dark blue) and (3) that the bronzes are very good electric conductors.[5]

The intention of this present work is to describe the still unknown qualities of tungsten bronzes and to find the end of the solid solution series.

## Preparation of the Bronzes

Because of the limited amount of the required high purity starting material (sodium tungstate, tungsten and tungstic oxide) available, the quantities of the bronzes obtained were insufficient for precise chemical analyses. In fact, chemical analyses are not necessary because the absorption of tungstic oxide by the bronze is accompanied by shrinkage of its lattice. This property was used to determine the composition of the resulting bronzes. The lattice constants were found by the powder method, applying the author's technique.[6] Although the work was not done in thermostats, the precision was sufficient to determine the tungstic oxide content of the bronzes with an accuracy of 0.1% by weight. The presence of other reaction products in the samples has also been confirmed by X-rays.

The purest yellow bronzes (without any excess tungstic oxide) have the highest lattice constants and they must be prepared first. It can be shown that these compounds become brighter when treated with sodium vapor. The reduction was carried out in small iron tubes (0.5 × 2 cm.); on the bottom of the tube there was a piece of sodium approximately 1 mm. in diameter; the rest of the tube was filled with bronze (*e. g.*, the blue); the tube was closed loosely with an iron stopper and then slipped into a slightly larger tube of "supremax" or quartz glass, which finally was evacuated, annealed and sealed off. On heating in a furnace at 700–800° the reaction was completed in half an hour. The reaction began at about 400°. The sodium vapor reacted to produce sodium tungstate and tungsten in the iron tube. On the top of these products were grains of yellow bronze, followed by grains of darker colored bronze. Powder diagrams of the bright yellow grains showed that the highest lattice constants obtained by Hägg[5] ($a$ = 3.850 kX) could be attained easily and even surpassed (see Table I).

TABLE I

HIGHEST LATTICE CONSTANTS OF THE YELLOW BRONZE, AFTER TREATMENT WITH LITHIUM OR SODIUM VAPOR, OR TUNGSTEN POWDER (UNDER FUSED $NaWO_4$)

| Sample | Reductant | $a$ in kX | Color |
|---|---|---|---|
| 81 | Li | 3.8479 | Golden |
| 76 | Na | 3.8479 | yellow |
| 183 | W | 3.8494 | Brighter golden yellow |
| 62 | Na | 3.8502 | Bright |
| 69 | Na | 3.8504 | yellow |
| 70 | Na | 3.8504 | Bright |
| 61 | Na | 3.8508 | yellow |
| 182 | W | 3.8520 | Bright |
| 182a | W | 3.8518 | yellow |

In the presence of tungsten under molten sodium tungstate the reaction evidently comes to equilibrium and an essentially purer bronze results. It is probable that sample 182 contains only a very small excess of $WO_3$.

This sample was prepared according to the reaction

$$3Na_2WO_4 + 2WO_3 + W = 6NaWO_3$$[7]

The best results were obtained when the reaction took place under a cover of excess sodium tungstate:

| | |
|---|---|
| W | 0.60 g. |
| $WO_3$ | 1.52 |
| $Na_2WO_4$ | 2.88 + 3 g. (anhydrous) |
| | 8.0 g. |

The dry mixture was slowly heated in vacuum up to 950° and then during the course of four hours uniformly cooled down to 700°. Then the current was turned off. The bronze crystals were completely under solid sodium tungstate, which could be removed with boiling water. On the sur-

face of the very nice cubic crystals of bronze, there still adhered sodium tungstate and fine tungsten powder (greenish appearance). These were easily removed with warm sodium hydroxide solution containing some sodium peroxide. Of course, the crystals then appeared slightly corroded (Fig. 1a). At higher temperatures larger crystals are obtained, but they were defective as evidently the bronze begins to decompose at 1000° (Fig. 1b). The sodium tungstate in excess obviously furthers the growth of the crystals; the bronze does not dissolve in it even at higher temperatures.

a b

Fig. 1.—Crystal diagrams: a, cubic crystal slightly stripped; b, a larger and defective crystal with intergrowth.

For preparation of any deeper colored bronze the exact stoichiometric reaction (in vacuum, one-half—one hour, 700–800°) $NaWO_3 + xWO_3 \rightarrow$ deeper colored bronze was used.

**Properties of Pure $NaWO_3$.**—A sketch of two crystals is shown (Fig. 1). The crystals are shiny, brittle and have weak cleavage parallel to 100. The cleavage planes also have a strong metallic luster.[8] The crystals are good electric conductors. The conductivity ($\sim$ 400 $\Omega^{-1}$/cm.$^{-1}$) is comparable with that of graphite.[9]

Under oxygen-free water the compound keeps its luster for several months and no appreciable solubility was detected. However, dissolution was observed in oxygen-rich water

$$2NaWO_3 + {}^1/_2O_2 \longrightarrow Na_2W_2O_7 \text{ (very slowly)}$$

The presence of $Na_2W_2O_7$ was proven beyond doubt by power photographs. An addition of hydrogen peroxide considerably increased the velocity of the reaction.

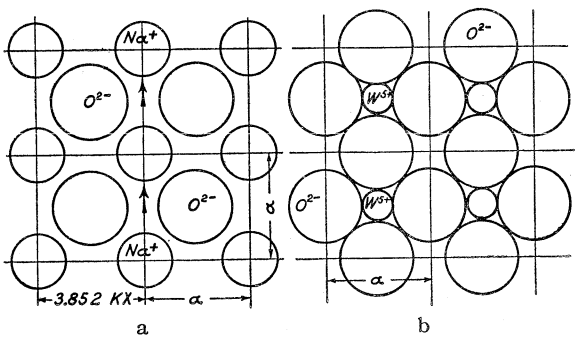
Strong bases dissolve sodium metatungstate only in the presence of oxidizing agents

$$2NaWO_3 + 2NaOH + {}^1/_2\,O_2 \text{ (air)} \longrightarrow 2Na_2WO_4 + H_2O \text{ (very slowly)}$$

$$2NaWO_3 + Na_2O_2 \longrightarrow 2Na_2WO_4 \text{ (quickly)}$$

The deeper colored bronzes dissolve in bases more readily the more tungstic oxide the compounds contain. The reaction is retarded by the pentavalent tungsten, it must be first oxidized to soluble tungstates.

The high resistance of sodium metatungstate to acids can be explained by the development of insoluble surface films containing tungstic acid. A mixture of nitric and hydrofluoric acids destroys the yellow bronze rather quickly. A greenish precipitate results which sometimes turns yellow (tungstic acid) and sometimes white.



The phenomena observed during heating of the bronze can be explained as follows: In the bronze crystals there is an equilibrium that is in accordance with the statements of Hägg[5] on the structure of $NaWO_3$

$$Na^+W^{V}O_3 \rightleftharpoons W^{VI}O_3 + Na^0 \qquad (1)$$

A rise in temperature promotes this oxidation–reduction reaction to the right. Sodium ion acts as oxidizing agent, converting $W^{5+}$ into $W^{6+}$

$$W^{V}O^-_3 \longrightarrow W^{VI}O_3 + e$$
$$Na^+ + e \longrightarrow Na^0 \qquad (2)$$

The electron has only to pass from $W^{5+}$ to sodium ion and the reaction is finished. The bronze must therefore have good electric conductivity[10] and the sodium ion must be very mobile. The mobility of sodium ion follows also from the structure of sodium metatungstate (see Fig. 2).

a b

Fig. 2.—Structure of $NaWO_3$ (according to Hägg), showing positions: $Na^+$ 000, $W^{5+}$ $\frac{111}{222}$, $3O^{2-}$ $\frac{11}{22}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{11}{22}$; a, first layer; b, second layer; the third is identical with the first.

The sodium ion squeezes from one 000-site to another, especially at higher temperatures. If tungstic oxide is only slightly in excess there will be many empty 000-sites in the crystals.

On heating the yellow bronze in air, it begins to cake and turns blue-black. According to (1), sodium oxidizes on the surface and the tungstic oxide distributes in the crystal

$$NaWO_3 + xWO_3 = NaWO_3(W^{VI}O_3)_x \qquad (3)$$
deeper colored bronze

Simultaneously on the surface occurs

$$2NaWO_3 + {}^1/_2O_2 \longrightarrow Na_2W_2O_7, \text{ and}$$
$$Na_2O + WO_3 \longrightarrow Na_2WO_4 \qquad (4)$$

On heating sodium metatungstate above 700–800° *in vacuo*, reaction (1) becomes noticeable and the sodium vapor reduces the sodium metatungstate. Tungsten, sodium tungstate and some not

(8) The polished, ground crystal is reddish and becomes yellow after few days. Moisture instantly causes the yellow color; however, it disappears soon.

(9) See the article of Straumanis and Dravnieks, THIS JOURNAL, **71**, 683 (1949).

(10) Friedrich, *Z. Physik*, **31**, 813 (1925); **34**, 637 (1925); see also Meyer, *Z. Elektrochem.*, **50**, 274 (1944).

yet identified products result. The latter cause the caking of the sodium metatungstate crystals (m. p. of sodium tungstate is $\sim$ 700°). A part of the sodium vapor reacts with the glass or porcelain; the color of the resulting bronze then becomes deeper.

These reduction reactions can be completely suppressed, if there is present in the tube a sodium acceptor (*e. g.*, iodine in an evacuated tube at 700° *ca.* one hour)

$$\begin{aligned} NaWO_3 &\rightleftarrows Na + WO_3 \\ Na + I &\longrightarrow NaI \\ NaWO_3 + xWO_3 &\longrightarrow NaW^{V}O_3(W^{VI}O_3)_x \end{aligned} \qquad (5)$$

With the help of iodine the sodium of the sodium metatungstate can be extracted almost completely; a few tenths of one per cent. remain in the resulting tungstic oxide which is then green.

A very good sodium acceptor is tungstic oxide itself (700°, vacuum); the bronze reacting according to (2) and (3) and the tungstic oxide with sodium according to (1), from right to left. A homogeneous composition finally results. The sodium metatungstate extracts the tungstic oxide even from a ($Na_2WO_4$ + $WO_3$)–melt.[11]

It follows from this that a deeper colored bronze must absorb the sodium from a brighter one until the sodium pressure is equal. Even 1-mm. crystals of the yellow bronze, embedded in an excess of the red bronze and heated under vacuum become red or in a similar fashion blue if embedded in a blue bronze (this corresponds to "mimicry" in the living world). However, they do not lose their single crystal properties.

By increasing the sodium vapor pressure, reaction (1) can be directed from right to left, the vacant 000-sites will be filled while the corresponding amount of W(VI) passes into W(V) and the bronze becomes brighter (Table I).

**The Solubility Limit of Tungstic Oxide in Sodium Metatungstate.**—For determination of this limit the reaction (3) and the reaction

$$NaWO_3 + xI \rightleftarrows Na_{(1-x)}(W^{V}O_3)_{1-x}(W^{VI}O_3)_x + xNaI \quad (x < 1) \qquad (6)$$

were used. All experiments were carried out at 800° in evacuated fused tubes. The results are summarized in Fig. 3. Between 27 and 30% tungstic oxide there is a transition zone; the red bronze absorbs tungstic oxide without changing the lattice. This phenomenon was proven by repeated experiments on different samples. Thus the succeeding violet and blue bronzes must have a slightly different structure although the difference is not visible from the X-ray diagram.[12] At the above-mentioned point the bronzes have the highest electric conductivity.[9]

The lattice contraction follows from the fact that the W(VI) has a smaller ionic radius than W(V). The deviation of the measured lattice constants from the calculated points is shown in Table II.

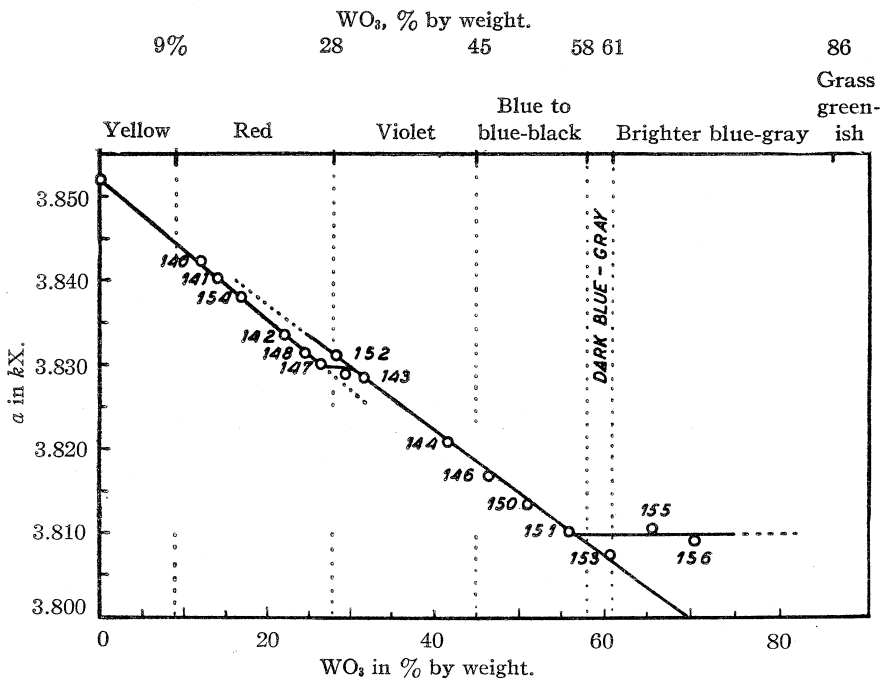


Fig. 3.—The solubility of tungstic oxide in cubic sodium metatungstate is between 56–57% by weight of tungstic oxide, using reaction (3) and 800°.

Up to 52% tungstic oxide the lines are sharp, then the background begins to darken. At 57% tungstic oxide new lines appear. The limit is between 56 and 57% tungstic oxide (at 800°, rapid cooling, see Fig. 3). The cubic bronze cannot absorb more than 57% tungstic oxide without changing its structure. This statement is only partially correct as it depends on the method of preparing the tungstic oxide rich sample.

If the sodium is extracted from the sodium metatungstate using reaction (6), one can obtain compounds with considerably higher tungstic oxide content without breaking down the old cubic lattice:

(11) If the yellow bronze and tungstic oxide in two adjacent dishes are heated under vacuum, the tungstic oxide becomes blue, violet or even red, because the bronze evaporates sodium and the tungstic oxide absorbes it readily.

(12) See v. Laue, "Röntgenstrahl-Interferenzen," Leipzig, 1940, p. 179b, or 1948, p. 193.

$$(W^{V}O_6)^{7-} \rightleftharpoons (W^{VI}O_6)^{6-} + e$$
$$e + Na \longrightarrow Na$$

and outside of the crystals

$$Na + I \longrightarrow NaI$$

The old structure remains in perfect order (sharp lines); only the lattice shrinks, while in the first case (reaction 3), a new lattice must be built up from the triclinic tungstic oxide. Extracting the sodium with iodine, a sample with a lattice constant $a$ = 3.7913 kX, corresponding to 81.9% tungstic oxide, was obtained. However, weak new lines were already on the film.

TABLE II

THE DEVIATION OF THE MEASURED POINTS FROM LINEARITY

The first 6 points: $a = 3.8519 - 0.000829.WO_3\%$; the last 7 points: $a = 3.8519 - 0.000743.WO_3\%$.

| No. | Wt. $WO_3$, % | $a$ meas. in kX | $a$ calcd. in kX | Diff. | Diff. in % |
|---|---|---|---|---|---|
| 140 | 12.08 | 3.8422 | 3.8419 | +0.0003 | +0.0078 |
| 141 | 13.96 | 3.8403 | 3.8403 | ± .0000 | ± .000 |
| 154 | 16.88 | 3.8380 | 3.8379 | + .0001 | + .0026 |
| 142 | 21.88 | 3.8335 | 3.8338 | − .0003 | − .0078 |
| 148 | 24.5 | 3.8312 | 3.8314 | − .0002 | − .0026 |
| 147 | 26.48 | 3.8303 | 3.8300 | + .0003 | + .0078 |
| 152 | 28.42 | 3.8311 | 3.8308 | + .0003 | + .0078 |
| 143 | 31.60 | 3.8285 | 3.8284 | + .0001 | + .0026 |
| 144 | 41.90 | 3.8208 | 3.8208 | ± .0000 | ± .000 |
| 146 | 46.5 | 3.8167 | 3.8174 | − .0007 | − .018 |
| 150 | 51.0 | 3.8134 | 3.8140 | − .0006 | − .016 |
| 151 | 56.0 | 3.8103 | 3.8103 | ± .0000 | ± .000 |
| 153 | 60.8 | 3.8075 | 3.8068 | + .0007 | + .018 |

The change in color of the samples with the contraction of the lattice (increasing tungstic oxide content) can also be seen from Fig. 3. Of course, the change is not sudden but gradual.

## The Nature of the Cubic Bronzes

From the description given it is evident that all the cubic tungsten bronzes from yellow to dark blue belong to the same series of anionic substitutional mixed crystals: the complexes $(W^{V}O_6)^{7-}$ of the sodium metatungstate are replaced at random by the slightly smaller $(W^{VI}O_6)^{6-}$ complexes (the corners of the octahedra are common); the sodium sites remain open. The ready replacement can be explained by the statement of Brakken that in tungstic oxide the $(W^{VI}O_6)^{6-}$ complexes are already present.[13]

The formation of solid solutions is therefore possible, even if the components belong to different crystal systems (here cubic and triclinic). The conditions are: (1) the dimensions of the replaceable structure units cannot differ more than 5% in any direction[14] and (2) the sum of the charges must be zero. This occurs frequently when the components have a similar chemical formula and a similar lattice structure with similar lattice constants (Grimm).

The samples of the bronzes also confirm the rule that compounds containing an element in two valencies are intensely colored.

**Compounds with a Higher Tungstic Oxide Content.**—Extracting sodium from the blue bronze (~ 80% tungstic oxide) by help of iodine, gives a blue-greenish sample that begins to sublime at 850°. In the sample there are thin, long, blue needles with a greenish lustre. Rotating crystal diagrams showed that these belong to the previously described tetragonal bronze (lattice constants: $a$ = 12.47 kX; $c$ = 3.819; $c/a$ = 0.306).[15] This diagram is similar to that of the cubic blue bronze.

With further loss of sodium (or tungstic oxide absorption) the samples become brighter and more greenish. The tetragonal cell contracts and new lines appear. At 92–96.4% tungstic oxide by weight a greenish-gray sample results. The diagrams have very many sharp lines and have a certain similarity with the tetragonal bronzes.

When the sodium is extracted still more, olive-green samples, brighter than the above-mentioned, can be obtained. The X-ray films are very rich with lines and show transition to the pure tungstic oxide patterns. In the region of 96.4–98.2% tungstic oxide the diagram of pure tungstic oxide can clearly be observed.

If the bronze contains more than 98.6% tungstic oxide, the powder photographs cannot be distinguished from pure tungstic oxide but the lines are, strange to say, sharper than the lines of the pure compound. Samples up to 99.3% tungstic oxide were prepared; their color is bright greenish-gray, they sublime to form thick, very brittle, slightly translucent crystals (not needles).

There are also some other compounds in the reaction tubes, especially when they are heated above 1000°. Even traces of sodium metatungstate give the tungstic oxide a greenish color.

**Acknowledgment.**—This work was carried out in the Institute for Metal Chemistry of Marburg (Germany). I am very grateful to the Director of that Institute, Geheimrat Professor Dr. R. Schenck, for the opportunity of working there for three years and for his considerate attitude and help. Likewise I am much indebted to the Director of the Mineralogical Institute of the University of Marburg, Professor Dr. F. Laves. I thank sincerely Dr. A. W. Schlechten and Professor A. Legsdin, School of Mines in Rolla, for correcting the English of my papers.

## Summary

It has been proven that the sodium tungsten

(13) Brakken, *Z. Krist.*, **78**, 487 (1931): tungstic oxide consists of octahedra also (with common oxygen corners). But these are oblique, because the symmetry of the lattice is triclinic or pseudo rhombic. The oblique octahedra evidently change into regular when absorbed by the bronze.

(14) Straumanis and Stahl, *Z. physik. Chem.*, **194**, 130 (1944).

(15) de Jong and Stek, ref. 4, found $a$ = 17.5 Å. (in the direction of the diagonal of the base 12.4Å); $c$ = 3.8; $c/a$ = 0.217. Hägg, ref. 5, found $a$ = 12.13 and $c$ = 3.77 Å.

bronzes ($NaWO_3$) can lose sodium according to the reversible reaction $NaW^{V}O_3 \rightleftarrows Na^0 + W^{VI}O_3$.

The tungstic oxide dissolves in the remaining sample with formation of anionic substitutional solid solutions. The cubic bronzes can contain up to 80% tungstic oxide. The lattice constants *versus* tungstic oxide-content are shown in Fig. 3.

The properties of pure sodium metatungstate and those of the solid solutions are described. The tetragonal blue bronzes contain 80–90% tungstic oxide. Their color is more greenish. Compounds with 92–96.4% tungstic oxide were green. For samples with still higher tungstic oxide concentration see above.

# The Sodium Tungsten Bronzes. II. The Electrical Conductivity of the Bronzes

BY M. E. STRAUMANIS[1] AND A. DRAVNIEKS[2]

**Introduction.**—The high electrical conductivity of tungsten bronzes was reported first by Hägg[3] who observed a large increase in conductivity with increase in temperature. He suggested that the increase was the result of progressive sintering.

More recent investigations made by the authors, however, show that the conductivity effect is much more complex in nature. The purpose of the present paper is to establish the factors responsible for these changes in conductivity.

**The General Behavior of Sintered Yellow Bronzes.**—The specimens were prepared from either a pure yellow powder of sodium tungsten bronze or from a corresponding mixture of tungsten powder, tungsten trioxide and sodium tungstate (composition given on page 684). The powder was pressed into small cylinders by means of a steel pellet press and the specimens were then sintered at 700–750° in high vacuum for one to two hours and cooled under vacuum. The specimens were 10–15 mm. long, about 6 mm. in diameter, hard and brittle. The color was yellow to orange. The ends of the specimens were ground parallel, polished and coated with graphite. To measure the electrical resistance, the specimens were fastened in a jig (Fig. 2b) supplied with suitable leads. The resistance was measured with a good technical ohmmeter.

Generally, the resistance of freshly prepared specimens was 0.2–0.6 ohm, depending on the composition. However, the resistance increased continuously,[4] reaching values of 10,000 ohms and even higher (Fig. 1). The reproducibility of the resistance *vs.* time curves was poor. Sections of the curve can be described by an equation of the form

$$r = r_0 (1 + \alpha\sqrt{t})$$

where $r_0$ = initial resistance, $t$ = time and $\alpha$ = coefficient which changes slowly with time. The weight of a specimen increased by 0.08–0.2% during a run.

(2) Illinois Institute of Technology, Chemistry Department, Corrosion Research Laboratory.

(3) Hägg, *Z. physik. Chem.*, **B29**, 201 (1935).

(4) Observed first by Dr. G. Münch, State Institute of Metal Chemistry, Marburg a. Lahn.

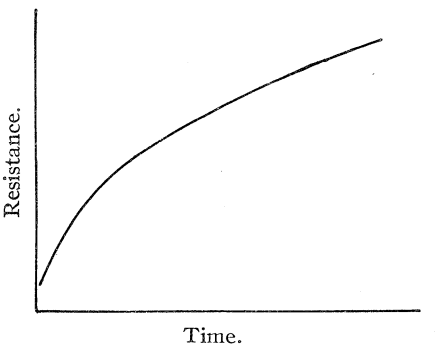

Fig. 1.—Increase of electrical resistance with time of a briquette of yellow bronze exposed to air.

The resistance of a specimen did not change when it was kept in vacuum, or in hydrogen, nitrogen, hydrogen sulfide, dry oxygen or pure water vapor, or when the specimen was protected from air by rubber tubing. When the atmospheric air was admitted, the resistance started to increase immediately. A particularly rapid and irregular increase in resistance was caused by oxygen saturated with moisture or moist air. The change due to moist air is shown in Table I.

TABLE I

RESISTANCE CHANGES OF TWO SPECIMENS OF BRONZE SPECIMEN $B_2$ IS YELLOW BRONZE, 10.3% $WO_3$; SPECIMEN $F_1$ IS RED-BROWN BRONZE, 12% $WO_3$; AIR SATURATED WITH WATER VAPOR AT 20°

| Specimen $B_2$ | | | Specimen $F_1$ | |
|---|---|---|---|---|
| Time, min. | Resistance, ohm | Remarks | Time, min. | Resistance, ohm |
| 0 | 0.45 | High | 0 | 0.54 |
| 90 | .46 | vacuum | 60 | .55 |
| 100 | .62 | Water | 70 | .58 |
| 120 | .67 | vapor | 210 | .64 |
| 130 | .70 | pure | 245 | .68 |
| 140 | 6.3 | Air | 250 | 3.3 |
| 150 | 23.0 | and | 260 | 18 |
| 160 | 55 | water | 270 | 53 |
| 170 | 101 | vapor | 280 | 115 |
| 180 | 160 | | 290 | 220 |
| 330 | 620 | | 300 | 330 |
| 360 | 640 | | 320 | 600 |
| | | | 350 | 1100 |

At resistances over 1000 ohms polarization effects were observed. This polarization was never observed when only small amounts of moisture were allowed to make contact with the specimens.

The lost conductivity can be easily restored to an appreciable extent by drying the specimen over phosphorus pentoxide or by placing it in a vacuum; *e. g.*

| | | |
|---|---|---|
| 50 ohms | (moist air) | 120 ohms |
| 120 hms | ($P_2O_5$) | 60 ohms |
| 60 ohms | (moist air) | 850 ohms |
| 850 ohms | ($P_2O_5$) | 200 ohms |

Full restoration is achieved only by sintering the sample in vacuum. Mild warming in air restores the conductivity in part, but the resistance increases again upon cooling, since renewed adsorption of oxygen and water vapor takes place. Table II shows the course of an experiment in air and in vacuum.

TABLE II

THE DECREASE OF RESISTANCE OF A SPECIMEN OF YELLOW BRONZE IN AIR AND IN VACUUM AT ELEVATED TEMPERATURES

| In air | | | In vacuum | | | |
|---|---|---|---|---|---|---|
| Time, min. | Temp., °C. | Resistance, ohm | Time, min. | Temp., °C. | Resistance, ohm | Press., mm. |
| 0 | 22 | >12000 | 0 | 20 | 12000 | 0 |
| 25 | 70 | 9200 | 20 | 280 | 2000 | 0 |
| 38 | 80 | 1090 | 30 | 290 | 620 | 0.2 (?) |
| 50 | 90 | 450 | 40 | 310 | 390 | 0.2 |
| 65 | 100 | 120 | 80 | 390 | 36 | 0.2 |
| 100 | 105 | 56 | 90 | 410 | 13 | 0.2 |
| 153 | 105 | 41 | 110 | 550 | 1.9 | 0.2 |
| 161 | 100 | 41 | 170 | 580 | 1.2 | 1.5 |
| 178 | 90 | 44 | 200 | 680 | 1.0 | 2.0 |
| 181 | 80 | 45 | 215 | 730 | 0.9 | 2.2 |
| 184 | 72 | 46 | 230 | 790 | 0.82 | 2.5 |
| 186 | 65 | 47 | 240 | 800 | 0.78 | 2.5 |

The pressure developed in vacuum is due to adsorbed gases evolved from the specimen.

The conductivity can also be restored if the specimen is heated by passing a strong electric current through it.

Consequently, it may be stated that the increase in resistance of sintered porous specimens of tungsten bronzes is caused by the simultaneous adsorption of oxygen and water vapor. The presence of both is necessary.

The small amounts of adsorbed oxygen and moisture (several tenths of a per cent.) causing the changes and easy desorption indicate that the formation of sodium tungstate is not the process responsible for the effects described. However, it is known that the conductivity of pure elements can be appreciably decreased by intercrystalline layers of poorly conducting surfaces. A typical example is boron.[5]

Sodium bronze ($NaWO_3$) decomposes at high temperatures; tungsten, sodium tungstate and other compounds are formed.[6] Sodium tungstate acts as an intercrystalline cement holding the grains of pure bronze (see sintering, page 686). But only the metallic tungsten could be expected to form unstable, poorly conducting adsorption compounds with water and oxygen.[7]

Investigations on very pure tungsten bronzes were conducted to eliminate the effects caused by the intercrystalline substance.

**The Conductivity of Pure Sodium Tungsten Bronzes.**—The apparatus as shown in Figs. 2a and b was employed to measure the conductivity, temperature coefficients and change of conductivity under the influence of different agents. The specimen was placed in the glass tube between the two well-fitted steel pistons of the jig (Fig. 2b). The screw was tightened until the measured resistance attained a constant value. Then the jig was placed in the apparatus shown in Fig. 2a. The resistance of the leads was subtracted from the total measured resistance. The device could also be employed for measuring the resistance of powders.

The procedure used for removing the tungsten and sodium tungstate particles from the specimens is described in the previous article.

The data measured on powders of two tungsten bronzes are shown in Table III.

TABLE III

THE SPECIFIC RESISTANCES ($\sigma$) AND CONDUCTIVITIES ($\kappa$) OF THE TWO PUREST SODIUM TUNGSTEN BRONZES IN VACUUM AT DIFFERENT TEMPERATURES, IN WATER VAPOR, AND IN WATER VAPOR WITH AIR

| $NaWO_3$, almost 100%, fine crystalline | | | | $NaWO_3 \cdot WO_3$ (11.6% $WO_3$), reddish, coarsely crystalline | | | |
|---|---|---|---|---|---|---|---|
| Time, min. | Temp., °C. | $\sigma$ ohm. | $\kappa$ $ohm^{-1}$ | Time, min. | Temp., °C. | $\sigma$ ohm. | $\kappa$ $ohm^{-1}$ |
| 0 | 450 | 0.0059 | 170 | 0 | 450 | 0.036 | 28 |
| 20 | 300 | .0029 | 350 | 25 | 400 | .033 | 30 |
| 65 | 20 | .0029 | 350 | 30 | 350 | .031 | 32 |
| Water vapor, 14 mm. | | | | 35 | 300 | .02 | 50 |
| 80 | 20 | .0029 | 350 | 90 | 20 | .0026 | 385 |
| 110 | 20 | .0029 | 350 | 1290 | 20 | .0026 | 385 |
| Air admitted, 90 mm. | | | | Water vapor with air | | | |
| 140 | 20 | .0029 | 350 | 1310 | 20 | .0026 | 385 |
| | | | | 1390 | 20 | .0026 | 385 |

The agreement in values obtained at 20° (350–385 $ohm^{-1}$) is satisfactory in view of the low reproducibility of such measurements.

The measurements on pressed and sintered specimens of yellow bronze are shown in Table IV. They possess lower conductivity, and the conductivity does not change in dry air, but decreases rapidly in moist air.

The negative temperature coefficient indicates a metallic (electronic) type of conductivity.[8]

The fact that some authors[8] have found a positive temperature coefficient of conductivity may be explained by the presence of moisture and oxy-

[a] The specimens contained adsorbed oxygen and water vapor.

gen in the nitrogen employed to blanket the specimens in earlier work. The present paper shows that water and oxygen are again adsorbed upon lowering the temperature. In this way a positive temperature coefficient is obtained due to reaction which is not germane to pure $NaWO_3$ (bronze) or to $NaWO_3$ containing tungsten trioxide.

The conductivities and temperature coefficients of bronzes with higher tungsten trioxide content are shown in Table V.

Here large differences in conductivity of different specimens were observed, even in parallel experiments. Generally, the conductivity decreases with increasing tungsten trioxide content. The temperature coefficient is negative throughout and its values lie within 1:10 ratio.

The specimens with still higher tungsten trioxide content are very brittle and collapse under pressure applied in the jig. Since for specimens with more than 35% tungsten trioxide the resistance was not affected by moist air, a simpler apparatus was employed.

| 115 | 92 | 70 | $WO_3$[a] | 100 | 200000 |

[a] Heated in vacuum at 920°

The violet specimen $G_1$ with 38.8% tungsten trioxide had the highest conductivity in the whole

series, 600 ohm$^{-1}$.[9] With higher tungsten trioxide contents the resistance increases rapidly but the results fluctuate. The addition of small amounts of $NaWO_3$ decreases the resistance of tungsten trioxide very effectively. Tungsten trioxide is a semiconductor of the excess type.[10,11,12]

**Reasons for Resistance Changes in Sintered Specimens.**—The measurements reported above demonstrate that the pure sodium tungsten bronzes possess constant conductivity at constant temperature. Therefore, the changes in resistance of sintered specimens of bronze are caused by an intercrystalline phenomenon and due to an intercrystalline substance.

If the metallic tungsten is assumed to take part in the effect, the behavior of a mixture of tungsten and sodium tungstate should be similar to that of the bronze specimens. Accordingly, an identical study was made with specimens of a tungstate and tungsten powder mixtures. These were pressed in the same way as the bronze specimens, with subsequent heating at 600° in vacuum. The resistances were as shown in Table VII.

TABLE VII

SPECIFIC RESISTANCE OF $Na_2WO_4$ WITH DIFFERENT AMOUNTS OF TUNGSTEN ADDED

| Wt. % W | 13 | 20 | 30 | 40 | 50 | 55 |
|---|---|---|---|---|---|---|
| Resist. ohm | 17000 | 12000 | 11400 | 334 | 0.29 | 0.067 |

The specimen with 50% tungsten was dark gray and its behavior studied in the apparatus of Fig. 2. The resistance in atmospheric air began to increase during the first day. The specimen showed the same behavior as the bronzes. At very high moisture contents the specimen became white and the changes in resistance were then irreversible, apparently due to the formation of sodium tungstate from the tungsten.

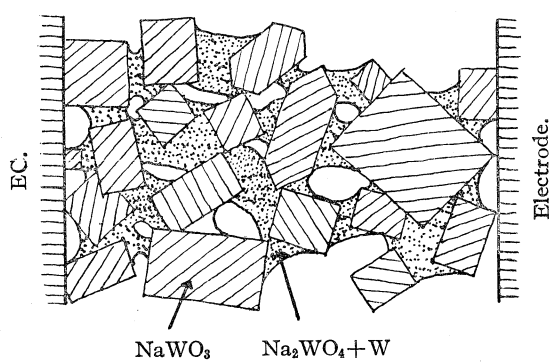

Fig. 3.—Structure of a sintered sodium tungsten bronze specimen: sodium tungstate cements the bronze grains, the black dots represent tungsten, the pores are white. The bronze crystals are shown smaller than they actually are in comparison with the intercrystalline tungstate–tungsten mass.

Similar specimens prepared from sodium tungstate with 30% silver powder added had 0.32 ohm resistance, but this value did not change in moist air. No changes of resistance were observed in pressed tungsten powders.

Consequently, it may be concluded that the resistance changes of sintered bronzes are caused by elementary tungsten in combination with sodium tungstate or similar products. The presence of elementary tungsten in sintered bronzes was also detected by X-ray diffraction patterns. Free tungsten and sodium tungstate are not found if the bronze specimens contain more than about 35% tungsten trioxide. Such specimens are therefore brittle and insensitive to moist air.

**The Structure of Sintered Bronze Specimens.**—The schematic structure of sintered specimens is suggested by the foregoing observations as shown in Fig. 3.

The conductivity of the aggregate is caused by tungsten particles which form conducting bridges in the mass of sodium tungstate. The latter also cements the grains of the bronze. In moist air the formation of adsorption compounds begins on the surface of the tungsten particles with a simultaneous binding of oxygen and water. As a result many bridges are ruptured and the resistance of the whole aggregate increases. The diffusion of moist oxygen proceeds deeper and deeper through the pores. Upon placing in vacuum or heating, the adsorption compound is decomposed and the conductivity improves. However, not all of the interrupted bridges can be regenerated. In many places the reaction may proceed to form sodium tungstate, a non-conductor. Also, $NaWO_3$ is slowly oxidized to tungstate. The volume increases and cracks are formed. The degree of destruction depends upon the duration of contact with moist oxygen and the amount of moisture. The regeneration is not complete in vacuum or by gentle heating as sodium tungstate does not decompose and is not reduced at low temperatures in hydrogen. Upon heating to 700° in vacuum the bronze decomposes partly to tungsten and sodium tungstate and new tungsten bridges are formed. In this way the effects observed concerning the conductivity behavior of tungsten bronzes are easily and completely explained.

**Adsorption Compound on the Surface of Tunsgten.**—The concept of the adsorption compound which is used as an explanation for the change of the conductivity of a tungsten–tungstate mass needs further elaboration. Although it is well known that at high temperatures tungsten easily forms oxide films,[13,14,15] this does not occur under ordinary conditions. The surface of a tungsten grain is probably in a particularly active state, as a result of being embedded in the sodium tung-

(9) Perhaps the bronzes of transition composition, THIS JOURNAL, **71**, 679 (1949), possess still higher conductivity.

state.[16] In this active state tungsten is able to react with oxygen and water forming an unstable adsorption compound. This view is supported by the following experiment: The purest yellow bronze was mixed with anhydrous sodium tungstate and tungsten powder and pressed. Specimens of this mixture behaved in the same way as the sintered bronze specimens.

**Acknowledgment.**—The above-mentioned work was performed in the State Institute for Metal Chemistry, Marburg a. d. Lahn, Germany. One of the authors (A. Dravnieks) would like to extend his gratitude to Dr. R. Schenck, director, for permission to use the Institute facilities for this investigation.

## Summary

The specific conductivity of pure yellow sodium tungsten bronze is about 400 $ohm^{-1}$ and the temperature coefficient is negative. The conductivity is electronic.

The temperature coefficient is definitely negative also for bronzes with up to 20% of tungsten trioxide (in solid solution). The highest specific conductivity (600 $ohm^{-1}$) is shown by the violet bronze with 38.8% of tungsten trioxide. At higher trioxide contents the resistance of the powder increases.

In the preparation of sintered specimens of sodium tungsten bronzes the $NaWO_3$ decomposes partly upon heating in vacuum, and tungsten, sodium tungstate and similar products are formed. These products cement the powder to a hard, brittle, porous specimen. Tungsten particles form conducting bridges between the crystals of actual bronze. The bridges are interrupted reversibly to some extent by moist oxygen. In this way the peculiar electrical behavior of sintered specimens can be completely explained.

Specimens with more than 35% of trioxide do not contain any free tungsten; therefore, the increase in resistance in moist air does not occur.

(16) Anhydrous sodium tungstate is quasicubic and the lattice constant is ~5.57 kX.

# The Oxidation States of Neptunium in Aqueous Solution[1,2]

BY J. C. HINDMAN, L. B. MAGNUSSON[3] AND T. J. LACHAPELLE[3a]

The preliminary investigation in 1940 by the discoverers of element 93 (neptunium), McMillan and Abelson,[4] led these authors to the conclusion that there were lower and upper oxidation states of neptunium analogous to the +4 and +6 oxidation states of uranium. These and other experiments,[5] including those by Voigt, Sleight, Hein and Wright,[6] which suggested the possible existence of a +5 oxidation state, were performed by tracer methods using the 2.3 day beta emitting isotope $Np^{239}$. By use of the long-lived alpha emitting $Np^{237}$ discovered in 1942 by Wahl and Seaborg,[7] it is possible to study neptunium with weighable amounts of material and in July, 1944, Magnusson and LaChapelle[8] succeeded in isolating the first pure compounds of neptunium using as the source of the $Np^{237}$ uranium irradiated with cyclotron neutrons. At this time these investigators definitely established the existence of the +4 and +6 oxidation states by the preparation of microgram quantities of the solid compounds, neptunium(IV) dioxide, $NpO_2$, and sodium neptunium(VI) dioxytriacetate, $Na_2NpO_2(OOCCH_3)_3$. Zachariasen[9] was able to show by X-ray diffraction studies that these compounds were isomorphous with the analogous compounds of uranium and plutonium.

The isolation and purification of milligram quanties of $Np^{237}$ made possible a more extensive investigation of the chemistry of this element. The first few milligrams were isolated as the result of special runs in the chemical extraction plant of the Clinton Laboratories (now the Oak Ridge National Laboratory) in Tennessee. The $Np^{237}$ from this source was concentrated and isolated in pure form by a group from the Metallurgical Laboratory. This group was headed by J. J. Katz and consisted of Magnusson, LaChapelle, J. R. Gilbreath and W. C. Beard. Larger quanti-

ties were obtained during 1945 as the by-product of the operation of the plutonium project plant at the Hanford Engineer Works in the State of Washington. This latter material was isolated as the result of a process designed for the recovery of neptunium at the Hanford Engineer Works by a group at the Metallurgical Laboratory under the direction of F. W. Albaugh and R. C. Thompson.

The initial objective of the work with pure neptunium was the identification of the oxidation states in aqueous solution. In the first part of this paper experiments are described which demonstrate the existence of the +4, +5 and +6 oxidation states of neptunium in solutions of perchloric, hydrochloric and sulfuric acids. That neptunium(III) could exist in aqueous solution was first shown polarographically by Watters.[10]

In the second part of the paper are described experiments on which are based a scheme of oxidation potentials relating the +3, +4, +5 and +6 oxidation states in hydrochloric acid solution.

## 1. The +4, +5 and +6 Oxidation States of Neptunium

It was expected that the various oxidation states of neptunium like those of uranium and plutonium would have highly characteristic absorption spectra in solution. After establishing the identity of a single oxidation state, one should then be able to titrate the neptunium solution spectrophotometrically with oxidizing or reducing agents and thus to determine the oxidation numbers of any higher or lower states produced.

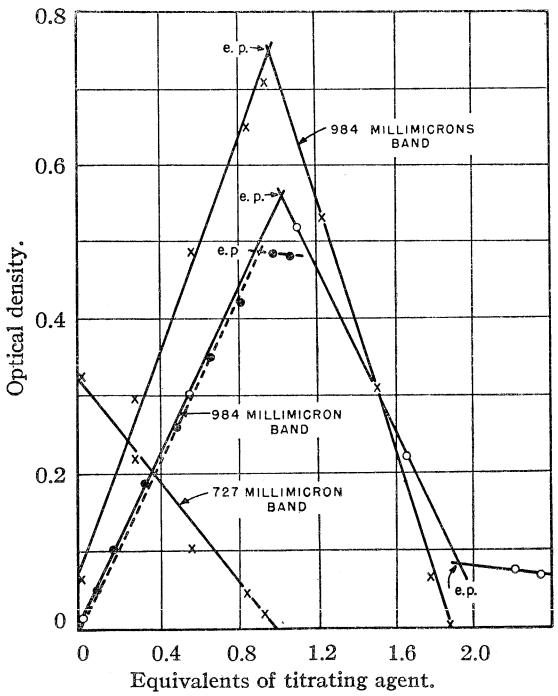

Fig. 1.—Titration of neptunium with oxidizing and reducing agents: ●, reduction of Np(VI) by Sn(II) in 1.0 *M* HCl; ×, oxidation of Np(IV) by Ce(IV) in 0.5 *M* $H_2SO_4$; O, reduction of Np(VI) by Fe(II) in 0.5 *M* $H_2SO_4$.

### Experimental

The absorption spectrum measurements were made with a Beckman quartz spectrophotometer. The instrument was operated, in general, at a slit width of 0.01 to 0.02 millimeter. Readings were made at 2 millimicron intervals in the spectral region from 350 to 600 millimicrons, at 2.5 millimicron intervals in the region from 600 to 1000 millimicrons, and at 5 millimicron intervals above 1000 millimicrons except in the vicinity of absorption bands where readings at 1 millimicron intervals were made. In the case of very sharp absorption bands the peak maximum was located by slowly rotating the wave length drum and finding the point of maximum deflection of the galvanometer. Special adapters were made so that Corex absorption cells of 1.000 ± 0.002 cm. and 0.500 ± 0.002 cm. could be used with samples of 1.1 and 0.5 milliliter of solution, respectively.

The first preparation for spectrophotometric examination was made by heating 1.16 mg. of dry, olive-green neptunium hydroxide (later identified as neptunium(IV) hydroxide) in 52 microliters of 9.40 molar perchloric acid. After several hours heating in a water-bath, dilution with water produced a clear, pale green solution, 1.0 molar in perchloric acid. The spectrum of this solution was marked by three sharp, strong absorption bands, at 723, 964 and 984 millimicrons. Later experiments showed this solution contained a mixture of oxidation states.

An excess of argentic oxide was added to the green solution, which turned nearly colorless with a faint pink cast. The strong, sharp absorption bands associated with the initial spectrum had disappeared. A dark brown "hydroxide" was precipitated from the solution by the addition of a slight excess of ammonia. This hydroxide was dissolved in warm 10 molar hydrochloric acid and the solution was diluted to 0.5 molar acid, becoming a yellow green in color. The spectrum was very similar to that of the perchloric acid solution after the argentic oxidation. The spectral identity was taken as evidence that the same oxidation state existed in both solutions.

The first production of a lower oxidation state was carried out by adding small aliquots of Sn(II) to the oxidized neptunium chloride solution. It was found that addition of stannous chloride caused the appearance of an absorption band at 984 millimicrons which increased in optical density until the amount of stannous chloride added was roughly equivalent to one-half mole per mole of neptunium. Further addition of stannous chloride produced only a slight reduction in peak height. A more precise duplication of this titration is illustrated in Fig. 1. An interesting phenomenon observed in the titration was the small growth of the 723 millimicron peak observed in the original perchloric acid solution. The peak disappeared rather quickly.

A neptunium fluoride precipitate (tentatively identified as $KNpF_5$ or $K_2NpF_6$) was made from the above solution by saturating the solution with sulfur dioxide, then making the solution one molar in potassium fluoride and four molar in hydrofluoric acid. This green precipitate was fumed to dryness with sulfuric acid yielding bright green crystals. An absorption spectrum of the solution produced when the crystals were dissolved in 0.5 molar sulfuric acid showed two prominent peaks at 727 and 971 millimicrons analogous to the peaks at 723 and 964 millimicrons observed in the original neptunium solution in perchloric acid.

Oxidation of the neptunium sulfate solution was carried out by adding aliquots of 0.069 molar Ce(IV) in 0.5 molar sulfuric acid. A peak at 984 millimicrons, corresponding to the peak produced by reduction of an oxidized solution with Sn(II), reached its maximum height when the mole ratio of added Ce(IV) to Np was approximately one. An additional equivalent of Ce(IV) reduced the peak to zero

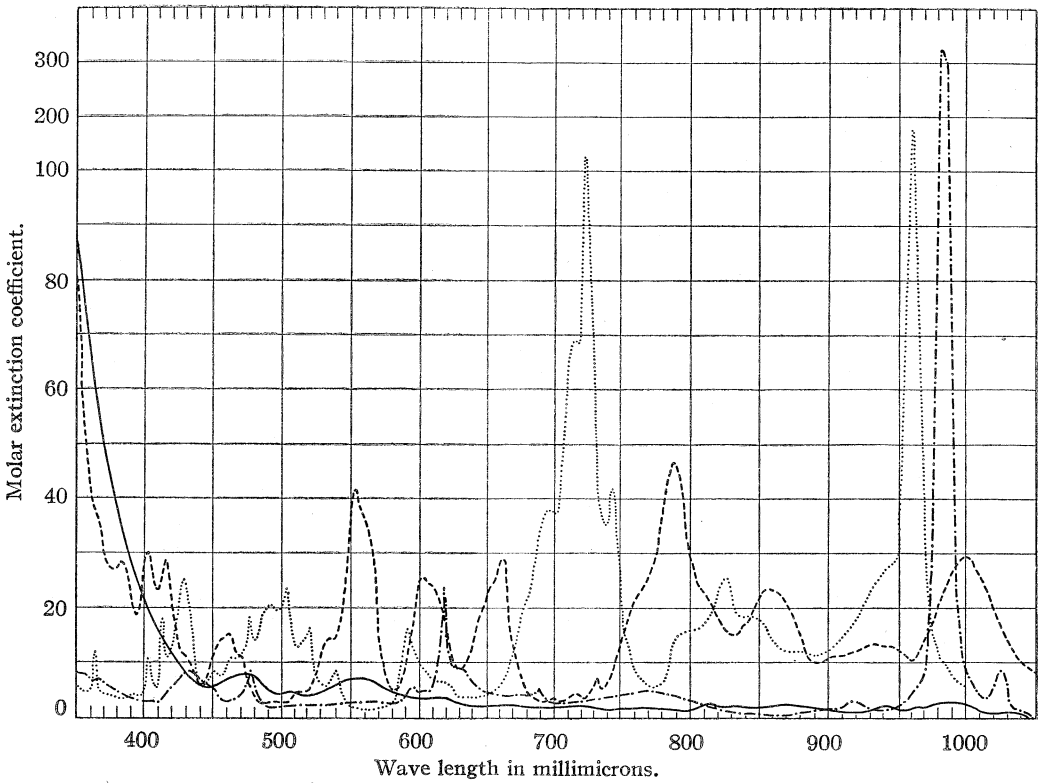

Fig. 2.—Absorption spectra of neptunium ions in aqueous solution: ---, Np(III) in 1.0 *M* HCl; . . ., Np(IV) in 1.0 *M* HCl; -·-, Np(V) in 1.0 *M* HCl; —, Np(VI) in 1.0 *M* $HClO_4$.

optical density (Fig. 1). The spectrum of the latter solution was similar to that of the oxidized perchloric and hydrochloric acid solutions.

A six microliter sample (10 micrograms of neptunium) was removed from the ceric oxidized solution and precipitated in a capillary by making the solution four molar in sodium ion and two molar in acetate ion. An X-ray diffraction pattern of the precipitate was found by Zachariasen[9] to be identical with that of the salt he had previously identified as sodium neptunyl acetate, $NaNpO_2(OOCCH_3)_3$. On the basis of this evidence, it was concluded that the highest oxidation state obtained was +6. The oxidation numbers of the other two states are, therefore, +4 and +5. Data on the stoichiometric reduction of Np(VI) in 0.5 molar sulfuric acid by ferrous ion are also given in Fig. 1.

## Discussion

Differences in absorption spectra have led to the identification of three oxidation states of neptunium in aqueous solution. The lowest state obtained is characterized by two strong, sharp absorption bands at 723 and 964 millimicrons in chloride or perchlorate solution. Figure 2 shows the spectrum of Np(IV) in 1.0 *M* hydrochloric acid solution. These bands are shifted to 727 and 971 millimicrons in 0.5 molar sulfuric acid solution. This shift is presumably caused by complex ion formation involving neptunium(IV) and sulfate ions. The next higher oxidation state, which differs in oxidation number by one unit from both the lowest state and highest state obtained as determined by stepwise spectrophotometric titration with oxidizing or reducing agents, has a spectrum characterized by a sharp, strong band at 984 millimicrons in perchlorate, chloride or sulfate solutions. Figure 2 shows the spectrum of the +5 oxidation state in 1.0 molar hydrochloric acid solution. Isolation of the salt $NaNpO_2(OOCCH_3)_3$ from the solution of highest oxidation number has been used to identify this state as the +6 oxidation state. The oxidation numbers of the other two states are +4 and +5. The spectrum of the +6 state shown in Fig. 2 has no marked absorption bands in the visible region of the spectrum. The spectrum of the +6 perchlorate is given rather than the chloride because of the difficulty in correcting the chloride spectrum for the presence of chlorine.

## 2. The Oxidation Potentials of Neptunium Couples

**The Np(III)–Np(IV) Potential.**—A preliminary attempt to prepare Np(III) by reduction of Np(IV) in 1.0 molar hydrochloric acid at a platinum cathode was unsuccessful, leading to the conclusion that the potential for the Np(III)–Np(IV) couple was more positive than zero. It has been found, however, that the failure to obtain Np(III) may be attributed to the extremely rapid oxidation of Np(III) in the presence of air. Watters[10] showed with the polarograph that Np(III) could be formed in solution; and, although the Np(III)–Np(IV) couple ap-

peared to be irreversible at the dropping mercury electrode, Watters[10] estimated the formal oxidation potential of the couple in 0.25 molar sulfuric acid to be approximately +0.1 volt. Further experiments by the authors revealed that Np(III) could be obtained in fair yield in hydrochloric acid by reduction of Np(IV) with a mercury pool cathode and that Np(III) is stable with respect to oxidation by hydrogen ion in one molar hydrochloric acid.

## Experimental

Gross neptunium concentrations were determined by radiometric assay. Assays of concentrations of the individual oxidation states were made spectrophotometrically. All potential measurements were made at 25 ± 1°, using a Rubicon precision potentiometer and galvanometer of 0.003 microampere per mm. sensitivity.

The micro-scale reduction cell employed for the preparation of Np(III) consisted of a 1-cm. corex spectrophotometer absorption cell with air-tight connections. Details of its construction are given elsewhere.[11] The complete electrolytic apparatus was mounted in a cell holder for convenient transfer to the Beckman spectrophotometer.

1.5 ml. of 0.00752 molar Np(IV) solution in 1.63 molar hydrochloric acid was placed in the cell and the cork sealed with ceresin wax. Oxygen was removed by bubbling pure nitrogen, saturated with water vapor, through the solution for ten minutes before the electrolysis. The solution was reduced by electrolyzing with a current density of *ca.* 8 milliamperes/sq. cm. Nitrogen was continuously bubbled through to stir the solution and to assist in maintaining an oxygen-free atmosphere. The reduction was stopped periodically and the nitrogen inlet and vent disconnected and sealed to permit insertion of the holder into the spectrophotometer. The extent of reduction was determined by observing the decrease in the 723 millimicron absorption band of Np(IV). The change in hydrochloric acid concentration was computed from the total number of coulombs passed through the cell. The solution was electrolyzed for a total of 1278 milliampere-minutes, resulting in a reduction of the hydrochloric acid concentration to 0.96 molar (no volume change perceptible). The optical density of the 723 millimicron band had been reduced to 16% of the value before electrolysis. The nitrogen inlet and vent were sealed and the complete absorption spectrum of the solution was measured over the range 350–1050 millimicrons. Over a period of two hours during the measurement of the absorption spectrum the optical density at 723 millimicrons increased by only 1% of the peak value.

A few bubbles of air were blown through the solution. Alternate measurements of the optical density of the 723 millimicron absorption band and the e.m.f. of the neptunium cell were made. The e.m.f. measurements were made using the $Hg^0$ cathode as the indicator electrode and a saturated potassium chloride–calomel electrode as the reference electrode. The 723 millimicron absorption band optical density was observed to increase steadily over a period of five hours to the maximum value observed in the pure Np(IV) solution before the electrolysis. The measured potentials were very stable, shifting slowly to less positive values as the oxidation proceeded. At the completion of the experiment radiometric assays showed the concentration of the neptunium to be the same as before the electrolysis.

## Results

The color of the Np(III) solution was pale purple, similar to that of U(III) and Pu(III). From a plot of the complete absorption spectrum measured immediately after the electrolysis, the amount of Np(IV) present in the solution was estimated by a series of approximations. It was concluded that the Np(IV) had been approximately 87% reduced to Np(III). The Np(III) absorption spectrum reproduced in Fig. 2 was obtained by correcting the observed spectrum for the Np(IV) contribution.

The optical density of the solution at the times of e. m. f. measurements was obtained by interpolation from a density–time plot. The Np(III) and Np(IV) concentrations were derived from the equation

$$D - E_{III}C/E_{IV} - E_{III} = C_{IV} \qquad (1)$$

where $C$ = total neptunium concentration in moles liter$^{-1}$; $D$ = measured optical density at 723 millimicrons; $E_{III}$ = molar extinction coefficient of Np(III) at 723 millimicrons; $E_{IV}$ = molar extinction coefficient of Np(IV) at 723 millimicrons; $C_{III}$ = concentration of Np(III) in moles liter$^{-1}$; $C_{IV}$ = concentration of Np(IV) in moles liter$^{-1}$.

The molar extinction coefficients, $E_{III}$ and $E_{IV}$, were evaluated as follows: The measured optical density of the Np(IV) 723 millimicron band has been found from independent measurements to conform to Beer's law over the range of concentrations of Np(IV) in this experiment, the molar extinction coefficient being equal to 126.[12] A value for the molar extinction coefficient, $E_{III}$, of 4.2 was obtained by subtracting the estimated peak height at 723 millimicrons contributed by Np(IV) in a complete spectrum measured after reduction. Concentrations of Np(III) and Np(IV) at the times of e. m. f. measurement were calculated directly from the interpolated density at 723 millimicrons using equation 1. The formal potential, $E_f$, of the Np(III)–Np(IV) couple was calculated by the use of equation 2.

$$E_f = -E_{measured} + E^0(Hg\text{–}HgCl) + 0.05914 \log (C_{IV}/C_{III}) \qquad (2)$$

The $E^0$ of the saturated calomel reference electrode was taken as −0.245 volt. The formal potential as defined by equation 2 is the potential of the Np(III)–Np(IV) couple in 1 molar hydrochloric acid at equal concentrations of Np(III) and Np(IV).

Although the precision of the measurements is higher, the measured potentials are not considered to be more accurate than ±0.005 volt. On this basis the potential of the couple

$$Np(III) \rightleftharpoons Np(IV) + e^- \qquad (3)$$

is −0.137 ± 0.005 volt.

**The Np(IV)–Np(V) Potential.**—The potential of a bright platinum electrode inserted in a solution containing Np(IV) and Np(V) in one molar hydrochloric acid drifts to less positive values with no indication of approaching constancy

| .707 | 5.55 | 2.98 | .080 | − .137 |
| .743 | 5.85 | 3.75 | .074 | − .137 |
| .781 | 6.16 | 4.92 | .065 | − .139 |
| .812 | 6.41 | 6.41 | .060 | − .137 |
| .814 | 6.43 | 6.56 | .058 | − .138 |
| .817 | 6.46 | 6.87 | .056 | − .139 |
| .849 | 6.72 | 9.75 | .049 | − .138 |
| .852 | 6.74 | 10.05 | .047 | − .139 |
| .856 | 6.78 | 10.8 | .045 | − .139 |

within a period of several hours. For this reason, an indirect method was used to obtain the potential of this couple. Preliminary experiments showed that the reduction of Np(V) by Fe(II) was not quantitative in one molar hydrochloric acid. Estimates of the potential were therefore obtained from measurements on solutions containing Np(V), Np(IV), Fe(III) and Fe(II) in equilibrium.

## Experimental

In the first experiment, 2.0 ml. of a 0.0042 molar Np(VI) solution in 1.00 molar hydrochloric acid was titrated with a 1.00 molar Fe(II) solution in 1.00 molar hydrochloric acid. The Fe(II) solution was prepared by dissolving a weighed quantity of $Fe^0$ in hydrochloric acid. The reduction was followed spectrophotometrically. Although the reduction of the Np(VI) to Np(V) was instantaneous the further reduction to Np(IV) took approximately eighty minutes to reach equilibrium after each addition of Fe(II). The concentration of Np(IV) was calculated from the optical density of the 723 millimicron band and the concentration of the Np(V) by difference. The electrode system used consisted of a bright platinum indicator electrode and a $Ag^0$–AgCl reference electrode.

TABLE II

POTENTIAL MEASUREMENTS ON Np(IV)–Np(V) COUPLE IN 1.00 *M* HCl (0.00423 *M* Np; $t$ = 25°)

| Np(V)/Np(IV) | $E$ obs., volt | $E_f$, volt |
|---|---|---|
| 5.04 | 0.530 | −0.734 |
| 2.01 | .510 | − .737 |
| 0.790 | .487 | − .738 |
| 0.447 | .471 | − .732 |
| 0.0944 | .440 | − .746 |
| | Av. | −0.737 |

TABLE III

POTENTIAL MEASUREMENTS ON Np(IV)–Np(V) COUPLE IN 1.00 *M* HCl ($t$ = 25°)

| Np, mole/liter | Np(V)/Np(IV) | $E$ obs., volt | $E_f$, volt |
|---|---|---|---|
| 0.00366 | 0.167 | 0.453 | −0.739 |
| .00366 | .0388 | .423 | − .750 |
| .00274 | .676 | .491 | − .746 |
| .00274 | .129 | .430 | − .727 |
| .00396 | .247 | .474 | − .737 |
| .00396 | .0883 | .436 | − .725 |
| | | Av. | −0.737 |

In two additional experiments, potential measurements were taken at two ratios of Np(IV) to Np(V).

## Calculations and Results

The formal oxidation potential of the Np(IV)–Np(V) couple was calculated from the equation

$$E_f = -E_{measured} + E_{Ag^0-AgCl} + 0.05914 \log a_{Cl^-} + 0.05914 \log \frac{C_V}{C_{IV}} \quad (4)$$

In this equation $C_V$ and $C_{IV}$ represent the molar concentrations of Np(V) and Np(IV), respectively. The $E$ value of the $Ag^0$–AgCl electrode is taken as −0.222 volt and the value of $a_{Cl^-}$ as 0.84 (the mean activity of a one molar hydrochloric acid solution).

The data are summarized in Tables II and III. The accuracy of the measurements is not considered to be greater than ±10 millivolts. The potential of the couple

$$Np(IV) \longrightarrow Np(V) + e^- \quad (5)$$

is −0.74 ± 0.01 volt in one molar hydrochloric acid at 25°.

**The Formal Potential of the Np(V)–Np(VI) Couple.**—The couple was measured in 1.00 molar hydrochloric acid solution during the course of a stannous ion reduction of Np(VI).

## Experimental

The cell consisted of a bright platinum wire indicator electrode and a silver–silver chloride reference electrode. The neptunium was reduced by adding an aliquot of 0.05 molar stannous chloride in 1.0 molar hydrochloric acid and measuring the potential after equilibrium was established as judged by a constant optical density for the 984 millimicron Np(V) absorption band. Reduction of Np(VI) by chloride caused a slow falling off of the measured potential so the first reading obtained upon inserting the electrode was taken as most nearly representing the true potential.

## Calculations and Results

The formal potential of the Np(V)–Np(VI) couple in 1.00 molar hydrochloric acid was calculated in two ways from the data obtained. The first method involved the determination of the Np(V) concentration spectrophotometrically and

the concentration of the Np(VI) by difference. Observation has shown that the Np(V) band at 984 millimicrons does not obey Beer's law. Since accurate calibration curves were not available the spectrophotometric densities were disregarded except for determination of equilibrium after each addition of stannous chloride. The amount of Np(VI) in the solution was obtained by subtraction according to the reaction equivalence

$$2Np(VI) + Sn(II) \rightleftarrows 2Np(V) + Sn(IV) \quad (6)$$

This method of calculation gave more consistent results. The potentials were calculated by an equation analogous to equation 4. The data are summarized in Table IV.

TABLE IV

FORMAL OXIDATION POTENTIALS FOR THE Np(V)–Np(VI) COUPLE in 1 *M* HCl, 0.00556 *M* Np; $t = 25°$

| $\frac{NpVI}{NpV}$ | $E_{meas.}$, volt | $E_f$, volt |
|---|---|---|
| 1.90 | 0.912 | −1.135 |
| 1.50 | .904 | −1.134 |
| 1.21 | .900 | −1.135 |
| 0.771 | .891 | −1.138 |
| .487 | .875 | −1.134 |
| .281 | .863 | −1.136 |
| .130 | .842 | −1.135 |

Although it is believed that the cell behaved reversibly, two complicating factors reduced the precision of measurement: (1) Np(VI) is slowly reduced by chloride in the presence of platinum, and (2) the reduction of Np(VI) by Sn(II) is rather slow, so that attainment of equilibrium is somewhat uncertain. The formal oxidation potential for the reaction

$$Np(V) \rightleftarrows Np(VI) + e^- \quad (7)$$

is $-1.14 \pm 0.02$ volt in one molar hydrochloric acid at 25°.

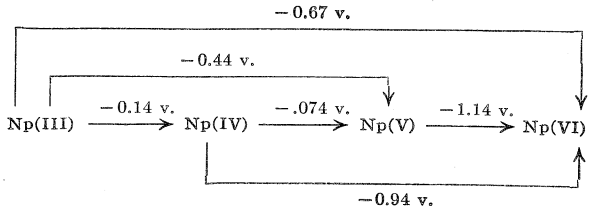
## Discussion

Although the oxidation potentials of the couples given in this paper are not thermodynamic $E^0$ values, they are nevertheless quite useful in predicting the stabilities of the different oxidation states and their probable reactions with various oxidizing and reducing agents.

Direct observation of the stabilities of the various oxidation states is in agreement with what would be expected on the basis of the reported oxidation potentials. Np(III) in one molar hydrochloric acid is extremely unstable to air oxidation and can be maintained in solution only by using precautionary measures to exclude oxygen. Both the +4 and +5 states have been found to be stable in one molar hydrochloric acid over periods of days. From the potential of the couple of −0.74 v., air oxidation of Np(IV) to Np(V) can occur, although the reaction is slow. Np(V) solutions exhibit the expected stability in one molar hydrochloric acid solution. Np(VI) is not stable in hot one molar hydrochloric acid, being slowly reduced to Np(V). Although the reaction with cold hydrochloric acid is very slow at room temperatures, contact with platinum catalyzes the reduction in some manner so that Np(V) is produced at an appreciable rate at the platinum surface. Np(III) undoubtedly cannot be maintained in a nitrate solution, and Np(IV) is slowly oxidized to Np(V) in nitric acid. Np(V) solutions have been prepared in one molar nitric acid with no evidence of disproportionation into Np(IV) and Np(VI). It is expected that the Np(IV)–Np(V) potential in one molar nitric acid is close to that in hydrochloric acid.

Np(V) disproportionates to a considerable extent in one molar sulfuric acid because of preferential complexing of Np(IV) and Np(VI) by the sulfate ion. In high concentration of sulfuric acid, Np(V) would be unstable since, in addition to the sulfate effect, the disproportionation reaction probably has a hydrogen ion dependence.

Considerable evidence has been accumulated to show that the ions of the +3, +4, +5 and +6 oxidation states of neptunium, like those of the corresponding oxidation states of the elements uranium and plutonium, are $Np^{+3}$, $Np^{+4}$, $NpO_2^+$ and $NpO_2^{++}$ in molar acid solution in the absence of complexing agents. Details of this evidence will appear in subsequent publications.



The reversibility of the Np(III)–Np(IV) and the Np(V)–Np(VI) couples is probably connected with the fact that only electron transfers are involved, whereas the irreversibility of the Np(IV)–Np(V) couple would appear to arise from the fact that oxygen transfer must also occur, a process which would appear to be slow at a noble metal electrode. The sluggishness of reactions involving the oxidation of Np(IV) or the reduction of Np(V), as by ferrous ion or stannous ion, would also presumably be attributable to the slowness of the oxygen transfer process.

**Acknowledgment.**—The authors wish to express their appreciation to Dr. G. T. Seaborg for his stimulating interest and advice during the course of this research. The authors also wish to acknowledge the many helpful suggestions made by Dr. B. B. Cunningham.

## Summary

Spectrophotometric titrations of neptunium solutions with oxidizing and reducing agents have been used, together with the isolation of the salt $NaNpO_2(OOCCH_3)_3$ from the solution of the highest oxidation state obtained, to establish the existence of the +4, +5 and +6 states of neptunium. In contrast to both uranium and plutonium, the +5 state of neptunium has been found to be quite stable in acid solution.

The formal oxidation potentials for the various neptunium couples have been measured in one molar hydrochloric acid. These may be represented schematically as follows:

The Np(III)–Np(IV) and Np(V)–Np(VI) couples have been found to behave reversibly while the Np(IV)–Np(V) couple is irreversible. In the latter case measurements of the potential in a system in equilibrium with Fe(II) and Fe(III) have been used to obtain the value of the couple.

# Supported Oxides of Manganese[1]

BY P. W. SELWOOD, T. E. MOORE,[2] MARYLINN ELLIS AND KATHRYN WETHINGTON

The applicability of the susceptibility isotherm method has already been described for supported oxides of chromium, and of copper. The present paper describes exploratory studies on the use of the method for supported oxides of manganese. Similar papers on nickel and on iron and other elements will shortly be forthcoming from this Laboratory.[3]

## Experimental Part

X-Ray, magnetic susceptibility and surface area studies were made by standard methods previously described.[3]

One of the objectives of all this work is the relation of inorganic structure to catalyst activity. The various supported oxide systems are, therefore, referred to as catalysts, even though their applicability as catalysts may not be obvious.

**Preparation of Catalysts.**—Manganese oxides supported on alumina were prepared as follows: a water solution made from recrystallized manganous nitrate was impregnated in excess on γ-alumina. The area of the alumina was about 200 m.$^2$ g.$^{-1}$ (BET nitrogen). The susceptibility of the alumina was $-0.3 \times 10^{-6}$ and was independent of temperature. The impregnated alumina was filtered with suction, then dried and heated to 150–160° for forty-eight hours under slightly reduced pressure. The product was removed, ground, screened and reheated for twenty-four hours at 200°. This procedure would normally be expected to yield a layer of manganese dioxide in the *pyrolusite* structure covering the alumina. A series of catalysts was prepared in this way. Variations in manganese content was obtained by changing the concentration of the impregnating solution. Manganese concentrations ran from about 1 to over 20%. The color of all the finished catalysts ranged from pale tan to black. Analytical and other data are given below.

Prolonged heating of manganese dioxide results in the quantitative formation of the sesquioxide in the *bixbyite* structure. Some of the catalysts described above were subjected to thermal decomposition at 600°. The properties of this series are also described below.

During the course of this work it became obvious that manganese oxides supported on high-area *rutile* would be an interesting system for study. Considerable difficulty was experienced in obtaining this support, but finally a laboratory prepared sample was obtained from the National Lead Company, Titanium Division. This titania was all in the *rutile* structure, had a surface area of about 129 m.$^2$ g.$^{-1}$ (BET nitrogen), and had a susceptibility of $-0.3 \times 10^{-6}$, which was substantially independent of temperature.

A series of supported manganese catalysts was prepared on the titania by procedures identical with those described for the alumina support, except that heating was not carried over 200°. Somewhat more concentrated impregnating solutions were found to be required to obtain equivalent concentrations of manganese on titania as compared with alumina.

One catalyst was made containing rhenium supported on alumina. γ-Alumina was impregnated with a hot saturated solution of potassium perrhenate. The mixture was kept hot for twenty minutes, then filtered and dried at 110°. The sample was then ignited in vacuum to 350°. After magnetic and other measurements had been made the sample was further heated in hydrogen at 350° for twenty-four hours. Before reduction the sample was white, and afterward gray. A few miscellaneous preparations are briefly indicated below.

**Analytical Procedures.**—The analytical data required were (1) manganese, and (2) "active" oxygen. For the manganese determination the sample was dissolved in sulfuric acid containing ferrous sulfate. The manganese was then oxidized with sodium bismuthate in nitric acid. The resulting permanganate was titrated with ferrous sulfate.

(1) This paper describes, in part, work performed under contract with the Squier Signal Laboratory, Signal Corps Engineering Laboratories, as part of their program for the improvement of dry cells.

(2) Present address: Department of Chemistry, Oklahoma A. and M. College, Stillwater, Oklahoma.

(3) This is the fifth paper on the susceptibility isotherm from this Laboratory. The third and fourth appeared in THIS JOURNAL, **70**, 2145, 2271 (1948).

For "active" oxygen a known excess of standard ferrous ammonium sulfate was employed in dissolution of the sample. The excess was then titrated with standard permanganate.

The titania-supported samples were very slow to dissolve. In fact, direct solution in sulfuric acid probably would not have been possible had not the original ignition temperature been kept down to 200°. Fortunately, higher ignition temperatures were not necessary.

The single sample of supported rhenium on alumina was analyzed by the nitron acetate method.[4]

## Results

The first series to be considered is that in which manganous nitrate is impregnated on γ-alumina and then ignited at not over 200°. The results are presented in Table I. Following plans used previously we give the weight per cent. of manganese in each sample, and the magnetic susceptibility per gram of sample at three temperatures. Directly below each measured susceptibility there is given the calculated susceptibility per gram of manganese in each corresponding sample. Thus the first catalyst sample had a susceptibility at 25° of $13.8 \times 10^{-6}$ per gram of sample. This sample contained 23.4% of manganese, and the susceptibility per gram of manganese is then $60.4 \times 10^{-6}$.

Table II shows similar data for the same system ignited at 600°, and Table III gives the corresponding data for the manganese oxide supported on high-area *rutile*.

[a] Sample was prepared by direct decomposition of manganous nitrate on alumina at 600°. The other samples were derived from those of Table I by further heat treatment at 600°. There does not seem to be any difference in the two preparations.

The remaining experimental and derived data are more conveniently shown graphically. Figure 1 shows susceptibility isotherms for the three states of supported manganese, namely, low-temperature ignition on alumina, high-temperature ignition on alumina, and ignition on *rutile*.

Figures 2, 3 and 4 show, respectively, the concentration of manganese plotted against magnetic moment for each of the three series. The magnetic moment is given in Bohr magnetons as calculated from the usual formula $\mu = 2.84\sqrt{\chi_M(T + \Delta)}$. On the same graphs there are

shown the apparent valences of the manganese obtained from the chemical analyses according to the following procedure: total gram-atoms of oxygen in a sample is equal to the sum of gram-atoms of active plus inactive oxygen, and this is equal to the sum of gram-atoms of active oxygen plus manganese. The valence of manganese is twice the gram-atoms of total oxygen per gram-atom of manganese.

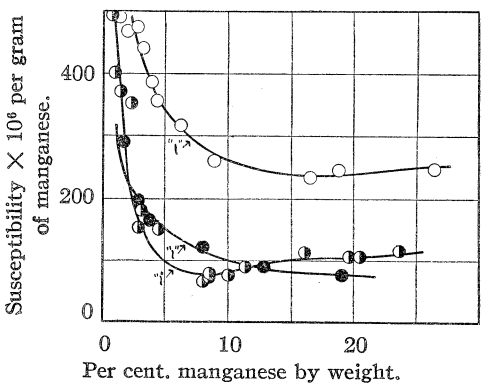

Fig. 1.—Susceptibility isotherms for supported manganese oxides at −171°: O, high ignition on $Al_2O_3$; ◑, low ignition on $Al_2O_3$; ●, $MnO_2$ on $TiO_2$.

Figure 5 shows percentage of manganese plotted against the Weiss constant ($\Delta$) for all three series of catalysts.

The single sample of supported rhenium on γ-alumina contained 4.8 per cent. of rhenium. The magnetic susceptibility before reduction was 0.3 × $10^{-6}$, and after reduction it was −0.1 × $10^{-6}$. Supported rhenium obviously does not show the magnetic dispersion effect.

## Discussion of Results

Supported manganese shows the same magnetic dispersion effect first reported for chromium and now shown to apply to nearly all paramagnetic ions except molybdenum and rhenium. The effect will, for obvious reasons, probably not be found in the paramagnetic rare earths. Its failure to appear in molybdenum and rhenium is probably due to covalent bonds between adjacent positive ions.

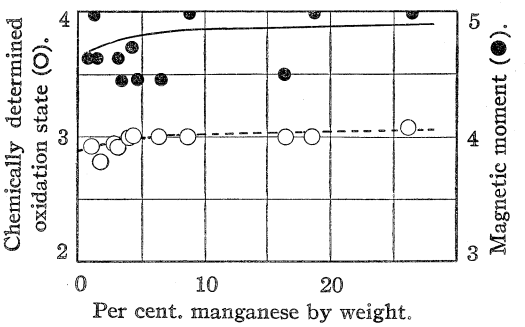

Fig. 3.—Oxidation state (O), and magnetic moment (●) for high-ignition series on alumina.

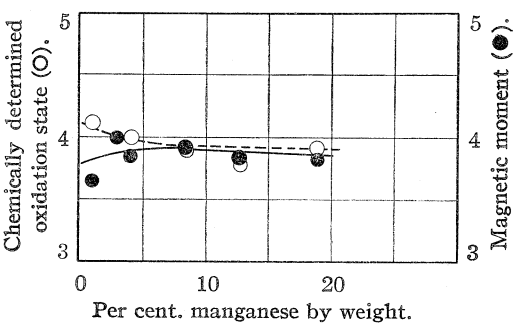

Fig. 4.—Oxidation state (O), and magnetic moment (●) for series on *rutile*.

The general shape of the susceptibility isotherm for supported manganese is the same as for the chromia–alumina system, except that the low-ignition series on alumina shows a very much sharper point "*l*" than anything heretofore observed. It is more convenient to discuss the high-ignition series on alumina first.

It would be expected that ignition of manganous nitrate at 600° would result in the formation of reasonably pure $Mn_2O_3$. The magnetic moment in the supported series ignited at this temperature is shown to be very close to the theoretical spin-only moment (4.9) for manganese in the plus three oxidation state. The conclusion that man-

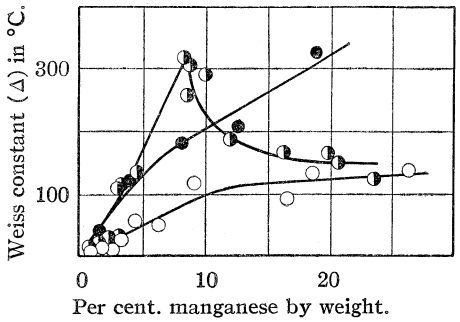

Fig. 5.—Weiss constants as a function of concentration: ○, high-ignition on $Al_2O_3$; ◑, low-ignition on $Al_2O_3$; ●, $MnO_2$ on $TiO_2$.

ganese has a valence of three throughout this series is amply verified by direct chemical analysis for total manganese and for active oxygen.

The shape of the susceptibility isotherm in this series is, therefore, in no way connected with changing oxidation state, and must be attributed to changing environment. The large change of the Weiss constant with manganese concentration is evidence that the number of nearest manganese neighbors possessed by each manganese ion changes rapidly at the lower manganese concentrations. Following the argument previously presented for chromium, with which this series is closely parallel, we conclude that the manganese ions are aggregated in microcrystals of $Mn_2O_3$, and that much of the alumina surface remains bare. Our conclusion is, again, that as at point "*l*" the manganese oxide layers are only three or four atoms thick. This general pattern seems to be the commonest susceptibility isotherm encountered.

The situation with respect to low temperature ignition of manganous nitrate on alumina is very different. Ignition at 200° would normally yield *pyrolusite*. The actual result, however, is that while the manganese clearly has an oxidation state of plus four at high concentrations, the oxidation state is definitely three at low concentrations. This result is shown both by the chemical analysis and by the magnetic moment, which are in excellent agreement with each other. (The theoretical spin-only moment for $Mn^{+4}$ is 3.87). Simultaneous with this change in oxidation state, the Weiss constant shows an astonishing maximum in the neighborhood of 8% manganese.

We shall first consider the surprising change in oxidation state from four to three as the manganese concentration is lowered. It is well known that the $Mn^{+3}$ ion has approximately the same radius as the $Al^{+3}$ ion, and also that the $\gamma$-form of $Mn_2O_3$ is isomorphous with $\gamma$-$Al_2O_3$. It is suggested that the crystal lattice of the alumina exerts an inductive action on the manganese sufficient to cause a change of valence. It might be said that the manganese oxide attempts to imitate the crystal structure of the support, even to the extent of changing oxidation state. The effect described is somewhat related to the phenomenon of oriented overgrowth, and is reminiscent of a current theory of nucleoprotein synthesis.[5]

This effect apparently is of fairly general occurrence with transition group ions, provided the proper charge and radius may be assumed without too much difficulty. The effect does not occur with copper or silver supported on alumina, but it does occur with nickel on alumina and on *rutile*. It occurs with iron on *rutile* as will be described in forthcoming papers, and it occurs with manganese on *rutile* as shown in the results given in this paper. The effect may be expected to have a number of applications in the field of promoters, catalysts in general, corrosion, coprecipitation, crystallography and in the preparation of unique oxidizing agents.

It remains to explain the peculiar Weiss constant found in this series. It seems probable that the layers of manganese atoms in actual contact with alumina always are subject to the inductive action of the alumina and consequently always have the manganese in the plus three oxidation state. When large amounts of manganese are present these surface layers are negligible in their percentage contribution to the magnetic susceptibility. But as the concentration of manganese goes down the relative importance of the layers next to the alumina progressively increases until they ultimately account, at the limit, for all the manganese present.

Hence, according to this picture, the apparent change of oxidation state in the manganese is not so much an actual change in valence as a change in the ratio of manganese touching alumina and hence in the +3 state, to manganese merely touching manganese and hence reverting to the normal +4 state.

If the degree of exchange interaction in *bixbyite* were greater than that in *pyrolusite*, then the anomalous Weiss constants obtained would be easily explained. Actually the Weiss constants for supported +3 manganese are consistently lower than those for +4 manganese. This is clearly shown in Fig. 5. In order to further establish this point some Mn(III) on alumina was prepared by hydrogen reduction at 200° rather than by thermal decomposition at 600°. This also showed a lower Weiss constant than the +4 state.

In seeking an explanation of the anomalous Weiss constants in the $MnO_2/Al_2O_3$ series consideration was given to the fact that many solids show a variety of peculiar properties when metal ions of differing charges occupy adjacent positions in the lattice. It was thought that possibly the exchange interaction would increase if a +3 Mn ion were adjacent to a +4 ion, and that the large increase of the Weiss constant might be a measure of the number of manganese ions in this peculiar

(5) A preliminary communication concerning this effect of valence inductivity was given in THIS JOURNAL, **70**, 883 (1948).

condition, namely, of being adjacent to manganese ions of different charge.

A further experiment was performed for the purpose of testing this idea. The experiment has some unusual features and will be described.

**Slow Reduction of $MnO_2/Al_2O_3$.**—A catalyst containing 20% manganese, substantially all in the +4 state, on alumina was slowly reduced in hydrogen at 180°. The reduction to the +3 state at this temperature took several weeks. At frequent intervals the sample was cooled, removed, and its susceptibility was determined. Figure 6 shows the Weiss constant of this sample plotted as a function of oxidation state.

In this experiment it was hoped that there would be produced a detectable proportion of +3 and +4 manganese ions in adjacent positions. The experiment is obviously one of some difficulty because of the tendency for heterogeneous reactions to proceed from discrete spots so that +3, +4 ion groups may occur only instantaneously at the reaction boundary. Furthermore, there is no reason to expect a maximum number of such groups at the point of 50% conversion from +4 to +3 manganese.

Under these circumstances the results are very gratifying. It is clearly shown that during the course of reduction the Weiss constant rises, but that when reduction is complete the Weiss constant is lower for the supported +3 state than for the +4 state. The erratic changes observed for the Weiss constant are not experimental error, but are probably a measure of the fluctuating proportion of +3, +4 ion groups present at the various stages of reduction.

The success of this experiment supports the view expressed concerning the anomalous Weiss constants found in this system.

The peculiar susceptibility isotherm found for the low-ignition manganese on alumina series is thus seen to be due to a combination of two changes both of which lead to greatly increased susceptibility at low manganese concentrations. These two changes are a change of oxidation state, and a change of environment. While both changes lead to an increase of susceptibility, the changing oxidation state alone at first produces an increase of the Weiss constant, but the increasing dispersion ultimately reduces the Weiss constant to zero. This is the first example we have encountered where the shape of the susceptibility isotherm is determined both by an oxidation state change and an environmental change.

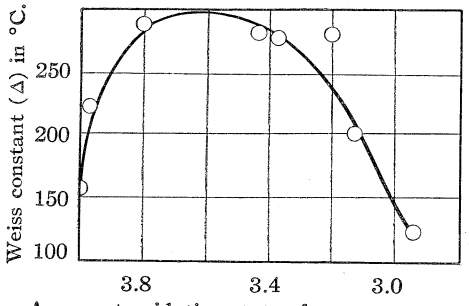

Fig. 6.—Weiss constants as a function of oxidation state during slow reduction of $MnO_2$ to $Mn_2O_?$.

The idea of supporting manganese on *rutile* was suggested by the considerations described above. It was clear that if our interpretation were correct then manganese on high-area *rutile* ought to yield all the manganese in the oxidation state of plus four. This proved to be the case and the susceptibility isotherm is a typical example of the type in which the whole change is due to change of environment and not to change of oxidation state. Titania seems to be the only diamagnetic solid isomorphous and approximately isometric with *pyrolusite*, of reasonable stability, and capable of being prepared in a high-area form.

It may be objected that manganous nitrate would give Mn(IV) even if ignited on low-area *rutile*. This is, of course, correct, but in that case the normal dispersion effect would be absent, the susceptibility of the manganese would be independent of concentration and the situation would resemble that previously reported for chromia supported on low-area corundum.

## Summary

The susceptibility isotherm method has been extended to supported manganese. It has been found that in favorable cases supported transition group oxides may imitate the crystal structure of the support even to the extent of changing oxidation state.

# Condensation of Saturated Halides with Unsaturated Compounds. V. Condensation of Cycloalkyl Halides with Ethylene and with Vinyl Halides

BY LOUIS SCHMERLING

The condensation of alkyl chlorides and bromides with olefins,[1] cycloölefins[2] and haloölefins[3] in the presence of metal halide catalysts was described in previous papers in this series. Examples of the reaction of cycloalkyl chlorides and bromides with ethylene and chloroethylene are given in the present communication (Table I).

The condensation of the tertiary chloride, 1-chloro-1-methylcyclohexane, with ethylene in the presence of aluminum chloride or ferric chloride yielded 1-(2-chloroethyl)-1-methylcyclohexane (II), the product of the addition of the chlorine atom and the 1-methylcyclohexyl group to the double bond of the olefin. Hydrolysis of the chloride yielded an alcohol, presumably 2-(1-methylcyclohexyl)-ethanol.

When the secondary chloride, chlorocyclohexane, was condensed with ethylene, the product was not the expected (2-chloroethyl)-cyclohexane (Ia) but rather 1-(2-chloroethyl)-1-ethylcyclohexane (I) formation of which involved the reaction of two molecular proportions of ethylene

The primary compound, Ia, contains a tertiary carbon atom and readily isomerizes to the tertiary chloride, Ib, which is more reactive than the original secondary chloride and rapidly condenses with ethylene to yield I. Since I does not contain a tertiary carbon atom, it undergoes no further reaction and is, therefore, the principal condensation product. The plausibility of this mechanism and of the structure assigned to the product was indicated by the fact that I was also obtained by the reaction of synthetic 1-chloro-1-ethylcyclohexane (Ib) with ethylene in the presence of aluminum chloride at −10 to 0°.

In a similar manner, the reaction of bromocyclohexane with ethylene in the presence of aluminum chloride produced 1-(2-bromoethyl)-1-ethylcyclohexane (III). That the bromo and chloro compounds had the same carbon skeleton was shown by converting them to the same derivative. Furthermore, condensation of (2-bromoethyl)-cyclohexane (Ia) with ethylene also yielded 1-(2-bromoethyl)-1-ethylcyclohexane, thus furnishing additional evidence in support of the mechanism.

The behavior of the secondary cycloalkyl halides is analogous to that of the secondary alkyl chloride, *s*-butyl chloride, which yielded 1-chloro-3-methyl-3-ethylpentane rather than 1-chloro-3-methylpentane when condensed with ethylene in the presence of aluminum chloride.[1]

The reaction of the halocyclohexanes with ethylene offers a means of synthesizing 1-alkyl-1-ethylcyclohexanes. Thus, reduction of 1-(2-bromoethyl)-1-ethylcyclohexane (III) yielded 1,1-diethylcyclohexane which had not been reported previously.

Condensation of vinyl chloride with chlorocyclohexane, 1-chloro-1-methylcyclohexane, and 1-chloro-1-methylcyclopentane, yielded, respectively, (2,2-dichloroethyl)-cyclohexane, 1-(2,2-dichloroethyl)-1-methylcyclohexane, and 1-(2,2-dichloroethyl)-1-methylcyclopentane. The structure of the (2,2-dichloroethyl)-cyclohexane was proved by hydrolyzing it to cyclohexaneacetaldehyde; that of the 1-(2,2-dichloroethyl)-1-methylcyclohexane was supported by its hydrolysis to an aldehyde identical with that obtained by oxidation of the alcohol prepared via the condensation of 1-chloro-1-methylcyclohexane with ethylene.

(2,2-Dibromoethyl)-cyclohexane was obtained by the reaction of bromocyclohexane with vinyl bromide in the presence of aluminum chloride.

## Experimental

**Procedures.**—The experimental procedures will be summarized very briefly since they were similar to those previously described for the analogous reactions of alkyl halides with ethylene[1] and with haloölefins.[2]

In Method A, ethylene was bubbled through a stirred mixture (cooled to about −60°) of the cycloalkyl halide, *n*-pentane diluent (if used) and the catalyst. The temperature of the mixture was permitted to rise until absorption of the olefin began and was then maintained at about that point for the duration of the experiment.

In Method B, the mixture of reactants (other than ethylene) and catalyst in a glass liner (cooled to about −78°) was sealed into an Ipatieff-type rotating autoclave which was then rotated at room temperature for four hours. When ethylene was used, it was charged to a pressure of 30 atmospheres.

In Method T, the mixture of reactants and catalyst in a large test-tube was shaken manually while the temperature rose gradually from −60° to the temperature of incipient reaction, indicated by the evolution of tiny bubbles of gas. The test-tube was intermittently cooled and warmed until there was little sign of reaction at a temperature at least 10° higher than the original reaction temperature. This method was admittedly crude and was not expected to give the highest possible yields of products;

[a] $C_6Cl$ and $C_6Br$ = cyclohexyl chloride and bromide, respectively. $MeC_6Cl$ = 1-chloro-1-methylcyclohexane. $EtC_6Cl$ = 1-chloro-1-ethylcyclohexane. $MeC_5Cl$ = 1-chloro-1-methylcyclopentane. [b] Determined by gain in weight of reaction mixture; includes dissolved gas. [c] *n*-Pentane (50 g.) used as diluent. [d] Time during which autoclave was rotated; it was permitted to set at room temperature overnight before it was opened. [e] The reaction mixture was warmed during eight minutes, with intermittent shaking, from −78 to −12°. There was a sudden rise in temperature to 35° even though the reaction tube was immersed in a Dry Ice–acetone-bath. After two minutes at 35–30°, the mixture cooled to −40°. The total reaction time was eleven minutes. [f] Obtained from Westvaco Chlorine Products Corp. [g] The mixture of reactants and catalyst was allowed to warm up from −78 to −40° during six minutes; most of the catalyst dissolved. There was a sudden reaction, the temperature rose to 50° in ten seconds and half of the mixture was blown from the reaction tube. The remaining 67 g. was a deep red solution. The yield shown is that of the product actually isolated. [h] (2-Bromoethyl)-cyclohexane.

[a] Calculated from boiling point under reduced pressure using nomograph prepared for hydrocarbon conversions. This was found to give accurate results for halogenated derivatives. [b] Microanalyses by Dr. T. S. Ma, then at the University of Chicago, and by Mr. C. W. Beazley, Micro-Tech Laboratories, Skokie, Illinois.

it had the advantage that the experiments could be carried out quickly.

**Materials.**—The chloro- and bromocyclohexane were Eastman Kodak Co. products. Vinyl chloride and (2-bromoethyl)-cyclohexane were obtained from The Dow Chemical Company; vinyl bromide, from Westvaco Chlorine Products Corp. The 1-chloro-1-methyl-cyclohexane was prepared in 35% yield by a modification of the method described by Bartlett, Condon and Schneider[4]; an equimolar mixture of methylcyclohexane and *t*-butyl chloride was stirred for one hour with 2% by weight of aluminum chloride at −25 to −10°. The 1-chloro-1-methylcyclopentane and the 1-chloro-1-ethylcyclohexane

(4) P. D. Bartlett, F. E. Condon and A. Schneider, THIS JOURNAL, **66**, 1534 (1944).

were each obtained in 20% yield in analogous manner. The former boiled at 79–81° at 197 mm. (120–122° at 760 mm.); $n^{20}D$ 1.4452. The latter boiled at 51–53° at 5.5 mm. (183–185° at 760 mm.); $n^{20}D$ 1.4590.

### Characterization of the Products

**1-(2-Chloroethyl)-1-ethylcyclohexane (I).**—The product prepared by the condensation of chlorocyclohexane with ethylene had the same boiling point and refractive index as that obtained by the reaction of 1-chloro-1-ethylcyclohexane with ethylene; the infrared spectra[5] showed that the two were identical (Fig. 1). Furthermore, both were converted to the same anilide, β-(1-ethylcyclohexyl)-propionanilide, by the reaction of the Grignard reagents with phenyl isocyanate[6]; m. p. and "mixed" m. p., 90–91°.

*Anal.* Calcd. for $C_{17}H_{25}ON$: N, 5.40. Found: N, 5.21.

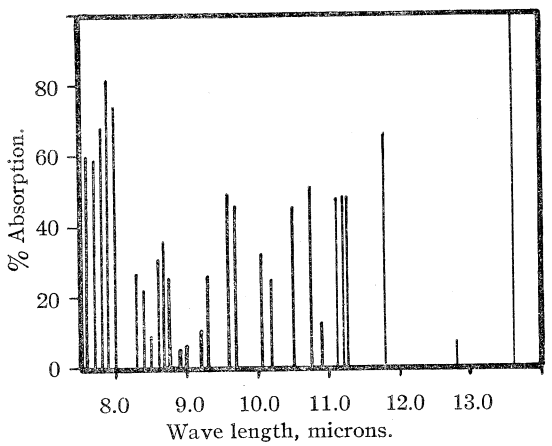

Fig. 1.—Infrared absorption spectrum of 1-(2-chloroethyl)-1-ethylcyclohexane.

**1-(2-Bromoethyl)-1-ethylcyclohexane (III).**—Both preparations of this compound (*i. e.*, the products of the reaction of ethylene with bromocyclohexane and with (2-bromoethyl)-cyclohexane) yielded the same anilide as did the corresponding chloride (I); m. p. and "mixed" m. p., 90–91°.

The bromide was converted to a new hydrocarbon, 1,1-diethylcyclohexane, by heating a solution of 20 g. (0.09 mole) of the compound in 50 cc. of propanol under reflux for eight hours with 9 g. of zinc granules (which had been pretreated by stirring with a solution of 1 g. of cupric chloride in 30 cc. of water and then washing with ethanol). There was recovered 10 g. (0.07 mole) of liquid boiling at 173–174°; $n^{20}D$ 1.4502.

*Anal.* Calcd. for $C_{10}H_{20}$: C, 85.62, H, 14.38. Found: C, 85.78; H, 14.20.

**1-(2-Chloroethyl)-1-methylcyclohexane (II).**—This compound was converted to the corresponding carbinol by heating 8 g. (0.05 mole) with a suspension of 3 g. of magnesium oxide in 110 g. of water in a sealed tube at 225° for four hours. There was obtained 3.5 g. (0.02 mole) of 2-(1-methylcyclohexyl)-ethanol, b. p. 82° at 3 mm.; $n^{20}D$ 1.4686.

*Anal.* Calcd. for $C_9H_{18}O$: C, 75.98; H, 12.76. Found: C, 76.17; H, 12.49.

The 3,5-dinitrobenzoate derivative of the alcohol melted at 95°.

*Anal.* Calcd. for $C_{16}H_{20}N_2O_6$: N, 8.33. Found: N, 8.38.

The α-naphthylamine addition compound of the 3,5-dinitrobenzoate melted at 107°.

The alcohol was oxidized by the repeated insertion of a hot, partially oxidized copper wire spiral (heated in flame) in the boiling liquid (0.5 cc.) and its vapor. The product yielded a 2,4-dinitrophenylhydrazone, m. p. 84–85°. There was no depression of the melting point when this derivative was mixed with the analogous derivative prepared, as shown below, from the aldehyde obtained by hydrolyzing 1-(2,2-dichloroethyl)-1-methylcyclohexane (V).

**(2,2-Dichloroethyl)-cyclohexane (IV).**—A mixture of 13 g. (0.07 mole) of the dichloride, 4 g. (0.1 mole) of magnesium oxide and 100 g. of water in a sealed tube was heated at 250° for four hours. There was obtained 5 g. (0.04 mole) of cyclohexaneacetaldehyde, b. p. 36–37° at 3 mm. (178–179° at atmospheric pressure); $n^{20}D$ 1.4668. The aldehyde yielded a 2,4-dinitrophenylhydrazone, m. p. 114°.

*Anal.* Calcd. for $C_{14}H_{18}O_4N_4$: N, 18.29. Found: N, 18.08.

The melting point of the semicarbazone of the aldehyde depended on the temperature at which the sample tube was inserted in the bath. It ranged from 155–156.5° (insertion at 145°) to 159° (insertion at 158°).

*Anal.* Calcd. for $C_9H_7ON_3$: N, 22.93. Found: N, 22.50.

Various melting points are reported in the literature for the semicarbazone of cyclohexaneacetaldehyde: 132–134°,[7] 153°,[8] 162°[9] and 171–172°.[10]

**1-(2,2-Dichloroethyl)-1-methylcyclohexane (V).**—When 21 g. (0.11 mole) of this dichloride was heated at 225° with 4.5 g. (0.1 mole) of magnesium oxide and 100 cc. of water, there was obtained 9 g. (0.06 mole) of aldehyde, presumably 1-methylcyclohexaneacetaldehyde, b. p. 78–80° at 12 mm.; $n^{20}D$ 1.4728. The analytical data indicated that the aldehyde was impure, a possible contaminant being 1-(2-chlorovinyl)-1-methylcyclohexane. No attempt was made to purify the product.

*Anal.* Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 71.18; H, 10.03.

The semicarbazone and 2,4-dinitrophenylhydrazone derivatives prepared from the impure aldehyde melted at 177–178° and 84–85°, respectively. The latter derivative did not depress the melting point of the analogous derivative of the aldehyde obtained by oxidizing the alcohol prepared by hydrolyzing 1-(2-chloroethyl)-1-methylcyclohexane (II). This may be taken as mutual confirmation of the structures assigned to compounds II and V.

*Anal.* Calcd. for $C_{10}H_{19}ON_3$ (semicarbazone): N, 21.30. Found: N, 20.82.

*Anal.* Calcd. for $C_{15}H_{20}O_4N_4$ (dinitrophenylhydrazone): N, 17.49. Found: N, 17.12.

**Acknowledgment.**—The author wishes to thank Mr. E. E. Meisinger for assistance with part of this work.

## Summary

Condensation of the tertiary chlorides, 1-chloro-1-methylcyclohexane and 1-chloro-1-ethylcyclohexane, with ethylene in the presence of aluminum chloride results in the formation of 1-(2-chloroethyl)-1-methylcyclohexane and 1-(2-chloroethyl)-1-ethylcyclohexane, respectively.

Condensation of the secondary cyclohexyl hal-

ides, chlorocyclohexane or bromocyclohexane, with ethylene yields the 1-(2-haloethyl)-1-ethylcyclohexanes, the reaction proceeding via the isomerization and subsequent condensation (with a second molecule of ethylene) of the primary product, (2-haloethyl)-cyclohexane.

(2,2-Dihaloethyl)-cycloalkanes are obtained by the reaction of vinyl chloride (or bromide) with chlorocyclohexane (or bromocyclohexane), 1-chloro-1-methylcyclohexane, and 1-chloro-1-methylcyclopentane.

A number of apparently new products including 1,1-diethylcyclohexane, 2-(1-methylcyclohexyl)-ethanol and crystalline derivatives, and 1-methylcyclohexaneacetyldehyde and crystalline derivatives have been prepared during the characterization of the condensation products.

# Condensation of Saturated Halides with Unsaturated Compounds. VI. Condensation of Alkyl and Cycloalkyl Chlorides with Vinylidene Chloride[1]

BY LOUIS SCHMERLING

The condensation of alkyl chlorides with 1,1-dichloroethylene (*i. e.*, vinylidene chloride) in the presence of metal halide catalysts offers a convenient means for preparing 1,1,1-trichloroalkanes and 1,1-dichloro-1-alkenes. Thus, for example, the ferric chloride catalyzed reaction of *t*-butyl chloride with the dichloroethylene yields both 1,1,1-trichloro-3,3-dimethylbutane (I) and its dehydrochlorination product, 1,1-dichloro-3,3-dimethyl-1-butene (II), the relative amounts of the two products depending on the reaction conditions.

When the temperature was kept at −10 to +10° (chiefly at −10 to 0°), a 65% yield of I and a 13% yield of II were obtained. At a somewhat higher temperature (8–23°) the yields were reversed, a 60% yield of II and a 14% yield of I being obtained.

It is interesting to note that no carbon skeletal rearrangement accompanied the formation of the dichlorohexene by the dehydrochlorination of the 1,1,1-trichloro-3,3-dimethylbutane. Confirmation of the structures of the two products is found in the fact that each yielded *t*-butylacetic acid when heated with water at 275°. The dichloride was shown to be identical with that obtained by the reaction of 1,1,2-trichloro-3,3-dimethylbutane with alcoholic potash.

The reaction of isopropyl chloride with vinylidene chloride at 0–25° in the presence of aluminum chloride resulted in a 30% yield of 1,1-dichloro-3-methyl-1-butene. The primary product, 1,1,1-trichloro-3-methylbutane was obtained in low yield only; the major portion underwent dehydrochlorination to the dichloropentene, the hydrogen chloride adding to the vinylidene chloride to form 1,1,1-trichloroethane which was also obtained in 30% yield. The structure of the 1,1-dichloro-3-methyl-1-butene was indicated by the fact that it was identical with the product of the the dehydrochlorination of 1,1,2-trichloro-3-methylbutane.

The reaction of vinylidene chloride with cyclohexyl chloride in the presence of aluminum chloride proceeded in a similar manner to that with isopropyl chloride. The principal product (30–50% yield) was the dichloroölefin, 1,1-dichloro-2-cyclohexylethylene, rather than the saturated trichloride, 1,1,1-trichloro-2-cyclohexylethane. 1,1,1-Trichloroethane was again obtained as by-product in yield corresponding to the hydrogen chloride evolved during the conversion of the intermediate trichlorocyclohexylethane to the dichlorocyclohexylethylene. Hydrolysis of the dichloride yielded cyclohexaneacetic acid.

## Experimental

**Procedures.**—The procedures were similar to those previously described for the condensation of alkyl halides with haloölefins.[2] In Method T, the mixture of reactants and catalyst in a large test-tube was shaken intermittently at the temperature range shown in the table. In Method S, the mixture of reactants was gradually added to a stirred mixture of the catalyst and *n*-pentane diluent.

### Identification of Products.

**1,1,1-Trichloro-3,3-dimethylbutane (I).**—A sealed tube containing 12.5 g. of the trichloride and 150 cc. of water was heated at 275° for four hours in a rotating autoclave. There was obtained 5.5 g. of organic acid, b. p. 182–183°; $n^{20}D$ 1.4153. It crystallized when cooled to 0°. Its *p*-phenylphenacyl ester melted at 92°. *t*-Butylacetic acid boils at 183°, melts at 6° and yields a *p*-phenylphenacyl ester[3] melting at 92°.

[a] Obtained from The Dow Chemical Co., redistilled immediately before use. [b] The catalyst was added to the mixture of reactants cooled to 8° by immersion in an ice–water-bath. The temperature rose to 23° and then dropped to 10° in two minutes. It was permitted to set at about this temperature for twenty minutes more, after which it was washed, dried and distilled. [c] The mixture of reactants was added during one and one-half hours to a stirred suspension of 4 g. of aluminum chloride in 62 g. of *n*-pentane at 1–3°. Additional catalyst (5 g.) was added and the temperature was permitted to rise (stirring continued) to 20° during the next one and one-half hours. [d] The catalyst was added to the mixture of reactants at −70° and the temperature was permitted to rise. A sudden reaction occurred at −20°; the temperature rose to 35° for a moment and then dropped to −10° when immersed in the bath at −78°. The total reaction time was three to four minutes.

[a] Calculated from boiling point under reduced pressure using nomograph prepared for hydrocarbon conversions. This was found to give accurate results for halogenated hydrocarbons. [b] Microanalyses by Mr. C. W. Beazley, Micro-Tech Laboratories, Skokie, Illinois.

**1,1-Dichloro-3,3-dimethyl-1-butene (II).**—The hydrolysis of 12 g. of this dichloride was carried out using the same procedure as was used for the trichloride. The sealed tube broke during the heating. The product which was recovered from the autoclave was made alkaline and ether extracted. About 5 g. of unreacted dichloride was recovered from the ether. Acidification of the alkaline solution yielded 1.5 g. of organic acid, m. p. 0–5°, the *p*-phenylphenacyl ester of which melted at 92°. There was no depression of the melting point of this ester when it was mixed with the corresponding derivative of the acid derived from 1,1,1-trichloro-2,2-dimethylbutane.

Further evidence in support of the structure assigned to dichlorodimethylbutene was obtained by showing that the same compound was obtained by the dehydrochlorination of 1,1,2-trichloro-3,3-dimethylbutane (prepared by the condensation of *t*-butyl chloride with *cis*-dichloroethylene[4]). Fifteen grams (0.08 mole) of the trichloride was added to a solution of 10 g. (0.18 mole) of potassium hydroxide in 40 cc. of ethanol. The temperature rose to 45° and potassium chloride began to precipitate out. The mixture was permitted to set overnight, the potassium chloride (6 g., 0.08 mole) was filtered off, and the filtrate was washed, dried and distilled. There was obtained 6.0 g. (0.04 mole) of product boiling at 55° at 40 mm. (138°

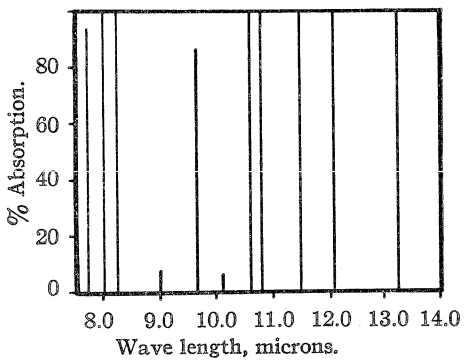

Fig. 1.—Infrared absorption spectrum of 1,1-dichloro-3,3-dimethyl-1-butene.

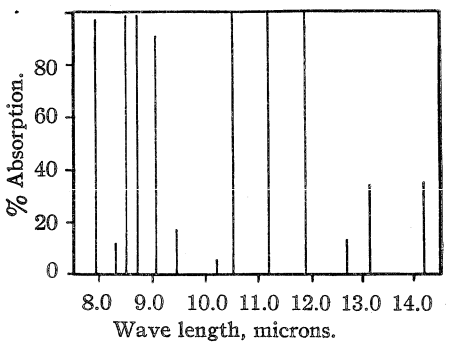

Fig. 2.—Infrared absorption spectrum of 1,1-dichloro-3-methyl-1-butene.

at 760 mm.); $n^{20}D$ 1.4530. The infrared absorption spectrum[5] of this product was identical with that of II (Fig. 1).

**1,1-Dichloro-3-methyl-1-butene (III).**—The infrared spectrum of this compound was identical with that of the product obtained by the dehydrochlorination of 1,1,2-trichloro-3-methylbutane, the condensation product of isopropyl chloride and *cis*-dichloroethylene[4] (Fig. 2). The dehydrochlorination of 17 g. (0.10 mole) of the trichloride by the procedure described above for the dehydrochlorination of 1,1,2-trichloro-3,3-dimethylbutane yielded 6 g. (0.08 mole) of potassium chloride and 6.5 g. (0.05 mole) of product boiling at 115–116° at atmospheric pressure; $n^{20}D$ 1.4460.

**1,1-Dichloro-2-cyclohexylethylene (IV).**—Hydrolysis of 10 g. of this compound by heating with 100 g. of water at 275° for four hours yielded 5 g. of an organic acid boiling at 244–247° and melting at 28–29°. It yielded an amide melting at 166–167°. The reported[6] properties of cyclohexaneacetic acid are: b. p. 245–247°; m. p. ranging from 27 to 32–33°; amide, m. p. 168°, 171–172° (cor.).

(5) The author is indebted to Dr. W. S. Gallaway, Physics Department, Universal Oil Products Company, for the infrared absorption analyses reported in this paper. For a description of the procedure used, see THIS JOURNAL, **69**, 1124 (1947).

**Acknowledgment.**—The author wishes to thank Mr. J. P. West for assistance in this work.

## Summary

The condensation of *t*-butyl chloride with vinylidene chloride in the presence of ferric chloride yields a mixture of 1,1,1-trichloro-3,3-dimethylbutane and 1,1-dichloro-3,3-dimethyl-1-butene, the relative amounts of the two products depending chiefly on the reaction temperature.

The aluminum chloride catalyzed condensation of the secondary chlorides, isopropyl chloride and cyclohexyl chloride, with vinylidene chloride yields as major products the unsaturated dichlorides, 1,1-dichloro-3-methyl-1-butene and 1,1-dichloro-2-cyclohexylethylene respectively. 1,1,1-Trichloroethane, formed by the hydrochlorination of vinylidene chloride is a by-product in both cases.

# Furfuryl and Thenylalkylamines from Schiff Bases[1,2]

BY BERTIN L. EMLING, J. E. BEATTY AND J. R. STEVENS

A number of secondary amines have been prepared[3] by the action of organomagnesium halides on Schiff bases. However, since none of the furfurylideneamines or thenylideneamines have as yet been utilized in this type of reaction, it was decided to investigate their behavior. Six isomeric alkylfurfurylamines have been prepared as represented by the equations

$$C_4H_3OCHO + H_2N{-}R' \xrightarrow{(-H_2O)}$$

$$C_4H_3O{-}CH{=}N{-}R' + RMgBr \xrightarrow[C_4H_3OCH(R){-}NHR']{\text{(hydrolysis)}} \quad (1)$$

One thenylamine, $C_4H_3S{-}CH(C_2H_5){-}NH(C_4H_9)$, was also prepared from thenylidenebutylamine and ethylmagnesium bromide. The Schiff bases prepared and used in the syntheses are listed in Table I. The methyl- and ethylfurfurylideneamines were prepared by Schwabbauer[4] who lists only their boiling points. The remaining Schiff bases are not described in the literature. Table II lists the furfurylamines, synthesized from the Schiff bases, and their α-naphthylurea derivatives. The ureas were prepared from the amines and α-naphthyl isocyanate.

[a] Thenylideneamine. [b] $n^{25}D$ and $d^{25}_4$. [c] *Anal.* Calcd. for $C_9H_{13}S$: S, 19.2. Found: S, 19.1.

Gilman, Kirby and Kinney[3c] reported a case of 1,4-addition to benzophenone anil under reaction conditions involving high temperature and a long period of heating. While we were of the opinion that 1,2-addition to the carbon–nitrogen structure took place under the mild conditions used in our reactions we desired to prove this. For this purpose one of the furfurylamines was synthesized from furan

$$C_4H_4O + (C_2H_5CO)_2O \xrightarrow{ZnCl_2}$$

$$C_4H_3O{-}COC_2H_5 \xrightarrow{NH_2OH}$$

$$C_4H_3O{-}C(NOH)C_2H_5 \xrightarrow[C_2H_5OH]{Na}$$

$$C_4H_3O{-}CH(NH_2)C_2H_5 + C_4H_9I \xrightarrow[C_4H_3O{-}C(H)(NHC_4H_9)(CH_2CH_3)]{\text{xylene}} \quad (I)$$

The amine, I, was not isolated but reacted in ligroin with α-naphthyl isocyanate to give the corresponding urea, 1-butyl-1-(α-ethylfuryl)-3-(α-naphthyl)-urea.

[a] Based on Schiff base. [b] Yields based on the isocyanate were all about 90%. [c] All melting points are corrected. [d] Thenylamine, $C_4H_3SCH(C_2H_5)NH(C_4H_9)$. [e] $n^{25}D$ and $d^{25}_4$. [f] *Anal.* Calcd. for $C_{11}H_{19}NS$: S, 16.25. Found: S, 16.18.

This proof of the 1,2-addition was further substantiated by oxidizing two of the furfurylamines, *i. e.*, N-butyl-α-ethyl and N-*n*-amyl-α-methyl, with potassium ferricyanide[5] to 2-furoic acid. N-Butyl-(α-ethylthenyl)-amine was also oxidized with alkaline potassium permanganate to 2-thiophenecarboxylic acid.

## Experimental

**Reagents.**—The chemicals used in all syntheses were reagent grade with the exception of furan which was kindly supplied by the Electrochemicals Department, E. I. du Pont de Nemours and Co.

**Furfurylidenebutylamine.**—All of the Schiff bases were prepared by essentially the same procedure.[6] The yields were uniformly 85% or better. Only the preparation of furfurylidenebutylamine will be outlined here. Freshly distilled furfural (96 g., 1 mole) was added dropwise with stirring to 88 g. (1.2 moles) of butylamine, kept at 15–20°, and the mixture was then stirred at room temperature for thirty minutes. Solid sodium hydroxide was added with cooling to saturate the aqueous layer, the mixture was extracted with ether and the ether extract dried over potassium hydroxide and distilled. The yield was 136 g., 90%.

**N-Butyl-(α-ethylfurfuryl)-amine.**—This procedure is typical. To the ethylmagnesium bromide obtained from 54.5 g. (0.5 mole) of ethyl bromide and 13 g. of magnesium turnings was added with cooling 68 g. (0.45 mole) of furfurylidenebutylamine dissolved in 70 ml. of ether. After refluxing for two hours the mixture was poured onto 300 g. of ice and then made acidic with hydrochloric acid. The ether layer was separated and the water layer after washing with an additional 75 ml. of ether was made basic with sodium hydroxide and steam distilled. The distillate was extracted with ether, dried over anhydrous magnesium sulfate and distilled; yield 49 g., 60%.

**α-Naphthylureas.**—These were prepared according to the procedure described by French and Wirtel[7] except that the amine was added to the α-naphthyl isocyanate in a 2:1 molar ratio. When no excess of amine was employed a glass resulted which was extremely difficult to crystallize. The urea of N-butyl-(α-ethylthenyl)-amine could not be crystallized. All of the ureas were recrystallized from ligroin.

**Furyl Ethyl Ketone**[8].—Eighty-eight grams (1.3 moles) of furan, 338 g. (2.6 moles) of propionic anhydride and about 5 g. of freshly fused zinc chloride were placed in a 1-liter 3-neck flask and stirred under anhydrous conditions for one hour and then at room temperature for two hours when 450 ml. of water was added. After stirring for an additional hour, potassium hydroxide was added with cooling until alkaline. The organic layer was extracted with ether, dried over anhydrous magnesium sulfate and distilled from a Claisen flask at 77–77.5° at 17 mm.; yield 84 g., 52%. The product crystallized on standing; m. p. 28°. The semicarbazone melted at 187–189° agreeing closely with the value reported by Asahina and Murayama.[9]

**Furylethylketoxime.**—This was prepared by a standard procedure[10]; yield, 68%; m. p. 46–48°.

**Reduction of Furylethylketoxime.**—Four hundred and fifty grams of absolute alcohol was placed in a 1-liter round-bottom flask provided with a wide mouth Liebig condenser. To this was added 32 g. of furylethylketoxime and then 80 g. of sodium in small pieces as rapidly as was consistent with the boiling of the alcohol. After one hour undissolved sodium was removed and the mixture cooled in an ice-bath and acidified with dilute sulfuric acid. Then 700 ml. of water was added. The alcohol was removed under vacuum. The residue was made alkaline with solid potassium hydroxide and then extracted with ether. The ether extract was dried over anhydrous magnesium sulfate and distilled; b. p. 63–65° at 7 mm.; yield, 10 g.; $n^{25}D$, 1.4673. The picrate of the amine melted at 168–173° with decomposition. Erlenmeyer and Simon[11] report a melting point of 168° but do not mention decomposition.

**1-Butyl-1-(α-ethylfurfuryl)-3-α-naphthylurea.**—In a 200-ml. round-bottom flask 20 ml. of technical xylene, 1.6 g. (0.013 mole) of (α-ethylfurfuryl)-amine and 4.2 g. (0.023 mole) of butyl iodide was refluxed gently for four hours. After cooling the xylene was extracted with 25 ml. of water. The water solution was made basic with sodium hydroxide and extracted with 6 ml. of ligroin. The ligroin solution was dried over sodium hydroxide and reacted with 2 ml. of α-naphthyl isocyanate dissolved in 2 ml. of ligroin. An oil precipitated. The ligroin was decanted and about 6 ml. more of ligroin was added to the oil and the mixture stirred. After the oil had separated the second ligroin solution was decanted. The residual oil solidified to a glass but could not be crystallized. Four drops of α-naphthyl isocyanate was now added to each of the decanted ligroin solutions and a precipitate formed in each. After combining the two precipitates and recrystallizing three times from ligroin the small quantity of crystals obtained melted at 76–77° (cor.) on a Fisher–Johns apparatus. Mixed m. p. with the urea prepared by means of the Grignard method was 76–77° (cor.). This was the only successful attempt at isolation of the pure urea. Other attempts under what appeared to be the same conditions failed.

**Oxidation of N-Butyl-(α-ethylfurfuryl)-amine.**—Two grams of the amine, 50 g. of potassium ferricyanide and 20 g. of potassium hydroxide were dissolved in 300 ml. of water and refluxed for two hours when 25 g. more of po-

tassium ferricyanide and 10 g. of potassium hydroxide were added and reflux continued for two more hours. Iron oxide was removed by filtering the hot mixture. The solution was then evaporated under 15 mm. pressure to one-half its original volume, cooled and filtered, made acidic with hydrochloric acid and extracted with ether. The ether was evaporated and the residue recrystallized from ligroin giving 0.02 g. of a solid; m. p. 130°; mixed m. p. with Eastman Kodak Co. white label furoic acid, 130°.

**Oxidation of N-Butyl-(α-ethylthenyl)-amine.**—To a solution of 8 g. of sodium hydroxide and 8.8 g. of potassium permanganate in 500 ml. of water was added slowly with stirring 1 g. of N-butyl-(α-ethylthenyl)-amine. After six hours the solution was filtered, evaporated to about 100 ml. and again filtered. The filtrate was washed with ether, made acidic with dilute hydrochloric acid and extracted with ether. Evaporation of the ether gave 0.55 g. of crystals; m. p. 126–126.5° after two recrystallizations from water.

Neutral equivalent: calcd. for 2-thiophenecarboxylic acid, 128.1; found, 128.8.

## Summary

1. Five furfurylideneamines, three of which are new, and one new thenylideneamine have been prepared.

2. Six new furfurylamines and one new thenylamine have been synthesized.

3. The structures of the furfurylamines and of the thenylamines have been shown to be most probably those which result from 1,2-addition of the alkylmagnesium halides to the carbon–nitrogen double bond of the Schiff bases.

# Leucenol. VI. A Total Synthesis

BY ROGER ADAMS AND J. L. JOHNSON[1]

Leucenol, from *Leucaena glauca Bentham*, has been shown through degradation studies to have formula I.[2] During the investigation of leucenol

I

in this Laboratory, a variation in the melting point and rotation was frequently observed, which appeared to be dependent on the method of extraction and purification. Experiments have now been completed which permit a clarification of this variability. As obtained directly from the extract by the procedure used originally in this Laboratory or by the method of Kostermans,[3] leucenol had a rotation of −21° in water and a melting point of 228–229°. One recrystallization from water does not cause any essential change in these constants. Mascré[4] and Adams, *et al.*,[2a] reported optical inactivity for leucenol, Bickel and Wibaut[2c] reported −9°, while still others[2e,3,5] gave values of −21° or −22°. The rotation in 1% hydrochloric acid was found to be +10° as compared with Bickel and Wibaut's[2c] value of +6.7°. Mascré[4] and Adams, *et al.*,[2a] observed melting point values of 283–287° and 291°, the latter authors specifying a Maquenne block, but in open tubes previous investigators have given values of 226–227°,[2c] 228°,[5] and 231°.[5]

An explanation of these variations is found in the following observations. Samples of leucenol, after two or three crystallizations from water, were found to have rotations of −16 to −18°, although the melting points were about the same as before recrystallization. By boiling in water for forty-eight hours, the optical activity completely disappeared. The product had obviously racemized. When the racemic modification crystallized from a boiling aqueous solution as the water was evaporated to a volume below that of saturation of the compound, the product had a melting point of 235–236°. On the other hand, if a cold aqueous solution was permitted to evaporate, the product which was obtained had a melting point of 227–228°. By analysis, the former was shown to be anhydrous and the latter hydrated with one-half molecule of water. The anhydrous and hydrated forms are interconvertible by the treatment described. The hydrate does not lose its water even at 150°, and at 180° it decomposes. These two products have quite different infrared absorption spectra (Fig. 1). It is noteworthy that 3,4-dihydroxypyridine (3-hydroxy-4-pyridone) and α-amino-β-(N-4-pyridone)-propionic acid, of which leucenol is a derivative, hydrate and the infrared absorption spectra of the anhydrous and hydrated forms differ.[2b] Optically active leucenol does not form a hydrate under the conditions used for preparing the hydrated racemic modification. The facile

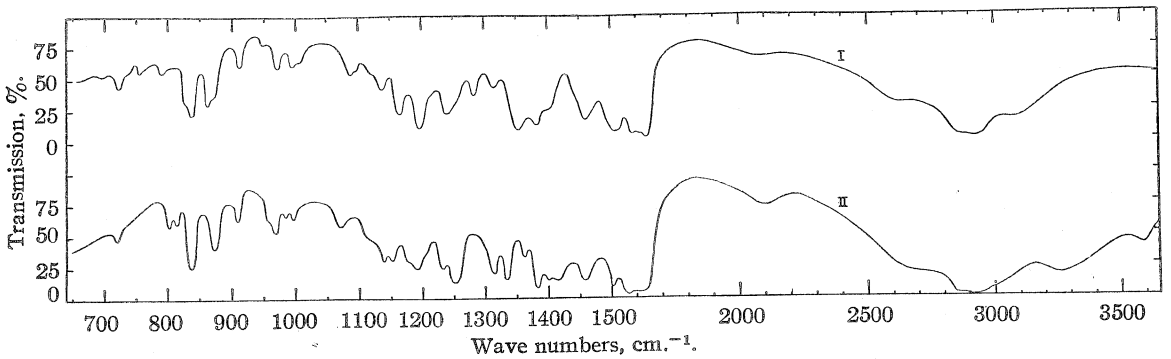

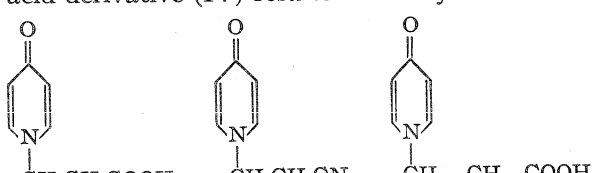

Fig. 1.—I, Anhydrous *dl*-leucenol; II, *dl*-leucenol hemihydrate. [The samples were prepared by grinding the crystalline compounds with paraffin oil to reduce light scattering. Absorptions due to the C–H frequencies of the paraffin oil occur at 2920, 2855, 1459 and 1378 cm.$^{-1}$, and mask the C–H frequencies of the compounds.]

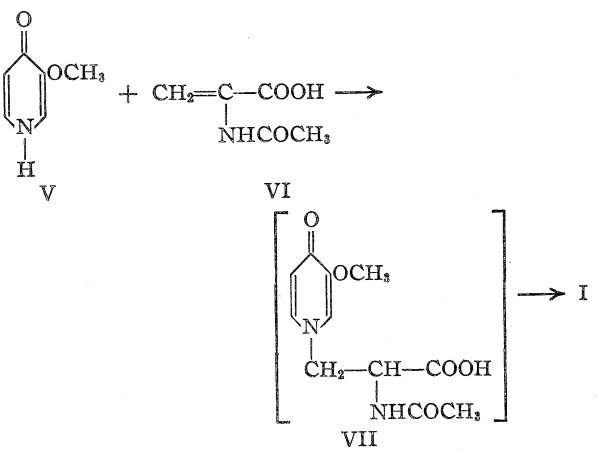
racemization of the natural product is fortunate since it provides a compound with which a *dl* synthetic product may be compared.



The initial approach to the synthesis involved a study of the conversion of γ-pyrone to the appropriate 4-pyridones by a reaction with primary amines. Ammonia and methylamine condense to give 4-pyridone and 1-methyl-4-pyridone, respectively.[6] β-Alanine was found to react similarly to give an 80% yield of 1-β-carboxyethyl-4-pyridone (II). β-Alanine ester did not react as smoothly and the primary condensation product could not be isolated in a pure state; however, on acid hydrolysis, an acid was obtained identical with that formed from β-alanine. The condensation of γ-pyrone with α,β-diaminopropionic acid or α-hydroxy-β-aminopropionic acid failed to give products from which pure compounds could be isolated.

Attention was next directed to reactions of 4-pyridone. Its condensation with β-bromopropionic acid was unsuccessful. On the other hand, it added to acrylonitrile with formation of 1-β-cyanoethyl-4-pyridone (III). Upon hydrolysis of this product, 1-β-carboxyethyl-4-pyridone (II) resulted which is the same compound as that derived from γ-pyrone and β-alanine. α-Acetamidoacrylic acid (VI) and 4-pyridone reacted in a similar manner, using dioxane as solvent. The product could not be isolated, but after hydrolysis with hydrochloric acid, the α-aminopropionic acid derivative (IV) resulted in low yield.

II III IV

The last reaction provided a possible route to the synthesis of the leucenol molecule through the use of 3-methoxy-4-pyridone (V) and α-acetamidoacrylic acid (VI). The condensation was effected merely by heating the two reactants together without catalyst at 90–100° in presence of dioxane. The reaction product (VII) did not crystallize and was therefore hydrolyzed directly with aqueous hydriodic acid in order to cleave the methoxyl group to hydroxyl and the acetamido group to the amine. After this was completed, the hydriodic acid was neutralized and the water removed. The by-products were extracted with

hot methanol and the residue crystallized by evaporating a water solution at room temperature. A 25.5% yield of *dl*-leucenol hemihydrate resulted. The *dl*-leucenol, anhydrous, was prepared by distilling off water from a saturated boiling solution and filtering the crystals from the hot solvent.

These products showed identical properties with those of racemized natural leucenol. The comparison was made of the melting points, infrared absorption spectra, and analyses of the hydrated and anhydrous forms. Melting points of mixtures of the synthetic and the racemic form from the natural product were not depressed. The color reactions with ferric chloride, ninhydrin, and Folin reagent were the same with synthetic *dl*-leucenol, racemized natural leucenol, and natural leucenol.

(6) Haitinger and Lieben, *Monatsh.*, **5**, 339 (1884); Meyer, *ibid.*, **26** 1311 (1905).

These experiments establish unequivocally the structure of leucenol as I.

The authors are indebted to Mrs. J. L. Johnson for the infrared analyses and their interpretation.

## Experimental

**Natural Leucenol.**—Crude leucenol obtained by the extraction procedure of Kostermans[3] was purified according to the method of Bickel and Wibaut.[2c] The product was obtained as white needles, m. p. 228–229° (cor.) with decomposition. The method of isolation previously used in this laboratory[2a] gives lower yields of leucenol having the same melting point and rotation.

*Anal.* Calcd. for $C_8H_{10}O_4N_2$: C, 48.48; H, 5.05; N, 14.14. Found: C, 48.57; H, 4.98; N, 14.42.

*Rotation.* 0.049 g. made up to 25 ml. with water at 22° gave $\alpha_D$ −0.084°; *l*, 2; $[\alpha]^{22}D$ −21°. 0.096 g. made up to 10 ml. with 1% hydrochloric acid at 23° gave $\alpha_D$ 0.098; *l*, 1; $[\alpha]^{23}D$ +10°.

An attempt to form a hydrate in the same manner used for preparing *dl*-leucenol hemihydrate from *dl*-leucenol failed.

**Racemization of Natural Leucenol.**—A solution of 2.5 g. of natural leucenol, ($[\alpha]^{23}D$ −20°) in 250 ml. of water was heated under reflux for forty-eight hours. The volume of the solution was reduced to approximately 50 ml. by distilling off water at atmospheric pressure. The crystals, which separate during this procedure, were filtered while the mixture of crystals and solution was hot. Brownish needles of anhydrous *dl*-leucenol weighing 1.0 g. were thus obtained. Two recrystallizations, in which a saturated boiling aqueous solution was evaporated to a smaller volume and filtered while still hot, resulted in white needles, m. p. 235–236° (cor.) with decomposition. No rotation could be observed.

*Anal.* Calcd. for $C_8H_{10}O_4N_2$: C, 48.48; H, 5.05; N, 14.14. Found: C, 48.57; H, 5.21; N, 14.32.

The procedure for forming the anhydrous *dl*-leucenol in a pure state is more reliable than merely cooling a boiling saturated solution which may result in anhydrous *dl*-leucenol contaminated with a small amount of the hydrate.

***dl*-Leucenol Hemihydrate.**—A solution of 0.25 g. of *dl*-leucenol, prepared from natural leucenol, in 30 ml. of water was evaporated to 15 ml. in a vacuum desiccator over phosphorus pentoxide. The hemihydrate separated in the form of white needles in a yield of 0.18 g. The product darkens at 215–226°, and melts at 227–228° (cor.) with decomposition.

*Anal.* Calcd. for $C_8H_{10}O_4N_2 \cdot {}^1/_2H_2O$: C, 46.46; H, 5.33; N, 13.55. Found: C, 46.42; H, 5.35; N, 13.44.

### 1-β-Carboxyethyl-4-pyridone

**A. From β-Alanine.**—A solution of 0.5 g. of γ-pyrone[7] and 0.5 g. of β-alanine in 3 ml. of water was sealed in a 14-mm. Pyrex glass tube, and the tube immersed in an oil-bath at 105° for four hours. The tube was cooled, opened, and the reaction mixture poured into 75 ml. of acetone. The yellow solid which separated was partially purified by dissolving it in 20 ml. of 90% methanol and adding acetone slowly to precipitate the product. Crystallization from water yielded white needles, m. p. 182.5–183.5° (cor.). The yield was 0.68 g. (81%).

*Anal.* Calcd. for $C_8H_9O_3N$: C, 57.47; H, 5.39. Found: C, 57.20; H, 5.49.

**B. From β-Alanine Methyl Ester.**—A solution of 1.1 g. of β-alanine methyl ester hydrochloride, in 30 ml. of ethanol was boiled with 2.2 g. of freshly prepared silver oxide for twenty minutes. The precipitated silver chloride and excess silver oxide were separated by filtration. The volume of the filtrate was increased to 50 ml., and 0.8 g. of γ-pyrone was added. The solution was evaporated to 10 ml., but no crystals separated from the yellow solution on standing overnight in a refrigerator. On evaporating the solution to dryness over phosphorus pentoxide in a vacuum desiccator a yellow oil was obtained.

This oil was dissolved in 10 ml. of 20% aqueous sulfuric acid, and the solution was heated under reflux for two hours. The hot solution was made basic by addition of barium hydroxide, and then acidic (*p*H 4) by addition of dilute sulfuric acid. The precipitated barium sulfate was separated by filtration, and the clear filtrate was evaporated to dryness yielding a glassy residue. The residue was extracted with four 10-ml. portions of warm 90% methanol. The methanol insoluble material was recrystallized from water to yield 0.3 g. of β-alanine; its identity was established by means of its infrared absorption spectrum. The methanol was evaporated to 10 ml., and acetone was added to precipitate 0.135 g. (10%) of 1-β-carboxyethyl-4-pyridone.

**Hydrolysis of 1-β-Cyanoethyl-4-pyridone to 1-β-Carboxyethyl-4-pyridone.**—The substituted propionitrile may be hydrolyzed to give an 80% yield of 1-β-carboxyethyl-4-pyridone; it is more convenient, however, to hydrolyze the cyanoethylation mixture directly.

The crude nitrile obtained from 2 g. of 4-pyridone was dissolved in 20 ml. of 30% aqueous sulfuric acid. The solution was heated under reflux for five hours. While still hot, it was made basic by addition of barium hydroxide, then acidic (*p*H 4) by addition of dilute sulfuric acid. The slurry was filtered to remove the precipitated barium sulfate. The filtrate was evaporated to dryness yielding a glassy yellow residue. The residue was dissolved in 100 ml. of 90% methanol, and the methanol allowed to evaporate off at room temperature. A powdery yellow product separated. After recrystallization from water 1.7 g. (50%) of white needles resulted, identical with the product obtained from the reaction of γ-pyrone with β-alanine.

**1-β-Cyanoethyl-4-pyridone.**—A mixture of 1.0 g. of 4-pyridone,[8] 0.85 g. of acrylonitrile, and approximately 10 mg. of sodium 4-pyridone was heated in an oil-bath at 60–65° for five hours. The solid dissolved slowly during the first three hours of heating. The yellow reaction mixture was warmed with 10 ml. of acetonitrile, the solution filtered to remove a small amount of gelatinous material, and the filtrate evaporated to approximately 3 ml. in a stream of filtered air. A yield of 1.2 g. of slightly yellow product was then obtained. Four recrystallizations from acetonitrile yielded a white product which after drying at 60° and 1 mm. pressure for five hours melted at 109–111° (cor.). The yield of dried product was 0.65 g. (42.5%).

*Anal.* Calcd. for $C_8H_8ON_2$: C, 64.85; H, 5.44. Found: C, 64.57; H, 5.59.

**α-Amino-β-(N-4-pyridone)-propionic Acid.**—A suspension of 1.0 g. of 4-pyridone and 1.45 g. of α-acetamidoacrylic acid[9] in 4 ml. of dioxane was heated in a metal-bath at 90–100° for four hours. The dioxane was evaporated off to yield a brown gum which failed to crystallize from ethanol or methanol. The impure α-acetamidopropionic acid derivative was dissolved in 15 ml. of concentrated hydrochloric acid, and the solution was heated under reflux for six hours. The excess hydrochloric acid and water were evaporated off, and the brown residue was dissolved in 5 ml. of concentrated aqueous ammonia. The ammonia and water were evaporated and the residue dried in a vacuum desiccator. The dry residue was washed with 200 ml. of boiling methanol in four portions. The methanol insoluble material, weighing 0.4 g. was recrystallized from 5 ml. of water to yield 0.25 g. (13%) of white needles, m. p. 178° (cor.) with decomposition. The product was a monohydrate. After heating at 100° and 1 mm. for thirty-six hours, the hydrate lost its water to yield the anhydrous amino acid. Slight decomposition occurred as judged by the sample becoming slightly yellow. The melting point of the anhydrous product was 170–172° (cor.) with decomposition. The anhydrous amino acid is extremely hygroscopic.

*Anal.* Calcd. for (monohydrate) $C_8H_{10}O_3N_2 \cdot H_2O$: C, 48.01; H, 6.05; N, 14.02. Found: C, 48.14; H, 6.15; N, 14.12. Calcd. for (anhydrous) $C_8H_{10}O_3N_2$: C, 52.75; H, 5.53. Found: C, 52.43; H, 5.54.

Synthetic *dl*-Leucenol.—A suspension of 0.9 g. of 3-methoxy-4-pyridone[2d] and 0.95 g. of α-acetamidoacrylic acid in 5 ml. of dioxane was heated at 95–100° for five hours. The dioxane was removed in a stream of air during the last hour of heating. A solution of the brown reaction mixture in 20 ml. of aqueous hydriodic acid (sp. gr. 1.50) was heated under reflux for six hours. The water and excess acid were removed under reduced pressure, and the residue was allowed to stand overnight in a vacuum desiccator over solid potassium hydroxide. The dry residue was dissolved in 20 ml. of water, and the solution was filtered to remove a small amount of insoluble brownish material. The filtrate was made just acid to brom cresol green (*p*H range, 3.8–5.4) by addition of dilute potassium hydroxide solution. Most of the water was distilled off under reduced pressure, and the residue was dried in a vacuum desiccator. The dry residue was washed with 200 ml. of hot methanol in 20-ml. portions to remove the potassium iodide and by-products. The insoluble material weighed 425 mg. and was reddish-brown in color. One recrystallization carried out by evaporating a water solution of the product at room temperature gave pinkish needles, m. p. 225–227° (cor.) with decomposition, and having the infrared absorption spectrum of *dl*-leucenol hemihydrate (Fig. 1). The yield was 380 mg. (25.5%). Two more recrystallizations carried out in the same way gave a white product; it darkens at 215–226° and melts at 227–228° (cor.) with decomposition. The melting point of a mixture of this product with racemized natural leucenol hemihydrate showed no depression.

*Anal.* Calcd. for (hemihydrate) $C_8H_{10}O_4N_2 \cdot {}^1/_2H_2O$: C, 46.46; H, 5.33; N, 13.55. Found: C, 46.21; H, 5.60; N, 13.56.

A portion of the hemihydrate was dissolved in water and the solution boiled down until crystals separated. The hot solution was filtered to give anhydrous *dl*-leucenol, m. p. 235–236° (cor.) with decomposition. The melting point of a mixture of this product with anhydrous racemized natural leucenol showed no depression.

*Anal.* Calcd. for (anhydrous) $C_8H_{10}O_4N_2$: C, 48.48; H, 5.05; N, 14.14. Found: C, 48.47; H, 5.16; N, 14.24.

Condensation of 3-hydroxy-4-pyridone[2b] with α-acetamidoacrylic acid proceeded much less smoothly than the reaction described above. Only a 4% yield of *dl*-leucenol was obtained.

## Summary

1. Natural leucenol, which is levorotatory, is racemized when heated in aqueous solution for forty-eight hours.

2. The *dl*-leucenol has been synthesized by condensation of 3-methoxy-4-pyridone with α-acetamidoacrylic acid, and hydrolysis of the primary condensation product.

3. *dl*-Leucenol can be isolated in an anhydrous or a hydrated form.

# Ethylene Imine Ketones. IV.[1] Isomerism and Absorption Spectra[2]

BY NORMAN H. CROMWELL AND HERMAN HOEKSEMA[3]

In previous investigations[1] of the reaction of primary amines with α,β-dibromoketones, ethylene imine ketones were obtained in yields of about 25%. The fact that diphenylethylenimine exists in *cis* and *trans* forms[4] suggests that these low yields may have been due to the formation of pairs of geometrical isomers, of which only the less soluble was isolated in each instance studied. It is also possible, of course, that products of other types, such as piperazines and α-imino ketones, are formed along with one or more forms of the ethylene imine ketones.

The reaction of benzylamine with α,β-dibromobenzyl-*p*-methylacetophenone[1] has now been found to give the isomeric products (IA) (29%) and (IB) (37%), when carried out in dry benzene solution at temperatures between 20 and 30°. No evidence for the formation of a piperazine was observed in these studies.

The low melting isomer (IB) was the more labile of the two. This compound partially decomposed and rearranged to the higher melting isomer (IA) when saturated petroleum ether solutions of it were exposed to sunlight at room temperature. An inspection of scale models for such ethylene imine ketone structures indicated that the racemate (IB) would be a more highly strained arrangement than (IA). Thus (IB) might be expected to undergo rearrangement, possibly through an enol form, to the less strained structure (IA). Acid and base catalyzed rearrange-

ments of ethylene imine ketones are under investigation at present in this laboratory.

Hot aqueous hydrogen chloride reacted with the isomers, (IA) and (IB), to give mixed chloroamino ketone hydrochlorides. Analysis and iodine release studies[5] of these two products indicated them to be mixtures of the two probable ring cleavage products, α-chloro-β-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (II) and β-chloro-α-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (III).

Excess dry hydrogen chloride reacted with (IA) to give good yields of the hydrochloride (III). The *cis* racemate (IB) gave a mixed hydrochloride product (IV) with this same reagent. Iodine release studies indicated this latter substance (IV) to be made up of approximately 46% (II) and 54% (III).

The reaction with two equivalents of hydrogen chloride is characteristic of an ethylene imine. If either (IA) or (IB) had possessed the structure of a β-amino-α,β-unsaturated ketone, or an α-amino-α,β-unsaturated ketone, or an α-imino ketone, hot aqueous hydrogen chloride should have formed a 1,3-diketone or a 1,2-diketone, respectively.[6] The following paper in this series[7] reports a more detailed study of the cleavage of ethylene imine ketone rings by hydrogen chloride.

Ultraviolet absorption spectra studies (see Table I and Fig. 1) of (IA), (IB) and 1-benzyl-2-phenyl-3-benzoylethylenimine[8] revealed a strong fundamental absorption band in the region of 2400–2600 Å. A low intensity absorption near 3300 Å. was again observed.[9]

These ethylene imine ketones show absorption spectra very similar to those of the parent saturated ketones (see Fig. 2). The only important grouping, other than the benzene rings, affecting ultraviolet light absorption by (IA), (IB) and 1-benzyl-2-phenyl-3-benzoylethylenimine is the two-chromophore, arylcarbonyl structure. The related β-amino-α,β-unsaturated ketones have a strong fundamental absorption band near 3450 Å.[9,10] α-Amino-α,β-unsaturated ketones absorb strongly at 2800–2900 Å. and at 2500 Å., and mildly and generally from 3600 to 4000 Å.[9,10]

The maximum absorption band of the isomer (IB) was 30–80 Å. nearer the red, with a 2000–3000 greater extinction coefficient value, as compared with (IA). The more strained structure (IB) would be expected to absorb light of longer wave lengths.

The changes in the absorption spectra after sunlight irradiation of solutions of (IA) and (IB) are shown in Tables III and IV and in Fig. 3. Hexane solutions of (IA) or (IB) were stable when stored in the dark for several days. Solutions of (IA) were unaffected by sunlight irradiation. It was found that hexane solutions of (IB) underwent considerable change upon exposure to sunlight. A general broadening (90 Å.) of the maximum absorption band was observed for this latter substance. A freshly prepared 50-50 mixture of (IA) and (IB) showed a similar absorption curve. This is further evidence of the ability of (IB) to rearrange to (IA) under the influence of sunlight.

**Acknowledgment.**—The senior author appreciates a grant from the Research Council of the University of Nebraska which aided in the completion of this investigation.

## Experimental

**1-Benzyl-2-phenyl-3-*p*-toluylethylenimines (IA) and (IB).**—To a suspension of 60.0 g. (0.15 mole) of α,β-dibromobenzyl-*p*-methylacetophenone[11] in 150 ml. of benzene was added 50.0 g. (0.45 mole) of benzylamine. The mixture was kept cool (15°) and stirred one hour, stored in the dark at room temperature for twenty-four hours, then filtered to remove 55 g. of benzylamine hydrobromide (94%). The volume of the residual reaction solution was reduced about two-thirds by vacuum distillation and 100 ml. of petroleum ether added to give 15.5 g. (29% yield) of a colorless crystalline product, m. p. 113–114°. One recrystallization of this product (IA) from absolute alcohol, raised the m. p. to 120–121°, while further recrystallization often lowered it to 116–118°.[1]

Upon exposure to light these colorless crystals rapidly developed a deep pink color. When returned to a dark environment for several days, the crystals again became colorless. This same color change was observed with (IA) under a nitrogen atmosphere in a sealed quartz tube.

The benzene–petroleum ether filtrate from (IA) was evaporated and the residue mixed with 200 ml. of petroleum ether and cooled for two days in the ice chest. Filtration gave 25.0 g. (49% yield) of a colorless, fluffy solid, m.p. 70–85°. Recrystallization of this product from low-boiling petroleum ether gave 19 g. (37% yield) of a colorless, fluffy product, m. p. 70–74°. Upon exposure to light this product, (IB), slowly acquired a yellow tint. Extensive manipulation of (IB) in various solvents converted some of it to (IA). Exposure of saturated petroleum ether solutions of (IB) to direct sunlight caused the precipitation of small amounts of (IA).

*Anal.* Calcd. for $C_{23}H_{21}NO$: mol. wt., 327; C, 84.37; H, 6.47; N, 4.28. Found for (IA): mol. wt., 318; C, 84.73; H, 6.64; N, 4.20. Found for (IB): mol. wt., 337; C, 84.51; H, 6.24.

**Reaction of 1-Benzyl-2-phenyl-3-*p*-toluylethylenimines (IA) and (IB) with Hydrogen Chloride**

**1. With Aqueous Hydrogen Chloride.**—Mixtures of 16 ml. of 6 *N* hydrochloric acid with 2.0-g. samples of (IA) and (IB) were refluxed for two hours and then allowed to stand at room temperature for a day. The solid precipitates were filtered from the solutions and recrystallized once from boiling methanol.

(IA) gave 1.5 g., m. p. 161–162.5°; iodine release was 33% in fifteen minutes at 66°.

(IB) gave 1.94 g., m. p. 161–162°; iodine release was 20% in fifteen minutes at 66°.

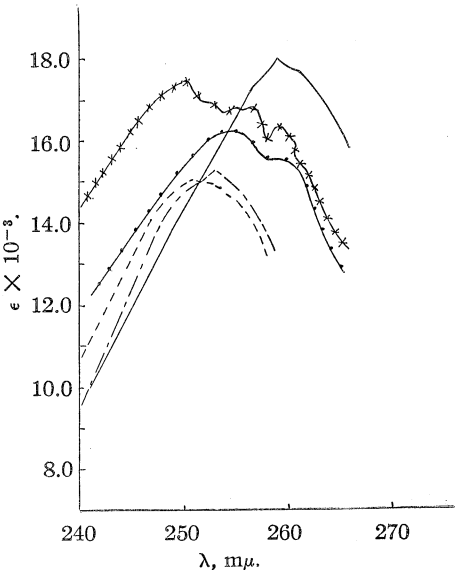

Fig. 3.—Absorption spectra in hexane of (IA): fresh solution, – – –; after two days in dark + two days in light, – – –; of (IB), fresh solution, —; after two days in dark + two days in light —×—×—; 50% (IA) + 50% (IB), fresh solution, —●—●—●—.

*Anal.* Calcd. for $C_{23}H_{23}NOCl_2$: Cl, 17.72. Found: for product from (IA), Cl, 17.80; for product from (IB), Cl, 17.91.

Mixtures of these two products showed m. p. 160–162°.

**2. With Excess Dry Hydrogen Chloride.**—Samples (2.0 g.) of (IA) and (IB) were dissolved in 10 ml. of acetone and the solutions cooled in an ice-bath. An excess of a saturated, dry, ether solution of hydrogen chloride was added, with stirring, in two minutes. After standing in the ice-chest for one day, the solutions were filtered.

(IA) gave 2.0 g. of a colorless crystalline product (III), m. p. 163–165°; recrystallized from methanol and ether, m. p. 167–170°; iodine release in thirty minutes at 66° was 0.0%.

(IB) gave 1.9 g. of colorless product (IV), m. p. 155–158°; recrystallized from methanol and ether, m. p. 161–165°; iodine release in fifteen minutes was 46.5% at 66°.

*Anal.* Calcd. for $C_{23}H_{23}NOCl_2$: C, 68.99; H, 5.79; N, 3.50; Cl, 17.72. Found for (III): C, 68.72; H, 5.79; N, 3.69; Cl, 17.48. Found for (IV): C, 68.79; H, 5.76; N, 3.57; Cl, 18.00.

**Absorption Spectra Studies of Ethylene Imine Ketones.**—These measurements were made with a Beckmann Model DU Photoelectric Quartz Spectrophotometer. At the sensitivity used, the maximum band width was one millimicron with an accuracy of 0.1% for the density measurements. The two solvents used were laboratory grade 95% ethyl alcohol and hexane-from-petroleum, purified by the procedure recommended by Weissberger.[12]

Using purified hexane, the ultraviolet absorption spectra of (IA), (IB), 1-benzyl-2-phenyl-3-benzoylethylenimine, benzal-*p*-methylacetophenone, benzylacetophenone, benzalacetophenone, and benzyl-*p*-methylacetophenone were observed. These studies were made within two hours of the time the solutions were prepared. The results are summarized in Table I, and the complete curves are shown in Fig. 1 and Fig. 2.

In Table II is given the summary of the results obtained when some of these compounds were studied in 95% alcohol solutions.

**Effect of Time and Light Exposure on the Absorption Spectra of *cis* and *trans* Ethylene Imine Ketones (IB) and (IA).**—A 0.000117 to 0.000100 molar solution in hexane of each of the highly purified samples of (IA) and (IB) was prepared. These solutions were stored in new, volumetric flasks which had been bathed in concentrated sulfuric acid for several days, and then rinsed with distilled water and dried. These solutions were stored in the dark The ultraviolet spectra were examined periodically and little or no change observed. After two days the solutions were each divided into two portions, one portion of each being exposed to direct sunlight for about forty-eight hours. The remaining portions were again stored in the dark. No significant changes in the spectra of (IA) were observed with either portion. With (IB) the portion again stored in the dark showed no change, but that exposed to sunlight displayed approximately a 100 Å. shift in the wave length of the maximum absorption band and a general broadening of the band.

In Table I and Fig. 3 are given the results of a study made with a freshly prepared 50–50 mixture of (IA) and (IB) in hexane solutions. These studies were made within two hours of the time the solution was prepared.

## Summary

*cis* and *trans* racemates of 1-benzyl-2-phenyl-3-*p*-toluylethylenimine have been isolated from the reaction of benzylamine with α,β-dibromobenzyl-*p*-methylacetophenone. The physical properties, absorption spectra and behavior with hydrogen chloride are consistent with the configurations that have been assigned. The interconvertibility of these geometrical isomers has been studied.

# Ethylene Imine Ketones. V.[1] Reaction with Hydrogen Chloride[2]

BY NORMAN H. CROMWELL AND RONALD A. WANKEL[3]

Previous investigations of the reactions of ethylene imine ketones with hydrogen halides have shown that the ethylene imine ring cleaves in the two directions under various conditions.[1,4]

It was of interest to re-investigate the reaction of benzylamine with α,β-dibromobenzylacetophenone[5] in an attempt to account for a larger portion of the starting materials. A further aim of this investigation was a quantitative product study of the reaction of ethylene imine ketones with minimum amounts of hydrogen chloride.

We were unable to isolate a lower-melting, more soluble form of 1-benzyl-2-phenyl-3-benzoylethylenimine. However, when the filtrate from the isolation of the higher-melting, less soluble form of this compound (I) (m. p. 108°)[5] was treated with

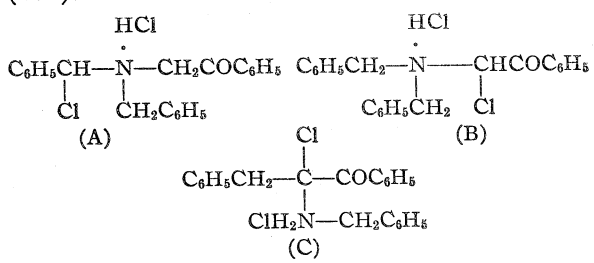
excess dry hydrogen chloride, most of the remaining starting materials were accounted for. A mixed dichloride product ($C_{22}H_{21}NOCl_2$) resulted which was separated by recrystallization into nearly equal amounts of β-chloro-α-benzylaminobenzylacetophenone hydrochloride (IIA) and α-chloro-β-benzylaminobenzylacetophenone hydrochloride (IIB). The isomer (IIA) had been obtained in a previous investigation of the reaction of ethylene imine ketone (I) with excess hydrogen chloride, and assigned this structure.[6]

The dichloride (IIB) reacted with dry, acidified acetone solutions of potassium iodide to release nearly one equivalent of iodine, while (IIA) gave almost no reaction under the same conditions.[6] Neither of these products showed any tendency to rearrange to the other on standing in either methyl alcohol or benzene saturated with dry hydrogen chloride.



When (IIA) was warmed with a benzene solution of benzylamine the base (III), α-benzylamino-β-chlorobenzylacetophenone, resulted. Compound (III) was readily hydrolyzed by warm aqueous alcohol to α-benzylamino-β-hydroxybenzylacetophenone hydrochloride (IV). Catalytic hydrogenation converted (III) into the known[7] 2-benzylamino-1,3-diphenylpropanol-1 hydrochloride (V) (and picrate). This latter experiment seems to afford unequivocal proof for the structure assigned to (IIA).

When the dichloride (IIB) was treated with a warm benzene solution of benzylamine, two equivalents of benzylamine hydrochloride were formed. This indicated that the chlorine attached to carbon was more readily removed here than in (IIA). Catalytic hydrogenation of (IIB) gave a good yield of benzylacetophenone. The intermediate product in this latter reaction may have been β-benzylaminobenzylacetophenone. It has been reported previously, from this laboratory, that such β-amino ketones readily undergo beta elimination during catalytic hydrogenation.[8]

We believe the structure of (IIB) has been definitely established. Other structures, such as (A), (B) and (C), for these products (IIA) and (IIB), seem to have been eliminated. Moreover, it is not possible for (IIA) and (IIB) to be related as racemates of the same position isomer, (IIA) or (IIB).

The isomeric dichlorides (IIA) and (IIB) were also obtained from a quantitative experiment with pure 1-benzyl-2-phenyl-3-benzoylethylenimine (m. p. 108°) (I). When minimum amounts of dry hydrogen chloride were employed, the α-chloro ketone (IIB) was the major (73.5%) product, while (IIA) was formed in lesser amounts (26.5%). Addition of one equivalent of dry hydrogen chloride to a cold acetone–ether solution of (I) resulted in the primary precipitation of quite pure (IIB). From the filtrate of (IIB) some unchanged ethylene imine ketone (I) was isolated. Addition of a second calculated amount of dry hydrogen chloride to the filtrate of (I) caused the formation of a mixed dichloride. This latter product was separated into the two isomers, (IIA) and (IIB), by taking advantage of the expected differences in the basic strengths of the free bases of these two dichlorides.

Iodine release data showed the above dichloride to be approximately a 50-50 mixture of (IIA) and (IIB). This product was treated with one equivalent of benzylamine and the precipitated benzylamine hydrochloride filtered off. One-half of an equivalent of hydrogen chloride was added to precipitate (IIB), the hydrochloride of the stronger base. A second one-half equivalent of the same reagent then precipitated (IIA).

It has been reported[1] that excess amounts of

dry hydrogen chloride reacted with *trans*-1-benzyl-2-phenyl-3-*p*-toluylethylenimine to give β-chloro-α-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (VI). The *cis* isomer gave a mixed dichloride which was indicated to contain approximately 54% of (VI) and 46% of α-chloro-β-benzylaminobenzyl-*p*-methylacetophenone hydrochloride (VII).

Quantitative experiments using minimum amounts of dry hydrogen chloride, as with the ethylene imine ketone (I), have been carried out with these *cis* and *trans* isomers mentioned above. The *trans* isomer gave 78% of the α-chloro ketone (VII) and 22% of the β-chloro ketone (VI). The *cis* isomer gave 54% of (VII) and 46% of (VI). These relative percentage yields were approximated from iodine release studies with the chloride products. Figure 1 compares the rate of iodine release by relatively pure α-chloro ketone (VII) with that of a pure sample of (IIB).

From both of these hydrogen chloride cleavage experiments some ethylene imine ketone was recovered. It is significant that, from the experiment starting with the *cis* isomer, we isolated the *trans* ethylene imine ketone. This indicates that the rearrangement of the *cis* isomer to the *trans* isomer may be catalyzed by acid as well as by light.[1]
