in addition, possessed remarkable toxicity toward *Aerobacter aerogenes*. This property was also characteristic of 2-butoxyethyl vanillate, but was not exhibited by trichloro-*t*-butyl vanillate. The esters of orthovanillic acid appear to be less specific in their toxicity. Of the 5-chlorovanillic acid esters, only the methyl and ethyl esters exhibited any toxicity whatsoever. Toxicity data are given in Table I.

**Acknowledgment.**—The authors are indebted to John F. McCoy and to Virginia West Martin, respectively, for the microbiological and chemical analyses reported in this paper.

## Summary

A large number of new esters of vanillic acid and the closely related acids, orthovanillic and 5-chlorovanillic, were prepared. The inhibiting concentrations of these esters were determined for representative microörganisms.

# Infrared and Ultraviolet Spectroscopic Studies on Ketones[1]

BY R. S. RASMUSSEN, D. D. TUNNICLIFF AND R. ROBERT BRATTAIN

The infrared, Raman, and ultraviolet spectra of aldehydes and ketones have been the subjects of numerous studies in the literature.[2] Some further investigations, which were made in connection with the OSRD program on penicillin structure, are reported here. These studies were made in order to gain a better insight into the influence of structure on the spectra of carbonylic compounds.

The infrared spectra, from 2 $\mu$ to 15 $\mu$, of the compounds studied are shown in tabular form in Table I; the ultraviolet spectra, from 2200 to 3500 Å., are given in Figure 1. All spectra are of pure liquids or solutions. The sources of samples and further spectroscopic experimental details are given at the end of this paper. Discussion of the infrared spectra is limited to the 3 $\mu$ region (NH, OH, and CH stretching vibrations) and 6 $\mu$ region (double-bond stretching vibrations). These were the regions actually used on the penicillin structure work and are the ones having an obvious correlation with structure. Thompson and Torkington, however, have noted several interesting regularities at longer wave lengths,[2] and such regularities are also present in Raman spectra.[2]

## Infrared Work

**Unconjugated Ketones.**—Previous published infrared and Raman work[2] together with unpublished work from this laboratory, indicates that unconjugated ketones exhibit their C=O absorption very near 5.83 $\mu$ (1715 cm.$^{-1}$). The only compound of this type discussed here in detail, diacetone alcohol, was examined to determine the effect of simple hydrogen bonding on the band position. Badger and Bauer[3] have given evidence, based on studies of the third harmonic of the OH stretching fundamental, that intramolecular hydrogen bonding is present in this compound. The band at 5.84 $\mu$ (1712 cm.$^{-1}$) indicates that the effect of hydrogen bonding on the C=O band is small, in contrast to the large effects noted by many investigators on the OH band position (*e. g.*, the shifts of 0.1–0.2 $\mu$ noted by Gordy[4] between $CH_3OD$ in benzene and in ketones and other proton acceptor solvents). An auxiliary experiment was carried out by examining a 10% (vol.) solution of methyl ethyl ketone in methanol. Under these conditions, where a large amount of hydrogen bonding of the type $CH_3OH \cdots O{=}CR_2$ is to be expected, the observed C=O band position was 5.86 $\mu$ (1706 cm.$^{-1}$), again indicating only a small effect.

The strong OH band is present in the diacetone alcohol spectrum at 2.87 $\mu$ (3484 cm.$^{-1}$), the usual position for hydrogen-bonded alcoholic OH groups.

**Conjugated Ketones.**—Two examples of ketone C=O conjugated to C=C, namely, isophorone and acetophenone, were examined. The strong bands at 5.98 $\mu$ and 5.93 $\mu$, respectively, (1672 and 1686 cm.$^{-1}$) are to be attributed to the C=O vibration. These positions are in the range found by others from Raman[5] and infrared[6] work for this band type (roughly 1670–1690 cm.$^{-1}$). The factors influencing the exact amount of this conjugation shift are not yet understood, due to lack of data on a sufficient number of compounds. It is clear, however, that conjugation with C=C effects a shift of the order of 30 cm.$^{-1}$.

Other features of interest in the spectrum of isophorone are: (1) The weak band at 5.83 $\mu$ (1715 cm.$^{-1}$) which is probably caused by an unconjugated ketonic impurity (1 or 2% impurity would be sufficient to give a band of this intensity);

(1) The major part of this work was done under contract between the Office of Scientific Research and Development, and the Shell Development Company (Contract OEM-cmr-445).

TABLE I

INFRARED SPECTRA OF KETONES

1. Diacetone alcohol (4-methyl-4-hydroxy-2-pentanone), 0.02 mm. pure liquid.
2. Acetophenone, 0.15 mm. 10% soln. in $CCl_4$.
3. Isophorone (3,5,5-trimethyl-2-cyclohexen-1-one), 0.02 mm. pure liquid.
4. Biacetyl, 0.15 mm. 5% soln. in $CCl_4$.
5. Benzil (bibenzoyl), 0.15 mm. 5% soln. in $CHCl_3$.
6. Dibenzoylmethane, 0.15 mm. 10% soln. in $CCl_4$.
7. Acetylacetone, 0.15 mm. 10% soln. in $CCl_4$.
8. Acetylacetone acetate (4-acetoxy-3-penten-2-one), 0.15 mm. 5% soln. in $CHCl_3$.
9. 5,5-Dimethyl-1,3-cyclohexanedione, 0.15 mm. 3% soln. in $CHCl_3$. (Wave lengths in $\mu$; intensity in units of 10% absorption; S = solvent interference.) Bands due to ketone C=O stretching vibrations are underlined.

(2) The moderately intense band at 6.10 $\mu$ (1639 cm.$^{-1}$) assignable as the C=C band shifted by conjugation. Other unpublished studies on this type of conjugated ketone reveal that the shifted C=C band falls in the range 6.07 $\mu$ to 6.17 $\mu$ (1647 to 1621 cm.$^{-1}$); published Raman data indicate the same thing.[5] Hence the shift from the unconjugated C=C position (*circa* 1660 cm.$^{-1}$) is of the order of 30 cm.$^{-1}$, about the same amount as the C=O shift noted above. In simple conjugated dienes, the shift is about the same in magnitude[7] so that it may be deduced that the amount of conjugation in the C=C—C=O system is about the same as in the C=C—C=C system.

The spectrum of acetophenone shows, in addition to the C=O band, the following features:

1. The three weak bands near 5.10 $\mu$, 5.30 $\mu$ and 5.60 $\mu$ (1961 cm.$^{-1}$, 1887 cm.$^{-1}$ and 1786 cm.$^{-1}$) observed in compounds containing the phenyl ring.[8] From their wave-length region and weakness, these must be assigned to overtones of the ring fundamentals.

2. The two bands of weak-to-moderate intensity at 6.25 $\mu$ and 6.315 $\mu$ (1600 cm.$^{-1}$ and 1584 cm.$^{-1}$) which, from work on other benzoyl-containing compounds (to be described in later papers

(7) Actually, infrared and Raman spectra of conjugated dienes show the two C=C frequencies split considerably apart: R. S. Rasmussen and R. R. Brattain, *J. Chem. Phys.*, **15**, 120 (1947); K. Bradacs and L. Kahovec, *Z. physik. Chem.*, **B48**, 63 (1940). The splitting in this case is due to mechanical interaction, and as a measure of the shift due to electronic resonance alone the average of these values has been used.

(8) *E. g.*, see Barnes, *et al.*, ref. 2, Table 4, p. 24.

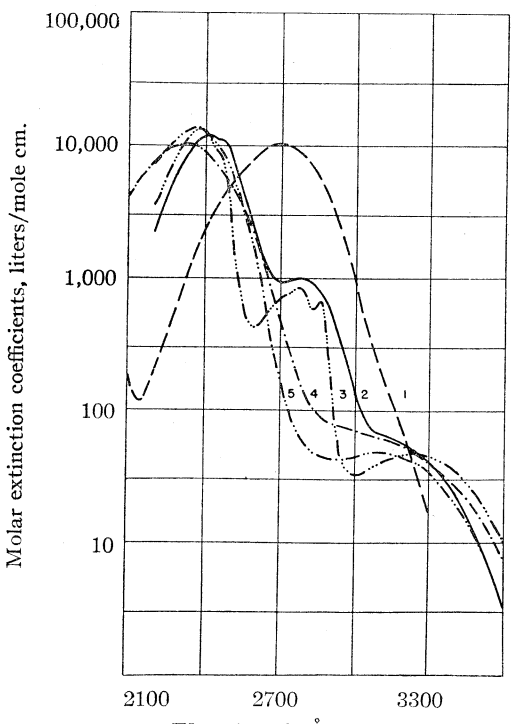

Fig. 1.—Ultraviolet absorption of conjugated ketones: 1, acetylacetone, in isoöctane; 2, acetophenone, in methanol; 3, hexadecanophenone, in isoöctane; 4, acetylacetone acetate (4-acetoxy-3-penten-2-one), in methanol; 5, isophorone, in methanol.

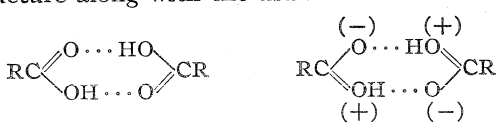
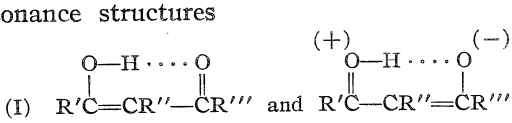


of this series), are universally found for the benzoyl group. The phenyl group itself, not conjugated to other groups, gives a single weak-to-moderate band near 6.25 $\mu$ (1600 cm.$^{-1}$).[8] Since one of the degenerate fundamental ring stretching frequencies of benzene lies at this position,[9] it is conceivable that in the unconjugated phenyl derivatives the analogous two ring frequencies are still very close even though the degeneracy is removed; but on conjugation with the C=O group, and the resulting change in character of the ring bonds, the two frequencies are split apart enough to exhibit themselves as the two bands at 6.25 $\mu$ and 6.31 $\mu$ (1600 cm.$^{-1}$ and 1584 cm.$^{-1}$) referred to above.

Spectra of two compounds in which one carbonyl is conjugated with another—biacetyl and benzil—are given in Table I. In each case only a single strong band attributable to C=O was found, at 5.82 $\mu$ and 5.95 $\mu$ (1718 cm.$^{-1}$ and 1681 cm.$^{-1}$), respectively. Since these positions are the ones expected for unconjugated and phenyl-conjugated C=O, respectively, it would seem that little or no conjugation between the adjacent C=O groups is present. Spectroscopic work on glyoxal[10] and electron diffraction work on biacetyl[11] indicate (not strongly) that the *trans* forms of these are the stable ones; benzil, by analogy and also because of repulsion of the phenyl groups, would be expected to be *trans*. Hence only one of the two C=O bands should be infrared active. Raman studies give 1725 cm.$^{-1}$ (5.80 $\mu$) and 1683 cm.$^{-1}$ (5.94 $\mu$) as the frequencies of the Raman-active vibration for biacetyl and benzil, respectively.[12] The small splitting between the infrared and Raman active frequencies is indicative of little mechanical interaction, and hence presumably indicates a weak central C–C bond and a low degree of conjugation. This result substantiates the conclusion made above from the C=O band position.



**$\beta$-Diketones.**—The Raman spectra of this class of compounds have been studied most intensively by Kohlrausch and collaborators,[13] who showed that the Raman spectrum of enolizable $\beta$-diketones is consistent with the usually formulated structure, R′C(OH)=CR″=CO—R‴, in some cases admixed with the keto form. Some further conclusions can be drawn from the infrared spectra. Spectra of acetylacetone and dibenzoylmethane are given in Table I. Both of these enolize almost completely as shown by chemical[14] and Raman spectral[13] methods.

Features of note in the 3 $\mu$ region are the lack of absorption near 3.0 $\mu$ (3333 cm.$^{-1}$) where simple hydrogen-bonded OH absorption occurs, and the weak band near 3.7 $\mu$ (2703 cm.$^{-1}$), an unusual absorption position. The latter absorption is very broad (not indicated in Table I), being in this respect reminiscent of the similar very broad OH band of fatty acid dimers[15]; the fatty acid dimer band is also shifted considerably beyond the normal hydrogen-bonded OH position (~3.0 $\mu$) to about 3.4 $\mu$ (2941 cm.$^{-1}$), where it becomes superposed on the narrower CH stretching bands near 3.4 $\mu$.

Pauling[16] has accounted for the greater strength of hydrogen bonds in fatty acid dimers on the basis of a large contribution of an ionic resonance structure along with the usual covalent structure

The ionic contribution is presumably increased in the dimer over its value in the monomer because of stabilization arising from the favorable position of the electropositive proton with respect to the negative carbonyl oxygen. The greater shift of the OH band in fatty acid dimers as compared with, for example, hydrogen-bonded alcohols, follows from this explanation as arising from the additional loosening of the OH bond due to the charges. It is clear that a similar explanation can be applied to the enolized $\beta$-diketones, since these can have contributions from the resonance structures

(I) R′C=CR″—CR‴ and R′C—CR″=CR‴

the latter being stabilized by the hydrogen bond. On this basis, the 3.7 $\mu$ (2703 cm.$^{-1}$) band may be accounted for as the OH vibration, extremely shifted and broadened in an analogous way to the fatty acid dimer band.

Enolized acetylacetone and dibenzoylmethane exhibit unusual absorption phenomena in the 6 $\mu$ region also. The former has a moderate band at 5.85 $\mu$ (1709 cm.$^{-1}$) which from its position is attributable to the keto form. No band is observed in the usual conjugated ketone region (5.90–5.98 $\mu$) (1695–1672 cm.$^{-1}$) for either compound. Each, however, exhibits a tremendously strong band in the 6.1–6.5 $\mu$ (1639–1538 cm.$^{-1}$) region, which from the breadth of the region of total absorption is estimated to be stronger by a factor of 100 or more than usual ketone C=O bands. Since C=C bands are usually not very intense in the infrared, these bands must be assigned as due to C=O. Both their extreme shifts from the usual ketone C=O positions and

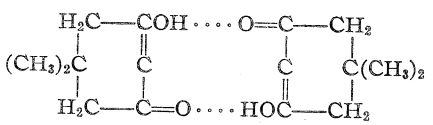
(16) L. Pauling, "The Nature of the Chemical Bond," 2nd ed., Cornell Press, Ithaca, N. Y., 1940, p. 306.

their extreme intensities may be explained reasonably in terms of the resonance structures written above. The enhanced participation of the ionic structure leads to a greater decrease in double-bond character of the C=O bond than would be the case with simple conjugation, thus resulting in the long wave-length shift; and the increased charge on the carbonylic oxygen results in the high intensity. If this interpretation is correct, the lack of an observed C=C band must be accounted for by its being hidden by the very strong C=O band, or by its being shifted out of the double-bond region because of loss of double-bond character.

It is clear that a conjugated system of the type

(II) 

where XH and Y can participate as a hydrogen bond donor-acceptor system, is necessary for this type of extreme shift. Examples other than enolized $\beta$-diketones which have also been found to exhibit this behavior will be described in ensuing papers. Since the structure II is a particular type of a chelate system, the name "conjugated chelate" system is suggested for it, to differentiate it from the type of structure represented by, say, diacetone alcohol, which is also a



chelate system but only by virtue of the ordinary sort of hydrogen bonding.

Resonance structures of the type I can be written for compounds in which the C=C is part of an aromatic ring. Thus Gordy[17] found the C=O bands of *o*-hydroxyacetophenone and salicylaldehyde, among other compounds, to be shifted to the 6.1–6.2 $\mu$ (1639–1613 cm.$^{-1}$) region, and he demonstrated that the hydroxyl group was necessary for the shift. On the basis of the above discussion, this shift is not to be attributed to simple hydrogen bonding, but to the existence of the conjugated chelate system. Also the early findings by Wulf, Liddel, and coworkers[18] that strongly intramolecularly hydrogen-bonded substances showed no absorption in the 7000 cm.$^{-1}$ region (second harmonic region of the usual 3.0 $\mu$ OH absorption) are attributable to the fact that all such compounds examined were of the conjugated chelate type, and hence the OH absorption was shifted completely out of the region examined. The second harmonic of this absorption should fall near 5000 cm.$^{-1}$.

The difference between ordinary conjugated systems and conjugated chelate systems is strikingly illustrated by the spectrum of acetylacetone acetate (spectrum 8, Table I). Acetylation of the OH group of enolized acetylacetone effectively removes the possibility of resonance indicated by formulae I, and reduces the system to the simple conjugated C=C—C=O type. The bands at 5.90 $\mu$ (1695 cm.$^{-1}$) and 6.125 $\mu$ (1633 cm.$^{-1}$) are attributable to conjugated C=O and C=C, respectively, being close to the regions noted above for such groups and being of the usual intensity for such bands. The somewhat enhanced intensity of the C=C band over its usually lower value may be ascribed to the oxygen substituent. The band at 5.68 $\mu$ (1761 cm.$^{-1}$) is at the position expected for the ester C=O of the vinyl ester grouping.[19]

The final spectrum of Table I, of 5,5-dimethyl-1,3-cyclohexanedione, illustrates a case in which the same resonance conditions as for acetylacetone can be realized in a different way. The moderately strong band at 5.875 $\mu$ (1702 cm.$^{-1}$) indicates that a good proportion of the molecules are in the keto form. However, the bands at 3.8 $\mu$ (2632 cm.$^{-1}$) and 6.23 $\mu$ (1605 cm.$^{-1}$) are indicative of the conjugated chelate type of enolization. Since the ring makes it impossible sterically for the OH of the enolized form to approach closely enough to the carbonylic oxygen of the same molecule to interact with it in the manner indicated by structures I, the necessary stabilization of the ionic structure must be accomplished through dimerization of the sort

**Ultraviolet Work.**—The conclusion drawn above as to the essential difference between a simple conjugated system (C=C—C=O) and the conjugated chelate system is well verified by ultraviolet spectra. Thus, spectra of the three simple conjugated ketones shown in Fig. 1 (isophorone, acetophenone, and hexadecanophenone) exhibit the characteristic strong band near 2350 Å. (molar extinction coefficient ~10,000) and the weak band or shoulder near 3200 Å. (molar extinction coefficient ~40) noted by many investigators[2] for the conjugated system and discussed theoretically by McMurry.[20] The two benzoyl-containing compounds show also the band or shoulder near 2800 Å. associated with the phenyl ring.

Acetylacetone gives a spectrum markedly different from the above cases, exhibiting a very strong band with a maximum at 2700 Å., and molar extinction coefficient ~10,000 (Fig. 1). This is at roughly the same position as the band of simple unconjugated ketones, but the latter band is much weaker (molar extinction coefficient ~20). Acetylation to acetylacetone acetate effects the same result here as it did in the infrared, converting the absorption from that of the con-

jugated chelate type to that of a simple conjugated ketone (Fig. 1), with maxima at 2300 and 3250 Å. (molar extinction coefficients ~13,000 and ~60, respectively).

## Experimental

**Infrared Spectra.**—These were obtained by means of the recording rock-salt prism spectrograph of this laboratory, described elsewhere.[21] Each spectrum given in Table I was the result of a single run. Wave-length values as read directly from the record were corrected for temperature effects or mechanical shifts by observing the deviation of the $CO_2$ 4.235 $\mu$ band, or of one of the known solvent bands, from its true position and correcting all wave lengths according to a standard correction curve. This curve was constructed from several calibration runs on $CO_2$, $NH_3$, and $C_2H_4$ vapors. The reproducibility for sharp bands is within $\pm 0.02$ $\mu$. Intensities were estimated visually on a scale of 0 to 10. Solutions were made up (not highly accurately) on a weight-to-volume basis.

**Ultraviolet Spectra.**—The ultraviolet spectra were obtained from point-by-point readings on a Beckman quartz photoelectric spectrophotometer (Model DU). Solutions were made up accurately in the solvents noted in Fig. 1, using spectroscopically pure solvents. Molar extinction coefficients quoted are in units of liters/mole cm.

**Sources of Samples.**—The sources and purification procedures for the samples used were as follows:

Diacetone alcohol was obtained from a laboratory distillation of commercial material, the fraction boiling at 167.6–168.2° being used.

Isophorone was obtained from a careful laboratory distillation of commercial material, the resulting pure fractions being used also for determination of other physical constants.

Eastman White Label acetophenone and benzil were used without further purification.

The sample of biacetyl used was from an earlier laboratory preparation, and was not further purified.

Commercial acetylacetone was fractionated and the cut boiling at 139.0–139.1° used.

A dibenzoylmethane sample already on hand was used for this material (m. p. 77.5–78.0°, lit. 78°).

The sample of 5,5-dimethyl-1,3-cyclohexanedione had been prepared earlier in these Laboratories by the procedure of "Organic Synthesis," Collective Volume 2. The sample melted at 148.5–149.0° (lit., 148–150°).

Acetylacetone acetate was prepared by the method of Spence and Degering.[22] A cut of b. p. 95.1–95.6° (20 mm.), $n^{20}D$ 1.4529, was used.

Hexadecanophenone was prepared from hexadecanonitrile plus phenyl Grignard reagent, and was purified by distillation at 1.5 mm. and crystallization from ether-alcohol mixture.

**Acknowledgments.**—We wish to thank Drs. D. S. Melstrom and C. W. Smith of these laboratories for furnishing the samples, and P. S. Zucco, Mrs. Z. Alcorn, Mrs. E. Dugle and Miss R. Hatch for operation of the spectrometers and measurement of the records.

## Summary

1. Infrared absorption maxima in the 2–15 $\mu$ region are tabulated for diacetone alcohol, isophorone, acetopheonone, biacetyl, benzil, acetylacetone, dibenzoylmethane, 5,5-dimethyl-1,3-cyclohexanedione, and acetylacetone acetate. Ultraviolet spectra from 2100 to 3600 Å. are given for isophorone, acetophenone, hexadecanophenone, acetylacetone, and acetylacetone acetate.

2. Simple hydrogen bonding to the ketone C=O group has practically no effect on the C=O vibrational frequency, the infrared band appearing very near 5.83 $\mu$ (1715 cm.$^{-1}$) as in simple ketones.

3. Conjugation of C=C to the ketone C=O group gives rise to typical conjugation shifts in the infrared, the C=O band going to the region 5.90–6.00 $\mu$ (1695–1667 cm.$^{-1}$) and the C=C to 6.07–6.17 $\mu$ (1647–1621 cm.$^{-1}$) and also gives rise to the typical strong ultraviolet band near 2350 Å. (molar extinction coefficient ~10,000) and weak band near 3200 Å. (molar extinction coefficient ~40).

4. Simultaneous conjugation and chelation ("conjugated chelation") as in enolized $\beta$-diketones leads to an extreme shift of the C=O infrared band (to ~6.2 $\mu$), (1613 cm.$^{-1}$) to a great enhancement of its intensity, and to the appearance of a broad weak band near 3.7 $\mu$ (2703 cm.$^{-1}$) attributable to an extremely perturbed OH vibration. The ultraviolet spectrum of one example of this class of compound exhibits a strong band at 2700 Å. (molar extinction coefficient ~10,000).

5. Conjugation of two ketonic C=O groups to each other has little or no effect on their observed infrared band positions.

# Infrared Spectra of Some Carboxylic Acid Derivatives[1]

BY ROBERT S. RASMUSSEN AND R. ROBERT BRATTAIN

In continuation of the discussion of spectroscopic studies initiated in the preceding paper, and done in connection with penicillin structure, this paper reports the infrared spectra of a series of esters, lactones, chlorides and salts of carboxylic acids.

Experimental details are the same as those given previously,[2] the reproducibility in wave length being better than $\pm 0.03$ $\mu$. The spectra are presented in tabular form in Tables I to IV. As with the previous paper of this series, discussion will be limited to the 3 $\mu$ (NH, OH and CH) and 6 $\mu$ (double-bond) regions. Thompson and Torkington,[3a] in a much more detailed study of a series of saturated esters, have described many other regularities at longer wave lengths. Recent papers containing some information on carboxylic acid derivatives have been published by Thompson[3b] and Jones, *et al.*[3c]

**Esters.**—The spectra of a series of esters, studied principally for information on the effects of induction and conjugation on the ester C=O band, are shown in Table I.

Normal aliphatic esters exhibit the C=O band very near 5.75 $\mu$ (1739 cm.$^{-1}$), from the work of Thompson and Torkington and others. The spectra of methyl pivalate, ethyl diphenylacetate, and methyl sarcosinate (Table I; 1, 2, 3) have bands so near this position that it is clear that inductive effects due to $\alpha$-alkyl, $\alpha$-aryl or $\alpha$-amino substituents exert no appreciable effect on the C=O force constant. Ethyl cyanoacetate, on the other hand, shows its band at a somewhat shorter wave length (5.71 $\mu$), (1751 cm.$^{-1}$), presumably due to the inductive effect of the C≡N group (Table I; 4). In addition to the C=O bands, the above compounds have the additional expected bands due to phenyl (6.24 and 6.68 $\mu$), (1603 cm.$^{-1}$ and 1497 cm.$^{-1}$), NH (2.985 $\mu$) (3350 cm.$^{-1}$) and C≡N (4.43 $\mu$), (2257 cm.$^{1}$).

The effect of conjugation of C=O with C=C is illustrated by methyl methacrylate (Table I; 5). The ester C=O band appears at 5.82 $\mu$ (1718 cm.$^{-1}$) and the C=C band at 6.11 $\mu$ (1637 cm.$^{-1}$) the shift of each to longer wave length being due to the conjugation. Conjugation of the C=O with the phenyl group, as in methyl benzoate (Table I; 7), seems to give a somewhat smaller shift (to 5.80 $\mu$) (1724 cm.$^{-1}$) although Thompson and Torkington[3] found that ethyl benzoate gave the band at 1716 cm.$^{-1}$ (5.83 $\mu$) within the limits of measurability of their published spectrum. Ethyl *o*-, *m*- and *p*-nitrobenzoates (Table I; 8, 9, 10) exhibit a marked lessening of the conjugation shift, the C=O bands occurring near 5.77 $\mu$ (1733 cm.$^{-1}$). Evidently the competition of the nitro group for electrons from the ring, through both resonance and induction, accounts for this effect. A similar phenomenon is observed for ethyl $\beta,\beta$-diethoxyacrylate (Table V; 6), where the band appears at 5.76 $\mu$ (1736 cm.$^{-1}$). In this case the decrease of conjugation must be attributed to the inductive attraction of the ethoxy groups for electrons, which opposes the ionic resonance structure (+)C—C=C—O(−).

Other bands in the 3 and 6 $\mu$ regions of the spectra of these conjugated esters are explicable as follows. Weak bands at 2.70 to 2.90 $\mu$ (3704 cm.$^{-1}$ to 3448 cm.$^{-1}$) are due to traces of water or hydroxylic impurities. The strong band of ethyl $\beta,\beta$-diethoxyacrylate at 6.20 $\mu$ (1613 cm.$^{-1}$) is attributable to the C=C vibration; the long wave-length shift from the usual C=C position near 6.0 $\mu$ (1667 cm.$^{-1}$) need not be attributed to conjugation (see above), but may presumably be due simply to the alkoxy substituents. Weak bands from 4.5 to 5.6 $\mu$ (2222 to 1786 cm.$^{-1}$) in spectra of the phenyl-containing compounds are overtones of the ring vibrations. Methyl benzoate exhibits the 6.25 and 6.69 $\mu$ (1600 and 1495 cm.$^{-1}$) bands which are common to all mono-substituted phenyl compounds, as well as the band at 6.29 $\mu$ (1590 cm.$^{-1}$) given by benzoyl compounds.[2] The nitro compounds have the very strong band near 6.50 $\mu$ (1538 cm.$^{-1}$) ascribable, from work on aliphatic nitro compounds, to the $NO_2$ group, and also show bands near 6.18 $\mu$ (1618 cm.$^{-1}$) and 6.75 $\mu$ (1481 cm.$^{-1}$) which are presumably the analogs of the 6.25 $\mu$ (1600 cm.$^{-1}$) and 6.69 $\mu$ (1495 cm.$^{-1}$) bands of simple phenyl compounds. Other weak bands in the 6 $\mu$ region do not occur with any regularity in similar compounds, and hence are attributable to impurities.

A further effect noted in ester spectra is to be found in the vinyl ester type of compound. Barnes, *et al.*,[4] give a spectrum of vinyl acetate in which the C=O band appears near 5.65 $\mu$ (1770 cm.$^{-1}$). This short wave-length shift is also exhibited by phenyl acetate and *o*-nitrophenyl acetate (Table V; 12, 13), the C=O bands being 5.70 and 5.60 $\mu$ (1754 and 1786 cm.$^{-1}$), respectively. The other bands observed are attributable to the phenyl or nitrophenyl groups, or to impurities.

The unusual compound 1,1-diacetoxypropane, $CH_3CH_2CH(OOCCH_3)_2$ (Table I; 11), also exhibits its ester C=O band at shorter wave length (5.68 $\mu$) (1761 cm.$^{-1}$) than normal. This indicates that there may be some inductive effect on the ester C=O band position due to negative $\alpha$-substituents on the alcohol part of the molecule, the substituent in this case being another acetoxy group. A similar effect has been noted with $\alpha$-cyano substituents (acetates of cyanohydrins).

In Table II are shown spectra of several esters which illustrate the effect of conjugated chelation.[2] Ethyl $\alpha,\alpha$-dimethylacetoacetate (Table II; 1) which has no possibility of enolizing to give a

conjugated chelate ring, shows only a single band in the double-bond region, at 5.79 $\mu$ (1727 cm.$^{-1}$). Examined in more dilute solution, this band is found to have a strong component at 5.82 $\mu$ (1718 cm.$^{-1}$), and a weaker one, appearing as a shoulder, at 5.74 $\mu$ (1742 cm.$^{-1}$). These are clearly to be ascribed to the ketone and ester groups, respectively. Ethyl $\alpha$-methylacetoacetate and ethyl acetoacetate (Table II; 2, 3) each exhibit an additional band near 6.06 $\mu$ (1650 cm.$^{-1}$), ascribable to the C=O of the conjugated chelate ring:

That the enolization is only partial is seen from the persistence of a strong 5.78 $\mu$ (1730 cm.$^{-1}$) band. This result is essentially identical with that from Raman work.[5] However, as with acetylacetone,[2] the 6.06 $\mu$ (1650 cm.$^{-1}$) band is more reasonably ascribed to the C=O rather than the C=C vibration in contradistinction to the assignment given by Kohlrausch and Pongratz. The 3.7 $\mu$ (2703 cm.$^{-1}$) band expected from the OH of the enol was not observed, very probably because the concentration of enol was not high enough to bring it out. Diethyl $\alpha,\beta$-diacetylsuccinate (Table II; 4) exhibits only the unmodified ester and ketone bands, with no evidence of enolization or chelation.

As an example of an aromatic conjugated chelate system, *n*-butyl salicylate was examined (Table II; 5). Bands are found at 3.14 $\mu$ (3185 cm.$^{-1}$) and 5.97 $\mu$ (1675 cm.$^{-1}$) attributable, respectively, to OH and to ester C=O in the conjugated chelate system:

Both bands are shifted considerably beyond their "normal" positions (hydrogen-bonded OH, 3.0 $\mu$ (3333 cm.$^{-1}$); conjugated ester, 5.82 $\mu$ (1718 cm.$^{-1}$)), but are not shifted as much as in enolized chelate $\beta$-diketones or $\beta$-ketoesters (OH = *circa* 3.7 $\mu$ (2703 cm.$^{-1}$) C=O, 6.05 $\mu$ (1653 cm.$^{-1}$) or more). Hence the chelation is apparently not quite so strong as with this latter class, probably due to the only partial double-bond character of the CC bonds of the ring. That conjugated chelation nevertheless has influenced the spectrum markedly is attested to by an examination of acetylated *n*-butyl salicylate (Table II; 6). The OH band disappears, and the salicylate C=O band returns to the usual conjugated ester position, appearing at 5.805 $\mu$ (1723 cm.$^{-1}$). The acetate C=O band, arising from the vinyl ester type of system, appears at a shorter wave length (5.65 $\mu$) (1770 cm.$^{-1}$) than normal unconjugated esters, as discussed above.

The final group of esters examined were derivatives of methyl anthranilate, and are of interest in ascertaining whether the NH group can participate in conjugated chelation in the same fashion as does OH.

Methyl N-methylanthranilate (Table II; 7) exhibits a C=O band at 5.935 $\mu$ (1685 cm.$^{-1}$) indicating some chelation effect of almost the same magnitude as with the salicylates. The NH band at 2.975 $\mu$ (3361 cm.$^{-1}$), however, appears not to be shifted from its usual position in simple hydrogen-bonding. Removal of the chelating hydrogen, as in methyl N,N-dimethylanthranilate or in methyl N-methyl-N-acetylanthranilate (Table II; 8, 9) results in disappearance of the NH band and in return of the ester C=O band to ~5.78 $\mu$ (1730 cm.$^{-1}$), near the usual position for conjugated esters. Actually, the shift due to conjugation with the phenyl ring is smaller than for other similar compounds (*e. g.*, *n*-butyl acetylsalicylate above), but the reason for this is not clear. The N-acetyl compound also shows the 6.05 $\mu$ (1653 cm.$^{-1}$) band due to amide C=O.

All the salicylic and anthranilic derivatives discussed above (Table II; 5, 6, 7, 8, 9) exhibit in the main the bands expected from the phenyl ring. These are: (1) the bands near 6.20 $\mu$ (1613 cm.$^{-1}$) and 6.6 to 6.7 $\mu$ (1515 to 1493 cm.$^{-1}$) found regularly with simple phenyl compounds, and (2) that near 6.30 $\mu$ (1587 cm.$^{-1}$) found also in benzoyl compounds. The 6.20 $\mu$ (1613 cm.$^{-1}$) bands, which are weak for phenyl rings with carbon substituents, are enhanced in intensity for O- or N-substituted rings, as noted from unpublished work of this Laboratory on phenols and anilines; this effect is to be seen also in the above described salicylate and anthranilate spectra. Two anomalies in the above explanation are: (1) the enhanced intensity of the 6.31 $\mu$ (1585 cm.$^{-1}$) band in methyl N-methylanthranilate as compared with the other compounds, and (2) the unexplained band at 6.55 $\mu$ (1527 cm.$^{-1}$) in the spectrum of methyl N-methyl-N-acetylanthranilate. Both of these may be due to impurities.

**Lactones.**—Spectra of some lactones are given in Table III.

As an exemplar of the simple saturated 5-membered lactones, $\gamma$-valerolactone was studied (Table III; 1). The sample was evidently considerably impure, as attested to by unexplainable bands at 5.76 and 6.12 $\mu$ (1736 and 1634 cm.$^{-1}$) (2.80 $\mu$ (3571 cm.$^{-1}$) is due to adventitious water). However, the strong 5.65 $\mu$ (1770 cm.$^{-1}$) band is certainly ascribable to the lactone C=O stretching vibration. The reason for this shift from the open chain ester position must be sought in ring strain, but the exact mechanism is unclear. Taufen and Murray[6] give the Raman spectrum of $\beta$-butyrolactone, from which it is apparent that the C=O band of this compound would appear near 5.50 $\mu$ (1818 cm.$^{-1}$), even further shifted from the open-chain position. On the other hand, $\delta$-valerolactone

exhibits its band at 5.75 μ (1739 cm.$^{-1}$), the same position as open-chain esters (Table III; 5). Hence the strain is sufficiently reduced in the six-membered ring to exert no effect spectroscopically. Similar shifts from the open-chain position are to be observed in five- and four-membered cycloketone and lactam rings.

The remaining lactones discussed here demonstrate further effects on the lactone C=O band position which are identical with effects described above for the open-chain esters. Thus β,γ-angelica lactone (Table III; 2) is essentially a vinyl ester type of compound. The shift of its C=O band to 5.56 μ (1799 cm.$^{-1}$), a short wave-length shift from the saturated 5-ring lactone position (5.65 μ), (1770 cm.$^{-1}$), parallels the shift of open-chain vinyl esters from the saturated open-chain ester position (see preceding section). The C=C band appears at 5.945 μ (1682 cm.$^{-1}$). Similarly, γ-acetoxy-γ-valerolactone (Table III; 3) exhibits its lactone C=O band at 5.565 μ (1797 cm.$^{-1}$) and its acetate group C=O band at 5.715 μ (1750 cm.$^{-1}$), the short wave-length shifts here paralleling the ones observed for 1,1-diacetoxypropane (see preceding section of this paper).

The β-ketoester type of lactone is represented by α-acetyl-γ-butyrolactone (Table III; 4). The non-enolized form is evidenced by a normal 5-ring lactone band at 5.64 μ (1773 cm.$^{-1}$) and a normal ketone band at 5.82 μ (1718 cm.$^{-1}$), whereas the rather weak band at 6.04 μ (1656 cm.$^{-1}$) indicates a small amount of enolization to a conjugated chelate system (see discussion of acetoacetic esters in preceding section).

A more complex lactone is illustrated by coumarin (Table III; 6). The multiple conjugation here makes it useless to attempt a specific assignment of the double-bond bands until such systems are further studied.

Salts.—Two examples of spectra of salts of carboxylic acids are given in Table IV. Sodium acetate possesses as its only absorption in the 6 μ region a band at 6.33 μ (1580 cm.$^{-1}$). This must be attributed to one of the vibrations of the $COO^-$ group. Work of other laboratories in the penicillin project on spectra of salts indicated considerable variability in the infrared band position, but it generally falls in the range 6.20 to 6.35 μ (1613 to 1575 cm.$^{-1}$). An example of an extreme shift in position is found in pyridine betaine (Table III; 2),

The band attributable to $COO^-$ occurs at 6.055 $\mu$ (1652 cm.$^{-1}$), indicating a powerful inductive or electrostatic effect of the positive nitrogen on the $COO^-$ group.

TABLE IV

INFRARED SPECTRA OF SALTS AND ACID CHLORIDES OF CARBOXYLIC ACIDS

1. Sodium acetate, 0.02 mm. 5% soln. in $CH_3OH$.
2. Pyridine betaine, 0.02 mm. 20% soln. in $CH_3OH$.

**Acid Chlorides.**—Spectra of three acid chlorides are given in Table IV. Both acetyl chloride and phenylacetyl chloride exhibit the C=O band near 5.55 $\mu$ (1802 cm.$^{-1}$). The moderately intense band of the former at 5.71 $\mu$ (1751 cm.$^{-1}$) is ascribable to a hydrolytic impurity of acetic acid, and the same explanation may be applicable for some of the weak bands of phenylacetyl chloride. The spectrum of benzoyl chloride is anomalous in that two bands appear in the double-bond region (5.64, 5.76 $\mu$) (1773, 1736 cm.$^{-1}$), aside from the bands of the phenyl ring (6.255, 6.305, 6.70 $\mu$) (1599, 1586, 1493 cm.$^{-1}$). It is improbable that one of these results from hydrolysis, since benzoic acid C=O bands are found near 5.9 $\mu$ (1695 cm.$^{-1}$), and since repeat experiments in which precautions were taken against hydrolysis yielded the same spectrum. Two possible causes of this doubling are partial association into dimers, and inter-action with a low thermally-excited vibration. Aside from this anomaly, the expected long wave-length shift due to conjugation is present, as is evident by a comparison with acetyl and phenylacetyl chlorides.

## Experimental

The sources and purities of samples used were as follows (synthetic work carried out by Drs. C. W. Smith and D. S. Melstrom):

**Methyl pivalate** was prepared by treatment of pivalic acid with diazomethane. The product was washed with bicarbonate, dried over sodium sulfate, and fractionated through a micro still. The heart cut, b. p. 100° (lit. 100 to 102°), $n^{20}D$ 1.3892, was used.

**Ethyl diphenylacetate** was prepared from diphenylketene and absolute ethanol. The product was recrystallized from absolute ethanol, m. p. 56.5 to 57° (lit., 57 to 59°).

**Methyl Sarcosinate.**—Methylaminoacetonitrile was prepared from methylamine hydrochloride, formaldehyde and potassium cyanide, according to the method of Lilly.[7] It was converted to methyl sarcosinate hydrochloride with hydrochloric acid in methanol. The ester was liberated from the hydrochloride, and fractionated twice. The final product used had the constants: b. p. (20 mm.) 43.0–43.5°, $n^{20}D$ 1.4154. *Anal.*: C, 46.76, 46.48; H, 8.83, 8.85. (Calcd.: C, 46.59; H, 8.80.)

**Ethyl Cyanoacetate.**—Eastman Kodak Co. White Label was used without further purification.

**Methyl methacrylate** was taken from a careful distillation of technical material.

**Ethyl $\beta,\beta$-diethoxyacrylate** was prepared from ethyl cyanoacetate with ethanol and hydrochloric acid by the method of Reitter and Weindel.[8] The product was distilled from a Claisen flask and a fraction b. p. 80 to 86° (1 mm.) was used for the spectroscopic work (lit. b. p. 127.8 to 128.2° (12 mm.)).

**Methyl benzoate,** the three ethyl nitrobenzoates, and phenyl acetate were Eastman Kodak Co. White Label products used without further purification. The *o*-nitrophenyl acetate sample was Eastman Yellow Label, with a stated m. p. of 37 to 39°, and was not further purified.

**1,1-Diacetoxy-2-propene** was prepared from acrolein and acetic anhydride by the method of Wohl and Maag.[9] The product was hydrogenated over nickel (15 p. s. i.) to give the diacetoxypropane, and had the constants: b. p. 62° (5 mm.), $n^{20}D$ 1.4070.

**The ethyl acetoacetate** used was a commercial sample, b. p. (10 mm.) 78 to 79°.

**Ethyl $\alpha$-methylacetoacetate** was prepared by alkylation of acetoacetic ester with methyl iodide according to the method of Folkers and Adkins.[10] The final product had a b. p. (23 mm.) of 81 to 84°. *Anal.*: C, 58.2, 58.45; H, 8.43, 8.43. (Calcd.: C, 58.32, H, 8.39.)

**Ethyl $\alpha,\alpha$-dimethylacetoacetate** was prepared by further methylation of the above monomethylated compound. Unreacted monomethylated ester was removed from the product by extraction of a benzene solution with 25% aqueous potassium hydroxide according to the method of Pedersen.[11]

**Diethyl $\alpha,\beta$-diacetylsuccinate** was prepared from sodium acetoacetic ester and iodine according to the procedure of Knorr and Haber[12]; m. p. 85 to 88° (lit. 85–88°).

**The *n*-butyl salicylate** sample used was Eastman White Label without further purification; b. p. (20 mm.) 145 to 146°. Its acetyl derivative was obtained by treatment with acetic anhydride in pyridine; b. p. (0.9–1 mm.) 128 to 130°; sp. gr. 20/4 1.101, 1.102; $n^{20}D$ 1.4989.

**Methyl N-methylanthranilate** was prepared from Eastman White Label N-methylanthranilic acid. The N,N-dimethyl compound was obtained from this and methyl iodide according to the method of Kahn.[13] The N-

methyl-N-acetyl compound was prepared from methyl N-methylanthranilate by treatment with acetic anhydride in pyridine, and removal of unreacted material under reduced pressure and by hydrochloric acid extraction. The product was an oil which failed to crystallize at the time the infrared spectrum was taken, but which crystallized later.

**γ-Valerolactone** was produced by catalytic reduction of β,γ-angelica lactone (see below) in absolute ethanol with Raney nickel at 25° and 40 p. s. i. (max.) hydrogen. The product was twice fractionated; b. p. (20 mm.) 93.5. *Anal.*: C, 58.99, 58.74; H, 8.40, 8.29. (Calcd.: C, 59.98; H, 8.06).

**β,γ-Angelica lactone** was prepared by destructive distillation of levulinic acid (lactone form) acetate (see below), following the method of Thiele, Tischbein, and Lossow.[14] The product was washed with bicarbonate solution and twice distilled; b. p. (12 mm.) 56.2–57.0°. *Anal.*: C, 60.87, 60.76; H, 6.19, 6.14. (Calcd.: C, 61.21; H, 6.17.)

**The acetate of the lactone form of levulinic acid** was prepared from freshly distilled levulinic acid, acetic anhydride and a trace of acetyl chloride, after the method of Thiele, *et al.*[14] The product was recrystallized twice from ethanol and once from dilute aqueous ethanol: m. p. 74.5 to 75°. *Anal.*: C, 52.94, 53.01; H, 6.45, 6.43. (Calcd.: C, 53.16; H, 6.37.)

**α-Acetyl-γ-butyrolactone** was prepared from sodium acetoacetic ester and ethylene oxide in absolute ethanol according to the method of Knunyantz, Chelintzev, and Osetrova[15]: b. p. (20 mm.) 135 to 136°; $n^{20}D$ 1.4600. *Anal.*: C, 56.19, 56.17; H, 6.39, 6.43. (Calcd.: C, 56.24; H, 6.29.)

**δ-Valerolactone** was made by hydrogen peroxide oxidation of δ-hydroxyvaleraldehyde in acetic acid. The product had b. p. 80° (4 mm.); $n^{20}D$ 1.4532. *Anal.*: C, 58.90, 58.89; H, 8.12, 8.13. (Calcd.: C, 59.98; H, 8.05.)

The coumarin used was Eastman White Label with no further purification.

Sodium acetate and acetyl chloride were taken from Baker's C. P. quality materials.

**Pyridine betaine hydrochloride** and the free betaine were prepared from pyridine and chloroacetic acid by the procedure of Edsall and Wyman.[16] A portion of the free pyridine betaine product was dried for 6.6 hours in a vacuum desiccator over phosphorus pentoxide. *Anal.*: N, 9.8, 9.9. (Calcd.: 10.22.)

Phenylacetyl chloride and benzoyl chloride were Eastman White Label samples.

Alcorn and Mrs. E. Dugle in operation of the spectrograph and measurement of the curves is acknowledged.

## Summary

1. Infrared absorption maxima in the 2-to-15 μ region are tabulated for a group of carboxylic acid esters, lactones, salts, and acid chlorides.

2. Unconjugated esters exhibit their C=O bands near 5.75 μ (1739 cm.$^{-1}$), although sufficiently electronegative α-substituents may shift the position down as far as 5.70 μ (1754 cm.$^{-1}$).

3. Conjugation of the ester C=O to C=C or phenyl shifts the C=O band position to *circa* 5.81 μ (1721 cm.$^{-1}$). The amount of this shift may be markedly modified by induction or resonance effects due to substituents on the conjugated system.

4. Vinyl ester or phenyl ester compounds exhibit the ester C=O band shifted to *circa* 5.65 μ (1770 cm.$^{-1}$).

5. Enolized β-ketoesters, and salicylic esters, show the enhanced shift in C=O position expected from conjugated chelate systems. The C=O bands appear near 6.0 μ (1667 cm.$^{-1}$) in these cases. An anthranilic ester showed a similar conjugated chelation effect, but the C=O shift was only to 5.935 μ (1685 cm.$^{-1}$).

6. Saturated five-membered lactone rings give a C=O band near 5.65 μ (1770 cm.$^{-1}$). This may be modified by conjugation, vinyl ester and chelation effects as described for open-chain esters. A saturated six-membered lactone gives a band at 5.75 μ (1739 cm.$^{-1}$), *i.e.*, unshifted from the open-chain ester position.

7. Salts of carboxylic acids yield a band near 6.3 μ (1587 cm.$^{-1}$).

8. Unconjugated acid chlorides exhibit the C=O band near 5.55 μ (1802 cm.$^{-1}$).

# Spectroscopic Evidence Concerning the Structure of 2-Phenyl-4,4-dimethyl-5(4)-oxazolone Hydrobromide

BY CURTIS W. SMITH AND ROBERT S. RASMUSSEN

The reactions of phosphorus tribromide, phosphorus trichloride, or thionyl chloride with α-acylamino acids give products which have been considered as oxazolone hydrohalides (I) or as α-acylamino acid halides (II). Treatment of an oxazolone with hydrogen chloride or hydrogen bromide gives similar products.

Fischer,[1] Mohr,[2] and Neher, Wettstein and Miescher[3] assigned the α-acylamino acid halide structure (II) to products of this type.

Evidence presented in two chapters[4,5] of the Monograph on Penicillin might be interpreted to favor the oxazolone hydrohalide structure. However, it was pointed out by Cornforth[5] that it was not possible to distinguish between the two structures, I and II, with the evidence at present available. He further suggested that the two structures may be in equilibrium.

In an attempt to gain further knowledge as to the structure of these reaction products the infrared absorption of the reaction product of α-benzamidoisobutyric acid with phosphorus tribromide has been obtained in these laboratories.

α-Benzamidoisobutyric acid in dry chloroform was treated with an equimolar quantity of phosphorus tribromide and the infrared absorption of the solution was examined shortly thereafter. This same procedure was carried out using as the solvent, dioxane, which had been freshly distilled over sodium. The spectra of the two solutions (see Table I, spectra 2 and 3) were consistent with each other and showed a broad general absorption around the 4 μ (2500 cm.$^{-1}$) region, a rather sharp band near 5.28 μ (1894 cm.$^{-1}$) and a strong, sharp band near 6.10 μ (1639 cm.$^{-1}$), with only a trace of absorption in the 5.78 μ (1730 cm.$^{-1}$) region. The lack of a 6.6 μ (1515 cm.$^{-1}$) band was evident in the chloroform solution but was especially striking in the dioxane solution.

In an experiment in which more concentrated solutions were used, phosphorus tribromide was added in equimolar quantity to a solution of α-benzamidoisobutyric acid in dry dioxane. The precipitate which separated was collected on a funnel and washed twice quickly with small quantities of dioxane with minimum exposure to air. A five per cent. solution of this material in chloroform was prepared immediately and its infrared absorption spectrum obtained within an hour. The spectrum (Table I, spectrum 4) still showed the strong bands at 5.28 μ (1894 cm.$^{-1}$) and 6.10 μ (1639 cm.$^{-1}$) observed in the preceding experiments but now showed in addition a band of about equal intensity at 5.75 μ (1739 cm.$^{-1}$) attributable to the expected hydrolysis product, α-benzamidoisobutyric acid (Table I, spectrum 1).

## Spectral Interpretations

On the basis of these infrared absorption spectra the reaction product of α-benzamidoisobutyric acid with phosphorus tribromide has been assigned the formula 2-phenyl-4,4-dimethyl-5(4)-oxazolone hydrobromide (II) instead of α-benzamidoisobutyryl bromide (I) for the following reasons:

(1) An extensive study of the infrared absorption of monosubstituted amides[6] has shown that this grouping almost without exception gives rise to two bands at about 6.0 and 6.6 μ (1667 and 1515 cm.$^{-1}$). With α-benzamidoisobutyric acid the bands due to the amide linkage are at 6.01 and 6.56 μ (1664 and 1524 cm.$^{-1}$). Two bands near these same positions would be expected from the amide grouping in the α-benzamidoisobutyryl bromide structure. The absence of the band in the 6.6 μ (1515 cm.$^{-1}$) region from the spectra under consideration furnishes strong evidence against the α-benzamidoisobutyryl bromide formula.

(2) The infrared absorption spectra of acetyl chloride, acetyl bromide and α-toluyl chloride[7] show strong bands respectively as follows: 5.52, 5.52 and 5.54 μ (1812, 1812 and 1805 cm.$^{-1}$). The acid bromide grouping of α-benzamidoisobutyryl bromide might be expected to give rise to a band in this region (5.5–5.65 μ) (1818–1770 cm.$^{-1}$). The absence of such a band in the

spectra observed for the reaction product of α-benzamidoisobutyric acid with phosphorus tribromide is evidence against the acid bromide structure. The band near 5.30 μ (1887 cm.$^{-1}$) observed with this reaction product is definitely outside the range found in known acid halides.

(3) Triamylamine hydrochloride and an N-alkyldialkylketimine hydrochloride[8] showed a broad general absorption in the 4 μ (2500 cm.$^{-1}$) region attributable to the $^{+}$NH grouping. The 2-phenyl-4,4-dimethyl-5(4)-oxazolone hydrobromide (I) would be expected to show this absorption. α-Benzamidoisobutyryl bromide (II) would not be expected to show this absorption. Thus the presence of the 4μ (2500 cm.$^{-1}$) band in the spectra observed might be considered evidence favoring the oxazolone hydrobromide formula. However, absorption due to dissolved hydrogen bromide[9] would appear at the 4 μ (2500 cm.$^{-1}$) position and have a similar appearance. Since some hydrogen bromide could have been present in each case where a 4 μ band appeared, evidence for an $^{+}$NH group is not without question.

During a study of the reaction of β-methyl benzylpenicilloate with phosphorus tribromide, collaborators from the University of Michigan and the Upjohn Company[4] determined the infrared absorption of a solution of the penicilloate and phosphorus tribromide in carefully dried dioxane immediately after combination and then again at short intervals. The oxazolone hydrobromide shown in the accompanying equation was considered as a more or less transitory (V) intermediate in the reaction.

V

In the spectrum obtained immediately after combination, and to a decreasing degree in later spectra, bands at 5.60 and 5.98 μ (1786 and 1672 cm.$^{-1}$) not present in the β-methyl benzylpenicilloate or phosphorus tribromide were noted. Since these bands were at 5.60 μ (1786 cm.$^{-1}$) and 5.98 μ (1672 cm.$^{-1}$) instead of at 5.28 μ (1899 cm.$^{-1}$) and 6.10 μ (1639 cm.$^{-1}$) as observed with the 2-phenyl-4,4-dimethyl-5(4)-oxazolone hydrobromide, it is difficult to see how the bands at 5.60 and 5.98 μ (1768 and 1672 cm.$^{-1}$) could be assigned to an oxazolone hydrobromide and, consequently, the infrared evidence may be considered as contraindicating the formation of a transitory oxazolone hydrobromide.

## Experimental

**2-Phenyl-4,4-dimethyl-5(4)-oxazolone Hydrobromide.**—**A. In Chloroform.**—A solution of 0.30 g. of α-benzamidoisobutyric acid,[10] m. p. 201.4–202.4°, in 15 ml. of chloroform was treated with 0.40 g. of phosphorus tribromide. After the solution had stood for thirty minutes its infrared absorption was determined (Table I (2)).

**B. In Dioxane.**—To 0.4 g. of α-benzamidoisobutyric acid in 35 ml. of dioxane was added 1.30 g. of phosphorus tribromide. The solution was allowed to stand for ten minutes before determining its infrared absorption (Table I (3)).

**C. Isolated.**—To a solution of 1.03 g. of α-benzamidoisobutyric acid in 25 ml. of dioxane, freshly distilled over sodium, was added 0.37 ml. of phosphorus tribromide. After the solution had stood for about three minutes, crystals began separating. The solution was allowed to stand at room temperature for ten minutes and was then cooled in an ice-bath. The precipitate was collected on a filter and washed twice with dry dioxane with a minimum of contact with air. The infrared absorption of a solution (5%) of this material in chloroform was obtained without delay (Table I (4)). Most of the crystalline material was dried over phosphorus pentoxide at 56° (0.05 mm.) for two and one-half hours. Another sample was placed immediately on a melting block under a cover glass and melted at 153–158° with decomposition.

The bromide content of the dried product was determined shortly by Volhard titration.

*Anal.* Calcd. for $C_{11}H_{12}NO_2Br$: Br, 29.58. Found: Br, 29.0, 28.8.

Two factors may be responsible for the low bromine content: (1) loss of hydrogen bromide; (2) absorption of water.

## Summary

On the basis of its infrared absorption spectrum the reaction product of α-benzamidoisobutyric acid with phosphorus tribromide has been assigned the structure, 2-phenyl-4,4-dimethyl-5(4)-oxazolone hydrobromide rather than α-benzamidoisobutyryl bromide. This is the first reported instance of an infrared absorption spectrum of a compound of this type.

Since the infrared absorption observed in the reaction of β-methyl benzylpenicilloate with phosphorus tribromide is at distinct variance with that of the above oxazolone hydrobromide, it would appear that this later reaction does not involve an oxazolone hydrobromide.

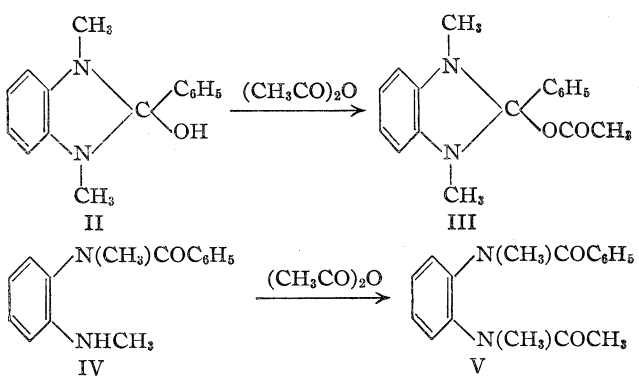
[CONTRIBUTION FROM THE SHELL DEVELOPMENT COMPANY]

# Assignment of Amide Structures to the Supposed 2,3-Dihydro-2-benzimidazolols and their Acylation Products[1]



BY CURTIS W. SMITH, ROBERT S. RASMUSSEN AND SEAVER A. BALLARD

One of the structures proposed for penicillin which had received much consideration before acceptance of the fused thiazolidine-β-lactam formula is shown as formula I.

I

As a part of the general program of examining the infrared absorption spectra of model compounds as nearly like the most plausible structures for penicillin as possible, the infrared absorption was obtained of a compound previously presumed from chemical evidence to be 1,3-dimethyl-2-phenyl-2,3-dihydro-2-benzimidazolol acetate[2] (III). However, when the infrared absorption spectrum of this compound was obtained in these laboratories, it was indicated that instead of the ester grouping shown in formula III there existed amide linkages which would be more consistent with the isomeric formula V, namely, N-acetyl-N′-benzoyl-N,N′-dimethyl-*o*-phenylenediamine. The compound previously thought to have structure III and now indicated as having structure V had been first prepared in the laboratories of Eli Lilly and Company,[2] by acetylation of a compound thought to be 1,3-dimethyl-2-phenyl-2,3-dihydro-2-benzimidazolol (II). The infrared absorption of this parent compound II or IV gave strong indication of the presence of an amide group and was thus in agreement with structure IV and contrary to structure II.

II III

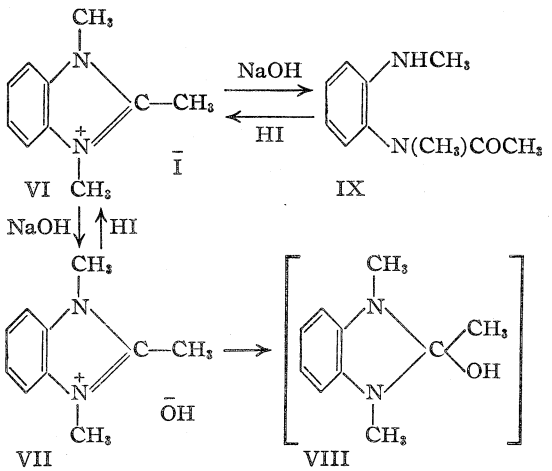
IV V

The first example of a compound thought to be of type II was prepared by Niementowski[3] in 1887. Subsequently Fischer and Romer[4] gave a serious and lengthy consideration to the structures of these compounds. The literature now contains a large number of compounds assigned the benzimidazolol structure.

The following discussion is divided into four sections. First is a critique of the literature designed to show the fallacy of some of the steps which led the earlier workers to favor the benzimidazolol formula (II) instead of the amide formula (IV). Second is the presentation of evidence definitely establishing for the first time the diamide structure of a compound N-acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XV), similar to V. Thus the benzimidazolol ester formula (III) has been eliminated as a possibility for this type of compound. Third is the presentation of new evidence strongly favoring the amide structure (IV) rather than the benzimidazolol structure (II) for a compound, N-acetyl-N,N′-dimethyl-4-methyl-1,2-phenylenediamine (XIII). Fourth is a short section on the stability of benzimidazolium hydroxides.

## I. Critique of the Literature on the Structure of 2-Benzimidazolols

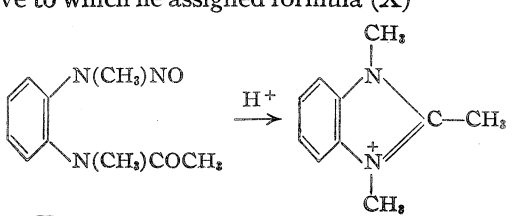
The arguments for the benzimidazolol, structure



(1) The work discussed in this paper was carried out at Shell Development Company, during a study of the structure of penicillin, under contract with the Office of Scientific Research and Development (O. S. R. D.). *Cf. Science*, **105**, 653 (1947).

(2) O. S. R. D., Penicillin Program, Eli Lilly and Company, L6, 6; 11, 14 (U. S. Office of Publication Board, PB/L80033 and 80037).

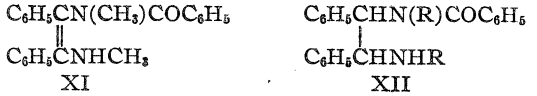
(3) Niementowski, *Ber.*, **20**, 1886 (1887).



(4) Fischer and Romer, *J. prakt. Chem.*, [2] **73**, 419 (1906).

VIII, seem to have been developed[3,4] in the literature on the following assumptions. The compound had been synthesized from the benzimidazolium iodide by reaction with caustic and could be reverted to the benzimidazolium salt on treatment in the cold with acid. Therefore, it seemed logical to assume that the cyclic structure would be retained. Furthermore, it was thought that inasmuch as the product was not strongly basic and was volatile with steam, it was not the corresponding quaternary hydroxide (VII) but rather had been converted to the benzimidazolol form (VIII).

When the open amide form (IX) was eventually considered, it seemed less likely to the original investigators that it would be converted to the quaternary salt (VI) on treatment with acid. And yet in the same paper[4] it was assumed that the amide form (IX) could not be separated in pure condition because it was so readily converted to the benzimidazolol (VIII). It is readily apparent that these two assumptions are irreconcilable, for if both the conversion of the amide (IX) to the benzimidazolol (VIII) and the conversion of the benzimidazolol (VIII) to the quaternary salt (VI) are fast and readily carried out then the over-all reaction (IX to VI) must be rapid and simple.

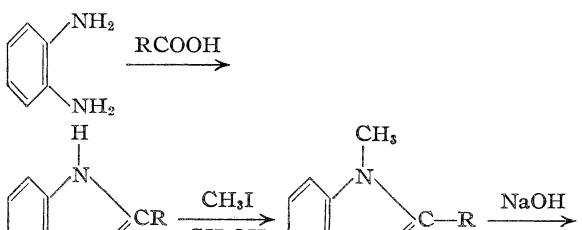


Several observations reported in the literature furnish corroborative evidence for the conversion of the amide form (IX) to the benzimidazolium salt (VI). Fischer[4] found that treatment of N-acetyl-N,N′-dimethyl-*o*-phenylenediamine (IX), thought to be 1,2,3-trimethyl-2,3-dihydro-2-benzimidazolol (VIII), with cold nitrous acid involving minimal contact with acid gave a nitroso derivative to which he assigned formula (X)

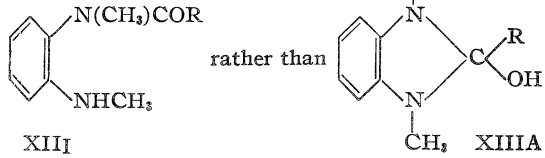
X VI

This compound was hydrolyzed readily with acid to give the benzimidazolium salt (VI). If Fischer's structure for the nitroso derivative is correct, as it appears to be, then it is obvious that conversion of the amide structure to the quaternary salt is a simple and feasible reaction.

If we accept the open amide structure postulated for the derivatives of lophin[4] (XI) and amarin[5] (XII) corresponding to structure (IX) then the ready conversion of the amide form (IX) to the corresponding benzimidazolium salt in acid has a ready parallel, for this type of transformation is known to occur with these compounds.



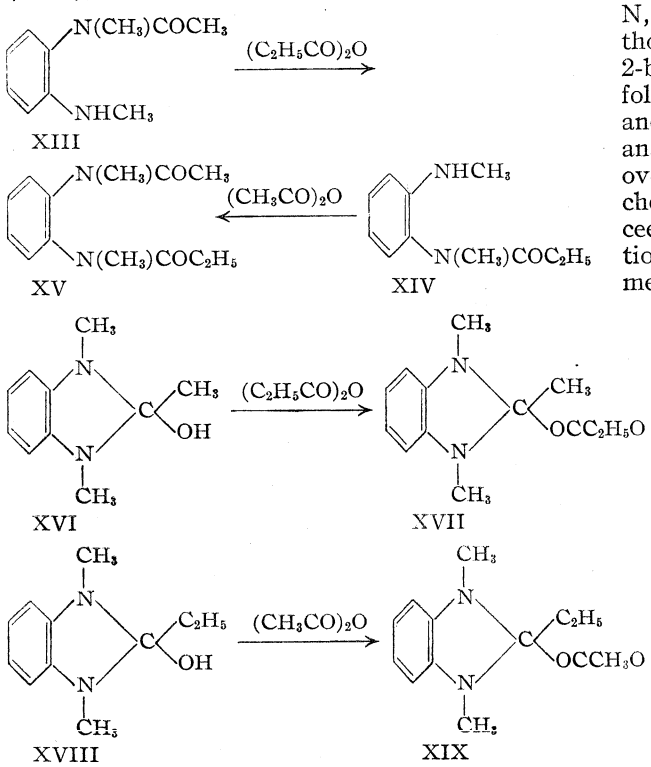
It is of interest to note that when hydrolysis products of lophonium salts were first obtained, they were assigned the carbinol structure,[6] (related to structure (VIII)), but when diacyl derivatives were prepared both these and the monoacyl derivatives (XI and XII) were assigned the amide structure.



It is also of interest to note that the amide structure has been assigned[7] N-benzoyl-N,N′-diphenyl-*o*-phenylenediamine, and that the diacetyl derivative of N,N′-diphenyl-*o*-phenylenediamine has been assigned[8] the diamide structure. However, no proof of structure was given in either instance.

## II. Proof of Structure for N-Acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine

In order to establish the diamide structure of N-acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XV) and consequently to eliminate the benzimidazolol ester structure the following series of reactions was carried out.



R = $CH_3$ and $C_2H_5$

(5) Japp and Moir, *J. Chem. Soc.*, **77**, 619 (1900).
(6) Japp and Davidson, *ibid.*, **67**, 33 (1895).
(7) Chapman and Perott, *ibid.*, 1775 (1932).
(8) Clemo, Perkin and Robinson, *ibid.*, **125**, 1751 (1924).

The reactions follow closely those outlined by workers at Eli Lilly and Company.[2] Starting with *o*-phenylenediamine and acetic acid 2-methylbenzimidazole was readily obtained by the method of Phillips.[9] Treatment of this material with methyl iodide gave the corresponding 1,2,3-trimethylbenzimidazolium iodide which was hydrolyzed with strong sodium hydroxide to give N-acetyl-N,N′-dimethyl-*o*-phenylenediamine (XIII). Starting with *o*-phenylenediamine and propionic acid the same series of reactions was carried out and there was obtained 2-ethylbenzimidazole, 1,3-dimethyl-2-ethylbenzimidazolium iodide and finally N-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XIV)

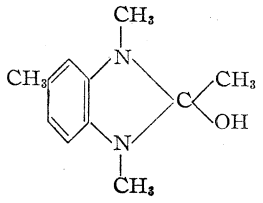
It can readily be seen that treatment of N-acetyl-N,N′-dimethyl-*o*-phenylenediamine (XIII) with propionic anhydride or of N-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XIV) with acetic anhydride should give the same compound, N-acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XV). However, if, as it had been previously thought, the products had the benzimidazolol structures, (XVI) and (XVIII), then the products of acylation, compounds (XVII) and (XIX), should be different.

These acylations were carried out by treatment with the respective acid anhydrides in pyridine at room temperature according to the method first used by Eli Lilly and Company.[2]

The two products had the same melting point, gave no depression of melting point in a mixture and gave identical infrared absorption spectra. From these results the structure of this compound has been considered established as N-acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (XV) and not as the benzimidazolol ester (XVII or XIX). With this structure established, it would seem logical that the product prior to acylation should have the amide structure (XIII) and not the benzimidazolol structure (XVI).

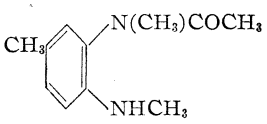
However, in consideration of the possibility that the conditions for the acylation of the supposed benzimidazolol might result in the opening of the ring and formation of the diamide, it is to be pointed out that the conditions for the acylation were quite mild, *i. e.*, acid anhydride in pyridine at room temperature followed by recrystallization from benzene–petroleum ether. These conditions were at least as mild as those by which the monoacetylated product is formed, *i. e.*, hot strong alkali on the benzimidazolium salt or acid anhydride on the N,N′-dialkyl-*o*-phenylenediamine.

## III. Structural Evidence for N-Acetyl-N,N′-dimethyl-4-methyl-1,2-phenylenediamine



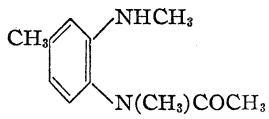
Niementowski[3] who first prepared N-acetyl-N,N′-dimethyl-4-methyl-1,2-phenylenediamine thought it to be 1,2,3,5-tetramethyl-2,3-dihydro-2-benzimidazolol. He purified it by distillation followed by recrystallization from aqueous ethanol and observed that in spite of the fact that the analysis was satisfactory the compound melted over a range, 115–135°. Fischer and Romer[4] checked these results and extending the study succeeded in separating this material into two fractions: One on recrystallization from ligroin melted at 148–150°; the other on recrystallization from aqueous ethanol or slow sublimation melted at 166–167°. However, they believed these to be two crystalline modifications of the benzimidazolol (XX).

If it could be proved that these two isomers isolated by Fischer and Romer[4] were really structural isomers as shown by (XXA) and (XXB) then the amide nature of the product would be established.



To gain additional information concerning these isomers, an attempt was made to repeat the work of Fischer and Romer.[4] The results were in agreement in that the first product gave a satisfactory analysis in spite of the fact that it melted at 115–125° and that a good yield of isomer which melted at 166–167° was obtained upon recrystallization from methanol.

Propionylation of the purified isomer which melted at 166–166.5° gave after evaporation of the excess liquid reagents a highly crystalline residue. One recrystallization from petroleum ether gave an 83% yield of the propionyl derivative which melted at 94.5–95.5°. It would appear that a uniform product had been obtained. Similar



(9) Phillips, *J. Chem. Soc.*, 2393 (1928).

XX

XXA

XXB

propionylation of the mixture of isomers which melted at 115–125° gave after removal of the liquid reagents a sirupy residue which could be converted to soft crystals only with difficulty. Recrystallization of this material gave a 63% yield of a propionyl derivative which melted at 75.3–78.3°. A mixture of this material and that from the preceding experiment (m. p. 94.5–95.5°) melted over a seven-degree range, 76–83°. The difference in the behavior of these two fractions on propionylation is taken as an indication that the fraction melting at 115–125° is a mixture of structural isomers (XXA and XXB) of the amide form.

## IV. Stability of Benzimidazolium Hydroxides

During the course of this work it has been found that benzimidazolium hydroxides are quite stable in the absence of excess soluble base. 1,3-Dimethyl-2-ethylbenzimidazolium hydroxide, prepared from the corresponding iodide by treatment with silver oxide, was not destroyed on standing in aqueous solution for a week followed by heating at 90° for two hours. This stability was demonstrated by the fact that the solution remained strongly alkaline, the ultraviolet absorption spectrum remained constant and the hydrolysis product, N,N′-dimethyl-N-propionyl-*o*-phenylenediamine, which is sparingly soluble in water, was not precipitated.

Tinkler[10] observed that an aqueous solution of the supposed 1,3-dimethyl-2,3-dihydro-2-benzimidazolol became strongly basic on standing and that its ultraviolet absorption spectrum changed from that of the "benzimidazolol" to that of benzimidazolium salt. No such change was observed by the present authors with the N-propionyl-N,N′-dimethyl-*o*-phenylenediamine in alcohol or aqueous solution. These solutions remained completely neutral and gave a constant ultraviolet absorption spectrum even after standing for one week. In the light of present knowledge, no explanation of Tinkler's observations presents itself.

**Acknowledgment.**—The assistance of Mr. Douglas G. Norton and Mr. Lloyd J. Mitchell in carrying out certain preparations is gratefully acknowledged.

(10) Tinkler, *J. Chem. Soc.*, **101**, 1245 (1912).

## Experimental

### A. N-Acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine

**2-Ethylbenzimidazole.**—This material was prepared from *o*-phenylenediamine with propionic acid according to the method of Phillips.[9] The 2-ethylbenzimidazole melted at 172–173° after recrystallization from 50% ethanol.

*Anal.* Calcd. for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74. Found: C, 66.67, 66.88; H, 7.77, 7.80.

**1,3-Dimethyl-2-ethylbenzimidazolium Iodide.**—A mixture of 40 g. of crude 2-ethylbenzimidazole, 80 g. of methyl iodide and 44 ml. of methanol was heated in sealed tubes at 150° for ten hours. The product was dissolved in 200 ml. of hot methanol and then 200 ml. of ether was added. Cooling the solution caused the separation of 50.2 g. (60% yield) of material which melted at 168–170°. A recrystallization of 40.2 g. of this material from 250 ml. of absolute alcohol involving treatment with charcoal gave 21 g. of crystals which melted at 170.5–172°. Addition of ether to the filtrate caused the separation of 11 g. of product which melted at 172.5–173°. Additional recrystallizations gave 1,3-dimethyl-2-ethylbenzimidazolium iodide which melted at 173–173.5°.

*Anal.* Calcd. for $C_{11}H_{15}N_2I$: I, 42.00. Found: I, 42.1, 41.7.

**N-Propionyl-N,N′-dimethyl-*o*-phenylenediamine.**—1,3-Dimethyl-2-ethylbenzimidazolium iodide, 23 g., was hydrolyzed with 46 g. of potassium hydroxide and 230 ml. of water at reflux for ninety minutes. The cooled solution was extracted with three 50-ml. portions of benzene. The extract was dried, concentrated to about 35 ml., and diluted with 60 ml. of petroleum ether. Cooling the solution caused the separation of 7 g. (48% yield) of crystals which melted at 160–162°. Recrystallization from a mixture of 50 ml. of benzene and 50 ml. of petroleum ether involving treatment with charcoal and then from 20 ml. of carbon tetrachloride gave 4.8 g. of N-propionyl-N,N′-dimethyl-*o*-phenylenediamine which melted at 161–162.2°.

*Anal.* Calcd. for $C_{11}H_{15}N_2O$: C, 69.08; H, 7.91. Found: C, 68.56, 68.61; H, 8.32, 8.34.

**N-Acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (By Acetylation).**—A solution of 1.23 g. (0.0066 mole) of crude N-propionyl-N,N′-dimethyl-*o*-phenylenediamine, m. p. 158–160°, in 13.5 g. of pyridine and 5.4 g. (0.053 mole) of acetic anhydride was allowed to stand at room temperature for seventy-two hours. Removal of liquid reagents under reduced pressure left a crystalline mass which melted at 120.5–121.5°. One recrystallization from a mixture of benzene and petroleum ether treated with charcoal gave 0.93 g. (62% yield) of N′-acetyl-N-propionyl-N,N′-dimethyl-*o*-phenylenediamine which melted at 121–121.5°. A mixture of this material with that subsequently obtained upon propionylation of N,N′-dimethyl-N-acetyl-*o*-phenylenediamine melted at 121–121.5°.

**N-Acetyl-N,N′-dimethyl-*o*-phenylenediamine.**—This material, m. p. 163–164°, was prepared according to the procedure outlined by workers at Eli Lilly and Company,[2] which is very similar to that just described for N,N′-dimethyl-N-propionyl-*o*-phenylenediamine. A mixture with a sample furnished by them melted at 163–164°.

**N-Acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine (By Propionylation).**—A solution of 1 g. (0.0056 mole) of N-acetyl-N,N′-dimethyl-*o*-phenylenediamine, 14.6 g. of pyridine and 5.85 g. (0.045 mole) of propionic anhydride was allowed to stand at room temperature for seventy-two hours. The solution was concentrated under reduced pressure (3 mm.) to a crystalline mass which melted at 121–121.5°. One recrystallization from a mixture of benzene and petroleum ether gave 1.06 g. of N-acetyl-N′-propionyl-N,N′-dimethyl-*o*-phenylenediamine which melted at 121–121.5°. Additional recrystallizations did not alter the melting point.

*Anal.* Calcd. for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74. Found: C, 66.67, 66.88; H, 7.77, 7.80.

### B. N-Acetyl-N,N'-dimethyl-4-methyl-1,2-phenylenediamine

**Hydrolysis of 1,2,3,5-Tetramethylbenzimidazolium Iodide.**—This procedure follows that of Fischer.[6] A mixture of 55 g. of 1,2,3,5-tetramethylbenzimidazolium iodide, 70 g. of potassium hydroxide and 210 g. of water was heated on a steam-cone for one hour. The mixture was cooled and the white solid which separated was collected on a filter. After drying in air overnight this material weighed 45 g. and melted from 115–135°. One recrystallization from ethanol and water gave 40 g. of crystalline material which melted at 115–125°. In agreement with the results of Niementowski[3] and Fischer and Romer[4] this material was found to give a satisfactory analysis in spite of the wide range of its melting point. These results have been interpreted as favoring the presence of isomers, *i. e.*, N-acetyl-N,N'-dimethyl-4-methyl-1,2-phenylenediamine and the N'-acetyl isomer, rather than impurity.

*Anal.* Calcd. for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39. Found: C, 68.9, 68.9; H, 8.3, 8.4.

In consideration of the possibility that the fraction melting at 115–125° contained some impurity other than a mixture of amide forms, there exist three experimental observations indicating that such is not the case: (1) satisfactory elementary analysis by three independent investigators; (2) infrared absorption spectrum of the fraction melting at 115–125° shows no evidence of impurity; (3) elementary analysis of the propionylation product, reported subsequently, was in close agreement with the theoretical values even though the product melted over a three-degree range.

This material was dissolved in 225 ml. of 95% ethanol and 25 ml. of water was added. Cooling the solution caused the separation of 7.5 g. of crystals which were collected from solution A by filtration and melted at 165–165.6°. After three additional crystallizations from ethanol, the N-acetyl-N,N'-dimethyl-4-methyl-1,2-phenylenediamine melted sharply at 166–166.5°.

*Anal.* Calcd. for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39; N, 14.57. Found: C, 68.7, 68.6; H, 8.1, 8.3; N, 14.0, 14.2.

Recrystallization of this material from petroleum ether did not change the melting point.

Evaporation of the solvent from solution A to a low volume followed by cooling gave 23 g. of crystalline material which melted at 163.5–167°. The solvent was removed from the residue to leave 9 g. of material which was taken up in petroleum ether. Successive cooling, concentration and cooling gave the following fractions: 1.6 g., m. p. 148–152°; 1.7 g., m. p. 120–125°; 2.0 g., m. p. 124–130°; 3.0 g., m. p. 100–110°. The first fraction was recrystallized from petroleum ether and gave 1.1 g., m. p. 160.0–162.8°. The second and third fractions were crystallized several times from petroleum ether with some elevation of melting point. Finally a sample which melted at 137.5–138° was analyzed.

*Anal.* Calcd. for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39. Found: C, 68.7; H, 8.2.

**Propionylation of Hydrolysis Products of 1,2,3,5-Tetramethylbenzimidazolium Iodide.**—One gram of the isomer, m. p. 166–166.5°, from the above experiment was placed in a glass-stoppered flask with 15 g. of pyridine and 6 g. of propionic anhydride and allowed to stand at room temperature for four days. The liquid materials were removed under reduced pressure. The crystalline residue was taken up in 60 ml. of boiling petroleum ether. After the hot solution had been treated with a little "Norite" it was cooled in ice. The white crystalline material which separated weighed 1 g. (83% yield) and melted at 94.5–95.5°. Another recrystallization from petroleum ether gave 0.75 g. of material, which melted at 95.5–96.3°.

*Anal.* Calcd. for $C_{14}H_{20}N_2O_2$: C, 67.71; H, 8.12. Found: C, 67.9, 67.9; H, 7.9, 8.2.

One gram of the mixture of isomers, m. p. 115–125°, from the previous hydrolysis experiment was placed in a glass-stoppered flask with 15 g. of pyridine and 6 g. of propionic anhydride and allowed to stand at room temperature for four days. Liquids were removed by stripping the product under reduced pressure. The sirupy residue was taken up in 60 ml. of boiling petroleum ether. The hot solution was treated with a little "Norite" and filtered. Cooling the filtrate in ice caused the separation of 0.8 g. (67% yield) of white crystalline material which melted at 75.3–78.3°. Recrystallization from petroleum ether gave 0.5 g. of product which melted at 75.5–78.3°.

*Anal.* Calcd. for $C_{14}H_{20}N_2O_2$: C, 67.71; H, 8.12. Found: C, 67.7, 67.6; H, 8.1, 8.2.

A mixture of this material and that from the preceding experiment which melted at 94.5–95.5°, melted at about 76–83°.

### C. 1,3-Dimethyl-2-ethylbenzimidazolium Hydroxide

A solution of 1,3-dimethyl-2-ethylbenzimidazolium iodide, 0.5 g. (0.00167 mole) in 60 ml. of water, was treated with silver oxide. (A solution of 0.425 g. (0.0025 mole) of silver nitrate in 2.1 ml. of water was treated with 0.112 g. (0.0028 mole) of sodium hydroxide in 1 ml. of water. The silver oxide was collected on a filter and washed well with water.) The silver iodide and slight excess of silver oxide were removed by filtration. The filtrate was strongly alkaline and gave a negative test for iodide ion. The ultraviolet absorption spectra of the solution shortly after preparation, and again after standing at room temperature for one week followed by additional heating at 90° for two hours were identical. The solution was still strongly alkaline after this heating had been completed. The fact that no material separated from this solution on cooling indicated that only a very small amount, if any, of N-propionyl-N,N'-dimethyl-*o*-phenylenediamine could have been formed since this material is insoluble in water.

### Interpretation of Infrared Spectra

**I. N-Acetyl-N'-propionyl-N,N'-dimethyl-*o*-phenylenediamine.**—The spectrum of this material as a 5% (wt./vol.) solution in chloroform showed one strong band at 6.04 $\mu$ (1656 cm.$^{-1}$) attributable to the amide carbonyl and a weaker band at 6.25 $\mu$ (1600 cm.$^{-1}$) attributable to the phenyl ring but with increased intensity due to the fact that the phenyl ring is attached to an amine nitrogen atom. If this compound were an ester of a benzimidazolol as this type of compound had been previously thought to be, it would be expected to show a strong band in the double bond region near 5.75 $\mu$ (1739 cm.$^{-1}$) and no band near 6.0 $\mu$ (1667 cm.$^{-1}$).

**II. N-Acetyl-N'-benzoyl-N,N'-dimethyl-*o*-phenylenediamine.**—The spectrum of this material (10% (wt./vol.) solution in chloroform) was very similar to that of the previous compound, I, but exhibited the additional weak band near 6.30 $\mu$ (1587 cm.$^{-1}$) arising from the benzoyl group.

**III. N-Acetyl-N,N'-dimethyl-*o*-phenylenediamine.**—The spectrum of this material (5% (wt./vol.) solution in chloroform) showed a weak band near 3.0 $\mu$ (3333 cm.$^{-1}$) attributable to —NH and a strong band at 6.07 $\mu$ (1647 cm.$^{-1}$) attributable to amide carbonyl. Weaker bands at 6.22 $\mu$ and 6.59 $\mu$ (1608 cm.$^{-1}$ and 1517 cm.$^{-1}$) are ascribable to the phenyl ring. This compound had been previously thought to be 1,2,3-trimethyl-2,3-dihydro-2-benzimidazolol. The absorption to be expected from such a compound would be a strong band near 3.0 $\mu$ (3333 cm.$^{-1}$) and only weak to moderate absorption in the double-bond region (5.5–6.4 $\mu$) (1818–1562 cm.$^{-1}$) due to the ring system, as indicated by studies on simpler benzimidazole derivatives.

**IV. N-Benzoyl-N,N'-dimethyl-*o*-phenylenediamine.**—The spectrum of a 3% (wt./vol.) solution of this material in carbon tetrachloride was very similar to that of the previous compound III, except that again a 6.32 $\mu$ (1582 cm.$^{-1}$) band was present, due to the benzoyl group.

The spectra reported in Table I were obtained with a 0.15 mm. cell width. The wave lengths are in "$\mu$." The intensities (figures in parentheses) are expressed in units of 10% absorption. The letter "S" represents solvent absorption.

## Summary

Spectroscopic and chemical data are presented which furnish strong evidence that the hydrolysis product of a 1,3-dialkylbenzimidazolium salt has an amide structure, N-acyl-N,N′-dialkyl-*o*-phenylenediamine instead of a 1,2,3-trialkyl-2,3-dihydro-2-benzimidazolol structure as previously supposed.

The product derived by subsequent acylation has been established as a diamide, N,N′-diacyl-N,N′-dialkyl-*o*-phenylenediamine rather than the previously supposed 1,2,3-trialkyl-2,3-dihydro-2-benzimidazolol ester.

In view of this disagreement, a critique of prior literature has been presented.

Finally it has been shown that the benzimidazolium hydroxides are stable in aqueous or alcohol solution in the absence of excess soluble base.

# Tetrahydroacenaphthene and the Mills–Nixon Effect

BY WILLIAM S. JOHNSON AND HOWARD J. GLENN[1]

The original postulate of Mills and Nixon[2]—that the double bonds of the hydrindene and tetralin molecules are stabilized in the forms I and II due to steric effects exerted on the benzenoid nucleus by the fused alicyclic rings—although not literally acceptable in view of current concepts, nevertheless leads to the suggestion that molecules containing these ring structures might be expected to exhibit behavior attributable to steric inhibition of resonance in which the forms I and II contribute more than the alternate (Kekulé) canonical forms to the electronic state of the molecule. Since all attempts thus far to detect any marked degree of such resonance inhibition have failed, it occurred to us that such an effect might be more recognizable with a molecule such as tetrahydroacenaphthene (IIIa or b) in which the tetralin molecule is superimposed on the hydrindene structure in such a way that the postulated straining effect of the exocyclic rings is reinforced.[3] Thus if this strain were sufficient to render the structure IIIb enough higher in energy than IIIa, it might be expected that tetrahydroacenaphthene and its derivatives would behave chemically more like IIIa than a hybrid of IIIa and IIIb. With a view to studying this hypothesis, we have prepared tetrahydroacenaphthene and certain derivatives, and have made preliminary observation of some of their properties.

I II IIIa IIIb

Tetrahydroacenaphthene was readily secured in 95% yield by hydrogenation of acenaphthene over Raney nickel catalyst. The difficulty in stopping the reduction at the tetrahydro stage, which has been the experience of previous workers,[4] was eliminated by limiting the amount of hydrogen available in the bomb to the calculated quantity. The reduction was thus simply carried out by shaking until all of the hydrogen was absorbed.[5] The in-

(2) Mills and Nixon, *J. Chem. Soc.*, 2510 (1930).

(3) This hypothesis involves the assumption—justified only on the basis of examination of crude molecular models—that the mutual fusion of the five-six-membered alicyclic rings of tetrahydroacenaphthene does not in some way counteract the steric influence which these rings independently exert upon the benzenoid nucleus.

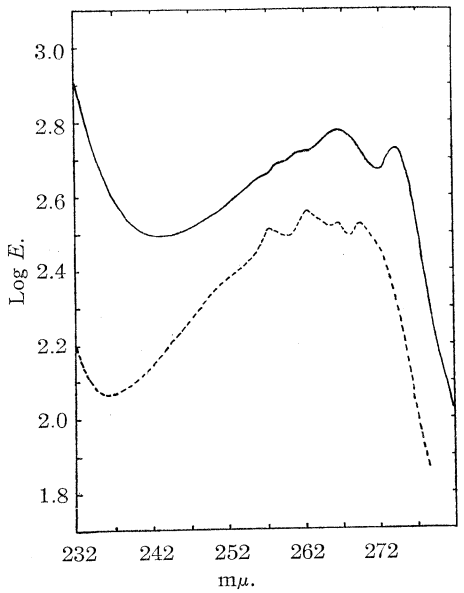

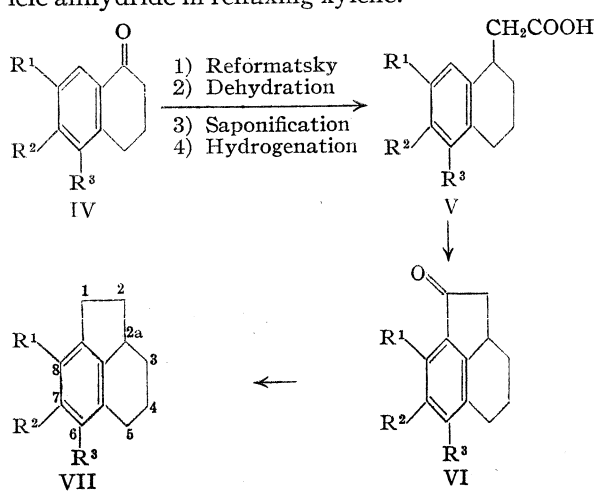

Fig. 1.—Solid line: 2a,3,4,5-tetrahydroacenaphthene; dotted line: 1,2,3-trimethylbenzene.[7]

dex of refraction ($n^{25}$D 1.5573) of the product was in fair agreement with that of material prepared by synthesis from 1-tetralone according to the scheme represented in the flow sheet (formulas IV → VII, $R^1 = R^2 = R^3 = H$), but did not agree with that ($n$D 1.5777) reported for a substance, supposedly tetrahydroacenaphthene prepared by sodium and alcohol reduction of acenaphthene.[6] The $M$D found for our material was 50.54, while the calculated value is 49.63. The chemical behavior of the hydrocarbon is like that of simple polyalkylbenzenes,[4a] and the ultraviolet absorption spectrum (Fig. 1) resembles that reported[7] for 1,2,3-trimethylbenzene, the former exhibiting a slight bathochromic shift and increase of log $E$. Tetrahydroacenaphthene did not react with maleic anhydride in refluxing xylene.

(7) The curve shown in Fig. 1 was constructed from data given by Conrad-Billroth, *Z. physik. Chem.*, **B29**, 170 (1935).

Although the hypothesis of "bond fixation" as tested by coupling experiments with hydroxy derivatives of hydrindene and tetralin has been largely abandoned,[8,9] it is suggested[8,9] that there may be a "qualitative" effect in hydrindene from the fact that in strongly alkaline solutions the 5-hydroxy-6-methyl derivative undergoes coupling with diazonium salts somewhat less effectively than 2,4-dimethylphenol or other 5-hydroxyhydrindene derivatives having the 6-position available. If this difference in reactivity is due to steric inhibition of resonance, it might be expected, granting certain assumptions,[3] that similar and possibly more pronounced behavior would be observed with the appropriately substituted hydroxytetrahydroacenaphthene. Accordingly VII ($R^1$ = OH, $R^2 = R^3$ = H) and VII ($R^1$ = H, $R^2$ = OH, $R^3 = CH_3$) might be expected to undergo coupling less effectively than VII ($R^2$ = OH, $R^1 = R^3$ = H) or than β-naphthol. These tricyclic phenols were, therefore, synthesized from the corresponding 1-tetralones, IV, by the scheme outlined in the accompanying flow sheet and the coupling behavior studied. In those cases where $R^2 = OCH_3$ the cyclization step V → VI was effected by the inverse Friedel–Crafts method.[10] The phenol, m. p. 98–99°, obtained by v. Braun and Kirschbaum[4a] by alkaline fusion of the sulfonic acid from direct sulfonation of tetrahydroacenaphthene and presumed to be the 7-hydroxy derivative, was shown to be a mixture.

The coupling experiments were carried out with *p*-nitrobenzenediazonium chloride at controlled alkalinity by approximately the same method employed by Lothrop.[8] The results which are summarized in Table I indicate that all of the hydroxytetrahydroacenaphthenes have comparably highly reactive coupling centers. They appear to be somewhat more effective couplers than β-naphthol at *p*H 11–13 and somewhat less in 0.4 *N* sodium hydroxide solution. It is striking that under the latter conditions where the test for relative reactivity was expected to be most critical by analogy to the behavior in the hydrindene series,[8]

TABLE I

COUPLING EXPERIMENTS WITH *p*-NITROBENZENEDIAZONIUM CHLORIDE

| Compound | % Yield of crude product at *p*H 8–10 | at *p*H 11–13 | in 0.4 *N* NaOH | in 1.0 *N* NaOH |

(10) Johnson and Glenn, THIS JOURNAL, **71**, 1092 (1949).

the 6-methyl-7-hydroxy compound, VII ($R^1$ = H, $R^2$ = OH, $R^3$ = $CH_3$)—in which the position that would be expected to be most active is blocked by the methyl group—is *more* effective in coupling than the compound VII ($R^2$ = OH, $R^1$ = $R^3$ = H), lacking the 6-methyl substituent.

It may be concluded that experiments thus far have failed to reveal any marked steric inhibition of resonance in the tetrahydroacenaphthene system. It is hoped to investigate the coupling of the phenol VIII which would be of particular interest, because the benzene nucleus is under the influence of two five-membered rings acting independently, thus eliminating certain assumptions required in the present study.[3]

VIII

## Experimental[11]

**2a,3,4,5-Tetrahydroacenaphthene, VII** ($R^1$ = $R^2$ = $R^3$ = H).—In a steel bomb (total void 270 ml.) was placed 30.8 g. (0.20 mole) of acenaphthene,[12] m. p. 94–94.5°, and enough ethanol to bring the total volume of suspension to 115 ml. at 23°. One-fourth teaspoon of Raney nickel catalyst[13] was added and hydrogen introduced to a pressure of 1010 p. s. i. (0.40 mole at 23°). The temperature was raised slowly as the bomb was shaken. At 100° the hydrogenation became rapid and slightly exothermic raising the temperature to 115°, and after fifteen minutes the hydrogenation appeared to be complete. The shaking was continued at 110° for an additional thirty minutes, and then the mixture was worked up in the usual way. The product was distilled through a 20-cm. modified Widmer column giving 29.84 g. (95% yield) of colorless hydrocarbon, b. p. 113.5–114° (10 mm.), $n^{25}D$ 1.5573. A sample of crude hydrogenation product was distilled through a 44-cm. Fenske column packed with glass helices and the refractive index was practically constant throughout, $n^{25}D$ 1.5570–1.5578; $d^{25}_4$ 1.0082; $M_D$ (found) 50.54, $M_D$ (calcd.) 49.63.

*Anal.* Calcd. for $C_{12}H_{14}$: C, 91.08; H, 8.92. Found: C, 91.25; H, 8.79.

The absorption spectrum (Fig. 1) was determined in ethanol on a Beckman ultraviolet spectrophotometer: λ max. 266 mμ (log $E$ 2.77), 274 (2.72).

**Sulfonation of 2a,3,4,5-tetrahydroacenaphthene** at 0° according to the method described by von Braun and Kirschbaum[4a] did not proceed satisfactorily, so the following modification was adopted.

A mixture of 16.80 g. of the hydrocarbon and 26.0 g. of 97% sulfuric acid was shaken vigorously for one hour with occasional cooling to maintain the temperature at about 23°. The dark red viscous solution was allowed to stand at room temperature overnight, then poured into 100 ml. of water. The solution was treated with Norit, washed once with ether to remove some unchanged hydrocarbon, neutralized with sodium carbonate and treated (at 65°) with about 50 ml. of saturated sodium chloride solution. On cooling 20.10 g. of crude sodium tetrahydroacenaphthenesulfonate crystallized. It was recrystallized from water before being employed in the alkaline fusion.

**Alkaline Fusion of Sodium Tetrahydroacenaphthenesulfonate.**—The procedure of von Braun and Kirschbaum,[4a] reported to give 10–15% yields, could not be repeated successfully. The following modification gave yields of phenol as high as 20%.

A mixture of 3.00 g. of dried sulfonate, 6.0 g. of potassium hydroxide and 4.0 g. of sodium hydroxide was placed in a steel bomb. The system was flushed with nitrogen, the bomb sealed, and heated with shaking for one and one-quarter hours as the temperature was raised to 335°. After an additional hour at this temperature, the bomb was cooled and the product worked up in the usual manner. The phenolic material after clarification with Norit was obtained as colorless crystals, m. p. 89.5–93.5° with previous softening; yield 0.40 g. Evaporative distillation at 110–120° (0.1 mm.) gave material (94% recovery) melting at 94.5–95.5°. A second evaporative distillation raised the m. p. to 96–97.2° with softening at 95°.

*Anal.* Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.09. Found: C, 82.55; H, 7.97.

Recrystallization of this phenol from ethyl acetate–petroleum ether (60–68°) did not improve the melting point (*cf.* the behavior of 8-hydroxy-2a,3,4,5-tetrahydroacenaphthene described below). A mixture with 7-hydroxy-2a,3,4,5-tetrahydroacenaphthene, m. p. 96.8–97.6°, prepared as described below, melted at 76–94° with softening at 71°. A mixture with the 8-hydroxy compound, m. p. 99.6–102.6°, melted at 92.5–98.5° with softening at 89°.

The crude aryloxyacetic acid derivative prepared from 0.103 g. of the phenol, 0.40 ml. of 33% sodium hydroxide, 0.30 ml. of a 50% solution of chloroacetic acid in water and 1.5 ml. of water according to the usual procedure[14] amounted to 0.068 g. (50% yield) and melted with dec. at 183–184° and softening at 179°. Successive recrystallizations from ethyl acetate–petroleum ether (60–68°) gave material with the m. ps. 190.5–192°, 194.5–198.5°, 196–197.5°, the last crystallizate amounting to 7 mg.

*Anal.* Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 72.48; H, 6.74.

On admixture with the aryloxyacetic acid derivative of 8-hydroxy-2a,3,4,5-tetrahydroacenaphthene, m. p. 202–203°, the m. p. was 197–200°.

### Synthesis of Tetrahydroacenaphthene Derivatives from Tetralones

The general scheme of synthesis is outlined in the flow sheet in the discussion part. For the Reformatsky reaction the procedure described by Bachmann, Cole and Wilds[15] with slight modifications proved most successful. The zinc was prepared from pure zinc foil which was cleaned with sandpaper, then cut into one-eighth inch squares and activated as described.[15] The proportion of solvent was decreased considerably, and mechanical stirring (mercury-sealed Hershberg wire stirrer) was employed throughout the heating period. No attempt was made to purify the hydroxy ester which was isolated in the crude form by evaporation of the ether–benzene solution and then dehydrated by refluxing for thirty minutes with 88–90% formic acid (about 2 ml. per gram of starting ketone). The acid was evaporated on the steam-bath in a current of air, and the brown oily residue saponified by refluxing for three and one-half hours with dilute methanolic potassium hydroxide (about 2–2.5 ml. each of methanol and 20% potassium hydroxide per gram of starting ketone). The methanol was removed on the steam-bath in a current of air, and the mixture diluted with two volumes of water. After cooling, the alkaline solution was washed with ether to remove unsaponified material, and after clarification with Norit, was acidified slowly in the cold with vigorous stirring. The unsaturated acid was thus obtained as a pale tan to colorless solid, melting over a wide range. This product was pure enough for low pressure hydrogenation in ethyl acetate solution over 5% palladium on charcoal,[16] which afforded the tetrahydronaphthylacetic acid V

(11) Unless otherwise specified all melting points are corrected.

in good yield. The remaining steps of the synthesis are described below in connection with the individual cases.

**2a,3,4,5-Tetrahydroacenaphthene, VII** ($R^1 = R^2 = R^3 = H$).—When the procedure of Schroeter[17] was employed for the Reformatsky reaction and the product hydrogenated either directly or after dehydration with phosphorus pentoxide, a very impure acid was produced which was shown to consist of a mixture of the desired 1,2,3,4-tetrahydronaphthyl-1-acetic acid (about 43%) and 1-naphthylacetic acid (about 47%) evidently produced by disproportionation. The latter substance remained unchanged when the mixture was treated with hydrogen fluoride and was identified by conversion to the amide.

The disproportionation was not observed with the procedure described above. Thus from 15.0 g. of 1-tetralone, 30.0 g. of zinc,[18] 16 ml. of methyl bromoacetate, and 200 ml. of 1 to 1 ether–benzene there was obtained after dehydration and saponification, 14.2 g. (73% yield) of mixture of unsaturated acids, m. p. 86–96°. Hydrogenation of 13.0 g. of this material in 75 ml. of ethyl acetate at 2–3 atmospheres over a total of 5 g. of 5% palladium on charcoal,[16] afforded 12.1 g. (92% yield) of crude 1,2,3,4-tetrahydronaphthyl-1-acetic acid, V ($R^1 = R^2 = R^3 = H$) which was obtained as a viscous oil (reported m. p. 35–36°[19]). Cyclization of 11.0 g. with hydrogen fluoride[20] (six hours at room temperature) gave 7.40 g. (74% yield) of almost colorless crystalline 2a,3,4,5-tetrahydro-1-acenaphthenone, VI ($R^1 = R^2 = R^3 = H$), m. p. 100–101.5° (reported,[21] 102°). A solution of 7.00 g. of the ketone in 75 ml. of acetic acid containing 0.5 ml. of 60% perchloric acid[22] was hydrogenated over 2.0 g. of 5% palladium on charcoal catalyst,[16] at 2–3 atmospheres. In this case the hydrogenation did not go to completion and it was necessary to remove the catalyst, treat the partially reduced material with Raney nickel, and then to continue the reduction with fresh palladium catalyst. The mixture was filtered, made alkaline with excess potassium hydroxide solution and the hydrocarbon extracted. Distillation through a 20-cm. modified Widmer column gave 1.83 g. of colorless material, b. p. 125–126° (17 mm.), $n^{25}D$ 1.5566. The remainder of the product was retained as hold-up in the distillation apparatus.

**8-Hydroxy-2a,3,4,5-tetrahydroacenaphthene, VI** ($R^1 = OH$, $R^2 = R^3 = H$).—From 34.7 g. of 7-methoxy-1-tetralone,[10] m. p. 61–62°, 60 g. of zinc,[18] 28 ml. of methyl bromoacetate, and 400 ml. of 1 to 1 ether–benzene, there was obtained after dehydration and saponification, 41.8 g. (97% yield) of mixture of unsaturated acids, m. p. 122.5–138.5°. Hydrogenation of 10.9 g. of material, which was recrystallized once from alcohol, in 50 ml. of ethyl acetate at 2–3 atmospheres over 1.0 g. of 5% palladium on charcoal[16] was complete in about twenty minutes and afforded after trituration of the crude product with petroleum ether (40–60°) 10.02 g. of crystalline 7-methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic acid, V ($R^1 = OCH_3$, $R^2 = R^3 = H$), m. p. 88.5–89.5° (reported,[23] 88–89°). An additional 0.36 g. of crude material, m. p. 77–85° was obtained from the petroleum ether solution.

A 10.00-g. sample of the above acid, m. p. 88.5–89.5°, was cyclized with hydrogen fluoride[20] (twenty hours at room temperature) to give 8.85 g. (96% yield) of crystalline **8-methoxy-2a,3,4,5-tetrahydro-1-acenaphthenone, VI** ($R^1 = OCH_3$, $R^2 = R^3 = H$), m. p. 98–99.5°. This material seemed to be somewhat unstable showing a tendency to turn yellow during recrystallization. It was obtained as plates or needles from benzene–petroleum ether (60–68°), and after three recrystallizations melted at 95.8–98° with slight previous softening.

*Anal.* Calcd. for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98. Found: C, 77.30; H, 6.80.

A 10.10-g. sample of the above ketone was reduced by the Clemmensen method,[24] and 5.00 g. of the resulting 9.12 g. (97% yield) of oil,[25] was demethylated by refluxing with 50 ml. of 48% hydrobromic acid and 25 ml. of glacial acetic acid for four and one-half hours in an atmosphere of nitrogen. Since insoluble oil still remained after this treatment 50 ml. of acetic acid was added and refluxing continued for eight and one-half hours. The mixture was concentrated to about one-third its volume, diluted with water, and extracted with ether. The ether solution was washed with 5% sodium bicarbonate, and the phenol was then extracted with 5% potassium hydroxide followed by Claisen alkali.[26] The alkaline extracts were combined and acidified liberating 3.11 g. of tan crystalline phenol, m. p. 96–98.5°. An additional 0.50 g. of material of the same m. p. was obtained from the filtrate by extraction, thus making the total yield 78%. Evaporative distillation at 145–150° (0.1 mm.) gave in 88% recovery colorless crystals, m. p. 102–103° with slight previous softening. This material proved to be quite sensitive and on boiling in 60–68° petroleum ether the solution became turbid as a small amount of insoluble material gradually precipitated. After two recrystallizations from this solvent (each time turbidity necessitated filtration), the product melted at 101.5–102.5° to a cloudy liquid which did not clear up completely until about 180°. The high-melting contaminant could be removed by evaporative distillation. After a second evaporative distillation the product was obtained as pale yellow needles, m. p. 99.5–102.5°. The lower m. p. than that observed with the crude sample may have been due to polymorphism.

*Anal.* Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.09. Found: C, 82.52; H, 8.00.

The **aryloxyacetic acid derivative** was prepared from 0.121 g. of 8-hydroxy-2a,3,4,5-tetrahydroacenaphthene, 0.40 ml. of 33% sodium hydroxide, 0.30 ml. of 50% chloroacetic acid in water, and 0.5 ml. of water according to the usual procedure.[14] The crude derivative amounted to 0.068 g. (42% yield), m. p. 202–203° with darkening and softening at 200°. Recrystallization from ethyl acetate gave colorless needles, m. p. 202–203° (turning red).

*Anal.* Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 72.22; H, 6.61.

**7-Hydroxy-2a,3,4,5-tetrahydroacenaphthene, VII** ($R^2 = OH$, $R^1 = R^3 = H$).—From 10.0 g. of 6-methoxy-1-tetralone,[27] m. p. 76–77.5°, 20 g. of zinc,[18] (10 ml.) of methyl bromoacetate, and 150 ml. of 1 to 1 ether–benzene, there was obtained after dehydration and saponification 9.50 g. (77% yield) of mixture of unsaturated acids, melting at about 64°, resolidifying at about 90° and remelting at 100–111°. Hydrogenation of 8.30 g. of this product in 75 ml. of ethyl acetate at 2–3 atmospheres over a total of 3 g. of 5% palladium on charcoal,[16] was complete after about three hours, and afforded 8.00 g. (95% yield) of crude 6-methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic acid, V ($R^2 = OCH_3$, $R^1 = R^3 = H$), m. p. 76–80°. Recrystallization from benzene–petroleum ether (60–68°) raised the m. p. to 79–81.5°. In other runs material of better quality, m. p. 81–83.5°, was obtained although in lower (83%) yield. Recrystallization gave an 88% recovery of material m. p. 82.5–84° (reported, 84°[28] and

87°[29]). The cyclization of this acid to 7-methoxy-2a,3,4,-5-tetrahydro-1-acenaphthenone, VI ($R^2$ = $OCH_3$, $R^1$ = $R^3$ = H) is described elsewhere.[10] A 1.015 g. sample of the ketone was reduced by the Clemmensen method[24] and 0.711 g. of the resulting 0.732 g. (77% yield) of oil,[25] was demethylated by refluxing with 10 ml. of 48% hydrobromic acid and 15 ml. of acetic acid for four hours in an atmosphere of nitrogen. The product was worked up essentially as described above for the 8-methoxy isomer except that the crude phenol being oily was separated by extraction. The total yield of crude semi-solid material was 0.620 g. (94%). Evaporative distillation at 100–110° (0.1 mm.) gave in about 65% recovery colorless crystalline phenol, m. p. 89–95°. The pure material was obtained by crystallization from petroleum ether (60–68°) followed by evaporative distillation. It was obtained as colorless needles, m. p. 96–97.6°.

*Anal.* Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.09. Found: C, 82.68; H, 7.96.

**6-Methyl-7-hydroxy-2a,3,4,5-tetrahydroacenaphthene, VII** ($R^1$ = H, $R^2$ = OH, $R^3$ = $CH_3$).—5-Methyl-6-methoxytetralone-1, IV ($R^1$ = H, $R^2$ = $OCH_3$, $R^3$ = $CH_3$), was prepared according to the method of Martin and Robinson.[30] By slight modifications in the oxidation step it was possible to improve the yield of ketone as follows. A solution of 11.4 g. of chromic oxide in 70 ml. of acetic acid and 10 ml. of water was added slowly over a period of one and one-half hours to a stirred solution of 11.4 g. of 5-methyl-6-methoxytetralin, m. p. 49–50°, in 115 ml. of acetic acid, the internal temperature being maintained at 10–15°. After the addition was complete the mixture was stirred for one and one-half hours in the cold (ice-bath) and two hours at room temperature. After eighteen hours at room temperature (without stirring) 25 ml. of methanol was added, the mixture stirred for thirty minutes and then concentrated under reduced pressure. The gummy residue was treated with 200 ml. of water and extracted with ether. The ether solution was washed with 5% sodium carbonate solution, saturated salt solution, clarified with Norit, and dried over anhydrous potassium carbonate. Evaporation of the ether gave 10.28 g. (83% yield) of yellow ketone, m. p. 106.5–109.5°. Martin and Robinson[30] report an average yield of 70% of light yellow ketone, m. p. 103–105°. Our material after two recrystallizations from methanol melted at 109.5–111° (reported m. p.,[30] 112–113°).

From 4.23 g. of the above ketone, 10 g. of zinc,[18] 8 ml. of methyl bromoacetate and 80 ml. of 1 to 1 ether–benzene there was obtained after dehydration and saponification 3.84 g. (74% yield) of mixture of unsaturated acids, m. p. 146–154° (dec.). Hydrogenation of 3.00 g. of this product in 25 ml. of ethyl acetate at atmospheric pressure over a total of 1.5 g. of 5% palladium on charcoal,[16] was complete after about fifteen hours, and afforded 2.77 g. (91% yield) of **5-methyl-6-methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic acid, V**, $R^1$ = H, $R^2$ = $OCH_3$, $R^3$ = $CH_3$, m. p. 154–156°. Recrystallization from ethyl acetate–petroleum ether (60–68°) gave a total of 2.38 g. of colorless blades, m. p. 158.5–159°. Further recrystallizations raised the m. p. to 159.2–159.8°.

*Anal.* Calcd. for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74. Found: C, 71.95; H. 7.47.

The cyclization of the above acid to 6-methyl-7-methoxy-2a,3,4,5-tetrahydro-1-acenaphthenone, VI ($R^1$ = H, $R^2$ = $OCH_3$, $R^3$ = $CH_3$), is described elsewhere.[10] A 0.173-g. sample of this ketone, m. p. 123–125.5°, in 15 ml. of acetic acid containing 0.2 ml. of 60% perchloric acid[22] was hydrogenated at atmospheric pressure over 0.150 g. of 30% palladium on charcoal.[31] The uptake of hydrogen ceased after one and three-quarters hours, the calculated amount being absorbed. The mixture was filtered, diluted with water, neutralized with solid sodium bicarbonate and extracted with ether. The ether solution was washed with water, then with saturated salt solution and dried over anhydrous potassium carbonate. Evaporation of the ether left 0.162 g. of a colorless oil which crystallized on drying, m. p. 35–40.5°. Two recrystallizations from petroleum ether (40–60°) solution cooled in a Dry Ice–acetone bath gave colorless plates of **6-methyl-7-methoxy-2a,3,4,5-tetrahydroacenaphthene, VII** ($R^1$ = H, $R^2$ = $OCH_3$, $R^3$ = $CH_3$), m. p. 42–44°.

*Anal.* Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found: C, 82.94; H, 8.74.

In another experiment it was noted that the perchloric acid was unnecessary for complete hydrogenolysis, but the rate of reaction was decreased, nine hours being required to reduce 0.458 g. of ketone. The yield was 0.430 g., m. p. 39.5–42.5°. A 0.430-g. sample of this material was demethylated by refluxing with 5 ml. of 48% hydrobromic acid and 10 ml. of acetic acid for ten hours in an atmosphere of nitrogen. The product was worked up essentially as described above for the 8-methoxy homolog to give 0.344 g. (86% yield) of crude tan crystalline phenol, m. p. 103–107.5°. Evaporative distillation at 130–140° (0.5 mm.) gave a 95% recovery of colorless needles, m. p. 106.5–108°. Recrystallization from ethyl acetate–petroleum ether (60–68°) gave colorless prisms, m. p. 109–110.4°.

*Anal.* Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.98; H, 8.35.

### Coupling Experiments

Five grams of *p*-nitroaniline hydrochloride, prepared by treating the amine in dioxane solution with anhydrous hydrogen chloride, was diazotized by the procedure of Hantzsch and Jochem[32] with the following modifications. *n*-Butyl nitrite was used instead of amyl nitrite. Attempts to use the dried diazonium salt for preparing a standard solution did not appear promising since water-insoluble material was produced. A satisfactory procedure consisted in separating the diazonium salt by filtration, washing well with anhydrous ether to remove acetic acid and dissolving the ether-moist product in water at 0°. The solution was diluted to 250 ml. and standardized by titration of an aliquot with alkali using phenolphthalein as an indicator. The solution then was shown to contain 0.106 millimole of *p*-nitrobenzenediazonium chloride per ml. of solution.

The coupling procedure was as follows: The phenol (0.201–0.202 millimole) was dissolved in 10 ml. of buffered (or alkaline) solution and 5 ml. of purified[33] dioxane, and the solution cooled to 0° in an ice-bath. To this was added 3.00 ml. of the standardized diazonium salt solution (also at 0°) and the mixture was kept at 0° for twenty minutes. The mixture was then warmed on the steam-bath for twenty minutes and the dark red precipitate separated by filtration, washed with water, digested for five to ten minutes with warm 5% potassium carbonate solution (steam-bath), separated by filtration, washed with the carbonate solution and finally with water. The dyes were dried to constant weight in a vacuum desiccator and the melting points determined on a micro hot stage.

The melting point of the crude coupling products from β-naphthol varied from 251–254° to 253–255° (reported m. p.,[34] 250–251°).

The crude coupling product obtained from 8-hydroxy-2a,3,4,5-tetrahydroacenaphthene at *p*H 8–10 had the m. p. 211–216° and at *p*H 11–13, 213–217°. A sample purified by recrystallization from dioxane was obtained as red-brown needles, m. p. 219.5–220.5°.

*Anal.* Calcd. for $C_{18}H_{17}O_3N_3$: C, 66.86; H, 5.30. Found: C, 66.91; H, 5.04.

The crude coupling product obtained from 7-hydroxy-2a,3,4,5-tetrahydroacenaphthene at *p*H 8–10 had the m. p. 168–172° and at *p*H 11–13, m. p. 172–175°. A

## Summary

2a,3,4,5-Tetrahydroacenaphthene has been prepared both by selective hydrogenation of acenaphthene and by synthesis from 1-tetralone. The properties of the hydrocarbon resemble those of simple polyalkylbenzenes.

7-Hydroxy-, 8-hydroxy-, and 6-methyl-7-hydroxy-2a,3,4,5-tetrahydroacenaphthene were prepared by synthesis from the appropriately substituted tetralones, and their coupling behavior with *p*-nitrobenzenediazonium chloride was observed at various concentrations of alkali. All of the phenols were comparably effective couplers, and it may be concluded that experiments thus far have failed to reveal any marked steric inhibition of resonance in the tetrahydroacenaphthene ring system.

# Intramolecular Acylation. II.[1] The Inverse Friedel–Crafts Method

BY WILLIAM S. JOHNSON AND HOWARD J. GLENN[2]

Of the numerous methods available for effecting ring closure of β-arylpropionic or γ-arylbutyric acid derivatives to cyclic ketones, the intramolecular Friedel–Crafts reaction of the acid chloride with aluminum chloride promises to be particularly useful for acids like β-*p*-methoxyphenylpropionic acid, which are resistant to cyclization due to unfavorable reactivity of the aromatic nucleus.[1] Excellent yields have not been generally realized by this method, probably because a large proportion of the cylizations reported in the literature have been conducted under unfavorable conditions. In the present work we are describing a cyclization technique which combines the best features suggested by previous experience.[3] This procedure, which has been tested with nine acids of varying susceptibility to cyclization, apparently differs from others previously reported only in minor respects, some of which nevertheless, have proved to be critical factors and merit emphasis. (1) It has been found important to use acids of good quality, since small amounts of impurities may result in a very impure product. (2) For preparation of the acid chloride, phosphorus pentachloride instead of thionyl chloride was employed because of occasional complications which have been reported to attend the use of the latter.[4] The phosphorus oxychloride produced was always carefully removed, because its presence has been shown to interfere with the cyclization giving lower yields.[5,1] (3) The Friedel–Crafts step was carried out in the inverse manner, *i.e.*, the acid chloride (in benzene solution) was added to a stirred suspension of aluminum chloride in benzene. This technique has the advantage over the conventional method of (*a*) facilitating temperature control through regulation of the rate of addition of the acid chloride and (*b*) maintaining a high concentration of catalyst, a condition that has been shown in *inter*molecular acylation to minimize self-condensation of the resulting ketone,[6] which is a side-reaction that also competes with certain *intra*molecular acylations.[7] The yields for fifteen cases that were found in the literature in which the inverse Friedel–Crafts cyclization was employed apparently without particular regard to other critical factors, were nevertheless generally well above average,[3] thus suggesting a real advantage in this method. (4) Since heating has been shown to have undesirable effects,[7] the temperature of the reaction mixture was never permitted to rise above 25° during the cyclization step. Even with acids that are unusually resistant to cyclization, this treatment afforded excellent yields of ketones. Thus with β-*p*-methoxyphenylpropionic acid, I ($R^1$ = $OCH_3$, $R^2$ = H), which is notoriously resistant to cyclization,[1,8] 6-methoxy-1-hydrindone, II ($R^1$ = $OCH_3$, $R^2$ = H), of fair purity was obtained in practically quantitative yield on a 3-g. scale.

The ring closure of α,γ-diphenylbutyric acid, III ($R^1$ = H, $R^2$ = $C_6H_5$), afforded an interesting test since Newman[9] had studied this cyclization

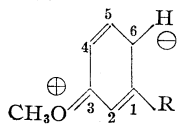
carefully and developed conditions requiring a rather critical heat treatment whereby yields as high as 94% could be realized. When the procedure described in the present work was applied, practically quantitative yields of the ketone, IV ($R^1$ = H, $R^2$ = $C_6H_5$), were produced without heating.



β-Phenylpropionyl chloride was cyclized to 1-hydrindone, II ($R^1$ = $R^2$ = H) in nearly quantitative yield, γ-phenylbutyric acid, III ($R^1$ = $R^2$ = H), to tetralone-1, IV ($R^1$ = $R^2$ = H), in 90% yield on a 50-g. scale,[10] γ-*p*-methoxyphenylbutyric acid, III ($R^1$ = $OCH_3$, $R^2$ = H), to 7-methoxytetralone, IV ($R^1$ = $OCH_3$, $R^2$ = H), in practically quantitative yield on a 20-g. scale, and β-*m*-methoxyphenylpropionic acid, I ($R^1$ = H, $R^2$ = $OCH_3$), to a mixture of 5- and 7-methoxy-1-hydrindone (predominantly the former) in 89% yield. The cyclization of 6-methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic acid, V (R = H), to VI (R = H) proceeded in only 77% yield, although the 5-methyl homolog V (R = $CH_3$) was cyclized to VI (R = $CH_3$) in quantitative yield. Both of these cases involve five-membered ring closure meta to a methoxyl group.

### Deactivation by Coördination with Catalyst

Application of the cyclization procedure to β-3,4-dimethoxyphenylpropionic acid, I ($R^1$ = $R^2$ = $OCH_3$), gave most unexpected results. Instead of 5,6-dimethoxy-1-hydrindone, II ($R^1$ = $R^2$ = $OCH_3$), we isolated as the preponderant product (70% yield) a crystalline ketone melting after purification at 68–68.5° and having an analysis compatible with the formula $C_{17}H_{18}O_3$. That this was 3,4-dimethoxybenzylacetophenone, VII, arising from intermolecular acylation of the solvent follows from the agreement of its properties with those reported for VII obtained by hydrogenation of 3,4-dimethoxybenzalacetophenone.[11] These observations were all the more surprising in view of the fact that under the same conditions the *p*-methoxy acid I ($R^1$ = $OCH_3$, $R^2$ = H) is cyclized in quantitative yield. It would be expected, however that the latter would be considerably less susceptible to cyclization than the acid I ($R^1$ = $R^2$ = $OCH_3$) which has the additional 3-methoxy group to activate the 6-position into which the ring closes, thus cancelling the de-activating influence of the 4-methoxy group. That I ($R^1$ = $R^2$ = $OCH_3$) does indeed have a greater intrinsic susceptibility to cyclization than I ($R^1$ = $OCH_3$, $R^2$ = H) is suggested by its behavior toward hydrogen fluoride which promoted ring closure to II ($R^1$ = $R^2$ = $OCH_3$) in 88% yield. The acid I ($R^1$ = $OCH_3$, $R^2$ = H) in contrast is cyclized in only 3% yield under the same conditions.[1]

VII

VIII

According to current theories the activating influence of the 3-methoxy group may be rationalized by its participation in the resonance of the benzene nucleus, thus enhancing the contribution of the polarized form VIII (or the corresponding *ortho* quinoid modification) to the electronic state of the molecule. The resultant high electron density at the 6-position favors reaction with the electrophilic carbon of the carbonyl group at the end of the side-chain R thus effecting cyclization. Coördination of the 3-methoxy group with an acid would inhibit the contribution of VIII and, if powerful enough, would tend to render the 6-position sufficiently less nucleophilic (by induction as in the de-activation of the benzene nucleus by the quaternary ammonium ion) than the carbon atom of the solvent benzene, so that reaction could occur more rapidly with the latter. This hypothetical situation was not actually realized with β-*m*-methoxyphenylpropionic acid, I ($R^1$ = H, $R^2$ = $OCH_3$), which underwent only intramolecular acylation (see above), but with the acid I ($R^1$ = $R^2$ = $OCH_3$) the second methoxy group in the 4-position exerts on the 6-position an additional de-activating influence of the type observed with β-*p*-methoxyphenylpropionic acid. The combined effects appear to render the nucleus so unreactive that the competing intermolecular reaction takes precedence. According to this postulate an acid somewhat weaker than aluminum chloride, should favor intramolecular reaction because the inhibition of resonance by coördination would be decreased. The reaction was therefore carried out with stannic instead of aluminum chloride, and indeed a 54% yield of cyclic ketone

(10) This represents an improvement over the procedure of Martin and Fieser, *Org. Syn.*, Coll. Vol. II, 569 (1943), which gives varying yields of 74–91% and involves a laborious steam distillation.

(11) Pfeiffer, Kalckbrenner, Kunze and Levin, *J. prakt. Chem.*, **119**, 109 (1928).

was obtained, none of the product VII of intermolecular acylation being found.

## Experimental[12]

**General Cyclization Procedure.**—To phosphorus pentachloride (in the ratio of 1.1 mole per mole of acid) in a flame-dried distilling flask (protected by a calcium chloride tube) was added 3.00 g. of pure, dried organic acid. In larger runs the acid was added in portions.[13] If the reaction did not start immediately the mixture was warmed gently or a few ml. of benzene added. After copious evolution of hydrogen chloride ceased (usually about fifteen minutes), 15 ml. of dried (over sodium) benzene was added and the flask was fitted with a stopper bearing a small addition funnel and a tube drawn out to a fine capillary extending to the bottom of the flask. The volatile phosphorus compounds were then co-distilled with the benzene at 60–70° (oil-bath temperature) under reduced pressure (water pump), dry air or nitrogen being admitted through the capillary tube. When the volatile materials were largely removed, another 15 ml. of benzene was added from the dropping funnel and the distillation continued. This process was repeated twice again each time with the addition of 15-ml. portions of benzene. The residual acid chloride was then cooled, dissolved in 20 ml. of dry, thiophene-free benzene and transferred with the aid of an additional 15 ml. of solvent through a plug of glass wool into a dropping funnel which was attached to a flame-dried flask bearing a Hershberg mercury-sealed wire stirrer, thermometer and calcium chloride tube. Aluminum chloride[14] (in the ratio of 1.2–1.4 mole per mole of acid) was introduced into the flask with 40 ml. of dry thiophene-free benzene and the suspension stirred with cooling (ice-bath) as the solution of acid chloride was added slowly at such a rate that the temperature of the reaction mixture never rose above 10°. The addition ordinarily required about fifteen minutes during which a highly colored complex formed. The funnel was finally rinsed with an additional 25 ml. of benzene and the stirring continued for two to five hours while the temperature was allowed to rise slowly to 22–24° (not higher).

The mixture was chilled, about 50 ml. of ether introduced to prevent emulsion formation, and then 100 ml. of cold 1:1 hydrochloric acid added with stirring at such a rate that the temperature remained below 15°. The organic layer was separated, washed successively with three portions of 1:1 hydrochloric acid, followed by saturated sodium bicarbonate,[15] 5% potassium hydroxide,[15] water and finally saturated salt solution. Appropriate washing of the aqueous layers in turn with a fresh portion of ether was necessary for effecting clean separations. The combined organic solutions were shaken with a small amount of Norit, dried over anhydrous potassium carbonate, filtered, evaporated and dried to constant weight *in vacuo*.

Any uncyclized acid was recovered by acidification of the bicarbonate solutions, and phenolic material (resulting from demethylation of methoxy derivatives) by acidification of the potassium hydroxide wash solutions.

### Cyclization Experiments

**β-*p*-Methoxyphenylpropionic Acid, I** ($R^1 = OCH_3$, $R^2 = H$).—A 3-g. sample of the pure acid,[1] m. p. 103.5–104° was treated by the above procedure with 3.64 g. of phosphorus pentachloride. Cyclization was effected with 3.10 g. of aluminum chloride for five hours. The crude tan ketone, II ($R^1 = OCH_3$, $R^2 = H$), amounted to 2.73 g. (quantitative yield), m. p. 103–106°. Distillation in a two-bulb flask at 0.1 mm. was attended by some mechanical hold-up giving 2.20 g. of colorless product, m. p. 108–108.5°. In another experiment with 2.50 g. of acid in which the molecular ratio of catalyst was dropped to 1.25 instead of 1.4, 2.10 g. (93% yield) of product melting at 105–106.2° was obtained. Evaporative distillation under reduced pressure gave a 95% recovery of colorless ketone, m. p. 108–108.5°. Cyclization of a specimen of the acid having approximately the same m. p. as the sample above, but having been submitted to one less recrystallization, gave a quantitative yield of crude ketone which, however, melted at 50–106°. Only 43% of this material could be obtained relatively pure, m. p. 103–105°.

**β-Phenylpropionic Acid, I** ($R^1 = R^2 = H$).—Since the acid chloride, b. p. 118–120° (17 mm.), was available, a 3.08-g. sample was treated with 3.04 g. of aluminum chloride for five hours. The yield of almost colorless hydrindone was 2.40 g. (99%), m. p. 39–39.6° with softening at 38.5°. Evaporative distillation at 0.3 mm. gave a 94% recovery of colorless ketone, m. p. 39.8–40.2° (reported,[16] 40–41°). Using the inverse Friedel-Crafts cyclization, Thiele and Wanscheidt,[17] obtained 1-hydrindone in 95% yield. They used petroleum ether as the solvent and warmed the reaction mixture until the complex dissolved.

**β-*m*-Methoxyphenylpropionic Acid, I** ($R^1 = H$, $R^2 = OCH_3$).—The acid was prepared by methylation of β-*m*-hydroxyphenylpropionic acid[18] with dimethyl sulfate followed by crystallization from ether–petroleum ether (40–60°) and recrystallization from dilute methanol; m. p. 44–46.5° (reported,[19] 45°). A 1.50-g. sample was treated with 1.90 g. of phosphorus pentachloride and cyclization was effected with 1.55 g. of aluminum chloride for three and one-half hours at 7–17°. The pale yellow product amounted to 1.20 g. (89% yield), m. p. 63–103°, evidently consisting of a crystalline mixture of 5- and 7-methoxy-1-hydrindone as shown by analysis of material sublimed at 75–90° (0.05 mm.) which melted at 63–100°.

*Anal.* Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22. Found: C, 74.01; H, 6.06.

On crystallization of the sublimate from dilute methanol three-fourths of the product separated as fairly pure 5-methoxy-1-hydrindone, m. p. 108–110.5°, with previous softening, indicating that this isomer was formed in preponderance. The m. p. after recrystallization was 109–110.5°, and was not depressed on admixture with an authentic specimen of the ketone.[18]

The only previous report of cyclization of this acid is by Ingold and Piggott[19] who used aluminum chloride in petroleum ether on the acid chloride. The conditions involved heating on the steam-bath which effected some demethylation. No yields were reported, but the presence of both possible isomers was demonstrated.

**γ-Phenylbutyric Acid, III** ($R^1 = R^2 = H$).—A 50-g. sample of the acid, m. p. 47–49.5°, was converted to the acid chloride with 70 g. of phosphorus pentachloride, five 25-ml. portions of benzene being used for removal of the phosphorus oxychloride. The acid chloride was then dissolved in 100 ml. of benzene and added to 56 g. of aluminum chloride suspended in 150 ml. of solvent. After the addition which required forty-five minutes, 50 ml. of benzene was used for rinsing the funnel. The mixture was stirred for fifteen minutes in the cold and four hours at 22–24°, and then the addition complex was decomposed with 100 ml. of ether and 250 ml. of 1:1 hydrochloric acid. The 1-tetralone, b. p. 165–170° (46–49 mm.) amounted to 40.0–40.4 g. (90–91% yield). Starting acid amounting to 2.4 g., m. p. 45–47.5°, was recovered from the bicarbonate washings.

**α,γ-Diphenylbutyric Acid, III** ($R^1 = H$, $R^2 = C_6H_5$).—A 3.00-g. sample of the acid[20] (m. p. 72.7–73.5° after

(12) All melting points are corrected.

(13) See footnote 116b of ref. 3.

(14) Aluminum chloride supplied by either Merck and Co. (yellow powdered material) or J. T. Baker Chemical Co. (reagent grade) was used with equal success.

(20) Prepared from α-phenyl-β-benzoylpropionitrile, *Org. Syn.*, Coll. Vol. II, 498 (1943), according to the procedure of Newman THIS JOURNAL, **60**, 2947 (1938).

three recrystallizations from 60–68° petroleum ether) was treated with 2.74 g. of phosphorus pentachloride, and cyclization was effected with 2.32 g. of aluminum chloride for five hours. The yield of crude product was 2.71–2.78 g. (98–100%) with a melting point varying from 75–76 to 73–75°. The acidic material recovered from the alkaline washings was negligible. Recrystallization of the 2.78-g. product from petroleum ether (60–68°) gave 2.38 g. melting at 76–77° and 0.24 g. melting at 74–76°, making the total yield of recrystallized material 94%. The reported m. p. is 76.2–77°.[20]

When a sample of the acid of approximately the same m. p., but having been recrystallized only twice was cyclized, the yield of crude product was good (97%) but the quality inferior (m. p. 69–73°). Recrystallization gave only 81% yield of ketone melting at 73–76°.

**γ-*p*-Methoxyphenylbutyric Acid, III** ($R^1 = OCH_3$, $R^2 = H$).—A 20.0-g. sample of the acid (m. p. 60.5–62° after recrystallization from petroleum ether (60–68°) containing a small proportion of benzene) was converted to the acid chloride with 24.0 g. of phosphorus pentachloride, four 15-ml. portions of benzene being used for removal of the phosphorus oxychloride. The acid chloride was then dissolved in 50 ml. of benzene and added to 19.3 g. of aluminum chloride suspended in 50 ml. of benzene. After the addition, which required twenty minutes, 25 ml. of benzene was used for rinsing making the total volume 125 ml. The mixture was stirred for fifteen minutes in the cold, then four hours at 22–24°. The yield of crude pale yellow crystalline ketone was 17.90 g. (99%), m. p. about 59–61°. Recrystallization from ether–petroleum ether (60–68°) gave in the first crop 14.33 g. of light tan prisms, m. p. 61–62° (reported,[21] 62–63°). From the bicarbonate wash 0.17 g. of acid was recovered, m. p. 54–57°. The potassium hydroxide washings yielded 0.08 g. of oil having a phenolic odor. This acid has been cyclized in 88% yield by the action of stannic chloride on the acid chloride.[22]

**6-Methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic Acid, V** (R = H).—A 3.00-g. sample of the acid, m. p. 83–84°,[23] was treated with 3.12 g. of phosphorus pentachloride, and cyclization was effected with 2.66 g. of aluminum chloride for four hours. The yield of crude 7-methoxy-2a,3,4,5-tetrahydro-1-acenaphthenone, VI (R = H), m. p. 78.5–82.5°, was 2.12 g. (77%). Only 0.10 g. of acidic product was recovered from the bicarbonate washings. Evaporative distillation at 130–140° (0.2 mm.) gave a 71% recovery of colorless material m. p. 88–89.5°. An additional 10% of less pure material, m. p. 84.5–88°, was recovered by continuing the distillation. An analytical sample was prepared from the first fraction by three recrystallizations from petroleum ether (60–68°) followed by evaporative distillation. The colorless needles melted at 89.6–90.8°.

*Anal.* Calcd. for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98. Found: C, 77.34; H, 6.86.

**5-Methyl-6-methoxy-1,2,3,4-tetrahydronaphthyl-1-acetic Acid, V** (R = $CH_3$).—A 1.00-g. sample of this acid, m. p. 159–159.5°,[23] was treated with 1.00 g. of phosphorus pentachloride, and cyclization was effected with 0.81 g. of aluminum chloride suspended in 20 ml. of benzene. The addition of the acid chloride in 15 ml. of solvent required fifteen minutes, 15 ml. of benzene being used for rinsing. The mixture was then stirred for an additional fifteen minutes in the cold, and for two and one-half hours at 22–24°. The yield of crude 6-methyl-7-methoxy-2a,3,4,-5-tetrahydro-1-acenaphthenone, VI (R = $CH_3$), m. p. 121–125.5°, was 0.925 g. (100%). A single crystallization of 0.920 g. from ethyl acetate–petroleum ether (60–68°) gave in the first crop 0.717 g., m. p. 123–125.5° and in the second 0.034 g., m. p. 122–124°. Recrystallization gave colorless blades, m. p. 124.4–126.4°.

*Anal.* Calcd. for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46. Found: C, 77.97; H, 7.16.

**β-3,4-Dimethoxyphenylpropionic Acid, I** ($R^1 = R_2 = OCH_3$).—3,4-Dimethoxycinnamic acid was prepared by the condensation of veratraldehyde (83 g.) with malonic acid (93 g.) in pyridine (115 ml.) with 1 ml. of piperidine according to the procedure for the preparation of *p*-methoxycinnamic acid.[1] The crude product was dissolved in 5% sodium carbonate, filtered, washed with ether, and acidified. The yield of 3,4-dimethoxycinnamic acid was 100 g. (96%), m. p. 183.4–184.2° with softening at 180° (reported,[24] 180°). Hydrogenation of once recrystallized (from benzene-petroleum ether) material in glacial acetic acid over platinum oxide catalyst gave a 94% yield of crude I ($R^1 = R^2 = OCH_3$), m. p. 95–97°, softening at 92°. Material for the cyclizations was twice recrystallized from benzene to give colorless crystals, m. p. 97.5–98.5° (reported,[25] 97°).

(*a*) *Cyclization with Hydrogen Fluoride.*—A 3.00-g. sample of the acid was treated with hydrogen fluoride overnight at room temperature by the procedure described for β-*p*-methoxyphenylpropionic acid.[1] The cyclization apparently proceeded in only one direction giving 2.42 g. (88% yield) of 5,6-dimethoxy-1-hydrindone, II ($R^1 = R^2 = OCH_3$), m. p. 118.8–119.5° (reported, 115,[25] and 116–117[26]). Recrystallization did not raise the melting point. When the reaction time was reduced to three hours the yield dropped to 73%.

The **semicarbazone** crystallized from alcohol in the form of pale yellow needles, m. p. 234–235° dec. (introduced at 200°).

*Anal.* Calcd. for $C_{12}H_{15}O_3N_3$: C, 57.82; H, 6.07. Found: C, 57.83; H, 6.52.

(*b*) *Cyclization with Phosphorus Pentoxide.*—Perkin and Robinson[25] obtained an 82% yield of the ketone by cyclization with phosphorus pentoxide. In our hands this procedure gave an 86% yield of quite impure material, m. p. 111–116° from which only a 51% yield of pure II ($R^1 = R^2 = OCH_3$), m. p. 118.4–119.4°, could be isolated by crystallization. The remaining material melted quite low, 93–108°, and may have contained some of the isomeric 6,7-dimethoxy-1-hydrindone.

(*c*) *Cyclization with Stannic Chloride.*—A 0.63-g. sample of the acid was cyclized with 0.700 g. of phosphorus pentachloride and 2.23 g. of stannic chloride according to the procedure of Wilds.[27] A total of 25 ml. of benzene was used, and the reaction mixture was allowed to stand for fifteen hours at room temperature. The total neutral product amounted to 0.311 g. (54% yield) of fairly pure 5,6-dimethoxy-1-hydrindone, m. p. 113.5–117°. Evaporative distillation at 130–135° (0.1 mm.) raised the m. p. to 116–117.5° which was not depressed on admixture with the specimen prepared by hydrogen fluoride cyclization (see above, part *a*).

(*d*) *Attempted Cyclization by the Inverse Aluminum Chloride Method.*—A 3.00-g. sample of the acid, m. p. 96.6–97.8°, was treated (according to the cyclization procedure described at the beginning of the experimental section) with 3.14 g. of phosphorus pentachloride, and then 5.75 g. of aluminum chloride for three hours. The neutral product amounted to 2.72 g., m. p. 59.6–65°. Crystallization of 1.00 g. from petroleum ether gave a total 0.90 g. of colorless plates melting between 63 and 67.8°, the first crop, 0.74 g., melting at 67.4–67.8°. A sample recrystallized four times melted at 67.8–68.4° which is in agreement with the m. p. (67.5–68.5°) reported for 3,4-dimethoxybenzylacetophenone (VII).[11]

*Anal.* Calcd. for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71. Found: C, 75.52; H, 6.65.

The oxime crystallized from benzene–petroleum ether (60–68°) in the form of almost colorless prisms, m. p. 109–109.8° (reported,[11] 109°).

The **semicarbazone** was unusually low-melting and sol-

uble in ether. Crystallization from ethyl acetate gave pale yellow needles, m. p. 124.4–125° dec.

*Anal.* Calcd. for $C_{18}H_{21}O_3N_3$: C, 66.04; H, 6.47. Found: C, 65.63; H, 6.63.

In order to test for the presence of 5,6-dimethoxy-1-hydrindone in the acylation experiment, a sample of the crude product was converted to the semicarbazone. The derivative was formed in 96% yield, and although the m. p. (115–120°) indicated some impurity the product was completely soluble in ether indicating the absence of the ether-insoluble semicarbazone of the dimethoxyhydrindone.

In order to discover if 3,4-dimethoxybenzylacetophenone is convertible to 5,6-dimethoxy-1-hydrindone, 1.00 g. of the former was treated with 1.53 g. of aluminum chloride in benzene for twelve hours at room temperature. The mixture was worked up in the usual way yielding 0.53 g. (53% recovery) of neutral material which was fairly pure starting ketone, m. p. 66–67.5°. The remainder of the material was phenolic and appeared in the potassium hydroxide washings. Methylation with dimethyl sulfate gave 0.46 g. (46%) of tan ketone, m. p. 67–68.5° undepressed on admixture with 3,4-dimethoxybenzylacetophenone.

## Summary

The behavior of nine acids of varying susceptibility to ring closure has been studied in connection with a cyclization procedure involving an inverse Friedel–Crafts technique in which a solution of the acid chloride in benzene is added to a suspension of aluminum chloride in benzene. The yields of cyclic ketones were generally excellent, except in the case of 3,4-dimethoxyphenylpropionic acid which was shown to effect intermolecular acylation of the solvent giving 3,4-dimethoxybenzylacetophenone. This unusual behavior may be attributed to an inhibition of resonance by coördination of the catalyst with the methoxyl groups. The weaker coördinating agent, stannic chloride, effects intramolecular acylation giving the cyclic ketone.

# The Synthesis of DL-Threonine.* I. From α-Bromo-β-methoxy-*n*-butyric Acid and Derivatives

BY KARL PFISTER, 3RD., E. E. HOWE, C. A. ROBINSON,[1a] A. C. SHABICA,[1b] E. W. PIETRUSZA[1c] AND MAX TISHLER

Of all the known essential α-amino acids DL-threonine is the most difficult to isolate and to synthesize. The increasing demand for mixtures of the essential amino acids prompted us to evaluate the existing syntheses for DL-threonine with the view of developing a low cost process.

The best-known synthesis of DL-threonine consists in the conversion of crotonic acid into α-bromo-β-methoxy-*n*-butyric acid followed by amination and cleavage of the methoxy group. This sequence of reactions however is complicated by the formation of a mixture of two diastereoisomeric bromo acids, one of which leads to O-methyl-DL-threonine and the other to O-methyl-DL-allothreonine. Of the various reported methods for the preparation of α-bromo-β-methoxy-*n*-butyric acids and their simple derivatives all but one lead to mixtures too poor in the DL-threonine precursor to be useful in the synthesis of this amino acid.

Previous studies of the synthesis of DL-threonine have been handicapped by the facts that no simple separation from DL-allothreonine was known, and no method of analysis of mixtures of the diastereoisomeric amino acids had been developed. The recent description of a microbial assay for L-threonine[2] has greatly simplified the problem. With the aid of this analysis it has become possible to make direct comparisons of the various reported syntheses of DL-threonine and DL-allothreonine and to test the effect of experimental variables and modifications on the relative amounts of the two substances formed in each synthesis. The present paper reports the results of such studies, together with a new practical synthesis of DL-threonine developed in the course of the work.

Until recently the best recorded synthesis of DL-threonine was that of Carter and West.[3] In this method, crotonic acid is treated with mercuric acetate in methanol, and the addition product is brominated. The mixture of bromo acids is aminated, and the reaction products are separated by formylation and isolation of N-formyl-O-methyl-DL-threonine. The latter is converted into pure DL-threonine by boiling hydrobromic acid. The over-all yield of DL-threonine from crotonic acid is about 20%. The yield of DL-threonine from the bromo acid mixture is 30–33% of theory as determined by microbial assay.

Attempts to alter the ratio of diastereoisomeric bromo acids formed by the bromination of α-acetoxymercuri-β-methoxy-*n*-butyric acid were

* This nomenclature is in accord with the rules approved by the American Chemical Society Committee on Nomenclature, Spelling and Pronunciation, as reported by Vickery, *J. Biol. Chem.*, **169**, 237 (1947) and Crane, *Chem. Eng. News*, **25**, 1363 (1947). Throughout this paper the small capital letter prefix will be used in the amino acid sense rather than in the carbohydrate sense. For the sake of brevity however, we have deleted the subscripts which refer to serine, the fundamental substance to which amino acids that bear structural resemblance to the carbohydrates can be formally related.

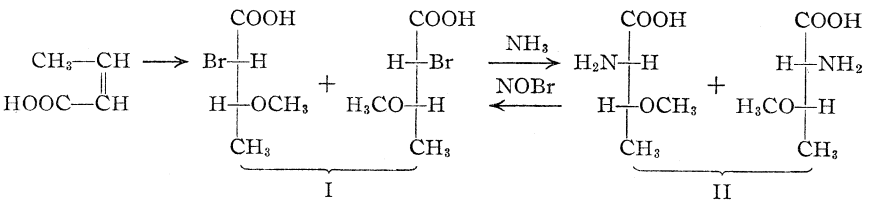
unsuccessful. Bromination in sunlight[3a] or in darkness, variation of the temperature or the reaction time did not significantly affect the ratio of isomers.

It is interesting that the same ratio of bromo acids is obtained when ethyl crotonate is methoxymercurated and the addition product is brominated as when the procedure of Abderhalden and Heyns[3b] is used. This fact was established by hydrolysis of the mixture of bromo esters to the free acids, amination of this mixture, cleaving the methoxy group and estimating microbially the L-threonine content of the mixture of isomers isolated from the cleavage.

Carter and Ney[4] also prepared a mixture of the bromo acids by treatment of ethyl α,β-dibromo-n-butyrate with two moles of sodium methoxide followed by saponification of the bromo esters. According to the authors, the mixed bromo acids on amination form predominantly DL-allothreonine. Microbial assay of the amination mixture (after cleavage of the methoxy group) indicated that DL-threonine is produced from the bromo acid mixture in 20–23% yield. The same results are obtained when ethyl α-bromocrotonate is substituted for ethyl α,β-dibromo-n-butyrate in the above sequence of reactions.



It was of interest to treat ethyl α-bromoisocrotonate with sodium methoxide since the unidirectional addition of methanol should produce a mixture of bromo acids richer in the precursor of DL-threonine.[5] The isolated mixture of amino acids, however, actually contained the same low proportion of DL-threonine as was found when ethyl α-bromocrotonate was the starting material. Both reactions presumably proceed through a common enolate ion.

The addition of the elements of methyl hypobromite to crotonic acid has been shown by West, Krummel and Carter[6] to yield essentially a pure bromo acid, which can be converted into DL-allothreonine. Microbial assays of the mixture resulting from amination of the crude bromo acid and subsequent cleavage indicated a maximum yield of 6–8% DL-threonine.

Since the addition of the elements of methyl hypobromite appears to be predominantly unidirectional, it was of interest to apply the same procedure to isocrotonic acid.[7]

Isocrotonic acid was converted in 80% yield into a crude α-bromo-β-methoxy-n-butyric acid, which on amination and hydrolysis formed DL-threonine in 52–55% yield as determined by microbial assay.[8] DL-Threonine was obtained in a 36% overall yield by isolation of O-methyl-DL-threonine as the N-formyl derivative followed by acid cleavage of the latter. From the mother liquors of the formylation step, a small amount of allothreonine was isolated.

Although the pure bromo acid (m. p. 62–63°) convertible into DL-allothreonine has been prepared,[3b,6] the preparation of the pure α-bromo-β-methoxy-n-butyric acid (I) corresponding to DL-threonine has not been reported. We prepared this compound by treatment of O-methyl-DL-threonine (II) with nitrosyl bromide. This bromo acid is lower melting (m. p. 48–50°) than its diastereoisomer and was converted into DL-threonine in 75% yield (microbial assay) or into pure N-formyl-O-methyl-DL-threonine in 61% yield. DL-Allothreonine could not be detected in the mother liquors. The pure high-melting bromo acid is also prepared by treatment of O-methyl-DL-allothreonine with nitrosyl bromide and on amination forms DL-threonine in only 2% yield (microbial assay). On the basis of these data, the bromo acid obtained from isocrotonic acid consists of about 70% low-melting acid. The presence of the higher melting acid may be due to the ease of isomerization of isocrotonic acid into crotonic acid.[9]

A summary of the amount of DL-threonine formed from the various bromo acid mixtures is presented in Table I. The recorded yields were ascertained by microbial assays of solutions of the different reaction mixtures processed by a standardized procedure described in the Experimental Section.

TABLE I

| Bromo acid mixture | Yield DL-threonine, % |
|---|---|
| West, Krummel and Carter[6] | |
| Crude, undistilled product (77.4% yield) | 6–8 |
| Recrystallized product (m. p. 59–61°) | 2–3 |
| Carter and Ney[4] | 20–23 |
| Carter and West[3a] | 30–33 |
| From isocrotonic acid | 52–55 |
| Pure low-melting bromo acid | 75 |

amination of the resulting low-melting bromo acid, I, evidently a Walden inversion occurs in neither step or in both steps of the cycle. If it is assumed that the carboxyl group does not participate through β-lactone formation,[10] and that the addition of the elements of methyl hypobromite to crotonic and isocrotonic acids occurs in a *trans* fashion; then the bromo acids have the same configuration as the derived amino acids. On this basis, the amination of our bromo acid takes place with retention of configuration. The O-methyl ethers of threonine and allothreonine are similar to valine and isoleucine, which have been shown to undergo no change in configuration when subjected to the action of nitrosyl bromide followed by amination of the bromo acids.[11] Other α-amino acids thus far examined undergo a change of configuration during the cycle of bromination and amination.[12]

A possible means of bringing about inversion during the amination step and thus utilizing the readily available high-melting bromo acid for the preparation of DL-threonine was suggested by the work of Fischer and Scheibler.[11a] These authors found that although the amination of dextrorotatory α-bromoisovaleric acid produced D-valine, conversion of this bromo acid into α-bromoisovalerylglycine followed by amination and hydrolysis of the amide linkage gave L-valine. Similarly Abderhalden and Zeisset[11b] obtained L-isoleucine by amination of (+)-β-bromo-β-methylvaleric acid but L-alloisoleucine on amination and hydrolysis of the glycine derivative of the same bromo acid.

A series of amide derivatives of the two diastereomeric forms of α-bromo-β-methoxy-*n*-butyric acid were prepared and aminated. The various amides studied are listed in Table II. As indicated in Table III, the amides behave toward amination differently from the free bromo acids. DL-Threonine was formed in significant yield from each of the amides of the higher melting bromo acid. The piperidide of this acid was studied most thoroughly; since it is readily isolated in a pure state and is converted into pure DL-threonine by amination, followed by cleavage of the methoxy group and hydrolysis of the amide linkage. The yields in the amination and in the subsequent steps are good, and the method constitutes a practical synthesis of DL-threonine.

The formation of DL-threonine from the amides of the high melting bromo acid indicates that amination occurred with inversion, and that with the piperidide the inversion was complete or nearly so. Inversion also occurs when the amides of the low melting bromo acid are aminated although the degree of inversion has not been ascertained. The anilide and piperidide of the low melting bromo acid on amination gave DL-threonine in 44.8 and 33.8% yield, respectively (micro-

[a] These figures were obtained by microbial assay of aliquots of the solutions obtained after hydrolysis of the amination products. [b] These yields are for analytically pure DL-threonine-DL-allothreonine mixtures. [c] Same result obtained whether aminated with methanol–liquid ammonia or aqueous ammonia. [d] After eight hours of hydrolysis the % yield of DL-threonine was only 42.5%. [e] Aminated twenty-four hours at 75° instead of 100° as were all other aminations.

bial assay), whereas the parent acid forms DL-threonine in 75% yield.

The difference in behavior of the bromo amides from the bromo acids in the ammonia replacement reaction indicates that the carboxyl ion plays a role that is suppressed when ionization is blocked. The "neighboring group" effect[13] is probably involved.

It is interesting to note that the bromo acids corresponding to threonine, valine and isoleucine have a substituent on the β-carbon atoms. This fact may be responsible for the difference in amination behavior of these α-bromo acids as compared to others. Before the nature of the stereochemical transformation can be definitely described, a kinetic study will be required to determine the reaction order.

## Experimental

**Amination of Bromo Acid Mixtures.**—For purposes of comparison, the various bromo acid mixtures were prepared as described in the literature. Amination, hydrolysis and microbial assay as described below gave the values reported in Table I.

Five grams of bromo acid mixture in 55 cc. of concd. ammonium hydroxide was heated at 100° for two hours. This solution was concentrated to dryness under reduced pressure, and the residue was redissolved in water and again concentrated. The residue was hydrolyzed by refluxing for two hours with 17.5 cc. of 40% hydrobromic acid. A solution for microbial assay was prepared by concentrating to dryness, dissolving in water and again concentrating to remove excess acid, adjusting *p*H to neutral, filtering and diluting.

**α-Bromoisocrotonic Acid.**—The method of Michael and Schulthess[14] was employed for preparing α-bromoisocrotonic acid, m. p. 92–93°, in 54% yield from crotonic acid. α-Bromoisocrotonic acid is reported to melt at 92° and α-bromocrotonic acid at 106.5°.

**Ethyl α-Bromoisocrotonate.**—α-Bromoisocrotonic acid was esterified according to the method of Auwers and Harres[15] with ethanol in the presence of sulfuric acid. Twice distilled product boiling at 72–73.5° (12 mm.) was obtained in 57% yield. A sample of the ester on hydrolysis gave pure α-bromoisocrotonic acid, which indicated that no isomerization had occurred.

**Ethyl α-Bromo-β-methoxybutyrate.**—To a vigorously agitated solution of 110 cc. of methanol containing 1.4 g. (0.03 mole) of sodium methoxide, 43 g. (0.223 mole) of ethyl α-bromoisocrotonate was slowly added while the temperature was held below 25°. The reaction mixture was agitated for an additional two hours and then poured into 250 cc. of ice water containing 5-cc. of concentrated hydrochloric acid. The ester layer was separated, and the aqueous phase was extracted with three 60-cc. portions of ether. The combined ester layer and ether extracts were washed once with a saturated solution of calcium chloride and dried with sodium sulfate. The ether was removed by evaporation, and the ester was distilled at reduced pressure. A product boiling at 85–87° (18 mm.) was obtained in 79% yield (39.3 g.).

This ester after saponification, amination, and cleavage with hydrobromic acid gave in 31% yield a mixture of DL-threonine and DL-allothreonine in an 18:82 ratio (microbial assay).

**Isocrotonic Acid.**—This material was prepared according to the procedure of Michael and Schulthess[14] by action of phosphorus pentachloride on acetoacetic ester to produce β-chlorocrotonic (18–20% yield) and β-chloroisocrotonic (29–30% yield) acid, which are separable by steam distillation. Reduction of the latter with sodium amalgam gave isocrotonic acid in 50% yield after purification as the sodium salt and distillation. Isocrotonic acid was also prepared by conversion of β-chlorocrotonic acid into tetrolic acid[16] (20–30% yield) followed by hydrogenation with palladium on Norit (75% yield).[17] All isocrotonic acid used was carefully separated from crotonic acid via the sodium salts and then distilled, b.p. 70–71° (16–17 mm.), m. p. 12–15°.

**α-Bromo-β-methoxy-n-butyric Acid from Isocrotonic Acid.**—A run was made exactly as described by West, Krummel and Carter,[6] but isocrotonic was substituted for crotonic acid. The yield of crude α-bromo-β-methoxy-*n*-butyric acid obtained as an oil by concentrating the ether solution to constant weight was 79.8% of theory. When crotonic acid was used, the crude product resulted in nearly identical yield (77.4%).

**Pure Low-melting α-Bromo-β-methoxy-n-butyric Acid from O-Methyl-DL-threonine.**—Pure N-formyl-O-methyl-DL-threonine[3a] (100 g., 0.621 mole) was refluxed for three hours with 1 l. of 1 *N* hydrobromic acid. The resulting solution of O-methyl-DL-threonine was concentrated under reduced pressure, and the gummy residue was dissolved in 200 cc. of water and again concentrated to dryness. The residue was dissolved in 1240 cc. of 2.5 *N* sulfuric acid containing 250 g. of potassium bromide. The solution was cooled to 0° and stirred while 65.5 g. of sodium nitrite was added in small portions over a period of one and one-half hours. The solution was stirred for an hour at 0°, then heated to 25° and stirred another hour. Ether extraction followed by washing with water, drying over sodium sulfate and concentrating gave α-bromo-β-methoxy-*n*-butyric acid (113.9 g., 93.7%). Fractional distillation yielded chiefly material (101 g.) that distilled at 126–128° (6 mm.) and on cooling gave a solid of m. p. 48–50°.

*Anal.* Calcd. for $C_5H_9O_3Br$: C, 30.48; H, 4.61. Found: C, 30.25; H, 4.65.

**N-Formyl-O-methyl-DL-threonine.**—The bromo acid (45.0 g., 0.228 mole) from isocrotonic acid and 495 cc. of concentrated aqueous ammonia were heated at 100° in an autoclave for two hours. Exactly 10% of the resulting solution was concentrated to dryness; the residue was dissolved in water and again concentrated to dryness. This residue was refluxed for two hours with 15.5 cc. of 40% hydrobromic acid and the resulting solution concentrated to dryness as described above. The residue was again taken up in water and the solution diluted to 100 cc. for microbial assay. Found: 14.1 mg. of DL-threonine/cc. or a total of 14.1 g. or 51.8%. The remaining 90% of the amination mixture was concentrated to dryness, diluted with 30 cc. of water and again concentrated to dryness. A solution of the solid white residue in 101 cc. of 88% formic acid at 45° was treated dropwise with 33.8 cc. of acetic anhydride. The addition took fifteen minutes, and the temperature rose to 60°. After fifteen minutes at 60°, concentration gave a residue, which was dissolved in 40 cc. of water and again concentrated to dryness. The residue was dissolved in 35 cc. of hot water and cooled to 0° for several hours. Filtration gave crude N-formyl-O-methyl-DL-threonine of m. p. 164–168° in 51.8% yield. Recrystallization of this material from water gave N-formyl-O-methyl-DL-threonine of m. p. 176–177.5° in two crops totaling 40.8% yield from the bromo acid.

The combined mother liquors were concentrated, and the residue dissolved in 84 cc. of 40% hydrobromic acid was refluxed for two hours. The mixture was concentrated to dryness, and the dried residue was extracted with 200 cc. of ethyl alcohol. The alcoholic solution was made alkaline with concentrated ammonia, and a small precipitate of inorganic material was filtered. On standing overnight at 0°, the filtrate deposited crystalline material (8.1 g.), which was recrystallized from 10 cc. of hot water and 23 cc. of alcohol. This product (3.4 g.) was again

(13) Defined and studied by S. Winstein and his students. The more recent papers are Winstein and Seymour, THIS JOURNAL, **68**, 119 (1946); Winstein and Grunwald, *ibid.*, **68**, 536 (1946).

recrystallized from water–alcohol to give a mixture of DL-threonine and DL-allothreonine melting at 213–214° (2.4 g., 9.8% yield).

*Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62. Found: C, 40.19; H, 7.59.

Since bioassay showed this material was 60% DL-threonine, the isolated yield of DL-allothreonine was 3.9%.

When the pure low melting (m. p. 48–50°) α-bromo-β-methoxy-*n*-butyric acid was subjected to the above amination steps, the yield of DL-threonine (microbial assay) was 75%. Application of the formylation step gave N-formyl-O-methyl-DL-threonine melting at 176–178° (no recrystallization) in 60.3% yield. When the mother liquors of the formylation step were hydrolyzed with hydrobromic acid, more pure DL-threonine was isolated (9% yield). No DL-allothreonine could be detected.

**Amides of α-Bromo-β-methoxy-*n*-butyric Acid.**—These derivatives were prepared essentially by the procedure described below for the piperidide of the high-melting bromo acid. Analyses and some physical properties of these derivatives are listed in Table II. The high melting acid employed in this work was the crude acid obtained by the procedure of West, Krummel and Carter,[6] whereas the low-melting acid was prepared from O-methyl-DL-threonine by the nitrosyl bromide reaction (b. p. 126–128° (6 mm.). The solid amides were recrystallized from benzene or Skelly-solve D.

**α-Bromo-β-methoxy-*n*-butyric Acid Piperidide.**—A mixture of 29.6 g. (0.15 mole) of high melting α-bromo-β-methoxy-*n*-butyric acid, 150 cc. benzene and 2 drops of pyridine was treated with 13.5 cc. of thionyl chloride and then refluxed for one and one-half hours. The mixture was concentrated under reduced pressure until 50 cc. of benzene was removed. After addition of 100 cc. of benzene, the solution was cooled to 5° and added dropwise at 4–5° over a period of one and one-fourth hours to an ice-cooled solution of 32.5 cc. (0.33 mole) of piperidine in 100 cc. of benzene. After removal of the ice-bath the mixture was stirred one-half hour before the piperidine hydrochloride was filtered.

The benzene solution was extracted with three 50-cc. portions of water and then concentrated under reduced pressure to constant weight, 36.1 g. (91.2%). The yellow oil crystallized on standing at 5° but became sticky at room temperature. The crude product was recrystallized from 20 cc. of Skelly-solve D, refrigerated overnight and filtered on a pre-cooled Buchner funnel. After being washed with a small amount of ice-cold Skelly-solve and dried, the product weighed 26.8 g. (67.7%), m. p. 41–43°. This piperidide is soluble in all the common solvents except water.

**Amination of the Bromo Amides.**—The amination of the bromo amides was carried out by the procedure described below for the piperidide of the high-melting bromo acid except that the reaction temperature was 100°. In every case, Volhard titration of the completed reaction mixture showed that over 98% of the organic bromine had been converted into bromide ion. A hydrolysis time of fifteen hours was found to give DL-threonine in maximum yields.

**DL-Threonine.**—A solution of 13.2 g. (0.05 mole) of the piperidide of the high-melting bromo acid in 60 cc. of methanol and 30 cc. of liquid ammonia was heated at 75° for twenty-four hours in a glass-lined bomb.

The solution was concentrated under reduced pressure and the residue refluxed with 40 cc. of 40% hydrobromic acid for fifteen hours. After the reaction mixture was concentrated to dryness water was added and again removed. This operation was repeated after which the residue was dissolved in 40 cc. of water and made alkaline with concentrated ammonium hydroxide solution. Piperidine was removed by extraction with ether and a sample of the aqueous solution taken for bioassay. Found: 63.7% of theoretical yield of DL-threonine.

The remaining solution was made acid to congo red with concentrated hydrochloric acid and concentrated to dryness. The residue was extracted with three 25-cc. portions of boiling isopropyl alcohol. After cooling a little more inorganic material precipitated in the isopropyl alcohol extract and was removed by filtration. Aniline (7.8 cc.) was added to the warm isopropyl alcohol solution, and the resulting slurry was stirred overnight at room temperature. The white product was filtered, washed with isopropyl alcohol and ether, and dried at 65°; yield, 3.8 g. (74.8%). The crude product was recrystallized by the addition of 45 cc. of isopropyl alcohol to a vigorously agitated solution in 19 cc. of hot water. After being chilled overnight DL-threonine was obtained (2.96 g., 58.2% from the piperidide).

*Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76. Found: C, 40.03; H, 7.70; N, 11.96.

Microbial assay indicated this material was 100% pure, while solubility analysis showed a purity of over 97%.

**Acknowledgment.**—We are indebted to Mr. R. N. Boos for the microanalytical data and to Dr. J. L. Stokes for the microbial assays.

## Summary

1. An evaluation of the previously described α-bromo-β-methoxy-*n*-butyric acid mixtures for the preparation of DL-threonine has been made.

2. DL-Threonine has been prepared from isocrotonic acid in substantially higher yields than from crotonic acid through the corresponding α-bromo-β-methoxy-*n*-butyric acids.

3. Evidence indicating that a Walden inversion does not occur during the amination of α-bromo-β-methoxy-*n*-butyric acid is presented. Amination of the amides of the bromo acid takes place with inversion.

4. A practical synthesis of DL-threonine from the piperidide of the readily available, high-melting α-bromo-β-methoxy-*n*-butyric acid is described.

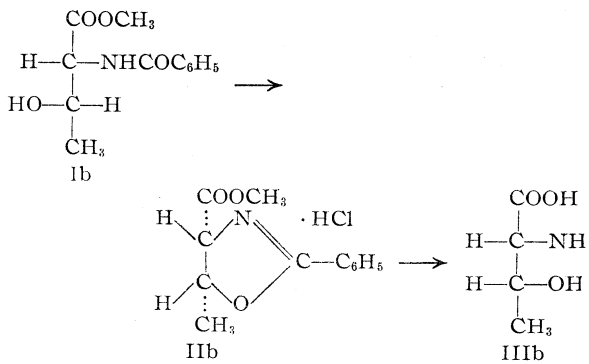
# The Synthesis of DL-Threonine. II. Interconversion of DL-Threonine and DL-Allothreonine[1]

BY KARL PFISTER, 3RD., C. A. ROBINSON,[2a] A. C. SHABICA[2b] AND MAX TISHLER

In connection with a search for more practical syntheses of DL-threonine, useful methods of converting the more readily available DL-allothreonine into its epimer were sought. A method of effecting the inversion was discovered and announced in a preliminary communication.[3] While that paper was in press a report[4a] in the recent British literature on the same subject reached this country, and was followed later by a second article.[4b] We wish to elaborate at this time our previous communication on the method for the interconversion of DL-allothreonine and DL-threonine, which is also the basis of a higher yielding synthesis of the latter.



The reaction of $\alpha$-acylamido-$\beta$-hydroxy compounds with dehydrating agents such as thionyl chloride and phosphorus chlorides to give oxazolines is of general application.[5] Accordingly, 2-phenyl-5-methyl-4-carbomethoxyoxazoline hydrochloride,[6] IIa, was prepared in quantitative yield by treatment of the methyl ester of N-benzoyl-DL-allothreonine, Ia, with thionyl chloride. The oxazoline, IIa, on treatment with dilute mineral acids gave DL-threonine, IIIa, in 96.7% yield as determined by microbial assay and in 70% yield as isolated pure material.

Ia IIa IIIa

The hydrolysis of the oxazoline, IIa, can be carried out stepwise. When a water solution is refluxed one hour, the methyl ester of O-benzoyl-DL-threonine hydrochloride is obtained in excellent yield. The latter is converted into DL-threonine by acid hydrolysis and is rearranged to N-benzoyl-DL-threonine by treatment with alkali.

The inversion described can be utilized to convert DL-threonine into DL-allothreonine. By the same series of reactions, DL-threonine was converted via N-benzoyl-DL-threonine methyl ester, Ib, and the isomeric 2-phenyl-5-methyl-4-carbomethoxyoxazoline hydrochloride, IIb, into DL-allothreonine, IIIb. The yield of isolated product from the oxazoline, IIb, was 81%.

Ib IIb IIIb

We overlooked the important observation made by Elliot[4b] that the oxazoline made from threonine, IIb, can be converted into the more stable isomeric oxazoline, IIa, by treatment with alkali. We did note that both isomers were sensitive to alkali; since on heating with 2.5 *N* sodium hydroxide for four hours, the yield of DL-threonine in each case was about 27% as determined by microbial assay. In agreement with Elliot, we also observed that when the ethyl ester of DL-allothreonine hydrochloride was treated with benzylimido ethyl ether and the resulting oxazoline subjected to acid hydrolysis, no threonine was formed.

Masking of the carboxyl group during oxazoline formation is necessary, since otherwise azlactonization occurs. Thus, after treatment of N-benzoyl-DL-allothreonine with thionyl chloride, only the azlactone, 2-phenyl-4-ethylidene-5-oxazolone, could be isolated. Hydrolysis of the reaction mixture from such treatment followed by microbial assay showed DL-threonine in less than 1.7% of the theoretical yield, indicating that oxazoline formation was entirely suppressed.

The formation of an oxazoline hydrochloride from N-acyl derivatives of DL-serine and some chemical properties of this oxazoline have been

(6) All configurational formulations in this paper are in accord with Fischer's conventions. To effect economy of space only one enantiomorph is given although it should be understood that the second enantiomorph is included when the text refers to the DL-form. The stereochemical formulations for the oxazolines (IIa, IIb and VII) are those suggested by the English workers.[4]

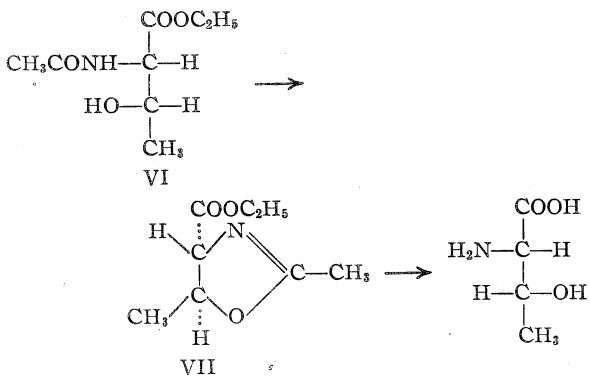
described by Bergmann.[7] Since serine contains only one asymmetric carbon atom, the full significance of this series of reactions was not realized. Nagai and Kanao,[8] however, did convert *dl*-N-benzoyl-norephedrine through the oxazoline into the diastereomeric *dl*-N-benzoyl-norisoephedrine. The latter report and the additional data we shall present in a later publication indicate the method is a general one for the interconversion of diastereoisomers containing an amino and a hydroxyl group on adjacent asymmetric carbon atoms.

The successful utilization of the oxazoline inversion reaction for a practical, total synthesis of DL-threonine requires an easy method for the preparation of esters of N-acyl derivatives of allothreonine. Acetoacetic ester proved to be an excellent starting point for this synthesis.

Ethyl α-acetamidoacetoacetate, V, was obtained in 88% yield from acetoacetic ester by the preparation and reductive acetylation of ethyl α-phenylazoacetoacetate, IV.

IV V

The preparation of this acetamido compound by the reductive acetylation of ethyl α-oximinoacetoacetate has been reported recently.[9] The present method is preferred, since the use of the unstable oximino compound is avoided, and a better over-all yield is obtained.[10]



The behavior of ethyl α-acetamidoacetoacetate toward catalytic hydrogenation was studied, since Adkins and Reeve[11] reported that a mixture of DL-threonine and DL-allothreonine was obtained on catalytic hydrogenation and subsequent hydrolysis of ethyl α-oximinoacetoacetate. A variety of hydrogenation procedures were tried and appraised by hydrolysis of the reaction mixture and determination of the DL-threonine content microbiologically. The results, listed in Table I, are similar to those reported by Albertson and co-workers[9] and establish the fact that the ethyl ester of N-acetyl-DL-allothreonine is formed predominantly.

TABLE I

| Catalyst | Solvent | DL-Threonine, % yield |
|---|---|---|
| Platinum oxide | Water | 15–20 |
| Platinum oxide | Glacial acetic acid | 19 |
| Platinum oxide | Alcohol | 26 |
| Raney nickel[a] | Water | 30 |
| Raney nickel | Water | 34 |

[a] This run was made at high pressure; all others at 15–40 p.s.i.

By the use of platinum oxide in aqueous solution, ethyl α-acetamidoacetoacetate was readily hydrogenated at room temperature and low pressure to give in theoretical yield a colorless oil having an 80–85% content of N-acetyl-DL-allothreonine ethyl ester. An identical product was also obtainable by catalytic reductive acetylation of ethyl α-phenylazoacetoacetate, removal of acetanilide and further hydrogenation. Repeated crystallization gave pure N-acetyl-DL-allothreonine ethyl ester (VI). Hydrolysis of this material and microbial assay of the solution showed DL-threonine in only a 0.7% yield. When the purified N-acetyl-DL-allothreonine ester was treated with thionyl chloride, the oxazoline VII was obtained. Acid hydrolysis of VII produced DL-threonine in 94.6% yield as established by microbial assay.

VI VII

When the entire hydrogenation product was treated with thionyl chloride and the oxazoline-containing reaction solution was hydrolyzed, crude DL-threonine of 83.2% purity (bioassay) was isolated in 88.7% yield. Simple crystallization in this case failed to yield DL-threonine free from contaminating DL-allothreonine produced by inversion of the N-acetyl-DL-threonine ethyl ester in the hydrogenation product. In order to avoid wasteful recrystallization of the hydrogenation product, it was necessary to devise a separation of the diastereoisomeric amino acids. Although a number of procedures are available for separating various derivatives of DL-threonine and DL-allothreonine,[12] none have been reported for the unsubstituted amino acids. We have found that the sodium salt of DL-threonine is far less soluble in ethanol than that of DL-allothreonine and is, in fact, well-suited to separation of these isomers. By this method the crude DL-threonine obtained without purification of the hydrogenation product was converted into pure DL-threonine sodium salt in 83.5% yield. Reconversion into DL-threonine in 91% yield followed by a recrystallization (96.8% recovery)

gave pure DL-threonine in 57% over-all yield from acetoacetic ester.

The oxazoline, VII, was found to be similar in chemical reactivity to the phenylated oxazoline, IIa. Its hydrochloride was converted into O-acetyl-DL-threonine ethyl ester hydrochloride on exposure to moist air. On treatment with alkali, the latter was transformed into N-acetyl-DL-threonine. Other reactions are described in the experimental section.

A study of the inversion mechanism using optically active compounds is under way. Our data support the views of the English investigators[4] that inversion occurs during ring closure involving the $\beta$-carbon atom. The oxazoline, convertible into DL-threonine by hydrolysis, has the same *trans* configuration as threonine, whereas the isomeric oxazoline has the *cis* configuration.

## Experimental

### I. Conversion of DL-Allothreonine into DL-Threonine

**N-Benzoyl-DL-allothreonine Methyl Ester, I.**—N-Benzoyl-DL-allothreonine[13] was treated with an ether solution containing an excess of diazomethane. After evaporation of solvent and reagent, the crystalline ester, m. p. 109–110°, remained. A sample crystallized from benzene in rosettes of needles, m. p. 110–111°.

*Anal.* Calcd. for $C_{12}H_{15}O_4N$: C, 60.76; H, 6.37. Found: C, 60.86; H, 5.99.

**2-Phenyl-5-methyl-4-carbomethoxyoxazoline Hydrochloride, IIa.**—The crude methyl ester from above (2.37 g.) was added in portions to 6.0 cc. of ice-cold thionyl chloride. A little heat was evolved, and the solution was allowed to stand at room temperature for two hours. The solution was poured into 150 cc. of absolute ether; the precipitated gum crystallized when scratched. The yield after filtering, washing with ether and drying was 2.55 g. (quantitative); m. p. 117–118° with HCl evolution.

Solution in cold dry chloroform (5 cc./g.) and precipitation with absolute ether (15 cc./g.) gave material that melted at 118–119° on rapid heating from 110°.

*Anal.* Calcd. for $C_{12}H_{13}O_3N\cdot HCl$: C, 56.36; H, 5.52. Found: C, 56.50; H, 5.71.

**DL-Threonine.**—Two grams of crude oxazoline IIa in 20 cc. of 10% hydrochloric acid was refluxed three hours. After the solution was cooled in ice for one-half hour the benzoic acid was removed by filtration (73.4% yield, m. p. 120–121°), and the filtrate was concentrated to dryness on an aspirator. The residue was again dissolved in water and concentrated, and the residue was taken up in water for microbial assay. The assay showed the presence of DL-threonine in 96.7% yield (0.90 g.).

Two-thirds of the bioassay solution was concentrated to dryness as described above, taken up in alcohol and again concentrated. The residue was dissolved in 15 cc. of warm anhydrous alcohol and the solution made alkaline to litmus with ammonium hydroxide. The crystalline product (0.75 g.) was dissolved in 4 cc. of water, and the solution was diluted with 9.3 cc. of alcohol. After four hours at 5°, the crystalline DL-threonine was filtered, washed with alcohol and ether, and dried. The product weighed 0.435 g. (70.1% yield) and melted at 229–230°.

*Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76. Found: C, 40.35; H, 7.70; N, 11.46.

Bioassay showed this material was 100% DL-threonine.

**O-Benzoyl-DL-threonine Methyl Ester Hydrochloride.**—Crude oxazoline hydrochloride IIa (1.28 g.) was refluxed for one hour in 10 cc. of water. The solution was concentrated under reduced pressure and the residue dissolved in chloroform was again concentrated to ensure the absence of water. A solution of the residue in 10 cc. of chloroform was treated with Norit, filtered and diluted with 20 cc. of absolute ether. The nicely crystalline precipitate weighed 1.2 g. (87.5%) and melted at 151–153°. Reprecipitation of a sample as above gave a product sintering at 145° and melting at 155–156° with gas evolution.

*Anal.* Calcd. for $C_{12}H_{15}O_4N\cdot HCl$: C, 52.66; H, 5.89; N, 5.12. Found: C, 52.60; H, 6.06; N, 5.37.

A solution of 0.25 g. in 3 cc. of 10% hydrochloric acid was boiled three hours, concentrated to dryness, and the residue was dissolved in water for microbial assay. Found: 0.105 g. of DL-threonine (88.3% yield).

N-Benzoyl-DL-threonine was obtained in 69% yield from the methyl ester of O-benzoyl-DL-threonine hydrochloride by storing a solution of the latter (0.5 g.) in 4.75 cc. of normal sodium hydroxide for fifteen hours. The resulting mixture was made acid to congo paper with hydrochloric acid and refrigerated for four hours. The product was obtained as needles, m. p. 145–146°; wt. 0.28 g., and was identified as N-benzoyl-DL-threonine by a mixed m. p. determination with an authentic sample.

**Benzoyl-$\alpha$-aminocrotonic Azlactone.**—A mixture of 2.33 g. of N-benzoyl-DL-allothreonine and 6 cc. of thionyl chloride was held at room temperature for two hours. The mixture was diluted with 50 cc. of ether, and the crystalline solid (0.35 g., m. p. 85–86°) was collected. After recrystallization from dilute alcohol, the product melted at 89–92° and did not depress the m. p. of an authentic sample of the "Azlactone I" described by Carter, Handler and Melville.[14]

A similar run was worked up by subjecting the completed reaction mixture to hydrolysis with 10% hydrochloric acid, separation of benzoic acid and microbial assay. The yield of DL-threonine was less than 1.7%.

### II. Conversion of DL-Threonine into DL-Allothreonine

**N-Benzoyl-DL-threonine Methyl Ester.**—A sample of N-benzoyl-DL-threonine treated with ethereal diazomethane and concentrated to dryness gave a viscous oil, which slowly crystallized, m. p. 82–84°. Recrystallization of a sample from benzene–ether did not change the melting point.

*Anal.* Calcd. for $C_{12}H_{14}O_4N$: C, 60.76; H, 6.37. Found: C, 60.97; H, 6.50.

The product is very sparingly soluble in ether or hot ligroin (b. p. 80–115°), but dissolves readily in benzene, alcohols or hot water.

**2-Phenyl-5-methyl-4-carbomethoxyoxazoline Hydrochloride, IIb.**—Treatment of N-benzoyl-DL-threonine methyl ester exactly as described for the N-benzoyl-DL-allothreonine ester gave material of m. p. 130–131° (2.45 g., 96%). A sample purified by precipitation from chloroform with ether melted at 131–132° (capillary inserted at 120°).

*Anal.* Calcd. for $C_{12}H_{13}O_3N\cdot HCl$: C, 56.36; H, 5.52. Found: C, 56.58; H, 4.91.

A mixture of IIb with pure oxazoline IIa (m. p. 118–119°) melted lower than the latter alone.

The oxazoline was converted into pure DL-allothreonine in 80.6% yield in the same way as the oxazoline IIa was transformed into DL-threonine. Microbial assays of a solution of the hydrolyzed oxazoline indicated less than 0.8% yield of DL-threonine.

### III. Synthesis of DL-Threonine from Acetoacetic Ester

**Ethyl $\alpha$-Phenylazoacetoacetate, IV.**—This intermediate was prepared in 92.7% yield from acetoacetic ester essentially by the method of Bülow and Neber.[15]

**Ethyl $\alpha$-Acetamidoacetoacetate, V.**—A mixture of glacial acetic acid (513 cc.) and acetic anhydride (257 cc.

(13) West and Carter, *J. Biol. Chem.*, **119**, 109 (1937).

(14) Carter, Handler and Melville, *ibid.*, **129**, 359 (1939).

(15) Bülow and Neber, *Ber.*, **45**, 3732 (1912).

was cooled to 10°, and 390 g. of zinc dust was added to the vigorously stirred solution. While the temperature was kept at 10–15°, a solution of 217.4 g. (0.927 mole) of ethyl α-phenylazoacetoacetate in 232 cc. of glacial acetic acid was added over one and one-half to two hours. The mixture was then allowed to warm to 25–30°, and stirring was continued for three hours. The slurry was filtered and the cake of zinc dust and zinc acetate washed well with glacial acetic acid. Concentration of the filtrate and washings under reduced pressure gave a residue to which was added 500 cc. of water at 55°. After being stirred for five minutes the mixture was cooled to 10°, and the remaining acetic acid was neutralized with solid sodium bicarbonate. The mixture was held at 0° for one-half hour, and the acetanilide (113.5 g., 91% yield) was collected.

The filtrate was extracted with four 250-cc. portions of chloroform, and the combined extracts were concentrated to dryness under reduced pressure. The viscous residue weighed 164.2 g. (94.6% yield) and solidified on standing; m. p. 39–42°.

A sample recrystallized from toluene melted at 47.5–48.5°.

*Anal.* Calcd. for $C_8H_{13}O_4N$: C, 51.34; H, 6.95. Found: C, 51.56; H, 7.08.

**Ethyl α-Acetamido-β-hydroxybutyrate, VI. (a) From Ethyl α-Acetamidoacetoacetate.**—A solution of 65.5 g. (0.35 mole) of ethyl α-acetamidoacetoacetate in 525 cc. of water was made barely alkaline by adding 5 cc. of 1 *N* sodium hydroxide and hydrogenated at 25° and 30–40 p. s. i. in the presence of 0.65 g. of platinum oxide catalyst. The theoretical amount of hydrogen was absorbed in four hours, and a ferric chloride test at this point was negative. After separation of the catalyst the filtrate was concentrated to dryness on the water aspirator and the residue dissolved in benzene and reconcentrated to constant weight. The thick, colorless oil (33.2 g.) is readily soluble in water, chloroform and alcohol, somewhat less soluble in benzene and ethyl acetate, and sparingly soluble in ether, toluene and carbon tetrachloride.

A considerable number of such reductions were made, and aliquots were hydrolyzed with hydrochloric acid and assayed microbiologically for DL-threonine. The assays fixed the DL-threonine yield as 15 to 20%, corresponding to a 15–20% content of N-acetyl-DL-threonine ethyl ester in the hydrogenation product.

The hydrogenation of ethyl α-acetamidoacetoacetate under other conditions was studied. As indicated in Table I, the yield of N-acetyl-DL-threonine ethyl ester does vary with the catalyst, solvent and temperature. Raney nickel at low pressure favors the formation of threonine. The yield of DL-threonine was established by microbial assays.

**(b) From Ethyl α-Phenylazoacetoacetate.**—A solution of ethyl α-phenylazoacetoacetate (36.5 g.) in 156 cc. of glacial acetic acid was treated with 0.5 g. of Darco and filtered. After the addition of 36.8 cc. of acetic anhydride and 4.0 g. of 5% palladium on Darco the solution was hydrogenated at room temperature and 25–40 p. s. i. Two moles of hydrogen were absorbed in six hours. The solution was filtered and concentrated to dryness. Two additions of water followed by concentration to dryness (reduced pressure) removed most of the acetic acid. The reddish oil was treated with 117 cc. of water, stirred at 0° for one-half hour, and the crystalline acetanilide was collected; wt. 19.3 g. (92% yield).

The filtrate was neutralized with sodium hydroxide, treated with charcoal and hydrogenated at room temperature and 25–40 p. s. i. in the presence of 0.3 g. of platinum oxide. The hydrogenation was slow, and only after fifteen hours was the ferric chloride test negative. Filtration and concentration of the reduced mixture gave the same type of product as above with acetanilide as a contaminant. Microbial assay of a hydrolyzed aliquot established a 15.8% yield of N-acetyl-DL-threonine ethyl ester.

**DL-Threonine. (a) From Partially Purified N-Acetyl-DL-allothreonine Ethyl Ester.**—The residue obtained from the reduction of 32.8 g. of ethyl α-acetamidoacetoacetate carried out and worked up in the manner described above was dissolved in 25 cc. of hot ethyl acetate and allowed to crystallize at 5° for sixteen hours. The product was filtered, washed with 5 cc. of cold ethyl acetate and dried; wt. 17.5 g. (52.8% recovery), m. p. 68–74°. (According to the microbial assay procedure, the product contained 3.6% of the DL-threonine precursor.) Repeated recrystallizations from ethyl acetate gave pure ester as large rectangular prisms melting at 76–77°.

*Anal.* Calcd. for $C_8H_{15}O_4N$: C, 50.78; H, 7.99. Found: C, 50.54; H, 8.04.

A solution of 16.0 g. of the partially purified ester (m. p. 68–74°) in 17.3 cc. of benzene was cooled to 10° and stirred; thionyl chloride (14 cc.) was added dropwise while the temperature was kept at 13–15°. After the addition (three-fourths hour) the temperature was raised to 30° and held there for an hour. The solution was cooled to below 10° while 43 cc. of cold water was added slowly. The layers were separated and the benzene layer extracted twice with 12-cc. portions of water. The combined aqueous extracts were washed with 5 cc. of benzene and refluxed for two and one-half hours. After treatment with charcoal, an aliquot was subjected to the microbial assay procedure. The assay yield of DL-threonine was 88.5%.

The remainder of the reaction mixture was concentrated to dryness under reduced pressure. The colorless residue was dissolved in 62 cc. of hot isopropyl alcohol, and 15 cc. of aniline was added to the solution. The mixture was agitated at room temperature for fourteen hours and filtered. The product (8.65 g., 89.4% yield) was found to be 98.6% DL-threonine by microbial assay. Recrystallization of 6.1 g. from 30.5 cc. of water and 71 cc. of absolute ethanol gave pure product; 5.5 g., 90.2% recovery, 37.6% yield from ethyl acetoacetate, m. p. 229–230°, bioassay 100%.

*Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62. Found: C, 40.46; H, 7.64.

When the pure ester (m. p. 76–77°) was subjected to the cyclization reaction, the yield of DL-threonine was 94.6% as established by the microbial assay.

**(b) From Crude Ethyl α-Acetamido-β-hydroxybutyrate.**—Ethyl α-acetamidoacetoacetate (29.1 g.) was hydrogenated as described above, and the residual oil in 32 cc. of benzene was treated with 25.9 cc. of thionyl chloride. The reaction mixture was worked up and hydrolyzed in the manner just described. The solid residue of threonine and allothreonine hydrochloride was dissolved in 116 cc. of hot isopropyl alcohol and precipitated by the addition of 28.2 cc. of aniline. The crystalline product weighed 16.4 g. (88.7% yield) and contained 83.2% DL-threonine (microbial assay).

For elimination of DL-allothreonine, 15.6 g. (0.131 mole) of this product was added to a hot solution of sodium ethoxide prepared from 3.02 g. (0.131 mole) of sodium and 60.4 cc. of anhydrous alcohol. The mixture was refluxed for five minutes to ensure complete solution. Shortly thereafter the crystalline sodium salt of DL-threonine separated. After storage for sixteen hours at room temperature the salt was collected, washed with 15 cc. of alcohol and dried at 50–55°; wt. 15.43 g.; 83.5% yield. Fifteen grams (0.106 mole) of sodium salt was added to 18.5 cc. (0.222 mole) of ice-cold concentrated hydrochloric acid, and while the solution was stirred 120 cc. of isopropyl alcohol was added. The mixture was heated to 60° to ensure completion of reaction and then refrigerated for twelve hours. The sodium chloride was filtered, and the filtrate was treated with 20.4 cc. of aniline and held at 5° for sixteen hours. The product (11.5 g., 91% yield) was recrystallized by solution in 28.8 cc. of hot water and dilution with 86 cc. warm ethanol. After refrigeration for twelve hours, the pure DL-threonine was collected; wt. 11.14 g.; 96.8% recovery; yield from ethyl acetoacetate, 57.2%.

*Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76. Found: C, 40.42; H, 7.32; N, 11.82.

**This material was 100% pure by microbial assay and 99.6% pure by solubility analysis.**

**Hydrolysis of N-Acetyl-DL-allothreonine Ethyl Ester.**—For complete identification of this compound, hydrolysis to N-acetyl-DL-allothreonine was carried out. A mixture of 1.69 g. of the ester (m. p. 76–77°) and 10 cc. of normal sodium hydroxide was held at room temperature for one hour. The mixture was acidified with hydrochloric acid to *p*H 3.5, and the solution was extracted with *n*-butyl alcohol. The extract was washed with a little water and concentrated to dryness. A solution of the residue in 10 cc. of absolute alcohol was filtered and concentrated to a pale yellow oil, which was extracted three times with 25 cc. portions of boiling ethyl acetate. The combined extracts on cooling deposited the product as small dense prisms. The combined yield of the first and second crops was 65.2%; m. p. 133–135°. Recrystallization from ethanol and ether gave pure N-acetyl-DL-allothreonine melting at 134–135°.

*Anal.* Calcd. for $C_6H_{11}O_4N$: C, 44.71; H, 6.88; N, 8.69. Found: C, 44.81; H, 7.04; N, 8.77.

**2,5-Dimethyl-4-carbethoxyoxazoline Hydrochloride, VII.**—The crude hydrogenation product (33.2 g.) from ethyl α-acetamidoacetoacetate was dissolved in 40 cc. of benzene and treated with 25.4 cc. of thionyl chloride at 10–15°. After being stirred an additional hour without cooling, the solution was poured into 965 cc. of anhydrous ether, and the mixture was refrigerated for sixteen hours. The crystalline product was collected, washed with ether and dried *in vacuo* over concentrated sulfuric acid; wt. 31.0 g.; m. p. 95–98°. An analytically pure sample was prepared by precipitation of a solution of 5.0 g. in 15.5 cc. of dry chloroform with 90 cc. of dry ether; m. p. 105–106°.

*Anal.* Calcd. for $C_8H_{13}O_3N\cdot HCl$: C, 46.27; H, 8.79; N, 6.75; N.E., 207.7. Found: C, 46.11; H, 6.87; N, 6.97; N. E., 202.2.

Very careful drying of all solvents used in this reaction is absolutely essential to obtain pure oxazoline, since this compound hydrolyzes rapidly. The pure oxazoline hydrochloride gave DL-threonine on hydrolysis in 92% yield (bioassay).

**O-Acetyl-DL-threonine Ethyl Ester Hydrochloride.**—A sample of 2,5-dimethyl-4-carbethoxyoxazoline hydrochloride (m. p. 102–103°) exposed to the air for twenty-four hours had a melting point of 128–130°. After drying at 56° and 5 mm. for one hour the weight loss was only 1.8% (calculated for one mole of water is 8.08%), and the melting point was 130–131°.

*Anal.* Calcd. for $C_8H_{15}O_4N\cdot HCl$: C, 42.57; H, 7.15; N. E., 225.7. Found: C, 42.33; H, 7.45; N. E., 225.3.

Hydrolysis of a sample with 10% hydrochloric acid gave DL-threonine in 91% yield (bioassay).

**N-Acetyl-DL-threonine.**—A solution of O-acetyl-DL-threonine ethyl ester hydrochloride (2.25 g.) in 26 cc. of 1 *N* sodium hydroxide was kept at room temperature overnight. After filtration to remove a trace of insoluble material, the solution was made acid to congo paper with 17 cc. of 1 *N* hydrochloric acid, and extracted with five 25-cc. portions of *n*-butyl alcohol. The extract was concentrated to dryness and the residue taken up in benzene and reconcentrated. A solution of this residue in 20 cc. of alcohol was filtered from a little inorganic material and concentrated to give a colorless oil (1.55 g., 96.3% yield), which crystallized on standing in the refrigerator; m. p. 126–128°. Two recrystallizations from ethyl acetate gave clusters of prisms melting at 129–130°.

*Anal.* Calcd. for $C_6H_{11}O_4N$: C, 44.71; H, 6.88; N, 8.69. Found: C, 44.73; H, 6.65; N, 8.65.

A mixture of this material and N-acetyl-DL-allothreonine (m. p. 134–135°) melted at 105–113°. Hydrolysis of this compound with hydrochloric acid gave a 96% yield of DL-threonine (microbial assay).

**N-Acetyl-DL-threonine Ethyl Ester.**—Oxazoline hydrochloride, VII (3.11 g.) was added to a solution of 1.4 g. of sodium bicarbonate in 20 cc. of water. After storage for fourteen hours at room temperature, the solution was extracted with eight 10-cc. portions of chloroform. The extract was washed with water, dried over anhyd. magnesium sulfate, and concentrated to an oil, which crystallized on refrigeration, wt. 1.75 g., m. p. 84–85°. Recrystallization from isopropyl alcohol gave flat prisms of the same melting point.

*Anal.* Calcd. for $C_8H_{15}O_4N$: C, 50.78; H, 7.99. Found: C, 50.98; H, 7.93.

The same ester was prepared in almost quantitative yield from N-acetyl-DL-threonine by treatment with ethereal diazoethane. When mixed with a sample of the above ester, the melting point remained unchanged.

**N-Acetyl-DL-threonine methyl ester** was also prepared from N-acetyl-DL-threonine and ethereal diazomethane. When recrystallized from benzene, it is obtained as lustrous needles, m. p. 105–106°.

*Anal.* Calcd. for $C_7H_{13}O_4N$: C, 47.99; H, 7.48. Found: C, 48.18; H, 7.40.

**Acknowledgment.**—We are happy to acknowledge the technical assistance of Mrs. E. V. Crabtree, and to express our thanks to Dr. J. L. Stokes and Mr. R. N. Boos and their associates for the microbial assays and microanalytical data, respectively. In addition we are grateful to Dr. Nelson Trenner for infrared absorption spectra, which facilitated rapid identification of the reaction products derived from 2,5-dimethyl-4-carbethoxyoxazoline hydrochloride.

## Summary

1. The interconversion of DL-threonine and DL-allothreonine in high yields has been described. The interconversion is based upon the inversion of the configuration about one of the asymmetric carbon atoms

2. By utilization of this inversion, the synthesis of DL-threonine from acetoacetic ester can be accomplished in an over-all yield of 57%.

3. A practical method for the separation of DL-threonine from DL-allothreonine has been developed. This method depends upon the difference in solubility of the sodium salts in ethanol.

4. A number of new derivatives of DL-threonine and DL-allothreonine have been prepared and reported.

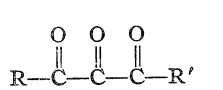
# A Mechanism for the Cleavage of Certain Phenylhydrazones by Bromine

BY DEXTER B. SHARP[1]

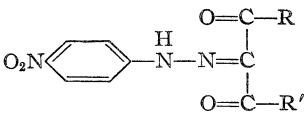
F. D. Chattaway and co-workers[2] published a number of papers describing the products obtained from the action of halogens on certain phenylhydrazones, represented by formula I. Bromine reacted almost quantitatively with



I II

Ar = $C_6H_5$- or substd. $C_6H_5$-
R = $C_2H_5O$-, $CH_3$-
R′ = $C_6H_5$-, $CH_3$-, $C_2H_5O_2C$-

compounds of type I in cold acetic acid–sodium acetate solution to give halides of type II, a cleavage of a carbon–carbon bond having occurred during the reaction. The papers cited above reported no mechanism studies. This paper presents the results of experiments designed to elucidate the mechanism of this cleavage reaction.

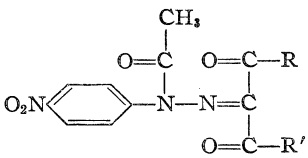


Two of the three parent compounds of this series, *i.e.*, vicinal tricarbonyl compounds, were found to be unaffected by bromine under the conditions favoring cleavage of the hydrazones of type I. Ethyl 3-phenyl-2,3-dioxopropanoate

| Cpd. | R | R′ |
|---|---|---|
| III | $C_2H_5O$- | $C_6H_5$- |
| IV | $C_2H_5O$- | $CH_3$- |
| V | $C_6H_5$- | $C_6H_5$- |

(III) and 1,3-diphenylpropane-1,2,3-trione (V) were prepared and added to a solution of bromine and sodium acetate in glacial acetic acid. After one to three days at room temperature, the reaction mixtures were diluted with water and the starting compounds were recovered as hydrates in good yields. Ethyl 2,3-dioxobutanoate (IV) decolorized bromine over a four-hour period and no hydrate was isolated. This result may be attributed to a bromine attack upon the terminal methyl group rather than a $C_2$–$C_3$ cleavage.

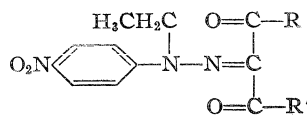
The stability of III and V toward bromine indicates that the hydrazone group at carbon number two is necessary for the cleavage reaction and it was found that the 2-*p*-nitrophenylhydrazone derivatives of compounds III, IV and V (VI, VII, VIII) were cleaved in excellent yields by bromine in acetic acid–sodium acetate solutions maintained at or below room temperature.



| Cpd. | R | R′ |
|---|---|---|
| VI | $C_2H_5O$- | $C_6H_5$- |
| VII | $C_2H_5O$- | $CH_3$- |
| VIII | $C_6H_5$- | $C_6H_5$- |

In all cases the bromine was decolorized as rapidly as it was added. Compounds VI and VII both gave the same bromo compound, ethyl α-bromoglyoxylate α-*p*-nitrophenylhydrazone (IX), the bromine having replaced a benzoyl and an acetyl group, respectively. Compound VIII gave ω-bromophenylglyoxal *p*-nitrophenylhydrazone (X), a benzoyl group having been replaced by a bromine atom. The cleavage of VII was reported by Chattaway,[2c] and earlier by Bowack and Lapworth.[3] The cleavage of VI and VIII is in line with the observations of Chattaway.

Bromine in glacial acetic acid containing no sodium acetate was found to have no action on compounds VI, VII or VIII. These compounds were recovered in very good yield. The influence of substances of higher basic strength than sodium acetate was not investigated due to the sensitivity of the halogen compounds (II) toward more basic agents.



The hydrazone groups in VI, VII and VIII were modified by direct N-acetylation with acetic anhydride. The N-acetyl compounds,

type I compounds. Compounds III and V with *p*-nitrophenylhydrazine gave substances identical with VI and VIII, respectively, whose structures as 2-*p*-nitrophenylhydrazones are fixed through their synthesis by the Japp–Klingemann reaction. By analogy, it is inferred that the central carbonyl groups in III and V were attacked by the disubstituted hydrazine molecule. Since IV with *p*-nitrophenylhydrazine gave a derivative which was not identical with VII from the coupling reaction, the corresponding ethyl-*p*-nitrophenylhydrazone was not prepared. Attempts to ethylate VI, VII and VIII directly were unsuccessful.

Summarizing the results above, the following facts are clear. (1) Rapid cleavage of compounds of type I by bromine occurred almost quantitatively under mild conditions in glacial acetic acid containing sodium acetate. (2) No cleavage occurred in the absence of sodium acetate. (3) Replacement of the hydrogen on the nitrogen of the hydrazone link by an acetyl or ethyl group prevented cleavage, thus demonstrating the requirement that this hydrogen is necessary for cleavage to occur.

From a consideration of these facts, the following base-catalyzed mechanism is proposed for the reaction.

## Experimental[4]

**Vicinal Tricarbonyl Compounds. Ethyl 3-Phenyl-2,3-dioxopropanoate (III).**—Ethyl benzoylacetate (96 g.) was converted to III by adapting the method described by Bigelow and Hanslick[5] for the preparation of 1,3-diphenylpropane-1,2,3-trione. The product (47 g., 45%) was a yellow oil; b. p. (2 mm.) 117–123° (reported,[6] 150–153° at 13 mm.), $d^{27}_4$ 1.179 (reported,[6] $d^{20}_4$ 1.188), $n^{20}D$ 1.5191.

**Ethyl 2,3-Dioxobutanoate (IV).**—Ethyl acetoacetate (130 g.) was converted to IV by the method of Denis.[7] The nitrogen oxides were generated by the action of sirupy phosphoric acid on excess sodium nitrite. The product (7.3 g., 5%) was a yellow oil; b. p. (14 mm.) 68.5–72° (reported,[7] 76–82° at 18–22 mm.), $d^{26}_4$ 1.151 (reported,[8] $d^{20}_4$ 1.125), $n^{20}D$ 1.4240 (reported,[8] $n^{15.8}D$ 1.42210).

**1,3-Diphenylpropane-1,2,3-trione (V).**—A sample of V hydrate, m. p. 89–91° (reported,[5] 90–92°), was dehydrated by distillation at reduced pressure to give V, a yellow-orange solid; m. p. 69–71° (reported,[5] 68–70°).

**Bromine Action on III, IV and V.**—Mole portions of III, IV and V, respectively, were added to appropriate volumes of glacial acetic acid containing an excess of anhydrous sodium acetate and a mole portion of bromine. The mixtures were maintained at room temperature for varying periods. Excess bromine was removed at reduced pressure, water was added, and the respective hydrates precipitated.

A sample of III (4.0 g.) gave III hydrate (3.6 g., 80%); m. p. and mixed m. p. 55–59° with authentic III hydrate.

Compound IV decolorized bromine over a four hour period, possibly due to an attack on the highly activated methyl group rather than $C_2$-$C_3$ cleavage. No IV hydrate was obtained from this reaction.

A portion of V (15.8 g.) gave V hydrate (15.2 g., 90%); m. p. and mixed m. p. 82–90° with authentic V hydrate.

**2-*p*-Nitrophenylhydrazone Derivatives of III, IV and V. A. Coupling Reaction.**—*p*-Nitrobenzenediazonium chloride coupled with the appropriate β-dicarbonyl compounds in sodium acetate buffered solutions to give the desired derivatives, following the method of Chattaway and Ashworth.[2c] Ethyl benzoylacetate (19 g.) gave ethyl 3-phenyl-2,3-dioxopropanoate 2-*p*-nitrophenylhydrazone (VI). The product (21 g., 61%) crystallized as yellow platelets from dilute ethanol; m. p. 112.5–114° (reported,[9] 114°).

Ethyl acetoacetate (65 g.) gave ethyl 2,3-dioxobutanoate 2-*p*-nitrophenylhydrazone (VIII). The product (120 g., 86%) crystallized as yellow needles from dilute ethanol; m. p. 126–127° (reported,[2c] 126–127°).

Dibenzoylmethane (22.5 g.) gave 1,3-diphenylpropane-1,2,3-trione 2-*p*-nitrophenylhydrazone (VIII). The product (24.5 g., 66%) separated as yellow needles from dilute acetone; m. p. 172–173° (reported,[10] 173°).

**B. Direct Action.**—Compounds VI and VIII were obtained by the direct action of *p*-nitrophenylhydrazine on III and V, respectively. Mole portions of the hydrazine and tricarbonyl compound were added to ethanol containing several drops of acetic acid. Filtration and dilution of the filtrate with water caused the product to crystallize.

By this method, III (1.0 g.) gave compound VI (1.6 g., 94%); m. p. and mixed m. p. 112–114° with VI prepared by the coupling reaction.

Similarly, V hydrate (3.33 g.) gave VIII (4.40 g., 86%); m. p. and mixed m. p. 170–171° with authentic VIII prepared by the coupling reaction.

Compound IV gave a red substance, m. p. 175–176°, quite different from the desired compound (VII); m. p. 126–127°.[2c]

**Bromine Action on VI, VII and VIII. A. With Sodium Acetate.**—A mole portion of VI, VII and VIII, respectively, was added to glacial acetic acid containing an excess of sodium acetate. The reaction mixture was stirred at room temperature or less while a mole portion of bromine in acetic acid was added. In each case a rapid decoloration of bromine was noted. The solid products were obtained by filtration after the reaction mixtures were diluted with water.

(4) Each m. p. and b. p. was corrected for stem exposure.

(5) Bigelow and Hanslick, "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1944, p. 244.

(6) Wahl, *Compt. rend.*, **144**, 212 (1907).

(8) von Auwers, *Ber.*, **51**, 1120 (1918).

(9) Bülow and Hailer, *ibid.*, **35**, 926 (1902).

(10) Dimroth, *ibid.*, **40**, 2409 (1907).

Compound VI (5.0 g.) gave ethyl α-bromoglyoxylate-α-*p*-nitrophenylhydrazone (IX). The product (4.3 g., 93%) crystallized as granular yellow crystals from benzene; m. p. 199–201° (reported,[2e] 202–203°).

*Anal.* Calcd. for $C_{10}H_{10}BrN_3O_4$: C, 37.99; H, 3.19. Found: C, 38.19; H, 3.60.

Compound VII (25.0 g.) gave IX (26.5 g., 94%); m. p. and mixed m. p. 199–201° with IX from the preceding reaction.

Compound VIII (5.0 g.) gave ω-bromophenylglyoxal *p*-nitrophenylhydrazone (X). The product (4.5 g., 96%) separated as yellow needles from ethyl acetate; m. p. 245–247° (reported,[2f] 247°).

**B. Without Sodium Acetate.**—The reactions in (A) were repeated without the sodium acetate: From VI (5.0 g.) there was recovered VI (4.7 g., 94%); m. p. 112–114°. From VII (5.0 g.) there was recovered VII (4.6 g., 92%); m. p. 125–127°. From VIII (5.0 g.) there was recovered VIII (4.7 g., 94%); m. p. 171–172°.

**N-Acetyl Derivatives of VI, VII and VIII.**—Following a method described by Bülow and Hailer,[9] compounds VI, VII and VIII were acetylated by treatment with acetic anhydride containing several drops of concentrated sulfuric acid. The excess acetic anhydride was hydrolyzed by pouring the reaction mixture onto ice and the solid product was collected and recrystallized repeatedly from dilute acetone and dilute acetic acid.

Compound VI (5.0 g.) gave ethyl 3-phenyl-2,3-dioxopropanoate 2-(acetyl-*p*-nitrophenylhydrazone) (XI). The product (1.0 g., 18%) crystallized as white needles from dilute acetone; m. p. 141–142°.

*Anal.* Calcd. for $C_{19}H_{17}N_3O_6$: C, 59.53; H, 4.47. Found: C, 59.90; H, 4.40.

Compound VII (28 g.) gave ethyl 2,3-dioxobutanoate-2-(acetyl-*p*-nitrophenylhydrazone) (XII). The product (2.5 g., 8%) crystallized as white needles from dilute acetone; m. p. 135–136°.

*Anal.* Calcd. for $C_{14}H_{15}N_3O_6$: C, 52.34; H, 4.71. Found: C, 52.37; H, 4.92.

Compound VIII (3.0 g.) gave 1,3-diphenylpropane-1,2,3-trione-2-(acetyl-*p*-nitrophenylhydrazone) (XIII). The product (1.1 g., 33%) separated as yellow needles from dilute acetic acid; m. p. 202–202.5°.

*Anal.* Calcd. for $C_{23}H_{17}N_3O_5$: C, 66.50; H, 4.13. Found: C, 66.39; H, 4.03.

**Bromine Action on Compounds XI, XII and XIII.**—Mole portions of XI, XII and XIII, respectively, were added to appropriate volumes of acetic acid containing mole portions of bromine and excess sodium acetate. After one day at room temperature the reaction mixtures were diluted with water and the solids were removed by filtration. From XI (0.452 g.) there was recovered XI (0.343 g., 76%); m. p. and mixed m. p. 138–140° with authentic XI. From XII (1.0 g.) there was recovered XII (1.0 g., 100%); m. p. and mixed m. p. 133–135° with authentic XII. From XIII (0.859 g.) there was recovered XIII (0.837 g., 97%); m. p. and mixed m. p. 201–202° with authentic XIII.

**N-Ethyl Derivatives of VI and VIII.**—Compound XIV, α-ethyl-α-*p*-nitrophenylhydrazine, was prepared in poor yield by the method of Ciusa and Rastelli.[11] Benzaldehyde *p*-nitrophenylhydrazone (50 g.) gave XIV (6.2 g., 16%), a yellow crystalline solid from ligroin; m. p. 68.5–69.5° (reported,[11] 74°).

*Anal.* Calcd. for $C_8H_{11}N_3O_2$: C, 53.02; H, 6.12. Found: C, 52.73; H, 6.07.

Mole portions of III and V, respectively, were added to ethanol–acetic acid (3:1 by volume) containing mole portions of XIV. The reaction mixtures, after one hour on the steam-bath and one day at room temperature, were diluted with water and the solid products were removed by filtration.

Compound III (1.60 g.) with XIV (1.36 g.) gave ethyl 3-phenyl-2,3-dioxopropanoate-2-(ethyl-*p*-nitrophenylhydrazone) (XV), (2.05 g., 74%). The product crystallized as yellow needles from dilute acetone; m. p. 128–129°.

*Anal.* Calcd. for $C_{19}H_{19}N_3O_5$: C, 61.78; H, 5.19. Found: C, 61.96; H, 5.40.

V hydrate (0.66 g.) with XIV (0.45 g.) gave 1,3-diphenylpropane-1,2,3-trione 2-(ethyl-*p*-nitrophenylhydrazone) (XVI). The product (0.35 g., 33%) crystallized as yellow needles from dilute acetone; m. p. 166–167°.

*Anal.* Calcd. for $C_{23}H_{19}N_3O_4$: C, 68.81; H, 4.77. Found: C, 69.08; H, 5.05.

In view of the anomalous behavior of IV with *p*-nitrophenylhydrazine the corresponding N-ethyl derivative was not prepared.

**Bromine Action on XV and XVI.**—Mole portions of XV and XVI, respectively, were added to appropriate volumes of glacial acetic acid containing mole portions of bromine and excess sodium acetate. The reaction mixtures, after one day at room temperature, were diluted with water and the solids were removed by filtration. From XV (1.60 g.) there was recovered XV (1.0 g., 62%); m. p. and mixed m. p. 126–128° with authentic XV. From XVI (0.50 g.) there was recovered XVI (0.46 g., 92%); m. p. and mixed m. p. 164–166° with authentic XVI.

**Acknowledgments.**—The author wishes to express his appreciation to Dr. C. F. Koelsch for his extremely helpful guidance and deep interest throughout this problem. The carbon–hydrogen microanalyses were carried out by Messrs. R. Amidon and J. Buckley, and Dr. S. Sundet.

## Summary

A study of the carbon–carbon cleavage by bromine of 2-*p*-nitrophenylhydrazones of 1,2,3-trioxo compounds revealed that the reaction is base-catalyzed and applies only to mono-substituted phenylhydrazones of the type mentioned.

A mechanism is proposed to account for these facts.

# Introduction of Alkylamino and Dialkylamino Groups into the Quinoline Nucleus

BY NYDIA G. LUTHY,[1] F. W. BERGSTROM[2] AND HARRY S. MOSHER

It has been shown that quinine is detoxified in the body by oxidation to the 2-hydroxy derivative which has much less therapeutic activity.[3] Since antimalarials containing a quinoline nucleus may suffer a similar fate, the problem of introducing groups into the 2-position in order to block this mode of detoxification was undertaken. It was hoped that amino and substituted alkylamino groups would overcome such objections, and so a study was made on the ease of substitution of such groups in the 2-position of quinoline and of finding the optimum conditions for such introduction.

The direct introduction of the amino group by the use of alkali amides in liquid ammonia, tertiary amines, or inert solvents has become a well established reaction.[4] It has been shown also, that alkylamino groups can be introduced by the use of the fused sodium–potassium amide eutectic in the presence of an excess of a primary amine.[5] It has now been shown that in some cases 2-aminoquinoline may also be produced in this reaction. In this Laboratory 2-methylaminoquinoline has been produced by the reaction of quinoline with lithium methylamide in ether solution and nitrogen atmosphere. However, the methods for the direct introduction of 2-dialkylamino groups have not been so well established. Roser[6] and Cohen, *et al.*,[7] alkylated the methiodide of 2-aminoquinoline stepwise to obtain 2-dimethylaminoquinoline. Quinoline 2-sulfonic acid (prepared from 2-chloroquinoline and sodium sulfite solution) when heated with an aqueous solution of a dialkylamine will yield compounds of the type of 2-dialkylaminoquinoline.[8] Fourneau, *et al.*,[9] combined 2-chloroquinoline itself with a benzene solution of diethylamine in a heated sealed tube to obtain 2-diethylaminoquinoline hydrochloride. Buchman and Hamilton[10] found that both halogen atoms in 2,4-dichloroquinoline were quite reactive and gave good yields of 2,4-di-(N-morpholino)-quinoline. Magidson and Rubtsov[11] and certain patent literature[12] make reference to the successful reaction of 2-chloroquinoline and 2-chloroquinoline derivatives with various basically substituted amines such as 1-diethylamino-4-aminopentane. In addition certain aromatic amino derivatives have been made by the reaction of 2-chloroquinoline with substituted anilines.[13]

We have not been able as yet to accomplish the direct introduction of dialkylamino groups into the quinoline nucleus using alkali dialkylamides. Even in a sealed two-legged tube, potassium dimethylamide in methylamine gave no reaction with quinoline, while only unreacted starting material could be obtained when quinoline was treated with lithium dimethylamide in anhydrous ether, benzene, or toluene. Therefore, it seemed advisable to investigate the general nature of the reaction of 2-chloroquinoline with dialkylamines and to study the properties of the compounds produced. The results are summarized in Tables I and II.

## Experimental

Accordingly a series of compounds ranging from 2-dimethylamino- to diamylaminoquinoline was prepared by treating 2-chloroquinoline with the corresponding amine either in a sealed tube or, if the boiling point of the amine was sufficiently high, by refluxing. Hydrolysis of the hydrochlorides so formed was effected by 20% sodium carbonate solution, and after the free base was separated by benzene extraction, it was purified by vacuum distillation.

In this series with the exception of the first compound, all were pale-yellow, stable oils boiling from 140–170° at 2 mm. forming only monomethiodides and hydrochlorides. As the alkyl group became larger, higher temperatures were needed to bring about the reaction of 2-chloroquinoline with the dialkylamine. The salts of the resulting compounds were crystallized with greater difficulty and their melting points tended to become lower.

In a similar manner 2-methylamino-, 2-propylamino- and 2-piperidinoquinoline were also prepared. By treating 4-chloroquinoline with methylamine in a sealed tube heated at 100° for five hours, a 96% yield of 4-methylaminoquinoline was obtained.

The monoalkylaminoquinolines were white crystalline solids which formed only mono-salts. Mono-salt formation may be explained by postulating an amidine type resonance (Fig. 1) in which the positive charge prevents the approach of another molecule of methyl iodide. That

it is the ring nitrogen which forms the quaternary salt is indicted by the fact that both 2-aminoquinoline methiodide and 2-dimethylaminoquinoline methiodide are converted to 1-methyl-2-quinolone by boiling in aqueous alkaline solution.[7]

## Summary

1. A series of 2-dialkylaminoquinolines and 2-alkylaminoquinolines has been prepared by heating 2-chloroquinoline with the corresponding anhydrous amine in a sealed tube. 4-Methylaminoquinoline was obtained from 4-chloroquinoline in a similar manner.

2. Only monomethiodides and monohydrochlorides could be formed from these quinoline bases. The platinum, gold, and picrate derivatives are described for a number of compounds of this series.

## 3,4-Dimethylaniline from Fenchone Using the Schmidt Reaction

By Frederic R. Benson, Lawrence W. Hartzel and Walter L. Savell

One of the newer methods for the preparation of 3,4-dimethylaniline which is convenient for laboratory use is that developed by Zaugg.[1] His procedure involves conversion of fenchone to 3,4-dimethylacetophenone, isolation as the oxime, Beckmann rearrangement and subsequent hydrolysis.

In order to reduce the time required for this synthesis, investigation of an alternative method has been made. The modification developed in this laboratory consists of subjecting the crude 3,4-dimethylacetophenone obtained from fenchone to the Schmidt reaction, followed by hydrolysis of the crude 3,4-dimethylacetanilide. The present procedure eliminates the need for isolation of dimethylacetophenone as the oxime and the time consuming Beckman rearrangement. In the method described below the benzene solution of crude dimethylacetophenone, obtained according to Zaugg, is treated directly with hydrazoic acid in benzene to form crude dimethylacetanilide. Hydrolysis and distillation affords a fairly pure product which can be recrystallized to form 3,4-dimethylaniline of good purity. The over-all yield from fenchone of completely purified material is 21%.

A by-product of the Schmidt reaction was obtained in small amounts from one run. This is probably 1-(3′,4′-dimethylphenyl-5-methyltetrazole, although it is possible that it may be the isomer, 1 methyl-5-(3′,4′-dimethylphenyl)-tetrazole.

### Experimental

A solution of 126 g. of crude 3,4-dimethylacetophenone in 585 ml. of dry benzene was prepared from 200 g. of commercial fenchone as described by Zaugg.[1]

To a 100-ml. portion of this solution (containing 21.4 g. of 3,4-dimethylacetophenone), mixed with 30 ml. of concentrated sulfuric acid was added with stirring 191 ml. of a 4.1% hydrazoic acid solution in benzene. The temperature was maintained at 38–41° during the addition, which took approximately fifty minutes. After all the solution had been added, the mixture was allowed to stir for five minutes longer, then cooled and poured into a separatory funnel. The sulfuric acid layer was poured into 400 ml. of water and made alkaline with ammonium hydroxide (120 ml.). The yellow oil which separated solidified on cooling. The precipitate was filtered off, washed once with water and refluxed for two hours with 75 ml. of concentrated hydrochloric acid. The solution was poured into 250 ml. of water, extracted with ether, and made alkaline with 6 *N* sodium hydroxide. The alkaline solution was extracted with ether, the ether solution dried over potassium hydroxide and distilled to yield 7.0 g. of crude 3,4-dimethylaniline, b. p. 138–143° (55 mm.), m. p. 47°. On recrystallization from light petroleum ether 5.7 g. of pure 3,4-dimethylaniline was obtained (21% yield from fenchone), m. p. 50–51°. Purity by titration with perchloric acid in glacial acetic acid, 99.1%.

In another experiment conducted as described above, except that the temperature of the Schmidt reaction was maintained at 10–15°, the ether extract of the acid hydrolysis product was allowed to evaporate. The dark, gummy crystals obtained were dissolved in boiling water and treated with charcoal. On filtration and cooling, white crystals separated. A second recrystallization from water afforded 100 mg. of white glistening crystals melting at 111–111.5°.

## Synthesis of 1-Aminofluorene

By E. Bergmann and Milton Orchin[1]

In view of the widespread current interest in the unusual carcinogenic properties of 2-aminofluorene,[2] we wish to report at this time the preparation of the isomeric 1-aminofluorene. The synthesis consisted essentially of the oxidation of fluoranthene to fluorenone-1-carboxylic acid, reduction of the latter to fluorene-1-carboxylic acid and replacement of the carboxyl group by an amino group.

### Experimental[3]

**Fluorenone-1-carboxylic Acid.** I.—Fluoranthene was purchased from the Reilly Tar and Chemical Company. It had a melting point of 107.0–109.4°. Careful chromatography on alumina–celite and determination of the ultraviolet absorption spectra of the fractions showed the presence of a small quantity of pyrene and the probable presence of phenanthrene as impurities. Sulfuric acid extraction of a tetrachloroethane solution of the fluoranthene,[4] resulted in a spectrographically pure fluoranthene, m. p. 110.4–111.2°. On a large scale, the purification was more conveniently achieved by heating fluoranthene at 200° with sodium for half an hour. The fluoranthene was distilled, b. p. 180–90° (4–5 mm.) and the distillate crystallized from ethanol whereby colorless material, m. p. 110.4–111.4°, was obtained. This fluoranthene (95 g.) was oxidized with chromic acid in acetic acid according to the directions of Fieser and Seligman.[5] The procedure for the isolation of the product was simplified as follows:

(1) We wish to thank the John Simon Guggenheim Foundation for a fellowship grant to M. O. which made this work possible. Present address, U. S. Bureau of Mines, Pittsburgh, Pa.

(5) Fieser and Seligman, This Journal, **57**, 2174 (1935).

After the acid was precipitated by dilution with ice and water, the product was filtered and washed twice with hot water. The product was digested in warm, dilute hydrochloric acid, filtered and washed well with hot water. The insoluble material was digested in 500 cc. of water containing 45 g. of sodium carbonate. The hot solution was treated with norite and filtered. The filtrate was acidified with cold, concentrated hydrochloric acid and the precipitate filtered and dried overnight at 80°. Crystallization from acetic acid gave 55.5 g. of the desired acid, brownish-red needles, m. p. 193.4–195.4°. A sample recrystallized from acetic acid had a melting point of 196.8–197.6°. The alkali insoluble material was treated with aqueous sodium bisulfite,[6] the mixture filtered and the filtrate acidified with concentrated sulfuric acid. The precipitated material was filtered and twice recrystallized from ethanol giving red brown crystals of fluoranthenequinone, m. p. 193.0–193.8°.[7]

**Ethyl Fluorenone-1-carboxylate.**—The keto acid, I, was esterified with ethanol and hydrogen chloride in the usual way. The ester was isolated as gold-yellow crystals after two crystallizations from ethanol, m. p. 84.8–85.4°; reported melting point, 75–76°[8] and 84–86°.[9] On a third recrystallization from ethanol, the crystals had a melting point of 76.0–76.5°. After melting, the melt was cooled and the solid remelted whereupon softening took place at 76° and sharp liquefaction occurred at 84.0–84.8°. Both the high and low melting forms gave identical ultraviolet absorption spectra.

**Methyl Fluorenone-1-carboxylate.**—This compound was prepared from I with methanol and hydrogen chloride and was crystallized from methanol as yellow needles, m. p. 86.6–87.4°; reported[9] melting point, 86–89°.

**Fluorenone-1-carboxamide.**—The keto acid, I, was converted *via* the chloride to the amide which was crystallized from acetic acid and separated as yellow-orange crystals, m. p. 235.8–237.0°; reported melting point, 229–230°,[8] and 226.5–227°.[10]

**1-Aminofluorenone.**—The Hofmann reaction on the amide gave the aminofluorenone. The amine was recrystallized first from ethanol and then from petroleum ether and was thus obtained as orange plates, m. p. 119.0–120.0°; reported melting point, 110°[8] and 118–118.5°.[10]

**Fluorene-1-carboxylic Acid, II.**—The keto acid, I, was reduced by the Huang–Minlon modification[11] of the Wolff–Kishner reduction. A mixture of 16.6 g. of I, 10 g. of sodium hydroxide, 10 cc. of 85% hydrazine hydrate and 130 cc. of trimethylene glycol was refluxed for three hours. The temperature of the boiling contents was about 150°. The condenser was removed and the boiling continued in the open (hood) until the temperature in the flask was about 205°. At this point refluxing was resumed and continued for two and one-half hours. The mixture was cooled and poured into ice and hydrochloric acid. The precipitate was filtered and dried overnight. Crystallization from acetic acid gave 13.0 g., m. p. 246–249° as a first crop and 1.0 g., m. p. 243–246° (90% yield) as a second crop. The reduction of the keto acid has been done previously[5] with sodium amalgam but in much poorer yield and we are indebted to Dr. Fieser for suggesting the application of the above procedure to improve his yield.

**Methyl Fluorene-1-carboxylate, III.**—A suspension of 5.16 g. of II in 100 cc. absolute methanol was saturated with hydrogen chloride and the ester isolated in the usual way. Crystallization of the ester from methanol gave 4.94 g. of colorless crystals, m. p. 86.6–87.4°. *Anal.* Calcd. for $C_{15}H_{12}O_2$: C, 80.3; H, 5.4. Found: C, 80.4; H, 5.2.

**Ethyl fluorene-1-carboxylate** was prepared from ethanol and II as above. Crystallization from ethanol gave colorless crystals, m. p. 53.6–54.8°. *Anal.* Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 5.9. Found: C, 80.9; H, 5.8.

**Fluorene-1-carboxamide** was prepared from II *via* the acid chloride. Crystallization from acetic acid gave colorless crystals, m. p. 251.0–253.0°. *Anal.* Calcd. for $C_{14}H_{11}ON$: C, 80.4; H, 5.3. Found: C, 79.8; H, 5.1.

**Hydrazide of Fluorene-1-carboxylic Acid, IV.**—A solution of 5.0 g. of the methyl ester, III, 20 cc. of absolute ethanol and 5 cc. of 85% hydrazine hydrate was refluxed for twenty-four hours. A white solid appeared during the refluxing. The mixture was cooled and filtered and washed with ethanol to give 3.84 g. of white fluffy needles, m. p. 216.6–218°. *Anal.* Calcd. for $C_{14}H_{12}N_2O$: N, 13.2. Found: N, 13.0.

**1-Fluorenylurethan, V.**—A solution of 1.06 g. of IV in 20 cc. of glacial acetic acid was treated with 0.5 cc. of concentrated hydrochloric acid. The suspension was cooled to 0° and 0.8 g. of sodium nitrite in 5 cc. of water added. The suspension was stirred in the cold for one hour then at room temperature for one hour. The mixture was diluted with water and filtered. The precipitate was washed with water and dried in a vacuum desiccator. The solid weighed 1.00 g.; it melted at 85° with gas evolution and was very soluble in organic solvents. *Anal.* Calcd. for $C_{14}H_9N_3O$; N, 17.9. Found: N, 18.6. A solution of 0.85 of the crude azide in 25 cc. of absolute ethanol was warmed to about 70°. Rapid gas evolution occurred. The solution was then refluxed for two hours. The solution was filtered from a small amount of insoluble material and the filtrate concentrated. The urethan (0.62 g.) was obtained from ethanol as colorless plates, m. p. 132.0–132.6°. *Anal.* Calcd. for $C_{16}H_{15}NO_2$: N, 5.6. Found: N, 5.8.

**1-Aminofluorene.**—A mixture of 0.5 g. of the urethan, V, 10 cc. of acetic acid and 15 cc. of concentrated hydrochloric acid was heated in a sealed tube at 140° for four hours. After cooling, the tube was opened, the contents diluted with water and filtered. The insoluble material (m. p. > 270°) was placed in a separatory funnel with 10% potassium hydroxide solution and ether. After shaking for several minutes, the solid disappeared. The ether layer was separated and evaporated to dryness and the residue crystallized from dilute ethanol to give 0.31 g. of tan crystals, m. p. 117–119°; recrystallized from benzene–petroleum ether, m. p. 124.0–124.6°. *Anal.* Calcd. for $C_{13}H_{11}N$: N, 7.7. Found: N, 8.0. The trinitrofluorenone complex[12] separated from benzene as beautiful, almost black needles, m. p. 211.0–211.8°. *Anal.* Calcd. for $C_{26}H_{16}N_4O_7$: N, 11.3. Found: N, 11.3.

(6) The procedure described in *Org. Syntheses*, **24**, 1 (1944), for the isolation of acenaphthenequinone was used.

(7) Fittig and Liepmann, *Ann.*, **200**, 5 (1879).

(8) Goldschmeidt, *Monatsh.*, **23**, 894 (1902).

(9) Goldschmeidt and Lipschitz, *ibid.*, **25**, 1175 (1904). In this article the authors state that the melting point of 75–76° reported for the ethyl ester in their earlier work (ref. 8) was a misprint. However, in view of our isolation of a low melting form, it is quite possible that their early observation was genuine. The melting point of our low melting form did not change even after standing more than a year.

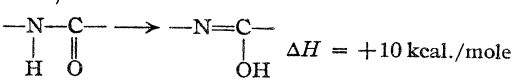
## On the Structure of Aromatic Aldehyde Semicarbazones[1]

BY GIUSEPPE CILENTO

By chemical evidence, structure (I) has been attributed to the semicarbazones. The enolic structure (II), although it might explain the abnormal ultraviolet absorption maximum of these compounds, has been ruled out, since essentially

(1) This investigation was supported by a grant from the Fundação Virginia Matarazzo, São Paulo, Brazil.



the same light absorption is shown by the corresponding N-methyl semicarbazones, where enolization cannot occur.[2] Additional information has been obtained by investigating the ultraviolet absorption spectra of aqueous solutions of benzaldehyde and *p*-nitrobenzaldehyde semicarbazones at different hydrogen ion concentrations.

(I) (II)

The spectrum of benzaldehyde semicarbazone remains almost the same in the range from *p*H 2.6 to 11.0, showing $\lambda_{max.} = 278$ m$\mu$, (Fig. 1). We conclude that the same kind of molecule must be present in these solutions.

That there is one kind only, and that kind must have the carbonyl structure, can be supported by energetic considerations, as the enol formation would be accompanied by an increase of ten kilocalories/mole.[3]

This cannot be overbalanced by the extra resonance energy.

At *p*H 1.0 the spectrum of benzaldehyde semicarbazone is modified, showing a new band at shorter wave length ($\lambda_{max.} = 249$ m$\mu$). The intensity of the new band increases and that of the original band decreases with time, but after four hours we noticed no further change (Fig. 1).

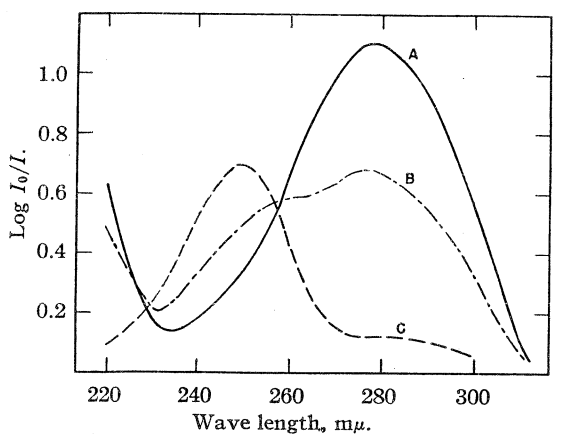


Fig. 1.—Ultraviolet absorption spectrum of benzaldehyde semicarbazone in aqueous solution: A, *p*H 11.0, *p*H 6.0 and *p*H 2.6; B, *p*H 1.0; C, *p*H 1.0 after four hours.

It is very probable that this alteration results from chemical, rather than physico-chemical changes. However, the possibility of hydrolysis can be ruled out on account of the value 0.0015 at 25° for the constant of limiting hydrolysis in acid solution.[4]

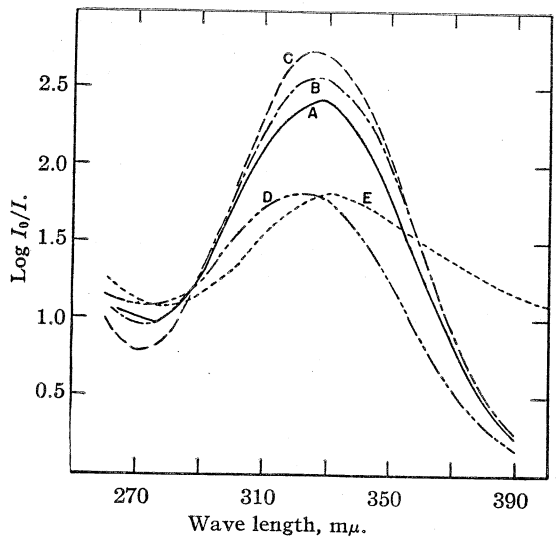
(4) J. B. Conant and P. D. Bartlett, THIS JOURNAL, **54**, 2881 (1932).



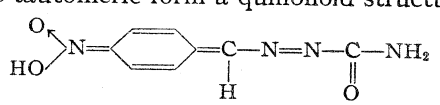


Fig. 2.—Ultraviolet absorption spectrum of *p*-nitrobenzaldehyde semicarbazone in aqueous solution: A, *p*H 1.3; B, *p*H 2.5; C, *p*H 5.7; D, *p*H 9.5; E, *p*H 11.3.

The effect of *p*H on the ultraviolet absorption spectrum of *p*-nitrobenzaldehyde semicarbazone is illustrated in Fig. 2. An isobestic point occurs at about 287 m$\mu$. The wave length of the absorption maximum remains at about 325 m$\mu$ but at *p*H 11.3 a shift of 5 m$\mu$ toward the red is observed. The isobestic point indicates a change in the molecular structure with a change in *p*H. We suggest for the tautomeric form a quinonoid structure

Such a structure can explain also the solubility in alkaline solution of this, and other aromatic nitro-aldehyde semicarbazones (such as *o*-nitrobenzaldehyde and 5-nitro-2-furfuraldehyde), and the insolubility of *m*-nitrobenzaldehyde semicarbazone.

The spectrum in 1 *N* hydrochloric acid solution shows a new band at 267 m$\mu$, the band at 287 m$\mu$ being reduced to an inflection.

On standing in alcoholic solution, the absorption spectrum of *p*-nitrobenzaldehyde semicarbazone showed a drop in intensity and a shift toward the shorter wave length (331 m$\mu$ → 320 m$\mu$), probably due to a *cis–trans* rearrangement. The Fisher–Hirschfelder–Taylor models suggest that the *cis* isomer cannot assume a planar configuration, due to steric hindrance between the secondary nitrogen atom and the ortho hydrogens.

On crystallization from water, *p*-nitrobenzaldehyde semicarbazone may separate in a white or a yellow form, depending upon conditions. These forms have been studied in a polarizing microscope. The yellow form is needle-like, with an extinction angle of 44°; the white form appeared in rectangular crystals, which showed practically no extinction when the microscope stage was turned

360°, the nicols being crossed. The crystals were bi-axial, section perpendicular to an optical axis; the isogyra was practically straight at rotation of the section. The angle between the optical axis must be nearly 90°; optically +.

### Experimental

The aldehydes and the semicarbazones have been prepared by the usual methods. The latter were recrystallized from water and dried in a vacuum desiccator over calcium chloride. A solution of approximately 100 mg. per liter of benzaldehyde semicarbazone was prepared and solutions at different *p*H values were obtained by adding 2 cc. of the above solution in a 25 cc. volumetric flask and filling up with distilled water and acid (HCl, 1 *N*) or base (NaOH, 1 *N*).[5] A similar procedure was used with the *p*-nitro derivative.

Spectral measurements were carried out in a Beckman D. U. Quartz Spectrophotometer, using 1 cm. silica cells.

(5) The *p*H's were checked with a potentiometer.

## Melting Point of Magnetite–Silica Mixtures in Air

BY L. S. DARKEN

In commenting on my recent paper, "Melting Points of Iron Oxides in Contact with Silica,"[1] one of the referees questioned the value (1442°) reported there for the melting point of magnetite–silica mixtures in air. Such question arises naturally from several statements in the literature. For example, Bowen and Schairer[2] found "no more than a little liquid" formed by heating mixtures of iron oxide and silica to temperatures approaching 1500°, even in a vacuum furnace. Cook[3] observed fusion of magnetite–silica mixtures only near and above 1600°.

An attempt was made to resolve this apparent discrepancy by determining the approximate melting point by a more common method, namely, to prepare an intimate mixture of magnetite and silica by a preliminary fusion and then to determine the melting point of the mixture. Equal weights of magnetite and quartz were mixed by grinding in a mortar to pass a 400-mesh sieve. The mixture was placed in a small (1 ml.) platinum crucible and heated in an air atmosphere in a tubular "Globar" furnace. Starting at 1540° it was held at each of successively higher temperatures for fifteen minutes, being removed and examined in between. This procedure was continued until 1680° (near the limiting temperature of furnace) was reached, at which temperature the charge had sintered only slightly and was easily broken by gentle tapping or probing with a needle.

The failure to obtain a premelt by the above method was somewhat surprising: In order to avoid a large excess of silica another method was tried. A 2-cm. length of clear vitreous silica rod was placed vertically in the crucible and surrounded with magnetite (the same used by Darken and Gurry[4]). This charge was then heated in air to slightly above the melting point of magnetite (1597°) and held there one hour. The molten oxide was thus undoubtedly saturated, or nearly saturated, with silica. The charge was cooled and removed from the crucible; the silica rod and adjacent portions of the melt were discarded.

Having thus obtained a fused intimate mixture of magnetite and silica the melting point was determined as follows: The finely crystalline massive oxide was broken into small pieces about 3 mm. across. One of these pieces was placed in a platinum wire helix[5] and held about ten minutes at a predetermined temperature in an air atmosphere in the furnace. If extensive melting occurred the molten oxide ran down the helix and adhered to the lowest convolution. If no melting occurred the sharp corners and edges of the broken piece were still visible after cooling. From a series of such tests it was found that melting did occur at 1455 ± 5° but did not occur 20° lower. No attempt was made to establish closer limits.

Thus the difficulty in melting the mechanical mixture confirms the reports of Bowen and Schairer and of Cook, whereas the determination of the melting point by remelting confirms roughly the results of my previous investigation which placed the melting point at 1442°.

(5) The platinum helix was previously loaded with the oxide and held near 1500° for several hours so that the surface would absorb sufficient iron to be in substantial equilibrium with the melt. This precaution was taken lest the platinum absorb sufficient iron from the test specimen to seriously lower the iron–oxygen ratio to a value below that corresponding to the gas equilibrium.

## Standard Potential of the Mercury–Mercury(I) Phosphate Electrode

BY THOMAS DE VRIES AND DONALD COHEN

A study was made of the mercury–mercury (I) phosphate electrode in phosphoric acid solutions of various concentrations with cells of the type: $H_2$, $H_3PO_4$ (*m*), $Hg_2HPO_4$ (s), Hg. There is very little information in the literature about mercurous phosphate. Gerhardt[1] in 1849 and Haack[2] in 1891 had prepared mercurous orthophosphate by adding a solution of mercurous nitrate to an excess of sodium phosphate solution. They obtained a white or yellow precipitate. Latimer and Hildebrand[3] give the formula of the orthophosphate as $Hg_6(PO_4)_2$.

### Experimental

**Mercurous Phosphate.**—Mercury(I) nitrate was dissolved in water acidified with nitric acid. This solution was slowly added at room temperature to a solution of primary sodium phosphate, $NaH_2PO_4$, present in excess. A fine white precipitate first formed and gradually changed to a pale yellow or even a deep yellow color. The temperature at which the precipitation was carried out had no effect on the color. Analysis indicated the yellow compound to be the tertiary phosphate, $Hg_3PO_4$.

*Anal.* Calcd. for $Hg_3PO_4$: Hg, 85.21. Found: Hg, 85.41, 85.50.

(1) Gerhardt, *Jahresber.*, 288 (1849).
(2) Haack, *Ann.*, **262**, 192 (1891).
(3) Latimer and Hildebrand, "Reference Book of Inorganic Chemistry," The Macmillan Co., New York, N. Y., 1940.

When mercury(I) nitrate was added to a dilute solution of orthophosphoric acid, a pure white crystalline precipitate was obtained which did not change color. The precipitate was filtered, washed with water and dried in a desiccator over anhydrous calcium chloride.

*Anal.* Calcd. for $Hg_2HPO_4$: Hg, 80.71. Found: Hg, 79.2, 80.8.

The various concentrations of phosphoric acid were made by diluting a stock solution which had been prepared from 85% acid and standardized by titration against standard sodium hydroxide using thymolphthalein as indicator.

The platinized platinum electrodes were prepared with the usual care. Several were used and they checked with each other to within 0.3 millivolt. The hydrogen was bubbled through a solution of chromous chloride acidified with acetic acid[4] to remove oxygen, then through a solution of phosphoric acid of the same concentration as that used in the cell. The cell was H-shaped with a sintered glass diaphragm in the horizontal arm. Potentials were measured with a Rubicon, type B, potentiometer at 25 ± 0.05°.

The cells made with the yellow tertiary mercurous phosphate did not give constant or reproducible potentials. In all cases the potential would decrease with time and approach a minimum value. In some cases the yellow phosphate had changed to a white color in the 0.2 *M* phosphoric acid after several days. Typical potentials were 0.7364, 0.7392 and 0.7492 decreasing to 0.7245, 0.7228 and 0.7313 after seven days.

The cells made with the white secondary mercurous phosphate gave fairly constant and reproducible results and equilibrium values were established within one day. For the cell $H_2$ ($a$ = 1), $H_3PO_4(m)$, $Hg_2HPO_4$(s), Hg, the cell reaction is $H_2 + Hg_2HPO_4 = H^+ + H_2PO_4^- + Hg$, and if the secondary and tertiary ionizations are assumed to be negligible, the potential at 25° is given by the equation $E = E^0 - 0.02957 \log a_{H^+}a_{H_2PO_4^-}$. For $a_{H^+}a_{H_2PO_4^-} = K_1 a_{H_3PO_4}$, the value of $K_1 = 7.516 \times 10^{-3}$ was used as reported by Nims.[5] The activities of the undissociated phosphoric acid were taken from the results of Mason and Blum.[6] The calculated molal standard potential of the cell is given in the last column of Table I. The $E^0$ for the most dilute solution does not agree with the other values. Excluding that value, the average is 0.639 ± 0.002 volt.

An independent calculation for the $E^0$ of the cell can be made by using the Debye–Hückel limiting law for the mean ion activity coefficient of phosphoric acid and by using the degree of dissociation, $\alpha$, tabulated by Mason and Blum,[6] to calculate the concentration, $m_1$, of the hydrogen and the dihydrogen phosphate ion. The previous equation becomes $E^{0\prime} = E + 0.05914 \log \alpha m = E^0 + 0.0301\sqrt{\alpha m}$, using $\log \gamma_\pm = -0.5085\sqrt{\mu}$ and $\mu = m_1 = \alpha m$. The results of such a calculation are given in Table II. The average value of 0.638 ± 0.002 for the $E^0$ of the cell agrees better than one should expect. The molal potential for the electrode Hg, $Hg_2HPO_4$, $H_2PO_4^-$ is −0.639 ± 0.002 volt at 25°.

## The Ziegler Bromination of Ethyl Tetrolate

BY J. ENGLISH, JR., AND J. DELAFIELD GREGORY[1]

In a recent review article Djerassi[2] commented on the lack of data on the reactions of N-bromosuccinimide with acetylenic compounds. This prompts us to record our observations on the bromination of ethyl tetrolate by this method.

Tetrolic acid was synthesized by the action of carbon dioxide on propynylmagnesium bromide and converted to its ethyl ester in the usual manner.[3] Pure samples of the ester were then dissolved in carbon tetrachloride and treated with N-bromosuccinimide at reflux temperatures, with addition of benzoyl peroxide, under ultraviolet light, without either, and finally in a sealed vessel at 150°. In all cases most of the ester was recovered unchanged. The only product that could be isolated in pure form was ethyl $\alpha,\beta$-dibromocrotonate, resulting apparently from the addition of two atoms of bromine at the triple bond.

A somewhat analogous addition reaction accompanying the Ziegler bromination of cyclobutene and methylene cyclobutane has been reported by Buchman and Howton.[4] In the present instance, although no hydrogen bromide was noted, the rather extensive decomposition observed might well have produced some of this substance and hence made bromine available to the reaction mixture as pointed out by these authors.

### Experimental

A suspension of 19.5 g. of N-bromosuccinimide in 30 cc. of carbon tetrachloride was mixed with 12.0 g. of ethyl tetrolate and 0.5 g. of freshly recrystallized dibenzoyl peroxide. After fifty minutes at reflux temperature the pale yellow solution was decanted from 15 g. of dark tarry material, the solvent evaporated and the residue distilled. In addition to 6.6 g. (55%) of ethyl tetrolate there was obtained 3.5 g. (12%) of a fraction boiling at 68–75° at 2 mm. This product was combined with those from other experiments and carefully fractionated to yield pure ethyl $\alpha,\beta$-dibromocrotonate b. p. 58.5–60° at 0.8 mm., $n^{20}D$ 1.5175, $d^{20}_4$ 1.744.

*Anal.* Calcd. for $C_6H_8O_2Br_2$: C, 26.50; H, 2.96; Br, 58.77. Found: C, 26.60; H, 3.05; Br, 58.62.

For further identification a sample was saponified by refluxing with 10% aqueous potassium hydroxide. From the highly colored product there was isolated by extraction with ligroin pure $\alpha,\beta$-dibromocrotonic acid, m. p. 118.5–119.5°. Michael reported the melting point of this substance as 120°.[5]

## The Condensation of 2′-Methyl-3′,5′-dinitrochalcone with Ethyl Malonate

BY REYNOLD C. FUSON AND GEORGE MUNN

2′-Methyl-3′,5′-dinitrochalcone (I) was prepared in the hope that it might undergo an intramolecular Michael condensation to yield the corresponding substituted $\alpha$-tetralone. However, under the conditions ordinarily employed for Michael condensations no ring closure occurred. That this chalcone is capable of undergoing reactions of the Michael type was demonstrated by condensing it intermolecularly with ethyl malonate.

The product (II) which was obtained when the chalcone was allowed to react with ethyl malonate was hydrolyzed and the resulting acid decarboxylated to form 2-phenyl-3-(2-methyl-3,5-dinitrobenzoyl)-butyric acid (III).

The 2′-methyl-3′,5′-dinitrochalcone yielded a monobromo derivative when it was allowed to react with bromine in acetic acid solution. Oxidation of the bromochalcone with permanganate produced 3,5-dinitro-*o*-toluic acid, showing that the bromine was not attached to the methyl group. It thus seems probable that the addition of bromine to the double bond is followed by the loss of hydrogen bromide, forming 2′-methyl-3′,5′-dinitro-$\alpha$-bromochalcone (IV).

### Experimental

**2-Methyl-3,5-dinitroacetophenone.**—2-Methyl-3,5-dinitrobenzoyl chloride was prepared by heating a mixture of 45 g. of 3,5-dinitro-*o*-toluic acid,[1] 35 ml. of purified thionyl chloride, and 200 ml. of dry benzene under reflux until the acid completely dissolved. The solvents were then removed by distillation under diminished pressure, and the residue was dissolved in 250 ml. of dry ether. This ether solution was used without further purification.

An ether solution of the ethoxymagnesium salt[2] of malonic ester was made in the following manner: Five milliliters of absolute ethanol, 0.5 ml. of carbon tetrachloride, and 5.25 g. of magnesium turnings were placed in a flask and allowed to react for a few minutes. Seventy-five milliliters of anhydrous ether was then added and to this mixture a solution of 35.2 g. of ethyl malonate, 20 ml. of absolute ethanol and 25 ml. of dry ether was added at a rate such that mild refluxing was maintained.

When the magnesium had dissolved, the solution of 2-methyl-3,5-dinitrobenzoyl chloride was added with stirring over a period of thirty minutes. The contents of the flask were then heated under reflux for an additional thirty minutes and then acidified with dilute sulfuric acid. The ether layer and an ether extract of the water layer were combined and the solvent was removed by distillation. The residual liquid was heated under reflux for four hours in a mixture of 60 ml. of acetic acid, 7.5 ml. of concentrated sulfuric acid and 40 ml. of water. The mixture was cooled, diluted with water and extracted with ether. The ether was washed with sodium bicarbonate solution, dried over calcium chloride, and the solvent was removed by distillation. The residue was distilled under diminished pressure at 150–152° (2 mm.). The yield was 27 g. (60%). When recrystallized from methanol, the 2-methyl-3,5-dinitroacetophenone melted at 72–73°.

*Anal.* Calcd. for $C_9H_8N_2O_5$: C, 48.24; H, 3.60; N, 12.50. Found: C, 48.47; H, 3.79; N, 12.40.

**2′-Methyl-3′,5′-dinitrochalcone (I).**—Dry hydrogen chloride was bubbled slowly over a period of two days into a solution of 22.6 g. of 2-methyl-3,5-dinitroacetophenone and 12 ml. of benzaldehyde in 150 ml. of glacial acetic acid. During this time a crystalline precipitate appeared. The mixture was then heated under reflux for two hours and poured on ice. The white precipitate which formed was collected on a filter and recrystallized from ethanol. Twenty-one grams of 2′-methyl-3′,5′-dinitrochalcone was obtained; m. p. 128–129°; 67%.

*Anal.* Calcd. for $C_{16}H_{12}N_2O_5$: C, 61.53; H, 3.88; Found: C, 61.65; H, 3.90.

**Condensation of 2′-Methyl-3′,5′-dinitrochalcone with Ethyl Malonate.**—A mixture of 3.1 g. of 2′-methyl-3′,5′-dinitrochalcone, 2 ml. of ethyl malonate, 100 ml. of absolute ethanol, and 5 drops of piperidine was heated under reflux for twenty-four hours. It was then diluted with water, acidified and extracted with ether. The ether layer was dried over calcium chloride, and the solvent was removed by distillation. The residue was recrystallized several times from methanol with the use of charcoal; 1.8 g. of white crystals (II) was obtained; m. p. 96–97°.

*Anal.* Calcd. for $C_{23}H_{24}N_2O_9$: C, 58.47; H, 5.12; N, 5.93. Found: C, 58.78; H, 5.16; N, 6.09.

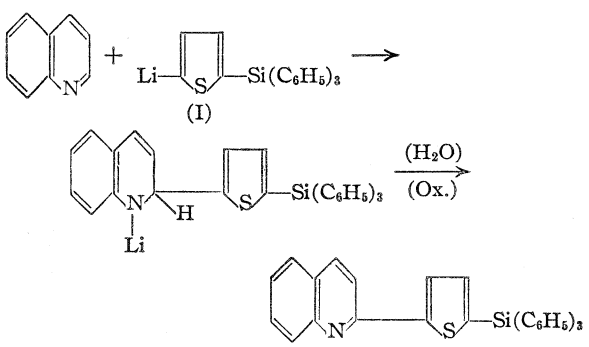
**2-Phenyl-3-(2-methyl-3,5-dinitrobenzoyl)-butyric Acid.**—One gram of the malonic ester adduct was heated under reflux for four hours in a mixture of 10 ml. of glacial acetic acid, 7 ml. of water, and 1.5 ml. of concentrated sulfuric acid. The reaction mixture was then poured into 100 ml. of cold water; the acid precipitated as a brown gum. When this substance was recrystallized from methanol with the use of charcoal, it yielded 2-phenyl-3-(2-methyl-3,5-dinitrobenzoyl)-butyric acid (III) as white crystals melting at 137–138°.

*Anal.* Calcd. for $C_{18}H_{16}N_2O_7$: C, 58.06; H, 4.33; N, 7.53. Found: C, 58.32; H, 4.42; N, 7.78.

**2′-Methyl-3′,5′-dinitro-α-bromochalcone.**—A solution of 3.1 g. of 2′-methyl-3′,5′-dinitrochalcone and 5 ml. of bromine in 100 ml. of glacial acetic acid was allowed to stand at room temperature for twenty-four hours. At the end of this time the reaction mixture was poured into ice water and the excess bromine was destroyed by the addition of sodium sulfite solution. The white precipitate which formed was collected on a filter and recrystallized from ethanol. The bromochalcone (IV) formed white crystals which melted at 137°; yield 3 g.

*Anal.* Calcd. for $C_{16}H_{11}BrN_2O_5$: C, 49.12; H, 2.83. Found: C, 49.44; H, 2.79.



When the bromochalcone was oxidized with potassium permanganate in aqueous acetone, 3,5-dinitro-*o*-toluic acid was formed.

## Some Anil Additions Involving Organosilicon Compounds

BY HENRY GILMAN AND MARY ALYS PLUNKETT[1]

In connection with studies on pharmacological action and chemical constitution, it seemed of interest to make a molecule containing both silicon and the quinoline nucleus. Consequently, compounds were prepared in which a lithiosilane was added to the anil linkage of a quinoline compound, as in the reaction

Triphenyl-[2-(5-lithio)-thienyl]-silane (I) reacted with quinoline, 6-methoxyquinoline and 4,7-dichloroquinoline. It is very probable that the substance isolated in each case was the 2-substituted quinoline, and not the 1,2-dihydro compound initially formed by hydrolysis of the N–Li intermediate from the addition of I across the azomethine linkage. Isolation through the picrates often leads to the oxidation of 1,2-dihydroquinolines by the picric acid.[2] The 1,2-dihydro compounds show an instability toward purification by crystallization, and cannot usually be obtained with a definite melting point range, as were the compounds described in this communication.

The preparation of I and a typical anil addition reaction are given in the experimental.

The authors are grateful to William Meikle for assistance, and particularly to Parke, Davis and Company for arranging for pharmacological testing, the results of which will be reported elsewhere.

### Experimental

**Triphenyl-[2-(5-lithio)-thienyl]-silane (I).**—To a solution of 5.5 g. (0.016 mole) of triphenyl-2-thienylsilane[3] under nitrogen in a mixture of equal parts of benzene and anhydrous ether was added 0.016 mole of *n*-butyllithium[4] in ether; the reaction mixture was refluxed for five hours. The solution gave a negative color test II.[5] It was used on the basis of an 80% yield, but the RLi compound was not, of course, isolated.

**Triphenyl-[5-(2′-quinolyl)-2-thienyl]-silane.**—To approximately 0.012 mole of I under nitrogen was added 1.5 g. (0.012 mole) of freshly distilled quinoline (previously dried over potassium hydroxide). A very slow reflux set in as the addition was made and the reaction mixture changed from red to dark yellow. After refluxing for one hour, the mixture was hydrolyzed and worked up to give 5 g. of crude solid, which was dissolved in dioxane and treated with a hot alcoholic solution of picric acid. The red picrate which precipitated was decomposed by boiling with a 5% solution of sodium hydroxide. After recrystallization from dilute dioxane, 40% of product melting at 168–170° was obtained.

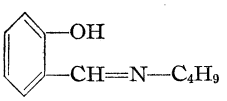
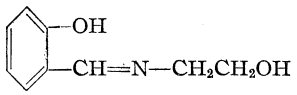
## The Reaction of *o*-Hydroxy and *o*-Chlorobenzaldehyde with Ethanolamine[1]

BY LOUIS H. GOODSON AND HOPE CHRISTOPHER



In studying the reaction of ethanolamine with salicylaldehyde and with *o*-chlorobenzaldehyde, M. Meltsner, E. Waldman and Chester B. Kremers[2] report that in these two cases addition com-

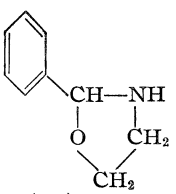
(1) This investigation was supported in part by a research grant from the National Cancer Institute of the National Institute of Health, U. S. Public Health Service.



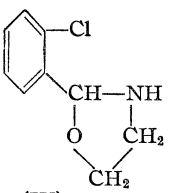
(2) M. Meltsner, E. Waldman and Chester B. Kremers, THIS JOURNAL, **62**, 3494 (1940).

pounds are formed without the elimination of water. They suggest that the failure of these two aldehydes to yield oxazolidines is due to chelation. We have found that water is eliminated in both of these reactions and that salicylaldehyde gives a Schiff base and that *o*-chlorobenzaldehyde yields an oxazolidine derivative.

In our initial experiments, salicylaldehyde was dissolved in an excess of benzene and treated with ethanolamine whereupon a mildly exothermic reaction took place and a water layer separated. Azeotropic distillation of the mixture effected the separation of one mole of water from one mole of each of the reactants. It was thought that perhaps the elimination of water in our experiment was due to the use of conditions differing from those used by Meltsner and co-workers.[2] Accordingly, we followed their procedure as carefully as possible but noted a layer of water in the receiver on removal of the butyl alcohol from the reaction mixture by slow distillation. The analyses and refractive indices of the products obtained from salicylaldehyde and ethanolamine show that the products are the same whether the reaction is carried out in benzene or in butyl alcohol. The intense yellow color of the material, even in thin layers, suggests that the Schiff base structure is the probable one. This structure is further supported by the ultraviolet absorption spectra (Fig. 1) of this and related compounds. Curve A is the absorption spectrum for N-*n*-butyl-2-hydroxybenzalamine (I) which was prepared by the reaction of salicylaldehyde and *n*-butylamine. Its absorption spectrum confirms the fact that it is a Schiff base possessing a double bond conjugated with a benzene ring. Curve B represents the absorption spectrum of the reaction product obtained from salicylaldehyde and ethanolamine. The similarity of these two curves indicates that this product is then the N-(2-hydroxyethyl)-2-hydroxybenzalamine (II), which is a Schiff base containing a double bond conjugated with the benzene ring.



(I)



(II)

The structure, 2-(2-hydroxyphenyl)-oxazolidine, is eliminated because it would be expected to have an absorption spectrum resembling curves C and D (Fig. 1).

Similarly the reaction of *o*-chlorobenzaldehyde with ethanolamine in benzene yielded the theoretical quantity of water necessary for the formation of the Schiff base or the oxazolidine. However, this colorless product is thought to be the 2-(2-chlorophenyl)-oxazolidine (IV) in spite of Meltsner's report that his analysis agreed with a chelation compound formed without the elimination of water. Curve D (Fig. 1) gives the ultraviolet absorption spectrum of 2-phenyloxazolidine[3] (III)

(III)

(IV)

whose assigned structure was based on an analogy with known oxazoles and on its method of preparation. Because the oxazolidine ring system is relatively unstable, compounds bearing this structure react in the same manner as the open chain Schiff bases. For example, treatment of 2-phenyloxazolidine with dilute acid readily gives benzaldehyde and ethanolamine hydrochloride. Further, treatment of 2-(4-methoxyphenyl)-oxazolidine[2] with benzylmagnesium chloride gives a product similar to that obtained with Grignard reagents on various Schiff bases.[4] For these and other reasons it is difficult in most cases to distinguish between the Schiff base and the oxazolidine structures by their chemical reactivities. Curve C gives the ultraviolet absorption spectrum of 2-(2-chlorophenyl)-oxazolidine, (IV). Comparison of this curve with Curve D indicates the absence of the Schiff base structure and also a similarity with the known oxazolidine spectrum.

The molecular refractivities of four compounds discussed in this paper have been reported. In each case there appears to be an exaltation ranging from 2.57 to 3.35 units. Other Schiff bases and oxazolidines to be reported later in connection with other work, show exaltations of similar magnitudes. An attempt to differentiate between

**N-(2-Hydroxyethyl)-2-hydroxybenzalamine (II).**—Method (a): A mixture of 61 g. of salicylaldehyde, 30.5 g. of ethanolamine and 200 ml. of benzene was refluxed using a water-trap (9 ml. of water was collected in two hours). The residue was distilled and the fraction b. p. 110–120° at 0.2 mm. was yellow and weighed 74 g.; $n^{25}D$ 1.6052; $d^{25}_4$ 1.1608; $MR_D$ (calcd.) 46.04; $MR_D$ (obsd.) 49.02.

*Anal.* Calcd. for $C_9H_{11}NO_2$: N, 8.48. Found: N, 8.48.

Method (b): To a solution of 30.5 g. of salicylaldehyde in 68 ml. of reagent grade *n*-butanol was added 15.2 g. of ethanolamine. An exothermic reaction caused the temperature to rise from 28 to 63°. The clear deep-yellow solution was boiled for four hours and then distilled. During the early part of the distillation a water layer was visible under the butanol. The fraction b. p. 110–115° at 0.2 mm. weighed 36 g.; $n^{25}D$ 1.6050; $d^{25}_4$ 1.1608.

*Anal.* Calcd. for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48. Found: C, 65.31; H, 6.80; N, 8.46.

**2-Phenyloxazolidine (III).**—This compound, prepared by the method of Knorr and Matthes,[3] was colorless, b. p. 86–88° at 0.1 mm.; $n^{25}D$ 1.5729; $d^{25}_4$ 1.0707; $MR_D$ (calcd.) 43.36; $MR_D$ (obsd.) 45.93.

**2-*o*-Chlorophenyloxazolidine (IV).**—A mixture of 70.3 g. of *o*-chlorobenzaldehyde, 30.5 g. of ethanolamine and 200 ml. of benzene (exothermic on mixing) was refluxed for two hours using a water-trap (9 ml. of water collected). The material was distilled and the fraction b. p. 102–104° at 0.2 mm., weighed 82 g. After redistillation it was a colorless oil weighing 78 g.; $n^{25}D$ 1.5793; $d^{25}_4$ 1.2073; $MR_D$ (calcd.) 47.22; $MR_D$ (obsd.) 50.57.

*Anal.* Calcd. for $C_9H_{10}ClNO$: C, 58.86; H, 5.49; N, 7.63. Found: C, 58.82; H, 5.46; N, 7.66.

**Ultraviolet Absorption Spectra.**—The data given in Fig. 1 were obtained using a Beckman quartz spectrophotometer with the hydrogen discharge lamp and quartz cells with a light path of 1 cm. A solution of 2.45 mg. of compound (I) in 100 ml. of absolute alcohol showed maxima at 255 mμ, $\epsilon$ = 95,500 and 315 mμ, $\epsilon$ = 30,000 (Curve A). A solution of 2.28 mg. of compound (II) in 100 ml. of absolute alcohol showed maxima at 252.5 mμ, $\epsilon$ = 100,000 and at 315 mμ, $\epsilon$ = 34,100 (Curve B). A solution of 2.53 mg. of compound (III) in 100 ml. of abs. alcohol showed maxima at 247.5 mμ, $\epsilon$ = 127,400 and 290 mμ, $\epsilon$ = 14,480 (Curve C). A solution of 2.28 mg. of compound (IV) in 100 ml. of abs. alcohol showed a maximum at 245 mμ, $\epsilon$ = 127,600 (Curve D).

## Preparation of Anhydrous Methyl Vinyl Ketone and Methyl Isopropenyl Ketone

BY HUGH J. HAGEMEYER, JR.

The preparation of methyl isopropenyl ketone by the aldol condensation of methyl ethyl ketone with formaldehyde and an evaluation of the method was reported by Landau and Irany.[1] In both the liquid phase aldol condensation and in the catalytic vapor phase condensation of formalin with methyl ketone[2,3] considerable difficulty is encountered in drying the unsaturated ketone and in removing traces of formaldehyde.

An alternate method of preparing methyl vinyl ketone and methyl isopropenyl ketone has now been evolved using the Mannich Reaction.[4,5,6,7] The Mannich base is prepared by treating a ketone with a secondary amine hydrochloride and formalin or paraformaldehyde. With acetone, diethylamine hydrochloride and formalin the reaction can be represented by the equation

$$CH_3COCH_3 + CH_2O + (C_2H_5)_2NH\cdot HCl \longrightarrow CH_3COCH_2CH_2N(C_2H_5)_2\cdot HCl + H_2O$$

The tertiary base is separated from the reaction mixture by treating the reaction product with 50% caustic. After drying and distillation it is suspended in an inert medium such as Dowtherm and an equivalent of anhydrous hydrogen chloride is added. The tertiary amine salt is then deaminated by heating to temperatures of 145–160°

$$CH_3COCH_2CH_2N(C_2H_5)_2\cdot HCl \longrightarrow CH_3COCH{=}CH_2 + (C_2H_5)_2NH\cdot HCl$$

The secondary amine hydrochloride can be recovered from the inert medium by filtration or extraction with water and reused in a subsequent batch. In practice it is preferred to add the tertiary amine hydrochloride gradually to the deaminating flask and the unsaturated ketone is distilled off continuously.

It is significant that with methyl ethyl ketone only methyl isopropenyl ketone was formed and there was no evidence for the formation of ethyl vinyl ketone. This indicates the mono-tertiary amine formed to be exclusively α-methyl-β-dimethylaminoethyl methyl ketone.

$$CH_3COCH_2CH_3 + CH_2O + (CH_3)_2NH\cdot HCl \longrightarrow CH_3COCH(CH_3)CH_2N(CH_3)_2HCl + H_2O$$

The methyl isopropenyl ketone prepared by deamination of this tertiary amine hydrochloride had the same constants as those reported for pure methyl isopropenyl ketone by Brant.[8]

### Experimental

**General Procedure.**—A mixture of ketone, dialkylamine hydrochloride and formaldehyde is refluxed for eight to twelve hours. A large excess of ketone is preferred in order to minimize the formation of di-tertiary amine products. In some instances the addition of a small amount of ethanol or isopropyl alcohol is advantageous in order to give a homogeneous mixture. At the end of the reaction excess ketone is removed by distillation. An excess

(7) Mannich and Haf, *Arch. Pharm.*, **265**, 589 (1927).
(8) Brant, THIS JOURNAL, **64**, 2224 (1942).

of 50% alkali hydroxide is added slowly with cooling and the tertiary amine layer is separated, dried and distilled. It is desirable to concentrate the water solution in order to complete the separation of the tertiary amine.

By varying the conditions and the mole ratios of the reactants yields of 80–90% of the mono-tertiary amine can be realized. The tertiary amine is diluted with a suitable inert solvent and treated with an equivalent of anhydrous hydrogen chloride. The amine hydrochloride is suspended in Dowtherm and is deaminated by heating to 145–165°. Care should be exercised in the deaminating reaction so that no decomposition of the secondary amine hydrochloride takes place.

**Methyl Vinyl Ketone.**—Acetone (700 g., 12 moles) and diethylamine hydrochloride (6 moles) in 30% aqueous solution are mixed together. To this are added paraformaldehyde (240 g., 8 moles) and 150 cc. of isopropyl alcohol. The mixture is refluxed for six hours and then concentrated at reduced pressure from a water-bath. Five hundred grams of a 50% alkali hydroxide solution was added gradually with cooling. The tertiary amine layer is separated off and dried by distillation. The anhydrous amine distils at 74–75° at 15 mm. and titrates the theoretical equivalent weight of 143. The yield is 690 g. or 80.5%.

One hundred and forty-three grams (1 mole) of the tertiary amine is suspended in Dowtherm (1000 cc.) and anhydrous hydrogen chloride (35 g.) is added to form the amine hydrochloride. The suspension is added gradually to 500 cc. of Dowtherm in a 3-liter flask heated to 150° and equipped with a sweep stirrer and a short Vigreux column (45 cm.). Pure anhydrous methyl vinyl ketone distils off at 81° (734 mm.). The deamination is quantitative and the diethylamine hydrochloride is separated from the Dowtherm by washing with water.

**Methyl Isopropenyl Ketone.**—Methyl ethyl ketone (12 moles), dimethylamine hydrochloride (6 moles) and paraformaldehyde (8 moles) together with 300 cc. of isopropyl alcohol are mixed and refluxed for eight hours. The solution is concentrated, treated with excess 50% alkali hydroxide and the α-methyl-β-dimethylaminomethyl ethyl ketone is separated off and distils at 58° and 15 mm. Yield is 695 g. or 89%.

One mole (165 g.) of the tertiary amine hydrochloride is suspended in Dowtherm and deaminated at 160°. A 92% yield of anhydrous methyl isopropenyl ketone distilling at 96–97° at 734 mm. is obtained.

## Surface Tension of Chloroform

BY M. CONSILIA HANNAN AND M. CLARE MARKHAM

Recently R. Fanelli[1] has discussed the values of surface tension of chloroform determined by many investigators using various methods. Since no values were determined by the pendant-drop method, it was interesting to use apparatus already constructed in this Laboratory in connection with other work, to determine values of surface tension of chloroform.

This apparatus was similar to that of Hauser and his associates[2] and the techniques and method of calculation used, have been developed by Hauser. The chloroform was prepared from C. P. analyzed grade by washing with water, drying over calcium chloride and fractionally distilling. The portion boiling at 61° was used.

(1) R. Fanelli, THIS JOURNAL, **70**, 1792 (1948).

(2) J. M. Andreas, E. A. Hauser and W. B. Tucker, *J. Phys. Chem.*, **42**, 1001 (1938).

The surface tension values obtained at 25.00° were: 26.6, 26.6, 26.5, 26.5, 26.4, 26.5; average 26.5 dynes per cm.

Fanelli reports average values of 26.53 dynes per cm. obtained at 25.0° by the maximum bubble pressure, Sugden's double capillary method, using dried nitrogen; and average 26.46 dynes per cm. using nitrogen saturated with chloroform. The values obtained as noted above by the pendant-drop method check very closely those of Fanelli.

## The Synthesis of Certain β-Diketones Containing a Furan Nucleus[1]

BY SAMUEL R. HARRIS[2] AND ROBERT LEVINE

The synthesis of a number of β-diketones by the acylation of 2-acetylthiophene with a series of esters has been reported in a recent communication from this Laboratory.[1] In the present investigation, several β-diketones containing a furan ring have been prepared. Two of these compounds have been prepared previously by other investigators.[3,4] Thus, acetyl-2-furoylmethane was prepared by acylating acetone with ethyl furoate using sodium ethoxide as the condensing agent[3] and benzoyl-2-furoylmethane has been synthesized by acylating acetophenone with ethyl furoate in the presence of sodium ethoxide[3] or metallic sodium.[4]

In the present work, two methods were used to prepare the β-diketones. The following equations, in which R represents an alkyl, aryl, or 2-thienyl group, indicate the reactions which take place.

The method of acylation used consists of allowing an ethereal suspension of two equivalents of sodium amide to react with two equivalents of the methyl ketone. The sodio derivative of the ketone thus formed is then acylated with an equivalent of the appropriate ester and the reaction mixture stirred and refluxed for two hours. This procedure is essentially that reported previously from this[1] and other laboratories.[5]

[a] See ref. 3. [b] *Anal.* Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27. Found: C, 68.11; H, 7.32. [c] *Anal.* Calcd. for $C_{12}H_{16}O_3$: C, 69.20; H, 7.75. Found: C, 69.12; H, 7.75. [d] *Anal.* Calcd. for $C_{11}H_8O_3S$: S, 14.56. Found: S, 14.81.

The results of the present study are found in Table I. It may be seen that when the same $\beta$-diketone is prepared according to Schemes I and II above, the yield using ethyl 2-furoate as the acylating ester is invariably much higher than when an aliphatic or aromatic ester is used to acylate 2-acetylfuran. This large discrepancy in yield might have been difficult to explain if there had not been a visible side reaction occurring. It was observed that as soon as the first few drops of the 2-acetylfuran, which was being added from an addition funnel, came in contact with the ethereal suspension of sodium amide in the reaction flask, the residual 2-acetylfuran in the funnel became cloudy and as the addition was continued a fluid solid material formed in the funnel. It was felt that this solid was formed by the interaction of the ketone with ammonia. Ammonia is present in the reaction mixture either because some remains in solution when the sodium amide is suspended in ether or because of the following reaction which is the first step in the acylation of ketones with esters.

$$RCOCH_3 + NaNH_2 \longrightarrow RCOCH_2Na + NH_3$$

A sample of freshly distilled 2-acetylfuran was dissolved in absolute ether and the solution was then saturated with gaseous ammonia. An exothermic reaction took place and a brown solid material precipitated out of solution. This solid was water-soluble and unreactive toward 2,4-dinitrophenylhydrazine reagent, indicating that the carbonyl group was no longer free. An analysis of this solid (calcd. N, 11.02. Found: N, 11.11) suggested a molecular formula, $C_6H_9O_2N$ for the compound. It is probably a ketone ammonia and should therefore not be acylated by esters.

A detailed investigation of the reactions of 2-acetylfuran with ammonia and amines is now in progress in this Laboratory.

### Experimental

**Synthesis of Acyl-2-furoylmethanes.**—The apparatus used in these reactions consisted of a 1000-ml. three-necked round-bottomed flask having ground-glass joints and equipped with a mercury-sealed stirrer, an addition funnel, and a condenser (protected from atmospheric moisture by a drying tube filled with Drierite). Four-tenths of a mole of sodium (9.2 g.) is converted to sodium amide and suspended in absolute ether as described previously.[6] To the rapidly stirred suspension of sodium amide in ether, 0.4 mole of the appropriate ketone dissolved in 50 ml. of absolute ether is added, followed after fifteen minutes by 0.2 mole of the acylating ester. The reaction mixture is refluxed for two hours on a water-bath and then worked up as described earlier.[1,6] The yields of the compounds prepared are found in Table I.

## Maleimide as a Dienophile

BY STEWART C. HARVEY[1]

Although maleic anhydride, maleic acid, and maleic esters have been used extensively as dienophiles in the Diels–Alder diene synthesis, the dienophilic character of maleimide has remained uninvestigated. In order to test its activity, maleimide was dissolved in ether with cyclopentadiene-1,3; the quantitative separation of a crystalline adduct, subsequently shown to be 3,6-endomethylene-1,2,3,6-tetrahydro-*o*-phthalimide, gave clear evidence of dienophilic activity. The structure of the adduct was confirmed by alkaline hydrolysis to give the known 3,6-endomethylene-1,2,3,6-tetrahydro-*o*-phthalic acid, which was identified by a mixed melting point procedure employing the same compound prepared in another manner.[2]

### Experimental

**3,6-Endomethylene-1,2,3,6-tetrahydro-*o*-phthalimide.**—A mixture consisting of 1.1 g. (1.4 ml.) of cyclopentadiene-1,3 and 1.6 g. of maleimide in 40 ml. of anhydrous ether was allowed to stand at room temperature. Evidence of a reaction was the appearance of a faint yellow color a few minutes after the reagents were brought together. The following morning 2.5 g. of gleaming white needles had separated from the solution. Recrystallization from alcohol–ether (1:2) gave a product melting at 187°. It was found to be very soluble in acetone, hot

(1) Present address: University of Texas School of Dentistry, Houston 4, Texas.

(2) O. Diels and K. Alder, *Ann.*, **460**, 98 (1928).

ethanol, 5% sodium hydroxide; slightly soluble in water, cold ethanol, cold acetic acid, diluted hydrochloric acid; insoluble ether. The adduct decomposed at temperatures above the melting point to give the original reagents; the addition was also somewhat reversible in cold sodium hydroxide solutions.

*Anal.* Calcd. for $C_9H_9O_2N$: N, 8.58. Found: N, 8.51.

**3,6-Endomethylene-1,2,3,6-tetrahydro-*o*-phthalic Acid.**—Two-tenths gram of 3,6-endomethylene-1,2,3,6-tetrahydro-*o*-phthalimide were placed on a steam-bath with 5 ml. of 10% potassium hydroxide and heated for three hours, at the end of which time no ammonia was detectable in the vapors above the flask. Concentrated hydrochloric acid was added in excess, and the mixture was then evaporated to dryness. The residue was then triturated in 20 ml. of ether to remove the maleic acid formed by the alkali-catalyzed reversal of the addition. The remaining organic constituents were taken up in 10 ml. of boiling acetone, and petroleum ether was added to the solution until it became cloudy, whereupon the mixture was left at 0° to crystallize. After one recrystallization from alcohol–ether (1:2) the melting point was observed to be 177°, which was not lowered by 3,6-endomethylene-1,2,3,6-tetrahydro-*o*-phthalic acid from another source.

## N,N-Dimethyl-N′-(2-pyridyl)-N′-(2-furfuryl)-ethylenediamine

BY L. P. KYRIDES AND M. F. ZIENTY

In a recent publication Vaughan and Anderson[1] described the preparation of N,N-dimethyl-N′-(2-pyridyl)-N′-(2-furfuryl)-ethylenediamine (I) originally synthesized by Viaud.[2]

These authors reported that (I) is very unstable at temperatures even as low as −80° and that they were unable to prepare its mineral acid salts.[3]

Prior to the disclosure of Vaughan, *et al.*, the monohydrochloride of (I) had been prepared in this Laboratory for pharmacological evaluation. Since our findings do not support the observations reported, we are prompted to record our results.

Furfuryl alcohol was converted to the chloride in 75% yield by a modification of a synthesis described by Kirner,[4] with thionyl chloride in ether solution in the presence of pyridine at −15–20°. Distilled furfuryl chloride[5] was then treated with the lithium salt of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine in benzene solution at room temperature. After removal of the solvent and unreacted N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine the desired product distilled as a yellow oil, stable at room temperature.

The monohydrochloride was prepared as well as the dihydrogen citrate salt.

The synthesis of (I) is described in detail.

### Experimental[6]

**N,N-Dimethyl-N′-(2-pyridyl)-N′-(furfuryl)-ethylenediamine.**—To a suspension of 8.3 g. (0.36 mole) of lithium amide in 500 cc. of dry benzene was added 59.4 g. (0.36 mole) of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine,[7,8] and the mixture refluxed for three hours with stirring. The reaction was cooled to 25° and maintained at this temperature while a solution of 42 g. (0.36 mole) of furfuryl chloride in 200 cc. of dry benzene was added dropwise during one hour, then refluxed for one hour. On cooling, the solid material was removed by suction filtration and the solvent distilled under reduced pressure. After a forerun of 17.7 g. (28.7% recovery) of the starting ethylenediamine (b. p. 100–105° (0.4 mm.)), 45.9 g. (52%) of the desired tertiary amine was collected as a light yellow oil, b. p. 117.5–118° (0.2 mm.). The dihydrogen citrate was prepared in 88% yield by treating a methanol solution of 4.9 g. (0.026 mole) anhydrous citric acid with a methanol solution of 10 g. (0.04 mole) of (I) and precipitation with dry ether. Recrystallization of this salt from methanol–ether gave colorless crystals, m. p. 95–97°.[1a]

The monohydrochloride was prepared by treating an ethyl acetate solution of 36.2 g. (0.14 mole) (I) with 5 g. (0.14 mole) dry hydrochloric acid in methanol. On cooling, 37.8 g. (92%) of monohydrochloride was obtained. Recrystallization from ethyl acetate yielded colorless needles, m. p. 117–119°.

(1) Vaughan and Anderson, THIS JOURNAL, **70**, 2607 (1948), reported m. p. 95–97°.

(2) Viaud, *Technologie Produits Pharmaceutiques*, **2**, 53 (1947).

(3) In a personal communication, Dr. Anderson, after receiving the manuscript of this article, has written us as follows: "We today converted a sample of our stable citrate to the base and then to the hydrochloride in solution. In contrast to our previous experience, the solution remained colorless. Our only explanation is that an impurity in the original base caused its instability to temperature and mineral acids, and in the process of preparing the citrate this impurity was removed. We found also that the 5-bromofurfuryl analog hydrochloride appears to be stable when made from the citrate," and authorizes us to publish this statement as a footnote.

## The Influence of Crystal Face in the Catalytic Deposition of Cobalt on a Single Crystal of Copper[1]

BY HENRY LEIDHEISER, JR., AND RICHARD MEELHEIM

It has previously been shown in two different cases[2,3] that the rate of gaseous, catalytic reactions on the surface of a metal differs with the crystal face exposed at the surface. It has also been shown by Beeck, Smith and Wheeler[4] that the rate of the reaction of hydrogen and ethylene on a nickel film with a (110) orientation parallel to the surface is greater than that on an unoriented film. Results reported herein show that the rate of another type of catalytic reaction, the

(1) This work was supported by a grant from the Research Corporation.

(2) Reaction of hydrogen and oxygen on copper: Leidheiser and Gwathmey, THIS JOURNAL, **70**, 1200 (1948).

(3) Decomposition of carbon monoxide on nickel: Leidheiser and Gwathmey, *ibid.*, **70**, 1206 (1948).

(4) Beeck, Smith and Wheeler, *Proc. Roy. Soc.* (*London*), **A177**, 62 (1940).

chemical deposition from solution of one metal on a crystal of another, differs with the face exposed at the surface. An explanation for the results is proposed on the basis of interatomic distances.

In the study of catalytic reactions with the aid of large single crystals, there are two general methods by which the rates of reaction on the different faces may be determined. When the products of the reaction are continually removed from the catalyst surface, it is necessary to expose only one face at a time. The rate of formation of the product is then determined by analysis of the exit gases or liquids. A second method consists of using a monocrystalline sphere[5] containing all crystal faces, and choosing a reaction which leaves a deposit on the surface, from which conclusions may be drawn concerning the comparative activity of the various faces. Both methods have their advantages and disadvantages but the latter method possesses the unique advantage of exposing all crystal faces simultaneously.

Monocrystalline spheres of copper, $^5/_8$ in. in diameter with a shaft $^3/_{16}$ in. in diameter, were mechanically and electrolytically polished by the method previously described.[6] They were immersed in potassium formate solutions of a cobalt salt at 180–250° and cobalt was catalytically[7] deposited on the surface. From the known reaction of other metallic salts in potassium formate solution,[8] the reaction was considered to be: $CoCl_2 + HCOOK \rightarrow Co + CO_2 + HCl + KCl$. The greatly different catalytic activities of the various faces were indicated by a pattern on the surface. The same pattern was observed over a large concentration range with cobalt chloride, cobalt carbonate, and cobalt sulfate solutions. The relative catalytic activities of the faces of copper in order of decreasing activity were as follows: (210), (310), (321), and (320); (311) and (211); (100); (331) and (221); (110); and (111). Faces whose indices were all different, such as (210), (310), etc., were far more active than any of the others. At 240° with a concentration of cobalt chloride hexahydrate of 1 g. per 100 g. of potassium formate, a cobalt deposit was observed on the (210) face in less than 30 seconds whereas the (111) face remained free of a visible deposit of cobalt for ten minutes.

There were two separate steps which took place in this catalytic reaction. First cobalt deposited catalytically on certain faces of the copper sphere. Then cobalt deposited catalytically on the cobalt deposits. From the pattern formed it was concluded that the rates of both of these reactions differed with the crystal face exposed at the surface.

Evidence was obtained in these experiments which suggests that the formate molecule was largely responsible for the relative rates of catalytic reaction on the different faces of a copper crystal in potassium formate solution. This evidence is summarized in the following statements. (1) The reaction pattern was independent of the anion of the metallic salt present in the solution. (2) An entirely different pattern was obtained when cobalt was chemically deposited on copper from a hypophosphite solution by the method of Brenner and Riddell.[9] (3) A third and different pattern was obtained when cobalt was electrodeposited on a copper crystal from several aqueous baths. Attempts were made to electrodeposit cobalt from formic acid solutions and from aqueous solutions containing formate, but secondary electrochemical reactions predominated. The essential process in all of these experiments was the reduction of cobalt ions in solution to cobalt at the surface of a monocrystalline sphere of copper. However, in each case the chemical environments were different. (4) Nickel salts in potassium formate yielded exactly the same pattern as cobalt salts. It should be pointed out that the chemical properties and interatomic spacings of nickel are similar to those of cobalt.

Additional indirect evidence for the influence of potassium formate on the reaction pattern is found in the comparative spacings of the formate radical and the copper–copper distance. At room temperature the spacing between oxygen atoms in the formate molecule is 2.24 Å.[10] and the distance of closest approach of copper atoms is 2.55 Å. The next shortest copper–copper spacing is 3.60 Å. No data are available for the formate molecule at the temperatures used in this study, but it would be expected that the qualitative relationship of these two important spacings would still hold. When the results are examined, it is observed that only those faces which do not have a 2.55 Å. copper–copper spacing parallel to the surface—thus faces with indices (*xyz*)—are the most active ones in the catalytic deposition of cobalt. In addition faces with the greatest number of 2.55 Å. spacings parallel to the surface are the least active. Thus it is proposed that the formate molecule or ion is adsorbed most strongly on the 2.55 Å. copper–copper spacing and partially blocks the surface for reaction. The activity of all faces containing

(5) In the case of the face-centered cubic metal copper, each face occurs on the sphere a minimum of six times. Thus when the various crystal faces react differently, a pattern, due to the repetition of results in each octant on the surface, occurs during reaction and the faces may be identified from the symmetry of this pattern.

(6) Gwathmey and Benton, *J. Phys. Chem.*, **44**, 35 (1940).

(7) The copper crystal is considered to be a catalyst in this study because it accelerated the rate of the reaction. It is appreciated that there might be objections to considering this reaction as a catalytic process according to the accepted definition in that the copper surface was visibly altered as the cobalt deposited. In the opinion of the authors, the same factors which make a substance a catalyst in the conventional sense were operative in the reaction described here.

(8) Gurevich and Pokrovskiĭ, *Ukrainskii Khem. Zhurnal*, **2**, 414 (1926): *Chem. Abst.*, **22**, 1714 (1928).

(10) L. Pauling, "Nature of the Chemical Bond," second edition, Cornell University Press, Ithaca, New York, 1945, p. 203.

the 2.55 Å. spacing would not be equal because of the unequal effectiveness of the blocking by interaction of or competition for sites by neighboring formate molecules. As regards the second of the catalytic reactions, the deposition of cobalt on cobalt, it is known[11] that thin deposits of cobalt on copper continue the orientation, structure, and approximate lattice constants of copper. Thus the interpretation of results on the basis of the spacing of the copper crystal would apply equally well to the catalytic deposition of cobalt on the cobalt surface.

We wish to express our appreciation to Dr. Allan T. Gwathmey for his encouragement and constructive criticism.

## Synthesis and Antifungal Action of 2-Methylmercapto-1,4-naphthoquinone[1,2]

BY JOHN E. LITTLE, THOMAS J. SPROSTON AND MURRAY W. FOOTE

Many methoxyquinones are known to possess marked antibiotic activity. Among these are fumigatin, spinulosin and javanicin. Many others have been tested and found to be remarkably inhibitory to various types of organisms.[3,4,5]

Since naturally occurring 2-methoxy-1,4-naphthoquinone was found to be highly fungistatic against several plant pathogenic fungi,[6] the synthesis of the sulfur analog of this compound was carried out and its fungistatic activity measured.

A simple synthesis in good yield was developed which was based upon mercaptan addition to 1,4-naphthoquinone. The work of Fieser and Turner,[7] involving the addition of mercaptans to 2-methyl-1,4-naphthoquinone, served as a pattern for the synthesis of this new compound.

We have found that the yield can be increased markedly by the well-timed addition of ferric chloride to the reaction mixture. This material probably causes the oxidation step to proceed farther toward completion.[7] It was found that the addition of the ferric chloride increased the yield of crude product (m. p. 183°) from 27 to 56%. When the salt was added at the beginning of the reaction, no product could be obtained. The final pure crystalline product separated from alcohol as yellow needles melting at 186.5–187° (cor.).

The spectrophotometric absorption curve of this compound was obtained. The wave length and intensities of the principal maxima are as follows: 256 mμ ($\epsilon$ = 19,700), 298 mμ ($\epsilon$ = 7,700) and 407 mμ ($\epsilon$ = 3,310). The characteristic naphthoquinone maximum at 330 is evident only as a slight inflection.

The substitution of a sulfur atom for oxygen in the 2-methoxy-1,4-naphthoquinone molecule results in a marked increase in antifungal activity. The L.D.$_{50}$ value for this compound as measured against the spores of *Monolinia fructicola*[8] was found to be 1.00 part per million (0.00100 mg. per ml.) as compared to 3.65 parts per million (0.00365 mg. per ml.) for 2-methoxy-1,4-naphthoquinone[6]; an increase in potency of approximately 3.5 fold.[9]

The solubility of 2-methylmercapto-1,4-naphthoquinone determined spectrophotometrically was found to be 7.0 mg. per liter at 26°. The insoluble nature of this material would be of benefit if it were to be used as a plant fungicide.

### Experimental

**Preparation of 2-Methylmercapto-1,4-naphthoquinone.**—16.5 g. of nearly pure naphthoquinone was dissolved in 1000 ml. of absolute alcohol by warming to 40°. The solution was cooled to room temperature and a small quantity of a dark impurity removed by filtration. The solution was then cooled in ice to 15° and 10 g. of ice-cold methyl mercaptan added suddenly while the flask was swirled.

After standing for thirty minutes at room temperature a yellow crystalline precipitate appeared; 15 ml. of 70% $FeCl_3 \cdot 6H_2O$ was now added and a further crystallization observed. After standing for fifteen minutes 22 ml. more of the ferric chloride solution was added and the quantity of precipitate again increased. Further addition of ferric chloride had no effect. The suspension was now cooled to 7°, filtered and dried with petroleum ether on the funnel; 11.9 g. of yellow crystalline material was obtained, m. p. 183°. The yield was 56% of the theoretical. One recrystallization of this material from hot alcohol after treatment with norite and filtration gave 9.16 g., m. p. 186.5–187°. The over-all yield was 45%.

*Anal.* Calcd. for $C_{11}H_8O_2S$: C, 64.69; H, 3.95; S, 15.70. Found: C, 64.88; H, 4.06; S, 15.93.

**Determination of Solubility.**—Fifteen milligrams of the finely ground 2-methylmercapto-1,4-naphthoquinone (m. p. 186.5–187°) was stirred in 5 l. of distilled water for thirty-six hours at room temperature. At the end of this time, all of the material had dissolved. The optical density of this solution at the 256 mμ maximum was found to be 0.309. Comparison of this density to that obtained with a saturated solution showed the solubility to be 7.0 mg. per liter.

## Configurations of Radicals Derived from *cis*- and *trans*-Isomers

BY FRANK R. MAYO AND KENNETH E. WILZBACH

To obtain evidence concerning the recent proposal of Kistiakowsky,[1] that radicals have a non-

(1) Kistiakowsky, *The Indicator*, **28**, No. 3, 6 (1947), Nichols Medal Address, March 7, 1947.

planar configuration, some copolymerization experiments with *cis*- and *trans*-dichloroethylenes have been carried out. If a monomer added to each isomer in the same way, *i. e.*, predominantly *cis* or *trans*, and if the configuration of the resulting radical was maintained until addition to another monomer occurred, stereoisomeric dichlorides would be produced. In view of the conclusions of Young and Dillon[2] that the stereoisomeric 2,3-dibromobutanes react with potassium iodide at widely different rates, it seemed probable that the steroisomeric dichloroethylene copolymers would also show a difference in rate of reaction with potassium iodide. Since no difference was found, and if it is assumed that addition to both isomers is predominantly *cis* or predominantly *trans*, then the results show that the R–CHCl–ĊHCl radicals involved have either a planar configuration or else a pyramidal configuration which inverts or racemizes faster than the radicals add to vinyl acetate. Racemization, indeed, might be anticipated from the racemization of optically active hydrocarbons during chlorination with sulfuryl chloride.[3]

Copolymers of vinyl acetate with *cis*- and *trans*-1,2-dichloroethylene, containing about four vinyl acetate units per dichloroethylene unit, were prepared[4] at 15% conversion at 60° and the rates of reaction of these copolymers with potassium iodide were followed at 100°.

TABLE I

RATE OF IODINE LIBERATION FROM COPOLYMERS OF *cis*- AND *trans*-DICHLOROETHYLENE WITH VINYL ACETATE AT 100°

| $t$, hours | $I_2$ formed, milliequiv in 20 ml. | $k_2 \times 10^3$[a] |
|---|---|---|
| *cis* (18.13% Cl), $[KI]_0 = 0.2503$, $[C_2H_4Cl_2]_0 = 0.0342$ | | |
| 24 | 0.0310 | 3.83 |
| 48 | .0425 | 2.64 |
| 72 | .0530 | 2.20 |
| 96 | .0689 | 2.17 |
| *trans* (19.09% Cl), $[KI]_0 = 0.2503$, $[C_2H_4Cl_2] = 0.0379$ | | |
| 24 | 0.0320 | 3.56 |
| 48 | .0493 | 2.77 |
| 72 | .0594 | 2.24 |
| 96 | .0719 | 2.10 |

[a] $k_2 = \frac{2.303}{t(a-2b)} \log \frac{a-2b\theta}{a(1-\theta)}$ where $a = [KI]_0$, $b = [C_2H_4Cl_2]_0$, and $\theta$ is the fraction of dichloroethylene units which have reacted. $k_2$ is defined by: $d[I_w]/dt = k_2[KI]\cdot[C_2H_4Cl_3]$.

The results in Table I show that, although the reactions do not follow the simple second order kinetics found[2] for the dibromobutanes, there is no significant difference in the rates of iodine liberation from the two copolymers.

(4) Lewis and Mayo, *ibid.*, **70**, 1533 (1948), present data from which the feeds required for preparation of these polymers can be calculated.

### Experimental

The polymers were prepared in evacuated tubes from carefully fractionated monomers and were isolated by the frozen benzene technique.[5] Methanol was distilled from potassium hydroxide before use. Tubes of 30-ml. capacity containing 5 milliequivalents of potassium iodide and sufficient polymer to provide about 1.5 milliequivalents of available iodine in 20 ml. of 96% methanol were sealed in vacuum and heated at 100° from one to four days. The contents of the tubes were then poured into 75 ml. of water containing 2 g. of potassium iodide and a known slight excess of sodium thiosulfate to prevent occlusion of iodine by the polymers as they precipitated in the aqueous solution. The solutions were then titrated to the starch end-point with 0.05 *N* iodine solution. A weighed amount of iodine added to one of two otherwise identical tubes required the calculated additional thiosulfate, showing that the titration was valid and a correction factor was unnecessary.

## Synthesis of 2- and 6-Fluoronicotinamides[1]

BY JOHN T. MINOR,[2] G. F. HAWKINS,[3] CALVIN A. VANDERWERF[2] AND ARTHUR ROE[4]

The current hypothesis which attributes the antimetabolite activity of such compounds as sulfanilamide and pyridine-3-sulfonic acid to the structural similarity but functional dissimilarity of these compounds to essential metabolites, suggests that a study of the physiological activity of various fluorine substituted vitamins should be of considerable interest.

Of the non-metallic elements, other than hydrogen, which commonly form single covalent bonds, fluorine is the one which most closely approximates hydrogen in atomic size and weight. The question of whether the substitution of a fluorine for a hydrogen atom in the molecules of various vitamins will lead to derivatives which possess vitamin or anti-vitamin activity is, therefore, a significant one. Of interest in this connection, is the observation of Mitchell and Niemann[5] that 3-fluorotyrosine and 3-fluorophenylalanine act as growth inhibitors for *Neurospora crassa* 8815–3a.

As part of a broad study, we have completed the synthesis of two compounds of this type, 2- and 6-fluoronicotinamides. The critical steps in these syntheses, the replacement of the amino-group by the fluorine atom in the commercially available compounds 2-amino-3-methylpyridine and 2-amino-5-methylpyridine, proceeded only in low yields when the amines were diazotized in anhydrous hydrogen fluoride and the resulting diazonium fluorides decomposed, and also when the conventional Schiemann reaction was employed. The modification of the Schiemann reaction de-

veloped by two of the present authors,[6] however, gave good results. Antimetabolite tests showed no inhibition of growth of *E. coli, Staph. aureus,* or *Strep. varidans in vitro* by 1:2000 dilution of either 2- or 6-fluoronicotinic acid. These tests were carried out by the Lilly Research Laboratories. Testing of the fluoronicotinamides is in progress.

### Experimental

**2-Fluoro-3-methylpyridine.**—To a solution of 80 g. (0.74 mole) of redistilled 2-amino-3-methylpyridine[7] in 310 g. of 40% fluoboric acid contained in an ice-cooled 1500 ml. beaker, 51 g. (0.74 mole) of sodium nitrite was gradually added in small portions with mechanical stirring. When the addition was complete, the solution was stirred for an additional thirty minutes at ice-bath temperature, and was then warmed to 45° to ensure complete decomposition. The solution was neutralized with sodium carbonate and steam-distilled. The yellow oil which separated from the distillate was removed and the remaining water layer extracted with ether. The oil and ether extracts were combined, dried over anhydrous sodium sulfate, and the ether removed. Distillation of the residue gave 39.5 g. (48%) of 2-fluoro-3-methylpyridine, b. p. 150.5–151.0° at 757 mm.

*Anal.* Calcd. for $C_6H_6NF$: C, 64.9; H, 5.4; N, 12.6. Found: C, 64.7; H, 5.6; N, 12.5.

**2-Fluoronicotinic Acid.**—A mixture of 38 g. (0.33 mole) of 2-fluoro-3-methylpyridine, 126 g. (0.80 mole) of potassium permanganate, and 1.5 l. of water contained in a 3-liter three-necked flask, fitted with condenser and sealed stirrer, was refluxed gently for four hours. The mixture was first steam-distilled to remove unreacted 2-fluoro-3-methylpyridine (8.0 g.) and then filtered hot. The resulting solution was evaporated to approximately 700 ml., cooled in an ice-bath, and acidified with concentrated hydrochloric acid. The precipitate which formed was filtered, dried, and recrystallized from water to yield 23.0 g. (49% based on starting methyl compound or 63% based on amount reacted) of 2-fluoronicotinic acid, m. p. 164–165°,[8] with decomposition.

*Anal.* Calcd. for $C_6H_4O_2NF$: C, 51.1; H, 2.9; N, 9.9; F, 13.5. Found: C, 51.2; H, 3.1; N, 9.9; F, 13.7.

**2-Fluoronicotinamide.**—A solution of 28.2 g. (0.20 mole) of 2-fluoronicotinic acid in 250 ml. of thionyl chloride was refluxed for forty-five hours. The excess thionyl chloride was then removed under reduced pressure, and the residue of 2-fluoronicotinyl chloride, b. p. 84.0–85.0° at 4 mm., was dissolved at once in 115 ml. of dry benzene. Dry ammonia was bubbled through the solution for thirty minutes and the solids formed were removed by filtration. These were extracted with dry acetone, the solvent was taken off, and the remaining yellow crystals were recrystallized from water. The yield of pure 2-fluoronicotinamide, m. p. 120.9–122.0° was 67.5%.

*Anal.* Calcd. for $C_6H_5ON_2F$: C, 51.4; H, 3.6; N, 20.0. Found: C, 51.4; H, 3.5; N, 19.8.

Approximately the same yield was obtained when the acid chloride was prepared by reaction of the acid with phosphorus pentachloride in phosphorus oxychloride solvent.

**2-Fluoro-5-methylpyridine.**—This compound was prepared according to the directions given for 2-fluoro-3-methylpyridine, except that 2-amino-5-methylpyridine was the starting material. A 46% yield of pure product, b. p. 155–156° at 752 mm., was obtained.

*Anal.* Calcd. for $C_6H_6NF$: C, 65.0; H, 5.4; N, 12.6. Found: C, 64.7; H, 5.5; N, 12.8.

**6-Fluoronicotinic Acid.**—This product was obtained in 60% yield, based on starting 2-fluoro-5-methylpyridine (71% based on that reacted), according to the method described for the preparation of the 2-fluoro-isomer. It was purified by sublimation and melted at 146–147° with decomposition.

*Anal.* Calcd. for $C_6H_4O_2NF$: C, 51.1; H, 2.9; N, 9.9; F, 13.5. Found: C, 51.0; H, 3.1; N, 9.8; F, 13.8.

**6-Fluoronicotinamide.**—Prepared in 65% yield from 6-fluoronicotinic acid by the method described for the 2-fluoro-isomer, this compound melted at 166.2–167.0°, after recrystallization from water.

*Anal.* Calcd. for $C_6H_5ON_2F$: C, 51.4; H, 3.6; N, 20.0. Found: C, 51.4; H, 3.8; N, 19.7.

## Aromatic Cyclodehydrogenation. VIII. Experiments with 2-Benzoyl-5,6,7,8-tetrahydronaphthalene[1]

BY MILTON ORCHIN,[2] E. O. WOOLFOLK[2] AND LESLIE REGGEL[2]

A possible convenient two-step synthesis of 3,4-benzfluorene, II, consists of its formation by direct cyclization of 2-benzoyl-5,6,7,8-tetrahydronaphthalene, I. The latter is readily available,

I II

since acylating agents substitute exclusively at the 6-position of 1,2,3,4-tetrahydronaphthalene. In the respect that the conversion would involve a cyclization of a diaryl ketone, accompanied by loss of water, the reaction bears a superficial resemblance to the Elbs reaction. Although no suitable catalyst has been found for the Elbs reaction,[3] it seemed reasonable to expect, in the present instance, that a chromia-on-alumina catalyst would combine dehydration and cyclization activity. It has been found that vapor-phase treatment of I over such a catalyst at 450-470° gave, as a major product, 2-benzylnaphthalene. Only a little of the expected 3,4-benzfluorene was formed, accompanied by a small quantity of 2,3-benzfluorene. Both benzfluorenes were probably formed *via* 2-benzylnaphthalene, the former by cyclization into the 1-position and the latter by closure at the 3-position.

Liquid-phase treatment of 2-benzoyl-5,6,7,8-

(1) Article not copyrighted.

(2) Organic Chemist, Bureau of Mines, Office of Synthetic Liquid Fuels, Research and Development Branch, Pittsburgh, Pa.

(3) For a review of this reaction see Fieser in "Organic Reactions," John Wiley & Sons, N. Y., Vol. I, p. 129.

tetrahydronaphthalene, I, in the presence of a palladium-on-charcoal catalyst also gave principally 2-benzylnaphthalene. An analogous internal dehydrogenation–hydrogenation has been reported with 2-acetyl-5,6,7,8-tetrahydronaphthalene.[4] Treatment of I with sulfur in the liquid phase gave 2-benzoylnaphthalene, in agreement with the work reported by Barbot.[5] In general, it appears that sulfur dehydrogenation of a hydroaromatic compound containing oxygen seldom results in elimination of oxygen. With palladium-on-charcoal, however, the hydrogen liberated from one part of a molecule during dehydrogenation is frequently used in the hydrogenation or hydrogenolysis of another susceptible portion of the molecule and may in suitable cases even be transferred intermolecularly.[6] It is of interest to note that, even in the vapor-phase reaction mentioned above, such an intramolecular dehydrogenation–hydrogenation occurred.

### Experimental[7]

**2-Benzoyl-5,6,7,8-tetrahydronaphthalene, I.**—This compound was prepared from benzoyl chloride and tetrahydronaphthalene according to the directions of Scharwin,[8] except that nitrobenzene was used as the solvent instead of carbon disulfide. Purification by crystallization from methanol gave pure I, m. p. 40.4–41.2°, which has previously been reported[8] as an oil.

**Sulfur Dehydrogenation of I.**—A mixture of 10 g. of I and 2.7 g. of sulfur was heated at 200–270° for seventy minutes. The crude product was distilled, and the distillate (7.8 g.) was chromatographed on alumina–celite whereby 5.8 g. of phenyl 2-naphthyl ketone was isolated. Crystallization from ethanol gave colorless crystals, m. p. 81.4–81.8°. A stable picrate could not be prepared.[9]

**Palladium Dehydrogenation of I.**—A mixture of 10 g. of I and 0.09 g. of 30% palladium-on-charcoal[10] was heated gradually from 220 to 320° over a period of ninety-five minutes. Vacuum distillation of the product gave 8.2 g. of oil. Chromatography of the crude product on alumina gave as a first, less strongly adsorbed fraction, 6.1 g. (66%) of 2-benzylnaphthalene, which after crystallization from ethanol was obtained as thick, colorless prisms, m. p. 54.3–55.3°. The picrate had a melting point of 94.2–95.0°.[11] The more strongly adsorbed fractions from the chromatogram gave 1.6 g. (16%) of phenyl 2-naphthyl ketone.

**Chromia-on-Alumina Dehydrogenation of I.**—During three and one-half hours, 15 g. of I was passed over 92 g. of the chromia-on-alumina catalyst[10] at 450–470°, using the apparatus previously described.[10] The product, a mixture of green oil and water, weighed 12.03 g. It was dissolved in benzene, the water distilled off, and an aliquot containing 4.83 g. chromatographed on alumina–supercel. The percolate fractions gave 0.12 g. of naphthalene, identified by melting point and mixed melting point. The column was extruded and divided into three sections. The bottom portion (non-fluorescent, least strongly adsorbed) gave 3.28 g. of 2-benzylnaphthalene, identified by melting point and mixed melting point of the hydrocarbon and its picrate. The intermediate purple-fluorescent band gave 0.07 g. of material, identified as 3,4-benzfluorene by its ultraviolet absorption spectrum.[12] The uppermost, green-fluorescent band gave 0.02 g. of material, identified as 2,3-benzfluorene by its ultraviolet absorption spectrum.[12] It is of interest to note that the separation of 3,4- and 2,3-benzfluorene was easily achieved by chromatography, whereas the separation of 1,2- and 2,3-benzfluorene is extremely difficult.[13]

## 1,2-Diphenylcyclohexane

BY STANLEY M. PARMERTER[1]

Although several preparations of 1,2-diphenylcyclohexane have been reported[2,3,4,5] subsequent investigations[6,7] have shown that the product was actually the 1,4-isomer.

The synthesis of 1,2-diphenylcyclohexane has now been accomplished by an unequivocal method. The reaction between phenylmagnesium bromide and 2-phenylcyclohexanone produced a carbinol which was dehydrated to a diphenylcyclohexene. Hydrogenation of the diphenylcyclohexene with palladium–on–charcoal catalyst yielded 1,2-diphenylcyclohexane, which the author presumes to be the *cis*-form.

### Experimental

**Diphenylcyclohexene.**—A solution of 62 g. (0.36 mole) of 2-phenylcyclohexanone[8] in 300 cc. of absolute ether was added in ninety minutes to a stirred, refluxing solution of phenylmagnesium bromide, prepared from 63 g. (0.40 mole) of bromobenzene and 9.7 g. (0.40 g. atom) of magnesium turnings in 250 cc. of absolute ether. After an additional two hours of stirring and refluxing, the mixture was left overnight at room temperature. The mixture was then decomposed with ammonium chloride solution and the product was extracted in two 300-cc. portions of ether. The dried ether solution upon evaporation left the crude carbinol which was dehydrated by stirring with an equal volume of 85% phosphoric acid for four hours on the steam-bath. The acid mixture was diluted with water and the product taken up in benzene. Distillation of the benzene solution gave a fraction of 64 g. boiling at 170–188° (10 mm.). Upon recrystallization from methanol there was obtained 44.5 g. (53%) of colorless needles, m. p. 50–52°. An analytical sample melted at 51–52°.

## Alkoxy-*s*-triazines. II

BY WILLIAM M. PEARLMAN AND C. K. BANKS

In the first paper of this series[1] a group of 2-alkoxy-4,6-diamino-*s*-triazines having antihistaminic activity was reported. Most of these compounds contained no alkyl substituents on nitrogen. Since the tautomeric possibilities of the triazine nucleus (I–III) are limited by the number and arrangement of alkyl substituents on nitrogen, it was considered of interest to prepare a series of ethers in which one to four of the hydrogens on the two amine groups were replaced by alkyl groups. These compounds were prepared by the reaction of the chosen sodium alkoxide with an appropriate 2-chloro-4,6-di-(amino or substituted amino)-*s*-triazine. The necessary chlorodiaminotriazines have been reported pre-

Footnotes the same as for Table I.

viously.[2] In order to limit the variables concerned, the methyl and *n*-butyl ethers of each triazine residue were prepared by the method reported previously.[1] The methyl ethers are reported in Table I and the butyl ethers in Table II.

During the preparation of the necessary chlorotriazines it was noted that the degree of substitution markedly influenced the physical properties of the resulting compounds. Thus, compounds having the structure of 2-chloro-4,6-diamino-*s*-triazine wherein one, any two, or three of the amino hydrogens were replaced by methyl groups were all high melting solids while the corresponding tetramethyl compound was very low melting. Similarly, the mono-, di- and triethyl, -allyl and -methylallyl derivatives were solids while the tetrasubstituted compounds were oils which failed to solidify at −40°. A similar relationship was expected with the ethers. While the tetraalkyldiamino ethers were all liquids except for one low melting solid, the melting points of the mono-, di- and tri-substituted ethers did not follow regular progression noted for the chloro compounds.

The compounds were tested for antihistamine activity in guinea pigs using the histamine–aerosol technique of E. R. Loew.[3] In the previous series of unsubstituted aminotriazine ethers, a regular variation in activity dependent on the length of the alkoxy chain was observed. No orderly variation in activity was noted with variation in the alkyl chain on nitrogen or with multiple substitution on the amine groups.

## The Resolution of Chloroquine, SN 7618[1]

BY BYRON RIEGEL AND L. T. SHERWOOD, JR.

Since 4-(4-diethylamino-1-methylbutylamino)-7-chloroquinoline (chloroquine) proved to be one of the most effective suppressive drugs for malaria developed during the war, its resolution was undertaken in the hope that the toxicity or activity of one of the forms might be favorably different. The salts of *l*-malic, *d*-camphorsulfonic, *l*-menthoxyacetic, *d*-tartaric and *dl*-mandelic were all unsuitable as resolving agents but an adaptation of the work of Chelintsev and Osetrova[2] on the resolution of atabrine with *d*-bromocamphorsulfonic acid proved fairly satisfactory.

(1) This work was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Northwestern University.

(2) G. V. Chelintsev and E. D. Osetrova, *J. Gen. Chem.* (*U. S. S. R.*), **10**, 1978 (1940).

The salts obtained by the addition of two moles of *d*-bromocamphorsulfonic acid to one of chloroquine were low melting, hygroscopic, finely divided, and somewhat unstable crystals. This made handling difficult and some mechanical loss unavoidable. The quality of the *d*-bromocamphorsulfonic acid was also of great importance and the poor results of some runs was supposed due to slight decomposition during preparation of the free acid. The enantimorphs of the drug are much more soluble than the racemic mixture.

Neither of the optically active forms submitted to the Survey Office showed any significant differences[3] in antimalarial activity in birds and for toxicity in dogs from the racemate.

### Experimental

**Starting Materials.**—Chloroquine diphosphate was kindly furnished by Dr. R. C. Elderfield of Columbia University. The free base was liberated from an aqueous solution of the salt with ammonia and was recrystallized from benzene and hexane. We are indebted to Dr. H. R. Snyder of the University of Illinois for the ammonium salt of *d*-bromocamphorsulfonic acid. The free acid was liberated from the salt by the method of Pope and Peachey.[4]

A solution was made of 21 g. of chloroquine and 45 g. of *d*-bromocamphorsulfonic acid in 300 ml. of hot absolute ethanol. The solution was filtered to remove any insoluble material and then allowed to crystallize in a cold room. The crystals were separated rapidly by filtration and recrystallized from about 150 ml. of absolute ethanol to a constant rotation of $[\alpha]^{27}D + 62°$ (0.200 g. was made up to 10 ml. with water). The base was obtained by dissolving the salt in water, adding an excess of ammonia, and extracting with benzene. The benzene solution was filtered and mixed with an equal volume of petroleum ether (b.p. 80–100°). The solution was concentrated until crystallization took place upon standing in the cold room. The crystals (9.7 g.) melted at 84–86°; $[\alpha]^{25}D + 12.3°$ (0.200 g. was made up to 10 ml. with 95% ethanol).

The *l*-form of the drug was liberated by evaporating the mother-liquor from the crystalline salt almost to dryness, dissolving in water, and treating as above. The concentration of the benzene and petroleum ether solution was adjusted so as to precipitate about one gram of solid in the cold. This material, almost inactive, was discarded and the solution was concentrated further. On cooling, 4.3 g., m.p. 84–87°, of the *l*-form separated; $[\alpha]^{27}D -13.2°$ (0.200 g. made up to 10 ml. with 95% ethanol).

## An Improved Laboratory Preparation of Copper–Chromium Oxide Catalyst

BY THOMAS W. RIENER[1]

During the course of an investigation[2] of copper chromium oxides as a catalyst for hydrogenation of fatty esters to alcohols, a very satisfactory laboratory procedure for the decomposition of the copper ammonium chromate was developed. A catalyst of high activity and long life was obtained by this improved technique.

The method described here is similar to that previously reported[3] except that the decomposition of the copper ammonium chromate is carried out under carefully controlled conditions. If excessive temperatures are reached during the decomposition of the copper ammonium chromate, the activity of the catalyst is seriously affected.

A batch of copper ammonium chromate was prepared in the usual manner[3] and divided into several portions. A portion (I) was placed in a muffle furnace at 320° and in a short time the temperature inside the mixture reached 635°. Another portion (II) was fired as described below at 400°. A third portion (III) was similarly fired at 350°.

The catalysts obtained in each experiment were used in the hydrogenation of the lauryl ester of coconut oil fatty acids. The reductions were carried out in a 480-cc. Parr Instrument shaking bomb using 2 g. catalyst and 80 g. ester and run for two hours at 275°/3000 lb. $H_2$: (I) gave 30.5% hydrogenation; (II) gave 88.3% hydrogenation; (III) gave 92.1% hydrogenation.

### Experimental

A solution of 260 g. of copper nitrate ($Cu(NO_3)_2 \cdot 3H_2O$) in 900 cc. of tap water at 80° was added while stirring to a solution of 178 g. of sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$) and 225 cc. of 28% ammonium hydroxide made up to 900 cc. at 25°. The precipitate was collected on a Buchner funnel and washed by slurrying in water three times. The copper ammonium chromate was dried at 75–80° overnight.

The copper ammonium chromate was powdered and added in small portions to a one-liter three-neck flask equipped with a stainless steel stirrer of the crescent type which scraped close to the bottom of the flask. The flask was partially immersed in a Woods metal-bath heated at 350°. The time of addition was fifteen minutes. The mixture was heated and stirred at 350° for fifteen minutes after all of the complex had been added. It was then passed through a 200-mesh screen with the aid of a camel's hair brush.

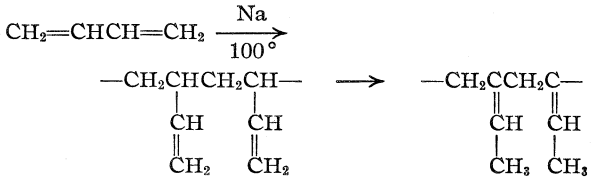
## The Effect of Heat and Sodium Sand upon Sodium Polybutadiene[1]

BY ROBERT M. ROSS

The percentage of external double bonds in sodium-polymerized polybutadiene has been shown to be dependent upon the temperature of polymerization.[2,3] Polybutadiene, polymerized with sodium at 30°, contains 65–75% external

(1) Present address: Industrial Rayon Corporation, Cleveland, Ohio.

(2) Work done at Rohm & Haas Company.



(1) The work described in this manuscript was done under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program. The author is deeply indebted to Dr. C. S. Marvel for initiating this investigation, as well as for his advice during the course of the work.

(3) Kolthoff, Lee and Mairs, *J. Polymer Sci.*, **2**, 220 (1947).

double bonds, whereas the polymer formed at 110° possesses about 15% external double bonds. In direct contrast to the product obtained from the sodium-catalyzed polymerization of butadiene, the terminal double bond percentage of polybutadiene, formed by emulsion methods, has been found to be independent of the polymerization temperature.[3]

Ziegler, Grimm and Willer[2] have explained these facts on the basis that at higher temperatures an increased amount of 1,4-addition occurs in the sodium-catalyzed polymerization. Another possible explanation is that the relative amount of 1,2- or 1,4-addition remains constant, but that an allylic rearrangement occurs in the presence of sodium so as to transform terminal methylene groups into ethylidene groups

Accordingly it was the objective of this work to learn if preformed polybutadiene, prepared by sodium-catalysis methods, showed a decrease in the percentage of terminal double bonds when it was treated with sodium and heated. When sodium-polymerized polybutadiene was heated to 110° for five hours in the presence of sodium sand, analysis by perbenzoic acid titration[4] of the product obtained indicated that no appreciable double bond shifts from external-to-internal positions had occurred. Similar results were obtained when butadiene was polymerized in the presence of sodium sand at 30° and then heated to 100° for five hours.

It may be concluded, therefore, that an allylic shift, catalyzed by sodium, is not responsible for the difference in the products obtained from the sodium-catalyzed polymerization of butadiene and polybutadiene prepared by emulsion methods. Furthermore, since the terminal double bond percentage in polybutadiene formed by emulsion methods is independent of polymerization temperature, the two polymerization methods must proceed by different mechanisms.[5]

## Experimental

**Attempted Isomerization of Sodium Polybutadiene with Sodium Sand.**—In a 500-ml., three-necked, round-bottomed flask were placed 3 g. of sodium-polymerized polybutadiene,[6] which had been reprecipitated by ethanol from benzene solution, and 250 ml. of redistilled toluene (b. p. 110–111°). The flask was equipped with a glass-sleeved Hershberg stirrer and reflux condenser. Solution was complete after about fifteen hours. At the end of this time, 0.3 g. of freshly cut sodium metal was added to the toluene solution. The contents of the flask were heated to the reflux temperature, and at this point vigorous stirring was commenced. The sodium was dispersed to a fine sand. The reaction mixture was then maintained at the reflux temperature with continuous stirring for five hours. At the end of this time, the mixture was allowed to cool to about 30°. A small amount of tarry material formed during the heating period. The excess sodium was destroyed by the addition of 100 ml. of absolute ethanol and stirring was stopped.

The insoluble macrogel and tarry material which had formed during the course of the experiment were removed by filtration through a wire screen. The filtrate was added in a fine stream to a rapidly stirred solution of 2 g. of phenyl β-naphthylamine in 1 liter of ethanol. The precipitated polymer was washed with 200 ml. of 0.2% phenyl β-naphthylamine in ethanol and finally dried at 80° for one hour under a reduced pressure of less than 1 mm. The dried polymer weighed 2.3 g. and was stored away from light and in a desiccator under reduced pressure. The polymer thus obtained and the reprecipitated polymer employed as starting material were analyzed for external double bonds by perbenzoic acid titration.[4] The results of the analyses expressed as % external double bonds are as follows: reprecipitated sodium-polymerized polybutadiene, 71.2%; reprecipitated sodium-polymerized polybutadiene, heated with sodium sand for five hours, 66.8%.

**Polymerization of Butadiene and the Subsequent Application of Heat to the Sodium Polybutadiene Formed.**—The sodium sand-catalyzed polymerization of butadiene was carried out according to the directions of Marvel, Bailey and Inskeep.[7] In conducting this experiment, two simultaneous and analogous polymerizations were carried out at 30° for twenty-one hours using about 0.4% by weight of sodium sand in terms of the weight of butadiene. At the end of this time, the polymerization bottles were removed from the constant temperature bath and chilled to 0°. One polymerization bottle was opened, flushed out with nitrogen, recapped, and finally heated on a water-bath for five hours at 100°. At the end of this time, the bottle and contents were cooled to room temperature and opened. The excess sodium was destroyed by the addition of 100 ml. of a 10% ethanol in benzene solution which contained 0.2 g. of phenyl β-naphthylamine. To this mixture was added 300 ml. of benzene, and the resulting suspension was allowed to stand with occasional stirring for about twenty-four hours. At the end of this time, solution was virtually complete, and the insoluble gel present was removed by filtration through a wire screen. The filtrate was added in a fine stream to 1 liter of a rapidly stirred solution of 0.2% phenyl β-naphthylamine in methanol. The precipitated polymer was washed with 200 ml. of 0.2% phenyl β-naphthylamine in methanol and finally dried at 80° for five hours under a reduced pressure of less than 1 mm.

The polymer contained in the second polymerization bottle was used as the control sample. After the twenty-one hour polymerization period at 30°, which was followed by cooling of the reaction mixture at 0°, the bottle was opened. The excess sodium was destroyed with a 10% solution of ethanol in benzene. The polymer was purified and isolated in exactly the fashion described in the previous paragraph for the heated polymer.

The products obtained above were analyzed by perbenzoic acid titration[4] for external double bonds. The analytical values obtained are expressed as per cent external double bonds as follows: control polymer, polymerized for twenty-one hours at 30°, 66.1%; polymer, heated to 100° for five hours after polymerization period of twenty-one hours at 30°, 65.8%.

## Matching Factors of Beckman Spectrophotometer Cells

BY H. SHEFFER AND H. J. HADOW

This note describes some sources of error which are of importance if the highest accuracy is demanded of the Beckman Quartz Spectrophotometer. One of these instruments (Model DU) is being used here to measure the turbidities of solutions of polystyrene in methyl ethyl ketone as standards for calibrating a light-scattering apparatus.[1] At a wave length of 546 mμ, the transmissions of such solutions in 5-cm. silica cells are in the range 93–97% of that of the solvent. These correspond to turbidities of 0.014 to 0.006 cm.$^{-1}$.

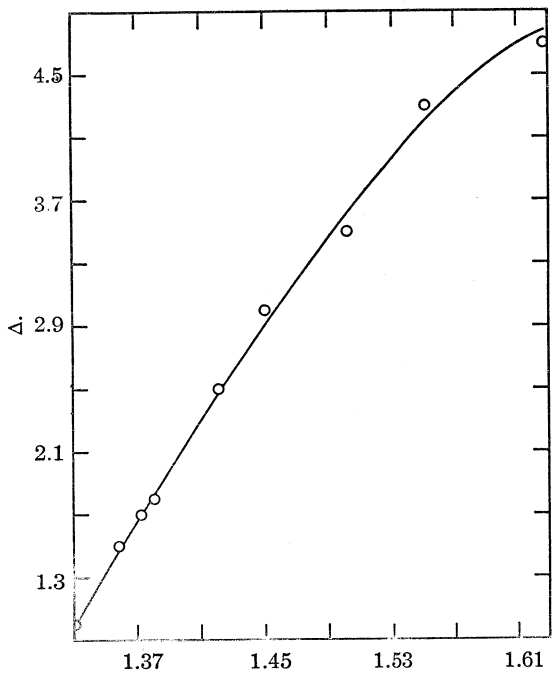

Fig. 1.—Δ plotted against refractive index of solvent.

Since there is a considerable range of wave lengths over which both the red-sensitive (RS) and the ultraviolet sensitive (UVS) phototubes may be used, it was decided to use one to check the other. With solvent in each, the 5-cm. cells were matched at 546 mμ using the RS-phototube, the correction being about 0.1%. The turbidity of a solution was then determined at this wave length using both the RS and UVS-tubes. Applying the matching correction of 0.1%, the transmissions measured by the two phototubes differed from one another by about 1%. This represents the very large discrepancy of 10–30% in turbidity. In addition there was no indication at this stage as to which tube gave the more nearly correct result. It was finally found that a separate matching factor must be determined using the UVS-tube and that, provided the appropriate factor was applied, results with the two phototubes agreed to within 0.1% in terms of transmission.

Since the matching factor is a measure of the *relative* intensity of light transmitted through the two cells filled with the same solvent, it was very surprising to find that its magnitude depended on the photo-tube used. The effects of slit width and of stray light were first eliminated as possible explanations for this behavior. The transmission of colored glass matched against air was found to be independent of the phototube used. However, the difference in the two matching factors rose to 3–4% using 10-cm. cells, indicating that the effect was more important with the longer cells.

When the wave length was increased over the range 400–600 mμ, it was found that the matching factors (10-cm. cells), using the RS-tube, varied in a random way between 0 and 0.5%, while the corresponding factors, using the UVS-tube rose gradually from about 1 to 3%. This led to the thought that differences in refractive index might be responsible for the large variations found with the UVS-phototube. In order to investigate this point the following solvents (in ascending order of refractive index) were used: water, acetone, ethyl acetate, ethyl methyl ketone, dioxane, cyclohexanone, benzene, *o*-dichlorobenzene and quinoline. With a transmission setting of 100% for benzene in one of the 10-cm. cells, readings were taken for each of the solvents in the other cell of the pair. This procedure was carried out using both phototubes at a wave length of 600 mμ and the results, expressed as RS-phototube reading minus UVS-phototube reading for each solvent (Δ), are shown plotted against refractive index in Fig. 1. From this it is apparent that the difference in matching factors increases markedly with increasing refractive index under these conditions. Values of Δ which varied similarly with refractive index were obtained at other wave lengths and also on a second Beckman Spectrophotometer.

In these instruments the light beam is not parallel but diverges slightly. Thus, even if the cells are lined up perfectly parallel to one another and perpendicular to the beam front, the spot of light striking the phototube will vary in area depending on the length of the cell and on the refractive index of the medium in it. If the cells are off by small angles, which is the case in practice, the position of the light spot will change slightly as well as its area. It appears, therefore, that a change in position of the light beam falling on the face of the phototube makes quite a difference in the response of the UVS-tube while that of the RS-tube is relatively unaffected. This point was tested by changing the angle of one of the cells by small amounts relative to the horizontal axis. With benzene in both 10-cm. cells, one cell was used as the standard while the position of the other was altered. Two successive changes of a little over one degree altered the difference in the matching factors for the two phototubes from +2.4 to 0 and from 0 to

(1) Doty, Affens and Zimm, *Trans. Faraday Soc.*, **42B**, 66 (1946).

−2.2. The effect of refractive index on the position and size of the light spot was measured directly by photographing the spot near the face of the phototube. A 30% decrease in area of the spot was observed when a 10-cm. cell filled with water was introduced into the beam. Further successive decreases in area of the order of 5% were observed when the water (R.I. = 1.33) was replaced first by dioxane (1.42) and then by benzene (1.50) and small changes in the positions of the spots were also noticed.

Although for the 5 and 10 cm. cells the differences in matching factors may be large and quite variable with refractive index, good agreement can be obtained using both phototubes as long as the matching factors at a given wave length are obtained separately for each phototube and each liquid used. In this way discontinuities in absorption curves, which are sometimes obtained at the point where the tubes are interchanged, can be eliminated. The source of error discussed is particularly important when solutions varying widely in refractive index are matched against one solvent.

The effect was also determined for 1-cm. cells which are used by the majority of investigators. The difference in the matching factors for several of these cells changed by 0.1–0.3% (in terms of transmission) when benzene in the cells was replaced by water. These amounts become appreciable in terms of optical density only when very low absorptions are being measured.

For work of the highest accuracy, matching factors should be rechecked with any change of operating conditions whatsoever. Due to the zonal variations in spectral sensitivity of phototubes, differences in matching factors may be expected whenever the effective area of the phototube illuminated is altered in any way. In addition to the effect of refractive index, such changes may be brought about by slight localized variations in transmission of the absorption cells due to striae, scratches, etc., and when cells are shifted in orientation with respect to the phototubes.

The authors wish to acknowledge the assistance of Mr. J. C. Hyde.

## Phenoxyacetaldehyde

BY ROBERT J. SPEER AND HENRY R. MAHLER

Hatch and Nesbitt[1] have reported the synthesis of phenoxyacetaldehyde in 45% yield by the lead tetraacetate oxidation of glycerol α-phenyl ether. In connection with the radiochemical program of this Laboratory, the aldehyde in question has been prepared as an intermediate for certain labeled amino acids. It has been found that a modification of the above preparative technique results in an improved yield.

(1) L. F. Hatch and S. S. Nesbitt, THIS JOURNAL, **67**, 39 (1945).

In order to avoid even a temporary excess of oxidant, the order of addition of reagents has been reversed. That is, a slurry of lead tetraacetate (1.0 mole) in benzene was added slowly to a stirred benzene solution of glycerol α-phenyl ether[2] (1.0 mole). This addition was accomplished during *ca.* two hours while the reaction mixture was stirred vigorously at a temperature of 20–25°. After isolation as previously described,[1] the product was fractionated through a 24-in. Widmer column, b. p. 82–83°(4–5 mm.). The aldehyde thus obtained represented a yield of 60% of theory; $n^{20}D$ 1.5360, $d^{20}_4$ 1.1308 (*cf.* Huntress and Mulliken[3] $n^{21}D$ 1.5380, $d^{21}_4$ 1.1310). Molecular refraction, 37.54 (found), 37.20 (calcd.).

The value of this simple modification has been confirmed by one of us[4] in the case of other sensitive aldehydes.

## Ascaridole in Oil of Chenopodium. III.[1] The Characterization of Ascaridole

BY H. HARRY SZMANT AND ALFRED HALPERN

In connection with the investigation of the chemistry of ascaridole in progress in our Laboratories[1,2] it was desirable to reexamine the physical properties of ascaridole in view of the discrepancies noted in the literature.[3] The physical properties of ascaridole are of particular importance since no solid derivative of ascaridole is known.

Oil of chenopodium[4] was fractionated using an all-glass system equipped with a Vigreux column. The physical properties and yields of the various fractions are summarized in Table I.

The fractions obtained from the preliminary distillation above, were analyzed for ascaridole content according to the method of Cocking and Hymas[5] and the results are included in Table I. A portion of fraction "C," which analyzed iodometrically for pure ascaridole, was subjected to a careful fractionation in a two-foot glass-helices-packed column. The physical properties of the fractions obtained during this refractionation are reported in Table II.

| Residue | ... | .. | .... | .... | .. |

[a] B. p. at 1.5 mm. [b] $M_D$ calcd. 46.80; found 46.79. The peroxide linkage assumed to be equivalent to two ether values.

Fraction "5" was analyzed[6] and was found to contain 71.00% carbon, and 9.45% hydrogen in agreement with the calculated analysis of ascaridole (calcd. for $C_{10}H_{16}O_2$: C, 71.38; H, 9.58). The ultraviolet absorption spectrum in absolute methanol determined by means of the Beckman quartz spectrophotometer, and the infrared absorption spectrum,[7] of fraction "5" are reproduced in Figs. 1 and 2, respectively.

It is of interest to note that the ultraviolet absorption spectrum indicates the presence of only one major absorbing group, namely, that of the simple carbon–carbon double bond. This is of significance since the oil of chenopodium contains an appreciable quantity of compounds possessing conjugated double bond systems.

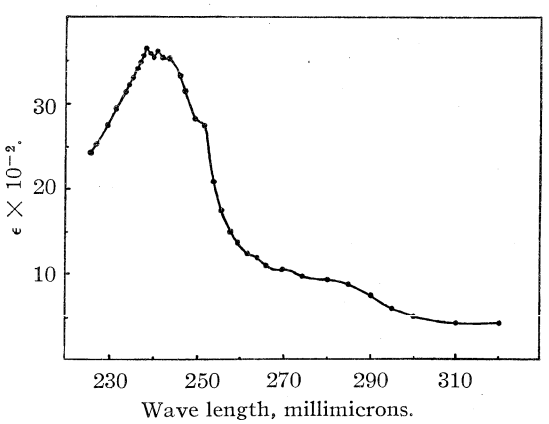

Fig. 1.—The ultraviolet absorption spectrum of ascaridole.

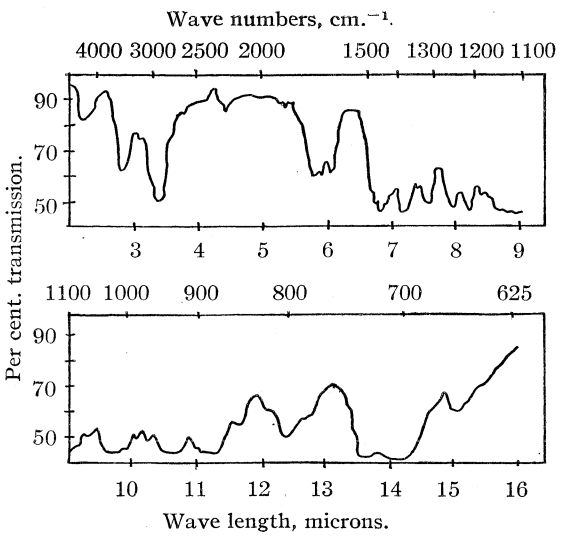

Fig. 2.—The infrared absorption spectrum of ascaridole.

In view of the correct analysis, the relative simplicity of the ultraviolet absorption spectrum, and the higher freezing point of our product, we believe to have obtained ascaridole of a higher purity than has hitherto been reported. The physical properties of ascaridole were found to be as follows: b. p. 75° (1.5 mm.); $n^{25}D$ 1.4718; $d^{25}_{25}$ 1.0061; f. p. 5°.

## The Preparation of 3,4-bis-(3′-Methyl-4′-hydroxy-5′-allylphenyl)-2,4-hexadiene

BY PHILIP WEISS[1] AND JOSEPH B. NIEDERL

Subsequent to studies in tetra alkyl substituted analogs of dienestrol and hexestrol,[2] an investigation was undertaken to study the estrogenic effects produced by the introduction of an allyl group in the 5′-position of the synthetic estrogen 3,4-bis-(3′-methyl-4′-hydroxyphenyl)-2,4-hexadiene.[3]

The synthesis of 3,4-bis-(3′-methyl-4′-hydroxy-5′-allylphenyl)-2,4-hexadiene was accomplished in the following manner. The diallyl ether of 3,4-bis-(3′-methyl-4′-hydroxyphenyl)-2,4-hexadiene was prepared by refluxing the substituted dienestrol with allyl bromide in the presence of anhydrous potassium carbonate, using dry acetone as the solvent. The Claisen rearrangement[4] was effected by refluxing with diethylaniline thus

(1) Present address: Wallace and Tiernan Products Inc., Belleville 9, New Jersey.

(2) J. B. Niederl and P. Weiss, THIS JOURNAL, **70**, 2894 (1948).

(4) E. Kaiser and J. J. Svarz, *ibid.*, **68**, 636 (1946).

yielding the desired 3,4-bis-(3′-methyl-4′-hydroxy-5′-allylphenyl)-2,4-hexadiene, as a red gum. This tetraalkyl substituted analog of dienestrol was characterized by the preparation of the corresponding diacetate and dipropionate.

The estrogenic assays on these compounds were carried out by administering orally the test sample to ovariectomized female rats. Vaginal smears were examined and only full cornification was regarded as a positive oestrus response. The results of preliminary measurements of gross estrogenic activity indicate that at the 100 microgram dose level; the 3,4-bis-(3′-methyl-4′-propionoxy-5′-allylphenyl)-2,4-hexadiene shows a 20% oestrus response; the 3,4-bis-(3′-methyl-4′-acetoxy-5′-allylphenyl)-2,4-hexadiene gives a 25% response, and the 3,4-bis-(3′-methyl-4′-hydroxy-5′-allylphenyl)-2,4-hexadiene shows a 35% oestrus response. Control rats injected with 0.65 microgram of U.S.P. Reference Estrone produced a 40% oestrus response.

**Acknowledgment.**—The authors desire to express their appreciation to Dr. C. T. Van Meter of Reed and Carnrick, Jersey City, N. J., for the estrogenic assays.

### Experimental[5]

**3,4-bis(3′-Methyl-4′-allyloxyphenyl)-2,4-hexadiene.**—A mixture of 15 g. (0.05 mole) of 3,4-bis-(3′-methyl-4′-hydroxyphenyl)-2,4-hexadiene,[3] 15 g. (0.11 mole) of allyl bromide, 15 g. (0.1 mole) of anhydrous potassium carbonate, and 200 ml. of dry acetone were refluxed for six hours, and then set aside at room temperature for twenty-four hours. Water was added to the reaction mixture, it was extracted with ether, and the ether layer was extracted with ice cold 10% aqueous sodium hydroxide solution to remove any unreacted dihydroxy compound. The excess alkali was removed by washing with water, the neutral ether solution was dried over anhydrous potassium carbonate, filtered, and the solvent removed by distillation. Crystallization and re-crystallization from dilute ethanol yielded 11.2 g. (59%) of a white crystalline solid; m. p. 67.5–68°.

*Anal.* Calcd. for $C_{26}H_{30}O_2$: C, 83.42; H, 8.02. Found: C, 83.57; H, 8.31.

**3,4-bis-(3′-Methyl-4′-hydroxy-5′-allylphenyl)-2,4-hexadiene.**—The procedure used by Kaiser and Svarz[4] for the preparation of 3,4-bis-(3′-allyl-4′-hydroxyphenyl)-hexene-3 was employed. A solution of 6.8 g. of 3,4-bis-(3′-methyl-4′-allyloxyphenyl)-2,4-hexadiene in 40 ml. of diethylaniline was refluxed for five hours in a nitrogen atmosphere. The desired product was isolated as a red gum (2.2 g. or 32%) which could not be crystallized, but gave proper analytical results.

*Anal.* Calcd. for $C_{26}H_{30}O_2$: C, 83.42; H, 8.02. Found: C, 83.20; H, 8.26.

The diacetate, prepared in 68% yield by refluxing in acetic anhydride for four hours, formed white crystals from dilute ethanol, m. p. 125–126°.

*Anal.* Calcd. for $C_{30}H_{34}O_4$: C, 78.60; H, 7.42. Found: C, 78.31; H, 7.29.

The dipropionate was prepared in 61% yield in a similar manner, m. p. 114–115°.

*Anal.* Calcd. for $C_{32}H_{38}O_4$: C, 79.01; H, 7.81. Found: C, 78.83; H, 7.71.

## Closed-Circuit Seals in Glassblowing

BY ROGER K. TAYLOR

In fabricating glass apparatus in which one part is multiply connected to the rest, the customary procedure is to make the seals after the first by using a thin rod to pull together or bridge over the edges of the open-ended immobilized tubes that are to be joined. Difficulties occasionally arise, especially when the seal is not readily accessible from all directions, in manipulating the rod and obtaining a completely tight seal.

The writer for some years has on occasion used an alternative method which avoids these troubles. Although it is difficult to believe that the same idea has not occurred to others, neither the method nor a description of it has been seen elsewhere; and it is in the hope that the scheme may be of some general assistance that the following exposition is offered.

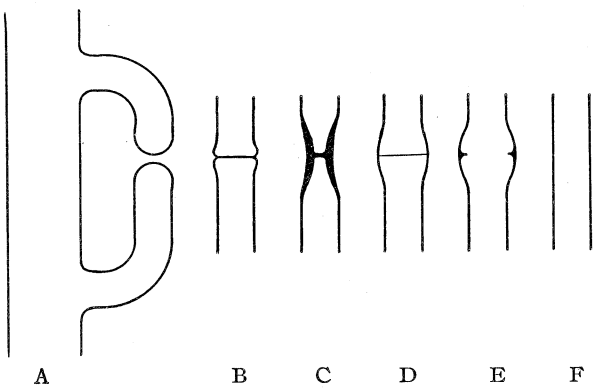

Fig. 1.—Closed-circuit seals in glassblowing.

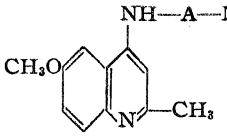

The innovation consists in closing the ends of the tubes where the joint is to be made (a). Then, when both ends are hot, blowing brings together the bulbs formed, producing a septum (b). When the enlarged portion is permitted to shrink (c), a portion of the glass of the septum is picked up by the wall; alternate blowing and shrinking (d, c) ultimately reduces the thickness of the septum to the point that it breaks (e), after which the joint is readily smoothed out (f). Glass can of course be added or removed with a thin rod as necessary, if the wall thickness at the seal does not match that of the rest of the tubing.

An advantage is that the annoyance of air leakage is avoided in the blowing, during making the seal; and this is particularly important when several connections have to be made between immobilized parts. It is also unnecessary to fit the parts so precisely, to give the small clearances required for easy working when the tubes are open. Furthermore there is no chance of leaving pinholes in the seals. The chief disadvantage is that prolonged working of the glass may lead to devitrification.

## Some Quinaldine and 3-Methylquinoline Derivatives

BY KEITH W. WHEELER, CHARLES H. TILFORD, M. G. VAN CAMPEN, JR., AND ROBERT S. SHELTON

Termination of our work on antimalarials left unfinished a proposed series of 4-substituted-6-methoxyquinaldines and a similar group of 3-methylquinoline derivatives. Since further work in this direction is not anticipated, it seems desirable to record the preparation and properties of those compounds we did obtain and which have not been previously described in the literature. None of these compounds was appreciably active against the malaria parasite, the activities ranging from $Q<0.03$ for SN9215 to $Q<1.0$ for SN5204, although serveral of them showed moderate activity against *T. equiperdum* in mice.[1]

The intermediates 4-chloro-6-methoxyquinaldine,[2] 4,5-dichloro-3-methylquinoline,[3] 4,7-dichloro-3-methylquinoline[3] and 2,7-dichloro-3-methylquinoline[4] were prepared by standard procedures. The required diamines were obtained from the catalytic hydrogenation of the β-(di)-alkylaminopropionitrile, or the commercially available *p*-aminodiethyl (or methyl) anilines, and from the phthalimide synthesis.

**Procedure.**—A mixture of 0.1 mole of the chloroquinoline and 0.2 mole of the diamine was heated for eight to fifteen hours at 175–200° or for twenty-four to thirty-six hours at 145–150°. Water and ether were added to the mixture, the layers were separated, and the ether layer was washed with 10% hydrochloric acid. The aqueous layer and acidic extracts were combined and made strongly basic. The liberated oil was taken up in ether, dried, and distilled under reduced pressure in some cases, while in other cases only the more volatile material was distilled, leaving the crude free base as a residue. The hydrochloride salts were prepared in the usual manner and recrystallized from mixtures of ethanol and butanone or from aqueous ethanol.

The yields, properties, and analyses of the new compounds prepared are recorded in Table I. The yields reported here do not take into account the quinoline bases recovered in some instances.

**Acknowledgment.**—We wish to express our appreciation to Mr. Wm. J. Corbett for technical assistance.

(4) This compound, m. p. 125–127°, was obtained along with the known 4,7-dichloro isomer from the action of phosphoryl chloride on 7-chloro-3-methylquinoline N-oxide. Although no analytical data are available, it is assumed to be the 2,7-isomer.

## Optically Active 2-Methylbutyl 3,5-Dinitrobenzoate

BY JONATHAN W. WHITE, JR., AND W. P. RATCHFORD

A lack of agreement in the literature concerning the melting point of optically active 2-

methylbutyl 3,5-dinitrobenzoate was encountered during a study of the volatile constituents of apple juice. The melting point of 2-methylbutyl 3,5-dinitrobenzoate is reported as 62°,[1] 70°[2] (both presumably from *d,l* alcohol), and 83–84°[3] (from alcohol of $[\alpha]$ +5.21°). The last value is the only one for a preparation obtained from an active alcohol of a given specific rotation. The stereoisomer available from fusel oil is *d*-2-methylbutanol, $[\alpha]^{20}D$ −5.90.[4] No data were found on the optical activity of the derivative.

An alcohol was obtained from apple juice which gave a dinitrobenzoate with a melting point of 81.5° (all melting points given here are uncorrected); its analysis was that of an amyl derivative. Mixed melting points with all inactive and racemic amyl derivatives were depressed below the melting point of either component except that with *dl*-2-methylbutyl dinitrobenzoate (m. p. 66.5°). The compound was optically active, $[\alpha]^{25}D$ +4.4°.

To determine which isomer had been obtained from apples, refined fusel oil was fractionally distilled. A fraction with $[\alpha]^{25}D$ −5.67° was obtained, equivalent to a purity of 96%. From this was prepared a 3,5-dinitrobenzoate, which melted at 83–84° and had $[\alpha]^{25}D$ +4.9°. This identified the alcohol from apples as *d*-2-methylbutanol, *i. e.*, the same as present in fusel oil.

### Experimental

**Dinitrobenzoate from Apple Fraction.**—A distillate fraction (the full procedure appears elsewhere,[5] 0.98 g. b. p. (150 mm.) 90–100°, $n^{20}D$ 1.4104, yielded a chromatographically[6] homogeneous 3,5-dinitrobenzoate on treatment with dinitrobenzoyl chloride in the presence of pyridine. It had a m. p. of 81.5–82.5°, analyzed as an amyl derivative, and failed to depress the m. p. of only the *dl*-2-methylbutyl derivative (m. p. 66.5°), in which case the melting range was 67–79°. It was then found to have $[\alpha]^{25}D$ +4.4° (4.8% in acetone). *Anal.* Calcd. for $C_{12}H_{14}O_6N_2$: C, 51.10, H, 4.96, N, 9.93. Found: C, 51.09; H, 5.04; N, 9.99.[7]

**Distillation of *d*-2-Methylbutanol from Fusel Oil.**—One gallon (3.78 l.) of "isoamyl alcohol"[8] was fractionated at atmospheric pressure in a Podbielniak column operated with intermittent take-off; it yielded 200 ml. of crude *d*-2-methylbutanol, b. p. 128–129°, estimated to be 53% pure. When redistilled, this fraction yielded 65 ml. of the alcohol, 93% pure. This material, redistilled in turn, yielded a fraction, b. p. 128.5°, $n^{20}D$ 1.4105, $[\alpha]^{25}D$ −5.67°, which is 96.1% of the accepted value.[4] The 3,5-dinitrobenzoate of this fraction melted at 83–84°, and had $[\alpha]^{25}D$ +4.9° (6.4% in acetone). *Anal.* Calcd. for $C_{12}H_{14}O_6N_2$: C, 51.10; H, 4.96. Found: C, 51.00; H, 5.00. A mixed melting point with the product from apple juice was 82–84°; therefore the alcohol from apples was -*d* 2-methylbutanol.

## 2,2-Disubstituted-thiazolidine-4-carboxylic Acids

BY RICHARD H. WILEY AND J. F. JEFFRIES

The present report describes the application of the method of Woodward and Schroeder,[1] first used to prepare thiazolidine carboxylic acids from cysteine and acetone, to cysteine and three other ketones to form the corresponding substituted thiazolidine carboxylic acids.

**2-Methyl-2-ethylthiazolidine-4-carboxylic acid.**—One gram of cysteine[2] was refluxed with 200 ml. of methyl ethyl ketone, b. p. 79–80°, in a 300-ml. flask attached by ground glass connection to a reflux condenser. After three hours the cysteine had nearly all dissolved. The solution was filtered, evaporated to 15 ml., and cooled to deposit crystals which were recrystallized from methyl ethyl ketone; yie d, 1.0 g., 70% of the theoretical amount, m. p. 131°. No reaction took place when rubber stoppered equipment was used.

*Anal.* Calcd. for $C_7H_{13}NO_2S$: C, 48.00; H, 7.42; N, 7.98; S, 18.28. Found: C, 47.75; H, 7.19; N, 8.02; S, 18.38.

**2-Methyl-2-isopropylthiazolidine-4-carboxylic acid** was prepared from methyl isopropyl ketone as in the preceding example; yield, 0.69 g. from 1 g. of cysteine, 44% of the theoretical amount, m. p. 154° recrystallized from methyl isopropyl ketone.

*Anal.* Calcd. for $C_8H_{15}NO_2S$: C, 50.8; H, 7.92; N, 7.40; S, 16.90. Found: C, 50.9; H, 7.94; N, 7.51; S, 17.20.

**2,2-Tetramethylenethiazolidine-4-carboxylic acid** was prepared from cysteine and cyclopentanone; yield 0.86 g. from 1 g. of cysteine, 56% of the theoretical amount, m. p. 138°, recrystallized from cyclopentanone.

*Anal.* Calcd. for $C_8H_{13}NO_2S$: C, 51.2; H, 6.94; N, 7.48; S, 17.10. Found: C, 50.8; H, 6.92; N, 7.34; S, 16.90.

# NEW COMPOUNDS

### Esters of Mono-, Di- and Tri-chloro-acetic Acids[1]

The new esters of mono-, di-, and tri-chloro-acetic acids, listed in Table I, have been synthesized by refluxing the alcohol with a slight molar excess of the acid in the presence of benzene. A Dean–Stark moisture trap was included in the apparatus to collect the water produced during the reaction. Refluxing was continued until the theo-

(1) Work done at the American Home Products Corp. Development Laboratory, New York, N. Y.

retical amount of water was collected. The reaction mixture was then cooled, washed with dilute bicarbonate solution and dried over anhydrous sodium sulfate. The product was isolated by vacuum distillation. Yields were in the neighborhood of 80–90%.

### 1-Benzyl-3-phenyl-2-thiohydantoin

**Ethyl N-Benzylglycinate.**—Ethyl chloroacetate was condensed with benzylamine according to the directions of Mason and Winder.[1] The yield of ethyl N-benzylglycinate on the second distillation, 128–131° at 6 mm., was 55%. The picrate derivative was prepared by mixing ethereal solutions of the two substances and scratching to induce crystallization. These yellow plates, washed with ether, melted 166–168° (micro-block).[2] A benzoyl derivative was also attempted but it could not be prepared by either the Schotten–Baumann method or by boiling with benzoyl chloride in benzene solution. This unexpected behavior prompted the attempt to form a thiourea derivative.

**1-Benzyl-3-phenyl-2-thiohydantoin.**—Approximately equal amounts of ethyl N-benzylglycinate and phenyl isothiocyanate were mixed in alcoholic solution and boiled for a minute or two. The product which separated on cooling was recrystallized from alcohol to give a good yield of long flat needles, m. p. 188.5–189.5° (micro-block). Instead of the expected thiourea the product indicated by analysis was the 2-thiohydantoin which resulted from cyclization of the thiourea by splitting out of ethanol. This type of cyclization is not unusual, though it generally requires higher temperatures[3] or acid catalysis.[4] *Anal.* Calcd. for $C_{16}H_{14}N_2OS$: C, 68.06; H, 5.00; N, 9.92. Found: C, 68.05; H, 5.12; N, 9.93.

# COMMUNICATIONS TO THE EDITOR

## STUDIES OF FIBRINOGEN AND FIBRIN WITH THE ELECTRON MICROSCOPE

*Sir:*

Electron micrographs of metal-shadowed bovine Fraction I and human fibrinogen have been obtained showing that these materials consist largely of filamentous elements which are nodous in outline, somewhat like a string of beads, about 40 Å in diameter. Since the filaments tend to intermingle, it is difficult to measure all lengths with certainty, but such filaments as can be discerned vary in length from 300 to 1100 Å., with an average of about 600 Å. From flow-birefringence data it has been concluded that the fibrinogen particle can be represented by a prolate ellipsoid with a major axis of 700 Å. and an axial ratio of 18:1.[1] The widths observed are not appreciably different from the calculated minor axis. Numerous filaments occur with lengths close to the 700 Å. predicted, but the correlation is unsatisfactory in that flow-birefringence data indicate a constancy in length, while the electron microscope observations show a distribution of lengths. The discrepancy might be due to differences in samples or to difficulties inherent in the electron microscope methods.

An axial periodicity of about 250 Å. has been reported in bovine fibrin[2] after staining with phosphotungstic acid. The macroperiod is superficially similar to that in collagen[3] and certain other protein fibrils. In the present investigation, electron micrographs were obtained with improved resolution, showing that in bovine and human fibrin, the macroperiod consists of narrow stain-receptive bands midway between denser and wider stain-receptive bands whose average distance center-to-center along the fibril axis is about 230 Å. The spacing is constant to about 3% in individual fibrils, but varies by as much as 20% between separate fibrils. The fibrils appear to consist of particles having diameters in the range 30 to 50 Å. Metal-shadowing shows that the stain-receptive bands represent higher portions, indicating that the intervening regions have shrunk during drying. It is concluded that the periodic structure represents regular fluctuations in protein concentration in the originally hydrated system.

(1) J. T. Edsall, J. F. Foster and H. Scheinberg, THIS JOURNAL, **69**, 2731 (1947).

(2) C. V. Z. Hawn and K. R. Porter, *J. Exp. Med.*, **86**, 285 (1947).

(3) C. E. Hall, M. A. Jakus and F. O. Schmitt, THIS JOURNAL, **64**, 1234 (1942).

The micrographs indicate that fibrin is produced through a predominantly lateral association of fibrinogen filaments. The characteristic striation does not appear under all circumstances, for example, in fibrils with widths below about 200 Å., or in tapered ends with widths less than this. Unstriated fibrils show a randomly particulate structure, while in the striated portions the particles are more concentrated in the stained bands. The micrographs of fibrinogen do not show any degree of regularity either in length or internal structure comparable to the regularity in fibrin. It appears that the periodicity in fibrin is not a manifestation of rigid dimensional units in fibrinogen, but is, rather, a characteristic developed subsequent to initial aggregation The anomalous variations in protein concentration indicate that some of the constituents have experienced local axial shifts to preferred positions.

## FERMENTATION OF GLUCOSE-1-C$^{14}$

*Sir:*

We have synthesized *d*-glucose-1-C$^{14}$ from *d*(−)-arabinose by the Fischer–Kiliani method.[1] The mixed glucono- and mannonolactones were reduced catalytically,[2] carrier glucose added, and the radioglucose isolated and recrystallized to constant specific activity (about 6000 counts per gram minute). The glucose (in 0.2-g. samples) was then fermented anaerobically by Fleischmann's baker's yeast in phosphate buffers in the absence of a source of combined nitrogen; the fermentation yields (based on the carbon dioxide obtained) were 75–90%. The Embden–Meyerhof fermentation mechanism[3] predicts that all the radiocarbon will appear in the methyl group of the alcohol so obtained; this prediction has been substantially confirmed.

The carbon dioxide obtained directly in the fermentation was counted as $BaCO_3$. The alcohol was degraded to acetone by the method outlined below; the latter was counted as its 2,4-dinitrophenylhydrazone.

$$C^{14}H_3CH_2OH \xrightarrow[H_2SO_4]{K_2Cr_2O_7} C^{14}H_3CO_2H \xrightarrow{Ba(OH)_2} (C^{14}H_3CO_2)Ba(O_2CCH_3) \xrightarrow[\text{Vacuum}]{530^\circ} C^{14}H_3COCH_3 + BaCO_3$$

In a set of control experiments on the pyrolysis using methyl-labelled acetic acid,[4] we found 0.1–0.3% of the activity in the barium carbonate produced. Further in these control experiments, the specific activity of the acetone 2,4-dinitrophenylhydrazone was only 77% of that anticipated from the specific activity of the barium acetate, even after making the usual corrections[5] for self-absorption, etc. The specific activities of all samples of acetone 2,4-dinitrophenylhydrazone were therefore corrected by the factor 1/0.77. The final results, together with the counting errors (95% confidence level), are given below:

| pH | Other conditions | Per cent. of radioactivity (based on glucose fermented) found in $CO_2$ | $CH_3$ | $CH_2OH$ |
|---|---|---|---|---|
| 6.2 | Live yeast | 6.5 ± 2.4 | 92 ± 4.0 | 4.8 ± 2.4 |
| 5.7 | Live yeast | 1.0 ± 1.8 | 76 ± 4.0 | 7.6 ± 2.8 |
| 5.7 | Dried yeast powder | 3.7 ± 1.8 | 92 ± 7.8 | 0.2 ± 0.4 |

We are currently investigating the causes of the slight radioactivity in the carbon dioxide obtained directly in the fermentation and in the barium carbonate from the pyrolysis.

## A NEW SYNTHESIS OF 2-PHENAZINOL, THROUGH THE DI-N-OXIDE

*Sir:*

The chlorine atom of 2-chlorophenazine can be labilized toward aqueous-alcoholic sodium or potassium hydroxide by converting the base to 2-chlorophenazine-5,10-dioxide (red-orange needles, m. p. 190–191° (dec.)[1] *Anal.*[2] Calcd. for $C_{12}H_7ClN_2O_2$: C, 58.4; H, 2.87. Found: C, 58.5; H, 3.06. This conversion is readily effected, using the method employed by Clemo and McIlwain[3] for other phenazines. Refluxing the chlorophenazine dioxide for about twelve hours with aqueous-alcoholic potassium or sodium hydroxide gives a deep purple solution of the alkali salt, from which hydrochloric acid precipitates the free 2-phenazinol-5,10-dioxide (orange-red, begins to darken at 236°). *Anal.* Calcd. for $C_{12}H_8N_2O_3$: C, 63.2; H, 3.54. Found: C, 63.1; H, 3.87. Reduction of this by sodium hyposulfite (sodium "hydrosulfite") in alkaline solution at room temperature gives a red solution of the sodium salt of 2-phenazinol, from which the free phenol[4] is precipitated by acid. (Clemo and McIlwain[3] found sodium hyposulfite effective in reducing 1-phenazinol-5,10-dioxide.) The 2-phenazinol may be purified by vacuum sublimation and chromatographic adsorp-

tion on alumina. *Anal.* Calcd. for $C_{12}H_8N_2O$: C, 73.4; H, 4.11. Found: C, 73.8; H, 4.25.

The 2-chlorophenazine was made by the method of Waterman and Vivian,[5] starting from 4-chloro-2-nitrodiphenylamine.

The antitubercular activity of the phenazine dioxides[6] makes both of the new dioxides reported above of interest, especially the alkali-soluble hydroxy compound; and by this synthesis the 2-phenazinol itself is rendered more easily accessible.

## PREPARATION OF HIGH-PURITY HYDROGEN DEUTERIDE FROM LITHIUM ALUMINUM HYDRIDE

*Sir:*

Hydrogen deuteride of very high purity has been prepared previously by the fractional distillation of a mixture of $H_2$, $D_2$, and HD at liquid hydrogen temperatures.[1] We have now found that very pure HD can be prepared more simply by the action of certain metallic hydrides on heavy water. Thus, sodium hydride with heavy water gives 87% HD with $H_2$ and $D_2$ as impurities. Lithium aluminum hydride with heavy water gives 93% HD in some cases and in others 97%, with 2.5% $H_2$ + 0.5% $D_2$.[2] Determinations were made on a consolidated mass spectrometer for which instrumental condition were: magnet current of 0.15 ampere and voltages of 3800 for mass 1 ($H^+$), 1900 for mass 2 ($H_2^+$ and $D^+$), 1267 for mass 3 ($HD^+$), and 950 for mass 4 ($D_2^+$).

It was suspected that the heat evolved in the reaction promoted the formation of $D_2$ and $H_2$. Accordingly the preparation with lithium aluminum hydride was carried out in a bath at 0°, with the resulting formation of 99% pure HD. The exact nature of the temperature dependence is not known, but the variation in composition of the gas product may be due to a shifting of the $H_2 + D_2 \rightleftarrows HD$ equilibrium, as well as to the presence of impurities in the lithium aluminum hydride.

Our preferred procedure for this preparation, therefore, was as follows:

Pure $D_2O$ (99.8%) contained in a hypodermic syringe was injected through a neoprene serum stopper, into a stirred ice-cold slurry of lithium aluminum hydride in *n*-butyl ether contained in the reaction flask of a modified Zerewitinoff apparatus.[3] After the vigorous reaction subsided, the evolved gas was collected in an evacuated sample bottle.

This very simple preparation of HD from lithium aluminum hydride and knowledge of its fragmentation pattern should improve the mass spectrometric analyses of $H_2$, $D_2$ and HD mixtures, especially those low in $H_2$.

We wish to acknowledge the helpful assistance of A. G. Sharkey, Jr.

# Report of Committee on Atomic Weights

BY G. E. F. LUNDELL, *Chairman*

The following pieces of work have been reported since the material was gathered for the Report which was published in *Chemical and Engineering News*, **26,** 1619 (1948), and reprinted in the *Journal of the American Chemical Society*, **70,** 3531 (1948).

**Cerium and Lanthanum.**—Inghram, Hayden and Hess[1] determined the isotopic constitution of cerium and of lanthanum by means of a mass spectrometer.

The abundances of the cerium isotopes of masses 136, 138, 140 and 142 were shown to be 0.193 ± 0.005, 0.250 ± 0.005, 88.48 ± 0.10, and 11.07 ± 0.01%, respectively. Calculation of the chemical atomic weight of cerium from these abundances, assuming a packing fraction of $-3.0 \times 10^{-4}$, and the factor 1.000275 in converting from physical to chemical atomic weights, gives 140.10, a value which is in agreement with the chemically determined International value of 140.13.

The abundances of the lanthanum isotopes of masses 138 and 139 were found to be 0.089 ± 0.001 and 99.911 ± 0.001%, respectively. Calculation of the chemical atomic weight from these abundances, using Dempster's value[2] of $-3.2 \times 10^{-4}$ for the packing fraction and the conversion factor 1.000275, gives 138.92, a value which is in complete agreement with the chemically determined International value of 138.92.

**Neodymium and Praseodymium.**—Inghram, Hess and Hayden[3] determined the isotopic constitution of neodymium and of praseodymium by means of a mass spectrometer.

The abundances of the neodymium isotopes of masses 142, 143, 144, 145, 146, 148 and 150 were found to be 27.13 ± 0.2, 12.20 ± 0.1, 23.87 ± 0.2, 8.30 ± 0.05, 17.18 ± 0.2, 5.72 ± 0.06 and 5.60 ± 0.06%, respectively. Assuming a packing fraction of $-2.7 \times 10^{-4}$, and with the conversion factor 1.000275, the chemical atomic weight is 144.25, which is in good agreement with the International chemical value of 144.27.

Assuming a packing fraction of $-3.0 \times 10^{-4}$ for praseodymium with its single isotope at mass 141, and with the conversion factor 1.000275, the chemical atomic weight is 140.92, which is in complete agreement with the International value of 140.92.

**Samarium.**—Inghram, Hess and Hayden[4] determined the isotopic composition of samarium.

The abundances of the samarium isotopes of masses 144, 147, 148, 149, 150, 152 and 154 were found to be 3.16 ± 0.10, 15.07 ± 0.15, 11.27 ± 0.11, 13.84 ± 0.14, 7.47 ± 0.07, 26.63 ± 0.26 and 22.53 ± 0.22%, respectively. Calculation of the chemical atomic weight from these abundances, assuming a packing fraction for samarium of $-2.4 \times 10^{-4}$, and with the conversion factor 1.000275, gives a value of 150.35. The International value is 150.43.

**Cadmium and Zinc.**—Leland and Nier[5] determined the relative abundances of the isotopes of cadmium and of zinc. The abundances of the cadmium isotopes of masses 106, 108, 110, 111, 112, 113, 114 and 116 were found to be 1.215, 0.875, 12.39, 12.75, 24.07, 12.26, 28.86 and 7.58% respectively. By using a packing fraction of $-6.0 \times 10^{-4}$ and the conversion factor 1.000275, the calculated value of the chemical atomic weight is 112.42, which agrees very well with the International chemical value of 112.41.

(5) Wallace T. Leland and Alfred O. Nier, *ibid.*, **73,** 1206-1207 (1948).

The relative abundances of the isotopes of zinc of masses 64, 66, 67, 68 and 70 were found to be 48.89, 27.81, 4.07, 18.61 and 0.620%, respectively. With a packing fraction of $-7.0 \times 10^{-4}$ and the conversion factor 1.000275, the computed chemical atomic weight is 65.40, whereas the International chemical value is 65.38.

# The System Aluminum Sulfate–Sulfuric Acid–Water at 60°

BY JACK L. HENRY[1] AND G. BROOKS KING

This report is part of a study of the more extensive system aluminum oxide–sulfur trioxide–water at 60° which is being investigated in connection with the development of an alumina-from-clay extraction process. The temperature 60° has been found most advantageous for the process as determined with laboratory scale and pilot plant extraction towers.[2] Although the leach operations are carried on within the basic region, it was felt desirable to conduct a study of the system in its entirety. In connection with the acid system presented in this paper, no complete ternary systems have been reported. F. Wirth[3] has studied the solubility of aluminum sulfate in sulfuric acid solutions of concentrations up to 75% at 25° and has reported but one solid phase, the 18 hydrate. At the same temperature Motida[4] has found the 16 hydrate in addition to the 18 hydrate, but presented no data for sulfuric acid concentrations above 48%. Kremann and Hüttinger[5] in their work on the solubility of freshly precipitated aluminum hydroxide in aluminum sulfate solutions report that the 16 hydrate exists as the solid phase in the less basic region at 20, 40 and 60°. This would seem to be in agreement with the views of P. M. Delacharlonny,[6] who favors the 16 hydrate. Horan and Skarulis,[7] however, failed to prepare the 18 hydrate and suggest the possibility of $Al_2(SO_4)_3 \cdot 17H_2O$ at the temperature 0°. Following this work, N. O. Smith,[8] by repeating at 25° the parts of three ternary systems which involve hydrated aluminum sulfate as the solid phase, showed further evidence in favor of the 17 hydrate. The following hydrates of aluminum sulfate have been found reported in the literature: 2, 3, 6, 9, 10, 12, 14, 16, 17, 18, 22, 24 and 27. That they are all true chemical individuals, however, seems questionable. The present paper treats the system over sulfuric acid concentrations up to 96.08% and shows the presence of the four solid phases at 60°: $Al_2(SO_4)_3 \cdot 16H_2O$, $Al_2(SO_4)_3 \cdot 9H_2O$, $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 12H_2O$ and $Al_2(SO_4)_3$.

## Experimental

**Materials and Apparatus.**—Mallinckrodt analytical reagent aluminum sulfate and sulfuric acid were employed throughout the system. Aluminum sulfate was recrystallized from a solution of specific gravity about 1.33 as suggested by Horan and Skarulis.[7] Extensive solubility studies on the system at 60° showed, however, that any deviations caused by impurities present in the unrecrystallized reagent could not be detected by the analytical methods used. Because of the high percentage of waste involved in recrystallization and the large amount of aluminum sulfate used, the unrecrystallized salt was employed in more than half the studies.

An electrically controlled thermostat which held the temperature at 60 ± 0.1° was employed. Evaporation loss from the bath was limited by a fabricated sheet aluminum cover. Glass-stoppered Pyrex tubes of about 40-ml. capacity which held the solutions under investigation were fitted with cotton-filled caps and secured to a wheel which rotated continually beneath the water surface of the bath. Such tumbling action provided efficient agitation during the time required for the solutions to reach equilibrium.

**Methods of Analysis.**—Aluminum sulfate was determined gravimetrically as $Al_2O_3$ by ignition at 1150°. Sulfuric acid was titrated directly in the presence of aluminum sulfate with standard sodium hydroxide solution. The aluminum which was combined in a complex by use of an excess of sodium oxalate[9] did not interfere with the titration. In regions of low sulfuric acid concentration the titrations were carried out electrometrically, whereas phenol red indicator was used at higher concentrations. The volumetric method for sulfuric acid gave satisfactory checks against the gravimetric barium sulfate procedure and proved to be much more rapid.

**Solubility Determinations.**—Various mixtures of aluminum sulfate, sulfuric acid and water were weighed out approximately and placed in the described tubes. The mixtures were brought to equilibrium from the supersaturated condition in most cases. Tubes were removed from the wheel at intervals and samples taken for analysis to determine the progress in attainment of equilibrium. Time for establishment of equilibrium conditions increased with increasing sulfuric acid concentration. Equilibrium was attained in the less acidic regions within forty-eight hours, but in no case did the time exceed six days. At lower sulfuric acid concentrations the crystals, although quite small, separated quickly and completely. Above 50% sulfuric acid the equilibrium mixture proved difficult to handle in that the resulting viscous slurries failed to separate well into liquid and solid phases. A constant temperature centrifuge was designed and built in which the samples could be centrifuged at 60 ± 0.1°. This incor-

(9) M. F. Adams (not yet published), presented at American Chemical Society regional meeting, Seattle, Washington, 1945.

porated an air-bath electrically controlled by a bimetallic spiral thermoregulator and a space heater. Successful separations were achieved by this means up to concentrations of sulfuric acid in excess of 85%. Above this concentration the density of the mother liquor so closely approached that of the minute crystals that centrifuging for a permissible length of time failed to bring about complete separation. The few points treated in this region were separated by gravitational settling over a period of from one to two weeks.

The method of "wet residues"[10] was used in nearly all cases except in the establishment of isothermally invariant points. In these, accurately synthesized complexes were employed. It was found that glass-stoppered tubes properly sealed with DeKhotinsky cement were highly satisfactory for the work with complexes.

## Results

The compositions of the solutions and residues are given in Table I and shown graphically in Fig. 1. Tie-lines are constructed to intersect at the probable solid phase.

[a] Complex made up against analytical balance. [b] Metastable. M = $Al_2(SO_4)_3 \cdot 16H_2O$, N = $Al_2(SO_4)_3 \cdot 9H_2O$, O = $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 12H_2O$, P = $Al_2(SO_4)_3$.

Data were plotted and graphical extrapolations made on an accurately drawn triangular diagram

(10) Schreinemakers, *Z. physik. Chem.*, **11**, 75 (1893).

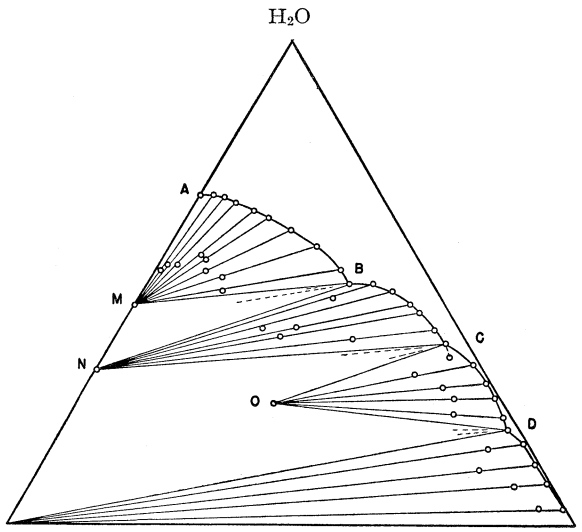

Fig. 1.—System $Al_2(SO_4)_3$–$H_2SO_4$–$H_2O$ at 60°: M = $Al_2(SO_4)_3 \cdot 16H_2O$, N = $Al_2(SO_4)_3 \cdot 9H_2O$, O = $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 12H_2O$, P = $Al_2(SO_4)_3$.

with edge dimensions of 50 cm. To check the accuracy of the solid phases determined by such graphical means, algebraic extrapolations[11] were carried out for each of the four solids. By algebraic extrapolation of data on curve AB the points nearest the edge of the triangle would seem to favor the 15 hydrate of aluminum sulfate, whereas those data nearer point B show the 16 hydrate to be the probable solid phase. Extrapolations of data nearest point A appear more erratic, however. This might be expected since the tie-lines are so nearly parallel to the edge of the diagram. Such uncertainty in this region would suggest that more weight be placed on those data nearer point B on the curve. Algebraic extrapolations from the four points nearest B show an average error in per cent. $Al_2(SO_4)_3$ of −0.53 from the 16 hydrate and +1.09 from the 15 hydrate. The 18 hydrate reported by Motida[4] to exist over the range of sulfuric acid concentration up to 7.24% at 25° was not observed at this higher isotherm although the possibility of a transition near A was given careful consideration. Extension of the work into the basic region, not yet published, throws little light on the possibility of an 18 hydrate because the curve breaks soon after passing the $Al_2(SO_4)_3$–$H_2O$ axis.

Since our value of 31.8% for the solubility of pure aluminum sulfate at 60° differs so greatly from the value 37.2% reported by Poggiale[12] it was felt that the binary system $Al_2(SO_4)_3$–$H_2O$ should be re-investigated at least in part. Whereas the solubilities near 25 and 30° lie close to the values obtained by Poggiale, a large negative deviation is observed at higher temperatures. The

(12) Poggiale, *Ann. Chim. Phys.*, [3] **8**, 467 (1843).

results reported by Poggiale are shown by the broken line in Fig. 2. Much work has been done on solubility studies of aluminum sulfate at 25 and 30°, but relatively little above these temperatures. The fact that Poggiale's binary study agrees with recent investigators in this more common range may explain why re-investigation of the system at elevated temperatures has not been conducted. Data for the binary study are given in Table II and shown graphically in Fig. 2. Equilibrium was established from both undersaturation and supersaturation in each case. No attempt was made to identify the solid phase, and although the curve is drawn as smooth the data do not rule out the possibility of a change in hydration in this range.

TABLE II

SOLUBILITY OF HYDRATED ALUMINUM SULFATE

| Temp., °C. | Solubility $Al_2(SO_4)_3$ (wt. %) Undersaturation value | Supersaturation value | Average |
|---|---|---|---|
| 25 | 28.3 | 28.3 | 28.3 |
| 30 | 28.6 | 28.6 | 28.6 |
| 35 | 28.9 | 28.9 | 28.9 |
| 40 | 29.5 | 29.7 | 29.6 |

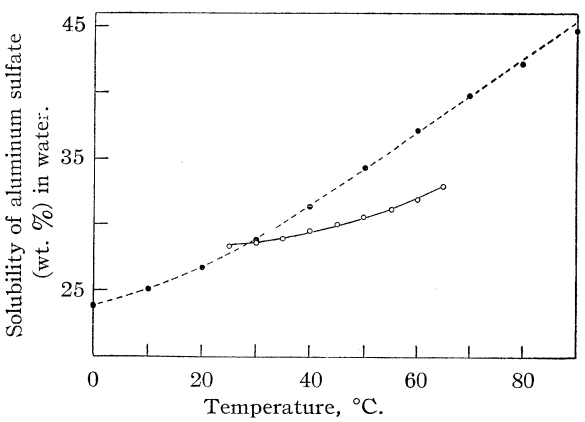

Fig. 2.—Solubility of hydrated $Al_2(SO_4)_3$ in $H_2O$ given as percentage by weight. Broken-line curve represents the values reported by Poggiale.[11]

The solubility curve BC, Fig. 1, shows $Al_2(SO_4)_3 \cdot 9H_2O$ to be the probable solid phase. The average deviation in per cent. $Al_2(SO_4)_3$ by algebraic extrapolation is +0.89. Metastability was encountered in this region as shown by the broken line extending beyond 60.8% sulfuric acid. Behavior of several samples prepared in the range of curve CD indicated that this metastable condition extends to about 65% sulfuric acid.

The curve CD represents solutions in equilibrium with the acid salt $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 12H_2O$. Average deviation in per cent. $Al_2(SO_4)_3$ from the composition of this solid phase as determined by algebraic extrapolation is +0.42. Three acid salts have been reported, $Al_2(SO_4)_3 \cdot H_2SO_4 \cdot 3H_2O$ by E. Baud,[13] $Al_2(SO_4)_3 \cdot 2H_2SO_4 \cdot 10H_2O$ by F. Jeremin,[14] and $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 7H_2O$ by R. Silberberger.[15] The later bisulfate was reported to have been prepared by the addition of aluminum sulfate to cold concentrated sulfuric acid and warming. The acid salt described in the present paper is very similar in physical properties to that reported by Silberberger but differs as to degree of hydration. When filtered and washed with ether the acid sulfate appears as a fine white powder. In contact with water it remains for several hours as a "silky" precipitate gradually decomposing and going into solution. The white powder appears to be slightly deliquescent and changes in moist air to form a paste-like mass which is readily soluble in water.

Beyond the isothermally invariant point *D* anhydrous aluminum sulfate is found to be the solid phase. The average error in per cent. $Al_2(SO_4)_3$ is +0.88. The highest concentration of sulfuric acid studied shows only a trace of dissolved aluminum sulfate. This may be compared with the work of Kendall and Davidson,[16] who report the molar solubility of anhydrous aluminum sulfate in anhydrous sulfuric acid at 25° to be less than 0.01. The amplification of analytical errors caused by failure to obtain a more complete separation of the residue from the solution has contributed greatly to the deviations in the extrapolations. The relatively large range of extrapolations may cast some doubt upon the degree of hydration of phases N and O as stated.

## Summary

The ternary system $Al_2(SO_4)_3$–$H_2SO_4$–$H_2O$ has been investigated at 60°. The four solid phases, $Al_2(SO_4)_3 \cdot 16H_2O$, $Al_2(SO_4)_3 \cdot 9H_2O$, $Al_2(SO_4)_3 \cdot 3H_2SO_4 \cdot 12H_2O$, and anhydrous $Al_2(SO_4)_3$ have been found.

Investigation of the binary system $Al_2(SO_4)_3$–$H_2O$ from 25 to 65° shows lower values of solubility in the higher temperature range than have been previously reported.

# A Comparison of the Long Spacings of Some Soap Hemihydrates

BY J. E. MINOR AND E. C. LINGAFELTER

Values for the cell dimensions of "alpha" sodium palmitate hemihydrate[1] and "alpha" sodium stearate hemihydrate have been published by Buerger.[2] These published values gave an increase in $d_{001}$ value between the palmitate and stearate which was larger than would have been expected. It was therefore thought to be of interest to check the values obtained for the palmitate and stearate, and to extend the series to include sodium myristate and sodium arachidate hemihydrates. An attempt was also made to grow crystals of sodium laurate hemihydrate, but to date no suitable crystals of this substance have been obtained.

## Experimental

The authors are indebted to M. J. Buerger for crystals of sodium arachidate hemihydrate obtained from him. Suggestions for growing crystals of the other hemihydrates were obtained from a publication[3] by de Brettville and Ryer.

The crystals obtained in this Laboratory were grown from sodium soaps produced by titrating the corresponding Eastman Kodak Co. fatty acid dissolved in alcohol with equimolar proportions of alcoholic sodium hydroxide, using phenolphthalein as an outside indicator. The resulting sodium soaps were recrystallized from alcohol before use. A series of analytical tests were run on the Eastman acids used, to determine their freedom from esters, unsaturation, and fatty acids of other molecular weights. Data on the methyl arachidate and arachidic acid from which the sodium arachidate was prepared have been furnished by Dr. F. V. Ryer of the Lever Bros. Company.

The equivalent weights were calculated from acid values run according to Scott's "Standard Methods of Analysis." Saponification values were also run according to Scott's "Standard Methods of Analysis." Iodine numbers required a more specialized technique because of the low percentage of unsaturation present in the fatty acids. Accordingly these determinations were run by M. Yasuda's method[4] using pyridine sulfate dibromide as the halogenating agent.

TABLE I

ANALYTICAL DATA

| Substance | Equiv. wt. | Dev., % | Sapon. value | Dev., % | Iodine no. | Temp., °C. Setting point | Setting point (Francis and Piper)[5] |
|---|---|---|---|---|---|---|---|
| Myristic acid | 228.4 | 0.0 | 245.7 | 1.0 | 0.1 | 52.92 | 53.65 |
| Palmitic acid | 256.6 | .1 | 224.7 | 2.7 | 0.1 | 61.54 | 62.60 |
| Stearic acid | 285.8 | .5 | 204.8 | 3.9 | 1.2 | 68.42 | 69.39 |
| Arachidic acid | | | 172.3(ester) | 0.3 | 0.2(ester) | 74.3(m. p.) | 75.35(m. p.) |

In the first attempt to grow crystals of NaL and NaMy, approximately 0.6% solutions of the compounds in 95% ethyl alcohol were made up, a few grains of sodium chloride were added, and the solutions were placed in a thermostat at 20°. A few tiny crystals of NaMy were obtained, and later proven to be "alpha" form, but no usable crystals of NaL appeared. Approximately 0.2% solutions of NaP, NaSt, and NaL were then made up in 95% ethyl alcohol, a few grains of sodium chloride added to the NaP and NaL solutions, and the solutions were allowed to evaporate slowly at room temperature. The NaL solution produced no single crystals. The NaSt solution produced a large number of single crystals of the "alpha" form. The NaP solution produced a few crystals of a rod shape which were shown by X-ray studies to be different from the "alpha" form. Immediately after these crystals appeared, another crystalline form began to grow, which proved to be "alpha" NaP.

The habit of the NaSt and NaAr crystals corresponds to that described by Buerger[6] for NaSt.

The habit of the NaP crystals corresponds to Buerger's description[6] except that the form (10 $l$) is present to about the same degree as the (11 $l$), making the crystal appearance hexagonal rather than diamond shape. The crystals have good (010) cleavage.

The few NaMy crystals obtained were not sufficiently well developed to obtain crystallographic characteristics.

Data on cell constants were obtained from oscillation photographs for $a_0$ and $b_0$ values, and from equi-inclination Weissenberg photographs for $c_0$ values. CuK radiation with nickel filter was used for all photographs. (Camera diameter = 56.85 mm., obtained by calibration with NaCl, $a_0$ = 5.6394 Å., CuK$\alpha\lambda$ = 1.5418 Å.) Constants of the unit cells appear in Table II.

TABLE II

CONSTANTS OF THE UNIT CELL

| Substance | $a_0$, Å. | $b_0$, Å. | $c_0$, Å. | $\beta$ |
|---|---|---|---|---|
| NaMy·$^1/_2$H$_2$O | 9.32 | 8.00 | 82.63 | 93$^3/_4$° |

[a] This $\beta$ value was not redetermined, but was taken from values published by Buerger.[2]

## Discussion

The published values[2] for the cell constants of NaP·$^1/_2$H$_2$O and NaSt·$^1/_2$H$_2$O show an increase in $d_{001}$ between the two of 11.02 Å.[7] Since the unit

(1) The following abbreviations are used in this paper for organic radicals:

| Composition | Name | Abbreviation |
|---|---|---|
| $C_{12}H_{23}O_2$ | Laurate | L |
| $C_{14}H_{27}O_2$ | Myristate | My |
| $C_{16}H_{31}O_2$ | Palmitate | P |
| $C_{18}H_{35}O_2$ | Stearate | St |
| $C_{20}H_{39}O_2$ | Arachidate | Ar |

(2) Buerger, *Am. Mineral.*, **30**, 551 (1945).

(3) de Brettville and Ryer, *J. Phys. Chem.*, **48**, 154 (1944).

(4) M. Yasuda, *J. Biol. Chem.*, **94**, 404 (1931–1932).

(5) Francis and Piper, THIS JOURNAL, **61**, 577 (1939).

(6) Buerger, *Proc. Nat. Acad. Sci.*, **28**, 529 (1942).

(7) This value is obtained by using a later value of $c_0$ for NaSt (private communication from M. J. Buerger, $c_0$ = 102.7 kX).

cell is four molecules long in the $c$ direction, this means that an increase of 8 carbon atoms in the chain direction has caused an increase in $d_{001}$ of 11.02 Å. In order for a change of this magnitude to occur, a change of tilt of the order of 7.5° would have to occur between the two compounds. That this difference in tilt actually exists is not probable, since Buerger[2] has shown that the symmetry properties of the two compounds are the same.

Using the cell constants determined in this Laboratory the following increases in $d_{001}$ between the pairs of substances are noted:

| Compounds | $\Delta d_{001}$, Å. |
|---|---|
| NaMy–NaP | 10.26 |
| NaP–NaSt | 10.19 |
| NaSt–NaAr | 10.32 |

Using a least squares approximation on values for $d_{001}$ *vs.* number of carbon atoms in the chain, the most probable value for change in $d_{001}$ is found to be 10.25 Å.

The work of MacArthur[8] on the extension of the C<C link in normal long chain aliphatic compounds indicates that an addition of 8 carbon atoms to a compound of this type should give an increase in chain length of 10.16 Å. MacArthur also lists the data of a number of other workers in this field, and shows that the average of their results would lead to a value of 10.19 Å. (It is not apparent whether the figures published by MacArthur are in kX or Å. units. If the published figures are in kX units, the two results in Å. would then be 10.18 and 10.21, respectively.)

The results of this Laboratory also show a difference of 0.09 Å. between the $a_0$ value for NaMy and the corresponding $a_0$ values for NaP and NaSt. There is no apparent reason for the existence of a real difference in the values, and it is assumed that this difference arises from experimental error since the NaMy crystals obtained were poorly formed.

The agreement in $d_{001}$ increase between pairs of compounds in this series and the agreement with the figures for other normal long chain aliphatic compounds indicates that the long axes of the chains in these compounds are very nearly normal to (001) and that there is little or no difference in tilt in the several crystals. This conclusion is also corroborated by unpublished work in this Laboratory on the hydrazides of $n$-aliphatic acids. In the hydrazides it is found that an increase of 8 carbon atoms in the chain direction leads to an increase in $d_{001}$ of 10.19 Å.

(8) MacArthur, *Proc. Leeds Phil. Lit. Soc., Sci. Sect.*, **4**, pt. 3, 170 (1944).

## Summary

1. The unit cell constants of the hemihydrates of NaMy and NaAr have been determined, and the values for NaP and NaSt redetermined.

2. The increase in $d_{001}$ with increase in chain length has been found to be 1.281 Å. per carbon atom, indicating that the chains are very nearly normal to (001).

# The Electrophoretic Properties of Plakalbumin

BY GERTRUDE E. PERLMANN

## Introduction

In a recent note, Linderstrøm-Lang and Ottesen[1] showed that ovalbumin is transformed, by the action of an enzyme from *Bacillus subtilis*, into a protein that crystallizes as rectangular plates from ammonium sulfate. They named this protein plakalbumin.[2] Since the transformation of ovalbumin to plakalbumin, A→P, occurs without serious degradation of the protein,[1] it seemed of interest to compare the electrophoretic behavior of the two materials. Consequently, the preliminary experiments[2] that indicated that plakalbumin differed electrophoretically from its parent substance, ovalbumin, have been extended and the new results are reported below.

## Experimental

Plakalbumin was obtained by incubating a 6% solution of thrice recrystallized ovalbumin[4] in 0.02 ionic strength phosphate buffer at *p*H 6.8 with an enzyme preparation from *B. subtilis*, kindly supplied by Linderstrøm-Lang. After incubation for six hours at 30°, the solution was acidified with hydrochloric acid to *p*H 5.4 and the protein crystallized as rectangular plates by the addition of saturated ammonium sulfate solution.[1]

The electrophoretic experiments were carried out at 0.5° in the apparatus described by Longsworth.[5,6] Unless noted otherwise below, a protein concentration of 1% was used in the experiments and prior to electrophoresis the protein solutions were dialyzed for two to three days against liberal portions of an appropriate buffer. The mobilities were computed from the descending patterns and refer to 0°.

## Results

In Fig. 1 are superimposed the tracings of the patterns obtained after electrophoresis of ovalbumin and plakalbumin in a 0.1 ionic strength phosphate buffer at *p*H 6.8 at a potential gradient of 6 volts per cm. for 9900 seconds. Under these conditions superposition of the patterns permits not only a direct comparison of the relative concentrations of the components but also of their approximate mobilities. It is thus clear from Fig. 1 that although the patterns are similar in appearance the plakalbumin has a lower mobility, $u$, than its parent substance ovalbumin. The actual values are $-5.9 \times 10^{-5}$ and $-5.5 \times 10^{-5}$ cm.$^2$ sec.$^{-1}$ volt$^{-1}$ for the main components, $A_1$ and $P_1$, of ovalbumin and plakalbumin, respectively, and $-4.8 \times 10^{-5}$ and $-4.3 \times 10^{-5}$ for the components $A_2$ and $P_2$. Plakalbumin from a sample of ovalbumin incubated for twenty-four hours gave the same results. Furthermore, as is the case with ovalbumin[7] at *p*H values below 4.0, plakalbumin also migrates over a distance of at least 7.0 cm. in the channel of the electrophoresis cell without resolution of the boundary into more than one peak.

In the preliminary work on plakalbumin it was observed that the relative concentration of the components, $P_1$ and $P_2$, but not their mobilities, changed on repeated crystallization of the freshly prepared protein. However, if the time between successive crystallizations is kept at a minimum and if the plakalbumin is stored as a paste under saturated ammonium sulfate, no significant alteration occurs. On the other hand, prolonged dialysis, or storage of plakalbumin in solution, causes marked changes. Thus, in a solution stored at 3° for ten days, the amount of the slowly moving component, $P_2$, had increased from 16 to 44% at the expense of the faster one, $P_1$. This result may be considered in connection with the observation of the Danish workers that in plakalbumin solutions at *p*H values above 5, even after repeated recrystallizations and dialysis, a slow liberation of non-protein nitrogen occurs.[2]

**Mobilities of Ovalbumin and Plakalbumin at Different *p*H Values.**—Much of this work has been directed toward the determination of the mobilities of the two proteins at various *p*H values. The results of these measurements are presented in Table I, in which the nature and composition of the buffers is listed in the first column while the *p*H of the protein solution in equilibrium therewith is given in column 2. The mobilities listed in this table refer in each case to the fast moving component of the proteins, except for those at *p*H values below 4.0 where the proteins migrate as a single peak. In these cases the mobilities are mean mobilities. A comparison of the figures for plakalbumin, column 3, with those for ovalbumin, column 4, shows that the mobilities of the two proteins at any given *p*H below about 7.0 differ by 0.5 to 0.6 $\times 10^{-5}$, column 5. At *p*H values above *p*H 7.8 the two proteins migrate with the same velocity.

| .1 *N* NaV—0.005 *N* HV | 9.10 | −5.93 | −5.92 | |

**The Behavior of Mixtures of Plakalbumin and Ovalbumin.**—Although the mobility differences below *p*H 7.0 are sufficient to lead one to expect resolution of the ovalbumin and plakalbumin on mixing, attempts in a 0.1 ionic strength phosphate buffer at *p*H 6.8 and in an 0.1 ionic strength hydrochloric acid–glycine buffer at *p*H 3.0 failed. The resulting patterns for the mixture were identical in appearance with those of either protein except that the boundary displacement corresponded to mobility values intermediate between those of the components of the mixture. Resolution is obtained, however, at a *p*H of 4.64, *i.e.*, between their isoelectric *p*H values. This is shown in Fig. 2 where the full line represents the patterns obtained after electrophoresis of a 1.2% solution of a mixture of 33% ovalbumin and 67% plakalbumin at a potential gradient of 6 volts per cm. for 28,800 seconds. The dashed and dotted curves superimposed upon this pattern are those of ovalbumin and plakalbumin, re-

spectively, obtained in separate experiments under identical conditions.

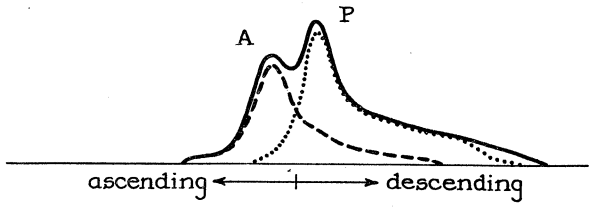

Fig. 2.—Superimposed tracings of electrophoretic patterns of a 1.2% mixture of 33% ovalbumin and 67% plakalbumin —, of a 0.4% solution of ovalbumin - - -, and of a 0.8% solution of plakalbumin . . . . , in 0.1 *N* sodium acetate buffer at *p*H 4.64 at 6 volts per cm. for 28800 seconds.

**Dependence of the Isoelectric *p*H of Plakalbumin upon Ionic Strength in Acetate Buffers.**—As is shown by the data of Table II the isoelectric *p*H of plakalbumin, designated here as *p*I, shifts to higher values at low ionic strength in acetate buffers. The *p*I values at each ionic strength, column 4, were obtained by linear interpolation of the *p*H mobility values listed in the two preceding columns of this table. Owing to the complexity of the electrophoretic patterns of plakalbumin at *p*H values just below the isoelectric *p*H, the first moment of the entire gradient curve of the descending pattern is used for the computation of the mean mobility, reported in Table II.

TABLE II

DEPENDENCE OF THE ISOELECTRIC *p*H ON IONIC STRENGTH

| 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|
| | | | *p*I | | |
| $\mu$ | *p*H[a] | $u_p \times 10^5$ | Plakalbumin | Ovalbumin | $\Delta pI$ |
| 0.1 | 4.50 | 1.06 | | | |
| | 4.67 | 0.29 | 4.72 | 4.58 | 0.14 |
| | 4.90 | −0.74 | | | |
| .05 | 4.68 | 0.82 | 4.77 | 4.63 | .14 |
| | 4.88 | −0.75 | | | |
| .02 | 4.73 | 0.7 | 4.82 | 4.68 | .14 |
| | 4.96 | −1.54 | | | |
| .01 | 4.68 | 1.95 | 4.86 | 4.71 | .15 |
| | 4.96 | −1.06 | | | |

[a] *p*H values refer to 0° by applying a correction of 0.02$_5$ to the values measured at 25°.[8]

For comparison, the *p*I values of ovalbumin obtained by Tiselius and Svensson[8] are listed in column 5 of Table II. Except for a constant difference of 0.14 *p*H unit, it is apparent that the isoelectric *p*H of plakalbumin changes with the buffer salt concentration in the same manner as does that of ovalbumin.

The response of plakalbumin to the partial substitution of chloride for acetate in these buffers is also similar to that of ovalbumin; thus if 80% of the acetate ion in a 0.1 *N* buffer is replaced by chloride ion, the isoelectric *p*H of plakalbumin is reduced to 4.58, whereas that of ovalbumin to 4.44, a difference of 0.14 *p*H unit as in the case of the pure acetate buffers, Table II. This displacement of the isoelectric *p*H on substitution of chloride for acetate toward a more acid reaction is comparable with that observed in the case of other proteins.[9]

(8) Tiselius and Svensson, *Trans. Faraday Soc.*, **36**, 16 (1940).

## Discussion

Since there is considerable evidence for a constant proportionality between mobility and the net charge of the protein ion[10,11] it is of interest to compare the change in mobility $\Delta u$, accompanying the A→P transformation, with other properties of these two proteins. Of the many explanations for this change that might be advanced the following is a reasonable one at the present time. It is based, in part, on the observation of Eeg-Larsen, Linderstrøm-Lang and Ottesen[2] that the fragments that are lost by the ovalbumin in the A→P process contain a glutamic and possibly an aspartic acid residue in addition to other amino acid residues that would not have ionizing groups when linked, in the $\alpha$-position, with peptide bonds in the intact protein molecule. In the following discussion the number of ionizing groups that are lost in the A→P process will simply be designated as $a$. If, therefore, ovalbumin can be idealized as peptide chain, $(HOOC)_mR(NH_2)_n$ with $m$ carboxyl groups that dissociate in the region from *p*H 2.0 to 6.5 and $n$ amino groups that dissociate above *p*H 8.5, plakalbumin would be $(HOOC)_{m-a}R'(NH_2)_n$. In strongly acid solution the ovalbumin ion would be $(HOOC)_mR(NH_3^+)_n$ with a net charge, $z$, of $+n$. Under these conditions plakalbumin should have the same net charge as ovalbumin and if the friction coefficients of the two molecules were the same the mobilities should be identical at a given low *p*H. A neutral reaction the ovalbumin ion would be $(^-OOC)_mR(NH_3^+)_n$ with a net charge of $n = m$ and since the mobility is negative at this *p*H one can conclude that $m > n$. Under these conditions the net charge of plakalbumin would be $n - m + a$ and a curve of $z$ against *p*H, as abscissas, for this protein should be above that of ovalbumin except in acid solutions where the two curves approach the common limiting value of $z = n$. If the $a$ carboxyl groups removed in the A→P reaction are strong ones they will lose their protons at *p*H values below the isoelectric zone and ovalbumin will thus have an isoelectric *p*H below that of plakalbumin in which these groups are missing. The experimental observation, Table II, that this is the case thus supports the view that the carboxyl groups that are involved in the A→P transformation are relatively strong ones.

However, the mobility values of plakalbumin

(9) Longsworth and Jacobsen, *J. Phys. and Coll. Chem.*, **53**, 126 (1949)

(10) Abramson, *J. Gen. Physiol.*, **15**, 575 (1931–1932).

(11) Longsworth, *Ann. N. Y. Acad. Sci.*, **41**, 267 (1941).

approach those of ovalbumin at neutrality instead of at acid reactions as the idealized case described above would require. This suggests that the friction coefficients, $f$, of the two proteins are not identical but that for plakalbumin, $f_P$ is enough lower than that for ovalbumin, $f_A$, to compensate for the smaller net negative charge at neutrality. At acid reactions where the net charge of both proteins approaches the common value, $n$, the smaller value of $f_P$, as compared with $f_A$, would lead to the higher mobilities for plakalbumin that are observed.

If at any given $p$H, the values of $u_A$ and $u_P$ refer to the same buffer solvent, the friction coefficients may be defined so that $u_A = z_A/f_A$ and $u_P = z_P/f_P$, where the ratio, $f_A/f_P$, should be independent of the $p$H, the ionic strength and the nature of the buffer ions. At the isoelectric $p$H of plakalbumin, $u_P = z_P = 0$ and since the valence of ovalbumin at this $p$H, *i.e.*, 4.72, is assumed to differ from that of plakalbumin only by the $a$ ionized carboxyl groups that are present in the one protein but missing from the other, $z_A = -a$, and the mobility of ovalbumin, $u_A = -0.6 \times 10^{-5} = a/f_A$ may then be used to estimate the value of $a$. Here $1/f_A$ may be taken as the slope, $3.0 \times 10^{-6}$, of the line that is obtained by plotting[9] as shown in Fig. 3, the mobilities of ovalbumin against the equivalents, $h$, of acid in alkali bound per mole of protein at an ionic strength 0.1 and at the given $p$H.[12] Hence $a = 2$, is in agreement with the result by Eeg-Larsen, Linderstrøm-Lang and Ottesen.[2] In view, however, of the arbitrary nature of the assumptions that have been made in the use of the mobility data for the evaluation of $a$, this agreement should not necessarily be interpreted as confirmation of the chemical analysis. Probably the most that should be said is that the electrophoretic results are not inconsistent with the analytical ones.

In experiments described elsewhere,[3] the author has also observed that plakalbumin differs electrophoretically from the ovalbumin modification reported by MacPherson, Moore and Longsworth.[13] Unpublished results further indicate that their modification is also a product of an enzymatic reaction. It, therefore, appears possible to transform, without serious degradation, a protein like ovalbumin into several other well-defined proteins which differ from each other in at least one property, namely, in their behavior in the electric field.

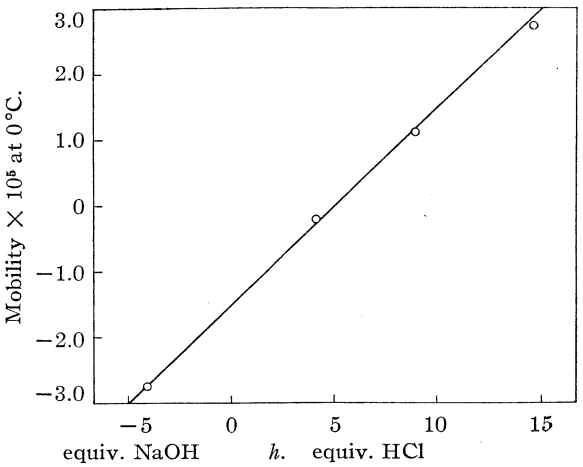

Fig. 3.—Plot for the evaluation of the proportionality factor between mobility and titration increment for ovalbumin.

**Acknowledgment.**—The author is much indebted to Dr. L. G. Longsworth of these Laboratories for suggestions as to the interpretation of the experimental results and also to him and to Dr. D. A. MacInnes for criticism of the manuscript. My thanks go also to Professor K. Linderstrøm-Lang of the Carlsberg Laboratory, Copenhagen, for his constant stimulating interest in this research.

## Summary

The electrophoretic behavior of plakalbumin, a protein derived from ovalbumin by the action of an enzyme from *B. subtilis*, has been compared with that of the parent substance. At $p$H values below about 7.0, the mobilities differ by 0.5 to $0.6 \times 10^{-5}$ whereas at more alkaline reactions plakalbumin and ovalbumin are indistinguishable electrophoretically. The isoelectric $p$H of plakalbumin at all ionic strengths investigated is 0.14 $p$H unit above that of ovalbumin.

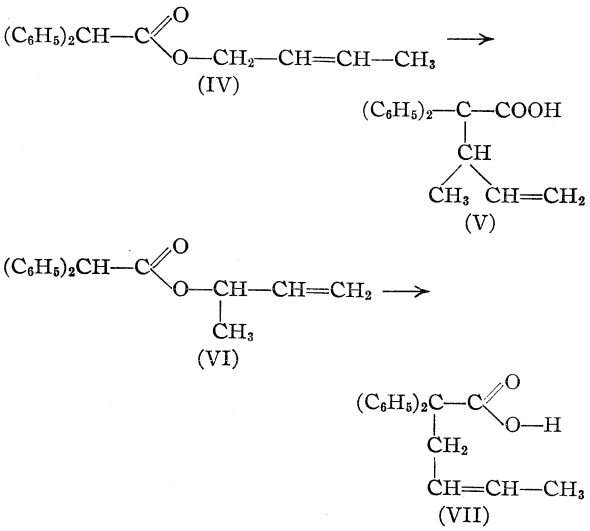
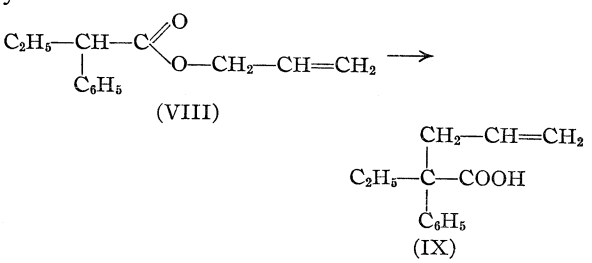
# A New Rearrangement of Allylic Esters

BY RICHARD T. ARNOLD AND SCOTT SEARLES, JR.[1,2]

In an earlier study[3,4,5,6] it was demonstrated that allylic esters of hindered, tertiary carboxylic acids react with the Grignard reagent to give olefins and halomagnesium salts according to the following equation.



In the event that the allylic ester (I) contains at least one alpha hydrogen atom, the Grignard anion ($R^-$) can act as a base and bring about formation of the anion (II). An intramolecular rearrangement can then occur to produce a thermodynamically more stable anion (III).



Several examples of this new intramolecular rearrangement have now been observed.[7]

In support of a mechanism involving the transient ring intermediate (II), it has been demonstrated that the allylic system undergoes an alpha-gamma shift during the course of this reaction. Thus, *n*-crotyl diphenylacetate (IV) yields 2,2-diphenyl-3-methylpenten-4-oic acid (V) and isocrotyl diphenylacetate (VI) is transformed into 2,2-diphenylhexen-4-oic acid (VII).

A wide variety of basic reagents (RMgX, NaH, and $R_2N$-MgX) have been employed with varying degrees of success. When R′ and R″ (in I) are aromatic, very satisfactory yields were obtained by the use of Grignard reagents or pulverized sodium hydride. To date, poor results have been observed when R′ = alkyl and R″ = aryl. However, by employing a base of the type $R_2N$-MgX, allyl α-phenylbutyrate (VIII) was converted into 2-ethyl-2-phenylpenten-4-oic acid (IX) in low yields.

**Acknowledgment.**—The authors wish to thank Dr. Ralph Manley and Mr. Jay S. Buckley, Jr., of the General Mills Laboratories for technical aid in connection with certain details of the experimental section. One of us (Scott Searles, Jr.) acknowledges with thanks a du Pont Fellowship for 1946–1947.

## Experimental

**Allyl Diphenylacetate.**—A solution containing allyl alcohol (10 g.) and dry pyridine (15 g.) was added dropwise into a solution of diphenylacetyl chloride (35 g., prepared by means of thionyl chloride on the acid) and chloroform (30 ml.) at 30–50°. After standing several hours at room temperature, the solution was washed with dilute alkali and with water and the chloroform layer was then dried with sodium sulfate. Direct distillation gave allyl diphenylacetate; b. p. 161–162° (3 mm.); yield 28.6 g.

(1) Most of the work reported here has been taken from the Ph.D. thesis of Scott Searles, Jr., University of Minnesota, July, 1947.

(6) Unpublished results by Scott Searles, Jr.

(7) A patent application covering this reaction was filed at the United States Patent Office on December 31, 1947.

*Anal.* Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39. Found: C, 80.82; H, 6.15.

**2,2-Diphenylpenten-4-oic Acid.**—(a) A Grignard solution prepared from bromomesitylene (25 g.), magnesium (3.1 g.) and ether (75 ml.) was allowed to react for fifteen hours at 25–35° with a solution composed of allyl diphenylacetate (25 g.) and anhydrous ether (25 ml.). After decomposition of the reaction mixture with slightly acidified ammonium chloride solution, the ether layer was extracted thoroughly with sodium hydroxide solution (5%). Distillation of the ether layer gave mesitylene (9.5 g., 63%) and unchanged allyl diphenylacetate (5.4 g.).

Acidification of the aqueous layer gave 2,2-diphenylpenten-4-oic acid (11.9 g.); m. p. 141.5–141.9°.[8]

*Anal.* Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39; neut. equiv., 252.3. Found: C, 80.73; H, 6.57; neut. equiv. 252.9.

(b) Allyl diphenylacetate (149 g.) was allowed to react with sodium hydride (18 g.) in boiling toluene in a nitrogen atmosphere for about twenty hours. The cooled mixture was poured into water and the whole shaken vigorously. From the toluene layer there was obtained, by distillation, unused allyl diphenylacetate (56 g.).

Acidification of the alkaline layer gave 2,2-diphenylpenten-4-oic acid which after recrystallization weighed 83.5 g. (56%) and melted at 142–142.5°.

**β-Methylallyl Diphenylacetate.**—Diphenylacetyl chloride (prepared by the action of thionyl chloride on diphenylacetic acid (159 g.)) was dissolved in chloroform (300 ml.). To this was added, at 0–10°, β-methylallyl alcohol (54 g.) dissolved in pyridine (59.5 g.). The solution stood overnight at room temperature and was worked up as described above for the allyl ester. Distillation of the chloroform layer gave the required ester; yield 163 g.; b. p. 153° (1.3 mm.).

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 81.11; H, 6.82.

**2,2-Diphenyl-4-methylpenten-4-oic Acid.**—β-Methylallyl diphenylacetate (163 g.) was allowed to react with pulverized sodium hydride (24 g.) in boiling toluene (1100 ml.) for twenty-two hours. The cooled mixture was decomposed with water and the aqueous alkaline layer was acidified. Recrystallization of the solid so formed gave pure 2,2-diphenyl-4-methylpenten-4-oic acid; yield 121.5 g. (76%); m. p. 120.5–121.5°.

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 80.99; H, 6.81.

**Isocrotyl Diphenylacetate.**—This ester was prepared by the above described method from methylvinylcarbinol (6 g.), pyridine (7 g.) and diphenylacetyl chloride (15.3 g.) in carbon tetrachloride (30 ml.) as solvent. When the reaction was complete, the mixture was poured into cold water and the organic layer was extracted with sodium hydroxide (5%). Removal of the solvent gave a solid residue which when crystallized from petroleum ether melted at 57–58°; yield 16.4 g. (93%).

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.19; H, 6.81. Found: C, 81.30; H, 7.11.

**2,2-Diphenylhexen-4-oic Acid.**—A solution of mesitylmagnesium bromide was prepared from bromomesitylene (10.75 g.), magnesium (1.3 g.) and ether (50 ml.). To this was added isocrotyl diphenylacetate (11.5 g.) dissolved in ether (50 ml.). A slightly exothermic reaction ensued and after refluxing for thirty minutes, the solution remained at room temperature for forty hours. Decomposition with ammonium chloride solution was followed by extraction of the ether layer with sodium hydroxide (5%). Distillation of the ether solution gave mesitylene (4.6 g., 88.4%) and unused isocrotyl diphenylacetate (0.9 g.).

Upon acidification, the alkaline layer gave 2,2-diphenylhexen-4-oic acid (8.5 g., 74%); m. p. 122.2–122.6°. A mixed melting point determination with diphenylacetic acid gave 108–111°.

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.19; H, 6.81; neut. equiv., 266.3. Found: C, 81.47; H, 6.88; neut. equiv., 266.6.

Ozonization of the above unsaturated acid gave acetaldehyde identified as its dimedon derivative.

***n*-Crotyl Diphenylacetate.**—This compound was prepared from *n*-crotyl alcohol (13 g.), pyridine (14.5 g.), diphenylacetyl chloride (34.7 g.) and chloroform (50 ml.) at 0°. The ester boiled at 155–162° (0.1 mm.); yield 22.6 g. (56.5%).

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.19; H, 6.81. Found: C, 80.84; H, 7.10.

**2,2-Diphenyl-3-methylpenten-4-oic Acid.**—This ester (12.5 g.) was treated with a solution of mesitylmagnesium bromide prepared from bromomesitylene (12.0 g.), magnesium (1.5 g.) and ether (75 ml.).

The mixture was refluxed for twelve hours and then allowed to stand at room temperature overnight. Decomposition with ammonium chloride solution gave an ether layer which was extracted with sodium hydroxide solution. From the ether layer, mesitylene (5 g.) was obtained by careful fractionation. Acidification of the alkaline aqueous layer gave a solid acid which was recrystallized from aqueous alcohol; yield 8.2 g. (65.5%); m. p. 138–138.5°.

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.19; H, 6.81; neut. equiv., 266.3. Found: C, 81.34; H, 7.10; neut. equiv., 266.5.

Ozonization of the above acid gave formaldehyde which was isolated as its dimedon derivative; yield 52.3%; m. p. 187–188°.

**2-Ethyl-2-phenylpenten-4-oic Acid.**—An ethereal solution of ethylmagnesium bromide (114 ml. of 1.76 *N*) was treated with diethylamine (14.6 ml.). To this was added allyl α-phenylbutyrate (40.8 g.). Heat was evolved and the solution was stirred for three days at room temperature before decomposition with dilute ammonium chloride.

Bicarbonate extraction of the ether layer followed by acidification gave a carboxylic acid which after recrystallization from aqueous methanol gave 2-ethyl-2-phenylpenten-4-oic acid; yield 3.1 g. (7.8%); m. p. 78.5–80°.

*Anal.* Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90; neut. equiv., 204.3. Found: C, 76.81; H, 7.99; neut. equiv., 204.8.

## Summary

1. It has been shown that allylic esters having at least one aryl group and one hydrogen atom attached to the alpha carbon atom undero intramolecular rearrangement in the presence of many strong basic reagents to give α-allylic substituted acids.

2. The allylic group undergoes an alpha–gamma shift during the course of the reaction.

# Chemistry of Epoxy Compounds. VIII.[2] Reaction of Allyl Alcohol with Unsymmetrical Oxirane Compounds. An Electronic Interpretation[2a]

BY DANIEL SWERN, GERALDINE N. BILLEN AND H. B. KNIGHT

When an unsymmetrical oxirane compound (I) reacts with an alcohol (equation I), two isomeric hydroxy ethers can form, depending on which carbon–oxygen bond of the oxirane group is cleaved. The literature on such reactions is voluminous, yet only two cases[3,4] have come to our

(Eq. I)

attention in which the reaction mixture has been carefully fractionated and the structure of the resulting products established. Furthermore, the effects of acidic or alkaline catalysts, and the electronic effect of substituent groups, on the direction of ring opening have been explored only to a limited extent,[3,4,5a,6,7] and in the case of extremely reactive oxirane compounds, notably 3,4-epoxy-1-butene, reaction conditions producing high yields (above 75%) of hydroxy ethers have not been reported, the usual yield being 20 to 68%.[4,5a,8] We have studied the reaction of allyl alcohol with propylene oxide, glycidol, epichlorohydrin, 3,4-epoxy-1-butene and styrene oxide [R-(I) = $CH_3$–, HO–$CH_2$–, Cl–$CH_2$–$CH_2$=CH–, and $C_6H_5$–] in the presence of acidic and alkaline catalysts, and the results of these experiments are described in this paper (Table I). A literature survey on ring opening reactions of this type (equation I) revealed no publications reporting the use of allyl alcohol. After our work was almost complete, however, the preparation of 2-alloxy-1-phenylethanol in 31% yield by the phosphoric acid-catalyzed reaction of allyl alcohol with styrene oxide was reported,[9] although proof of structure was not given.

The procedure which we followed in studying this reaction (equation I) consisted of four steps: (a) Determination of reaction conditions which gave high yields of hydroxy ethers in the presence of alkaline and acidic catalysts (alkaline catalysts could not be employed with epichlorohydrin). The yield was usually determined by distillation of the neutralized reaction mixture through a low hold-up fractionating column of the Vigreux type, which was capable of cleanly separating unreacted allyl alcohol from hydroxy ether and also of separating the latter from di- and polyethers. (b) Redistillation of the hydroxy ether fraction through a low hold-up, highly efficient fractionating column (more than one hundred theoretical plates) in an attempt to separate isomeric hydroxy ethers which might have formed; (c) determination of the identity and purity of the products by well-known means (iodine absorption, per cent. hydroxyl, carbon analysis, etc.); (d) determination of the position of the hydroxyl group, introduced as a result of the ring opening reaction, by one or more chemical diagnostic tests. For example, by oxidation with periodic acid,[10] the α-glycol group was determined in the reaction prod-

ucts of allyl alcohol with glycidol. The degree of reaction of benzoyl chloride with the hydroxy ethers obtained from allyl alcohol and epichlorohydrin, styrene oxide and 3,4-epoxy-1-butene was determined under controlled conditions,[5a,11] and the values so obtained were compared with those for related primary and secondary alcohols of known structure. In addition, with the exception of the reaction products of allyl alcohol with epichlorohydrin and glycidol, the time required to dissolve 0.05 g. of metallic sodium in a large molar excess of hydroxy ether was determined. When isomers could be cleanly separated by distillation, the last two tests permitted unequivocal identification of the primary and secondary alcohol (secondary and primary ether, respectively) since the degree of reaction with benzoyl chloride was significantly higher and the time required to dissolve the sodium was significantly lower in the case of the primary alcohol (secondary ether) (Tables II and III). Furthermore, in every instance in which we were able to separate the isomers, and in the few cases reported in the literature, the primary alcohol (secondary ether) had a higher boiling point, density and index of refraction than the secondary alcohol (primary ether).

TABLE II

SOLUTION TIME OF SODIUM[a] IN VARIOUS HYDROXY COMPOUNDS

| Compound | OH | Max. temp. attained during reaction, °C. | Sol. time, minutes |

[a] Primary and Secondary. Prepared by the acid-catalyzed reaction of allyl alcohol with 3,4-epoxy-1-butene.

(11) Norris and Haines, THIS JOURNAL, **57**, 1425 (1935).

## Experimental[11a]

**Materials.**—Allyl alcohol, propylene oxide, 3,4-epoxy-1-butene, epichlorohydrin and styrene oxide were the purest commercial products obtainable, and they were distilled (styrene oxide under vacuum) through efficient fractionating columns immediately before use. Glycidol was prepared by the dehydrohalogenation of freshly distilled glycerol α-monochlorohydrin in isopropyl alcohol, substantially as reported by Marple and Evans.[12] A twice-distilled product, b. p. 40° at 2.5 mm., and $n^{25}D$ 1.4292, was employed in the reactions. Oxirane oxygen,[13] calcd., 21.6; found, 21.2.

**Propylene Oxide and Allyl Alcohol. (a) Preparation of 1-Alloxy-2-propanol (II).**—To a stirred solution of 3.2 g. of freshly cut sodium in 290 g. (5 moles) of allyl alcohol in a 500-ml. round-bottom distilling flask at 25°, 29.1 g. (0.5 mole) of propylene oxide was added dropwise. No rise in temperature was observed. The resulting solution was refluxed for one hour, and most of the unreacted allyl alcohol was then separated by distillation at atmospheric pressure (maximum pot temperature, 120°) through a short helix-packed column. Sufficient 6 *N* aqueous sulfuric acid was added to the residual solution at room temperature to neutralize the sodium alloxide, and distillation was continued at about 30 mm. through a Vigreux column 2 feet long and ½ inch in diameter. After recovery of an additional quantity of allyl alcohol, 51 g. (88% yield) of a colorless liquid, b. p. 72–73° at 30–31 mm., $n^{30}D$ 1.4258–1.4264, which was identified as alloxypropanol, was obtained. This was redistilled through a Podbielniak column 90 cm. long and 13 mm. in diameter; 90% of the product boiled at 71–71.5° at 31 mm., $n^{30}D$ 1.4258. The remainder consisted of allyl alcohol and distillation residue. Comparison of the physical properties of the main fraction with those of the products obtained in (b) below indicated that it was 1-alloxy-2-propanol. This was confirmed by the sodium solution test (Table II).

(b) **Preparation of 2-Alloxy-1-propanol (III) and II.**—To a stirred solution of 58.1 g. (1.0 mole) of propylene oxide and 581 g. (10 moles) of allyl alcohol at 25°, 0.58 g. of 95% sulfuric acid was added dropwise. The temperature rose spontaneously from 25 to 30°, and the solution was then refluxed for one hour. (Elimination of the refluxing step caused a considerable reduction in yield.) Sufficient sodium hydroxide was then added to the solution, after it was cooled to room temperature, to neutralize the sulfuric acid, and the solution was distilled through a short helix-packed column. After distillation of the unreacted allyl alcohol at atmospheric pressure, the distillation was completed at 30 mm., yielding 97 g. (84% yield) of a colorless liquid, b. p. 72–75° at 30 mm., $n^{30}D$ 1.4288, which was identified as alloxypropanol. Redistillation through the Podbielniak column gave two distinct fractions, b. p. 71–73° at 30 mm., $n^{30}D$ 1.4258 (II), and b. p. 77–78° at 30 mm., $n^{30}D$ 1.4298 (III). The relative proportions of these fractions (based on hydroxy ether employed as distillation charge) were about 60% of III and 40% of II. The results are summarized in Tables I and II.

(11a) All reactions and distillations were conducted in an atmosphere of nitrogen.

(12) Marple and Evans, U. S. Patent 2,248,635 (1941).

(13) Swern, Findley, Billen and Scanlan, *Anal. Chem.*, **19**, 414 (1947).

**Epichlorohydrin and Allyl Alcohol. Preparation of 1-Alloxy-3-chloro-2-propanol (IV).**—To a stirred solution of 581 g. (10 moles) of allyl alcohol containing 0.92 g. of 95% sulfuric acid at 25°, 92.4 g. (1.0 mole) of epichlorohydrin was added dropwise in five minutes. No rise in temperature was obtained. The solution was refluxed for three hours (a one-hour reflux time caused a considerable reduction in yield) and was then worked up as described under alloxypropanol. Eighty-nine grams (59% yield) of a colorless liquid, b. p. 106–107.5° at 29 to 30 mm., $n^{30}D$ 1.458–1.459, which was identified as alloxychloropropanol, was obtained. Redistillation through the Podbielniak column yielded 1-alloxy-3-chloro-2-propanol (IV), b. p. 107–108° at 31 mm., $n^{30}D$ 1.4582. None of the isomeric 2-alloxy-3-chloro-1-propanol (V) appeared to be present. The results are summarized in Tables I and III.

Alkaline catalysts could not be employed in this system because of the ease with which the chlorine atom in epichlorohydrin was detached. The following alkaline catalysts were tried: potassium hydroxide, sodium hydroxide, sodium, benzyltrimethylammonium hydroxide, trimethylamine and pyridine.

**Glycidol and Allyl Alcohol. Preparation of 1-Alloxy-2,3-propanediol (VI) and 2-Alloxy-1,3-propanediol (VII).**—To a stirred solution of 5.3 g. of sodium in 470 g. (8.1 moles) of allyl alcohol at 25°, 60 g. (0.81 mole) of glycidol was added dropwise. No rise in temperature was observed. The solution was refluxed for three hours, and then worked up as described under alloxypropanol. Seventy-five grams (71% yield) of a colorless liquid, b. p. 104–107° at 3.1 mm., which was identified as alloxypropanediol, was obtained. It was redistilled through the Podbielniak column, b. p. 107–109° at 4.3 to 4.5 mm., $n^{30}D$ 1.4589, but no separation of isomers could be effected. Periodic acid oxidation[10] indicated that the mixed hydroxy ethers consisted of 70 to 75% of VI and 25 to 30% of VII.

Almost identical results (74% yield) were obtained in a similar experiment in which 5.3 g. of 95% sulfuric acid was substituted for the sodium employed above. The catalyst was neutralized with sodium hydroxide. The results are summarized in Table I.

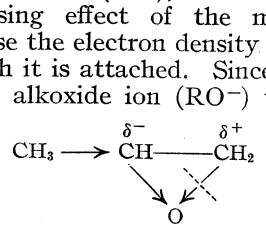
**Styrene Oxide and Allyl Alcohol. (a) Preparation of 2-Alloxy-2-phenylethanol (VIII).**—To a stirred solution of 2.8 g. of sodium in 232 g. (4.0 moles) of allyl alcohol at 25°, 48 g. (0.4 mole) of styrene oxide was added dropwise in five minutes. No rise in temperature was observed over a one-hour period, after which the solution was refluxed for one hour and then worked up as previously described. Fifty-eight g. (81% yield) of a colorless liquid, b. p. 113–117° at 4.5 to 5.0 mm., which was identified as alloxyphenylethanol, was obtained. Redistillation through the Podbielniak column yielded two distinct fractions, b. p. 114° at 4.7 mm., $n^{30}D$ 1.5158, and b. p. 118–119° at 4.5 mm., $n^{30}D$ 1.5167, which were identified as 2-alloxy-1-phenylethanol (IX) and 2-alloxy-2-phenylethanol (VIII), respectively. The latter represented about 90% of the material redistilled.

**(b) Preparation of 2-Alloxy-1-phenylethanol (IX).**—To a stirred solution of 1.2 g. of 95% sulfuric acid and 581 g. (10 moles) of allyl alcohol at 25°, 120 g. (1.0 mole) of styrene oxide was added dropwise in twenty minutes, the temperature being maintained between 25 and 30° by means of an ice–water-bath. The reaction was strongly exothermic. When the exothermic reaction was complete, the solution was refluxed for one hour, and then worked up as described earlier. One hundred and forty-eight grams (83% yield) of a colorless liquid, b. p. 116–118° at 4.8 mm., which was identified as alloxyphenylethanol, was obtained. Redistillation through the Podbielniak column indicated that the product consisted solely of 2-alloxy-1-phenylethanol (IX), b. p. 114–114.5° at 4.6 to 4.8 mm., $n^{30}D$ 1.5159. The results are summarized in Tables I, II and III.

**3,4-Epoxy-1-butene and Allyl Alcohol. Preparation of 3-Alloxy-4-hydroxy-1-butene (X).**—To a stirred solution of 6.5 g. of sodium in 581 g. (10 moles) of allyl alcohol at 25°, 70.1 g. (1.0 mole) of 3,4-epoxy-1-butene was added dropwise in twenty minutes. No rise in temperature was observed. The reaction mixture was allowed to stand for about thirty hours, and then worked up as described earlier. Eighty-five grams (66% yield) of a colorless liquid, b. p. 86–90° at 30 to 32 mm., $n^{30}D$ 1.444, was obtained. This was identified as alloxyhydroxybutene. Redistillation through the Podbielniak column yielded 3-alloxy-4-hydroxy-1-butene (X), b. p. 86–87° at 30 to 31 mm., $n^{30}D$ 1.4449–1.4452.

A similar experiment was conducted in which the 3,4-epoxy-1-butene was added dropwise to allyl alcohol containing 0.70 g. of 95% sulfuric acid as the catalyst. The reaction was extremely exothermic, and the reaction flask had to be kept in an ice-bath to maintain the temperature between 25 and 30° during the addition. After the exothermic reaction was complete, the reaction mixture was stirred at 25 to 30° for one hour (refluxing for one hour resulted in only a 60% yield of hydroxy ether), and then worked up as described earlier. One hundred and one grams (79% yield) of a colorless liquid, b. p. 83–87° at 25 mm., $n^{30}D$ 1.445, which was identified as alloxyhydroxybutene, was obtained. Redistillation through the Podbielniak column gave a main fraction which appeared to be identical (b. p., $d^{30}_4$, $n^{30}D$, etc.) with the product (X) obtained from the alkali-catalyzed experiment, but the benzoyl chloride test suggested that the product from the acid-catalyzed reaction contained some of the secondary alcohol (primary ether) (XI). The results are summarized in Tables I, II and III.

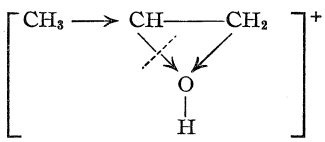
In a smaller scale run, the sulfuric acid catalyst was added dropwise to an uncooled but stirred solution of allyl alcohol and 3,4-epoxy-1-butene. The reaction was vigorously exothermic, and only a 30% yield of hydroxy ether was obtained.



**Sodium Solution Test.**—A freshly cut piece of sodium (0.05 g., 0.00217 mole) was added at 25° to 0.0434 mole of hydroxy compound contained in a test-tube. The test-tube was immediately stoppered with a loosely fitting cork supporting a thermometer which reached to the bottom. The maximum temperature attained during the solution of the sodium, as well as the time required for complete solution, was observed. Solution times could be duplicated within 10 to 20%. The results obtained with some of the hydroxy ethers prepared during this investigation and also with some simple primary and secondary alcohols are shown in Table II.

**Degree of Reaction with Benzoyl Chloride.**—The benzoylation procedure of Kadesch[5a] and Norris and Haines[11] was employed. The results obtained with some of the hydroxy ethers prepared during this investigation and also with some primary and secondary alcohols of known structure are shown in Table III.

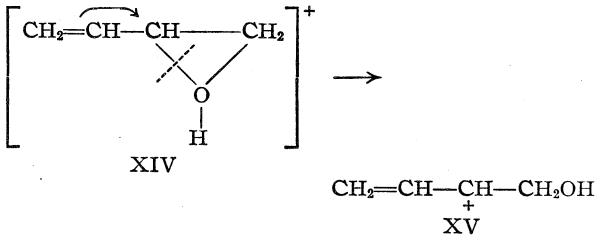
**3,5-Dinitrobenzoates.**—Attempts to prepare the 3,5-dinitrobenzoates of the hydroxy ethers by reaction with 3,5-dinitrobenzoyl chloride in pyridine solution yielded oils which could not be induced to crystallize.



## Discussion

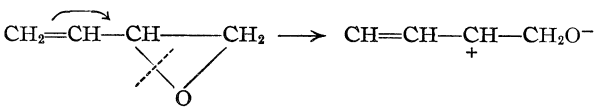
In propylene oxide (XII), the well-known mild electron-releasing effect of the methyl group should increase the electron density of the carbon atom to which it is attached. Since nucleophilic attack by an alkoxide ion ($RO^-$) would be expected to take place preferentially at the carbon atom of lower electron density, namely, at the terminal carbon atom, a secondary alcohol (primary ether) should be obtained. Confirmation of

XII



this hypothesis is afforded both by our study of the alkali-catalyzed reaction of allyl alcohol with propylene oxide, in which II is obtained exclusively, and by the work of Chitwood and Freure[3] and Reeve and Sadle,[14] who obtained the secondary alcohol (primary ether) almost exclusively from the alkali-catalyzed reaction of propylene oxide with methanol, ethanol, isopropyl alcohol, *n*-butanol and 2-ethylhexanol. When an acidic catalyst is employed, both carbon–oxygen bonds of the oxirane ring are weakened,[3,15] but because of

XIII

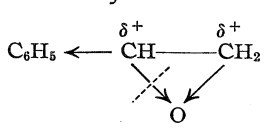


the higher electron density of the carbon atom to which the methyl group is attached, coupled with the repelling effect exerted on the (negative) oxygen atom, this carbon–oxygen bond should be weaker than the other. Cleavage, therefore, should occur as shown in XIII, and a primary alcohol (secondary ether) (III) should be obtained. The hydroxy ethers obtained in the acid-catalyzed reaction of allyl alcohol with propylene oxide consisted mainly of III, as the theory indicates, although II was also obtained in fair yield. The formation of II was not unexpected, since both carbon–oxygen bonds are weakened and the methyl group does not exert a sufficiently powerful electron-releasing effect to cause one carbon–oxygen bond to be so much weaker than the other that preferential cleavage occurs exclusively. As the quantity of acid catalyst is decreased,[3] smaller proportions of primary alcohol (secondary ether) and larger proportions of secondary alcohol (primary ether) form, since the bond-weakening effect diminishes and the electron-releasing effect of the methyl group becomes the major determining factor in influencing the direction of ring opening.

In 3,4-epoxy-1-butene, however, the nature of the catalyst exerted a relatively small effect, the acid-catalyzed reaction yielding a mixture consisting predominantly of the primary alcohol (secondary ether) (X) and the alkali-catalyzed reaction apparently yielding X exclusively. The results of the acid-catalyzed reaction are in agreement with the results previously reported by Kadesch[5a] and by Bartlett and Ross[4] on the acid-catalyzed reaction of 3,4-epoxy-1-butene with methanol. The formation of X in the acid-catalyzed reaction can be explained by assuming the presence of an intermediate carbonium ion, XV,[5a] which should form readily from 3,4-epoxy-1-butene (XIV), since the bond-weakening effect of the strongly electron-releasing vinyl group and the bond-weakening effect of the oxonium ion operate in the same direction. Such an ion should be stabilized as a result of resonance.

XIV XV

The alkali-catalyzed reaction of 3,4-epoxy-1-butene with methanol, however, yields a secondary alcohol (primary ether) predominantly.[4,5a] Since the only difference between our work and that previously reported is the employment by us of allyl alcohol, it can be concluded, perhaps, that allyl alcohol or sodium alloxide enhances the electron-release effect of the vinyl group to such an extent at the precise moment of attack that a considerable bond-weakening effect occurs between the non-terminal carbon atom and the oxirane oxygen atom, yielding an ion as an intermediate (XVI → XVII).



XVI XVII

Nucleophilic attack would occur, of course, at the positive carbon atom, and a primary alcohol would again be obtained.

The ease with which 3,4-epoxy-1-butene and analogous compounds form aldehydes during acid-catalyzed hydration[5,16,17] supports the formulation XIV → XV.

Since the phenyl group can exert either a mild electron-releasing or electron-attracting effect,[18,19,20] the products obtained in the reaction of allyl alcohol with styrene oxide will depend on which effect is taking place. The product obtained in the alkali-catalyzed reaction consisted almost exclusively of primary alcohol (secondary ether) (VIII). The phenyl group, therefore, must exert an electron-attracting effect (XVIII), since formation of the primary alcohol occurs as a result of nucleophilic attack by alkoxide ion on the car-

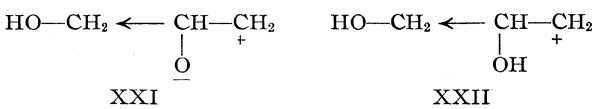
bon atom with the lower electron density, the non-terminal carbon atom in this case. When an acidic catalyst is employed, the lower electron density on the non-terminal carbon atom makes this carbon–oxygen bond stronger than the other because of the increased attraction of the non-terminal carbon atom for the oxygen atom (XIX).

XIX

Since the terminal carbon–oxygen bond is the weaker of the two, the secondary alcohol (primary ether) (IX) should, and does, form in good yield.



The chloromethyl group in epichlorohydrin (XX) must also exert an electron-attracting effect, since the product obtained when it was treated with allyl alcohol in the presence of sulfuric acid was the secondary alcohol (primary ether) (IV).

XX

The failure to obtain the isomeric primary alcohol (secondary ether) (V) was somewhat surprising, since the chloromethyl group should exert a less powerful electron-attracting effect than the phenyl group.

In the reaction of glycidol with allyl alcohol, the nature of the catalyst was without effect in determining the direction of ring opening. Since the hydroxymethyl group is a strong electron-attracting group, it may be assumed that the ions XXI and XXII exist in alkaline and acidic media, respectively.

XXI XXII

This formulation is analogous to that proposed earlier for 3,4-epoxy-1-butene, except that in glycidol there should be a powerful bond-strengthening effect between the non-terminal carbon atom and the oxirane oxygen atom caused by the strongly electron-attracting hydroxymethyl group, which would favor formation of XXI and XXII.[21] On the basis of this formulation, only α-glycol (VI) should be obtained regardless of the alkalinity or acidity of the systems. The fact that α-glycol formation predominated appears to substantiate the premise, in the main, but the formation of considerable and identical quantities of VII is still without explanation.

**Acknowledgment.**—We are indebted to Frances Cooper and Mary Jane Welsh for the carbon analyses, to R. E. Koos for some of the iodine number and per cent. hydroxyl determinations, and to M. E. Coy for determining the degree of reaction of the hydroxy compounds with benzoyl chloride.

## Summary

The reaction of allyl alcohol with the unsymmetrical oxirane compounds propylene oxide, glycidol, 3,4-epoxy-1-butene, epichlorohydrin and styrene oxide, in the presence of acidic and alkaline catalysts, has been studied. Reaction conditions are described for obtaining good yields (60 to 90%) of hydroxy ethers.

A technique is reported for determining the structure of the hydroxy ethers. This consists in efficient fractional distillation of the reaction products and analysis of the main fractions, followed by the application of one or more chemical diagnostic tests. These include periodic acid oxidation, measurement of the time required to dissolve a known weight of sodium in a large molar excess of hydroxy ether, and determination of the degree of reaction of benzoyl chloride with the hydroxy ether under controlled conditions. When employed under the proper conditions and with suitable substrates, the benzoyl chloride test should be generally applicable in determining whether a hydroxyl group is primary or secondary.

Electronic mechanisms for the reactions have been suggested.

# The Addition of Bromine to Olefinic Double Bonds. N-Bromoacetamide as a Source of Bromine.[1]

BY ROBERT E. BUCKLES

N-Bromoacetamide has been found to react with several unsaturated compounds to form dibromides in appreciable amounts. Such formations of significant amounts of dibromides of olefins with N-bromoacetamide as the sole source of bromine have not previously been reported.[1a]

In Table I are listed the results of the reactions of various unsaturated compounds with N-bromoacetamide in chloroform. In all cases the reactions were promoted by ultraviolet light or simply by heat. Styrene reacted quite rapidly with the N-bromoacetamide. There was no appreciable bromine color in the reaction mixture. In all the other cases the reaction mixtures maintained a noticeable bromine color, and the olefin seemed to be reacting with the bromine as it formed from the decomposition of the N-bromoacetamide.[2]

TABLE I

MELTING POINTS AND YIELDS OF DIBROMIDES FROM VARIOUS SOURCES

| Olefin | AcNHBr Yield, % | AcNHBr M. p.[a] | AcNHBr + HBr (crude product) Yield, % | AcNHBr + HBr (crude product) M. p.[a] | $Br_2$ M. p.[a] |

[a] All m. p.'s corrected. [b] Dibromide isolated by distillation. [c] The product was triphenylbromoethylene.

The rapid reaction of styrene whether induced thermally or photochemically usually had an induction period. The liberation of heat which followed the induction period often caused the reaction mixture to boil violently. This behavior of styrene with N-bromoacetamide took place with chloroform, carbon tetrachloride or excess styrene as solvent. The presence of small amounts of alcohol or water in the chloroform or of *p-t*-butylcatechol in the styrene did not change the nature of the reaction. Polystyrene accompanied styrene dibromide as a product only when styrene was used as a solvent. In no case did the reaction give anywhere near a quantitative yield of the solid dibromide.

Styrene reacted with N-bromoacetamide to form dibromide at room temperature in the absence of light when the mixture merely stood overnight. When *cis*-stilbene was treated similarly there was still unchanged N-bromoacetamide after five days. A low yield of *trans*-stilbene dibromide as well as a nearly identical yield of *trans*-stilbene, itself, was obtained from the reaction mixture.

A great deal of difficulty was encountered in the isolation of reaction products which could be traced to the acetamido group of the N-bromoacetamide. It was expected at first that diacetylhydrazine would be the product, but no isolable amount of this compound was formed. The only products successfully identified were small amounts of acetamide and diacetamide hydrobromide or their hydrolysis products. These two compounds, however, have both been isolated as decomposition products of N-bromoacetamide.[2] A small amount of decomposition accompanying the olefin reaction would account for these by-products.

In contrast to these addition reactions with N-bromoacetamide as the sole source of bromine was the formation of dibromides in a much more clean-cut fashion when the unsaturated compounds reacted with N-bromoacetamide in chloroform in presence of excess anhydrous hydrogen bromide. In every case the reaction was carried out so that there was little or no bromine color in the reaction mixture until all the olefin had reacted. In each case, also, the reaction was immediate, and heat was liberated. No external stimulus was necessary for starting the reaction. The yields of crude dibromides are listed in Table I.

## Discussion

N-Bromoamides seem to be capable of supplying either bromine atoms or positive bromine[3] during a reaction. It has been reported[4] that the preferential bromination[5] of the carbon atom adjacent to the double bond is catalyzed by peroxides. Substitution reactions have also been reported for N-bromoacetamide with various olefins[6] as well as for N-bromosuccinimide at the

$\alpha$-carbon atom of ketones.[7] These reactions are often promoted by ultraviolet light.[7] Reactions of this sort which exhibit catalysis by peroxides or light are generally interpreted[8] as involving bromine atoms and free radical intermediates.

On the other hand N-bromosuccinimide reacts with aromatic hydrocarbons in the presence of anhydrous aluminum chloride to give ring bromination as opposed to the side chain substitution observed with a peroxide catalyst.[4a] N-Bromoacetamide has been reported[9] to be a source of bromine for acid catalyzed olefin addition reactions of olefins in which a hydroxylic solvent is also involved; *e.g.*, water as a solvent giving rise to the bromohydrin as the predominant product. Such reactions are best interpreted[10] as ionic with the bromine behaving as if it were positive.[3]

The formation of dibromide of unsaturated molecules with N-bromoacetamide as the sole source of bromine most likely takes place through free radical intermediates. This interpretation s especially applicable in the case of styrene reacting with N-bromoacetamide because of the induction period followed by an accelerating reaction. The effect of light on the reaction also points to a free radical mechanism. The fact that *cis*-stilbene was isomerized to the *trans* isomer at room temperature in the absence of activating light shows that bromine atoms are available from N-bromoacetamide without the intermediate formation of bromine molecules. Bromine itself reacts with *cis*-stilbene at room temperature in the absence of light to give the *dl*-dibromide as the principle product.[11] On the other hand bromine atoms catalyze the *cis–trans* isomerization of olefins.[8] Thus, it seems reasonable to postulate that in the photochemical reaction N-bromoacetamide first forms a bromine atom (Step 1) which attacks the double bond (Step 2). The resulting radical would be capable of relatively free rotation about the bond that was originally the double bond. It would be expected to react with a N-bromoacetamide molecule to form the dibromide of most stable configuration (Step 3). At the present time it is impossible to say what might happen to the acetamidyl radical, AcNH·.

$$\text{AcNHBr} + h\nu \longrightarrow \text{AcNH}\cdot + \text{Br}\cdot \quad (1)$$

$$>\text{C=C}< + \text{Br}\cdot \longrightarrow >\text{CBr—}\dot{\text{C}}< \quad (2)$$

$$>\text{CBr—}\dot{\text{C}}< + \text{AcNHBr} \longrightarrow >\text{CBr—CBr}< + \text{AcNH}\cdot \quad (3)$$

$$\text{Br}\cdot + \text{AcNHBr} \longrightarrow \text{Br}_2 + \text{AcNH}\cdot \quad (4)$$

$$\text{Br}_2 + h\nu \longrightarrow 2\text{Br}\cdot \quad (5)$$

$$\text{Br}_2 + >\text{CBr—}\dot{\text{C}}< \longrightarrow >\text{CBr—CBr}< + \text{Br}\cdot \quad (6)$$

In the cases where a definite bromine color was observed during the reaction, Steps 4, 5 and 6 must also be considered. No matter what the source of bromine atoms, however, the most stable dibromide isomer would be formed. This was found to be the case when the *meso*-dibromide was the product from either of the stilbene isomers.

The clean-cut reaction of the olefins with N-bromoacetamide in the presence of hydrogen bromide, on the other hand, most likely involves ionic intermediates (ion pairs or triplets in nonpolar solvents). Such addition reactions are best interpreted as involving ionic intermediates, *e.g.*, the bromonium ion,[12] which maintain their steric identity. Only with such an interpretation can the formation of *dl*-dibromide from *cis*-stilbene be explained. Either the conjugate acid of N-bromoacetamide or molecular bromine could act as a source of positive bromine[3] for the usual ionic mechanism of bromine addition.[10]

$$\text{AcNHBr} + \text{HBr} \rightleftharpoons \text{AcNH}_2\text{Br}^+ + \text{Br}^-$$

$$\text{AcNH}_2\text{Br}^+ + \text{Br}^- \longrightarrow \text{AcNH}_2 + \text{Br}_2$$

## Experimental

**N-Bromoacetamide.**—This material was prepared by the reaction of equimolar amounts of acetamide, bromine and potassium hydroxide in a minimum amount of water at 0–5°.[13] The reaction product was dissolved in chloroform and the solution distilled until there was no more water in the distillate. Cooling crystallized the product. The m. p. fell somewhere between 95 and 105° with a range of several degrees. The pure anhydrous N-bromoacetamide has m. p. 108°.[2a] The yields of product were generally around 45%.

**Unsaturated Compounds.**—The styrene (stabilized with *p-t*-butylcatechol) was supplied by Eastman Kodak Co. Thanks are due Mr. Norris G. Wheeler of this Laboratory who prepared the *cis*-stilbene by the decarboxylation of $\alpha$-phenylcinnamic acid.[14]

**Authentic Samples of Dibromides.**—These were all prepared by the action of bromine in either chloroform or carbon tetrachloride on the respective olefins. In the case of triphenylethylene the resulting dibromide lost hydrogen bromide so that triphenylbromoethylene was the product. In all cases except *cis*-stilbene the yields exceeded 80%. The *cis*-stilbene dibromide was generally obtained in about 70% yields with a small amount of *trans*-dibromide.

The m. p.'s of the dibromides check favorably with the accepted values in the chemical literature; they are tabulated in Table I. The capillary m. p. of *meso*-stilbene dibromide from the addition of bromine to *trans*-stilbene, depended on the length of time necessary to heat the sample to the m. p. Only when the sample was placed in the bath preheated to about 210° was decomposition minimized enough for the recorded m. p. of 237° to be observed. Otherwise the m. p. was much lower. On the Maquenne block the m. p. was 254–255° (dec.).

**Reactions of the Unsaturated Compounds with N-Bromoacetamide.**—In most of the experiments 0.005 to 0.02 mole of the unsaturated compound in 15–25 ml. of unpurified commercial chloroform containing 0.75% alcohol was treated with twice as many moles of N-bromoacetamide. In the case of triphenylethylene an equimolar amount was used. The reaction mixture was usually heated gently and illuminated with ultraviolet light. Either sunlight or a Hanovia quartz mercury arc was used as a source of illumination. Usually the solution became

light brown in color and remained so for several hours. If an excess of N-bromoacetamide was used the end of the reaction was characterized by a distinct darkening of the bromine color. When no olefin was present the brown color deepened much faster. After several hours of illumination the reaction mixture was filtered and washed with warm water and chloroform. A crystalline product remained if the dibromide was an insoluble one.

The two phase filtrate was shaken, and the water layer was removed. In all cases the aqueous layer contained acetamide and bromide ion, and if it was evaporated to dryness by standing for some time the residue contained ammonium ion and acetic acid as well. In some of the experiments a small amount of a water soluble crystalline product was filtered from the chloroform solution before water was added. This compound proved to be diacetamide hydrobromide[2] of m. p. somewhere in the range 130–139°.

The chloroform solution was distilled at reduced pressure and the dibromide residue was recrystallized from alcohol or alcohol–water. The results of these experiments are given in Table I.

**The Reaction of Styrene with N-Bromoacetamide.**—Several experiments with 0.1 and 0.2 mole of styrene with equivalent amounts of N-bromoacetamide were carried out. In 50 to 100 ml. of unpurified chloroform containing 0.75% ethyl alcohol the reaction was quite violent as soon as it started unless the N-bromoacetamide or the styrene was added portionwise. It was possible to start this violent reaction either by the application of heat to or illumination of the reaction mixture. It made no difference whether the N-bromoacetamide was hydrated or anhydrous. In fact the addition of a mole of water per mole of styrene had no effect on the reaction. In most of these cases the dibromide crystallized from an alcohol solution following the removal of the chloroform. In one case the dibromide was distilled from the residue, b. p. 108–110° (3–4 mm.) (see Table I).

In one experiment 15 ml. of chloroform washed with concentrated sulfuric acid and dried over anhydrous potassium carbonate was distilled into a cooled flask containing 1.4 g. (0.010 mole) of N-bromoacetamide. Two ml. of styrene was then distilled at reduced pressure into the same flask. The reaction exhibited an induction period as before, but the reaction mixture heated up noticeably once it started. A control experiment using unpurified chloroform and styrene stabilized with *p-t*-butylcatechol behaved the same way. Both reactions yielded styrene dibromide.

Similarly 0.01 mole of N-bromoacetamide reacted with styrene alone and with styrene in carbon tetrachloride to give the dibrom de.

At room temperature in the absence of light, a successful reaction of 0.01 mole of N-bromoacetamide with a slight excess of styrene in chloroform was observed only if the reaction mixture stood overnight or longer.

**The Reaction of *cis*-Stilbene with N-Bromoacetamide in the Absence of Light.**—A solution of 1.38 g. (0.010 mole) of N-bromoacetamide in 50 ml. of chloroform was prepared in a Pyrex Lifetime Red Low Actinic glass flask. The solution was cooled, and 0.90 g. (0.005 mole) of *cis*-stilbene was added. The flask was stoppered and the solution was allowed to stand five days at room temperature. The solution was extracted with water. The aqueous phase gave an iodine color when potassium iodide was added. Chloroform was distilled from the organic layer and alcohol was added. Cooling yielded 0.13 g. (8%) of *trans*-stilbene dibromide. The solution was concentrated and cooled and 0.07 g. (8%) of *trans*-stilbene of m. p. 118–120° was isolated. Recrystallization of the *trans*-stilbene from aqueous alcohol yielded crystals of m. p. 122.5–123.5°; no depression when mixed with an authentic sample. Evaporation of the mother liquor gave a little oily residue containing no crystals.

**Reactions of the Unsaturated Compounds with N-Bromoacetamide and Anhydrous Hydrogen Bromide.**—A slight excess of anydrous N-bromoacetamide was added portionwise to a solution of 0.005 mole of the unsaturated compound in 15 ml. of unpurified commercial chloroform which was kept saturated with anhydrous hydrogen bromide. There was an immediate evolution of heat. The N-bromoacetamide was added at a rate such that only local concentrations of bromine were observed by color. At the end of the reaction the bromine color became pronounced and a white precipitate of diacetamide hydrobromide was observed.[2a] The reaction mixture was shaken with water, and the chloroform layer was evaporated on a tared watch glass. The solid residue was weighed and the melting point taken. These data are in Table I. The crude products were recrystallized when necessary and identified by mixed m. p. with authentic samples. When this method of isolation was attempted with the reactions of the olefins with N-bromoacetamide alone, only sticky, viscous liquids were obtained as residues.

## Summary

1. N-Bromoacetamide has been shown to act as the sole source of bromine for addition to the double or triple bonds of certain unsaturated compounds.

2. The reactions of the unsaturated compounds with N-bromoacetamide have been interpreted as involving free radical intermediates.

3. N-Bromoacetamide has been shown to be a source of bromine atoms capable of isomerizing *cis*-stilbene to the *trans* isomer.

4. The reactions of unsaturated compounds with N-bromoacetamide in the presence of anhydrous hydrogen bromide have been interpreted as following the usual polar mechanism of *trans* addition.

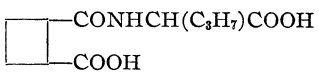
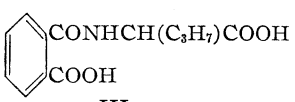
# Studies on Antipodes. VI.[1] The Synthesis of Some Derivatives of Enantiomorphs of Valine[2]

BY FREDERICK N. MINARD[3] AND SIDNEY W. FOX



The possible significance of the D-amino acid component in antibiotics has been previously considered.[1a,4] Partly as the result of the finding of inhibition of bacterial growth by D-amino acids[1a,b,d] fundamental relationships involving D-amino acids, proteases, growth, and antibiotics have been suggested. Initial attempts to prepare model antibiotics in this laboratory were based on the knowledge surrounding gramicidin and tyrocidine.[1a] Since that time the penicillins have been shown to be D-amino acid derivatives[5] and the D-amino acid residue has been found to be one critical structural feature in this type.[6] Evidence now exists for the presence of D-amino acid residues in other antibiotics besides gramicidin (D-leucine and D-valine), tyrocidine (D-phenylalanine), and the penicillins (D-penicillamine). These include gramicidin S (D-phenylalanine),[7] bacitracin[8] (D-phenylalanine), and aerosporin[9] (D-leucine and D-$\alpha,\gamma$-diaminobutyric acid). The D-amino acid residue thus appears to be a unit of widespread significance in the comparative biochemistry of antibiotics. The value of the D-amino acid unit may depend upon its contribution to inhibitory action, to non-metabolizability, to cyclizability of the whole molecule,[10] or upon some other function.[11]

All of the above antibiotics are peptides or peptide derivatives. Large natural peptide molecules subjected to treatment resulting in inversion of L-residues have given products which have so far not been found to possess antibacterial activity.[1e] Treatment of "racemized casein" aimed at bringing about cyclization of this material as for the diketopiperazines[12,13] has given products which possess relatively weak antibacterial activity not, however, found in the peptides prior to such treatment.[14]



The natural profusion of antibiotics of the D-amino acid derivative class increases interest in chemical attempts to synthesize D-amino acid derivatives with antibacterial activity. Among other working hypotheses for the synthetic approach to the antibiotic problem is the inclusion of strained structures in compounds with groups that may function to attract enzymes. To this end some cyclobutane[15] derivatives (Types I and II) have been prepared and are recorded in this article (Table I). These derivatives contain peptide and carboxyl groups, although not in a relationship such as is found in penicillin or in peptidase substrates.[16] The amino acid residues are L-valine, D-valine, and DL-valine. The *o*-carboxybenzoyl derivatives of the valine isomers (III) are also reported.

I

II

III

The phthaloyl-DL-valine reported in Table I has been recorded earlier by Billman and Harting.[17] The product described here is included for comparative purposes, since it was purified in a different manner. This compound formed a hydrate when crystallized from aqueous solutions. In the case of the corresponding cyclobutane compounds, the optical isomers yielded hydrates from aqueous solution, whereas the racemate did not.

The opening of the ring in the phthaloyl derivatives and the corresponding ring in the cyclobutane analog proceeded very rapidly. Mere warming of the cyclic imides with dilute alkali served to hydrolyze the cyclic imides without appreciable rupture of the remaining peptide linkage.

[a] By recrystallization of the anhydrous imide from ethanol–water. [b] The anhydrous peptide was hygroscopic and was not obtained.

Preliminary tests of the above compounds on *Lactobacillus arabinosus* and *Escherichia coli* showed neither high antibacterial activity nor antipodal specificity.[18] Activity was found at dilutions of 0.8 mg./ml., but not at half this concentration.

## Experimental

**Preparation of Imides.**—The valine isomer was fused with either phthalic anhydride as previously described[1c,17] or with cyclobutane-1,2-*cis*-dicarboxylic anhydride[19] in equimolar ratio. The phthaloyl-DL-valine was recrystallized from carbon tetrachloride and the cyclobutanedicarbonyl valines were recrystallized from water.

**Hydrolysis of Imides.**—Compounds of Types II and III were prepared as follows: Five grams of the imide was titrated in a 125-ml. Erlenmeyer flask with 2 *N* sodium hydroxide solution to a phenolphthalein end-point. An equal amount of dilute alkali, plus 0.5 ml. excess, was added. The flask was placed in a water-bath (previously at the boiling-point) until the inside temperature reached 70°, and then quickly cooled in an ice-bath. The solution was acidified with concentrated hydrochloric acid solution, and an excess added to precipitate the organic acid. After one hour the product was filtered and dried.

The *o*-carboxybenzoyl derivatives were purified by solution of the dried material in acetone, filtration from undissolved sodium chloride, and addition of carbon tetrachloride to incipient precipitation. The peptides came out slowly and after several such purifications appeared as well-formed crystals.

The carboxycyclobutane derivatives were freed from inorganic matter by solution in anhydrous ethanol. After filtration, several ml. of dry ethyl acetate was added to prevent layering, and then enough hexane to cause incipient precipitation.

Yields were 50–75% for type I compounds, 40–50% for type II, and 60–75% for type III.

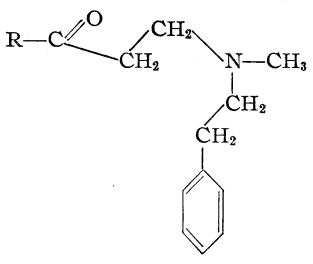
# Synthetic Analogs of Oxytocic Drugs. I. Phenethyl β-Alanine Derivatives[1]



BY RICHARD BALTZLY, VLADIMIR DVORKOVITZ[2] AND ARTHUR P. PHILLIPS

The important natural oxytocic drug ergonovine (ergometrine, ergobasine) has been assigned the structure I (R = $NHCH(CH_3)CH_2OH$[3]) in which the dotted lines indicate the existing uncertainty[4] as to the location of the double bond which is known to shift from the 5-10 to the 9-10 position in transformations between the lysergic and isolysergic acid families of the ergot alkaloids. The contributions of the various portions of the molecule to its physiological activity are not known, although some information is available.

The other ergot alkaloids, in which the group R is replaced by complex cyclic structures, manifest very different physiological behavior, not essentially of an oxytocic character. Stoll and Hofmann[5] have prepared a number of ergonovine analogs and homologs in which 2-amino-1-propanol was replaced by other alkanolamines. A number of these were approximately as active as ergonovine as was α-lysergic acid diethylamide. In contrast to this last finding, Smith and Timmis[6] reported that both ergine and iso-ergine (I, R = $NH_2$) had only vestigial activity. It does not appear that other derivatives of lysergic acid have been tested. The double bond is apparently not of critical importance since Kharasch[7] has claimed therapeutic efficacy for a dihydro-compound. On the other hand, the presence of the double bond in an unfavorable position (as in the isolysergic acid family) abolishes activity.

I

II

Inspection of Formulas I and II shows that lysergic acid (I, R = OH) may be regarded as an N-methyl-N-phenethyl-β-alanine. It is therefore possible to consider a phenethyl-β-alanine alkanolamide as an open-chain model of ergonovine.

A number of phenethyl-β-alanine esters were prepared from N-methylphenethylamines with the intention of transforming them into ethanolamides. While this transformation proved to be unexpectedly tedious and expensive some of the esters themselves showed marked oxytocic activity in laboratory animals. Since the two ethanolamides that have been prepared (compounds IV and XVIII in Table I) appeared to be no more active than the corresponding esters most of our attention was given to the preparation of the latter. It had been hoped that activity could be correlated with structural features. This has been possible only in a general sense. The maximum activity so far observed in this series (5–10% of that shown by ergonovine per unit weight) is manifested by those compounds having two ether substitutions on the phenyl ring. Possibly such substitution of a polar nature may be equivalent roughly to the indole nitrogen in the natural compounds (which would not be cationic under physiological conditions). The activity of the monoalkoxy compounds is perhaps one-tenth that of the di-alkoxy, and the unsubstituted compound (I in Table I) appears inactive. Within the above mentioned classes little differentiation is possible. Differences of less than 100% in potency probably could not be detected by the methods available and the question whether true ergonovine-like action will be manifested in human beings remains to be settled.[8] The secondary amine (XX) and the quaternary salt (XXIV) corresponding to one of the most potent compounds (XXII) showed the same order of activity. The size of the ester alkyl was not critical. On the other hand, the phenolic compounds (II, VI and XIX) were completely inactive. All of these substances showed rather low (in some cases extremely low) toxicities and minimal physiological action of non-oxytocic nature.

The iodinated compounds (VII and VIII) were prepared in the hope that they would partake of the physiological inertness of the parent compound (VI) and would be of interest as radiopaques. Iodination was found, however, to have increased toxicity very considerably.

## Experimental

Physical properties and analytical figures for the phenethyl-β-alanine derivatives are presented in Table I. Analytical results were at times rather unsatisfactory. In general, the most serious error in analysis of amine salts results from difficulty in drying. The present series of compounds presents all the usual complications in drying

with the additional disadvantage that β-alanine esters have some tendency to split off acrylic esters.

The general stability of β-alanine derivatives under varying conditions has not been studied thoroughly. We are at present in a position to offer only incidental observations. The salts, as crystalline solids, are not noticeably unstable—only two of the melting points listed in Table I appeared to be accompanied by decomposition. On the other hand, the odor of acrylic esters is usually noticeable when a bottle containing one of these salts is opened. One or two compounds, on standing several years in stoppered bottles, were observed to liquefy and this has been attributed to decomposition. Despite the above, the demethylation reactions leading to the formation of II, VI, and XIX resulted in satisfactory yields. Further, the ester-exchange reactions leading to the formation of XI, XXVII and XXVIII were effectively quantitative and hence could not have been accompanied by significant decomposition. The stability of the free bases appears to be less than that of the salts. Compounds IX and XXI (as bases) were distilled *in vacuo* of 1–5 mm. The boiling points varied from 140–170° and there was obviously considerable decomposition.

The phenethyl-β-alanine esters were prepared from the appropriate secondary amines[9] by reaction either with methyl acrylate or with ethyl β-bromopropionate. The former reaction affords the methyl esters in nearly quantitative yield. In the earlier part of this work the desired ethyl esters were obtained from ethyl bromopropionate and compounds I, III, V, XII–XV, XXII, XXIII and XXIV were first prepared in this way. This reaction, however, is relatively unsatisfactory both on its own merits and in comparison with the excellent methyl acrylate procedure. After it was found that higher esters could be obtained readily by ester exchange from the methyl esters, the us of ethyl bromopropionate was discontinued.

Compounds XIII, XV and XXIX were isolated as acid oxalates, the corresponding hydrochlorides proving uncrystallizable.

**N-Phenethyl-β-alanine Methyl Esters.**—The bases to be transformed were mixed with about two equivalents of methyl acrylate (Eastman Kodak Co. "Practical Grade") in 5–10 volumes of benzene. The solutions were allowed to stand overnight and refluxed thirty to sixty minutes. On cooling, phenyl isocyanate was added in small portions (0.5–1 cc.) until its odor was detectable after standing for ten minutes; usually only 1–2 cc. of phenyl isocyanate was required.[10] Sufficient methanol was then added to combine with excess isocyanate and, after standing about twenty minutes, basic material was extracted with dilute hydrochloric acid. The aqueous solutions were basified with sodium carbonate and the oily bases were taken into ether and dried over potassium carbonate. The ethereal solutions were then run into methanol containing excess hydrogen chloride. In a number of cases the hydrochlorides could be induced to crystallize during this neutralization, never separating as oils or sirups. More often the sirupy layer of hydrochloride had to be worked over considerably before crystallization ensued.

N-Homoveratryl-β-alanine methyl ester hydrochloride (XX) was prepared by hydrogenation of the corresponding N-benzyl derivative with palladized charcoal. The N-benzyl compound, formed by the reaction of the known benzyl homoveratrylamine[11] with methyl acrylate, was

(9) With the exception of the precursor of compound XXV, whose preparation is described, all of these amines were known previously.

(10) This treatment with phenyl isocyanate is probably an unnecessary precaution. In the preparation of analogous substances from β-hydroxyphenethylamines, it appeared better to dispense with this operation, but the products were still obtained in semi-quantitative yields and substantially pure as first isolated.

(11) Buck, THIS JOURNAL, **53**, 2192 (1931).

not obtained analytically pure. Compound XX was also the only isolable product from the reaction of homoveratrylamine with excess methyl acrylate on the steam-bath (homoveratrylamine bis propionic ester had been expected and has subsequently been obtained by variation in reaction conditions).

**Ester Exchange Reactions.**—The methyl ester hydrochlorides to be transformed were dissolved in 10–20 parts by weight of the appropriate higher alcohol and a considerable amount of alcoholic hydrogen chloride. In the preparation of compound XXVII, 3.5 g. of compound XXVI, 100 cc. of absolute ethanol and 10 g. of ethanolic hydrogen chloride (33% by wt.) were refluxed four hours under a fractionating column, solvent being allowed to distil gradually until the volume was about 10 cc. On cooling and dilution with acetone and ether there was obtained 3.5 g. of product melting at 133–134°. The exchange was effectively quantitative.

The corresponding *n*-amyl ester (XXVIII) was recovered in only 70% yield from the reaction of 5 g. of XXVI 50 cc. of *n*-amyl alcohol and 15 cc. of methanolic hydrogen chloride (reflux time, two days with distillation of about half the amyl alcohol) but, since the amyl ester hydrochloride was pure as first isolated it is to be presumed that transformation had been virtually complete.

Compounds XI, XXVII and XXVIII were first prepared from the corresponding methyl esters by the above procedure. Compounds XVII and XXII were prepared in this fashion when additional material was required. It is to be presumed that any of the compounds actually prepared by the ethyl bromopropionate reaction could be obtained more advantageously through the methyl acrylate method followed by ester exchange.

**Preparation of Hydroxyphenethyl-β-alanine Esters.**—Compounds II, VI and XIX were formed by the demethylation of the corresponding methyl ethers (III, IX and XXI) with concentrated hydrochloric acid at 160–165° in glass bombs (four hours of heating). On opening the bombs the solutions were evaporated *in vacuo* and the residual solids were re-esterified by refluxing with ethanolic hydrogen chloride.

In the preparation of the diiodo compounds VII and VIII, the initial product of the demethylation of IX (presumably the acid corresponding to VI) was dissolved in ammonium hydroxide solution and iodinated by addition of a solution of iodine in dioxane.[12] When the disappearance of iodine had become very slow, the solution was evaporated *in vacuo* to small volume. Compound VII (probably a zwitter-ion) crystallized during this evaporation and was purified by crystallization from water. Compound VIII was formed by esterification of VII with ethanolic hydrogen chloride.

**Preparation of the Ethanolamides.**—When the β-alanine esters III and XVI were refluxed with excess ethanolamine compounds IV and XVIII were isolated from the reaction mixtures in poor yield and with difficulty. The analogous reaction with phenethyl glycine esters is very satisfactory and it is apparent that the present process involves decomposition of some sort. From one reaction between ethanolamine and XVI, run in methanol, a picrate was isolated corresponding to about one-third of the starting material. This picrate proved to be that of 2,5-dimethoxyphenethylmethylamine which must have been formed by loss of methyl acrylate from XVI. The methyl acrylate released may have combined with ethanolamine.

Somewhat better results were obtained by the method of Stoll[5]: Ester → hydrazide → azide → ethanolamide. This gave XVIII in about 25% yield. A major difficulty in the application of Stoll's procedure to substances of this type is found in the physical properties of the azide. Stoll's procedure was especially devised for the transformation of lysergic acid hydrazide into alkanolamides of lysergic acid. According to Stoll the azide of lysergic acid can be precipitated from aqueous solution by bicarbonate. The azides corresponding to compounds III and XVI are very soluble in water and salt solutions and are poorly and incompletely extracted therefrom by ether. Furthermore, the extractions prolong the operation which is probably undesirable.

**The Bromophenethyl Derivatives.**—Compound X resulted from the reaction of methyl acrylate with N-methyl-3-bromohomoanisylamine. This secondary amine had been prepared previously[13] by bromination of N-methylhomoanisylamine dissolved in hydrochloric acid. It had been assumed that substitution took place in the 3-position. This has now been confirmed by oxidation (with alkaline permanganate solution) to 3-bromo-4-methoxybenzoic acid. Compound XI was obtained from X by ester exchange.

**N-Methyl-6-bromo-3,4-dimethoxyphenethylamine.**—Bromination of N-methylhomoveratrylamine hydrochloride in aqueous solution proceeded smoothly. After one mol of bromine had been absorbed, the solution was basified, the amine taken into ether, dried over potassium carbonate and transformed to the hydrochloride which crystallized from ethanol–ethyl acetate–ether mixtures; m. p., 152–3°. *Anal.* Calcd. for $C_{11}H_{17}BrClNO_2$: C, 42.49; H, 5.52. Found: C, 42.48; H, 5.28. Substitution was shown to have been in the 6-position by oxidation (permanganate) to the known 6-bromoveratric acid (m. p., 184–185°).

Reaction of the base with methyl acrylate afforded XXV.

**Acknowledgment.**—The authors wish to express their gratitude to Messrs. Walter S. Ide and Samuel W. Blackman for the performance of the microanalyses here recorded.

## Summary

1. A number of esters of substituted phenethyl-β-alanines have been prepared.

2. Some of these substances show oxytocic activity in laboratory animals.

# Stereoisomeric Substituted 11-Keto-20-hydroxypregnanes. I

BY L. H. SARETT

In the course of synthetic studies in this Laboratory in the field of the adrenal steroids[1,2,3,4] a group of substituted 11-keto-20-hydroxypregnanes has been prepared. Some of the reactions which afford members of this group—reduction of a 20-ketopregnane, hydroxylation of a $\Delta^{17}$- or $\Delta^{20}$-pregnene—give both epimers in different but characteristic ratios. In order to illumine regularities peculiar to these reactions, as well as to make a needed nomenclatural integration, we have undertaken the stereochemical correlation of some of these compounds. The results of such an investigation are readily treated in four divisions: first, the correlation of the 11-ketopregnanes bearing the 20-hydroxy (Class A) and the 20,21-dihydroxy (Class B) side chains together with their derivatives which differ only in the substituent at C-3; second, the correlation of 11-ketopregnanes having 17,20-dihydroxy (Class C) and 17,-20,21-trihydroxy (Class D) side chains with their respective derivatives; third, the correlation *inter ipsos* of the four classes; fourth, the linking of this group of compounds with Reichstein's Substances J and O, the adrenal steroids which form the standard of references adopted by Reichstein and co-workers,[5,6,7] for 20-hydroxypregnanes. The present publication is concerned with the first of these divisions. For convenience in reference the results described in the succeeding divisions of this study will be used as the basis for assigning configurational indices to C-20 substituents. The assignment of these indices has been made in such a way as to indicate a very probable configurational correspondence with substances J and O at the C-20 position.

## Class A. Simple 11-Keto-20-hydroxypregnanes

The catalytic reduction of pregnane-3$\alpha$-ol-11,20-dione acetate to pregnane-3$\alpha$,20$\beta$-diol-11-one 3-acetate (I) and the corresponding 3$\alpha$,20$\alpha$-diol (isolated as the diacetate IX)[8] has been described.[3] The corresponding 3-keto derivatives have now been prepared. In the 20$\beta$-series this was accomplished by benzoylating I, partially saponifying the acetate benzoate (II), oxidizing the hydroxy benzoate (III) to the ketobenzoate (IV) and finally hydrolyzing to the ol-dione (V). In the 20$\alpha$-series the 20-monoacetate (X) was obtained by partial saponification[9] of the diacetate (IX). Oxidation then yielded pregnane-20$\alpha$-ol-3,11-dione acetate (XI).

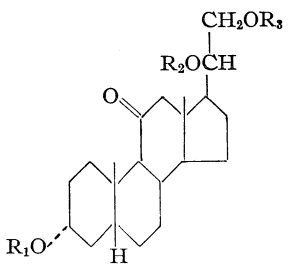
I $R_1$ = Ac, $R_2$ = H
II $R_1$ = Ac, $R_2$ = $COC_6H_5$
III $R_1$ = H, $R_2$ = $COC_6H_5$

VIII $R_1$ = H, $R_2$ = H
IX $R_1$ = Ac, $R_2$ = Ac
X $R_1$ = H, $R_2$ = Ac

IV R = $COC_6H_5$
V R = H
VI R = Ac
VII R = $SO_2C_6H_4CH_3$-*p*

XI R = Ac
XII R = H

An additional source of pregnane-3$\alpha$,20$\alpha$-diol-11-one (VIII) was the alcoholic fraction obtained by diazotization of 20-aminopregnane-3$\alpha$-ol-11-one 3-acetate.[1] After chromatographic separation of the pregnen-3$\alpha$-ol-11-one acetate isomers, which constituted the chief product of the reaction, the crude alcoholic fraction was saponified and the diolone was readily purified by crystallization. In one experiment the 3$\alpha$,20$\beta$-diolone could also be isolated.[10]



## Class B. 11-Keto-20,21-dihydroxypregnanes

The mixture of pregnen-3$\alpha$-ol-11-one acetate isomers mentioned above has been utilized to prepare pregnane-20$\beta$,21-diol-3,11-dione (XXI) and pregnane-20$\alpha$,21-diol-3,11-dione (XXVIII).[2] If, instead of conversion to the 3-keto derivative, the pregnene mixture was hydroxylated directly, a mixture of three triolones was obtained. These

(8) In the cited publication the former compound was named without a configurational index for the 20-hydroxy group; the latter compound was called pregnane-3$\alpha$,20(epi)-diol-11-one. In writing the projection formulas in the present group of papers, a suggestion by Fieser and Fieser, *Experientia*, **4**, 285 (1948), has been followed. According to this suggestion the respective 20$\beta$- or 20$\alpha$-substituent is written on the left or the right of the C-20 carbon atom.

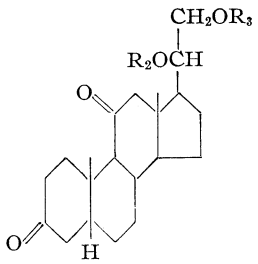
(10) Hückel (*Ann.*, **533**, 1 (1938)) has demonstrated that the diazotization of optically active secondary amines with additional centers of asymmetry in the molecule may or may not proceed with retention of configuration.

consisted of the two pregnane-3$\alpha$,20,21-triol-11-one epimers (XIII and XXIII) corresponding to the dioldiones XXI and XXV, and also a 3$\alpha$,17$\alpha$,-20$\beta$-triolone.[11] Separation of XIII and XXIII was effected by chromatography of the 3-acetate acetonides (XIV and XXV). By the usual procedures, XIV and XXV could be converted to the partially acetylated triols, such as the 3-monoacetates (XVI and XXVI) and the 3,21-diacetates (XVII and XXVII).



In order to correlate the pair of triolones with the dioldiones one of the former was converted[12] to its acetonide. Oxidation of the latter with N-bromacetamide in dry pyridine–*t*-butanol[13] afforded a nearly quantitative yield of the dioldione acetonide (XX). Hydrolysis and acetylation then yielded the previously described pregnane-20$\beta$,21-diol-3,11-dione diacetate (XXII). That the triolone isomeric with XIII must have the structure pregnane-3$\alpha$,20$\alpha$,21-triol-11-one (XXIII) was shown by oxidation to 3$\alpha$-hydroxy-11-ketoetiocholanic acid. The 3,21-diacetate (XXVII) in the 20$\alpha$-series, which was required for certain rotation data, was prepared through the intermediate acetonide (XXV) and monoacetate (XXVI).

The preparation of 11-keto-20,21-dihydroxypregnanes by catalytic reduction of the ketol or ketol acetate gave results similar to those found on reduction of the simple 11,20-diketone. One isomer was the major product and it also belonged to the 20$\beta$-series.[14] Reduction of pregnane-3$\alpha$,21-diol-11,20-dione diacetate (XXX) yielded pregnane-3$\alpha$,20$\beta$,21-triol-11-one 3,21-diacetate (XVII), acetylation of which gave the triacetate (XV).

A second and more convenient method of preparing pregnane-3$\alpha$,20$\beta$,21-triol-11-one 3-acetate (XVI) employed as starting material 21-diazopregnane-3$\alpha$-ol-11,20-dione acetate.[15] This was treated with 90% formic acid, giving the acetate formate (XXXI), which hydrolyzed very rapidly in aqueous methanolic potassium bicarbonate to pregnane-3$\alpha$,21-diol-11,20-dione 3-acetate (XXXII). Catalytic reduction then gave XVI. The partial tosylation of this compound gave an amorphous 21-monotosylate which could be acetylated to give the crystalline diacetate tosylate (XVIII).

## Experimental[16]

**Pregnane-3$\alpha$,20$\beta$-diol-11-one 3-Acetate 20-Benzoate (II).**—A solution of 1.85 g. of pregnane-3$\alpha$,20$\beta$-diol-11-one 3-acetate (I), m.p. 205–206°, in 10 cc. of pyridine was treated with 2.0 cc. of benzoyl chloride and warmed at

(11) The structure of this compound is discussed in Part II.

(12) A slight modification of the method of Fischer and Taube (*Ber.*, **60**, 485 (1927)), using a 5% solution of zinc chloride in acetone, has been found to give excellent results with steroid glycols including the 17,20,21-triols.

(13) Reich and Reichstein (*Helv. Chim. Acta*, **26**, 562 (1943)) have shown that N-bromacetamide in aqueous acetone solution smoothly oxidizes secondary alcohols to ketones. These conditions are unsuitable, however, for molecules containing acid-sensitive functional groups.

(14) This relationship is discussed in Part III.

(15) The preparation of the 3$\beta$-acetoxy isomer of this compound from the corresponding etio acid has been described by Lardon and Reichstein (*Helv. Chim. Acta*, **26**, 747 (1943)).

(16) Melting points were taken on the Kofler micro hot stage and thus represent corrected values. Rotations were taken in acetone, $c$ = 1.0, except where otherwise indicated.

50° for five minutes. The product after recrystallization from alcohol melted at 188–189°; yield, 1.90 g.

*Anal.* Calcd. for $C_{30}H_{40}O_5$: C, 74.97; H, 8.39. Found: C, 75.25; H, 8.60.

**Pregnane-3α,20β-diol-11-one 20-Benzoate (III).**—A solution of 2.05 g. of acetate benzoate (II) in 10 cc. of benzene was treated at 25° with 10 cc. of 1.1 *N* methanolic potassium hydroxide. After eight minutes the solution was neutralized with acetic acid and the benzene removed *in vacuo*, giving the crystalline hydroxybenzoate (III). After recrystallization from dilute alcohol and acetone, it melted at 236–237°; yield, 1.58 g.

*Anal.* Calcd. for $C_{28}H_{38}O_4$: C, 76.67; H, 8.74. Found: C, 76.95; H, 8.45.

**Pregnane-20β-ol-3,11-dione Benzoate (IV).**—A solution of 1.55 g. of hydroxybenzoate (III) in 25 cc. of 90% acetic acid was treated at 15° with the solution of 0.80 g. of chromic acid in 16 cc. of 90% acetic acid. After one hour the solution was diluted with water, extracted with benzene, the latter washed with aqueous carbonate and concentrated to dryness *in vacuo*. The keto benzoate after crystallization from ether and from methanol melted at 161–162°; yield, 1.10 g.

*Anal.* Calcd. for $C_{28}H_{36}O_4$: C, 77.03; H, 8.31. Found: C, 77.00; H, 8.24.

**Pregnane-20β-ol-3,11-dione (V).**—A solution of 1.0 g. of the keto benzoate in 15 cc. of 0.7 *N* methanolic potassium hydroxide was refluxed for forty-five minutes with gradual addition of water. The methanol was then removed *in vacuo*, the aqueous suspension extracted with chloroform, the latter washed with water and concentrated to dryness *in vacuo*. Crystallization from acetone gave 700 mg. of the ol-dione; m. p. 200°, $[\alpha]^{25}D$ + 52.5°.

*Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.70. Found: C, 75.99; H, 9.40.

**Pregnane-20β-ol-3,11-dione Acetate (VI).**—A sample (22 mg.) of the ol-dione was warmed on the steam-bath for a few minutes with pyridine–acetic anhydride. Addition of water and recrystallization from a small volume of methanol gave the acetate; m. p. 201–203°, $[\alpha]^{25}D$ + 75.5°.

**Pregnane-20β-ol-3,11-dione Tosylate (VII).**—A solution of 498 mg. of 20β-ol-dione in 2.1 cc. of pyridine was treated at 0° with 600 mg. of freshly recrystallized tosyl chloride. After three hours the solution was warmed to room temperature and permitted to stand overnight. After the addition of water, the tosylate was extracted with ether, washed with dilute hydrochloric acid, dilute potassium carbonate and water. Concentration of the ethereal solution and several recrystallizations of the residue from alcohol and ethyl acetate–petroleum ether gave crystals, m. p. 153°; yield, 500 mg.

*Anal.* Calcd. for $C_{28}H_{38}O_5S$: C, 69.11; H, 7.87. Found: C, 68.89; H, 8.10.

The tosylate reacted with refluxing collidine to give a crystalline mixture, m. p. 158–162°, the analysis of which corresponded roughly to a formula of $C_{21}H_{30}O_3$.

**Pregnane-3α,20α-diol-11-one 20-Acetate (X).**—To a solution of 230 mg. of pregnane-3α,20α-diol-11-one diacetate (IX), m. p. 235–236°, in 5 cc. of benzene was added 5 cc. of 1.1 *N* methanolic potassium hydroxide at 25°. After two and one-half minutes, the solution was acidified with acetic acid, concentrated to dryness *in vacuo* and extracted with benzene. The washed benzene solution was concentrated to a small volume and percolated through a column of alumina. Elution with petroleum ether–benzene mixtures removed diacetate and with ether–chloroform the 20-monoacetate (X). The latter weighed 80 mg. after recrystallization from dilute methanol and ether; m. p. 184–185°; $[\alpha]^{25}D$ + 50°.

*Anal.* Calcd. for $C_{23}H_{34}O_4$: C, 73.36; H, 9.65. Found: C, 73.47; H, 9.48.

**Pregnane-20α-ol-3,11-dione Acetate (XI).**—Oxidation of 53 mg. of the 20α-monoacetate with chromic acid in the usual manner gave 51 mg. of crude crystals which were purified first by the use of Girard reagent T and then by chromatography. Twenty-four milligrams of the pure 20α-ol-dione acetate was obtained; m. p. 135°, $[\alpha]^{25}D$ + 54°. A mixture with pregnane-3α-ol-11,20-dione acetate (m. p. 136°) melted at 110–120°.

**Pregnane-20α-ol-3,11-dione (XII).**—The acetate (23 mg.) was saponified by warming on the steam-bath with dilute methanolic potassium hydroxide (0.5 *N*) for ten minutes. Recrystallization of the product gave 12.5 mg. of the 20α-ol-dione; m. p. 190–192°, $[\alpha]^{25}D$ +69.5° (*c* = 0.5). A mixed m. p. with pregnane-20β-ol-3,11-dione showed a depression of 20°.

*Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.70. Found: C, 76.13; H, 9.52.

**Pregnane-3α,20α-diol-11-one Diacetate (IX) from 20-Aminopregnane-3α-ol-11-one 3-Acetate.**—A portion (7.0 g.) of 20-aminopregnane-3α-ol-11-one acetate was heated with sodium nitrite and pyridine hydrochloride in aqueous pyridine as previously described.[1] Chromatography of the product gave 3.7 g. of unsaturated compounds, eluted with 8:2 petroleum ether–ether and 2.2 g. of material eluted with ether. Several crystallizations of the latter from ether and dilute acetone gave 200 mg. of pregnane-3α,20β-diol-11-one 3-acetate, m. p. 201–204°. A mixed m. p. with an authentic sample (m. p. 204–205°) was 202–204°. The mother liquors of the 3α,20β-diol monoacetate (2.0 g.) were acetylated and the product recrystallized from acetic acid, giving 600 mg. of pregnane-3α,20α-diol-11-one diacetate (IX), m. p. and mixed m. p. 234–235°. Saponification gave the 3α,20α-diol, m. p. and mixed m. p. 219°, $[\alpha]^{25}D$ + 61° (alc.). A number of repetitions of this experiment, using 2.0 equivalents of mineral acid in place of the pyridine hydrochloride yielded only the 3α,-20α-diol monoacetate in the ether eluates (isolated as the diacetate from acetylation).

**Pregnane-3α,20β,21-triol-11-one 3-Acetate 20,21-Acetonide (XIV) and Pregnane-3α,20α,21-triol-11-one Acetate 20,21-Acetonide (XXV).**—The chromatographically purified mixture of pregnene-3α-ol-11-one acetates from the diazotization of 3.0 g. of 20-aminopregnane-3α-ol-11-one 3-acetate amounted to 1.8 g. This material was treated with osmium tetroxide, the osmate esters hydrolyzed with hot aqueous alcoholic sodium sulfite and the product extracted in the usual manner (*e. g.*, ref. 2). The residual crude triols were dissolved in 45 cc. of acetone containing 2.3 g. of anhydrous zinc chloride and the solution permitted to stand overnight. A solution of 3.5 g. of potassium carbonate in 10 cc. of water was added, the mixture was shaken for a few minutes and the supernatant layer decanted. The residue was extracted again with acetone, the extracts combined and concentrated to a small volume after the addition of 5 cc. of a 10% solution of potassium carbonate. The oily precipitate was then extracted with ether, washed with water and concentrated to dryness. The residue (2.0 g.) was heated on the steam-bath with a mixture of 2.0 cc. of pyridine and 1.0 cc. of acetic anhydride for ten minutes, the solvents then removed *in vacuo*, the residue dissolved in 8:2 petroleum ether–benzene and chromatographed over 60 g. of (alkaline) alumina. The fractions eluted with 4:6 petroleum ether–benzene were combined and gave, after several recrystallizations from methanol, 400 mg. of pregnane-3α,20β-21-triol-11-one 3-acetate 20,21-acetonide (XIV); m. p. 137–139°, $[\alpha]^{25}D$ + 63.5°.

*Anal.* Calcd. for $C_{26}H_{40}O_5$: C, 72.20; H, 9.32. Found: C, 72.43; H, 9.38.

Subsequent elution with benzene and recrystallization of the combined eluates gave an equal amount of pregnane-3α,20α,21-triol-11-one 3-acetate 20,21-acetonide (XXV); m. p. 160–162°, $[\alpha]^{25}D$ + 68°.

*Anal.* Calcd. for $C_{26}H_{40}O_5$: C, 72.20; H, 9.32. Found: C, 72.46, 72.34; H, 9.23, 9.30.

Further elution with ether–benzene mixtures gave pregnane-3α,17α,20β-triol-11-one 3,20-diacetate, m. p. 249–250°, $[\alpha]^{25}D$ + 78.5°.

*Anal.* Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.82. Found: C, 69.06; H, 8.60.

**Pregnane-3α,20β,21-triol-11-one 3-Acetate (XVI).**—A solution of 200 mg. of pregnane-3α,20β,21-triol-11-one 3-acetate 20,21-acetonide, m. p. 136–138°, in 2.0 cc. of acetic acid was diluted with 2.0 cc. of water and the mixture heated at 100° for fifteen minutes. Dilution with water, and extraction with ether followed by concentration of the washed ethereal solution to dryness gave 179 mg. of residue, which was crystallized from a small volume of cold ether, giving fluffy crystals of pregnane-3α,20β,21-triol-11-one 3-acetate; m. p. 121–123°, $[\alpha]^{25}D$ + 66°. The rotation was taken on a sample which had been heated briefly *in vacuo* at 130° to remove solvent of crystallization, which clung tenaciously to the crystals.

**Pregnane-3α,20α,21-triol-11-one 3-Acetate (XXVI).**—This compound was prepared from the corresponding 3-acetate acetonide (XXV) in the same manner. After recrystallization from dilute methanol it melted at 156–158°; $[\alpha]^{25}D$ + 74°.

*Anal.* Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.22; H, 9.21.

The two epimeric 3-monoacetates (XXVI and XVI) formed a molecular compound, m. p. 188–193°. A sample of this compound was chromatographed and then melted at about 195–197°.

**Pregnane-3α,20β,21-triol-11-one Triacetate (XV).**—Acetylation of pregnane-3α,20β,21-triol-11-one 3-acetate, m. p. 121–123°, with pyridine–acetic anhydride in the usual manner gave the triacetate; m. p. 158–159°, $[\alpha]^{25}D$ + 78°.

*Anal.* Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 68.11; H, 8.40.

**Pregnane-3α,20α,21-triol-11-one Triacetate (XXIV).**—Acetylation of the corresponding 3α,20α,21-triolone 3-acetate, m. p. 156–158°, gave the triacetate; m. p. 148°, $[\alpha]^{25}D$ + 49.5°.

*Anal.* Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Found: C, 67.96; H, 8.17.

**Pregnane-3α,20β,21-triol-11-one (XII).**—Saponification of pregnane-3α,20β,21-triol-11-one triacetate, m. p. 158–159°, gave the readily crystalline triol as heavy prisms from dilute alcohol; m. p. 235°, $[\alpha]^{25}D$ + 53° (alc.).

*Anal.* Calcd. for $C_{21}H_{34}O_4$: C, 71.95; H, 9.77. Found: C, 72.03; H, 9.51.

**Pregnane-3α,20α,21-triol-11-one (XXIII).**—Saponification of the 3α,20α,21-triolone triacetate gave the free triolone, m. p. 219–221°, $[\alpha]^{25}D$ + 55°.

*Anal.* Calcd. for $C_{21}H_{34}O_4$: C, 71.95; H, 9.77. Found: C, 72.10; H, 9.40.

**Pregnane-3α,20α,21-triol-11-one 3,21-Diacetate (XXVII).**—A solution of 207 mg. of pregnane-3α,20α,21-triol-11-one 3-acetate, m. p. 156–158°, in 0.58 cc. of pyridine containing 58 mg. (1.2 molecular equivalents) of acetic anhydride was left at room temperature overnight. Removal of the solvents *in vacuo* and chromatography of the residue gave 113 mg. of crude diacetate fractions following the elution of 60 mg. of the triacetate, m. p. 148°. Recrystallization from ether–petroleum ether afforded 90 mg. of the 3,21-diacetate; m. p. 136–137°, $[\alpha]^{25}D$ + 67°.

*Anal.* Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.81. Found: C, 69.32; H, 8.99.

**3α-Hydroxy-11-ketoetiocholanic Acid from Pregnane-3α,20α,21-triol-11-one.**—To a solution of 30 mg. of pregnane-3α,20α,21-triol-11-one, m. p. 219–221°, in 3 cc. of methanol was added 0.20 cc. of a 0.200 *N* solution of periodic acid. After standing at room temperature for two hours, the solution was diluted with 5 cc. of water, the methanol removed *in vacuo* and the oily aldehyde extracted with ether. The washed ethereal solution was concentrated to dryness, the residue dissolved in 1.5 cc. of acetone and treated with 0.40 cc. of a 5% aqueous solution of potassium permanganate. After ten minutes a few drops of dilute sulfurous acid was added, the acetone removed *in vacuo* and the crystalline precipitate filtered and washed with water. Recrystallization by concentration in a relatively large volume of acetone gave 3α-hydroxy-11-ketoetiocholanic acid, m. p. 282–286°. A mixed m. p. with an authentic sample (m. p. 289–293°) melted at 282–286°.

**Pregnane-3α,20β,21-triol-11-one 20,21-Acetonide.**—A suspension of 7.75 g. of pregnane-3α,20β,21-triol-11-one (XIII), m. p. 235°, in 300 cc. of acetone containing 15 g. of anhydrous zinc chloride was stirred until all of the crystals dissolved. After twenty hours the solution was treated in the usual manner (see above), giving a residue after removal of ether, which crystallized readily from ether–petroleum ether. The yield was 7.0 g. of acetonide, m. p. 138–141°, with 0.80 g. of a second crop melting slightly lower. Recrystallization of a sample from acetone–petroleum ether raised the m. p. to 141–142°.

*Anal.* Calcd. for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81. Found: C, 73.51; H, 9.57.

**Pregnane-20β,21-diol-3,11-dione Acetonide (XX).**—To a solution of 7.0 g. of pregnane-3α,20β,21-triol-11-one acetonide, m. p. 141–142°, in 100 cc. of dry *t*-butyl alcohol was added 5.0 g. of N-bromacetamide (monohydrate) followed by 10 cc. of pyridine. After the bromacetamide had gone into solution, the mixture was permitted to stand at room temperature for eighteen hours, then poured into a separatory funnel containing ether and a solution of 10 g. of sodium sulfite in 60 cc. of water. The mixture was shaken vigorously, the ethereal layer washed with water and concentrated to dryness. Crystallization from dilute alcohol gave 6.2 g. of diol-dione acetonide, which melted at about 163°, partially resolidified and melted again at 171–174°. A sample which was chromatographed and recrystallized from ether–petroleum ether consisted of fine needles, m. p. 168.5–169.0° with transformation into prisms; m. p. 179–180°, $[\alpha]^{25}D$ +55°.

*Anal.* Calcd. for $C_{24}H_{36}O_4$: C, 74.18; H, 9.34. Found: C, 74.25; H, 9.14.

**Pregnane-20β,21-diol-3,11-dione Diacetate (XXII) from Pregnane-20β,21-diol-3,11-dione Acetonide (XX).**—A sample of pregnane-20β,21-diol-3,11-dione acetonide, m. p. 169°; 180°, was hydrolyzed with hot dilute acetic acid, the solvents removed *in vacuo* and the residue acetylated in the usual manner. Crystals of pregnane-20β,21-diol-3,11-dione diacetate were obtained, m. p. and mixed m. p. 175°.

**Pregnane-3α,20β,21-triol-11-one 3,21-Diacetate (XVII).**—Pregnane-3α,21-diol-11,20-dione diacetate (XXX) (13.2 g., containing 10% of ether of crystallization) was dissolved in 30 cc. of acetic acid. The solution was concentrated to two-thirds volume *in vacuo* to remove ether, then diluted with 80 cc. of acetic acid and reduced under a pressure of 45 lb. of hydrogen, using 1.0 g. of platinum oxide as catalyst. After 1.0 mole of hydrogen had been consumed the reduction came nearly to a halt. The solution was filtered, concentrated to dryness *in vacuo* and taken up in ether. The ethereal solution was washed with dilute carbonate solution and with water, and concentrated to dryness. Crystallization of the residue from benzene–petroleum ether gave 8.35 g. of the 3α,20β,-21-triolone diacetate. After recrystallization from dilute methanol it melted at 189–190°; $[\alpha]^{25}D$ + 65° (+68° in alcohol).

*Anal.* Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.81. Found: C, 69.21; H, 8.90.

With acetic anhydride–pyridine the diacetate was converted to the 3α,20β,21-triolone triacetate, m. p. 159°. The mother liquors from the reduction product were acetylated and chromatographed. In addition to some starting material (diketone) and 3α,20β,21-triolone triacetate, about 5% of the 3α,20α,21-triolone triacetate, m. p. and mixed m. p. 148°, was isolated. Fractional crystallization of the two isomeric triacetates was facilitated by the fact that the 20β-triacetate was somewhat less soluble in cold ether than the 20α, while the latter was less soluble in cold methanol.

**Pregnane-3α,20β,21-triol-11-one 3,21-Diacetate 20-Tosylate (XVIII).**—A cold solution of 6.25 g. of pregnane-3α,20β,21-triol-11-one 3,21-diacetate in 30 cc. of pyridine was treated with 6.0 g. of recrystallized tosyl chloride. After three days at 0° the solution was diluted with water, extracted with benzene, the benzene layer washed with dilute hydrochloric acid, dilute carbonate and with water, then concentrated to dryness *in vacuo*. Crystallization of the residue from ether gave 7.4 g. of the diacetate tosylate, m. p. 175–176°.

*Anal.* Calcd. for $C_{32}H_{44}O_8S$: C, 65.28; H, 7.53. Found: C, 65.18; H, 7.56.

**Pregnane-3α,21-diol-11,20-dione 3-Acetate 21-Formate (XXI).**—A portion (500 mg.) of 21-diazopregnane-3α-ol-11,20-dione acetate (dec. 117–124°; prepared according to the method of Lardon and Reichstein, ref. 15) was added to 3.5 cc. of 90% formic acid. After three minutes the crystals had dissolved with evolution of nitrogen. The solution was warmed gently on the steam-bath for a few seconds, until a pink color began to replace the pale yellow cast. The solution was then diluted with water, extracted with ether, the ethereal layer washed with alkali and with water and concentrated to dryness. Crystallization from a small volume of ether gave dense prisms of the formate, m. p. 153° after recrystallization from alcohol and from ether. The mother liquor was chromatographed, giving in all 430 mg. of acetate formate.

*Anal.* Calcd. for $C_{24}H_{34}O_6$: C, 68.87; H, 8.19. Found: C, 69.02; H, 8.03.

**Pregnane-3α,21-diol-11,20-dione 3-Acetate (XXXII).**—A solution of 170 mg. of the acetate formate, m. p. 153°, in 5 cc. of methanol was treated with a solution of 200 mg. of potassium bicarbonate in 2.0 cc. of water. The mixture was stirred for ten minutes, acidified with a few drops of acetic acid, concentrated to a small volume *in vacuo* and extracted with ether. Evaporation of the washed ethereal solution, followed by crystallization of the residue from a small volume of ether gave 129 mg. of pregnane-3α,21-diol-11,20-dione 3-acetate, m. p. 137–138°.

*Anal.* Calcd. for $C_{23}H_{34}O_5$: C, 70.73; H, 8.79. Found: C, 70.69; H, 8.75.

**Pregnane-3α,20β,21-triol-11-one (VI) 3-Acetate from Pregnane-3α,21-diol-11,20-dione 2-Acetate (XXXII).**—The catalytic reduction of 2.48 g. of pregnane-3α,21-diol-11,20-dione 3-acetate, m. p. 137–138°, in 100 cc. of glacial acetic acid, using 1.0 g. of platinum oxide under 45 lb. of pressure was completed in an hour. The filtered solution was concentrated to dryness *in vacuo*, the residue dissolved in ether, washed with alkali and water and concentrated to dryness. Crystallization from a small volume of cold absolute ether gave 2.1 g. of fluffy solvated crystals, m. p. 120–126°. Recrystallization from ethyl acetate–petroleum ether gave a sample of m. p. 100–106° (bubbling). Saponification gave pregnane-3α,20β,21-triol-11-one, m. p. and mixed m. p. 235–236°. For analysis a sample was dried in a weighing pig at 130°.

*Anal.* Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.55; H, 9.10. Weight loss: 2.18%.

**Acknowledgments.**—The author wishes to express his indebtedness to Dr. Karl Folkers for his active association with this work, to Dr. Everett S. Wallis of Princeton University for valuable suggestions, and to Miss Jean E. Andrews for assistance. The author is indebted to Mr. R. N. Boos and his associates for microanalyses.

## Summary

The preparation and correlation of derivatives of pregnane-3α,20α and β-diol-11-one and the corresponding 3-ketones have been described. Similar correlations in the pregnane-3α,20α and β-21-triol-11-one series have been made.

# Stereoisomeric Substituted 11-Keto-20-hydroxypregnanes. II

BY L. H. SARETT

In Part I of this series[1] the preparation of various derivatives of the stereoisomeric 11-keto-20-hydroxypregnanes and 11-keto-20,21-dihydroxypregnanes was described. Part II deals with the two remaining classes of 11-keto-20-hydroxypregnanes.

## Class C. 11-Keto-17(α),20-dihydroxypregnanes[2]

A useful starting material for the preparation of compounds of this class is pregnane-3α,17α-diol-11,20-dione[3] (I). Since the assignment of the α-configuration to the C-17 hydroxyl was, however, based on indirect evidence, it was felt that more conclusive stereochemical proof was desirable before proceeding to an investigation of the reduction products of this compound. To this end a device employed by von Euw and Reichstein[4] for converting substance P to substance L was used. Pregnane-3α,17α,21-triol-11,20-dione 3,21-diacetate,[2] which has been linked[5] sterically with the naturally occurring $\Delta^4$-pregnene-17α,21-diol-3,11,-20-trione (Kendall's compound E), was treated with methylmagnesium iodide, giving 20-methylpregnane-3α,17α,20 (α and β), 21-tetrol-11-one. When periodic acid cleavage of this mixture then yielded I, the α-configuration of the 17-hydroxyl in the latter compound was established.

The catalytic reduction of pregnane-3α,17α-diol-11,20-dione 3-acetate (II) gave both of the epimeric triolones. By benzoylation of the reduction mixture 15% of a highly crystalline 3-acetate 20-benzoate (XII) could be isolated. Upon saponification it yielded the 3α,17α,20α-triolone (VIII) which was identical with that previously obtained[6]

by hydroxylation of a $\Delta^{17}$-pregnen-3$\alpha$-ol-11-one. The major product of the reduction was best separated by conversion of the reduction mixture to the diacetates. Repeated crystallization then yielded pregnane-3$\alpha$,17$\alpha$,20$\beta$-triol-11-one 3,20-diacetate[7] (V). By saponification the new 3$\alpha$,-17$\alpha$,20$\beta$-triolone (III) was obtained.

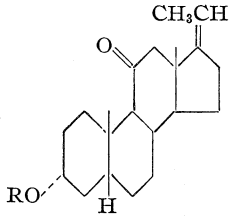
XV R = Ac

In order to prepare the 3-keto derivatives corresponding to the triolones III and VIII, the respective 20-monoacetates were required. In the 20$\beta$-series the 20-monoacetate (IV) was readily obtained by partial saponification of the diacetate. Oxidation and hydrolysis then yielded pregnane-17$\alpha$,20$\beta$-diol-3,11-dione (VI). This compound was identical with a pregnane-17,20-diol-3,11-dione previously described in the literature.[8] Pregnane-17$\alpha$,20$\alpha$-diol-3,11-dione (XIV) was derived from the free triolone VIII by partial acetylation. Surprisingly enough, the product which was isolated by chromatography was the 20-monoacetate (X), although doubtless the anticipated 3-monoacetate was also formed. Conversion of X to pregnane-17$\alpha$,20$\alpha$-diol-3,11-dione (XIV) was then carried out as before.

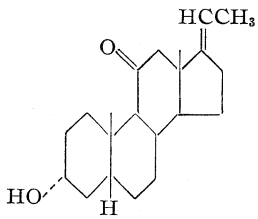
A second method for obtaining derivatives of 11-keto-17,20-dihydroxypregnanes was the hydroxylation of $\Delta^{17}$-11-ketopregnenes. Insofar as the simple preparation of one or both of the dihydroxypregnanes (III and VIII) was concerned, hydroxylation of one of the mixtures of $\Delta^{17}$- and $\Delta^{20}$-pregnenes formed by various reactions was quite satisfactory. It rapidly became apparent, however, that the nature of the products depended so markedly on the nature of the starting mixture that the simple interpretation of the latter as composed of one of the two possible geometrically isomeric $\Delta^{17}$-pregnenes together with the $\Delta^{20}$-pregnene was dubious. Hence a closer examination of the components of these mixtures was undertaken.

The preparation and hydroxylation of a pure $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one (XVI) which melted at 192° have been described.[7] When a crystalline product from the mother liquors of this compound was treated with osmium tetroxide, hydrolyzed and the product acetylated, it was not, however, the 3$\alpha$,17$\alpha$,20$\alpha$-triol diacetate (IX) which was isolated but the epimeric 3$\alpha$,17$\alpha$,20$\beta$-triol diacetate (IV). Only two explanations for these results seemed possible: Either the presence of impurities altered the stereochemical course of the reaction in some unknown way or else a second component reacted with the osmium tetroxide to form IV. In order to test the first possibility, the hydroxylation of mixtures of the pure $\Delta^{17}$-pregnene with coprostanone and also with benzoyl peroxide was carried out. The addition of these substances neither altered the nature of the product (VIII) nor diminished the yield. Hence the second and likelier possibility was explored.



If a second component gave rise to the 3$\alpha$,17$\alpha$,-20$\beta$-triolone, it could only be the geometrically isomeric $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one (XVIa), which upon attack of the osmium tetroxide at the rear of the 17,20 linkage would give a 17$\alpha$,20$\beta$-glycol osmate ester. Attempts to isolate this hypothetical geometrical isomer by chromatography and fractional crystallization of the detosylated mother liquor unfortunately were unsuccessful. The higher melting fractions eventually gave pure XVI, while the lower melting fractions remained mixtures with inconstant properties.

The mixture of pregnenes prepared by diazotization of 20-aminopregnane-3$\alpha$-ol-11-one 3-acetate was then examined. Since only one 3$\alpha$,17,20-triolone was obtained by hydroxylation of this mixture and it was the 17$\alpha$,20$\beta$-isomer (see Part I), it seemed possible that the sought for $\Delta^{17}$-geometrical isomer might be present. Accordingly, the pregnene mixture was submitted to extensive recrystallization. A compound which melted at 154° was isolated in small amount but it appeared



(7) Evidence for the assignment of configuration to the C-20 hydroxyl group is presented in Part III of this series.

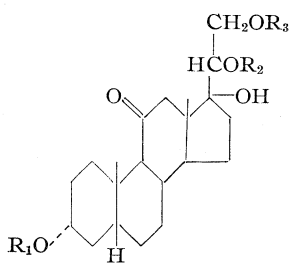
When $\Delta^{17}$-21-bromopregnene-3$\alpha$-ol-11-one acetate[10] was reduced with zinc and acetic acid and the product saponified, a compound which gave pregnane-3$\alpha$,20($\alpha$ and $\beta$),21-triol-11-one upon hydroxylation was isolated. Evidently the bromide was reduced as a resonating ion, giving a mixture of isomeric pregnenes of which only the least soluble—the $\Delta^{20}$—was separated. The dehydration of pregnane-3$\alpha$,17$\beta$-diol-11-one acetate with phosphorus oxychloride also gave a mixture of crystalline unsaturates, from which no pure compound was obtained. However, in spite of the failure to obtain a pure sample of the geometrical isomer of $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one, the evidence described appears strongly to indicate its existence in those mixtures which yielded the triolone III on hydroxylation.



An interesting and perhaps generally useful procedure for the hydrolysis of osmate esters under milder conditions than previously suggested[11] was uncovered in our work on the 17,20-glycols. Since even the relatively gentle conditions described by Criegee and co-workers[11] lead to partial hydrolysis of acetate groups in the molecule, the restoration of such an acetate group must ordinarily be accomplished by preferential esterification. This must be the approach, for example, in the preparation of the 3-monoacetate of a 3,-17,20-triol, in which the protection of the glycol group by an acetonide bridge is not possible. It was found, however, that if the aqueous sodium sulfite solution was added at room temperature to the solution of osmate ester in alcohol containing about 20% of ether, hydrolysis of the osmate linkages occurred far more rapidly than hydrolysis of the acetate group. By this method $\Delta^{17}$-pregnene-3$\alpha$-ol-11 one acetate gave 80% of pregnene-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one 3-acetate (XI). The difference is probably to be ascribed to the physical state of the sodium sulfite, which in the presence of ether separates as a gummy, moderately soluble layer instead of the ordinary nearly insoluble crystals.

## Class D. 11-Keto-17$\alpha$,20,21-trihydroxypregnanes

An important source of members of this class is the $\Delta^{17}$-21-hydroxypregnenes. These have been prepared by the classical allylic rearrangement method[12] and also by the 20-tosylate–collidine reaction.[6] Since the problem of geometrical isomerism arose in connection with the preparation of 17,20-dihydroxypregnanes from $\Delta^{17}$-pregnenes, evidence for this type of isomerism in the 21-hydroxy-$\Delta^{17}$-pregnene series was sought. However, it was found that by either method of preparation only one $\Delta^{17}$-pregnene-3$\alpha$,21-diol-11-one[8] was obtained. Hydroxylation of this compound yielded pregnane-3$\alpha$,17$\alpha$,20$\beta$,21-tetrol-11-one (XX), which could be linked sterically with the previously described pregnane-17$\alpha$,20$\beta$,21-triol-3,11-dione[13] by oxidation of the acetonide (XXIII). The 3,21-diacetate (XXI) was prepared by reduction of pregnane-3$\alpha$,17$\alpha$,21-triol-11,20-dione 3,21-diacetate. Acetylation of the mother

XX $R_1 = R_2 = R_3 = H$
XXI $R_1 = R_3 = Ac$, $R_2 = H$
XXII $R_1 = R_2 = R_3 = Ac$
XXIII $R_1 = H$, $R_2R_3 = >C(CH_3)_2$
XXIV $R_1 = Ac$, $R_2R_3 = >C(CH_3)_2$

XXV $R_1 = R_2 = R_3 = H$
XXVI $R_1 = R_2 = R_3 = Ac$

(9) The two samples agreed in all properties except the melting points of the acetates. Very likely neither sample was entirely free from isomorphous pregnene-3$\alpha$-ol-11-one isomers.

(13) This compound was named according to the earlier system of nomenclature pregnane-17$\beta$,20$\beta$,21-triol-3,11-dione.

liquors of XXI, followed by chromatographic separation permitted the isolation of 10% of the epimer (XXVI), pregnane-3α,17α,20α,21-tetrol-11-one triacetate.

## Experimental[14]

**Pregnane-3α,17α-diol-11,20-dione (I) from Pregnane-3α,17α,21-triol-11,20-dione Diacetate.**—A solution of 511 mg. of pregnane-3α,17α,21-triol-11,20-dione 3,21-diacetate, m. p. 233–236°, in 40 cc. of warm anhydrous benzene was treated with 20 cc. of an ethereal solution of methylmagnesium iodide prepared from 5 g. of methyl iodide and 0.75 g. of magnesium. The suspension was permitted to stand at room temperature for two days, then poured into 0.1 *N* hydrochloric acid, the benzene layer washed and concentrated to dryness. The residue deposited 160 mg. of poorly formed crystals from a small volume of acetone, which after recrystallization gave 44 mg., m. p. 215–237°. This partially purified product, 20-methylpregnane-3α,17α,20,21-tetrol-11-one, was then dissolved in 3 cc. of methanol, and treated with 1.5 cc. of 0.200 *N* periodic acid. The solution was then concentrated *in vacuo* to half-volume, left at room temperature for three hours, then concentrated to *ca.* 1.5 cc. *in vacuo*. Recrystallization of the precipitate from dilute methanol and from ether gave pregnane-3α,17α,diol-11,20-dione, m. p. 205–207°. A mixed m. p. with an authentic sample, m. p. 206–208°, showed no depression.

**Pregnane-3α,17α,20α-triol-11-one 3-Acetate 20-Benzoate (XII).**—A solution of 250 mg. of pregnane-3α,17α-diol-11,20-dione 3-acetate (II) in 25 cc. of acetic acid was shaken under hydrogen with 300 mg. of platinum oxide until 1.0 mole of hydrogen was consumed. After the usual working up, the residue was dissolved in 2.0 cc. of pyridine and treated with 0.4 cc. of benzoyl chloride. The mixture was left at room temperature overnight, diluted with water, extracted with ether, the ethereal layer washed with dilute hydrochloric acid, dilute carbonate solution and with water. Concentration to dryness gave 350 mg. of residue which deposited 48 mg. of crystals from a small volume of methanol. Recrystallization from chloroform–alcohol and chloroform–ether gave the 3α,17α,20α-triolone acetate benzoate, m. p. 264–265°.

*Anal.* Calcd. for $C_{30}H_{40}O_6$: C, 72.55; H, 8.11. Found: C, 72.88; H, 7.84.

Saponification of a sample of the acetate benzoate gave pregnane-3α,17α,20α-11-one; m. p. 211–212°, $[\alpha]^{25}D$ +23°. A mixed m. p. with an authentic sample gave no depression. It was found that an unsolvated, well-crystallized form could be obtained by crystallization from anhydrous acetone.

*Anal.* Calcd. for $C_{21}H_{34}O_4$: C, 71.95; H, 9.79. Found: C, 71.97; H, 9.81.

**Pregnane-3α,17α,20β-triol-11-one 3,20-Diacetate (V) from Pregnane-3α,17α-diol-11,20-dione (I).**—The crude product from the catalytic reduction of 420 mg. of pregnane-3α,17α-diol-11,20-dione was acetylated in the usual manner. After several recrystallizations of the product from dilute acetone, 320 mg. of pregnane-3α,17α,20β-triol-11-one 3,20-diacetate was obtained, m. p. and mixed m. p. 249–250°. Chromatography of the mother liquors gave lower melting mixtures from which no pure 3α,17α,20α-triolone diacetate could be isolated.

**Pregnane-3α,17α,20β-triol-11-one (III).**—Saponification of pregnane-3α,17α,20β-triol-11-one 3,20-diacetate, m. p. 249–250°, afforded the free triolone, m. p. 220° after recrystallization from dilute methanol or acetone–ether. A double melting point of 179°, 220° was occasionally observed; $[\alpha]^{25}D$ +38°.

*Anal.* Calcd. for $C_{21}H_{34}O_4$: C, 71.95; H, 9.79. Found: C, 72.04; H, 9.76.

**Pregnane-3α,17α,20β-triol-11-one 20-Acetate (IV).**—To a warm mixture of 10.0 cc. of benzene and 1.0 cc. of methanol was added 565 mg. of pregnane-3α,17α,20β-triol-11-one 3,20-diacetate. The solution was quickly cooled to 25° and treated with 10 cc. of a solution of 1.1*N* methanolic potassium hydroxide. After two and one-half minutes, the potassium hydroxide was neutralized with acetic acid, the solvents removed *in vacuo*, and the residue extracted with chloroform. The washed chloroform extract was concentrated to dryness, the partially crystalline residue dissolved in benzene and chromatographed over 15 g. of acid-washed alumina. After elution of diacetate (ether) 235 mg. of crude 20-monoacetate was eluted with chloroform. Recrystallization from ethyl acetate and dilute methanol gave 180 mg. of the 3α,17α,20β-triolone 20-acetate; m. p. 231–234°, $[\alpha]^{25}D$ + 55°.

*Anal.* Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.34; H, 9.44.

**Pregnane-17α,20β-diol-3,11-dione 20-Acetate (VII) from Pregnane-3α,17α,20β-triol-11-one 20-Acetate (IV).**—A solution of 17 mg. of the 3α,17α,20β-triolone 20-acetate, m. p. 231–234°, in 1.0 cc. of 90% acetic acid was treated at 15° with 0.30 cc. of 90% acetic acid containing 15 mg. of chromic acid. The solution was allowed to warm to 25° and, after forty-five minutes, water was added to induce crystallization of the product. Recrystallization from methanol gave pregnane-17α,20β-diol-3,11-dione 20-acetate, m. p. 222–224°. Admixture with an authentic specimen, m. p. 222.0–224.5°, showed no depression.[15]

**Pregnane-3α,17α,20α-triol-11-one 20-Acetate (X).**—To 0.60 cc. of pyridine containing 91 mg. of acetic anhydride was added 248 mg. of pregnane-3α,17α,20α-triol-11-one, m. p. 211–212°. After standing at room temperature overnight, the solution was concentrated to dryness *in vacuo*, the residue dissolved in benzene and chromatographed. The fractions eluted with chloroform gave 164 mg. of crystalline 3α,17α,20α-triolone 20-acetate; m. p. 212°, $[\alpha]^{25}D$ +2°.

*Anal.* Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.65; H, 9.40.

**Pregnane-17α,20α-diol-3,11-dione 20-Acetate (XV).**—A solution of 131 mg. of pregnane-3α,17α,20α-triol-11-one 20-acetate (X) was oxidized with chromic acid in the usual manner. Dilution of the oxidation mixture with water and addition of sufficient solid potassium carbonate to neutralize most of the acetic acid gave a crystalline precipitate, which after recrystallization from dilute methanol and ether afforded 90 mg. of pure 17α,20α-diol-dione 20-acetate; m. p. 182–183°, $[\alpha]^{25}D$ + 12°.

*Anal.* Calcd. for $C_{23}H_{34}O_5$: C, 70.73; H, 8.79. Found: C, 70.77; H, 8.53.

**Pregnane-17α,20α-diol-3,11-dione (XIV).**—A solution of 90 mg. of pregnane-17α,20α-diol-3,11-dione 20-acetate, m. p. 182–183°, in a mixture of 3.0 cc. of methanol and 1.0 cc. of 1 *N* aqueous potassium hydroxide was refluxed for three minutes. The methanol was then removed *in vacuo*, the aqueous suspension acidified with a few drops of acetic acid and extracted with chloroform. The washed chloroform solution was concentrated to dryness *in vacuo*, the residue crystallized from ether and again from acetone–ether; m. p. 190–191°, $[\alpha]^{25}D$ +32.5°.

*Anal.* Calcd. for $C_{21}H_{32}O_4$: C, 72.39; H, 9.25. Found: C, 72.55: H, 9.31.

**Pregnane-3α,17α,20β-triol-11-one Diacetate (IV) from Crude $\Delta^{17}$-Pregnene-3α-ol-11-one.**—The mother liquors obtained from the methanol recrystallizations of $\Delta^{17}$-pregnene-3α-ol-11-one (prepared by treatment of the 3α,20β-diolone acetate tosylate with collidine, followed by saponification of the product) were concentrated to a small volume, diluted with a small volume of water, and left at 0°. A fluffy crystalline precipitate formed, m. p. 130–160°. Since fractional recrystallization of this mixture led only to the isolation of small amounts of the high

(14) Melting points were taken on the Kofler micro hot stage; rotations unless otherwise indicated were taken in acetone, $c$ = 1.0.

(15) These values are characteristic of freshly prepared samples of this compound. Long heating *in vacuo* raises the m. p. as much as 7°.

melting $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one, together with various fractions of inconstant properties, and chromatography likewise gave no appreciable separation, a portion of the crystalline mixture was hydroxylated with osmium tetroxide in the usual manner, and the product acetylated. After chromatography about 25% of the 3$\alpha$,17$\alpha$,20$\beta$-triolone diacetate, m. p. and mixed m. p. 249–250°, was obtained.

**Reaction of Pure $\Delta^{17}$-Pregnene-3$\alpha$-ol-11-one with Osmium Tetroxide in the Presence of:**

**A. Benzoyl Peroxide.**—A solution of 100 mg. of $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one, m. p. 192°, in 20 cc. of absolute ether containing 25 mg. of benzoyl peroxide was treated with 100 mg. of osmium tetroxide followed by 0.05 cc. of pyridine. The precipitated osmate ester was filtered, hydrolyzed and the triol acetylated as usual. Pregnane-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one diacetate, m. p. 228–229°, was obtained in 80% yield.

**B. Acetone.**—Repetition of the reaction, substituting 45 mg. of acetone for the benzoyl peroxide led to the same results.

**C. Coprostanone.**—Substitution of 125 mg. of coprostanone for the benzoyl peroxide gave the same results.

**$\Delta^{20}$-Pregnene-3$\alpha$-ol-11-one (XVIII) from 20-Aminopregnane-3$\alpha$-ol-11-one 3-Acetate.**—One gram of the chromatographically purified mixture of pregnene-3$\alpha$-ol-11-one acetate isomers obtained by diazotization of the 20-amine was saponified by refluxing for fifteen minutes with 20 cc. of 1 *N* methanolic potassium hydroxide. Dilution and cooling of the solution gave 380 mg. of an almost gelatinous crystal mass, m. p. 136–140°. Repeated recrystallization from dilute methanol and ether–petroleum ether raised the melting point to 153–154°; $[\alpha]^{25}D$ +37°. It did not depress the m. p. of $\Delta^{20}$-pregnene-3$\alpha$-ol-11-one (see below). Acetylation gave an acetate, m. p. 115–116°.

The addition of water to the mother liquors of the original saponification product caused the slow deposition of 400 mg. of crystals of the same appearance as the pregnene-3$\alpha$-ol-11-one of m. p. 153°. They melted, however, at 97–99° and, after four recrystallizations, more or less constantly at 116–117°; there was not enough of this material for an analysis of the hydroxylation products.

**$\Delta^{20}$-Pregnene-3$\alpha$-ol-11-one (XVIII) from $\Delta^{17}$-21-Bromopregnene-3$\alpha$-ol-11-one Acetate.**—To a solution of 1.35 g. of $\Delta^{17}$-21-bromopregnene-3$\alpha$-ol-11-one acetate in 10 cc. of acetic acid was added 2.0 g. of zinc dust portionwise, with warming on the steam-bath. After fifteen minutes, the solution was cooled, diluted with water, extracted with ether, the ether layer washed with aqueous carbonate and concentrated to dryness. The residue was refluxed with 1.0 *N* methanolic potassium hydroxide for ten minutes, water added, the methanol removed *in vacuo* and the precipitated product extracted with ether. The residue from the concentration of the ethereal solution weighed 935 mg. and was purified chromatographically, giving 550 mg. of $\Delta^{20}$-pregnene-3$\alpha$-ol-11-one; m. p. 153–154°; $[\alpha]^{25}D$ + 38.5°.

*Anal.* Calcd. for $C_{21}H_{32}O_2$: C, 79.68; H, 10.12. Found: C, 79.46; H, 10.26.

Acetylation of a sample of this alcohol gave an acetate, m. p. 106°. A mixed m. p. with the $\Delta^{20}$ acetate of m. p. 116° was 109–111°. Refluxing a sample of the alcohol with collidine–collidinium tosylate did not appreciably alter its properties.

Treatment of the $\Delta^{20}$-pregnenolone, m. p. 153–154°, with osmium tetroxide and acetylation of the hydrolysis product in the usual manner gave a mixture of prismatic crystals and clusters of needles, resembling the usual mixture of pregnane-3$\alpha$,20($\alpha$ and $\beta$), 21-triol-11-one triacetate. Recrystallization from methanol gave the pure 3$\alpha$,20$\alpha$,21-triolone triacetate, m. p. and mixed m. p. 147.5–148.5°. Several crystallizations of the mother liquors from ether yielded the 3$\alpha$,20$\beta$,21-triolone triacetate, m. p. and mixed m. p. 157–159°.

**Pregnane-3$\alpha$,17$\beta$-diol-11-one 3-Acetate.**—A solution of 899 mg. of $\Delta^{20}$-pregnene-3$\alpha$,17$\beta$-diol-11-one in 50 cc. of alcohol was shaken under hydrogen with 200 mg. of platinum oxide until absorption of hydrogen ceased. The solution was then filtered, concentrated to a small volume and precipitated as the crystalline hydrate, m. p. 123°; 175–177°, by addition of water. Recrystallization from wet ether did not change the properties. The acetate was prepared by permitting 815 mg. of the diol to stand at room temperature overnight in 2.0 cc. of pyridine and 2.0 cc. of acetic anhydride. It melted at 208–209°; $[\alpha]^{25}D$ + 60°.

*Anal.* Calcd. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64. Found: C, 73.58; H, 9.70.

**Dehydration of Pregnane-3$\alpha$,17$\beta$-diol-11-one 3-Acetate.**—A solution of 800 mg. of pregnane-3$\alpha$,17$\beta$-diol 3-acetate in 4 cc. of pyridine was treated with 0.5 cc. of phosphorus oxychloride and the solution left overnight. Dilution with water, followed by extraction with petroleum ether and concentration of the washed solution gave 680 mg. of a mobile colorless oil which would not crystallize from a small volume of cold methanol, even upon seeding with any of the low melting isomorphous mixtures of pregnene-3$\alpha$-ol-11-one acetate isomers. Saponification of the unsaturated acetate and dilution of the cold methanolic solution gave a flocculent mass which melted at *ca.* 130°. Recrystallizations from dilute methanol gave similar mixtures, m. p. 125–128°.

**Pregnane-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one 3-Acetate (XI).**—To a solution of 900 mg. of $\Delta^{17}$-pregnene-3$\alpha$-ol-11-one acetate, m. p. 122–123°, in 10 cc. of absolute ether was added 800 mg. of osmium tetroxide and 0.4 cc. of pyridine. After five minutes the precipitated osmate ester was redissolved by addition of 45 cc. of alcohol and 5 cc. of benzene. To this solution was added 2.0 g. of sodium sulfite dissolved in 30 cc. of water, and the reddish mixture was shaken for ten minutes at room temperature. The upper layer, which was then nearly colorless, was decanted, the semi-solid lower layer washed with 70% alcohol, the combined alcoholic extracts acidified with a few drops of acetic acid and concentrated to a small volume *in vacuo*. The crystalline precipitate (920 mg.) was filtered, washed with water, and recrystallized from dilute alcohol and acetone–petroleum ether, giving 750 mg. of the 3$\alpha$,17$\alpha$,20$\alpha$-triolone 3-acetate; m. p. 220–223°, $[\alpha]^{25}D$ + 43°.

*Anal.* Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24. Found: C, 70.22; H, 9.23.

Upon acetylation a sample gave pregnane-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one 3,20-diacetate, m. p. and mixed m. p. 228–229°.

**Pregnane-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one 3-Acetate 20-Tosylate (XIII).**—A solution of 456 mg. of pregnane-3$\alpha$,17$\alpha$,20$\alpha$-triol-11-one 3-acetate, m. p. 220–223°, in 1.0 cc. of pyridine was treated with 450 mg. of tosyl chloride and left at 0° overnight. After dilution with water, extraction with benzene, washing with dilute hydrochloric acid, dilute sodium carbonate and with water and concentration to dryness *in vacuo*, the tosylate was obtained as prisms from ether; yield, 489 mg. The compound melted with decomposition at temperatures ranging from 145–146° to 158–159°, depending on the rate of heating.

*Anal.* Calcd. for $C_{30}H_{42}O_7S$: C, 65.92; H, 7.73. Found: C, 66.08; H, 7.51.

**$\Delta^{17}$-Pregnene-3$\alpha$,21-diol-11-one from Pregnane-3$\alpha$,-20$\beta$,21-triol 3,21-Diacetate 20-Tosylate.**—A solution of 9.0 g. of pregnane-3$\alpha$,20$\beta$,21-triol-11-one 3,21-diacetate 20-tosylate in 50 cc. of collidine (purified through the hydrobromide), was refluxed for twenty-five minutes. The cooled solution was diluted with ether, cooled with ice and washed with sufficient dilute hydrochloric acid to remove the collidine. The ethereal solution was then washed with dilute sodium carbonate and with water and concentrated to dryness. The residue was dissolved in 50 cc. of benzene–petroleum ether and put on a column of 130 g. of alumina. Elution with 500 cc. of ether gave 6.4 g. of colorless oil, which was saponified by heating with 1 *N* methanolic potassium hydroxide. Dilution of the cooled solution with water gave crystals which after recrystallization from dilute alcohol and acetone–ether yielded 2.6 g. of impure $\Delta^{17}$-pregnene-3$\alpha$,21-diol-11-one.

This was purified through the diacetate, m. p. and mixed m. p. 112–113°. Saponification afforded the diol, m. p. and mixed m. p. 200–201°. Further crystallization of the mother liquors led only to isolation of an additional amount of the same diol.

**Pregnane-3α,17α,20β,21-tetrol-11-one 20,21-Acetonide (XXIII).**—A sample (422 mg.) of $\Delta^{17}$-pregnene-3α,21-diol-11-one diacetate, m. p. 113°, in absolute ether was treated with osmium tetroxide and pyridine, then hydrolyzed with hot aqueous alcoholic sodium sulfite in the usual manner. The filtered and concentrated aqueous suspension was extracted thrice with 50 cc. of chloroform and the chloroform solution concentrated to dryness. The residue (271 mg.) was crystallized from acetone and from alcohol. The crude tetrol melted at 245–255° and was purified through the acetonide; 196 mg. of crude tetrol was dissolved in 10 cc. of a 5% solution of zinc chloride in acetone. After standing at room temperature overnight, the solution was treated with aqueous sodium carbonate, the acetone layer decanted, concentrated to a small volume *in vacuo*, extracted with ether and the product crystallized from ether, giving 170 mg. of the acetonide, m. p. 187°.

*Anal.* Calcd. for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42. Found: C, 70.82; H, 9.56.

Hydrolysis of a sample of the acetonide with hot aqueous acetic acid gave pure pregnane-3α,17α,20β,21-tetrol-11-one; m. p. 263–264°, $[\alpha]^{25}D$ + 37° (alc.).

**Pregnane-17α,20β,21-triol-3,11-dione Diacetate from Pregnane-3α,17α,20β,21-tetrol-11-one Acetonide (XXIII).**—A solution of 102 mg. of the 3α,17α,20β,21-tetrolone acetonide, m. p. 187°, in 5 cc. of dry benzene was treated with 3 cc. of anhydrous acetone and 300 mg. of aluminum isopropoxide. The mixture was refluxed overnight, then diluted with ether, washed with dilute hydrochloric acid and water and concentrated to dryness. The residue was heated with 1.0 cc. of 75% acetic acid for fifteen minutes, the solvents removed *in vacuo* and the residue heated with a mixture of acetic anhydride–pyridine for five minutes on the steam-bath. The solvents were again removed *in vacuo* and the residue chromatographed giving 20 mg. of the 17α,20β,21-triol-dione diacetate, m. p. 208–210°. A mixed melting point with an authentic sample (m. p. 209–211°) did not show a depression. A total of 65 mg. of the original tetrolone, in the form of its triacetate, m. p. 200–201°, was also obtained from the chromatogram.

**Pregnane-3α,17α,20β,21-tetrol-11-one 3,21-Diacetate (XXI).**—A solution of 2.25 g. of pregnane-3α,17α,21-triol-11,20-dione 3,21-diacetate in 75 cc. of acetic acid was shaken with 1.0 g. of platinum oxide under a pressure of 45 lb. of hydrogen until hydrogen uptake nearly ceased (1.0 mole consumed). Filtration of the solution and concentration *in vacuo* to dryness gave a residue which after crystallization from ether and from methanol yielded 1.15 g. of dense prisms. The 3α,17α,20β,21-tetrolone 3,21-diacetate melted at 201–203°; $[\alpha]^{25}D$ + 67°.

*Anal.* Calcd. for $C_{25}H_{38}O_7$; C, 66.54; H, 8.50. Found: C, 66.64; H, 8.74.

**Pregnane-3α,17α,20β,21-tetrol-11-one 3,20,21-Triacetate (XXII).**—The acetylation of a sample of the 3α,17α,-20β,21-tetrolone with pyridine–acetic anhydride gave crystals from dilute methanol; m. p. 201°, $[\alpha]^{25}D$ + 103°.

*Anal.* Calcd. for $C_{27}H_{30}O_8$: C, 65.83; H, 8.18. Found: C, 66.01; H, 7.88.

**Pregnane-3α,17α,20α,21-tetrol-11-one 3,20,21-Triacetate (XXVI).**—The mother liquors from the crystallization of pregnane-3α,17α,20β,21-tetrol-11-one 3,21-diacetate (see above), amounting to 1.15 g., were chromatographed on 40 g. of alumina. Elution with ether–chloroform mixtures with an increasing proportion of chloroform gave oily fractions which were combined and deposited an additional 300 mg. of the 3α,17α,20β,21-tetrolone diacetate from a small volume of ether. The mother liquors from this crystallization were evaporated to dryness and the residue (416 mg.) acetylated with acetic anhydride–pyridine. Dilution of the reaction mixture with water gave 353 mg. of crude 3α,17α,20α,21-tetrolone triacetate. After six recrystallizations from dilute acetone and from methanol, the pure triacetate was obtained; m. p. 213–214°, $[\alpha]^{25}D$ + 18°.

*Anal.* Calcd. for $C_{27}H_{40}O_8$: C, 65.83; H, 8.18. Found: C, 65.90; H, 8.19.

**Pregnane-3α,17α,20α,21-tetrol-11-one (XXV).**—Saponification of 30 mg. of the 3α,17α,20α,21-tetrolone triacetate, m.p. 213–214°, followed by concentration of the solution *in vacuo* and extraction of the aqueous suspension with a large volume of chloroform gave 16 mg. of amorphous residue. Crystallization from a small volume of acetone yielded 14 mg. of the tetrolone; m.p. 208–209°, $[\alpha]^{25}D$ + 44° (alc., $c = 0.5$).

**Pregnane-3α,17α,20β,21-tetrol-11-one 3-Acetate 20,-21-Acetonide (XXIV).**—A portion (700 mg.) of pregnane-3α,17α,20β,21-tetrol-11-one 20,21-acetonide was dissolved in a mixture of 2.0 cc. of pyridine and 1.0 cc. of acetic anhydride and heated on the steam-bath for ten minutes. The solvents were removed *in vacuo* and the residue chromatographed over alkaline alumina. Mixtures of ether–petroleum ether eluted 700 mg. of the crystalline acetate acetonide, which melted after recrystallization from benzene–petroleum ether at 190–191°.

*Anal.* Calcd. for $C_{26}H_{40}O_6$: C, 69.62; H, 8.98. Found: C, 69.53; H, 8.91.

**Acknowledgments.**—The author wishes to express his indebtedness to Dr. Karl Folkers for his active association with this work, to Dr. Everett S. Wallis of Princeton University for various suggestions, and to Miss Jean E. Andrews for assistance. The author is indebted to Mr. R. N. Boos and his associates for microanalyses.

## Summary

The preparation and properties of a number of pregnane-3α,17α,20(α and β)-triol-11-one derivatives and correlations with the corresponding 3-keto compounds are described. Similar investigations of the 3α,17α,20(α and β), 21-tetrol-11-one series are described.

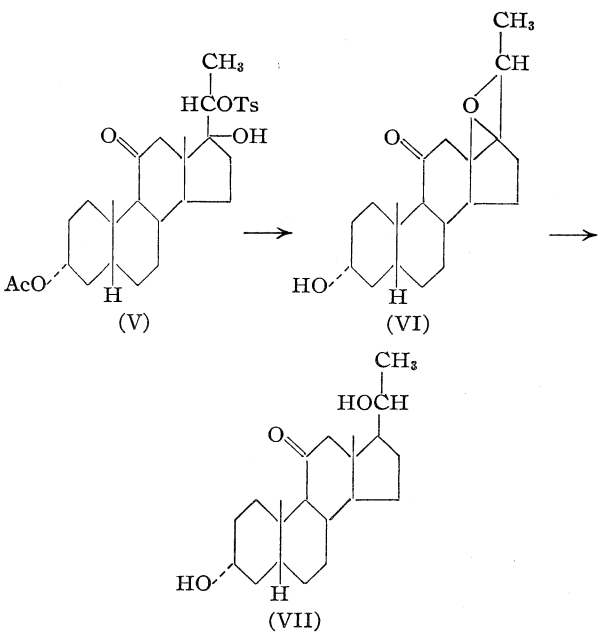
# Stereoisomeric Substituted 11-Keto-20-hydroxypregnanes. III



BY L. H. SARETT

In Parts I and II[1,2] of this series, derivatives of 11-ketopregnane with the following side chain substituents have been described: 20-hydroxy (Class A), 20,21-dihydroxy (Class B), 17α,-20-dihydroxy (Class C) and 17α,20,21-trihydroxy (Class D). Within each class the 3α,20α- and 3α,20β-dihydroxypregnanes were linked with the corresponding 3-keto derivatives. Inasmuch as the arbitrary assignment of the α- and β-indices to a pair of 20-hydroxypregnanes in a given class and the repetition of this assignment at random to a pair in a second, a third and a fourth class is unappealing, the stereochemical correlation of the classes among themselves becomes desirable. The elucidation of this problem[3] forms the subject of Part III.

The reference pair for the four classes mentioned above may be conveniently selected from the simplest group, Class A. We designate the pregnane-3α,20-diol-11-one which melts at 237° as the 20β-isomer (VII) and its epimer (IV) as the 20α-form. In order to convert one of the two pregnane-3α,20,21-triol-11-one isomers into a 3α,20-diolone in such a manner that the relative configuration at C-20 might be known with certainty at all stages, a device which has been employed to prepare desoxy sugars was utilized.[4] A pregnane-3α,20,21-triol-11-one in the form of its 3,21-diacetate 20-tosylate (I)[1] was treated with aqueous alkali in acetone solution, giving the oxide (II). Since reactions of this kind proceed with inversion[5] on the carbon atom bearing the tosylate group the C-20 oxygen–carbon linkage is epimeric with that in the original triol. The oxide reacted smoothly with sodium methyl mercaptide to give the thioether (III) in which the configuration at C-20 remained unchanged, the attack of the methyl mercaptide ion having occurred at C-21. Direct treatment of the acetate tosylate with sodium methyl mercaptide also gave the 21-thioether in excellent yield. Evidently, the oxide is an intermediate.[6] Desulfurization[7] of III then gave pregnane-3α,20α-diol-11-one (IV). Hence the original triol is a member of the 20β-series.

The correlation of a member of Class C with the diolone reference pair followed a somewhat similar scheme. The 20-tosylate of one of the epimeric 3α,17α,20-triolones (V)[1] was converted to the oxide (VI), thus inverting the configuration at C-20. Reductive cleavage of the oxide appeared to proceed exclusively at C-17,[8] since

(6) The possibility of a dioxolone type of intermediate such as has been postulated by Winstein, Hass and Buckles (THIS JOURNAL, **64**, 2796 (1942)) in the solvolysis of 1,2-acetate tosylates appears unlikely, considering the strongly basic character of the reaction medium.

(8) *Cf.* Vischer and Reichstein, also Salamon and Reichstein, ref. 5.

pregnane-3$\alpha$,20$\beta$-diol-11-one was the sole product. This series indicated the C-20 hydroxyl group in the original triolone was alpha.

Finally, a pregnane-3$\alpha$,17$\alpha$,20,21-tetrol-11-one[2] was linked with one of the pregnane-3$\alpha$,17$\alpha$,20-triol-11-one epimers. The 3,20-diacetate 21-tosylate of the tetrolone (VIII) was prepared by hydrolysis of pregnane-3$\alpha$,17$\alpha$, 20,21-tetrol-11-one 3-acetate 20,21-acetonide followed by partial tosylation of the tetrolone 3-monoacetate (VIII). Since this derivative (IX) was not crystalline, the 20-hydroxy group was acetylated. Treatment of the tosylate diacetate (X) with sodium methyl mercaptide, followed by reacetylation of the triolone thioether gave the nicely crystalline diacetate (XI) in 89% yield.[9] With Raney nickel the 3$\alpha$,-17$\alpha$,20$\beta$-triolone diacetate (XII) was formed, from which it could be concluded that the parent tetrolone also was a 20$\beta$-hydroxypregnane.

Certain regularities are apparent from the results described above and in Parts I and II. Catalytic hydrogenation of an 11,20-diketopregnane gave predominantly one epimeric form of the 11-keto-20-hydroxypregnane,[10] the $\beta$-form according to our nomenclature. The quantity of $\alpha$-isomer occurring as a by-product increased with the substitution of hydroxyl groups at the 17- and 21-positions but did not exceed about 20%. With osmium tetroxide $\Delta^{17}$-11-ketopregnenes reacted to give glycols, the C-17 hydroxyl of which was invariably alpha[11] and the C-20 hydroxyl usually beta. The 17$\alpha$,20$\alpha$-glycol was obtained from a presumably geometrically isomeric $\Delta^{17}$-pregnene. Confirming the results of other investigators,[12] we have found that hydroxylation of the 20,21-bond is less sterically selective, approximately equal amounts of both C-20 epimers being formed.

With the hope of finding a generally valid criterion for the diagnosis of configuration of the C-20 hydroxyl group, an examination of the molecular rotations of pairs of 11-keto-20-hydroxypregnane epimers was made. Although no particular regularity could be discerned, it presently became apparent that such a differentiation could be made on the basis of another type of rotational comparison. This consisted in the calculation of a characteristic increment or decrement in the molecular rotations of the 20$\beta$- and 20$\alpha$-hydroxypregnanes, respectively, upon acetylation. That the "rule of shift"[13] could be applied to the steroids by analysis of such differences has been shown by Bernstein, Wilson and Wallis.[14] These workers demonstrated that the difference in molecular rotation of a 3$\beta$-hydroxystenol or stanol and its ester was constant and independent of the presence of subsidiary asymmetric centers or functional groups, providing that the latter were sufficiently distant from ring A to prevent the effects of vicinal action. Similarly, Plattner and Heusser[15] found in a study of partially acetylated cholic acid derivatives that the shifts of rotation caused by acetylation at the 3-, 7- and 12-positions were independent of each other. Barton in a series of papers[16] developed this approach (the "Method of Molecular Rotation Differences") and demonstrated its considerable versatility in the steroids and triterpenoids. This method of molecular rotation differences has been very recently applied to certain 20-hydroxypregnanes by Fieser and Fieser.[17] Since we have also carried out comparable calculations, with similar results, an elaboration of the excellent treatment given by these workers is superfluous.

(9) See remarks above on formation of thioether (III). Here, again the oxide is probably the intermediate, but whether or not this is the case, the configuration at C-20 must remain unaltered, since only the C-21 carbon–oxygen bond is broken.

(10) Marker, Kamm, Wittle, Oakwood, Lawson and Laucius (ref. 24) found that catalytic reduction of pregnane-3-ol-20-one's gave only one diol. For a discussion of Marker's system of nomenclature, see below.

[a] Molecular rotation = $M[\alpha]_D/100$ where $M$ = molecular weight and $[\alpha]_D$ = specific rotation; values to nearest 5°. [b] $\Delta\beta$ = molecular rotation of 20β-acetoxypregnane—molecular rotation of corresponding 20β-hydroxypregnane and similarly for $\Delta_\alpha$.

However, a short analysis of the rotational data of the 11-keto-20-hydroxypregnanes described in the present series of papers is not out of place.

Although it has been repeatedly demonstrated that the presence of neighboring asymmetric centers very seriously disturbs the constancy of a molecular rotation difference, we have attempted to apply the method to substituted 20-hydroxypregnanes in as quantitative a manner as possible. From an analysis of the rotational data in Table I, it appears that, independent of the presence of an oxygen function at C-21 or an α-hydroxyl group at C-17, the following rule is valid: In proceeding from the free 20-hydroxypregnane to the acetate, an increment in the molecular rotation may be observed in one of the configurational series while in the epimeric series a decrement is found. In addition, since the difference in rotation between the two 20-hydroxy-pregnanes[18] seems always to be less than the "spreading" effect produced by acetylation, the rotations of the 20-acetates of one configurational series are always greater than those of the other. In Table I, the column headed $\Delta_\beta$ gives the increment in molecular rotation observed upon acetylation of 11-keto-20-hydroxypregnanes having what we have called the β-configuration. Similarly $\Delta_\alpha$ corresponds to the α-series. Although, considering all four classes, $\Delta_\beta$ and $\Delta_\alpha$ vary in magnitude, within a given class their differences from the average do not lie far outside the experimental error.[19,20] Thus the relatively small fluctuation of Δ occurring with the introduction of one adjacent oxygen function is noteworthy. The cause of the great increase in Δ with the introduction of both adjacent oxygen functions (Class D) is not apparent.

Some sample calculations are given

Example 1. Pregnane-3α,20-diol-11-one

$\Delta_\beta = (+340°) - (+250°) = +90°$

$\Delta_\alpha = (+190°) - (+205°) = -15°$

Example 2. Pregnane-3α,20,21-triol-11-one

$\Delta_\beta = (+370°) - (+280°) = +90°$

$\Delta_\alpha = (+235°) - (+290°) = -55°$

Example 3. Pregnane-3α,17α-20,21-tetrol-11-one

$\Delta_\beta = (+505°) - (+300°) = +205°$

$\Delta_\alpha = +90° - [M]_D$ diacetate

(18) Pregnane is used here in a broad sense, to include allopregnane, Δ⁴-pregnene and the like.

(19) A difference of ±2° in the specific rotation is equivalent to an error of about ±8° in the molecular rotation and ±16° in Δ.

(20) The specific rotations taken in alcohol because of low solubility in acetone introduced a small additional error. In an effort to assess this quantity the rotations of five typical substituted pregnanes were measured in both solvents. Those in alcohol had the greater rotations by ±2, +4, +1, +3, and −1°. This small and inconstant difference (*cf.* Barton, Part III, ref. 16) was essentially within the experimental error and was not considered in calculating the values of Δ.

where [M]D diacetate is the molecular rotation of pregnane-3$\alpha$,17$\alpha$,20$\alpha$,21-tetrol-11-one 3,21-diacetate. This quantity may be estimated by adding to the molecular rotation of the free tetrol, the contributions from acetylation at C-3 and C-21. The former, taken as the average of a number of rotation differences of 3$\alpha$-hydroxy- and acetoxypregnanes is +90°.[21] If the latter be borrowed from a comparison of the rotations of a pair of 3,21-diacetates with the corresponding 3-monoacetates (Table I, Class B), according to which the rotation change produced by acetylation of a C-21 hydroxyl is negligible, the calculation may then be completed

$$\Delta_\alpha = (+90°) - [(+160°) + (+90°) + (0°)] = -160°$$

If the assumption is made that the rotational changes described above are at least qualitatively valid for 20-hydroxypregnanes[18] independent of the presence of an 11-keto group or C-3-hydroxyl configuration, a significant steric comparison may be made between this group of compounds and certain naturally occurring adrenal steroids. In particular, Reichstein's substance J, the C-20-hydroxyl of which has been arbitrarily defined as beta by Prins and Reichstein[22] and substance O, its C-20 epimer, may be linked with the present series. When this calculation is performed, it may be seen that J and O qualitatively follow the criteria for the 20$\beta$- and 20$\alpha$-configurations, respectively. On this basis, the assignment of those 20-hydroxypregnanes which we have called beta to the same steric series as substance J has been made.

Allopregnane-3$\beta$,17$\alpha$-20-triol (substance J)[23]

$$\Delta = (+100°) - (-25°) - (-15°) = +150°$$

Allopregnane-3$\beta$,17$\alpha$,20-triol (substance O)[23]

$$\Delta = (-125°) - (-40°) - (-15°) = -70°$$

Another convention which has been used to designate epimeric 20-hydroxypregnanes is that of Marker and co-workers.[24] According to this system those 20-hydroxypregnanes occurring as urinary metabolites are given the alpha index and their epimers, produced in high yield by catalytic reduction of 20-ketopregnanes, the beta-designation. From the combined results of Butenandt and Schmide–Thomé[25] and Prins and Reichstein (ref. 23), who, in essence, converted substance J into the diol called according to Marker's nomenclature allopregnane-3$\beta$,20$\beta$-diol without disturbing the asymmetry at C-20, it is apparent that Marker's convention is also in agreement with those of Reichstein. In order further to test the rule of configuration described above, the rotation of the pregnane-3$\alpha$,20-diols was compared with those of the corresponding diacetates.[26] Using the value [$\alpha$]D+27° (alc.),[27] or [M]D+85°, for the rotation of the 3$\alpha$,20$\alpha$-diol (Marker's nomenclature) together with our experimental values for the rotations of the 3$\alpha$,20$\beta$-diol, and the two diacetates, the two $\Delta$ values may be calculated

Pregnane-3$\alpha$,20$\beta$-diol

$$\Delta = (+275°) - (+90°) - (+90°) = +105°$$

Pregnane-3$\alpha$,20$\alpha$-diol

$$\Delta = (+165°) - (+85°) - (+90°) = -10°.$$

These $\Delta$'s agree well with the $\Delta_\beta$ of +90° and the $\Delta_\alpha$ of −15° found in the 11-ketodiol series. From these results it appears that the rotational rule rests on substantial ground.

Consideration of this rule reveals no *a priori* likelihood of its precise application to the 17$\beta$,20-dihydroxypregnanes, since the validity of the principal of optical superposition, upon which such a prediction must be based, is dubious in this system of adjacent asymmetric centers. That the "Rule of Shift," however, might find application in some manner not necessarily related to that in the 17$\alpha$,20-dihydroxypregnane series, appears quite possible. Indeed, Reich, Montigel and Reichstein (ref. 12) have pointed out that in a series of three sterically correlated epimeric pairs of 17$\beta$,20-dihydroxypregnane derivatives, the fully acetylated compounds of the 20 "$\beta$"-group[28] all have the higher rotations. However, an examination of the rotations of all of the pertinent 17$\beta$-triols, tetrols and their acetates[29] shows that, unfortunately, no simple regularity based upon the "Rule of Shift" exists.

## Experimental[30]

**20$\alpha$,21-Oxidopregnane-3$\alpha$-ol-11-one** (II).—A solution of 1.10 g. of pregnane-3$\alpha$,20$\beta$,21-triol-11-one 3,21-diacetate 20-tosylate (I) m. p. 176–177°, in 35 cc. of 0.50 *N* methanolic potassium hydroxide was permitted to stand at 30° for two hours. Concentration of the solution *in vacuo* gave a crystalline precipitate which yielded after several recrystallizations from dilute acetone 400 mg. of the oxide; m. p. 173–174°, [$\alpha$]$^{25}$D + 50°.

*Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.58; H, 9.40.

**Pregnane-3$\alpha$,20$\alpha$-diol-21-thiol-11-one Methyl Thioether (III)**

**A. From 20$\alpha$,21-Oxidopregnane-3$\alpha$-ol-11-one** (II).—A solution of 183 mg. of the 20$\alpha$,21-oxide, m. p. 173–174°, in 2.0 cc. of methanol containing 300 mg. of sodium methyl mercaptide was refluxed for one hour. The solution was diluted with water and extracted with ether. Concentration of the washed ethereal solution to dryness and recrystallization of the residue from a small volume of ether

(21) Plattner and Heusser (ref. 15) found +91° (alc.) and Barton (ref. 16) found +83° (all solvents).

(22) Prins and Reichstein, *Helv. Chim. Acta*, **23**, 1490 (1940).

(23) Calculated from data of Prins and Reichstein, ref. 22. The value for the conversion of the C-3 $\beta$-hydroxyl to acetate was taken as −15° (Barton, Part III, ref. 16).

(24) Marker, Kamm, Wittle, Oakwood, Lawson and Laucius, THIS JOURNAL, **59**, 2291 (1937).

(25) Butenandt and Schmide–Thomé, *Ber.*, **72**, 1960 (1939).

(26) We are indebted to Dr. K. Dobriner and to Dr. T. F. Gallagher of the Sloan–Kettering Institute for samples of these compounds.

(27) Beall, *Biochem. J.*, **31**, 35 (1937).

(28) The indices in the 17$\beta$,20-diol and 17$\beta$,20,21-triol series were assigned arbitrarily and, while they agree with each other (Salamon and Reichstein, ref. 3), they do not necessarily agree with those used in the 17$\alpha$,20-diol and 17$\alpha$,20, 21-triol series.

(29) Data collected by Salamon and Reichstein, ref. 3.

(30) Melting points were taken on the Kofler micro hot stage. Rotations were taken in acetone, $c$ = 1.0, unless otherwise indicated.

yielded 171 mg. of the thioether, m. p. 147–148°. When the thioether was dissolved in a small volume of methanol, dense prisms of a solvated form quickly appeared, which lost solvent at *ca.* 140°, resolidified and remelted at 146–147°.

*Anal.* Calcd. for $C_{22}H_{36}O_3S$: C, 69.42; H, 9.54. Found: C, 69.46; H, 9.24.

**B. From Pregnane-3α,20β,21-triol-11-one 3,21-Diacetate 20-Tosylate (I).**—Treatment of 140 mg. of the tosylate with sodium methyl mercaptide in the manner described above and two crystallizations of the product from methanol yielded 60 mg. of the thioether (III), m. p. and mixed m. p. 141°, 147°.

**Pregnane-3α,20α-diol-11-one (IV) from Pregnane-3α,-20α-diol-21-thiol-11-one Methyl Thioether (III).**—To a suspension of 3 g. of Raney nickel in 25 cc. of 80% alcohol was added an alcoholic solution of 102 mg. of the thioether (III). The mixture was warmed on the steam-bath for ten minutes, filtered and concentrated to dryness *in vacuo*. The crystalline residue (65 mg.) was acetylated in the usual manner and the product oxidized with 50 mg. of chromic acid in 90% acetic acid to convert any 11-hydroxy compound to the 11-ketone. Addition of water to the acetic acid solution gave 60 mg. of crystals. After recrystallization from alcohol the 3α,20α-diolone diacetate had m. p. 235–237°. A mixed m. p. with an authentic sample showed no depression. Saponification of the diacetate gave pregnane-3α,20α-diol-11-one, m. p. and mixed m. p. 221°. A sample (15 mg.) of the diolone was oxidized with chromic acid (15 mg.) in 90% acetic acid and yielded pregnane-3,11,20-trione, m. p. and mixed m. p. 161–163°.

**17α,20β-Oxidopregnane-3α-ol-11-one (VI).**—To a solution of 350 mg. of pregnane-3α,17α,20α-triol-11-one 3-acetate 20-tosylate (V) in 6 cc. of acetone was added 4 cc. of 1 *N* aqueous potassium hydroxide. After two and one-half hours at room temperature the solution was concentrated *in vacuo* to a small volume, extracted with ether and the washed ethereal solution concentrated to dryness. The residue was dissolved in a small volume of methanol, water was added to turbidity and the solution then chilled to 0°. The difficultly crystalline hydrate of the oxide slowly separated. It decomposed (loss of solvent of crystallization) at about 102–105°. After several recrystallizations from cold dilute methanol, the crystals melted at 103–112°; $[\alpha]_D$ +54.5° ($c$ = 0.5) (not corrected for water of crystallization). For analysis a sample was dried in a weighing pig at 110°.

*Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.70. Found: C, 75.76; H, 9.30. Loss in weight on drying: 2.2%.

**Pregnane-3α,20β-diol-11-one (VII) from 17α,20β-Oxidopregnane-3α-ol-11-one (IV).**—A solution of 30 mg. of 17α,20β-oxidopregnane-3α-ol-11-one in 50 cc. of alcohol with 1/4 teaspoonful of Raney nickel was shaken in a bomb under hydrogen at 120° for two hours. The cooled solution was filtered, concentrated nearly to dryness *in vacuo* and the residue dissolved in acetone. The acetone solution was filtered to remove traces of inorganic matter, the solution concentrated to dryness and the residue crystallized from dilute alcohol. The diol melted at 236–237° and did not depress the m. p. of an authentic sample of pregnane-3α,20β-diol-11-one. Acetylation gave the 3α,-20β-diolone diacetate, m. p. and mixed m. p. 161.5–162.0°.

**Pregnane-3α,17α,20β,21-tetrol-11-one 3-Acetate (VIII).**—A solution of 600 mg. of pregnane-3α,17α,20β,21-tetrol-11-one 3-acetate 20,21-acetonide, m. p. 190–191°, in 1 cc. of warm acetic acid was treated with 1 cc. of water and the mixture heated on the steam-bath for fifteen minutes. Water was added and the suspension extracted with three 25-cc. portions of chloroform. The chloroform solution was washed with a little sodium carbonate solution, then with water and concentrated to dryness *in vacuo*. The tetrolone monoacetate was obtained as a white amorphous powder; yield, 471 mg.

**Pregnane-3α,17α,20β-21-tetrol-11-one 3,20-Diacetate 20-Tosylate (X).**—The 471 mg. of amorphous pregnane-3α,17α,20β,21-tetrol-11-one 3-acetate was dissolved in 2.0 cc. of pyridine and treated with 280 mg. of freshly recrystallized tosyl chloride (1.28 molecular equivalents). The solution was kept at room temperature overnight, then diluted with water and extracted with chloroform. The chloroform solution was washed successively with dilute hydrochloric acid, dilute sodium bicarbonate and water, then concentrated to dryness *in vacuo* at 20°. The amorphous residue was sparingly soluble in ether and weighed 671 mg. (103%). The amorphous 21-monotosylate (IX) was next converted to the 3,20-diacetate (X) by heating on the steam-bath with a mixture of 2.0 cc. of acetic anhydride and 1.5 cc. of pyridine for six minutes. The solution was cooled, and carefully diluted with water, giving 420 mg. of the crystalline diacetate tosylate. Recrystallization from chloroform–ether gave prisms, m. p. 145° (dec.). Another crystalline form, m. p. 140° (dec.), could be obtained by crystallization from methanol.

*Anal.* Calcd. for $C_{32}H_{44}O_9S$: C, 63.55; H, 7.33. Found: C, 63.27; H, 7.52.

**Pregnane-3α,17α,20β-triol-21-thiol-11-one 3,20-Diacetate Methyl Thioether (XI).**—A solution of 200 mg. of the tosylate (X), m. p. 145° (dec.), in 4 cc. of methanol containing 600 mg. of sodium methyl mercaptide was refluxed for one hour. Dilution with water and removal of the methanol *in vacuo* gave hydrated crystals which could not be recrystallized from organic solvents. These crystals were combined with the amorphous product obtained by extraction of the mother liquors with chloroform, giving 160 mg. of crude reaction product, which contained some extraneous sulfur compounds. This material was acetylated with pyridine–acetic anhydride in the usual manner and dilution of the reaction mixture with water then gave 140 mg. (89%) of the diacetate, m. p. 191–194°. Recrystallization from methanol gave a product melting at 194–196°.

*Anal.* Calcd. for $C_{26}H_{40}O_6S$: C, 64.98; H, 8.39. Found: C, 65.18; H, 8.42.

**Pregnane-3α,17α,20β-triol-11-one Diacetate (XII) from Pregnane-3α,17α,20β-triol-21-thiol 3,20-Diacetate Methyl Thioether.**—A solution of 28 mg. of the thioether (XI) in 10 cc. of alcohol was refluxed with 0.5 teaspoonful of Raney nickel for ten minutes, the nickel removed by centrifugation, and the solvent removed *in vacuo*. The crystalline residue was dissolved in ether and recrystallized by concentration. The product, which melted at 233–245°, was best separated from a small amount of high melting impurity (11-hydroxy analog(?)) by chromatography over 3 g. of alumina. The eluates obtained with 1:1 ether–petroleum ether through ether were combined and recrystallized from a small volume of ethyl acetate. The pregnane-3α,17α,20β-triol-11-one diacetate then had m. p. 248–249°. A mixed melting point with an authentic sample (m. p. 249–250°) showed no depression.

**Rotations of Pregnanediols.**—Pregnane-3α,20α-diol, +27° (alc.); pregnane-3α,20β-diol (m. p. 239°), +25° (alc.); pregnane-3α,20α-diol diacetate (m. p. 180.5–182.0°), +41°; pregnane-3α,20β-diol diacetate (m. p. 112–113°), +68°.

**Acknowledgments.**—The author wishes to express his indebtedness to Dr. Karl Folkers for his active association with this work, to Dr. Everett S. Wallis of Princeton University for various suggestions, and to Miss Jean E. Andrews for assistance. The author is indebted to Mr. R. N. Boos and his associates for microanalyses.

## Summary

The stereochemical correlation of the 11-ketopregnane-3α,20,21-triols, the 11-ketopregnane-3α,-17α,20-triols, and the 11-ketopregnane-3α,17α,20,-21 tetrols with the 11-ketopregnane 3α,20-diols is

described. Analysis of the rotations of various 11-keto-20-hydroxypregnanes by the "Method of Molecular Rotation Differences" shows certain regularities independent of the presence of oxygen functions at the C-17 or C-21 positions.

# Senecio Alkaloids: α- and β-Longilobine from *Senecio longilobus*

BY ROGER ADAMS AND T. R. GOVINDACHARI

The investigations[1] on *Senecio* alkaloids, of which nearly forty have been isolated so far, have brought to light the striking similarities of many members belonging to this group. Essentially, most of these alkaloids are alkamine esters, in which a pyrrolizidine base carrying two hydroxyls is esterified with aliphatic acids either on one or both hydroxyls. While the heterocyclic component has proved to be retronecine in a large number of cases, the acid fragments exhibit a bewildering variety. These necic acids, although many of them are isomeric, differ widely in melting point, optical rotation, etc., and only in a few cases has the acid moiety been found to be common to two different alkaloids.

The work presented here comprises an investigation of the alkaloids of *Senecio longilobus*, a plant to which a large percentage of the West Texas cattle losses may probably be attributed rather than to the loco plant. Manske[2] was the first to isolate a product from this source which he designated as longilobine. It became apparent very early in the course of the work that longilobine was not a single entity, but a mixture of at least two components. It has been known for a long time that many species of *Senecio* elaborate more than one alkaloid and several alkaloids have been isolated from the same species by fractional crystallization procedures.[3,4] In some instances, however, the attempts at separation of such mixtures have failed completely.[5,6]

Manske has reported longilobine to be $C_{18}H_{23}O_5N$ and the acid obtained by hydrolysis $C_{10}H_{14}O_5$, although his analytical data did not agree satisfactorily with these empirical formulas. The analysis of a sample of longilobine prepared in this Laboratory suggested the same formula as proposed by Manske but likewise was not as close to the theoretical as might be expected of a pure product. In spite of several crystallizations a constant melting point and specific rotation were not reached and the values obtained did not coincide with those reported by Manske.

It has been suggested[3a,6] that these alkaloids are difficult to burn and often gave low values for carbon. It seemed more likely that some other alkaloid with lower carbon content was associated with the $C_{18}H_{23}O_5N$ alkaloid and that this could not be effectively removed by crystallization.

The use of chromatographic adsorption methods for the separation and purification of alkaloids has been a well-established procedure but no application of chromatography has been made so far in the case of the *Senecio* alkaloids. The chromatography of colorless substances presents a difficult problem and many ingenious ways have been devised to locate the invisible zones.[7] Mention may be made of the use of the ultraviolet lamp,[8] the brush method,[9] the use of fluorescent adsorbents[10] and the use of total reflection on a thick glass plate[11] for the detection of boundaries.

They proved unsatisfactory for the separation of the constituents of the crude alkaloid from *Senecio longilobus* for various reasons. Preliminary tests indicated that the "brush method" might have been successfully applied if a further careful study had been undertaken. Investigations along these lines were abandoned when it was found that two main fractions corresponding to $C_{18}H_{23}O_5N$ and $C_{18}H_{25}O_6N$ could be separated easily on a column of alumina by a simple empirical procedure. The criterion of purity was set as a constant optical rotation, which did not change or lead to fractions having higher and lower optical rotations on further adsorption and fractional elution. The liquid chromatogram method, combined with the examination of the column cut into portions arbitrarily, proved sufficiently useful for the purpose.

An initial treatment of the crude alkaloid with alumina was used for effecting a preliminary separation of products before the usual chromatographic procedure. Longilobine with a specific

TABLE I

PURIFICATION OF α-LONGILOBINE[a]

6 g. of α-fraction (2.8 g. of sp. rot. −116° and 3.2 g. of sp. rot. −110°) in 150 ml. chloroform was poured onto 12 × 2 cm. column of alumina (30 g.) and the alumina washed with 800 ml. of chloroform

| Filtrate | | | Alumina (ext. with methyl alcohol) |
|---|---|---|---|
| First 400 ml. 4.94 g. (−118.5°) | Second 400 ml. 0.24 g. (−111°) | Bottom half 0.15 g. | Top half 0.5 g. |

Solution in 50 ml. chloroform poured onto 12 × 2 cm. column of alumina (30 g.)

| | | |
|---|---|---|
| First 400 ml. 3.8 g. (−123.8°)[b] | Second 300 ml. 0.2 g. | Alumina (ext. with methyl alcohol) |

| | |
|---|---|
| Top half 0.4 g. | Bottom half 0.4 g. |

0.5 g. in 10 ml. chloroform on 16 cm. × 1 cm. alumina (15 g.) column—washed with chloroform

| nil. | 0.142 g. (−123.2°) | 0.126 g. (−124.6°) | 0.095 g. (−124.4°) | 0.046 g. (−123.8°) | 0.021 g. | trace |

[a] Figures in parentheses denote the specific rotation of the sample in chloroform. [b] This product was crystallized twice from ethanol. The product had a rotation in chloroform $[\alpha]^{25}D$ −125.2°. Further chromatographing of this fraction was employed to demonstrate a constant optical rotation.

TABLE II

PURIFICATION OF β-LONGILOBINE[a]

4 g. of β-fraction (1.8 g. of sp. rot. −66.5° and 2.2 g. of sp. rot. −72.5°) in 100 ml. chloroform was poured onto 7.5 × 4.5 cm. column of alumina (100 g.) and the alumina washed with 3500 ml. of chloroform

| Filtrate | Alumina (eluted with N-acetic acid, basified, extracted with chloroform) |
|---|---|
| 3500 ml. 0.54 g. (−106.5°) | 2.62 g. (−66.3°) |

Solution in 50 ml. of chloroform poured onto 1 × 3.5 cm. column of alumina (25 g.)—washed with chloroform

| First 500 ml. | 500 ml. | 250 ml. | Alumina (eluted with N-acetic acid, basified, extracted with chloroform) |
|---|---|---|---|
| 0.616 g. (−70.5°) | 0.19 g. (−70.0°) | 0.04 g. (−62.5°) | 1.54 g. (−65°) |

Solution in 25 ml. of chloroform—column 62.5 × 1 cm.—50 g. of alumina—developed with chloroform and chloroform–ethyl alcohol

| 200 ml. $CHCl_3$ | 250 ml. $CHCl_3$ | 100 ml. $CHCl_3$ | Alumina column cut in ten portions and eluted with N-acetic acid, basified, extracted with chloroform |

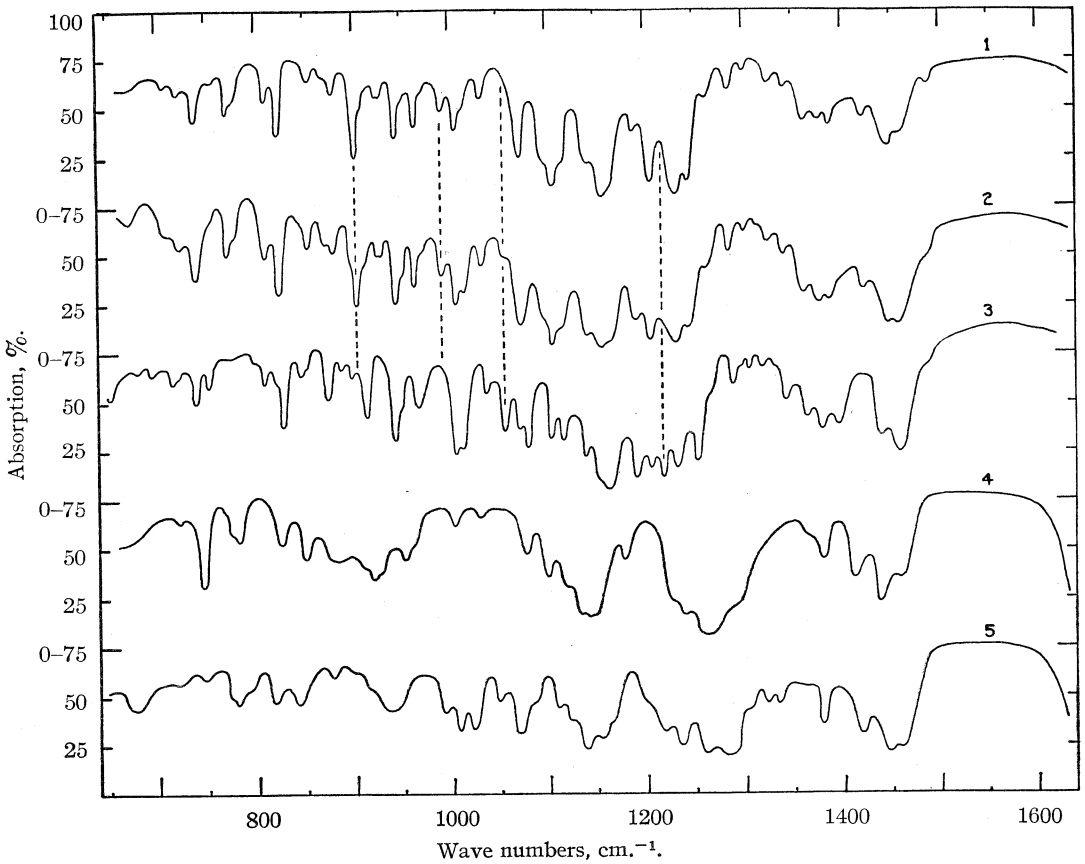
[a] Figures in parentheses denote the specific rotation of the sample in chloroform. [b] A mixture of samples 8 and 9 were combined and recrystallized from ethanol. The product had a rotation in chloroform $[\alpha]^{28}D$ −48.6°.



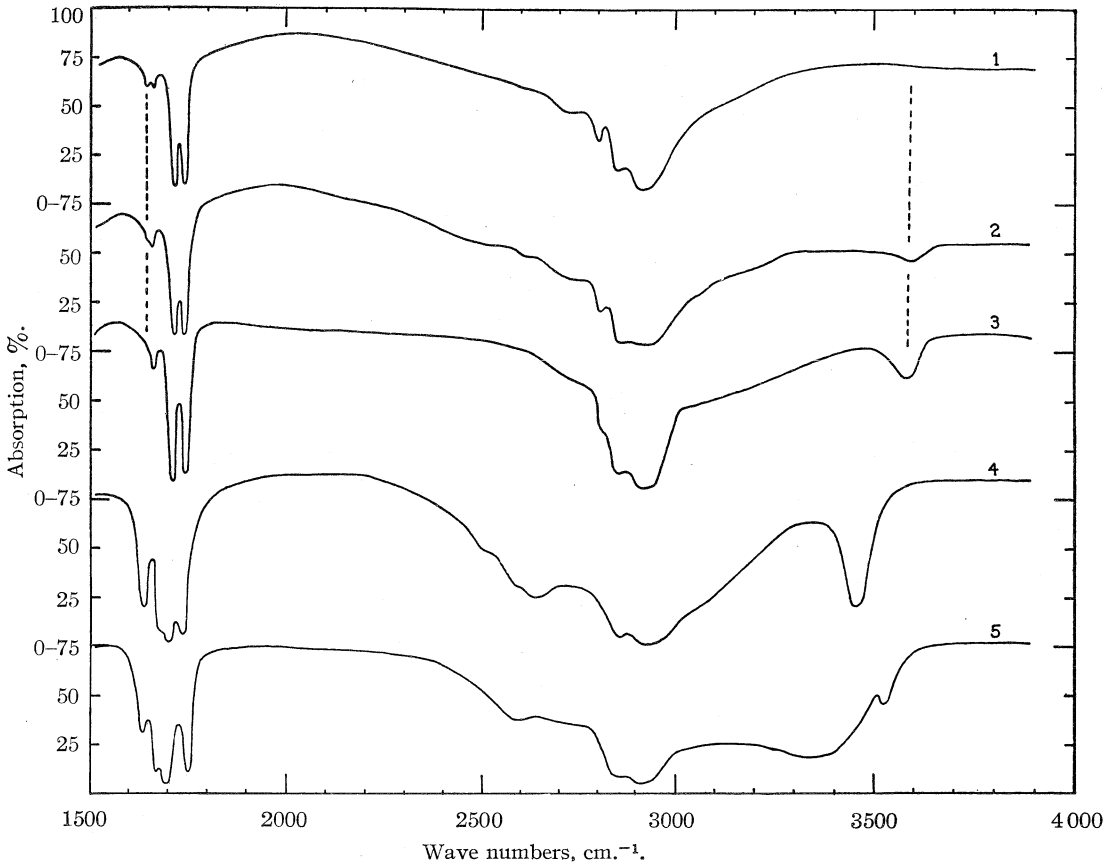


Fig. 1.—Infrared absorption spectra; all spectra are of crystalline solids ground up in Nujol between rock salt plates: 1, $\alpha$-longilobine; 2, crude longilobine; 3, $\beta$-longilobine; 4, $\alpha$-longinecic acid; 5, $\beta$-longinecic acid.

rotation of $-91°$ was stirred with chloroform and alumina for thirty minutes. The filtrate from the alumina had a specific rotation in chloroform of $-116°$. The alumina was eluted with ether and the solvent was found to contain very little product. This was followed by elution with methanol from which solvent material of specific rotation $-66.5°$ was obtained.

The purification of the higher rotating fraction designated as $\alpha$-longilobine was achieved by two passages of a solution in chloroform through alumina columns. The $\alpha$-longilobine passed with the solvent into the filtrate and the impurities were retained on the adsorbent. The pure $\alpha$-longilobine was obtained by evaporation of the chloroform and after crystallization from ethanol had a specific rotation of $-125.2°$ in chloroform at 28°. It melted at 217–218° and the analysis was in good agreement with the empirical formula $C_{18}H_{23}O_5N$.

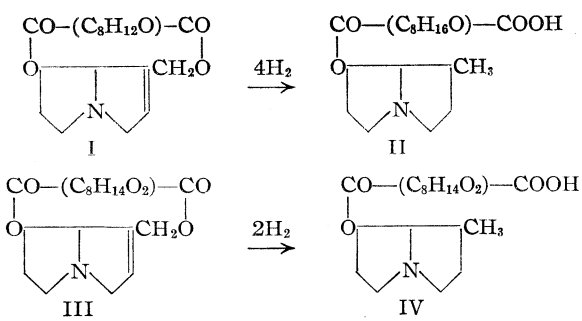
The lower rotating fraction, called $\beta$-longilobine, was also chromatographed several times, first through short columns then through a long narrow alumina column in chloroform as solvent. The first operation eliminated practically all of the $\alpha$-longilobine. The subsequent operations served for the isolation of $\beta$-longilobine in optically pure state. A certain amount of a third alkaloid was obviously present (probably riddelliine) which was more strongly adsorbed than $\beta$-longilobine. As a consequence, the optically pure product was usually obtained from the lower quarter of the column. Pure $\beta$-longilobine had a specific rotation of $-48.6°$ in chloroform. It melted at 207–208° and analyzed correctly for $C_{18}H_{25}O_6N$.

The infrared spectra of $\alpha$- and $\beta$-longilobine were complementary and when combined were essentially identical with that of crude longilobine. They are shown in Chart I. Both $\alpha$- and $\beta$-longilobine show the same two frequencies at 1740 cm.$^{-1}$ and 1717 cm.$^{-1}$ indicating that the molecules must have virtually identical carbonyl linkages. The former is in the region where normal esters, six-membered lactones, cyclopentanones and some acids are found. The latter lies in the region where conjugated esters or six-membered lactones, ketones and acids are found. Both the alkaloids contain the carbon–carbon double bond absorptions at about 1664 cm.$^{-1}$. In addition, $\alpha$-longilobine has a second absorption at 1645 cm.$^{-1}$. Certain absorptions appearing in the low frequency region and common to both seem to be due to the retronecine part of the

molecule, *e.g.*, those at 738 cm.$^{-1}$, 824 cm.$^{-1}$, and 1006 cm.$^{-1}$. The characteristic bands used in identification of α-longilobine were those at 992 cm.$^{-1}$ and 902 cm.$^{-1}$ and of β-longilobine at 1055 cm.$^{-1}$ and the hydroxyl band at 3590 cm.$^{-1}$.

Crude longilobine on hydrolysis furnished retronecine and an acid which was difficult to purify. Pure α-longilobine on hydrolysis yielded retronecine and an acid melting at 114–115° which analyzed correctly for $C_{10}H_{14}O_5$. The acid was dibasic and on heating *in vacuo* was converted to a glassy mass, possibly by lactonization. β-Longilobine gave on hydrolysis retronecine and an acid melting at 146–147°, which analyzed correctly for $C_{10}H_{16}O_6$. On direct titration two carboxyls were indicated.

The infrared spectra of the two acids (Chart I) show many similarities and differences. Both contain the same strong absorption band between 1675 cm.$^{-1}$ and 1700 cm.$^{-1}$, which could be due to acid or keto carbonyl absorption. In addition, the α-acid shows another carbonyl absorption at 1735 cm.$^{-1}$ and the β-acid at 1750 cm.$^{-1}$. These two bands could be due to the carbonyl of an acid, ester, or lactone. The carbon–carbon double bond stretching frequency at 1637 cm.$^{-1}$ appears in both spectra.



The α-acid shows a single strong hydroxyl frequency at 3452 cm.$^{-1}$. The β-acid appears to have two hydroxyl frequencies, one at 3350 cm.$^{-1}$ and the other at 3525 cm.$^{-1}$. The latter corresponds to the hydroxyl frequency found in β-longilobine itself at 3585 cm.$^{-1}$. The consistently high frequency of this band (above 3500 cm.$^{-1}$) both in β-longilobine and in β-longinecic acid probably indicates that the hydroxyl group is in a hindered position, preventing inter-molecular and intra-molecular bonding. It seems unlikely that these hydroxyl absorptions could be due to an acid hydroxyl group, since few cases are known in which a solid acid gives an absorption in this region. Structural work on α- and β-longinecic acids are under way.

On hydrogenation in the presence of Raney nickel catalyst, α-longilobine furnished a single product in quantitative yield, taking up two mole equivalents of hydrogen. This tetrahydro-α-longilobine is a crystalline compound possessing the physical properties of an amino acid and on hydrolysis furnished retronecanol and an acid identical with α-longinecic acid obtained by direct hydrolysis of the alkaloid with barium hydroxide. It is, therefore, evident that hydrogenation in the presence of Raney nickel as catalyst cleaves one ester linkage in the alkaloid and saturates the retronecine double bond, but leaves the unsaturation in the acid part of the molecule unaffected.

On the other hand, when α-longilobine was

hydrogenated in the presence of platinum-oxide catalyst, four mole equivalents of hydrogen were taken up and a single product was obtained in excellent yield. This product was amorphous and could not be crystallized. It showed the physical properties of an amino acid and on hydrolysis yielded retronecanol and an acid which could not be induced to solidify. The additional two moles of hydrogen taken up in the presence of platinum-oxide catalyst must therefore be accounted for by unsaturation in the acid moiety of the alkaloid. The intermediates obtained in the hydrogenation with either catalyst were certainly amino acids and there is a striking similarity in the behavior of α-longilobine on hydrogenation to riddelliine.[1b] With the structure of retronecine and retronecanol established[12] the general structural formula for α-longilobine may be indicated as I and the reduction product resulting from the absorption of four moles of hydrogen as II.

β-Longilobine in the presence of platinum-oxide catalyst absorbs merely two mole equivalents of hydrogen to give a single product in excellent yield. This product like those from α-longilobine appears to be an amino acid, since it is easily soluble in water and ethanol but insoluble in ether and other non-polar solvents. It was amorphous and could not be crystallized. On hydrolysis, retronecanol was obtained and an acid, m.p. 146°, identical with that from β-longilobine by hydrolysis with baryta. The two moles of hydrogen have obviously been used in hydrogenolysis and saturation of the retronecine double bond. The acid portion is saturated or contains no easily reduced unsaturation. The formula for β-longilobine may be designated as III and its reduction product as IV.

The authors are grateful to Mrs. J. L. Johnson for determination and interpretation of infrared spectra.

## Experimental

**Extraction of Longilobine from Senecio longilobus.**—The powdered plant material (whole plant) was extracted continuously in a Soxhlet for twenty-four to thirty hours with ethanol. The alkaloid was isolated as previously described for riddelliine.[1b] The residue from the chloroform extract was once recrystallized from methanol. The yield of longilobine from 27 lb. of dried material was 29.8 g. (0.24%). The product melted at 203–204° (cor.) with sintering from 197°. It was recrystallized thrice from absolute ethanol and then melted at 209–210° (cor.). This was the sample analyzed.

*Rotation:* (once recrystallized product) 0.2819 g. made up to 10 ml. in chloroform at 30° gave $\alpha_D$ −2.565°; *l*, 1; $[\alpha]^{30}D$ −91°.

*Anal.* Calcd. for $C_{18}H_{23}O_5N$: C, 64.86; H, 6.91; N, 4.2. Found: C, 63.88; H, 7.12; N, 3.98.

**Hydrolysis of Crude Longilobine.**—One gram of crude longilobine (once crystallized) was refluxed with 2 g. of barium hydroxide octahydrate in 7 ml. of water for one hour. The necine and necic acid portions were isolated as in the case of riddelliine.[1b] Retronecine hydrochloride in yield of 0.41 g. was obtained. Crystallization from ethanol gave a product, m.p. 162–163° (cor.), which did not depress the melting point of an authentic specimen of retronecine hydrochloride from monocrotaline.[1a]

*Anal.* Calcd. for $C_8H_{13}O_2N\cdot HCl$: C, 50.11; H, 7.36; Cl, 18.51. Found: C, 50.24; H, 7.16; Cl, 18.49.

The retronecine was also identified by conversion to diacetylretronecine picrate prepared from the base according to the directions of Barger, *et al.*[12a] The m.p. was 143° (cor.).

*Anal.* Calcd. for $C_{12}H_{17}O_4N\cdot C_6H_3O_7N_3$: N, 11.95. Found: N, 11.91.

The necic acid portion weighed 0.61 g. and was an amber-colored oil which could not be induced to crystallize.

**Chromatographic Procedure.**—Alumina[13] was used exclusively as the adsorbent in these experiments. The columns were packed dry with the adsorbent and washed with pure solvent before introducing the substance. Chloroform was found to be the ideal solvent. The α-longilobine was eluted from the column by washing with chloroform or with a mixture of chloroform and ethanol (one to two per cent.). In many early experiments, the β-longilobine was eluted by extracting the alumina residue with methanol. A purer product was obtained in better yield by stirring the alumina, after removal from the column, with fifteen to twenty parts of normal acetic acid, filtering from the alumina, basifying the filtrate with ammonia and extracting with chloroform. This was the preferred procedure in all later experiments.

The chloroform extract of the several "cuts," either from the filtrate or from the alumina, was distilled and the residue was made up to a known volume in pure chloroform. An aliquot portion was transferred to a tared watch glass and the amount of material in each fraction determined by evaporation. Another portion was utilized for determining the rotation. From these data, the specific rotation of each fraction was calculated.

**Preliminary Separation of α- and β-Longilobine.**—A solution of 5 g. of crude longilobine ($[\alpha]^{30}D$ −91°) in 150 ml. of dry chloroform was stirred for thirty minutes with 10 g. of freshly ignited alumina. The alumina was allowed to settle and the chloroform was decanted off through a filter paper. The process was repeated with two 150-ml. portions of chloroform (filtrate A).

The alumina was stirred with a total of 500 ml. of absolute ether in three lots and the ether decanted off (filtrate B).

The alumina was then stirred with a total of 500 ml. of methanol in five portions (filtrate C).

Filtrate A gave 2.9 g. of material. *Rotation:* 0.0521 g. made up to 2 ml. in chloroform at 30° gave $\alpha_D$ −3.02°; *l*, 1; $[\alpha]^{30}D$ −116°.

Filtrate B gave 0.1 g. of material. This was discarded.

Filtrate C gave 1.8 g. of material. *Rotation:* 0.0694 g. made up to 2 ml. in chloroform at 30° gave $\alpha_D$ −2.3°; *l*, 1; $[\alpha]^{30}D$ −66.2°.

Further purification of the two main fractions from

(12) Adams and Leonard, THIS JOURNAL, **66**, 257 (1944).

(12a) Barger, *et al.*, *J. Chem. Soc.*, 11 (1935).

(13) Activated alumina, Grade F 20, made by Aluminum Ore Co., East St. Louis, Illinois, was found to be quite satisfactory.

filtrates A and C was achieved as shown in Tables I and II.

**α-Longilobine.**—From absolute ethanol, m. p. 217–218° (cor.). *Rotation:* 0.0412 g. made up to 2 ml. in chloroform at 25° gave $\alpha_D$ −2.58°; *l*, 1; $[\alpha]^{25}D$ −125.2°.

*Anal.* Calcd. for $C_{18}H_{23}O_5N$: C, 64.86; H, 6.91; N, 4.2. Found: C, 65.21; H, 7.00; N, 4.37.

**α-Longilobine Methiodide.**—The methiodide was prepared by warming the alkaloid in chloroform solution with an excess of methyl iodide. After removing the chloroform, the product was twice recrystallized from ethanol with the addition of a few drops of water; white crystals, m. p. 240° (cor.).

*Rotation:* 0.0151 g. made up to 1 ml. in water at 28° gave $\alpha_D$ −1.06°; *l*, 1; $[\alpha]^{28}D$ −70.1°.

*Anal.* Calcd. for $C_{18}H_{23}O_5N{\cdot}CH_3I$: C, 48.0; H, 5.48; N, 2.95; I, 26.4. Found: C, 47.92; H, 5.64; N, 3.17; I, 26.51.

**β-Longilobine.**—From absolute ethanol, m. p. 207–208° (cor.). *Rotation:* 0.0367 g. made up to 2 ml. in chloroform at 28° gave $\alpha_D$ −0.89°; *l*, 1; $[\alpha]^{28}D$ −48.6°.

*Anal.* Calcd. for $C_{18}H_{25}O_6N$: C, 61.5; H, 7.12; N, 3.98. Found: C, 61.41; H, 7.28; N, 4.15.

**β-Longilobine Methiodide.**—This was prepared in the same manner as the α-longilobine derivative. After two recrystallizations from ethanol containing water, the product melted at 256° (cor.).

*Rotation:* 0.0168 g. made up to 1 ml. in water at 28° gave $\alpha_D$ −0.40°; *l*, 1; $[\alpha]^{28}D$ −23.8°.

*Anal.* Calcd. for $C_{18}H_{25}O_6N{\cdot}CH_3I$: C, 46.25; H, 5.68; N, 2.88. Found: C, 46.02; H, 5.93; N, 2.81.

**α-Longinecic Acid.**—A mixture of 0.5 g. of α-longilobine, 1 g. of barium hydroxide octahydrate and 7 ml. of water was refluxed for one hour. The necine and necic acid portions were isolated by the usual procedure. The yield of retronecine hydrochloride was 0.205 g. (72%), m. p. 163–164° (cor.).

The yield of α-longinecic acid was 0.289 g. (80%). This was recrystallized from absolute ether, with addition of petroleum ether to incipient turbidity. The product melted at 114–115° (cor.). By titration it was shown to be dibasic.

*Anal.* Calcd. for $C_{10}H_{14}O_5$: C, 56.08; H, 6.54; neut. equiv., 107. Found: C, 56.16; H, 6.34; neut. equiv., 103.9.

*Rotation:* 0.0249 g. made up to 1 ml. in water at 28° gave $\alpha_D$ −0.33°; *l*, 1; $[\alpha]^{28}D$ −13.25°.

On heating α-longinecic acid, water was evolved and a glassy product resulted which could possibly be a lactone. It could not be purified.

*Anal.* Calcd. for $C_{10}H_{12}O_4$: C, 61.2; H, 6.12. Found: C, 59.77; H, 6.58.

**β-Longinecic Acid.**—From 0.5 g. of β-longilobine by a similar hydrolysis, 0.19 g. (66.5%) of retronecine hydrochloride, m. p. 163–164°, was obtained. The yield of β-longinecic acid was 0.26 g. (78.6%). The acid was less soluble in absolute ether than α-longinecic acid. It was recrystallized by dissolving in a large volume of ether, concentrating to a small volume, adding a few drops of petroleum ether and rubbing with a glass rod. The recrystallized acid melted at 146–147° (cor.). Direct titration of β-longinecic acid indicated dibasicity. By adding excess of alkali, permitting to stand overnight and back titrating with standard hydrochloric acid, three carboxyls were indicated (Calcd. 77.3. Found 83.9).

*Anal.* Calcd. for $C_{10}H_{16}O_6$: C, 51.8; H, 6.95; neut. equiv., 116. Found: C, 51.58; H, 7.00; neut. equiv., 115.9.

*Rotation:* 0.0298 g. made up to 1 ml. in water at 28° gave $\alpha_D$ −0.27°; *l*, 1; $[\alpha]^{28}D$ −9.06°.

**Hydrogenolysis of α-Longilobine (Raney Nickel Catalyst). Tetrahydro-α-longilobine.**—A solution of 0.4 g. of α-longilobine in 15 ml. of ethanol and 2.5 ml. of water was hydrogenated at slightly over atmospheric pressure in the presence of approximately 0.5 g. of Raney nickel. A total of two mole equivalents of hydrogen were absorbed during three hours, after which no more hydrogen was taken up. The catalyst was filtered off and the solvent removed *in vacuo*. The residue was a colorless crystalline solid in a yield of 0.4 g. It was fairly soluble in water, more soluble in ethanol and acetic acid and insoluble in ether. It was best crystallized from a small volume of water, m. p. 190–191° (cor.). *Rotation:* 0.0187 g. made up to 2 ml. with water at 28° gave $\alpha_D$ −0.61°; *l*, 1; $[\alpha]^{28}D$ −65.2°.

*Anal.* Calcd. for $C_{18}H_{27}O_5N$: C, 64.10; H, 7.81. Found: C, 63.95; H, 7.96.

**Hydrolysis of Tetrahydro-α-longilobine.**—A mixture of 0.2 g. of tetrahydro-α-longilobine and 0.5 g. of barium hydroxide octahydrate in 5 ml. of water was refluxed for one hour and cooled. After saturating with carbon dioxide, the solution was filtered and made acid to congo red. Continuous extraction with ether for twenty-four hours and removal of solvent yielded an oil which solidified on rubbing. Recrystallization from ether–petroleum ether (b. p. 30–60°) gave a solid which melted at 114°. The melting point of a mixture of this product with α-longinecic acid gave no depression.

The aqueous solution remaining after ether extraction was made alkaline with sodium hydroxide and extracted with ether. After drying the ether extract with anhydrous magnesium sulfate and distilling the ether, a solid remained which was converted to a picrate with aqueous picric acid. The picrate, after recrystallization from water, melted at 211° and was identical with an authentic specimen of retronecanol picrate.

**Hydrogenolysis of α-Longilobine (Platinum Oxide Catalyst).**—A solution of 0.5 g. α-longilobine in 15 ml. of absolute ethanol and 1.5 ml. of acetic acid was hydrogenated at slightly over atmospheric pressure in the presence of 0.05 g. of platinum oxide catalyst. A total of four mole equivalents of hydrogen was absorbed. The catalyst was filtered off and the solvent was removed *in vacuo*. The residue was a glassy mass which could be broken down to a brittle powder; yield, 0.51 g. (quant.). If the acetic acid was omitted, the residue was an amorphous solid in nearly the same yield. Attempts to crystallize the product were unsuccessful. Accurate analysis was not possible because of the extreme hygroscopicity of the material.

A solution of 0.5 g. of the above material in 20 ml. of a 10% aqueous solution of sodium hydroxide was refluxed for one hour and cooled. The solution was repeatedly extracted with ether, the ether extract dried over anhydrous magnesium sulfate and the ether distilled. The residue was an oil which solidified on keeping in the desiccator. On recrystallization from petroleum ether (b. p. 30–60°), a white crystalline solid was obtained, m. p. 95–96° (cor.) identical with an authentic specimen of retronecanol.

The aqueous layer in acidification and continuous extraction with ether gave 0.25 g. of an amber-colored liquid which did not solidify.

**Hydrogenolysis of β-Longilobine.**—When 0.5 g. of β-longilobine was similarly hydrogenated in the presence of 0.05 g. of platinum oxide catalyst, only two mole equivalents of hydrogen were taken up. After filtration of catalyst and removal of solvent, a glassy mass was left behind which was converted to an amorphous powder on treatment with ether. This material (0.45 g.) was insoluble in ether and easily soluble in water and ethanol. On dissolving in absolute ethanol and adding absolute ether, the material separated as an oil which solidified on rubbing. This solid melted at 55–60°, forming a voluminous foam. Attempts to purify the material for analysis were unsuccessful.

A solution of 0.4 g. of the above material in 4 ml. of water was refluxed for one hour with one gram of barium hydroxide octahydrate. The acid portion was isolated by saturating with carbon dioxide, filtering the barium carbonate, acidifying the filtrate and extracting continuously with ether; yield, 0.21 g. After two recrystalliza-

tions from ether–petroleum ether mixture, the acid melted at 146° (cor.) and was identical with β-longinecic acid, obtained by direct hydrolysis of β-longilobine. The basic portion was isolated in the usual way and proved to be retronecanol identified conveniently as the picrate, m. p. 211°.

## Summary

1. The alkaloid from *Senecio longilobus*, first isolated by Manske, has been shown to be a mixture of two components designated as α- and β-longilobine, whose empirical formulas are $C_{18}H_{23}O_5N$ and $C_{18}H_{25}O_6N$, respectively. The separation was achieved by an empirical chromatographic procedure, combining the liquid chromatogram method and examination of the column. The course of the chromatogram was followed by determining the specific rotations of the different fractions and the two main components were rechromatographed until a constant specific rotation was attained.

2. On hydrolysis α-longilobine gives one molecule of retronecine and one molecule of a crystalline dibasic acid $C_{10}H_{14}O_5$, designated as α-longinecic acid.

3. Similarly β-longilobine gives one molecule of retronecine and one molecule of a crystalline dibasic acid $C_{10}H_{16}O_6$, designated as β-longinecic acid.

4. On reduction with hydrogen and Raney nickel, α-longilobine absorbs two moles of hydrogen to form tetrahydro-α-longilobine which has the properties of an amino acid and on hydrolysis yields retronecanol and α-longinecic acid. With platinum oxide as catalyst four moles of hydrogen are absorbed, yielding an amorphous product which gives on saponification retronecanol and an oily acid which was not purified.

5. β-Longilobine absorbs only two moles of hydrogen in the presence of platinum oxide as catalyst, yielding an amorphous product which gives on hydrolysis retronecanol and β-longinecic acid.

6. Both α- and β-longilobine are shown to be cyclic diesters, from one mole of retronecine and one mole of a dibasic acid, each of the two hydroxyls in retronecine being utilized.

# Condensation Reactions of N-Substituted Pyridones[1]

BY ROGER ADAMS AND ANTHONY W. SCHRECKER

A consideration of possible methods for the synthesis of cytisine[2] (I) leads to the necessity of further knowledge of the activity of a 6-methyl

I

group in N-substituted 2-pyridones. This communication is devoted primarily to the description of the reactivity of the ring-substituted methyl group in 1,6-dimethyl-2-pyridone. It includes also the results of a similar study of 1,4-dimethyl-2-pyridone. 6-Methyl-2-pyridone-1-β-propionitrile and ethyl 6-methyl-2-pyridone-1-acetate were synthesized and preliminary experiments on pyridocoline formation were attempted. The activity of the methyl group in 2-acetamido-6(and 4)-methylpyridine is also described.

The ability of such compounds as 2-picoline to undergo condensation reactions with carbonyl compounds has been attributed to the double bond linking the nitrogen with the carbon atom carrying the methyl group.[3] A molecule carrying such a structural unit can undergo an electromeric shift permitting formation of a carbanion and subsequent condensation with a carbonyl group.[4] No such double bond appears in the formula of a compound such as 1,6-dimethyl-2-pyridone (IIa). If N-alkylpyridones are, however, resonance hybrids of an uncharged and a betaine (IIb) structure, as postulated by Arndt and Kalischek,[5] and the carbanion (III) is stabilized by resonance, then the requirement for base-catalyzed condensation reactions should be fulfilled. Replacement of the 6-methyl group by a carbethoxymethyl group would render the compound somewhat similar in its behavior to a β-keto ester and replacement by a cyanomethyl group similar to a β-carbonylated nitrile, such as ethyl cyanoacetate. Such compounds should form sodium enolates which react with alkyl and acyl halides. These predictions have been realized experimentally.

The predictions were supported by the experiments of Kaslow and Cook[6] who demonstrated the reactivity of the 4-methyl group in 1,4-dimethylcarbostyril toward ethyl oxalate. The condensation product was readily transformed into 1-methyl-4-carbostyrilacetonitrile, which underwent condensation with benzaldehyde.

The starting materials, 1,6-dimethyl-2-pyridone

(II) and 1,4-dimethyl-2-pyridone, were prepared from the sodium salts of 6-methyl-2-pyridone and 4-methyl-2-pyridone by alkylation with dimethyl sulfate. They were low-melting, water-soluble compounds, which was to be expected from a consideration of the physical properties of the previously characterized 1-methyl-2-pyridone[7] and 1,4,6-trimethyl-2-pyridone.[8] Mumm[9] has described a product reputed to be 1,6-dimethyl-2-pyridone. He obtained it in a series of reactions starting with diethyl 2,6-dimethylpyridine-3,5-dicarboxylate and reported it to melt at 352° and to be difficultly soluble in water. The physical properties and chemical reactions of the compound, m. p. 56.5–58°, described in the present paper, prove conclusively that this substance is actually 1,6-dimethyl-2-pyridone.

1,6-Dimethyl-2-pyridone underwent condensation with ethyl oxalate in the presence of potassium or sodium ethoxide to form the yellow potassium or sodium salt of ethyl 1-methyl-2-pyridone-6-pyruvate in 95% yield, from which the free ester (IV) was obtained by acidification. The same reaction proceeded at a somewhat lower rate with 1,4-dimethyl-2-pyridone to give the potassium salt (84% yield) and from it ethyl 1-methyl-2-pyridone-4-pyruvate. Hydrolysis of the esters gave 1-methyl-2-pyridone-6-pyruvic acid (V) and 1-methyl-2-pyridone-4-pyruvic acid.

The pyruvic acids underwent oxidative decarboxylation when treated with aqueous sodium hydroxide and hydrogen peroxide to give respectively 1-methyl-2-pyridone-6-acetic acid (VI) (84–87% yield) and 1-methyl-2-pyridone-4-acetic acid (46–59% yield). The former was also obtained when the pyruvic ester instead of the acid was treated with hydrogen peroxide in aqueous sodium hydroxide, though in lower yield. The oxidation took a different course when the potassium salt of ethyl 1-methyl-2-pyridone-6-pyruvate was treated with hydrogen peroxide, and one mole of dilute sodium hydroxide was added only after some time. None of the 6-acetic acid was obtained, but 1-methyl-2-pyridone-6-carboxylic acid[10] (VII) was formed in a 58% yield. 1-Methyl-2-pyridone-6-acetic acid (VI), m. p. 188°, and 1-methyl-2-pyridone-6-carboxylic acid (VII), m. p. 260°, decompose at their melting points with loss of carbon dioxide to give, respectively, 1,6-dimethyl-2-pyridone and 1-methyl-2-pyridone. Consideration of the betaine structure of pyridones (IIb) shows that the former acid is somewhat analogous to a β-keto acid, the latter to an α-keto acid.

By treatment of 1-methyl-2-pyridone-6-pyruvic acid (V) with hydroxylamine or by alkaline hydrolysis of the oximino ester prepared similarly from the pyruvic ester (IV), 1-methyl-2-pyridone-6-(α-oximino)-propionic acid (VIII) was readily formed and this was converted in 93% yield to 1-methyl-2-pyridone-6-acetonitrile (IX) by pyrolysis. By alkaline hydrolysis of the nitrile the 6-acetic acid (VI) results. Ethyl 1-methyl 2-pyridone-6-acetate (X), formed by esterification of the corresponding acid (VI), and 1-methyl-2-pyridone-6-acetonitrile (IX) condensed with benzyl chloride in the presence of ethanolic sodium ethoxide, the former to give ethyl 1-methyl-2-pyridone-6-(α-benzyl)-acetate (XI, R = $C_6H_5CH_2$-) in 61% yield and the latter to give the corresponding nitrile in 42% yield. On hydrolysis, the ethyl 1-methyl-2-pyridone-6-(α-benzyl)-acetate as well as the nitrile gave the corresponding acid (XII, R = $C_6H_5CH_2$-) which melted at 155° with evolution of carbon dioxide and formation of 1-methyl-6-phenethyl-2-pyridone (XIII, R = $C_6H_5CH_2$-). An analogous condensation of ethyl 1-methyl-2-pyridone-6-acetate with *n*-butyl bromide or better *n*-butyl iodide gave the α-*n*-butyl derivative (XI, R = $C_4H_9$-) which was hydrolyzed and decarboxylated to 6-*n*-amyl-1-methyl-2-pyridone (XIII, R = $C_4H_9$-).

The sodium derivative of ethyl 1-methyl-2-pyridone-6-acetate also reacted with acetyl chloride to give in 38% yield a β-keto ester (XI, R = $CH_3CO$-) which was an oil. It was not purified, but hydrolyzed and decarboxylated directly with formation of 6-acetonyl-1-methyl-2-pyridone (XIII, R = $CH_3CO$-).

| R′ = | R′ = |
|---|---|
| IV, $CH_2COCOOEt$ | IX, $CH_2CN$ |

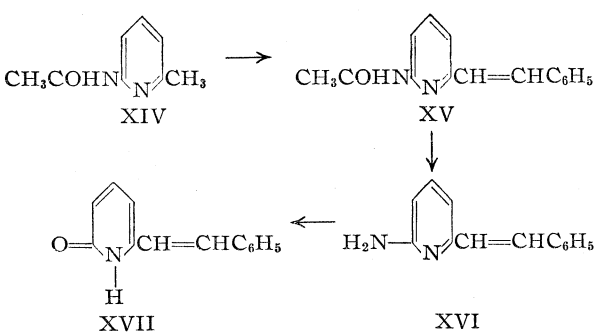
| VIII, $CH_2C(=NOH)COOH$ | XIII, $CH_2R$ |



Condensation of 1,6-dimethyl-2-pyridone with *m*-nitrobenzaldehyde in the presence of acetic anhydride gave only about 1% yield of 1-methyl-6-(*m*-nitrostyryl)-2-pyridone, in contrast to a 90% yield obtained in the reaction of *m*-nitrobenzaldehyde with 2-picoline.[11] In view of the unsatisfactory result of the attempts to prepare condensation products of pyridone homologs with alde-

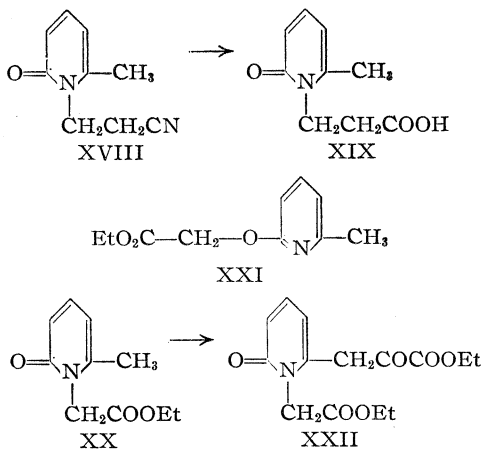
hydes, the possibility of obtaining such compounds by an indirect route was investigated.



2-Acetamido-6-methylpyridine (XIV) was condensed with benzaldehyde in the presence of acetic anhydride to give 6-acetamido-2-stilbazole (XV) in 12% yield. A yield of 87% is reported in the condensation of benzaldehyde with 2-picoline.[11] The acetamidostilbazole was hydrolyzed in hydrochloric acid and the 6-amino-2-stilbazole (XVI) purified by taking advantage of the low solubility of its hydrochloride in cold 20% hydrochloric acid. Diazotization of the amino compound gave a 48% yield of 6-hydroxy-2-stilbazole (6-styryl-2-pyridone) (XVII). When the same series of reactions was carried out with 2-acetamido-4-methylpyridine, a 14% yield of 2-amino-4-stilbazole resulted. In this case the intermediary acetamido compound was not isolated but the reaction mixture hydrolyzed directly by boiling with hydrochloric acid. Diazotization of the aminostilbazole gave a 36% yield of 2-hydroxy-4-stilbazole(4-styryl-2-pyridone). In the formation of 2-amino-4-stilbazole there was isolated from the condensation a yellow crystalline by-product, m. p. 234–235°, the structure of which was not determined.

6-Methyl-2-pyridone condenses in the same manner as 2-pyridone[12] in presence of alkaline

catalysts with acrylonitrile to form 6-methyl-2-pyridone-1-β-propionitrile (XVIII). This product was hydrolyzed to the corresponding acid (XIX). Esterification of the acid by the usual methods failed to give a pure product. On distillation the oily esters were unstable and decomposed into 6-methyl-2-pyridone and acrylic esters. The nitrile (XVIII), which can be readily purified since it is a crystalline solid, also decomposes on distillation. All attempts to cause a ring closure between the carbalkoxy group and the 6-methyl group in the esters of XIX in order to obtain a bicyclic molecule more closely resembling cytisine were unsuccessful.

The stable ethyl 6-methyl-2-pyridone-1-acetate (XX) was prepared by the reaction of 6-methyl-2-pyridone sodium with ethyl bromoacetate. A 70% yield resulted, with 5% of the corresponding 2-pyridyl ether (XXI) as a by-product. Ethyl oxalate condensed with ethyl 6-methyl-2-pyridone-1-acetate (XX) to form probably ethyl 1-carbethoxymethyl-2-pyridone-6-pyruvate (XII), but no bicyclic product which might result from the elimination of two moles of ethanol.

Attempts to introduce halogen into the 6-methyl group of 6-methyl-2-pyridone failed. Bromination invariably resulted in ring substitution.

## Experimental

**6-Methyl-2-pyridone.**—A solution of 108 g. of 2-amino-6-methylpyridine (b. p. 209–210°) in a cold mixture of 111 ml. of concd. sulfuric acid and 830 ml. of water was placed in an ice–salt-bath. With mechanical stirring a solution of 73 g. of 97% sodium nitrite in 140 ml. of water was introduced through a dropping funnel, the orifice of which reached nearly to the bottom of the beaker, at such a rate that the temperature of the reaction mixture did not rise above 5°. To complete the reaction, it was stirred for an additional hour below 10° and finally heated on a steam-bath until the temperature reached 90°.

The yellow solution was made alkaline by adding 205 g. of anhydrous potassium carbonate and evaporated to dryness on the steam-bath. The residue was powdered in a mortar and then extracted exhaustively with boiling benzene. The extract was clarified with Norit, filtered hot, concentrated to a volume of about 500 ml. and allowed to cool in an icebox. The yellow crystals were collected on a Büchner funnel and, after drying, weighed 95.3 g. By working up the mother liquor, an impure product was obtained which after recrystallization from benzene weighed 5.9 g. The over-all yield was thus 101.2 g. (92.8%). The material as initially obtained and after crystallization from benzene melted at 158–159° (cor.). By recrystallization from acetone or by distillation, b. p. 282° (760 mm.), colorless prismatic needles of the same melting point resulted.

This compound was first described by Errera[13] who obtained it by decarboxylation of 6-methyl-2-pyridone-3,5-dicarboxylic acid. He reported a melting point of 159°. A somewhat similar procedure was described by Seide,[14] who also reported the same melting point.

**6-Methyl-2-pyridone Sodium.**—The diazotized solution of 108 g. of 2-amino-6-methylpyridine was heated to boiling and neutralized by the addition of 568 g. of barium hydroxide octahydrate dissolved in 1500 ml. of boiling water. Barium sulfate was removed by filtration on a Büchner funnel and extracted several times with boiling water. The combined filtrate and washings, after addition of 50 ml. of 25% aqueous sodium hydroxide, were evaporated to dryness and the residue extracted exhaus-

(13) Errera, *Ber.*, **33**, 2969 (1900).

(14) Seide, *J. Russ. Phys.-Chem. Soc.*, **50**, 534 (1918).

tively with hot 95% ethanol. Cooling of the extract caused the separation of yellowish leaflets. Recrystallization from 95% ethanol served for purification. The product formed colorless glittering leaflets. The yield was 115.5 g. (88%), after drying *in vacuo* at 100°; m. p. 290°.

The sodium salt is very soluble in water, moderately soluble in ethanol, difficultly soluble in acetone and insoluble in ether.

*Anal.* Calcd. for $C_6H_6ONNa$: Na, 17.54. Found: Na, 17.48.

**1,6-Dimethyl-2-pyridone (II).**—This product was prepared in a manner similar to that used for the preparation of 1-methyl-2-pyridone from 2-pyridone potassium.[7]

In a 2-l. round-bottomed flask fitted with reflux condenser and dropping funnel, 98.7 g. of 6-methyl-2-pyridone was dissolved in a warm, freshly prepared solution of 21.0 g. of sodium in 250 ml. of methanol. After cooling to room temperature, 130 g. of dimethyl sulfate was added with shaking during a period of fifteen minutes. After refluxing on a water-bath for two hours, the solution was made strongly alkaline by adding 220 g. of 25% aqueous sodium hydroxide and steam-distilled until the odor of the by-product, 2-methoxy-6-methylpyridine, had disappeared from a sample of the distillate. After cooling to room temperature, sodium sulfate was removed from the steam-distillation residue by filtration on a Büchner funnel and the filter-cake washed with two 75-ml. portions, then with four 50-ml. portions of chloroform. The successive chloroform washings were used to extract the filtrate. After drying over potassium carbonate, the solvent was removed under reduced pressure and the product distilled, b. p. 110° (2 mm.). The yield was 82 g. (74%). The distillate solidified to a colorless crystalline mass which was recrystallized from dry ether; deliquescent plates, m. p. 56.5–58°.

The compound is very soluble in water, ethanol, chloroform and benzene, moderately soluble in ether, insoluble in petroleum ether. Its aqueous solutions are neutral.

*Anal.* Calcd. for $C_7H_9ON$: C, 68.27; H, 7.37; N, 11.37. Found: C, 68.40; H, 7.33; N, 11.36.

Attempts to prepare this compound by alkaline hydrolysis of the product from methyl iodide and 2-amino-6-methylpyridine according to the procedure of Chichibabin and Konovalova[15] gave only a 23% yield. The use of dimethyl sulfate on α-picoline followed by the action of alkaline ferricyanide[16] failed to give any product.

**1,6-Dimethyl-2-pyridone Hydrochloride.**—This hydrochloride was prepared in absolute ether with dry hydrogen chloride. After several recrystallizations from absolute ethanol, it formed colorless prismatic needles, m. p. 202–203° (cor.). The compound had to be dried at room temperature, as it sublimes readily at 75° (3 mm.).

*Anal.* Calcd. for $C_7H_{10}ONCl$: C, 52.67; H, 6.32; N, 8.78; Cl, 22.21. Found: C, 52.75; H, 6.30; N, 8.92; Cl, 22.31.

**1,6-Dimethyl-2-pyridone Picrate.**—The picrate was obtained by the usual procedure. It was purified by crystallization from 95% ethanol and formed long yellow needles, m. p. 134–136° (cor.).

*Anal.* Calcd. for $C_{13}H_{12}O_8N_4$: C, 44.32; H, 3.43; N, 15.91. Found: C, 44.53; H, 3.58; N, 15.84.

**4-Methyl-2-pyridone.**—This product was synthesized in a manner similar to that described for converting 2-amino-6-methylpyridine to 6-methyl-2-pyridone. Two runs of 54 g. of 2-amino-4-methylpyridine were diazotized, combined and then made alkaline by adding 210 g. of anhydrous potassium carbonate. After evaporation on a steam-bath, the nearly dry residue was extracted several times with a total of 1 l. of boiling ethanol. The brown extract was freed from ethanol under reduced pressure and the residue distilled. The 4-methyl-2-pyridone boiled at 186–187° (12 mm.) and solidified in the receiver to a colorless crystalline mass which was recrystallized from benzene and washed with petroleum ether (b. p. 30–60°). The yield was 85.1 g. (78%) of large colorless prisms, m. p. 130° (cor.).

Seide[17] reported a melting point of 130° and a boiling point of 307–309° (atm. press.).

**1,4-Dimethyl-2-pyridone.**—This compound was prepared in a manner analogous to the preparation of 1,6-dimethyl-2-pyridone from 6-methyl-2-pyridone. The crude reaction product, obtained from 85.1 g. of 4-methyl-2-pyridone by methylation, addition of base, steam-distillation and extraction of the residue with chloroform, was distilled *in vacuo*, b.p. 110° (1 mm.). The yield was 73.6 g. (77%). The product solidified in the receiver to a colorless mass, which after crystallization from dry ether formed colorless needles, m. p. 59°. It is somewhat deliquescent, though less so than 1,6-dimethyl-2-pyridone.

*Anal.* Calcd. for $C_7H_9ON$: C, 68.27; H, 7.37. Found: C, 68.05; H, 7.52.

**1,4-Dimethyl-2-pyridone Hydrochloride.**—This compound was prepared by saturating a solution of the base in a little absolute ethanol with dry hydrogen chloride, while cooling in ice water, and then adding dry ether. Recrystallization was accomplished from ethanol–ether; small colorless needles, m. p. 173–174° (cor.).

*Anal.* Calcd. for $C_7H_{10}ONCl$: Cl, 22.21. Found: Cl, 22.22.

**1,4-Dimethyl-2-pyridone Picrate.**—The picrate crystallized from 95% ethanol as yellow needles, m. p. 168–169° (cor.).

*Anal.* Calcd. for $C_{13}H_{12}O_8N_4$: N, 15.91. Found: N, 15.84.

**Ethyl 1-Methyl-2-pyridone-6-pyruvate (IV).**—A procedure was employed somewhat similar to one described for quinaldine.[18]

(a) **Potassium Ethoxide.**—A solution of potassium ethoxide was prepared by adding cautiously through a dropping funnel 69 ml. of absolute ethanol to 10.55 g. of potassium previously covered with 60 ml. of absolute ether and finally refluxing the mixture until the potassium had completely dissolved. After cooling to room temperature a solution of 39.5 g. of anhydrous ethyl oxalate in 250 ml. of absolute ether was added and the slightly yellow solution allowed to stand at room temperature for ten minutes. Then 30.75 g. of 1,6-dimethyl-2-pyridone was introduced and the flask stoppered securely and shaken until the dimethylpyridone had dissolved. The potassium salt of the keto ester started to separate immediately as a dense yellow powder. The mixture was allowed to stand at room temperature for three days, after which the potassium salt was collected on a Büchner funnel, washed with a liberal amount of absolute ether and dried in a vacuum desiccator over phosphorus pentoxide. The yield was 61.8 g. (94.7%).

Recrystallization from absolute ethanol gave yellow microcrystals, m. p. 310–320°, with decomposition.

*Anal.* Calcd. for $C_{11}H_{12}O_4NK$: C, 50.56; H, 4.63; N, 5.36; K, 14.96. Found: C, 51.19; H, 4.90; N, 5.55; K, 14.76.

Conversion to the free ester was accomplished by adding 61.8 g. of the crude potassium salt gradually to a well-stirred ice-cold solution of 27 g. of concd. sulfuric acid in 450 ml. of water. The yellow microcrystalline precipitate was collected on a Büchner funnel, washed with cold water, suspended in 300 ml. of cold water, refiltered, washed again and dried. The yield of ester was 42.8 g. (81.1% based on potassium salt, 76.8% based on dimethylpyridone). After recrystallization from 95% ethanol it formed small yellow needles; m. p. 175–176° (cor.). The product is very difficultly soluble in water; soluble in ten parts of boiling ethanol.

*Anal.* Calcd. for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87; N, 6.28. Found: C, 59.39; H, 5.79; N, 6.23.

(17) Seide, *Ber.*, **57**, 791 (1924).

(18) Wislicenus and Kleisinger, *ibid.*, **42**, 1140 (1909).

(b) **Sodium Ethoxide.**—By use of sodium ethoxide prepared from sodium hydride in absolute ether and absolute ethanol, following the procedure just described, a 95% yield of sodium salt and from it a yield of 85% of ester (based on sodium salt) was obtained.

When the same procedure was applied to condensations of ethyl oxalate with 2-picoline, 6-methyl-2-pyridone or 2-acetamido-6-methylpyridine, no pyruvic esters could be obtained.

**Ethyl 1-Methyl-2-pyridone-4-pyruvate.**—The procedure described for making ethyl 1-methyl-2-pyridone-6-pyruvate was used. The potassium salt of the keto ester separated only very gradually as a dense yellow powder. It was collected on a Büchner funnel after standing for four and one-half days at room temperature, washed with absolute ether and dried over phosphorus pentoxide in a vacuum desiccator. The yield was 84%.

Conversion to the free ester was carried out by adding 12.0 g. of the potassium salt to a mixture of 5.25 g. of concd. sulfuric acid in 55 ml. of water, 30 g. of chopped ice and 100 ml. of chloroform, which was agitated by an efficient mechanical stirrer. The chloroform layer was decanted and the aqueous phase extracted with 50 ml. of chloroform. It was then made nearly neutral by adding with stirring 3.5 ml. of 28% aqueous ammonia in 30 ml. of water and again extracted with 50 ml. of chloroform. The combined chloroform solutions were washed twice with a small amount of water, filtered and concentrated to a volume of 49 ml., then diluted with 200 ml. of petroleum ether (b. p. 30–60°). The ester separated as small yellow crystals, which were filtered and washed with petroleum ether (b. p. 30–60°) after standing for three hours in the icebox. The yield was 8.1 g. (79% based on potassium salt, 67% based on dimethylpyridone). The ester crystallized from acetone or from ethanol–benzene as small colorless needles, m. p. 157–158° (cor.). The product is very soluble in ethanol and chloroform, moderately soluble in acetone, sparingly soluble in benzene, insoluble in water and petroleum ether.

*Anal.* Calcd. for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87. Found: C, 59.14; H, 5.89.

When the potassium salt was converted into the free ester by the method described under the preparation of ethyl 1-methyl-2-pyridone-6-pyruvate, the yield based on the potassium salt was only 56%.

The condensation was also effected by the use of sodium ethoxide in a similar manner. The over-all yield was 65%.

**1-Methyl-2-pyridone-6-pyruvic Acid (V).**—A mixture of 22.3 g. of 6% sulfuric acid and 2.23 g. of ethyl 1-methyl-2-pyridone-6-pyruvate was boiled under reflux for one-half hour with mechanical stirring. At first the ester dissolved, then after several minutes the acid started to separate. The mixture was allowed to stand in the icebox for several hours, the acid collected on a filter, washed with cold water and dried. There was obtained 1.78 g. (91%) of yellowish-white fine small needles. After recrystallization from water the acid melted at 239–240° (cor.) with effervescence.

*Anal.* Calcd. for $C_9H_9O_4N$: C, 55.38; H, 4.65; N, 7.18. Found: C, 55.06; H, 4.78; N, 7.21.

**1-Methyl-2-pyridone-4-pyruvic Acid.**—The hydrolysis of the ester was carried out as described for the analogous 6-pyruvic ester. The product was obtained in 55% yield. It was purified by recrystallization from 50% acetic acid; small pale yellow needles, m. p. 246° (cor.) with effervescence.

*Anal.* Calcd. for $C_9H_9O_4N$: C, 55.38; H, 4.65. Found: C, 55.31; H, 4.88.

### 1-Methyl-2-pyridone-6-acetic Acid (VI)

(a) **From 1-Methyl-2-pyridone-6-pyruvic Acid.**—A solution of 1.95 g. of the keto acid in 18 ml. of ice-cold 10% aqueous sodium hydroxide was cooled in an ice–salt-bath and shaken vigorously, while 3.3 ml. of 30% hydrogen peroxide diluted with 5 ml. of water was added at such a rate that the temperature did not rise above 0°. The solution, which at first was yellow but became colorless after some time, was kept in the icebox for forty-eight hours. A little powdered manganese dioxide was then added to cause decomposition to excess hydrogen peroxide and the mixture left in the icebox for another hour. Manganese dioxide was removed by filtration and washed with a little water and the combined filtrate and washings were acidified to congo red by the cautious addition of concd. hydrochloric acid. Crystals separated from the blue solution which, when heated, turned red, then yellowish. After boiling for several minutes, the mixture was cooled and allowed to stand in the icebox to complete crystallization. The pinkish crystals were collected on a filter and washed with ice-cold water; 1.46 g. (87%). By recrystallization from water the acid formed colorless crystals, m. p. 188° (cor.) with effervescence.

*Anal.* Calcd. for $C_8H_9O_3N$: C, 57.48; H, 5.43; N, 8.38. Found: C, 57.54; H, 5.33; N, 8.25.

When 0.3 g. of the acid was heated at its melting point, it formed 1,6-dimethyl-2-pyridone with evolution of carbon dioxide. The dimethylpyridone was identified as the picrate; yellow needles from ethanol; m. p. 134–136°.

(b) **From Ethyl 1-Methyl-2-pyridone-6-pyruvate.**—To 0.446 g. of the keto ester was added a mixture of 3.6 ml. of 10% aqueous sodium hydroxide, 0.7 ml. of 30% hydrogen peroxide and 2 g. of ice. After standing for fourteen hours in the icebox, 0.3 ml. of 30% hydrogen peroxide was added to the still slightly yellow solution, which then was allowed to stand in the icebox for another twenty-four hours. A little powdered manganese dioxide was added to the now colorless solution, which was filtered after several minutes and acidified to congo red with concd. hydrochloric acid. When heated, the blue solution turned tan-colored. Cooling caused crystals to separate which were washed with ice-cold water after standing for some time in an ice-bath. The yield was 0.18 g. (54%) of colorless crystals, m. p. 186.5° (cor.) with effervescence.

**1-Methyl-2-pyridone-4-acetic Acid.**—This acid was prepared in a manner similar to the 6-acetic acid analog. From 3.9 g. of 1-methyl-2-pyridone-4-pyruvic acid 1.98 g. (59%) of product resulted. It was purified by crystallization from water; colorless needles, m. p. 184° (cor.) with effervescence.

*Anal.* Calcd. for $C_8H_9O_3N$: C, 57.48; H, 5.43; neut. equiv., 167.2. Found: C, 57.50; H, 5.57; neut. equiv., 167.7.

**1-Methyl-2-pyridone-6-carboxylic Acid (VII).**—To 10.4 g. of the potassium salt of ethyl 1-methyl-2-pyridone-6-pyruvate was added 92 g. of ice, followed by 14 ml. of 30% hydrogen peroxide and the solution kept in the icebox for one and one-half hours. An ice-cold solution of 1.8 g. of sodium hydroxide in 10 ml. of water was added and, after forty-two hours in the ice-box, excess hydrogen peroxide was decomposed by adding a little manganese dioxide. The mixture was allowed to stand in the ice-box for another hour, filtered and acidified with 7.5 ml. of concd. hydrochloric acid, which caused the blue solution to turn brown. Tan crystals separated immediately; they were filtered after standing for two hours in the icebox, 3.55 g. (58%). The acid was purified by dissolving it in dilute aqueous sodium carbonate, boiling the solution with Darco, then filtering and acidifying with dilute hydrochloric acid and recrystallizing the precipitate twice from glacial acetic acid. It formed colorless needles, m. p. 260° (cor.) with effervescence. Späth and Koller[10] reported m. p. 247–248° for the compound as prepared by methylation of 6-hydroxypyridine-2-carboxylic acid.

*Anal.* Calcd. for $C_7H_7O_3N$: C, 54.90; H, 4.61. Found: C, 54.87; H, 4.79.

A small quantity of the acid was melted in a small tube and the liquid distilled. The distillate was dissolved in ether and an ethereal solution of mercuric chloride added. The colorless needles of the mercuric chloride double salt of 1-methyl-2-pyridone, m. p. 127°, as reported by Späth and Koller, resulted.

**Methyl 1-Methyl-2-pyridone-6-acetate.**—A mixture of 0.55 g. of 1-methyl-2-pyridone-6-acetic acid, 14 ml. of

methanol and 0.5 ml. of concd. sulfuric acid was boiled under reflux for two hours, cooled, poured into an excess of aqueous potassium carbonate and the resulting solution extracted several times with chloroform. Addition of petroleum ether (b. p. 30–60°) to the chloroform solution which had been concentrated to a small volume caused the separation of 0.46 g. (77%) of crystals. Recrystallization from ether–petroleum ether (b. p. 30–60°) yielded small colorless needles, m. p. 102°.

*Anal.* Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.90; H, 6.01; N, 8.06.

**Ethyl 1-Methyl-2-pyridone-6-acetate (X).**—A mixture of 17.6 g. of 1-methyl-2-pyridone-6-acetic acid, 500 ml. of absolute ethanol and 6 ml. of concd. sulfuric acid was boiled under reflux for two hours. After addition of 50 ml. of benzene, the solution was distilled slowly for one hour on the steam-bath until about half volume was reached and then concentrated under reduced pressure to a volume of about 110 ml. Upon adding carefully 20 g. of anhydrous potassium carbonate, then 50 g. of chopped ice, followed by 200 ml. of water, and extracting of the solution with eight 25-ml. portions of chloroform, a chloroform solution was obtained. This was dried, concentrated to about 30 ml. and diluted with 100 ml. of petroleum ether (b. p. 30–60°) which caused the deposition of 17.8 g. of colorless needles, m. p. 100–101° (cor.). Another 0.5 g. of less pure product was obtained from the filtrate, giving a total yield of 18.3 g. (89%). Recrystallization of the first crop from dry ether did not cause modification of the melting point.

The ester was very soluble in water, benzene and chloroform, moderately soluble in ether, sparingly soluble in petroleum ether.

*Anal.* Calcd. for $C_9H_{13}O_3N$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.59; H, 6.61; N, 7.12.

The ester failed to undergo condensation with aromatic aldehydes in the presence of piperidine or with ethyl oxalate in the presence of potassium ethoxide.

**Ethyl 1-Methyl-2-pyridone-6-(α-oximino)-propionate.**—A solution of 15.0 g. of ethyl 1-methyl-2-pyridone-6-pyruvate and 15 g. of hydroxylamine hydrochloride in 75 ml. of pyridine and 75 ml. of absolute ethanol was refluxed for four hours on the steam-bath. The hot solution was filtered to remove a small amount of impurity and the filtrate freed from solvents by distillation under reduced pressure. The yellowish gelatinous residue was triturated with 75 ml. of cold water. White crystals separated which were collected on a filter, washed with water and dried. The yield was 13.8 g. (86%). The ester was purified by crystallization from 95% ethanol; colorless needles, m. p. 198° (cor.).

*Anal.* Calcd. for $C_{11}H_{14}O_4N_2$: C, 55.45; H, 5.92; N, 11.76. Found: C, 55.49; H, 6.15; N, 11.86.

**1-Methyl-2-pyridone-6-(α-oximino)-propionic Acid (VIII)**

(a) **By Hydrolysis of the Oximino Ester.**—A solution of 8.91 g. of the oximino ester in 45 ml. of 2 *N* aqueous sodium hydroxide was boiled under reflux for one hour and twenty minutes. A small amount of impurity was removed by filtration, 10 ml. of water being used for washing flask and filter. The combined yellow filtrate and washings were cooled in an ice-bath and acidified with 9 ml. of concd. hydrochloric acid. Small colorless needles separated; 7.49 g. (95%), m. p. 182° (cor.) with decomposition. Purification by crystallization from 50% acetic acid did not change the melting point.

*Anal.* Calcd. for $C_9H_{10}O_4N_2$: C, 51.43; H, 4.80. Found: C, 51.31; H, 4.87.

(b) **By Action of Hydroxylamine on 1-Methyl-2-pyridone-6-pyruvic Acid.**—To 19.5 g. of the keto acid was added an ice-cold solution of 14.75 g. of 95% sodium hydroxide in 60 ml. of water, followed by an ice-cold solution of 10.42 g. of hydroxylamine hydrochloride in 20 ml. of water. The mixture was shaken to dissolve the acid, then allowed to stand at 30° for forty-three hours. A small amount of impurity was removed by filtration and the yellow filtrate, which was cooled in an ice-bath to 5°, acidified by the addition of 33 ml. of concd. hydrochloric acid. Small colorless needles separated, which were filtered after standing for several hours in the icebox, washed with ice-cold water and, when dried, melted at 182° (cor.) with decomposition. The yield was 19.15 g. (91%).

**1-Methyl-2-pyridone-6-acetonitrile (IX).**—A distilling flask containing 19.1 g. of 1-methyl-2-pyridone-6-(α-oximino)-propionic acid was heated cautiously with a free flame. The solid melted with copious evolution of carbon dioxide and water. The residue was then distilled under reduced pressure, b. p. 168° (1 mm.), as a yellow oil which solidified in the receiver. The yield was 12.5 g. (93%). After recrystallization from benzene–ether and a second vacuum-distillation the product formed colorless needles, m. p. 95.5–96.5°, very soluble in water, ethanol and acetone, moderately soluble in benzene, sparingly soluble in ether.

*Anal.* Calcd. for $C_8H_8ON_2$: C, 64.85; H, 5.44. Found: C, 64.78; H, 5.33.

The nitrile failed to condense with ethyl carbonate. With benzaldehyde in the presence of pyridine and piperidine, a yellow condensation product, m. p. 260–262° (cor.), formed in a high yield, but could not be obtained in analytically pure form.

The nitrile was readily hydrolyzed by boiling with dilute ethanolic sodium hydroxide for three hours. After acidification 1-methyl-2-pyridone-6-acetic acid, m. p. 187° (cor.) with effervescence, resulted in 86% yield.

**Ethyl 1-Methyl-2-pyridone-6-(α-benzyl)-acetate (XI, R = $C_6H_5CH_2$).**—To a solution of 0.084 g. of sodium in 2 ml. of absolute ethanol was added 0.69 g. of ethyl 1-methyl-2-pyridone-6-acetate, followed by 0.45 ml. of benzyl chloride. The mixture was refluxed on the steam-bath for twenty-one hours with exclusion of moisture. Another 0.2 ml. of benzyl chloride was added and refluxing continued for three hours until the reaction mixture was neutral. After steam-distillation to remove excess benzyl chloride, the oil which had separated from the residue was dissolved in ether. The ether solution was washed twice with dilute aqueous sodium carbonate, dried over potassium carbonate and concentrated to a volume of about 3 ml., which caused colorless crystals to separate. Crystallization was completed by adding 30 ml. of petroleum ether (b. p. 30–60°) and chilling in an ice-bath for one hour. The solid weighed 0.62 g. (61%). After two recrystallizations from 35% ethanol it formed small colorless needles, m. p. 104–105° (cor.), very soluble in benzene and ethanol, moderately soluble in ether, insoluble in water.

*Anal.* Calcd. for $C_{17}H_{19}O_3N$: C, 71.56; H, 6.71; N, 4.91. Found: C, 71.74; H, 6.96; N, 4.80.

**1-Methyl-2-pyridone-6-(α-benzyl)-acetic Acid (XII, R = $C_6H_5CH_2$-).**—To 1.0 g. of sodium hydroxide dissolved in 2 ml. of water and 5 ml. of ethanol was added 0.74 g. of the ester and the solution refluxed for two hours. After cooling and acidification to congo red with dilute hydrochloric acid, colorless crystals separated. The yield of material was 0.59 g. (88%). It was purified by dissolving in dilute aqueous ammonia, filtering (Darco) and reprecipitating it with dilute hydrochloric acid; small colorless needles, m. p. 155° (cor.) with effervescence.

*Anal.* Calcd. for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88. Found: C, 70.15; H, 5.88.

**1-Methyl-6-phenethyl-2-pyridone (XIII, R = $C_6H_5$-$CH_2$-).**—In a vacuum-sublimation apparatus 0.1 g. of 1-methyl-2-pyridone-6-(α-benzyl)-acetic acid was heated carefully in an oil-bath. At approximately 150° the crystals melted with evolution of carbon dioxide. When gas evolution had ceased, the temperature was raised slowly to 180°, maintained there for five minutes and again decreased to 150°. When the pressure was reduced to 2 mm., the material distilled and solidified on the cold finger. Redistillation at 2 mm. gave small colorless needles, m. p. 95.5–96.5°, soluble in ether, difficultly soluble in water.

*Anal.* Calcd. for $C_{14}H_{15}ON$: C, 78.84; H, 7.09. Found: C, 79.05; H, 6.99.

**1-Methyl-2-pyridone-6-($\alpha$-benzyl)-acetonitrile.**—To a solution of 0.23 g. of sodium in 4 ml. of absolute ethanol was added dropwise with mechanical stirring and exclusion of moisture a solution of 1.48 g. of 1-methyl-2-pyridone-6-acetonitrile in 5 ml. of absolute ethanol and 5 ml. of dry benzene, followed by 1.3 ml. of benzyl chloride in 5 ml. of dry benzene. The dark mixture was stirred at room temperature for fifteen minutes, then at the refluxing temperature for fifteen hours. Water was added and the brown benzene layer extracted several times with water, dried over potassium carbonate and boiled with Darco. The yellow filtrate was heated, diluted with petroleum ether (b. p. 30–60°) until it became cloudy, and filtered rapidly. Cooling and scratching with a glass rod caused separation of light tan-colored crystals. The yield was 1.0 g. (42%). After recrystallization from dilute ethanol, then from benzene–ether, the nitrile formed small colorless leaflets, m. p. 132° (cor.).

*Anal.* Calcd. for $C_{15}H_{14}ON_2$: C, 75.60; H, 5.92; N, 11.76. Found: C, 75.71; H, 5.66; N, 11.11.

The nitrile was hydrolyzed by 62% sulfuric acid or preferably by dilute ethanolic potassium hydroxide to form the corresponding acid, m. p. 155°, previously described.

**Ethyl 1-Methyl-2-pyridone-6-($\alpha$-*n*-butyl)-acetate (XI, R = $C_4H_9$-).**—To a solution of 0.51 g. of sodium in 10 ml. of absolute ethanol was added 4.30 g. of ethyl 1-methyl-2-pyridone-6-acetate, followed by 3.5 ml. of *n*-butyl iodide. The orange-colored solution was refluxed with exclusion of moisture on the steam-bath for twenty hours, after which time it was no longer alkaline. Solvent and unreacted butyl iodide were evaporated on the steam-bath under reduced pressure; then 20 ml. of water was added to dissolve sodium iodide. The oil was dissolved in ether and the solution washed twice with aqueous sodium bicarbonate, then thrice with water and dried. Removal of the solvent and fractionation under reduced pressure gave 3.6 g. (65%), b. p. 159–160° (2 mm.). After another distillation the product was a pale yellow oil, $n^{20}D$ 1.5180. It solidified to colorless crystals on cooling in Dry Ice–acetone.

*Anal.* Calcd. for $C_{14}H_{21}O_3N$: C, 66.90; H, 8.42; N, 5.57. Found: C, 66.87; H, 8.58; N, 5.81.

The reaction was carried out also with *n*-butyl bromide, but somewhat less satisfactory results were obtained.

**Hydrolysis and Decarboxylation of Ethyl 1-Methyl-2-pyridone-6-($\alpha$-*n*-butyl)-acetate.**—A mixture of 0.59 g. of the ester and 0.93 g. of 33% aqueous sodium hydroxide was heated on the hot-plate until a homogeneous solution resulted, then on the steam-bath for one hour. The solution was diluted with 1 ml. of water, cooled in an ice-bath and acidified by the addition of 0.7 ml. of concd. hydrochloric acid. The 1-methyl-2-pyridone-6-($\alpha$-*n*-butyl)-acetic acid separated as a viscous oil which could not be induced to solidify. This oil was dissolved in chloroform, the solution washed with water, then concentrated to a small volume and placed in the terminal bulb of a three-bulb microdistillation tube. Chloroform was removed and the residue heated in an oil-bath. The acid decomposed at 150° with evolution of carbon dioxide. The temperature was slowly raised to 185° and maintained there for five minutes. The residue was then distilled into the other bulbs in a vacuum (below 1 mm.) by placing the tube partly in an air-bath heated at 90°. The 6-*n*-amyl-1-methyl-2-pyridone (XIII, R = $C_4H_9$-) was obtained as a colorless oil; $n^{20}D$ 1.5250 (after redistillation).

*Anal.* Calcd. for $C_{11}H_{17}ON$: C, 73.70; H, 9.56; N, 7.81. Found: C, 73.26; H, 10.06; N, 8.41.

**6-Acetonyl-1-methyl-2-pyridone (XIII, R = $CH_3CO$-).**—To 0.31 g. of sodium hydride and 10 ml. of absolute ether in a 50-ml. round-bottomed flask provided with a mechanical stirrer and a reflux condenser fitted with a calcium chloride tube, was added 0.77 ml. of absolute ethanol diluted with 10 ml. of absolute ether. As soon as the sodium hydride had been transformed completely into sodium ethoxide, 2.52 g. of ethyl 1-methyl-2-pyridone-6-acetate was added and the mixture refluxed with stirring for fifteen minutes. After cooling in an ice-bath, 0.97 ml. of acetyl chloride, diluted with 10 ml. of absolute ether, was added in one lot. The yellow suspension turned colorless and sodium chloride separated. Stirring was continued for five minutes while keeping the flask in the ice-bath, then for two hours at the boiling point of ether. The slightly acid reaction mixture was extracted with aqueous sodium bicarbonate, then with water. The ethereal solution, after drying, was treated with petroleum ether (b. p. 30–60°) to cause the separation of an oil which partly solidified at 6°, but became liquid again at room temperature. The ether and petroleum ether were evaporated and the residual oil freed from traces of solvent in a vacuum desiccator. The yield of $\beta$-keto ester, which was not further purified, was 1.16 g. (38%).

A mixture of 0.97 g. of the crude keto ester and 15 ml. of concd. hydrochloric acid was boiled under reflux on the steam-bath for twenty-two hours. The solution was concentrated under reduced pressure to a small volume, made alkaline by the addition of a large excess of saturated aqueous sodium carbonate and extracted twice with chloroform. The extract was boiled with Darco and the yellow filtrate evaporated on the steam-bath. When petroleum ether (b. p. 30–60°) was added, the oil solidified to pale yellow crystals. The yield was 0.18 g. (27% based on the crude keto ester, 10% based on starting material). The ketone crystallized from benzene as almost white needles, m. p. 135.5–136.5° (cor.). After distillation in a vacuum-sublimation apparatus (bath 150°, 5 mm.) it formed colorless oblong leaflets, m. p. 136.5–137.5° (cor.), very soluble in water and acetone.

*Anal.* Calcd. for $C_9H_{11}O_2N$: C, 65.44; H, 6.71. Found: C, 65.62; H, 6.83.

**6-Acetonyl-1-methyl-2-pyridone *p*-Nitrophenylhydrazone.**—A solution of 55 mg. of the ketone and of 60 mg. of *p*-nitrophenylhydrazine in 2 ml. of glacial acetic acid was boiled under reflux for thirty minutes. After dilution with water, 79 mg. (79%) of small yellow needles separated. After two recrystallizations from 95% ethanol, the product melted at 209–210° (cor.) with blackening.

*Anal.* Calcd. for $C_{15}H_{16}O_3N_4$: C, 59.99; H, 5.37. Found: C, 60.14; H, 5.42.

**1-Methyl-6-*m*-nitrostyryl-2-pyridone.**—A mixture of 2.1 g. of 1,6-dimethyl-2-pyridone, 2.58 g. of *m*-nitrobenzaldehyde and 1.77 g. of acetic anhydride was heated in an oil-bath at 175–180° for twenty hours. The black oil was dissolved in 30 ml. of methanol, the solution boiled with 0.2 g. of Norit for five minutes and filtered, diluted with 3 ml. of concd. hydrochloric acid and 20 ml. of water and boiled on the hot plate to remove methanol. The yellow solution, in which a black-brown oil was suspended, was cooled to room temperature and extracted with benzene to remove tar and unreacted aldehyde. The benzene phase was extracted twice with dilute hydrochloric acid. The combined light yellow acid solutions were boiled for two minutes and made alkaline with 25% aqueous sodium carbonate. A yellow microcrystalline precipitate separated; 0.05 g. (1.1%). It was purified by dissolving in 2 ml. of boiling ethanol, filtering from a black impurity and diluting with 30 ml. of water. The solid was recrystallized from benzene–petroleum ether, then from 95% ethanol, and formed small yellow crystals, m. p. 216–218° (cor.).

*Anal.* Calcd. for $C_{14}H_{12}O_3N_2$: C, 65.62; H, 4.72; N, 10.93. Found: C, 65.56; H, 4.77; N, 11.04.

**6-Acetamido-2-stilbazole (XV).**—A mixture of 15.0 g. of 2-acetamido-6-methylpyridine,[14] 10.6 g. of benzaldehyde and 5.1 g. of acetic anhydride was boiled under reflux for thirty hours. The reaction mixture was steam-distilled to remove unreacted benzaldehyde, of which 50% was recovered as the semicarbazone. The residue from the steam-distillation was diluted with water to 250 ml., acidified with hydrochloric acid, treated with Norit and Celite to remove a tarry impurity and filtered through a

Büchner funnel. The yellow filtrate was rendered alkaline by adding aqueous ammonia. A yellow oil separated which was dissolved in ether. After drying and removal of the ether, the residue was dissolved in a small amount of chloroform and the solution diluted with petroleum ether. A solid separated which was dissolved in dilute hydrochloric acid, filtered from a tarry impurity; then ice was added to the solution, followed by an excess of aqueous ammonia. A yellow flocculent mass separated which was filtered and washed with ice-cold water. It was then dissolved in 95% ethanol, the solution boiled with Norit, filtered hot and diluted with hot water until a precipitate started to form. When cooled slowly, a yellow solid separated weighing 2.94 g. (12.3%). After one recrystallization from benzene–petroleum ether (b. p. 90–110°) and one recrystallization from 70% ethanol, the compound formed colorless needles, m. p. 149–150° (cor.).

*Anal.* Calcd. for $C_{15}H_{14}ON_2$: C, 75.60; H, 5.92; N, 11.76. Found: C, 75.85; H, 6.15; N, 11.86.

**6-Amino-2-stilbazole Hydrochloride.**—A solution of 4.2 g. of 6-acetamido-2-stilbazole in 70 ml. of concd. hydrochloric acid and 70 ml. of water was boiled under reflux for three hours, then cooled and allowed to stand in the icebox overnight. The hydrochloride was collected on a filter, washed with ice-cold 20% hydrochloric acid, then with ether and dried; yield 3.98 g. (97%), m. p. 249–252° (cor.). It was recrystallized from ethanol to form yellow needles of the same melting point.

*Anal.* Calcd. for $C_{13}H_{13}N_2Cl$: C, 67.09; H, 5.63; N, 12.04; Cl, 15.24. Found: C, 67.02; H, 5.72; N, 12.12; Cl, 15.37.

**6-Amino-2-stilbazole (XVI).**—A solution of 0.67 g. of the hydrochloride in a small amount of water was made alkaline with aqueous ammonia. A pale yellow oil separated which solidified rapidly on standing; yield 0.54 g. (96%). It was purified by crystallization from benzene–petroleum ether (b. p. 90–110°); small colorless prismatic needles, m. p. 110°.

*Anal.* Calcd. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.28. Found: C, 79.74; H, 6.09; N, 14.46.

**6-Hydroxy-2-stilbazole (6-Styryl-2-pyridone) (XVII).**—To a warm solution of 0.165 g. of 6-amino-2-stilbazole in 0.1 ml. of concd. sulfuric acid and 3 ml. of water was added 0.07 g. of powdered sodium nitrite. A brown flocculent mass separated. After boiling the mixture for five minutes, an excess of aqueous ammonia was added and boiling continued for two minutes. The red-brown powder was removed by filtration and treated with hot dilute aqueous potassium hydroxide. A black tarry impurity was removed by filtration and the yellow filtrate buffered with Dry Ice. The hydroxystilbazole separated as a yellow oil which rapidly solidified. The yield was 0.08 (48%). Two recrystallizations from 95% ethanol (Norit) yielded small yellow needles, m. p. 210–211° (cor.).

*Anal.* Calcd. for $C_{13}H_{11}NO$: C, 79.16; H, 5.62; N, 7.10. Found: C, 78.67; H, 5.77; N, 7.52.

**2-Amino-4-stilbazole.**—A mixture of 8.0 g. of 2-acetamido-4-methylpyridine,[17] 6.3 g. of benzaldehyde and 2.7 g. of acetic anhydride was refluxed under nitrogen for forty-six hours. The dark oil, to which 15 ml. of concd. hydrochloric acid had been added, was steam-distilled to remove unreacted benzaldehyde. To the residue, consisting of a dark sticky mass and about 50 ml. of an aqueous solution, was added 50 ml. of concd. hydrochloric acid. The mixture was heated to boiling and filtered from a brown solid, which was then boiled with 50 ml. of concd. hydrochloric acid and refiltered.

The combined filtrates were boiled with Norit and filtered. The clear dark yellow solution was boiled under reflux for three hours, diluted with 50 ml. of water and refluxed for an additional four hours. When cooled, a yellow flocculent precipitate separated. It was collected on a filter, dissolved in boiling ethanol, the solution made alkaline with aqueous ammonia and diluted with water. The tan flocculent precipitate was dissolved in 50 ml. of concd. hydrochloric acid, the solution boiled with Norit, filtered hot and diluted with 50 ml. of boiling water. After standing for three hours in the icebox, the material which had separated was isolated by filtration, washed with cold water and dissolved in 50 ml. of hot ethanol; to the boiling solution was added 4 ml. of 28% aqueous ammonia in 10 ml. of ethanol, then water, until crystallization started, and the mixture allowed to stand in the icebox. The tan-colored leaflets of the aminostilbazole weighed 1.52 g. (14.5%). After two recrystallizations from 95% ethanol it formed pale yellow glittering leaflets, m. p. 216–217° (cor.).

*Anal.* Calcd. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.28. Found: C, 79.76; H, 6.09; N, 14.23.

The solid, which proved to be insoluble when the original reaction mixture was extracted with hydrochloric acid, was digested with ice-cold acetone, then with boiling concd. hydrochloric acid and refiltered. It was then dissolved in 70 ml. of boiling ethanol, the solution filtered and heated with 40 ml. of concd. hydrochloric acid. Upon slow dilution with 100 ml. of boiling water a yellow flocculent solid separated. After dissolving in ethanol and adding aqueous ammonia to the boiling solution, yellow microcrystals formed. The product (0.29 g.) was recrystallized from ethanol–methyl ethyl ketone; small yellow needles, m. p. 234–235° (cor.).

Analysis did not serve to identify the product.

*Anal.* Found: C, 84.26; H, 5.59; N, 6.87.

**2-Hydroxy-4-stilbazole (4-Styryl-2-pyridone).**—A solution of 2.4 g. of 2-amino-4-stilbazole in 1.5 ml. of concd. sulfuric acid and 10 ml. of glacial acetic acid was stirred and cooled in an ice–salt-bath, which caused separation of the sulfate. It was diazotized by the gradual addition of 1.0 g. of sodium nitrite in 2 ml. of water. The mixture was then allowed to come to room temperature and treated with small portions of solid sodium nitrite until it gave a positive reaction with starch–iodide paper (ten minutes). Addition of 100 ml. of water caused separation of a tan-colored flocculent solid. The suspension was heated to 90° and made alkaline with aqueous ammonia. The solid was removed by filtration, dissolved in 100 ml. of boiling ethanol, a tan-colored impurity removed by filtration and the filtrate allowed to stand in the icebox. The greyish-brown crystals were collected and weighed 0.86 g. (36%). By repeated recrystallizations from 95% ethanol (Darco), yellowish prismatic needles, m. p. 238–239° (cor.), resulted.

*Anal.* Calcd. for $C_{13}H_{11}NO$: C, 79.16; H, 5.62; N, 7.10. Found: C, 79.04; H, 5.71; N, 7.45.

**6-Methyl-2-pyridone-1-β-propionitrile (XVIII).**—An intimate mixture of 42.5 g. of 6-methyl-2-pyridone and 1.3 g. of 6-methyl-2-pyridone sodium was heated under reflux on a steam-bath with 22.8 g. of acrylonitrile. The mixture was shaken frequently until it had liquefied, which took about ten minutes, then heated for twenty more minutes. After addition of 1 ml. of glacial acetic acid in 110 ml. of boiling benzene, the solution was filtered hot from sodium acetate and allowed to cool in the icebox. Tan crystals separated, which were collected on a filter and washed with a small amount of ice-cold benzene. The yield was 52.5 (81% based on total methylpyridone, 83% based on free methylpyridone). It was recrystallized from methyl ethyl ketone to give colorless prisms, m. p. 109–110° (cor.), very soluble in water, moderately soluble in benzene, acetone and methyl ethyl ketone, insoluble in petroleum ether.

*Anal.* Calcd. for $C_9H_{10}ON_2$: C, 66.65; H, 6.22; N, 17.27. Found: C, 66.88; H, 6.20; N, 17.13.

Other catalysts, such as 50% aqueous potassium hydroxide, powdered sodium hydroxide, Triton B (with addition of dioxane) gave satisfactory results, although the yield of product was slightly less.

Pyrolysis of the nitrile in a small distilling flask gave acrylonitrile and 6-methyl-2-pyridone, showing the reversibility of this reaction.

**6-Methyl-2-pyridone-1-β-propionic Acid (XIX).**—A solution of 18.4 g. of the propionitrile in 92 ml. of water

and 6 ml. of concd. sulfuric acid was refluxed for three hours. When cooled in the icebox, colorless crystals separated; the yield was 18.9 g. (92%). After recrystallization from water, then from acetone, the acid formed colorless plates or prisms, m. p. 165–166° (cor.).

*Anal.* Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.73; H, 6.24; N, 7.82.

Many experiments were performed to prepare the esters of this acid. None gave satisfactory results. An oil which could not be distilled without decomposition into acrylic ester and 6-methyl-2-pyridone always resulted. The methods employed were alcoholysis of the corresponding nitrile, condensation of 6-methyl-2-pyridone sodium with ethyl β-bromopropionate, esterification of the acid with hydrogen chloride and ethanol, reaction of the silver salt of the acid with methyl or ethyl iodide, attempted condensation of 6-methyl-2-pyridone with ethyl acrylate, the action of diazomethane on the acid.

The crude oil obtained in many of these experiments was treated with reagents such as potassium, potassium ethoxide, and sodium hydride in an attempt to eliminate ethanol or methanol from the ester grouping and 6-methyl group in order to obtain a pyridocoline ring. All experiments failed.

**Ethyl 6-Methyl-2-pyridone-1-acetate (XX) and 2-Carbethoxymethoxy-6-methylpyridine (XXI).**—To a solution of 2.3 g. of sodium in 50 ml. of absolute ethanol and 20 ml. of dry benzene was added 10.9 g. of 6-methyl-2-pyridone, followed by 18 g. of ethyl bromoacetate. The mixture was refluxed in a boiling water-bath for two hours; then ethanol, benzene and most of the unreacted ethyl bromoacetate were removed on the steam-bath under reduced pressure. After addition of 100 ml. of hot water, the mixture was steam-distilled. The steam-distillate from which a heavy oil had separated was extracted with chloroform and the extract dried over potassium carbonate. Chloroform was removed under reduced pressure and the residual oil distilled *in vacuo*. The 2-carbethoxymethoxy-6-methylpyridine boiled at 132° (15 mm.), $n^{20}D$ 1.4909. The yield was 1 g. (5%).

*Anal.* Calcd. for $C_{10}H_{13}O_3N$: C, 61.52; H, 6.71. Found: C, 61.56; H, 6.88.

The residue of the steam-distillation was made alkaline by the addition of 2 g. of potassium carbonate and extracted with chloroform in a continuous extractor. The extract was dried over potassium carbonate and freed completely from chloroform by heating on the steam-bath under reduced pressure. The ethyl 6-methyl-2-pyridone-1-acetate remained as a brown liquid which on cooling solidified to a tan-colored solid. The yield was 13.7 g. (70%). It was dissolved in hot benzene, the solution boiled with Norit, filtered and diluted with petroleum ether (b. p. 30–60°) until incipient cloudiness. When cooled in the ice-box, 11.7 g. (60%) of crystals separated. They were dissolved in cold acetone, a colorless impurity removed by filtration and the filtrate diluted with petroleum ether (b. p. 30–60°). Repeated recrystallizations gave colorless needles, m. p. 81–82°. The ester was purified for analysis by vacuum-sublimation.

*Anal.* Calcd. for $C_{10}H_{13}O_3N$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.41; H, 6.44; N, 7.04.

**6-Methyl-2-pyridone-1-acetic Acid.**—A mixture of 1.24 g. of the ester (XX) and 7.4 ml. of 35% aqueous potassium hydroxide was boiled under reflux for thirty minutes. The solution was filtered, diluted with 10 ml. of water and acidified by the addition of 5.7 ml. of concd. hydrochloric acid. The colorless prisms were collected on a filter after standing in an ice-box overnight; yield 0.68 g. (64%). The acid was purified from ethanol; m. p. 229° (cor.) with effervescence.

*Anal.* Calcd. for $C_8H_9O_3N$: N, 8.38. Found: N, 8.77.

The same compound was made as follows. To a solution of 2.18 g. of 6-methyl-2-pyridone in 4.62 g. of hot 50% aqueous potassium hydroxide was added 1.98 g. of chloroacetic acid and the mixture boiled on the hot plate for two minutes. The solid which formed was dissolved by adding 2 ml. of water and boiling was continued for three more minutes. When cooled, the mixture solidified to a crystalline mass. It was dissolved in 7 ml. of hot water and acidified by the addition of 1.8 ml. of concd. hydrochloric acid. Cooling to room temperature and scratching the wall of the container with a glass rod caused separation of colorless crystals; yield 0.4 g. (12%). After washing with a little acetone, the remaining 0.3 g. was recrystallized from boiling water, then ethanol; m. p. 229° (cor.) with effervescence.

**Ethyl 1-Carbethoxymethyl-2-pyridone-6-pyruvate (XXII).**—To a solution of 0.76 g. of potassium in 4.3 ml. of absolute ethanol and 9 ml. of absolute ether was added at 0° 2.84 g. of ethyl oxalate, then after ten minutes 3.48 g. of ethyl 6-methyl-2-pyridone-1-acetate, followed by 15 ml. of dry benzene and 26 ml. of absolute ether. The flask was flushed with nitrogen, tightly stoppered and allowed to stand at room temperature for nineteen hours. In a short time the potassium salt started to separate as a yellow powder and the solution turned at first bright yellow, then orange, finally dark red-brown. The potassium salt of the condensation product was collected on a Büchner funnel, washed with absolute ether and weighed 2.42 g. (41%).

The potassium salt was stirred into a mixture of 0.5 ml. of concd. sulfuric acid and 20 g. of ice. A yellow oil separated which rapidly solidified. The ester was collected on a filter, washed with water and dried. It weighed 1.61 g. (30.6%). It was purified by crystallization from 95% ethanol (Norit); small lemon-yellow leaflets, m. p. 137–138°.

*Anal.* Calcd. for $C_{14}H_{17}O_6N$: C, 56.94; H, 5.80; N, 4.74. Found: C, 56.90; H, 5.73; N, 4.84.

**Reaction of 6-Methyl-2-pyridone with N-Bromosuccinimide.**—A mixture of 2.18 g. of 6-methyl-2-pyridone, 7.12 g. of N-bromosuccinimide and 0.25 g. of benzoyl peroxide in 60 ml. of carbon tetrachloride was boiled under reflux for thirty minutes. Succinimide was removed by filtering the hot mixture and washing with boiling carbon tetrachloride. The combined filtrate and washings were evaporated to dryness and the residue recrystallized from 95% ethanol. The product consisted of 1.2 g. of colorless needles, which after recrystallization melted at 254–255° (cor.). Admixture of an authentic sample of 3,5-dibromo-6-methyl-2-pyridone did not depress the melting point.

**2-Amino-5-bromo-6-methylpyridine.**—A solution of 10.8 g. of 2-amino-6-methylpyridine in 47 g. of 20% sulfuric acid was cooled in ice water and 18.7 g. of bromine was added dropwise over fifteen minutes with continuous swirling. It was then shaken at room temperature until a colorless solution resulted (about fifteen minutes). cooled again in ice water and made alkaline by adding 80 g. of ice-cold aqueous 20% sodium hydroxide. A partly crystalline, partly oily white mass separated which solidified completely after standing for several hours in the ice-box. The crude product weighed 14.6 g. (78%). Recrystallization from petroleum ether (b. p. 90–110°) in which the contaminants are very soluble, gave 9.3 g. (50%) of long silky colorless needles, m. p. 83–84°. The analytical sample was prepared by vacuum-sublimation.

*Anal.* Calcd. for $C_6H_7N_2Br$: N, 14.98; Br, 42.73. Found: N, 15.00; Br, 42.76.

**2-Amino-3,5-dibromo-6-methylpyridine.**—To a solution of 10.8 g. of 2-amino-6-methylpyridine in 47 g. of 20% sulfuric acid was added with continuous swirling 32 g. of bromine. The temperature was maintained below 35° by occasional immersion in ice water. The mixture was heated on the steam-bath for two hours, then allowed to stand in the icebox overnight. The white crystalline sulfate was collected on a filter and washed with ice-cold 20% sulfuric acid, then with acetone. The yield was 24.6 g. (78%).

The sulfate was added in small portions with stirring to 50 g. of ice-cold 10% aqueous sodium hydroxide and the mixture allowed to stand in the icebox for several hours. The colorless crystals weighed 17.15 g. (82.5% based on sulfate). After recrystallization from 95% ethanol, the

base formed short colorless prismatic needles, m. p. 144° (cor.).

*Anal.* Calcd. for $C_6H_6N_2Br_2$: C, 27.09; H, 2.27; N, 10.53; Br, 60.10. Found: C, 27.31; H, 2.33; N, 10.63; Br, 59.93.

**5-Bromo-6-methyl-2-pyridone.**—A solution of 8.4 g. of 2-amino-5-bromo-6-methylpyridine in 40 g. of ice-cold 20% sulfuric acid was diazotized below 10° by adding dropwise a solution of 3.3 g. of sodium nitrite in 7 ml. of water. The sulfate of the pyridone separated during the reaction. The paste was diluted with 30 ml. of water and the suspension heated on the steam-bath for five minutes. A solution of 9 g. of potassium carbonate in 15 ml. of water was added with stirring and the yellow suspension heated to boiling, then allowed to stand in the icebox. The yield of tan needles was 6.9 g. (82%). The compound was recrystallized from 95% ethanol, then from benzene to form colorless needles, m. p. 204° (cor.). The analytical sample was prepared by vacuum-sublimation.

*Anal.* Calcd. for $C_6H_6ONBr$: N, 7.45; Br, 42.50. Found: N, 7.28; Br, 42.50.

**3,5-Dibromo-6-methyl-2-pyridone.**—A warm solution of 13.3 g. of 2-amino-3,5-dibromo-6-methylpyridine in 54 g. of 20% sulfuric acid was cooled rapidly in an ice-salt bath with efficient stirring to cause separation of very small crystals, then diazotized by adding dropwise a solution of 3.7 g. of sodium nitrite in 10 ml. of water. The mixture became pasty as the sulfate of the pyridone separated. The suspension obtained by adding 300 ml. of water was heated to boiling and made alkaline by adding slowly with stirring a solution of 13 g. of potassium carbonate in 50 ml. of water. The yield of colorless crystals was 12.9 g. (97%). After recrystallization from ethanol-benzene and then from 95% ethanol, colorless needles, m. p. 254–255° (cor.), resulted. Errera[13] reported m. p. 238–239°.

## Summary

1. In order to devise methods by which cytisine might be synthesized, a further knowledge of the activity of a 6-methyl group in 1-substituted 2-pyridones was required. It has been shown that the 6-methyl group in 1,6-dimethyl-2-pyridone condenses readily with ethyl oxalate in presence of potassium or sodium ethoxide to give the corresponding pyruvate. The same is true of the 4-methyl group in 1,4-dimethyl-2-pyridone.

2. These pyruvic esters were saponified to the corresponding acids and these by means of alkali and hydrogen peroxide degraded to the corresponding 1-methyl-2-pyridone-6(or 4)-acetic acids. The 6-pyruvic ester was converted directly in one step to the 6-acetic acid with alkali and hydrogen peroxide. Its potassium salt, however, by treatment with hydrogen peroxide, gave 1-methyl-2-pyridone-6-carboxylic acid.

3. Pyrolysis of 1-methyl-2-pyridone-6-(α-oximino)-propionic acid, obtained by reaction of the 6-pyruvic acid and hydroxylamine or by hydrolysis of the oximino ester, gave the 6-acetonitrile which could be alkylated with alkyl halides in the presence of sodium ethoxide. In the same way the 6-acetic ester, obtained from the acid, was alkylated with benzyl chloride and *n*-butyl iodide and acylated with acetyl chloride, the resulting products saponified and the corresponding acids decarboxylated by pyrolysis. 1-Methyl-6-phenethyl-2-pyridone, 6-*n*-amyl-1-methyl-2-pyridone and 6-acetonyl-1-methyl-2-pyridone were thus obtained.

4. 1,6-Dimethyl-2-pyridone condensed with *m*-nitrobenzaldehyde in presence of acetic anhydride to give a very low yield of 1-methyl-6-*m*-nitrostyryl-2-pyridone.

5. 2-Acetamido-6(or 4)-methylpyridine condensed with benzaldehyde to give 2-acetamido-6(or 4)-stilbazole, from which by saponification of the acetyl group and diazotization, 6- or 4-styryl-2-pyridone resulted.

6. 6-Methyl-2-pyridone condensed with acrylonitrile in presence of alkaline catalysts to give 6-methyl-2-pyridone-1-β-propionitrile, which was hydrolyzed to the corresponding acid. 6-Methyl-2-pyridone sodium condensed with bromoacetic ester to give ethyl 6-methyl-2-pyridone-1-acetate which in turn condensed with ethyl oxalate to form a pyruvate.

# Hyperconjugation. III. Relative Rates of Bromination of Twelve Monoalkylbenzenes

BY ERNST BERLINER AND FRANCES BERLINER

The relative rates of bromination of toluene, ethylbenzene, *i*-propylbenzene and *t*-butylbenzene in aqueous acetic acid at 25° are 100, 76, 44 and 23, respectively.[1] A competitive bromination study of toluene and *t*-butylbenzene has confirmed the order for the latter two compounds.[2] These results have been explained by hyperconjugation involving the hydrogen atoms on the carbon atom alpha to the benzene ring.[1,2,3] In the work presented here the above order of reactivity is confirmed and investigation of the relative rates of bromination of monoalkylbenzenes is extended to include both propylbenzenes, all four butylbenzenes, and four of the eight amylbenzenes. The results are considered in the light of hyperconjugation.

**Method.** The procedure adopted for measuring the relative rates of bromination was similar to that used by De la Mare and Robertson.[1] The relative rates were calculated by comparing the times necessary for ten per cent. reaction of bro-

mine with the hydrocarbon. However, in the present investigation the reactions were conducted with a ten-fold excess of hydrocarbon and in the presence of excess sodium acetate. Sodium acetate increased the rates considerably and made it possible to conclude the reactions in a much shorter time.[4] In view of the work of Robertson, De la Mare and Johnston[1,5] it has seemed justified to assume that the order of the reaction with respect to bromine is the same for all monoalkylbenzenes.[6]

## Experimental Part

### Preparation of Materials

**Glacial Acetic Acid.**—C. P. acetic acid ("Niacet") was purified according to the method of Orton and Bradfield,[7] m. p. 16.4–16.5°. The "85% acetic acid" was prepared by adding 15 parts by volume of water from a buret to 85 parts of the above acetic acid, measured in a volumetric flask. The stock solution was kept in an amber bottle.

**Bromine.**—C. P. bromine was used without purification.

**Sodium Acetate.**—J. T. Baker C. P. Analyzed anhydrous sodium acetate was used without purification. The 0.15 *M* solution contained 6.1530 g. of sodium acetate in 85% acetic acid made up to volume in a 500-ml. flask.

Table I records the monoalkylbenzenes which were prepared for this study, their properties and the methods of synthesis.

TABLE I

PREPARATION AND PROPERTIES OF MONOALKYLBENZENES

| Hydrocarbon | Boiling point °C. | Mm. | $n^{25}D$ | Acetamino derivatives,[a] m. p., °C. |
|---|---|---|---|---|
| Toluene[b] | 109.8–110.1 | 750 | 1.4930 | |
| Ethylbenzene[b] | 135.9–136.9 | 760 | 1.4930 | |

[a] Ipatieff and Schmerling, THIS JOURNAL, **59**, 1056 (1937); **60**, 1476 (1938); **65**, 2470 (1943). The melting points of the derivatives must be taken as indications of the identity rather than the purity of the hydrocarbons. [b] A C. P. chemical grade was purified with cold concentrated sulfuric acid according to Fieser, "Experiments in Organic Chemistry," 2nd ed., D. C. Heath and Company, Boston, 1941, p. 364. [c] Prepared in 79% yield (b. p. 158–160° (758 mm.)) from 0.6 mole of propiophenone by a Wolff–Kishner reduction as modified by Huang–Minlon, THIS JOURNAL, **68**, 2487 (1946). [d] Prepared in 78% yield by a Clemmensen reduction (with stirring) of butyrophenone. [e] Prepared by a Wurtz reaction of bromobenzene and *n*-butyl bromide ("Organic Syntheses," **25**, 11(1945)). [f] Prepared in 79% yield (b. p. 170–172°) from 189 g. of *i*-butyrophenone, see ref. in (*c*). The *i*-butyrophenone was prepared in 81% yield (b. p. 66–67 (2 mm.)) from 300 g. of aluminum chloride suspended in 1200 ml. of thiophene-free benzene and 168 g. of *i*-butyryl chloride in 200 ml. of thiophene-free benzene at ice-bath temperature (Schmidt, Hopp and Schoeller, *Ber.*, **72**, 1893 (1939); Hennion and Auspos, THIS JOURNAL, **65**, 1603 (1943)); m. p. dinitrophenylhydrazone 161.3–162.8°. [g] Prepared according to Price and Lund, THIS JOURNAL, **62**, 3105 (1940), using three times their amounts and letting the reaction mixture stand overnight, yield 70% (b. p. 170–173°). [h] Prepared as previously described, see ref. 2. [i] Prepared in 80% yield (b. p. 202–203° (750 mm.)) from 0.8 mole of *n*-valerophenone, see ref. in (*c*); $n^{20}D$ 1.4878 for the pure sample. The valerophenone was prepared as described for *i*-butyrophenone in 77.5% yield (b. p. 81.2° (2 mm.)); m. p. dinitrophenylhydrazone 166–167°. [j] Prepared by the method of Bygden, *Ber.*, **45**, 3479 (1912), from benzylmagnesium chloride and *t*-butyl chloride. The yield was raised from 39 to 57.5% by adding benzene to the reaction mixture and refluxing it for several hours, b. p. 185.1–185.9° (755 mm.), $n^{25}D$ 1.4855, $n^{20}D$ 1.4875, m. p. monoacetamino derivative 164.9–165.8°. The diacetamino derivative melted between 236° and 242° after three crystallizations and was not pure. This sample was later found to contain small amounts of *p*-*t*-butyltoluene (see last paragraph of the experimental part) and was repurified in the following manner. Thirty-five milliliters of the hydrocarbon was treated with 10% of bromine in a brown bottle in the presence of a catalytic amount of iodine; after three days a trace of iron was added and the reaction mixture was heated briefly to 50° to complete the bromination. The product was washed and fractonally distilled affording the sample of neopentylbenzene recorded in the table, $n^{20}D$ 1.4870. [k] Prepared by catalytic reduction of 2-methyl-3-phenylbutene-2 in the presence of Adams catalyst at room temperature. The reduction proceeded slowly and never exceeded 75% of the theoretical. The olefin was prepared in about 45% yields from 0.5 mole of acetophenone and *i*-propylmagnesium chloride (Ipatieff, Pines and Schmerling, THIS JOURNAL, **60**, 353 (1938); Klages, *Ber.*, **36**, 3688 (1903)). [l] Prepared in 60% yield from 2 moles of *t*-amyl alcohol and 10 moles of thiophene-free benzene by the method of Huston, Fox and Binder, *J. Org. Chem.*, **3**, 252 (1938), $n^{20}D$ of pure sample 1.4928.

All of the samples recorded in Table I were purified with cold concentrated sulfuric acid, or with aqueous potassium permanganate (agitated overnight at room temperature) followed by sulfuric acid, prior to final fractionations from metallic sodium. The ice-cold concentrated sulfuric acid extracted acid-darkening material from the reaction products regardless of the method of synthesis, and whereas it alone is effective in removing rapidly brominated impurities from the hydrocarbons, treatment with permanganate had to be followed by washing with sulfuric acid. It is believed that the ice-cold sulfuric acid did not cause any rearrangement. Of all of the compounds described above, only the purity of the 2-methyl-3-phenylbutane is questionable. Bromination of several samples was erratic, and there was never a sufficient amount available for rigorous purification.

The following samples were generously supplied by the Sun Oil Company, Norwood, Pennsylvania, the Phillips

(4) The increase in rate produced by sodium acetate may be due to the formation of a more active brominating agent or may be connected with the removal of a proton from the activated complex by the acetate ion, the strongest base in the system. See also Bennett, Brand, James, Saunders and Williams, *J. Chem. Soc.*, 474 (1947).

(5) Robertson, De la Mare and Johnston, *J. Chem. Soc.*, 276 (1943); De la Mare and Robertson, *ibid.*, 100 (1948).

(6) In the bromination of aromatic compounds in acetic acid the order with respect to bromine is dependent on the temperature, the dilution and the type of compound. In the present case it is probably between two and three (see ref. 1 and 5). The bromination of benzene in benzene as a solvent is also kinetically of a higher order with respect to bromine. Bruner, *Z. physik. Chem.*, **41**, 513 (1902); Price, THIS JOURNAL, **58**, 2101 (1936).

(7) Orton and Bradfield, *J. Chem. Soc.*, 983 (1927).

Petroleum Company, Bartlesville, Oklahoma, and the Universal Oil Products Company, Riverside, Illinois: toluene, 99.7% pure; ethylbenzene, 99.82%; ethylbenzene, 99.3%; *n*-propylbenzene 99.0%; *i*-propylbenzene, 98%; *n*-butylbenzene 99.5%; *i*-butylbenzene, 99.8%; *s*-butylbenzene, 99.2%; *s*-butylbenzene, 98%; *s*-butylbenzene; *t*-butylbenzene, 99.9%; *t*-butylbenzene, 99.76%; *t*-butylbenzene, 98%. Each sample was redistilled from metallic sodium immediately before use.

All samples of hydrocarbons used in the bromination study were stored in amber bottles over sodium wire.

## General Procedure

The bromination experiments were conducted as follows in a room provided with black curtains and lighted with a red lamp. To 20 ml. of an 85% acetic acid solution, 0.4 *M* in hydrocarbon and 0.15 *M* in sodium acetate, contained in a blackened bottle and brought to 25 ± 0.05° in a thermostat, was added 20 ml. of an 85% acetic acid solution, 0.04 *M* in bromine and 0.15 *M* in sodium acetate.[8] The solutions were mixed and a 5-ml. portion was immediately withdrawn and analyzed for bromine iodimetrically with 0.04 *M* sodium thiosulfate, contained in a microburet graduated to 0.01 ml., using starch as an indicator. This reading was taken as the zero point. The thiosulfate solution was prepared for each run from a 0.1000 *M* stock solution. A freshly prepared 6% solution of potassium iodide was used for each titration. A blank was run simultaneously with each reaction in order to provide corrections for loss of bromine by evaporation. The loss occurred only during sampling and became rather large and irregular after four or five samples had been withdrawn. In order to reduce to a minimum the corrections for loss of bromine by evaporation, preliminary studies were made for each monoalkylbenzene in which six to eight readings were taken in order to establish the approximate time for 10% reaction of bromine. Then subsequent runs were made for each compound in which only four readings were taken, one to establish the zero point, two shortly before 10% reaction, and one shortly after 10% reaction, in order to determine accurately the 10% reaction time. The error, introduced chiefly through the uncertainty of the blank, was about ±1% of the final reaction time. The results were well reproducible. Due to the volatility of the bromine the initial concentration usually deviated slightly from 0.02 *M*, but corrections for this deviation were applied to the final results and never amounted to more than a few minutes. A large number of check runs was made for each monoalkylbenzene and all samples listed above were used, although some were found to contain small amounts of rapidly brominated impurities. Results obtained with such samples were discarded. A rapidly brominated impurity was easily recognized by the large deviation of the initial titer from the blank. Small amounts of impurities which are brominated more slowly than the hydrocarbons would not have affected the rates. All compounds were studied independently by each investigator; a total of about 200 runs was made. Some results of a typical study (*n*-propylbenzene) are listed below. (The blanks found were on the average 0.15, 0.25, 0.35 for each successive opening.)

Sample I (synthetic)

| Time | Sodium thiosulfate, ml. of 0.04 *M* | Reaction, % |

The sample of neopentylbenzene, prepared by the method of Bygden (Table I, ref. *j*) was found kinetically to contain a by-product, although the impurity was not brominated rapidly enough to show a deviation of the initial titer from the blank. The sample showed a 10% reaction time of about 400 minutes, almost identical with *n*-propylbenzene (415 minutes). A comparison of the time/% reaction curves for the two compounds up to 15% reaction showed, however, that they were not identical in shape. The neopentyl curve rose more rapidly and slowed down appreciably after 10%, suggesting that the sample contained an impurity, present to the extent of about 1%, which was brominated more rapidly than neopentylbenzene. A 5-ml. sample of the impure neopentylbenzene was oxidized with potassium permanganate[9] in aqueous pyridine and afforded a small amount of *p*-*t*-butylbenzoic acid, m. p. after crystallization from dilute alcohol 165–166°. Mixed melting point with an authentic sample of *p*-*t*-butylbenzoic acid[10] showed no depression. The formation of *p*-*t*-butyltoluene from benzylmagnesium chloride and *t*-butyl chloride is similar to the recently reported formation of *p*-ethyltoluene from benzylmagnesium chloride and ethyl sulfate.[11]

## Results and Discussion

In Table II are recorded the compounds that were brominated and the times required for 10% reaction of each. Table III summarizes some of the pertinent relative rates.

The members of Series I (first column of Table III) fall in an order demanded by the Baker–Nathan effect and identical with that obtained by De la Mare and Robertson.[1] Under the present experimental conditions the differences in relative rates of bromination of the four compounds (100:70:40:18) are larger than those obtained by the latter investigators (100:76:44:23). That the solvent composition (the presence of sodium acetate) should influence the spacing of the rates is not unreasonable and was discussed in a previous communication.[12] The relative rates of bro-

(8) The amylbenzenes required more dilute solutions since they were not sufficiently soluble for the preparation of 0.4 *M* solutions in 85% acetic acid. The bromine solution was therefore concentrated accordingly so that after mixing the concentrations of bromine and hydrocarbon were still 0.02 and 0.2 *M*, respectively.

TABLE II

TEN PER CENT. REACTION TIMES FOR BROMINATION OF MONOALKYLBENZENES

| Alkylbenzene | Time in minutes for 10% reaction |
|---|---|
| Toluene | 230 |
| Ethylbenzene | 330 |
| *n*-Propylbenzene | 415 |
| *i*-Propylbenzene | 570 |
| *n*-Butylbenzene | 390 |
| *i*-Butylbenzene | 620 |
| *s*-Butylbenzene | 710 |
| *t*-Butylbenzene | 1300 |
| *n*-Amylbenzene | 440 |
| Neopentylbenzene | 1110 |
| 2-Methyl-3-phenylbutane | (800) |
| *t*-Amylbenzene | 1000 |

TABLE III

RELATIVE RATES OF BROMINATION OF MONOALKYLBENZENES

| R | Series I Ph–R | Series II $PhCH_2$–R | Series III $PhCHRCH_3$ |
|---|---|---|---|
| Methyl | 100 | 100 | 100 |
| Ethyl | 70 | 80 | 80 |
| *i*-Propyl | 40 | 53 | (71) |
| *t*-Butyl | 18 | 30 | |

mination of the two propylbenzenes and the four butylbenzenes also follow the general pattern of the Baker–Nathan effect, *i. e.*, are dependent on the number of hydrogen atoms available on the alpha carbon atom for conjugation with the benzene ring. Thus *n*-propylbenzene with two alpha hydrogen atoms is brominated faster than *i*-propylbenzene with only one (100:73). The four butylbenzenes fall in the order *n*-butyl > *i*-butyl > *s*-butyl > *t*-butyl (100:63:55:30). The difference between *i*-butyl and *s*-butylbenzene, although in accord with the theory, is not very large. On the other hand, the difference between the normal and the iso compound seems quite pronounced, where on the basis of the Baker–Nathan effect *per se* no statement could have been made regarding a difference as both compounds carry the same number of hydrogen atoms on the carbon atom alpha to the ring and have, moreover, identical molecular weights. Series II (second column of Table III) affords a more comprehensive example of the same type. This series corresponds to Series I with a methylene group placed between the ring and the variable alkyl group. The rates of bromination decrease in the order R = methyl > ethyl > *i*-propyl > *t*-butyl, *i. e.*, the order of reactivity corresponds to that for Series I, although the relative rates can no longer be accounted for by the Baker–Nathan effect. A similar situation exists for Series III (last column of Table III).[13]

(13) These series are not the only cases in which the number of hydrogen atoms alpha to the ring is not the decisive factor. *i*-Butylbenzene (two hydrogens) clearly reacts slower than *i*-propylbenzene (one hydrogen), and neopentylbenzene is brominated appreciably slower than *t*-amylbenzene, in spite of a difference of two hydrogen atoms.

Since the relative reactivities of the members of Series II (and Series III) cannot be accounted for on the basis of the number of hydrogen atoms on the carbon atom next to the benzene ring, as all four compounds have two such hydrogen atoms, the determining factor might conceivably be the extent of carbon–carbon hyperconjugation, the electrostatic inductive effect, or the size and polarizabilities of the four alkyl groups. Neopentylbenzene in all cases then should react the most rapidly,[14] ethylbenzene the least, and the total order of reactivity for the series should be exactly the reverse of the order actually obtained. Increasing steric hindrance in the *ortho* positions with increasing size of the alkyl group *might* account for the observed order and therefore merits consideration. Moreover, there has been a recent demonstration that the rates of propylation of alkylbenzenes can be accounted for by such an hypothesis.[15]

Toluene, on bromination in excess toluene as a solvent, yields 60.3% *para* and 39.7% *ortho* product.[16] That the ratio will not be appreciably changed in another solvent can be assumed and is borne out by experiments of Ingold, *et al.*[17] If one assumes the least favorable case, that *t*-butylbenzene affords *no ortho* substitution, a comparison of only the *para* positions shows that toluene reacts $5.7 \times 60/100 = 3.42$ times faster than *t*-butylbenzene in the *para* position.[18] Thus steric hindrance can account for only a fraction of the difference in rates of bromination of the two sterically extreme members of Series I. It must therefore contribute even less to the other relative rates of the series.[19]

(14) If carbon–carbon hyperconjugation were the determining factor, contributions like $ArCH_2\ominus\oplus C(CH_3)_3$ would make neopentylbenzene the most reactive.

(17) Ingold, Lapworth, Rothstein and Ward, *J. Chem. Soc.*, 1959 (1931); Bird and Ingold, *ibid.*, 918 (1938).

(18) Actually some *ortho* substitution in bromination of *t*-butylbenzene does occur. Kozak (*Bull. Akad. Sci. Cracow*, 407 (1906); *Chem. Zentr.*, **78**, I, 1787 (1907)) prepared *o*-*t*-butyltoluene by a Wurtz–Fittig reaction of the bromination product of *t*-butylbenzene. The rate of bromination of toluene in the *para* position relative to that of *t*-butylbenzene is therefore greater than 3.42. In the nitration of *t*-butylbenzene 23% *ortho* and 77% *para* substitution has been reported (Craig, THIS JOURNAL, **57**, 195 (1935)).

(19) Schramm (*Ber.*, **18**, 1272 (1885); *Monatsh.*, **9**, 842 (1888)) has demonstrated the formation of *ortho* products in the bromination of ethylbenzene and cumene. However, the only existent numerical data for *ortho*–*para* ratios of ethylbenzene, cumene and *t*-butylbenzene were obtained in preparative nitration (see data quoted by Le Fevre (*J. Chem. Soc.*, 980 (1933)) and see also Sterling and Bogert (*J. Org. Chem.*, **4**, 20 (1939)), Mayes and Turner (*J. Chem. Soc.*, 500 (1929)) and Craig (ref. 18). The data show qualitatively that *para* substitution increases successively in the four compounds of Series I as *ortho* substitution decreases. Since bromination affords more *para* substitution in general than nitration (about 20% for toluene), one can tentatively assign to the four compounds, on the basis of the nitration data, the *ortho*–*para* ratios 40/60, 30/70, 20/80, and 10/90 in bromination. Using these data the relative reactivities for the four compounds in the *para* positions become 100:81:54:27 as compared with the original 100:70:40:18. These corrected relative rates are numerically very close to the relative rates obtained in Series II (100:80:53:30) and Series III (100:80:(71)). However, as the *ortho*–*para* ratios assigned to the members of Series I are only approximate, one cannot attach great significance to the similarity of the numerical values for the relative rates in the three series.

If steric hindrance is not decisive in Series I, it cannot be decisive in Series II where the branching occurs on a carbon atom once removed from the benzene ring.[20] The contributions from steric factors to the reactivities of the compounds of series II can, as a first approximation, be assumed to be the same. The relevant data in the literature are not very extensive, but the data that exist point toward little difference in the *ortho–para* ratios for the members of this series.[21] In the alpha-methyl series (III) steric hindrance also probably has an insignificant effect on the relative rates. The data on the third compound of Series III, however, are less accurate than those for all other compounds and this series will not be considered further.

One is, therefore, left with a situation in which neither steric effects, first-order hyperconjugation of the carbon–hydrogen bonds, carbon–carbon hyperconjugation nor the electrostatic inductive effect can account for the observed decrease in rates of Series II. The experimental facts, apart from any theories, demonstrate the following. The four alkyl groups methyl, ethyl, *i*-propyl, *t*-butyl, attached directly to the benzene ring, release electrons into the ring (or accommodate a positive charge in the transition state) in the order methyl > ethyl > etc. If a methylene group is placed between the alkyl group and the benzene ring, the effect of these alkyl groups passes through the methylene group in the same order. It is reasonable to assume that whatever causes the four alkyl groups to act as they do in Series I is also responsible for the relative rates in Series II and that this effect is transmitted through the saturated methylene group, contrary to accepted views. If it is correct that the differences in rate in the first series are due to hyperconjugation of the carbon–hydrogen bonds, and there seem to be enough indications that this is the case, one is forced to conclude that the second series is also affected by a similar type of hyperconjugation and that the relative rates depend on the number of hydrogen atoms on the beta carbon atom. A second-order hyperconjugation involving the beta hydrogens as is shown in Fig. 1 is therefore tentatively suggested to account for the relative rates of bromination of the compounds of Series II. The structures would clearly account for the experimentally observed facts, provided that only the number of hydrogen atoms on the *beta* carbon atom

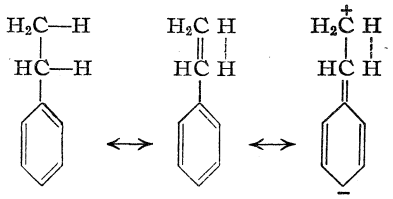

Fig. 1.

determines the stability of the transition state (when the number of *alpha* hydrogen atoms is constant). This type of hyperconjugation must be less important than hyperconjugation involving *alpha* hydrogens, for otherwise ethylbenzene would be brominated faster than toluene and isopropylbenzene would be brominated faster than *n*-propylbenzene, whereas the reverse is true. On the other hand, *n*-butylbenzene with two *beta* hydrogen atoms is brominated faster than isobutylbenzene with only one as previously pointed out, and the difference may be attributed at least in part to a difference in hyperconjugation involving the beta hydrogens. Although it is true that second-order hyperconjugation is supposed to be insignificant (although ever present),[22] it is, in this case, enhanced by conjugation with the benzene ring. Similar forms have been suggested for bibenzyl (where two rings are available for conjugation) and for geranylamine hydrochloride (where a single bond is flanked by two double bonds) to account for the shortening of the central carbon–carbon bond.[23] In looking for other possible explanations the following suggest themselves. There is the possibility of structures of type $ArCH_2^{\oplus}\ \ominus R$ which would withdraw electrons from the ring and account for the order, but such a possibility is not supported by any other evidence. Steric inhibition of resonance due to a lack of coplanarity is not expected to be a decisive factor, nor is it assumed that the observed order is due to a change in mechanism of the substitution by bromine. However, none of these factors can be ruled out completely on the basis of the available experimental evidence.

It is noteworthy that the order of the rates of bromination of the alkylbenzenes of Series II is identical with that of $S_N1$ displacement reactions on the corresponding halides (ethyl bromide, *n*-propyl bromide, etc.).[24,25] The order for the $S_N1$ reactions has been ascribed by Benfey[25] to hyperconjugation of the hydrogen atoms on the beta carbon atoms. $S_N1$ reactions, like aromatic substitution, are electron demanding and go through a positively charged transition state. Although the reactions of the alkyl halides are different from

(20) Note the related case of "classical" steric hindrance in 2,4,6-trimethylbenzoic acid and its esters, and the absence of steric hindrance in the corresponding phenylacetic acid: Meyer and Sudborough, *Ber.*, **27**, 1580 (1894); Watson, "Modern Theories of Organic Chemistry," Oxford University Press, 2nd ed., 1941, pp. 246 ff.

(21) *Nitration* of *n*-propylbenzene affords the *ortho* isomer to about the same extent as ethylbenzene (Baddeley and Kenner, *J. Chem. Soc.*, 303 (1935)). The presence of the *ortho* isomer in the *bromination* of the former has been demonstrated through oxidation to *o*-bromobenzoic acid (Schramm, Ref. 19). Furthermore, all normal alkylbenzenes afford a dinitro product with great ease (*o*/*p*), and with the amylbenzenes having two hydrogen atoms next to the ring, including neopentylbenzene, appreciable *ortho* substitution occurs (Ipatieff and Schmerling, Table I, ref. *a*).

(25) Benfey, THIS JOURNAL, **70**, 2163 (1948).

those of the alkylbenzenes, in that in the latter the alkyl groups are far removed from the seat of the reaction, it would seem plausible that alkyl groups exhibit the same electronic effect in both alkyl halides and alkylbenzenes. Granted the similarity, it is then perhaps no coincidence that *t*-amylbenzene is brominated faster than *t*-butylbenzene where *t*-amyl chloride is hydrolyzed faster than *t*-butyl chloride.[26] In the case of the two tertiary alkylbenzenes it may mean that in the complete absence of alpha hydrogen atoms carbon–carbon hyperconjugation takes precedence—an hypothesis which will be further tested.

*n*-Butylbenzene is brominated faster than *n*-propylbenzene to a small but definite extent. The result, tested on two different samples, indicates an apparent anomaly, particularly in view of the fact that *n*-amylbenzene is brominated slower than *n*-propylbenzene.[27] This anomality of the *n*-butyl group is manifested in other reactions and equilibria such as the strengths of aliphatic acids[28] and amines,[29] the enolization of phenyl alkyl ketones[30] and the basic dissociation constants of *p*-alkyldimethylanilines and their reactions with methyl iodide.[31] In the last two cases the order is methyl

(31) Davies, *ibid.*, 1865 (1938). The author assigns the anomality to the *n*-propyl rather than the *n*-butyl group: also ref. 32.

> ethyl > *n*-butyl > *n*-propyl > *i*-butyl. The anomalous effect has variously been attributed to a field effect,[31,32] or chelation and hydrogen bonding[28,30] resulting from the interaction of the terminal hydrogen atoms with the functional group. In the case of *n*-butylbenzene (and higher alkylbenzenes) chelation, if it occurs, might be pictured in terms of hyperconjugation structures as shown in Fig. 2. Such additional hyperconjugation should increase the rate of bromination and the amount of meta product.[33]

**Acknowledgments.**—We gratefully acknowledge the help afforded by a Frederick Gardner Cottrell Grant of the Research Corporation. Schmerling of the Universal Oil Products Company, and to the Phillips Petroleum Company for samples of pure hydrocarbons.

## Summary

The relative rates of bromination of twelve monoalkylbenzenes are toluene 100, ethylbenzene 70, *n*-propylbenzene 55, *i*-propylbenzene 40, *n*-butylbenzene 59, *i*-butylbenzene 37, *s*-butylbenzene 32, *t*-butylbenzene 18, *n*-amylbenzene 52, neopentylbenzene 21, 2-methyl-3-phenylbutane 29, *t*-amylbenzene 23. A second-order hyperconjugation involving beta hydrogen atoms is suggested to account for part of this order of relative rates.

Neopentylbenzene prepared from benzylmagnesium chloride and *t*-butyl chloride contains some *p*-*t*-butyltoluene.

BRYN MAWR, PA. RECEIVED SEPTEMBER 21, 1948

(32) Ayling, *ibid.*, 1014 (1938).

(33) The possibility of accounting for the anomalous effect of the *n*-butyl group by hyperconjugation structures of the above type was suggested by one of the Referees of this paper, who proposed structures involving second-order hyperconjugation throughout the *n*-butyl group.

# The Effect of Benzoyl Peroxide on the Bromination of Methylthiophenes by N-Bromosuccinimide[1]

BY KARL DITTMER, ROBERT P. MARTIN, WERNER HERZ[2] AND STANLEY J. CRISTOL

In the course of our work dealing with the synthesis of possible amino acid antagonists, we had occasion to study the reaction of 2- and 3-methylthiophenes with N-bromosuccinimide. Of particular interest was the preparation of thiophene intermediates which could be used in the synthesis of β-3-thienylalanine.

Steinkopf and co-workers[3,4] reported that they obtained side chain bromination in the reaction of bromine with 2- and 3-methylthiophenes only after the thiophene ring had been completely brominated.

Buu-Hoi and Lecocq[5] obtained brominated side-chain derivatives of α-methylnaphthalene, 2-methylfuran and 2,5-dimethylfuran by the reaction with N-bromosuccinimide. With 2,5-dimethylthiophene the yields were lower because of the greater ease of nuclear substitution in the thiophene ring.

The results of Schmid and Karrer[6] on the catalytic effect exerted by benzoyl peroxide in initiating and maintaining the free radical formation necessary for side-chain bromination of toluene by N-bromosuccinimide suggested the possibility of introducing a bromine atom into the side chain of 2- and 3-methylthiophene without ring bromination.

Recently Campaigne and LeSuer[7] prepared 3-bromomethylthiophene by treating 3-methylthiophene with N-bromosuccinimide in the presence of benzoyl peroxide. We have obtained similar results. In this paper we wish to report on the effect of benzoyl peroxide on the bromination of 2- and 3-methylthiophenes by one and two molar equivalents of N-bromosuccinimide.

When 2-methylthiophene (I) was treated with one equivalent of N-bromosuccinimide without benzoyl peroxide, a good yield of monobromo-2-methylthiophene was obtained by distillation of the crude product. This material was about 66% 2-methyl-5-bromothiophene (III) and 34% 2-thenyl bromide (II). With benzoyl peroxide present the major fraction consisted primarily of 2-thenyl bromide (II) (84%), but contained some 2-methyl-5-bromothiophene (III). The composition of these fractions was estimated by analysis for total bromine and for hydrolyzable bromine, the latter being a measure of side chain bromination. These conclusions were confirmed by fractional distillation analysis.

In the absence of benzoyl peroxide, 3-methylthiophene reacted with one molar equivalent of N-bromosuccinimide to form a mixture of monobromo-3-methylthiophenes which consisted of approximately 90% 2-bromo-3-methylthiophene (XII) and 10% 3-thenyl bromide (XIII); with benzoyl peroxide the monobromomethylthiophene fraction contained 90% 3-thenyl bromide and 10% 2-bromo-3-methylthiophene.[8]

The reaction between 2-methylthiophene and two molar equivalents of N-bromosuccinimide formed a fraction which analyzed correctly for dibromomethylthiophene. Fractional bromine analysis indicated that this sample was practically pure 2-bromomethyl-5-bromothiophene (IV). Benzoyl peroxide did not significantly change the yield or composition of this product. The structure of 2-bromomethyl-5-bromothiophene (IV) was proved by conversion to 5-bromo-2-thenylacetamidomalonate (VI) and 5-bromo-2-thenylacetamidocyanoacetate (VII).

When 3-methylthiophene was treated with two molar equivalents of N-bromosuccinimide, a fraction of dibromomethylthiophenes was obtained which contained about 20% 2-bromo-3-bromomethylthiophene (XIV) and 80% 2,5-dibromo-3-methylthiophene (XV). The possibility of the presence of some 2,4-dibromo-3-methylthiophene is not completely ruled out. The addition of benzoyl peroxide gave a dibromo-3-methylthiophene fraction which consisted of about 84% 2-bromo-3-bromomethylthiophene (XIV) and 16% 2,5-dibromo-3-methylthiophene (XV). In one experiment evidence was obtained which indicated that some 3-thenylidine bromide was also formed. The structure of 2-bromo-3-bromomethylthiophene (XIV) was established by condensation with acetamidomalonate to form 2-bromo-3-thenylacetamidomalonate (XVI). A free alpha position was indicated by the ease with which it formed a chloromercuri derivative.

Most of the compounds formed were stable enough to permit distillation *in vacuo*. All 2-thenyl bromide derivatives lost hydrogen bromide and polymerized into tarry masses within a few days even though they were stored in the cold.

(7) Campaigne and LeSuer, THIS JOURNAL, **70**, 1555 (1948).

(8) In an earlier attempt when a different sample of N-bromosuccinimide was used, only traces of side chain-brominated material were obtained from 2-methyl- and 3-methylthiophenes. This misleading result prompted the preparation of 2-bromo-3-thenyl bromide with two molar equivalents of N-bromosuccinimide. The 2-bromo-3-thenyl bromide has been used for the preparation of β-3-thienylalanine.[9]

(9) Dittmer, THIS JOURNAL, **70**, 1205 (1948).

This ease of decomposition was not observed with any of the 3-thenyl bromide derivatives.

**Acknowledgment.**—The authors wish to thank Mr. T. D. Waugh of the Arapahoe Chemicals, Inc., for a gift of N-bromosuccinimide, and Mr. G. A. Harrington of the Socony-Vacuum Oil Company for generous gifts of the 2- and 3-methylthiophene used in these experiments. The authors also wish to thank Mrs. Philippa Szerwo of this department for the analyses reported in this paper.

## Experimental

**Reaction of Methylthiophenes with N-Bromosuccinimide.**—All of the brominations were conducted with from 0.13 to 0.40 mole of either 2- or 3-methylthiophene with either one or two molar equivalent amounts of N-bromosuccinimide suspended in 50 to 100 ml. of dry carbon tetrachloride. When benzoyl peroxide was used, between 0.10 and 0.25 g. per 0.1 mole of methylthiophene was added when the reaction started and, after ten minutes of refluxing, an additional 0.10 g. was added. Each reaction mixture was heated under reflux for four to five hours. After filtration the carbon tetrachloride was removed *in vacuo*. The residue was distilled at 2–4 mm. pressure and fractions boiling within 5° ranges were collected. The major fractions, most of which had a fairly constant boiling point, were analyzed for total bromine by the semi-micro Parr combustion method, and for active bromine by the determination of the bromide formed after alcoholic potassium hydroxide hydrolysis. The amounts of reactants used and the results obtained in each experiment are summarized in Table I.

The boiling points, densities and refractive indices listed in Table II were determined with further purified material obtained by fractional distillation through a column of helices 30 cm. in length and 1.2 cm. in diameter.

**Diethyl 2-Thenylacetamidomalonate (V).**—The structure of 2-thenyl bromide (II) was established by condensation with diethyl acetamidomalonate. The reaction of 15 g. (0.084 mole) of thenyl bromide (II) with 18.2 g. (0.084 mole) of diethyl acetamidomalonate in 100 ml. of absolute ethanol containing 1.9 g. (0.084 gram atom) of sodium after three hours reflux, followed by concentration, yielded 18.0 g. (67%) of diethyl 2-thenylacetamidomalonate (V), m. p. 115–116°, which was identical with the same compound prepared previously[10] from 2-chloromethylthiophene.

**N-Acetyl-β-2-thienylalanine (VIII).**—Hydrolysis of 5 g. (0.016 mole) of V by the method of Snyder and co-workers[11] gave 2.9 g. (85%) of N-acetyl-β-2-thienylalanine (VIII). The white needles obtained on recrystallization from hot water melted at 130°.

*Anal.* Calcd. for $C_9H_{11}NO_3S$: N, 6.57. Found: N, 6.44.

**Diethyl 2-(5-Bromo)-thenylacetamidomalonate (VI).**—The reaction of 13 g. (0.05 mole) of 2-bromomethyl-5-bromothiophene (IV) with a solution of 50 ml. of absolute ethanol containing 1.15 g. (0.05 gram atom) of sodium and 10.8 (0.05 mole) of diethyl acetamidomalonate yielded 12 g. (0.03 mole, 60%) of slightly-colored product (VI). White needles, m. p. 108°, were obtained by decolorizing

an acetone solution of the product, concentrating, chilling and diluting with water.

*Anal.* Calcd. for $C_{14}H_{18}BrNO_5S$: C, 42.86; H, 4.62; N, 3.57. Found: C, 42.5; H, 5.05; N, 3.60.

The same compound (VI) was also obtained by brominating diethyl 2-thenylacetamidomalonate (V).[10] A solution of 5.0 g. (0.031 mole) of bromine in 50 ml. of glacial acetic acid was slowly added with stirring to 10 g. (0.032 mole) of diethyl 2-thenylacetamidomalonate dissolved in 60 ml. of glacial acetic acid and 25 ml. of water. Dilution with water yielded 11.4 g. (0.029 mole, 91%) of nearly white needles. On recrystallization from 40% ethanol, the compound VI melted at 107–108°; mixed melting point with the first sample, 107–108°.

**N-Acetyl-β-2-(5-bromo)-thienylalanine (IX).**—Eleven and three-tenths gram (0.029 mole) of VI, hydrolyzed as in the preparation of VIII above, gave 7.9 g. (94%) of IX. The product melted at 177° after recrystallization from 20% ethanol.

Bromination of 1 g. of VIII in the manner described above gave 0.75 g. of IX, m. p. 177°.

*Anal.* Calcd. for $C_9H_{10}BrNO_3S$: N, 4.79; neut. equiv., 292. Found: N, 4.82; neut. equiv., 295.

**Ethyl 2-(5-Bromo)-thenylacetamidocyanoacetate (VII).**—Thirteen grams (0.05 mole) of IV was added to 50 ml. of absolute ethanol containing 1.15 g. (0.05 gram atom) of sodium and 8.5 g. (0.05 mole) of ethyl acetamidocyanoacetate. A reaction occurred immediately and a precipitate appeared. The mixture was refluxed for one and one-half hours. The alcohol was evaporated *in vacuo* and 50 ml. of water was added to the residue. The water was evaporated *in vacuo;* the residue was again diluted with 100 ml. of water and chilled for two days. Seventeen grams of dark colored material separated. The product was dissolved in 75 ml. of acetone and treated repeatedly with charcoal until the color of the solution had become a light orange. The solution was concentrated to 40 ml. in a vacuum and chilled for a day. The yield of yellow crystals was 5.2 g. An additional 5.7 g. was recovered from the mother liquor, giving a total of 10.9 g. (0.03 mole, 60%). Recrystallization from 30% ethanol yielded shiny white plates of VII, m. p. 116.5–117°.

*Anal.* Calcd. for $C_{12}H_{13}BrN_2O_3S$: N, 8.12. Found: N, 8.04.

**β-2-(5-Bromo)-thienylalanine (X).**—A solution obtained by the hydrolysis of 7.2 g. (0.025 mole) of IX with 40 ml. of 10% sodium hydroxide for four hours was treated with charcoal, filtered, diluted with 50 ml. of ethanol, neutralized with concentrated hydrochloric acid to *p*H 6 and chilled. One and two-tenths grams of nearly white plates separated. The mother liquor was evaporated to dryness *in vacuo*, triturated with 30 ml. of water and

filtered. The residue was washed with a little water, ethanol and ether and weighed 1.2 g. Acidification of the filtrate yielded 3.6 g. of unhydrolyzed starting material. The yield of crude amino acid (X), 2.4 g., was therefore 78% of the material which reacted.

The product was dissolved in 25 ml. of hot water containing 3 ml. of concentrated hydrochloric acid, treated with charcoal, filtered, diluted with 30 ml. of ethanol while hot and neutralized with concentrated ammonium hydroxide. The pure amino acid separated on cooling. It melted at 235–238° (capillary) with decomposition and at 256° on a Dennis melting point bar. Another recrystallization did not change the melting point when taken in a capillary tube, but raised the melting point on the bar to 262°.

*Anal.* Calcd. for $C_7H_8BrNO_2S$: N, 5.60. Found: N, 5.47.

The amino acid was also obtained when 5 g. of VII was refluxed with 50 ml. of 10% sodium hydroxide for eighteen hours. The hot solution was treated with charcoal, filtered, neutralized to *p*H 6 with concentrated hydrochloric acid and cooled. The precipitate, when purified as before, yielded 1.3 g. of X. Another 280 mg. was recovered by working up the mother liquors.

Two hundred and fifty milligrams of X, when treated with the calculated amount of sodium hydroxide and phenyl isocyanate in the usual manner,[12] yielded 300 mg. of the α-phenylureido derivative of X. Recrystallization from 30% ethanol gave white plates, m. p. 166–167° (capillary), 172–173° on the Dennis melting point bar.

*Anal.* Calcd. for $C_{14}H_{13}BrN_2O_3S$: neut. equiv., 369. Found: neut. equiv., 367.

Four hundred and twenty milligrams of the N-carbobenzoxy derivative of X was obtained by treating 500 mg. of X with the calculated amounts of sodium hydroxide and carbobenzoxy chloride. Recrystallization from dilute ethanol gave white crystals, m. p. 109–110°.

*Anal.* Calcd. for $C_{15}H_{14}BrNO_4S$: neut. equiv., 384. Found: neut. equiv., 390.

**Diethyl 3-(2-Bromo)-thenylacetamidomalonate (XVI).**—Four grams (0.0156 mole) of the lachrymatory material (XIV) obtained by the bromination of 3-methylthiophene with two molar equivalents of N-bromosuccinimide was added to 40 ml. of absolute ethanol containing 0.36 g. (0.0156 gram atom) of sodium and 3.38 g. (0.0156 mole) of diethyl acetamidomalonate. The mixture was refluxed for three hours, cooled and diluted with some water. After evaporation to dryness *in vacuo*, more water was added and the mixture was again evaporated to dryness *in vacuo*. The residue was diluted with a little water, chilled, filtered and washed with water. The yield of slightly-colored product was 5.5 g. (90%). Recrystallization from 50% ethanol gave shiny white plates of XVI, m. p. 84.5–85°.

*Anal.* Calcd. for $C_{14}H_{18}BrNO_5S$: C, 42.86; H, 4.62; N, 3.57. Found: C, 43.0; H, 4.27; N, 3.38.

This compound (XVI) formed a chloromercuri derivative, m. p. 216°.

## Summary

The effect of benzoyl peroxide on the bromination of 2-methyl- and 3-methylthiophene by the action of N-bromosuccinimide has been investigated.

When one molar equivalent of N-bromosuccinimide was permitted to react with 2-methylthiophene, the product was mainly 2-methyl-5-bromothiophene with some 2-thenyl bromide. The addition of benzoyl peroxide to this reaction mixture resulted in the formation of mostly 2-thenyl bromide.

When two molar equivalents of N-bromosuccinimide were allowed to react with 2-methylthiophene, the main product was 2-bromomethyl-5-bromothiophene. Benzoyl peroxide did not affect the yield of 2-bromomethyl-5-bromothiophene. The 2-bromomethyl-5-bromothiophene was condensed with ethyl acetamidocyanoacetate and diethyl acetamidomalonate to yield solid derivatives which were characterized and hydrolyzed to β-2-(5-bromo)-thienylalanine.

When one molar equivalent of N-bromosuccinimide was permitted to react with 3-methylthiophene in the absence of benzoyl peroxide, the product was mainly 2-bromo-3-methylthiophene, whereas in the presence of benzoyl peroxide 3-bromomethylthiophene was the chief product.

When two molar amounts of N-bromosuccinimide were reacted with 3-methylthiophene in the absence of benzoyl peroxide, the main product was 2,5-dibromo-3-methylthiophene with some 2-bromo-3-bromomethylthiophene. The addition of benzoyl peroxide resulted in the formation of mainly 2-bromo-3-bromomethylthiophene and some 2,5-dibromo-3-methylthiophene. The 2-bromo-3-bromomethylthiophene was characterized and converted to the diethyl 2-bromo-3-thenylacetamidomalonate.

# The Synthesis and Microbiological Properties of β-3-Thienylalanine, a New *anti*-Phenylalanine[1,2]

BY KARL DITTMER

That β-2-thienylalanine is an antagonist of phenylalanine has been demonstrated by du Vigneaud and co-workers.[3] This inhibitory physiological action is brought about by the interchange of a vinylene group for an aromatic sulfide, a structural change which has also produced antagonists of nicotinic acid[4] and thiamine.[5]

As part of a large research program designed to further establish what structural changes consistently yield metabolite antagonists and what changes do not, the preparations of other heterocyclic amino acids related to phenylalanine have been completed in this Laboratory. Clark and Dittmer[6] found that β-2-furylalanine is about one-third as good a phenylalanine antagonist as β-2-thienylalanine. Herz, Dittmer and Cristol[7] prepared β-2-pyrrylalanine and, although not obtained in pure form, found that it is an antiphenylalanine.

Since all of these β-2-heterocyclic alanines were active as antagonists of phenylalanine it seemed important to determine what influence the position of the alanine side chain would have on the antiphenylalanine activity of the thiophene analog. To determine which of the two possible isomers of thienylalanine is the better antagonist, the β-3-thienylalanine was prepared by the reactions.

During a study of the bromination of 3-methylthiophene with N-bromosuccinimide, 2-bromo-3-(bromomethyl)-thiophene (II) was obtained in good yield.[8,9] The condensation with diethyl acetamidomalonate resulted in a 73% yield of diethyl (2-bromo-3-thenyl)-acetamidomalonate (III). Pure samples of β-(2-bromo-3-thienyl)-alanine hydrobromide (V) were most easily obtained if the condensation product (III) was converted to the water insoluble N-acetyl intermediate (IV) which was then hydrolyzed with hydrobromic acid to yield V. The removal of the bromine with hydrogen in the presence of palladium catalyst on charcoal according to the method of Mozingo and co-workers[11] was tried on compounds III, IV and V. Best results were obtained when the bromine was removed from β-(2-bromo-3-thienyl)-alanine hydrobromide (V).

The structure of β-3-thienylalanine (VI) could be inferred by its synthesis from 3-methylthiophene (I), it was strengthened by analysis, and established by oxidizing it with alkaline permanganate to 3-thiophenecarboxylic acid which showed no depression of the melting point with an authentic sample of 3-thiophenecarboxylic acid.

β-3-Thienylalanine was tested for its inhibitory action on the growth of *Saccharomyces cerevisiae*, strain 139, and an unidentified strain of *Escherichia coli*.

## Experimental

**N-Acetyl-β-(2-bromo-3-thienyl)-alanine (IV).**—Partial hydrolysis of 8.66 g. (0.022 mole) of diethyl (2-bromo-3-thenyl)-acetamidomalonate (III), prepared as previously described,[8] was accomplished by heating under reflux for four hours with 50 ml. of 10% sodium hydroxide.[12] The reaction mixture was acidified to *p*H 3 with hydrochloric acid and heated for one hour. It was treated with Darco, filtered and cooled overnight. The yield of fairly pure N-acetyl-β-(2-bromo-3-thienyl)-alanine (IV) was 2.72 g. (45%). Recrystallization from water yielded a pure crystalline product, m. p. 148–149°.

*Anal.* Calcd. for $C_9H_{10}O_3BrNS$: N, 4.79; neut. equiv., 292. Found: N, 4.59; neut. equiv., 289.

**β-(2-Bromo-3-thienyl)-alanine Hydrobromide (V).**—With vigorous stirring 3.6 g. (0.012 mole) of IV and 150 ml. of 10% hydrobromic acid solution were heated for four hours. The hydrobromic acid and water were removed *in vacuo*. The residue was dissolved in ethyl alcohol; the solution was treated with Darco and filtered; and ethyl acetate was added to induce crystallization. Upon cooling and the addition of more ethyl acetate, 2.42 g. (61% yield) of white crystalline hydrobromide (V) was obtained.

*Anal.* Calcd. for $C_7H_9Br_2O_2NS$: N, 4.23; neut. equiv., 331. Found: N, 4.18; neut. equiv., 330.

**β-3-Thienyl-DL-alanine (VI).**—To 2 g. of reduced palladium on charcoal catalyst in 30 ml. of 50% aqueous methanol was added 1.05 g. (0.0032 mole) of β-(2-bromo-3-thienyl)-alanine hydrobromide (V). The catalyst was prepared and reduced at 60 cm. of mercury pressure according to Mozingo and co-workers.[11] During the first ten minutes of shaking at room temperature 64 ml. (STP) of hydrogen at 1.6 atmospheres pressure was absorbed which represents 90% of the theoretical amount required to debrominate V. After shaking another hour the theoretical amount of hydrogen was used. The catalyst was removed by filtration. The filtrate was concentrated to dryness *in vacuo*, dissolved in 5 ml. of water and again taken to dryness. The β-3-thienylalanine hydrobromide was dissolved in 10 ml. of absolute ethanol; the solution was treated with Darco, filtered, and the filtrate was exactly neutralized with 10 *N* ammonium hydroxide. Crystals began to form almost immediately and after cooling, 330 mg. (61% yield) of β-3-thienylalanine (VI) was collected. This sample gave a negative Beilstein test and a positive ninhydrin reaction. β-3-Thienylalanine was recrystallized by dissolving in a small amount of absolute ethanol containing a slight excess of hydrobromic acid. After the solution had been treated with Darco the hydrobromic acid was exactly neutralized with 10 *N* aqueous ammonium hydroxide. The crystals were washed with absolute alcohol and dried, melting point 244–248° in a capillary when placed into the bath at 240°.

*Anal.* Calcd. for $C_7H_9O_2NS$: C, 49.10; H, 5.30; N, 8.18. Found: C, 48.98; H, 5.65; N, 8.34.

The position of the side chain was established by oxidizing the β-3-thienylalanine to 3-thiophenecarboxylic acid. To 40 ml. of water containing 1.8 g. of sodium hydroxide was added 256 mg. (0.0015 mole) of β-3-thenylalanine and 1.0 g. of potassium permanganate. The reaction mixture was heated to boiling and kept warm for two hours. After cooling, the manganese dioxide was removed by filtration and the filtrate was acidified and extracted with ether. The ether solution was dried with sodium sulfate and then concentrated to a small amount of oil which soon crystallized. The solid was dissolved in 1 ml. of hot water; the hot solution was treated with Darco, filtered and cooled overnight. The yield of 3-thiophenecarboxylic acid was 110 mg. (57%), m. p. 137–138°. Mixed melting point with an authentic sample of 3-thiophenecarboxylic acid, was 137–138°, whereas, when mixed with 2-thiophenecarboxylic acid the melting point was 120–124°.

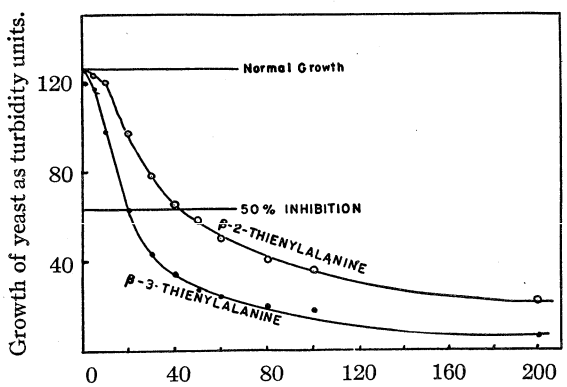

Fig. 1.—A comparison of the properties of two isomeric thienylalanines as yeast growth inhibitors.

**Microbiological Tests.**—The methods of comparing the inhibitory properties of β-3-thienylalanine with the antiphenylalanine properties of β-2-thienylalanine on the growth of *Saccharomyces cerevisiae*, strain 139, and on an unidentified strain of *Escherichia coli* were the same as previously described.[6]

The curve in Fig. 1 illustrates the relative potency of the two thienylalanines as growth inhibitors of *S. cerevisiae*. It will be observed that 20.0 micrograms of β-3-thienyl-DL-alanine per 7.5 ml. of medium inhibited growth to 50% of normal, whereas for the same degree of inhibition 42.5 micrograms of β-2-thienyl-DL-alanine were required. Figure 2 illustrates that phenylalanine completely reversed the toxicity of β-3-thienylalanine. In addition to phenylalanine, tryptophan, leucine, isoleucine and valine also reversed the toxicity of β-3-thienylalanine. These are the same amino acids which nullified the toxicity of β-2-thienylalanine.[13] β-(2-Bromo-3-thienyl)-alanine (V) did not inhibit the growth of yeast when tested up to a concentration of 1 mg. per 7.5 ml.

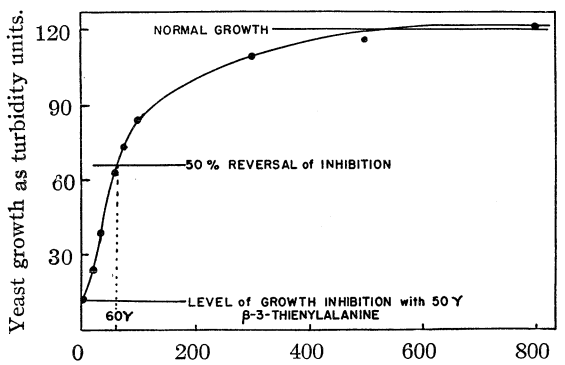

Fig. 2.—Nullification of the β-3-thienylalanine inhibition of the growth of *S. cerevisiae*.

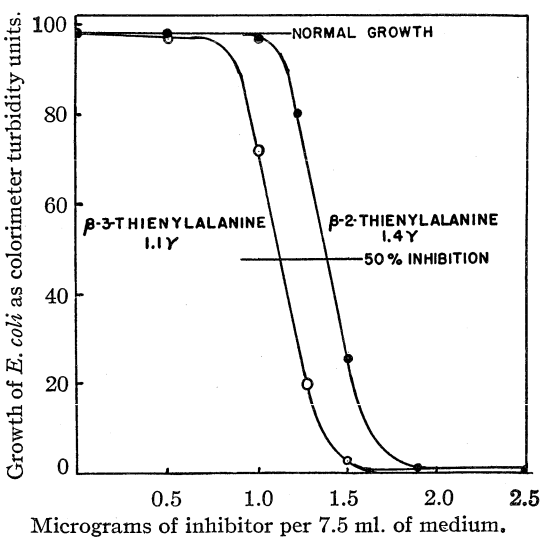

Fig. 3.—A comparison of the properties of two isomeric thienylalanines as inhibitors of *E. coli*.

(13) Dittmer, Ellis, McKennis and du Vigneaud, *J. Biol. Chem.*, **164**, 761 (1946).

When increasing amounts of β-3-thienyl-DL-alanine were added to the medium in which *E. coli* grew well, it completely inhibited the growth and was about 30% more effective than β-2-thienylalanine. This is illustrated by the data of Fig. 3. The toxicity on the growth of *E. coli* was also prevented by phenylalanine.

## Discussion

The results of previous work[3,6,7,13] show that the replacement of the benzene ring in phenylalanine by the thiophene, furan or pyrrole ring results in the formation of antagonists of phenylalanine. Of these three antagonists the thiophene analog was probably the most active. The results described in this paper indicate that when the alanine side chain is in the 3-position the antagonist is more potent than if it is in the 2-position. These results suggest that if the best antagonist of a compound which contains a phenyl ring is to be designed it would be most likely obtained by replacing the phenyl group by a thiophene ring with the side chain in the 3-position.

**Acknowledgment.**—The author wishes to acknowledge the very excellent assistance of Mr. Robert P. Martin in the chemical phase of this work, and of Mrs. Charmion McMillan and Mrs. Virginia Janda for the microbiological tests. The analyses were made by Mrs. Philippa Szerwo of this department. The author also wishes to thank Mr. G. A. Harrington of the Socony–Vacuum Oil Company for a generous gift of 3-methylthiophene.

## Summary

β-3-Thienyl-DL-alanine was synthesized by alkaline hydrolysis of diethyl (2-bromo-3-thenyl)-acetamidomalonate, yielding N-acetyl-β-(2-bromo-3-thienyl)-alanine. The N-acetyl derivative was converted to the β-(2-bromo-3-thienyl)-alanine hydrobromide by acid hydrolysis. The bromine was removed by hydrogenation in the presence of palladium on charcoal catalyst, yielding pure β-3-thienylalanine.

This new isostere of phenylalanine was tested for its inhibitory properties on the growth of *Saccharomyces cerevisiae*, strain 139, and on an unidentified strain of *Escherichia coli*. For yeast, the β-3-thienylalanine was about twice as active as β-2-thienylalanine. It was about 30% more effective against *E. coli*. In each instance the toxicity was reversed by phenylalanine.

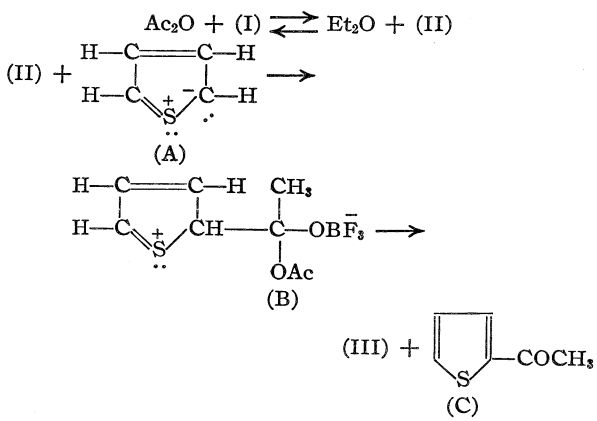
# Further Studies in the Acylation of Thiophene and Furan in the Presence of Boron Fluoride Complexes[1]

BY ROBERT LEVINE, JOHN V. HEID[2] AND MARTIN W. FARRAR



In an earlier paper[3] from this Laboratory it was reported that high yields of 2-thienyl and 2-furyl ketones are obtained when thiophene and furan are acylated with anhydrides in the presence of catalytic amounts of boron fluoride etherate as the condensing agent.

In the present work, we were interested in investigating the course of these acylations. In this discussion, the boron fluoride complexes will be referred to as follows

| (I) | (II) | (III) |
|---|---|---|
| Etherate | Complex with acetic anhydride | Complex with acetic acid |

The following scheme indicates a possible reaction mechanism whereby catalytic amounts of (I) could result in high yields of the heterocyclic ketones. The acylation of thiophene with acetic anhydride is taken as an example.

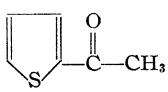
The first step in the reaction probably involves the interaction between acetic anhydride and (I) to give (II). This reactive intermediate then condenses with thiophene (A), to give the complex of (II) and thiophene (B), which then decomposes to produce (III) and 2-thienyl methyl ketone (C). We postulate that the acylating agent is (II) and the actual condensing agent (the catalyst) is (III). As this complex of acetic acid and boron fluoride (III) is formed it functions as (I) did in the first step of the reaction and is con-

(1) Presented before the Organic Division of the American Chemical Society, St. Louis Meeting, September, 1948.

(2) Present address: Mellon Institute, Pittsburgh, Pa.

(3) Heid and Levine, *J. Org. Chem.*, **13**, 409 (1948).

tinually being recycled. Hence catalytic amounts of (I) could result in high yields of ketone.[4]



Some support of the mechanism proposed above would be available if the acylations of thiophene and furan could be effected using a complex of boron fluoride and a carboxylic acid as the condensing agent. Therefore, thiophene and furan were acylated with acetic, propionic and *n*-butyric anhydrides in the presence of catalytic amounts of (III). High yields of the 2-acyl derivatives of thiophene and furan were obtained. These yields compare favorably with those obtained in the same acylations using (I) as the condensing agent,[3] and hence it is felt that the above mechanism represents the actual course of the reaction.[5]

We then prepared 2-thienyl methyl (51%), ethyl (55%), *n*-propyl (69%), and phenyl (38%) ketones by acylating thiophene with the appropriate acid chlorides in the presence of (I) as the condensing agent.

The direct acylation of thiophene with acetic acid in the presence of two boron fluoride complexes was then studied. Two types of experiments were performed. In the first experiment one equivalent of boron fluoride etherate was allowed to react with equivalents of thiophene and glacial acetic acid. It was anticipated that the following reactions would occur.

(a) $BF_3.Et_2O + CH_3COOH \rightleftharpoons Et_2O + BF_3.CH_3COOH$

(b)  $+ BF_3.CH_3COOH \longrightarrow$

Apparently, under the conditions employed, the equilibrium of reaction (a) lies largely to the left, since only 7% of 2-thienyl methyl ketone was obtained. In the second experiment, in which the preformed complex of boron fluoride and acetic acid was allowed to react with thiophene (reaction b), a 25% yield of the ketone was obtained. Earlier, Hartough and Kosak[6] reported the direct acylation of thiophene and furan with carboxylic acids in the presence of phosphorus pentoxide in fair to good yield.

Finally, 2,5-dimethylfuran was acylated with acetic, propionic and *n*-butyric anhydrides in the presence of catalytic amounts of boron fluoride etherate to give the corresponding 3-acyl-2,5-dimethylfurans in good yields. One of these, 3-acetyl-2,5-dimethylfuran, was prepared in high yield by Hurd and Wilkinson,[7] by the interaction of 2,5-dimethylfuran and acetic anhydride in the presence of a catalytic amount of stannic chloride as the condensing agent.

(4) It should be pointed out that in the acylations involving propionic and *n*-butyric anhydrides, the actual condensing agent is probably the complex of boron fluoride and the corresponding carboxylic acid.

(5) Although no study was made of the use of the complexes of boron fluoride and propionic and *n*-butyric acids as condensing agents, yields comparable to those obtained with (III) would probably have been obtained had such experiments been performed.

## Experimental

**Acylation of Thiophene and Furan with Anhydrides in the Presence of the Complex of Boron Fuoride and Acetic Acid. General Procedure.**—The apparatus used in these experiments consisted of a 500-ml. three-necked round-bottomed flask equipped with a mercury-sealed stirrer, a reflux condenser (protected from atmospheric moisture by a drying tube filled with Drierite), and a thermometer so that the temperature of the reaction mixture could be recorded. One mole of furan (68 g.), or thiophene (84 g.), and 1.15 moles of the appropriate anhydride were placed in the flask. To the rapidly stirred solution of furan and anhydride, cooled to 0° in an ice-bath, or of thiophene and anhydride at room temperature, 18.5 g. of the complex of boron fluoride and acetic acid was added all at once. The temperature of the reaction mixture rapidly rose to 100–115° and then dropped to room temperature over a period of about fifteen minutes. Stirring was continued for one-half hour longer and then about 200 ml. of water was added to hydrolyze the reaction mixture. The contents of the reaction flask were made basic with sodium carbonate solution, extracted with ether, and the ethereal phase dried over Drierite. The solvent was distilled at atmospheric pressure and the residue distilled in vacuum. From 75–92% yield of the ketones were obtained. The m. p. of the semicarbazones agreed with those reported previously.[3]

**Acylation of Thiophene with Acid Chlorides in the Presence of Boron Fluoride Etherate. General Procedure.**—The apparatus used was the same as that described above except that a hydrogen chloride trap was attached to the top of the condenser. The thiophene (1.5 moles) and acid chloride (0.5 mole) were placed in the flask, and 14 g. of boron fluoride etherate was added all at once. The reaction mixture was then refluxed until the evolution of hydrogen chloride was practically complete (one to two hours). The reaction mixture was then worked up as described above.

**The Acylation of 2,5-Dimethylfuran with Anhydrides in the Presence of Boron Fluoride Etherate. General Procedure.**—The reactions were carried out exactly as described above for the acylation of furan with anhydrides in the presence of the complex of boron fluoride and acetic acid, except that boron fluoride etherate (14 g.) was used as the condensing agent and that the 2,5-dimethylfuran and the anhydrides were at room temperature when the catalyst was added.

In this way the following 3-acyl-2,5-dimethylfurans were prepared: 3-acetyl (65%), b. p. 95° (23 mm.), oxime, m. p. 75–76°[7]; 3-propionyl (63%), b. p. 105–108° (23 mm.). *Anal.* Calcd. for $C_9H_{12}O_2$: C, 71.05; H, 7.89. Found: C, 71.07; H, 7.74; 2,4-dinitrophenylhydrazone, m. p. 171–172°; 3-*n*-butyryl (60%), b. p. 115–117° (23 mm.). *Anal.* Calcd. for $C_{10}H_{14}O_2$: C, 72.29; H, 8.43. Found: C, 72.54; H, 8.77; 2,4-dinitrophenylhydrazone, m. p. 146–147°.

**The Direct Acylation of Thiophene with the Complex of Boron Fluoride and Acetic Acid.**—Thiophene (64 g., 0.76 mole) and 200 ml. of carbon disulfide were placed in the apparatus described above, and heated to 45°. Forty-nine grams (0.38 mole) of the complex of boron fluoride and acetic acid was then added over a two-hour period. The reaction mixture was then refluxed for one hour longer and worked up as described above for the other acylations. Upon distillation, there was obtained 12.2 g. (25.4%) of 2-acetylthiophene, b. p. 79–80° (7 mm.).

**Acknowledgment.**—The authors are very grateful to Dr. P. E. Cholet of the General Chemical Division of the Allied Chemical and Dye Corpora-

(7) Hurd and Wilkinson, *ibid.*, 70, 740 (1948).

tion for supplying the complex of boron fluoride and acetic acid, and to E. I du Pont de Nemours and Company for contributing the furan used in this investigation.

## Summary

Thiophene and furan have been acylated with several aliphatic acid anhydrides in the presence of the complex of boron fluoride and acetic acid to give high yields of the corresponding 2-acyl derivatives.

Thiophene has been acylated with four acid chlorides in the presence of boron fluoride etherate in fair yields.

The direct acylation of thiophene with the complex of boron fluoride and acetic acid has given only a low yield of 2-thienyl methyl ketone.

# Esters of Nitrogen-substituted *p*-Aminobenzoic Acid

BY J. M. FULMER AND HOWARD BURKETT

In 1942 it was suggested by Dr. H. G. Johnson[1] that from *p*-(2-nitro-2-methylpropylamino)-benzoic acid[2] (I) (see Chart I) alkyl *p*-(2-dialkylamino-2-methylpropylamino)-benzoates (VI, R = alkyl) be prepared and tested for local anesthetic activity. He synthesized *p*-(2-amino-2-methylpropylamino)-benzoic acid[2] (II) by the catalytic hydrogenation of I.

CHART I

The authors have made a number of esters (IV, V, VI) in which R is methyl, ethyl, *n*-propyl and γ-diethylaminopropyl, according to the equations shown. Methyl *p*-(2-amino-2-methylpropylamino)-benzoate (V, R = $CH_3$) was prepared in good yield both from the hydrogenation of the corresponding nitro-ester (IV, R = $CH_3$) and by the esterification of the acid (II). Using methyl sulfate, attempts to methylate the primary amine group in the acid (II) or the ester (V, R = $CH_3$) to give III or VI (R = $CH_3$), respectively, failed. However, no reactions were tried at elevated pressures. Use of the methylation procedure described by Clarke, *et al.*,[3] gave good yields in both cases.

All of the esters were prepared by direct esterification, except the γ-diethylaminopropyl esters, which were synthesized by the reaction of γ-diethylaminopropyl chloride on the sodium salt of the appropriate acid. The ethyl and *n*-propyl esters of VI were obtained only in poor yields by esterification. It was found in the case of the ethyl ester that better yields were obtained by the methylation of V (R = $C_2H_5$).

The pharmacological properties of these compounds are being studied by Graam, Ott and Schultz, who plan to publish their report in the *Journal of Pharmacology and Experimental Therapeutics*.

**Acknowledgment.**—The authors thank Dr. Jerome Martin for his suggestions and Commercial Solvents Corporation for the financial aid which made this investigation possible. The authors also thank Commercial Solvents Corporation for running all high-pressure hydrogenations and analyses.

## Experimental

**Procedure A. Ethyl *p*-(2-Nitro-2-methylpropylamino)-benzoate.**—To a mixture of 25 g. of *p*-(2-nitro-2-methylpropylamino)-benzoic acid[2] and 150 ml. of ethanol was added 2 ml. of concd. sulfuric acid, with shaking. After refluxing for twelve hours, the reaction mixture was cooled and filtered. Two recrystallizations from ethanol yielded 15.7 g. (56%) of ester, m. p. 137–138°.

The methyl and *n*-propyl esters, as noted in Table I, were prepared in a similar manner. They were recrystallized from methanol and *n*-propanol, respectively.

**Procedure B. γ-Diethylaminopropyl *p*-(2-Nitro-2-methylpropylamino)-benzoate.**—To a suspension of 29.0 g. (0.12 mole) of finely powdered *p*-(2-nitro-2-methylpropylamino)-benzoic acid in 150 ml. of ethanol was added 72.5 ml. (0.12 mole) of a 1.660 *N* solution of sodium hydroxide in ethanol. After a few minutes, 19.8 g. (0.132 mole) of γ-diethylaminopropyl chloride, along with 50 ml. of ethanol, was added. After refluxing for four and one-half hours, the solution was filtered hot, collecting 7.0 g. of sodium chloride (theory was 7.0 g.). The filtrate was cooled overnight in the refrigerator. Filtration, followed by washing with ethanol and drying, gave 33.2 g. of the ester, m. p. 110–110.5°. Evaporation

| $CH_3$ | $(CH_3)_2N$ | E68 | 90.5–91.5 | | |
| $C_2H_5$ | $(CH_3)_2N$ | E66 | 70–71 | 10.60 | 10.57 |
| $C_2H_5$ | $(CH_3)_2N$ | C12 | 72–73 | | |
| $CH_3CH_2CH_2$ | $(CH_3)_2N$ | C35[d] | 65.5–66.5 | 10.08 | 10.33 |
| $(C_2H_5)_2N(CH_2)_3$ | $(CH_3)_2N$ | B92 | 38–39 | 12.03 | 12.56 |

[a] This is the hydrochloride, m. p., 166–168° (dec.). [b] The hydrochloride melts at 256° (dec.). [c] Analysis after further drying: Calcd. for C, 67.20; H, 8.70. Found: C, 67.40; H, 8.39. [d] Yields for other runs of this compound were much lower. [e] Letter preceding percentage yield represents procedure followed.

to one-fourth volume, adding water and cooling gave an additional 6.4 g. (94% yield).

The other γ-diethylaminopropyl esters (V and VI, R = $(C_2H_5)_2N(CH_2)_3$) were prepared in a similar way with the following exceptions. After refluxing, the solvent was removed under reduced pressure, water was added and the product was extracted with ether. After washing the ether solution with dilute sodium carbonate solution, the ether was evaporated. Solid esters were recrystallized from petroleum ether.

**Procedure C. Methyl *p*-(2-Amino-2-methylpropylamino)-benzoate.**—A suspension of 9 g. of finely divided *p*-(2-amino-2-methylpropylamino)-benzoic acid[2] in 100 ml. of methanol was saturated with dry hydrogen chloride, finally with cooling in ice. After standing at room temperature overnight, the reaction mixture was refluxed for twenty minutes. After cooling in the refrigerator, the mixture was filtered and washed with methanol, yielding 11.7 g. of the hydrochloride of the ester, V (R = $CH_3$).

A portion of the hydrochloride was dissolved in water. Upon adding sodium hydroxide, the ester, m. p. 79–80.5°, precipitated.

Other esters required refluxing for a longer time (up to twenty-four hours) in order to get satisfactory yields. In most cases the product was isolated as described in the last paragraph under Procedure B.

**Procedure D. Methyl *p*-(2-Amino-2-methylpropylamino)-benzoate.**—A solution of 130 g. of methyl *p*-(2-nitro-2-methylpropylamino)-benzoate in 1000 ml. of methanol, to which was added 10 g. of Raney nickel, was hydrogenated at 100° and 1000 p.s.i. After filtering off the catalyst, the methanol was distilled and the remaining liquid distilled under reduced pressure. There was obtained 94.5 g. of the ester, b. p. 160–161° at 1 mm., which solidified upon standing, m. p. 79–81°.

γ-Diethylaminopropyl *p*-(2-nitro-2-methylpropylamino)-benzoate was hydrogenated in benzene. The amine was purified by washing with aqueous sodium hydroxide, drying over anhyd. sodium carbonate and removing the solvent under reduced pressure.

**Procedure E. *p*-(2-Dimethylamino-2-methylpropylamino)-benzoic Acid.**—To 41.6 g. (0.2 mole) of *p*-(2-amino-2-methylpropylamino)-benzoic acid was added 50 ml. of formalin and 52 ml. of 98% formic acid. In about fifteen minutes the flask was placed in an oil-bath heated to 140° and the mixture was allowed to reflux for four hours. After adding 24 ml. of concd. hydrochloric acid to the hot reaction mixture, it was evaporated to dryness under reduced pressure with warming on the steam-bath. After adding 50 ml. of warm water and cooling in the refrigerator, the mixture was filtered and the solid washed with water, yielding 37.1 g. of the hydrochloride of the acid, m. p. 256° (dec.).

A sample of the hydrochloride was dissolved in boiling water and sufficient 20% aqueous sodium hydroxide was added to make the solution faintly basic. Filtering and washing with hot water gave the free acid, m. p. 238° (dec.).

Esters prepared in this manner were purified as in Procedure C.

## Summary

A number of esters of *p*-(2-nitro-2-methylpropylamino)-, *p*-(2-amino-2-methylpropylamino)- and *p*-(2-dimethylamino-2-methylpropylamino)-benzoic acid have been prepared.

# Ring Substituted Benzoylacrylic Acids as Antibacterial Agents

BY FRED. K. KIRCHNER, JOHN HAYS BAILEY AND CHESTER J. CAVALLITO

In an investigation of model antimicrobial compounds containing unsaturated lactone or carbonyl structures, one of the types which appeared to be of interest because of its solubility and activity against both gram positive and gram negative bacteria was benzoylacrylic acid. Worrall[1] has reported antibacterial activity of methyl and propyl esters of the acid and Rinderknecht, *et al.*,[2] have observed activity of the acid as well as the *p*-chloro-, 2,4-dichloro- and *p*-acetamido derivatives.[2,3]

Observations have been made relative to some non-ionic antibiotics that the degree of activity against gram positive bacteria was associated with the lipophilic properties of the compound.[4,5] It was of interest to determine whether this relationship could be shown with the anionic benzoylacrylic acids.

Para alkyl-substituted β-benzoylacrylic acids

(1) Worrall, "Med. World" (London), 1946, 2 pp., *C. A.*, **41**, 6598 (1947).

(2) Rinderknecht, Ward, Bergel and Morrison, *Biochem. J.*, **41**, 463 (1947).

(3) British Patent 588,108; *C. A.*, **42**, 329 (1948).

(5) Cavallito and Bailey, *J. Bact.*, in press.

have been prepared with substituent groups ranging from methyl to dodecyl. A marked increase in activity against gram positive bacteria resulted up to approximately the nonyl derivative, beyond which there was a decrease. The *p*-methoxy and ethoxy derivatives were of the same order of activity as the methyl and ethyl compounds. The 2,4-dihydroxy derivative was prepared with some difficulty and was found to be less active than benzoylacrylic acid. The *m*-nitro-, *p*-chloro- and *p*-bromobenzoylacrylic acids were only moderately active.

The benzoylacrylic acids prepared were presumably all of the *trans* form.[6] Orientation in the benzene ring was determined by hypobromite oxidation of the benzoylacrylic acids to the corresponding alkylbenzoic acids.

Unsaturated lactones and other carbonyl derivatives have been indicated to inhibit growth by reaction with biologically essential —SH and possibly amino groups.[7,8] It was thus of interest to determine the nature of the reaction of cysteine with benzoylacrylic acid. An amphoteric reaction product was obtained and it appeared to be a simple addition product of cysteine to the —CO—CH=CH—COOH system to yield the —CO—$CH_2$—CH(SR)—COOH type of derivative. The cysteine derivative retained considerable antibacterial activity which is believed to result from the ease of dissociation of the addition product to regenerate benzoylacrylic acid.

The low activity of 2,4-dihydroxybenzoylacrylic acid is believed to result from interruption of the conjugated system by chelation involving the carbonyl and the 2-hydroxy group. It would be of interest to determine whether the alkyl substituted phenylglyoxylic acids of Hunsberger and Amstutz[9] would be more active if devoid of the orthohydroxy group.

With the lichesterinic acid type of antibiotic[10] it was found that the unsaturated structure was subordinate to the surface-active properties in contributing to antibacterial activity. The higher alkyl-substituted benzoylacrylic acids, on the other hand, have been found to be relatively poor surface tension depressants. The importance of the double bond in contributing to antibacterial activity was demonstrated by *p*-hexylbenzoylacrylic acid which was approximately one-hundred fold as active as *p*-hexylbenzoylpropionic acid.

## Experimental[11]

**Phenyl Alkyl Ketones.**—Except for propiophenone, which was purchased, the ketones were prepared through the Friedel–Crafts reaction. The acid chlorides were prepared according to Bauer's recommendation.[12]

**Alkyl Benzenes.**—Toluene, and ethyl and isopropyl benzene, were purchased and redistilled before use. The *t*-butylbenzene was prepared by the method of Norris and Sturgis.[13] The remaining *n*-alkyl benzenes were obtained by the Wolff–Kishner reduction of the phenyl *n*-alkyl ketones, using the Huang-Minlon modification.[14]

The constants previously reported[15] for *n*-decylbenzene were determined on a substance whose structure was questioned. Reduction of the *n*-nonyl phenyl ketone gave *n*-decylbenzene of b. p. 115–116° (2 mm.), and $n^{25}D$ 1.4816.

*Anal.* Calcd. for $C_{16}H_{26}$: C, 88.00; H, 12.00. Found: C, 88.17; H, 11.76.

**β-(4-Alkylbenzoyl)-acrylic Acids.**—The methyl derivative was prepared using an excess of toluene as a solvent.[16] The other alkyl derivatives were prepared by the following general procedure. In a suitably equipped flask, cooled with an ice-bath, were placed 0.20 mole of the alkyl benzene, 0.21 mole of powdered maleic anhydride, and 300 ml. of dry carbon disulfide. There was added in small portions with stirring a total of 0.42 mole of anhydrous aluminum chloride. When the addition was complete the ice-bath temperature was maintained for twenty minutes longer, whereupon the ice-bath was removed and stirring was continued at room temperature for four hours. The flask then was warmed gently for two hours, with continued stirring.

At the end of this period the cooled reaction mixture was decomposed with 300 g. of ice and 10 ml. of concentrated hydrochloric acid. The resulting mixture was steam-distilled and the yellow residue was taken up in ether and the ether solution dried with Drierite.

After removing the Drierite and ether, the yellow residue was recrystallized from a hot benzene–Skellysolve B mixture, or from hot Skellysolve B alone. In this manner there was obtained the compounds listed in Table I.

With the isopropyl and the *t*-butyl derivatives the above procedure was modified at one point. When the aluminum chloride addition was completed, the stirring was continued for four hours at ice-bath temperature, then two hours at room temperature.

The orientation of the substituents in the benzene ring was determined by the sodium hypobromite oxidation[17] of the acrylic acids to known alkylbenzoic acids, and comparison of their constants. The melting point of 4-*n*-octylbenzoic acid was found to be 98–99°, in close agreement with Zaki and Fahim. Beran[18] had reported a melting point of 139°. Melting points for the 4-*n*-nonyl-, 4-*n*-decyl- and 4-*n*-dodecylbenzoic[19] acids were not found in the literature; therefore, we are reporting the following values based on analytically pure samples.

4-*n*-Nonylbenzoic acid, m. p. 96–97° (cor.)

*Anal.* Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.38; H, 9.56.

4-*n*-Decylbenzoic acid, m. p. 95–96° (cor.)

*Anal.* Calcd. for $C_{17}H_{26}O_2$: C, 77.81; H, 9.99. Found: C, 77.53; H, 9.77.

4-*n*-Dodecylbenzoic acid, m. p. 93–95° (cor.)

*Anal.* Calcd. for $C_{19}H_{30}O_2$: C, 78.60; H, 10.42. Found: C, 78.44; H, 10.20.

The above acids, oxidized with potassium permanganate, gave terephthalic acid, identified through its methyl ester, m. p. 140°.

[a] Corrected. [b] Solvent is 0.1 molar potassium phosphate buffer of *p*H 7; solvent surface tension = 72.0 dynes per cm. Measurements made with a Du Nouy interfacial tensiometer at 27°. Concentration of acids = $7 \times 10^{-3}$ moles per ml. [c] The bactericidal activity is approximately one-tenth the bacteriostatic power. [d] Calcd.: Cl, 16.84. Found: Cl, 16.90. [e] Calcd.: Br, 31.33. Found: Br, 30.90. [f] Calcd.: N, 6.33. Found: N (Kjeldahl), 6.01. [g] Calcd.: N, 4.71. Found: N (Kjeldahl), 4.70. [h] Lack of solubility prevented attaining a bacteriostatic concentration. [i] Fieser and Fieser, THIS JOURNAL, **57**, 1679 (1935). [j] Price, *et al.*, *J. Org. Chem.*, **7**, 517 (1942).

**β-(2,4-Dihydroxybenzoyl)-acrylic Acid.**[20]—In a round-bottom flask were placed 40 g. (0.4 mole) of resorcinol, 40 g. (0.41 mole) of powdered maleic anhydride, and 600 ml. of freshly-distilled nitrobenzene. A solution of 108 g. (0.81 mole) of anhydrous aluminum chloride in 300 ml. of nitrobenzene was added dropwise to the stirred solution over a period of ninety minutes, keeping the temperature of the reaction mixture between 20–30°. When the addition was complete stirring was continued for three hours longer, maintaining the temperature at 50–60°. At the end of this period the stirring was discontinued and the reaction allowed to cool to room temperature and stand overnight.

To the reaction mixture was added 300 ml. of ice-cold 12% hydrochloric acid solution and the mixture was stirred for three hours while keeping the temperature at 0–10°. At the end of this period the supernatant liquors were decanted from the brown, viscous mass which had formed. The latter was washed several times with benzene, then crystallized from 60% ethanol. A second smaller crop of the product was obtained by concentrating and cooling the nitrobenzene liquor. The orange-colored product was dried at 100° to give a lemon-yellow compound of m. p. 195°, yield 20–25%.

Catalytic hydrogenation of the unsaturated acid with platinum catalyst gave β-(2,4-dihydroxybenzoyl)-propionic acid, m. p. 199–200°, previously reported by Desai and Shroff.[21]

**Other β-Substituted Benzoylacrylic Acids.**—The 4-methoxy,[22] 4-ethoxy,[23] 4-chloro,[24] 4-bromo,[25] and 3-nitro[26] compounds were prepared according to procedures in the literature.

The hexyloxy compound was prepared according to the method used for the *n*-alkyl derivatives with a slight modification. After the addition of the aluminum chloride was complete, the reaction mixture became so viscous that it was allowed to stand at room temperature for five hours. At the end of this period the solvent was decanted and the viscous mass decomposed with ice and concentrated hydrochloric acid. The required hexyloxybenzene[27] was prepared according to a procedure given by Vogel.[28]

(20) Bogert and Ritter, *Proc. Nat. Acad. Sci. Washington*, **10**, 363 (1924); *cf.* Thomas "Anhydrous Aluminum Chloride in Organic Chemistry," Reinhold Pub. Corp., N. Y., 1941, p. 581. In the original article the authors make no mention of an attempt to prepare this acid. However, the article in Thomas states that Bogert and Ritter had obtained only fumaric acid in attempting to condense resorcinol with maleic anhydride in the presence of aluminum chloride and carbon disulfide.

(23) Rice, THIS JOURNAL, **46**, 2319 (1924).

(24) Rinderknecht, *et al.*, *Biochem. J.*, **41**, 463 (1947).

(25) Kohler and Woodward, THIS JOURNAL, **58**, 1933 (1936).

(26) Bogert and Ritter, *ibid.*, **47**, 526 (1925).

(27) Tronow and Ladigina, *Ber.*, **62**, 2844 (1929).

(28) Vogel, "A Textbook of Practical Organic Chemistry," Longmans, Green and Co., N. Y., 1948, p. 641.

The hexyloxy compound was oxidized[17] to the known 4-*n*-hexyloxybenzoic acid.[29]

**β-(4-*n*-Hexylbenzoyl)-propionic Acid.**—This compound was prepared in the same manner as the majority of the aroylacrylic acids. The compound was oxidized[17] to the known 4-*n*-hexylbenzoic acid.

**Reaction Product of β-Benzoylacrylic Acid with Cysteine.**—Three grams (0.017 mole) of β-benzoylacrylic acid was dissolved in 12 ml. of water and the solution adjusted to *p*H 7 with aqueous sodium hydroxide solution. A solution of 2.68 g. (0.017 mole) of cysteine hydrochloride in 12 ml. of water was treated with aqueous sodium hydroxide until the *p*H was 7. The solutions were mixed and allowed to stand overnight.

The mixture had become slightly yellow and the *p*H was 7.3. Dilute hydrochloric acid was added dropwise until *p*H 2 was reached. The white precipitate was filtered off, washed several times with water, then recrystallized from 60% ethanol solution.

**Antibacterial Tests.**—The compounds were tested as growth inhibitors of *Staphylococcus aureus*, *Escherichia coli* and *Klebsiella pneumoniae* in nutrient broth by the serial dilution method using as an inoculum, 1 ml. of a 1:1000 dilution of a twenty-four hour culture of the test organism and a final volume of 5 ml. in each tube. Incubation was for eighteen hours at 37°. Tests with *Clostridium perfringens* and *Mycobacterium tuberculosis* H37Rv were conducted as previously described.[10] To avoid fluctuations in susceptibility of the test organisms, all compounds of a series were tested against a single organism at the same time and benzoylacrylic acid was used as a reference test compound for series of tests conducted on different days.

**Acknowledgment.**—The authors wish to express their appreciation for the analytical determinations and the corrected melting points which were carried out under the direction of Mr. M. E. Auerbach in the Analytical Laboratories of this Institute. We are indebted to Dr. F. C. Nachod and his staff for the surface-tension measurements. We are appreciative also of the technical assistance given by Mrs. G. W. Schraver during the course of this investigation.

(29) Jones, *J. Chem. Soc.*, 1874 (1935).

## Summary

1. A number of substituted β-aroylacrylic acids were prepared and their antibacterial activity determined *in vitro*.

2. With the *n*-alkyl series there was a noticeable increase in activity against gram positive bacteria as the length of the alkyl chain was increased, the $C_9$ chain being approximately the optimum chain length. The antibacterial activity appears to result from the presence of the highly conjugated benzoylacryl- system which may react with biologically essential —SH groups; the lipophilic ring substituents quantitatively increase the activity against gram positive bacteria.

3. The following 4-*n*-alkylbenzoic acids are considered to be reported for the first time: *viz.*, *n*-nonyl, *n*-decyl and *n*-dodecyl.

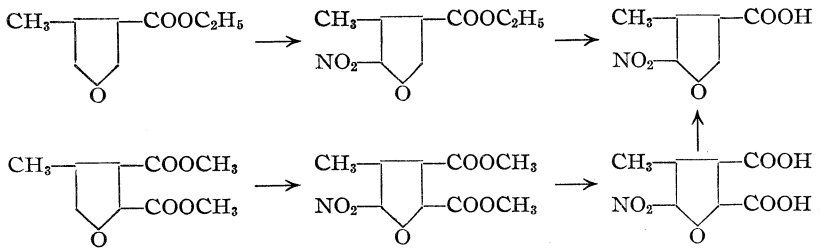
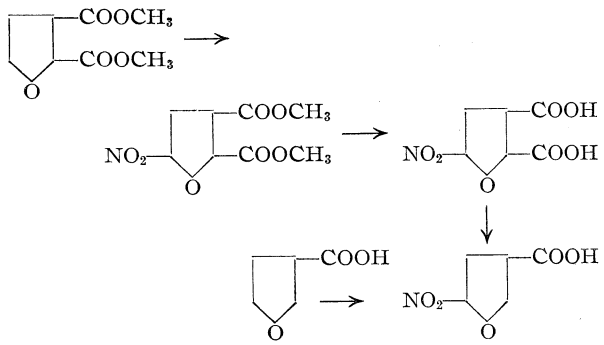
# Orientation in the Furan Nucleus. XII. 3-Methyl-4-furoic Acid and Some of its Derivatives



BY HENRY GILMAN AND ROBERT R. BURTNER[1]

In a previous paper dealing with orientation of β-substituted furans[2] the prediction was made on the basis of evidence then available that nuclear substitution of 3-methyl-4-furoic acid would involve replacement of hydrogen on the 2-position. The validity of this assumption as regards bromination of the acid, mercuration of the methyl ester, and nitration of the ethyl ester has now been established by a sequence of reactions as shown.



(1) Present address: G. D. Searle & Co., Chicago, Ill.

(2) Gilman and Burtner, THIS JOURNAL, **55**, 2903 (1933).

The above transformations are based on the nominal yields of products isolated from these somewhat sensitive compounds.

In addition, the position of the nitro group in 2-nitro-4-furoic acid[2] has been definitely established in the following manner

## Experimental Part

**2-Bromo-3-methyl-4-furoic acid.**—Nine and six-tenths grams (0.06 mole) of bromine was added dropwise to a stirred solution of 6.3 g. (0.05 mole) of 3-methyl-4-furoic acid[3] in 40 ml. of acetic acid at 15–20°. The reaction mixture was then stirred for twelve hours at laboratory temperature, placed under reduced pressure for one hour to remove excess bromine and finally poured onto 250 g. of ice. The crude product was filtered, crystallized from hot water and sublimed in vacuum to yield 2 g. of the acid melting at 163–164°.

*Anal.* Calcd. for $C_6H_5O_3Br$: Br, 39.02. Found: Br, 39.11.

**Methyl 2-Chloromercuri-3-methyl-4-furoate.**—A solution of 2.5 g. (0.017 mole) of methyl 3-methyl-4-furoate in 10 ml. of ethanol was added to a solution of 4.6 g. (0.017 mole) of mercuric chloride and 2.88 g. (0.034 mole) of anhydrous sodium acetate in 100 ml. of water. The mixture was stirred for twelve hours, filtered to remove a flocculent white precipitate and the filtrate gently refluxed with stirring for four hours. Filtration of the cooled mixture yielded a second crop of the crude mercurial. Both fractions were combined and crystallized from ethanol to give 2 g. of the desired material, which melted at 175°.

*Anal.* Calcd. for $C_7H_7O_3ClHg$: Hg, 53.49. Found: Hg, 53.18.

**Conversion of Methyl 2-Chloromercuri-3-methyl-4-furoate to 2-Bromo-3-methyl-4-furoic Acid.**—One and two-tenths grams (0.0075 mole) of bromine was added to a stirred suspension of 1.8 g. (0.005 mole) of the mercurial in 15 ml. of acetic acid at laboratory temperature. There was a mild heat effect, and the mercurial dissolved. The solution was stirred for three hours, diluted with 400 ml. of water and the excess bromine reduced with sulfur dioxide. The mixture was then saturated with hydrogen sulfide, refluxed for one hour and filtered hot to remove the mercuric sulfide. Ether extraction of the cold filtrate yielded a yellow crystalline solid, which after crystallization from water melted at 161°. A mixed melting point determination proved this acid to be identical with that described above.

**2-Bromo-3-methylfuran-4,5-dicarboxylic Acid.**—Six and four-tenths grams (0.04 mole) of bromine was added dropwise at 20° to a stirred solution of 4.4 g. (0.022 mole) of dimethyl 3-methylfuran-4,5-dicarboxylate[3] in 25 ml. of chloroform. The mixture was stirred for three hours longer after which the solvent and excess bromine were removed under reduced pressure. The residual crystals, after being washed with a small amount of ether, melted at 131–132°. Saponification was effected by refluxing for three hours with an alcoholic solution of potassium hydroxide. Removal of the solvent followed by solution of the residue in water and acidification yielded 1.5 g. of a colorless acid melting at 257° with gas evolution.

*Anal.* Calcd. for $C_7H_5O_5Br$: Br, 32.13. Found: Br, 31.5.

**Decarboxylation of 2-Bromo-3-methylfuran-4,5-dicarboxylic Acid.**—A solution of 1.1 g. (0.004 mole) of the bromo acid, 1.2 g. (0.004 mole) of mercuric chloride and 0.25 g. of sodium hydroxide in 40 ml. of water was refluxed for one hour, by which time carbon dioxide evolution had ceased. The mixture was made alkaline to phenolphthalein with sodium hydroxide, filtered and the filtrate acidified. After dilution with water to a volume of 200 ml. and saturation with hydrogen sulfide the mixture was boiled briefly, filtered and the filtrate chilled. The product thus obtained was recrystallized from water to yield 0.3 g. of an acid which melted at 165°. A mixed melting point determination showed this acid to be identical with that obtained by direct bromination of 3-methyl-4-furoic acid.

**3-Methyl-4-carbomethoxy-5-furoic Acid.**—A solution of 12 g. (0.06 mole) of dimethyl 3-methylfuran-4,5-dicarboxylate and 3.4 g. (0.06 mole) of potassium hydroxide in 60 ml. of methanol was refluxed until it was no longer alkaline to phenolphthalein. After removal of the solvent under reduced pressure the residue was dissolved in 15 ml. of water, acidified and the crude product filtered. Crystallization from 50% ethanol and finally from benzene gave 8.5 g. of the desired product melting at 119.5°.

*Anal.* Calcd. for $C_8H_8O_5$: C, 55.10; H, 4.08; neut. equiv., 184. Found: C, 55.01; H, 4.36; neut. equiv., 182.7.

**3-Methyl-4-carbomethoxy-5-chloromercurifuran.**—Four grams (0.021 mole) of 3-methyl-4-carbomethoxy-5-furoic acid was dissolved in 40 ml. of water containing 0.84 g. (0.021 mole) of sodium hydroxide and added to a solution of 5.7 g. (0.021 mole) of mercuric chloride in 100 ml. of water. After standing for one and one-half hours the mixture was filtered and the filtrate refluxed with stirring for thirty minutes at which point carbon dioxide evolution had ceased. The precipitate, obtained by filtering the chilled reaction mixture, was extracted with boiling methanol for one and one-half hours. The chilled extract yielded a small amount of an unidentified white crystalline solid which decomposed at 235–240°. After a week's storage in the refrigerator the alcoholic filtrate was evaporated to yield a pale yellow crystalline material which upon recrystallization from methanol melted at 141–142°. A mixture of this mercurial with the isomeric 5-chloromercuri derivative melted at 122°.

*Anal.* Calcd. for $C_7H_7O_3ClHg$: Hg, 53.49. Found: Hg, 53.08.

**2-Nitro-3-methyl-4-furoic Acid.**—A solution of 9 g. (0.06 mole) of ethyl 3-methyl-4-furoate in 12 ml. of acetic anhydride was added dropwise with stirring at −10° to a nitrating mixture prepared in the customary manner from 18.9 g. (0.3 mole) of nitric acid (sp. gr. 1.51) and 30 ml. of acetic anhydride. The mixture was stirred for

(3) Reichstein and Zschokke, *Helv. Chim. Acta*, **14**, 1270 (1931).

thirty minutes longer at −10° and then poured onto 150 g. of ice. The excess acid was carefully neutralized with 40% sodium hydroxide and the mixture extracted with ether. The extract was immediately treated with 20 ml. of pyridine and allowed to stand for twelve hours in the refrigerator. Removal of the solvent and acidification of the residue with an excess of ice cold 10% hydrochloric acid gave the crude ester, which after crystallization from methanol, weighed 5 g. and melted at 42°.

*Anal.* Calcd. for $C_8H_9O_5N$: C, 48.24; H, 4.52. Found: C, 48.15; H, 4.71.

The ester was hydrolyzed by refluxing for two hours with a solution of 10 g. of sulfuric acid and 25 ml. of water. The acid melted at 194° after crystallization from water.

*Anal.* Calcd. for $C_6H_5O_5N$: C, 42.10; H, 2.92. Found: C, 41.93; H, 3.08.

This acid may also be obtained by direct nitration of 3-methyl-4-furoic acid. Twelve and one-half grams of the acid was added portionwise at −15° to a stirred nitrating mixture prepared from 36.6 g. of nitric acid (sp. gr. 1.51) and 78 ml. of acetic anhydride. The mixture was stirred for one hour longer at −10°, poured onto 500 g. of ice and extracted with ether. The solvent was evaporated and the crude product crystallized from water to give 4.2 g. of the acid melting at 193°.

**2-Nitro-3-methylfuran-4,5-dicarboxylic Acid.**—Five grams of dimethyl 3-methylfuran-4,5-dicarboxylate was added in small portions with stirring at −10° to a nitrating mixture composed of 7.9 g. of nitric acid (sp. gr. 1.51) and 12 ml. of acetic anhydride. Stirring was continued for one hour at −10°, followed by dilution with ice, extraction and treatment with pyridine as previously described. The crude nitro ester was hydrolyzed by refluxing for seven hours with a solution of 10 g. of sulfuric acid and 25 ml. of water. After treatment with decolorizing charcoal the hot filtrate was chilled to give the crude acid. Crystallization from benzene yielded 1.5 g. of the acid melting at 218°.

*Anal.* Calcd. for $C_7H_5O_7N$: C, 38.88; H, 2.31; neut. equiv., 108. Found: C, 38.78; H, 2.81; neut. equiv., 107.3.

**Decarboxylation of 2-Nitro-3-methylfuran-4,5-dicarboxylic Acid.**—One-tenth gram of the dicarboxylic acid contained in a long, narrow test-tube was heated in a metal-bath at 225°. Carbon dioxide was evolved, and a white crystalline solid condensed on the upper walls of the tube. This material melted at 194° and showed no depression in melting point when mixed with samples of 2-nitro-3-methyl-4-furoic acid previously described.

**Dimethyl 2-Nitrofuran-4,5-dicarboxylate.**—A solution of 6.2 g. (0.033 mole) of dimethyl furan-2,3-dicarboxylate[4] in 9 ml. of acetic anhydride was added dropwise at −10° to a stirred nitrating mixture prepared from 10.3 g. (0.16 mole) of nitric acid (sp. gr. 1.51) and 15.6 ml. of acetic anhydride. The mixture was stirred for an additional hour at −10°, poured onto ice, neutralized with caustic solution, extracted with ether and the extract treated with 20 ml. of pyridine. After twelve hours of storage in the refrigerator the solvent was removed and the residue suspended in an excess of ice-cold 10% hydrochloric acid. The crude product thus obtained was crystallized from methanol to give 5.1 g. of the nitro ester melting at 97°.

*Anal.* Calcd. for $C_8H_7O_7N$: C, 41.92; H, 3.05. Found: C, 42.15; H, 3.79.

**Decarboxylation of 2-Nitrofuran-4,5-dicarboxylic Acid.**—Four grams of the above ester was hydrolyzed by refluxing for four hours with a solution of 12 g. of sulfuric acid and 24 ml. of water. The chilled hydrolysate was washed once with chloroform to remove any unchanged ester and then extracted thoroughly with ether. Evaporation of the solvent yielded the crude 2-nitrofuran-4,5-dicarboxylic acid, which after crystallization from a mixture of ether and benzene melted at about 225° with gas evolution.

This material contained in a long, narrow test-tube was heated in a metal-bath at 235°. Carbon dioxide was evolved and a white crystalline solid deposited on the upper part of the tube. Resublimation followed by crystallization from water afforded an acid melting at 137°, which was identical with that obtained by the direct nitration of 3-furoic acid.[2]

## Summary

Bromination of 3-methyl-4-furoic acid, mercuration of the methyl ester, and nitration of the ethyl ester result in substitution in the 2-position. The structure of 2-nitro-4-furoic acid has been established.

# The Ultraviolet Absorption Spectra of Aliphatic Sulfides and Polysulfides[1]

JOHN E. BAER[2] AND MARVIN CARMACK

Various organic polysulfides, $RS_xR'$, have been prepared in which R and R′ are simple alkyl groups.[3] Recently interest has been aroused in the 2-chloroethyl polysulfides in connection with the characterization of the by-products of the manufacture of mustard gas by the Levinstein process.[4,5] Other aliphatic polysulfides of particular interest are the Thiokol types of elastomers and possible intermediates in the vulcanization of rubber.

In view of the differing opinions regarding the manner of attachment of the sulfur atoms in the organic polysulfides, new methods for the recognition of different types of linkages are of interest, particularly methods which do not alter the polysulfide groups chemically.

We have found that aliphatic polysulfides have intense and characteristic ultraviolet absorption

(1) The essential material of this paper was presented before the Organic Division of the American Chemical Society at the National Meeting in Chicago, Illinois, April 22, 1948. It is from the Ph.D. dissertation of John E. Baer, accepted by the Faculty of the Graduate School of Arts and Sciences of the University of Pennsylvania, June, 1948.

(2) Abbott Laboratories Fellow, 1946–1947. Present address: Department of Chemistry, Carleton College, Northfield, Minnesota.

spectra. The locations of the peaks and the intensities differ widely depending upon the number of sulfur atoms in the polysulfide function. Consequently, the preliminary results suggest that spectrometric measurements may afford a convenient method for the qualitative identification of different types of polysulfides. In some cases, also, absorption spectrometry may be applied to the analysis of mixtures.

We were led to investigate the absorption spectra of polysulfides by the following considerations. (1) Simple mercaptans and alkyl sulfides, unlike most organic compounds containing no multiple linkages, show a characteristic sharp absorption band in the far ultraviolet region (near 200 mμ).[6] Appearance of such a peak indicates that the unshared electrons of the sulfur atom can be excited by frequencies of light possessing about the same energy as those which excite the carbon-carbon double bond. (2) Many chemical analogies between the —S̈— and the —C=C— groups have been observed and classified under the general term, isosterism, based upon similarities in the electronic systems. (3) Resonance forms of compounds containing the —S̈— function have been postulated[7] in which the sulfur atom expands its valence shell to ten or more electrons; such assumptions are considered necessary to account for dipole moments and other physical and chemical properties of certain sulfur-containing compounds.

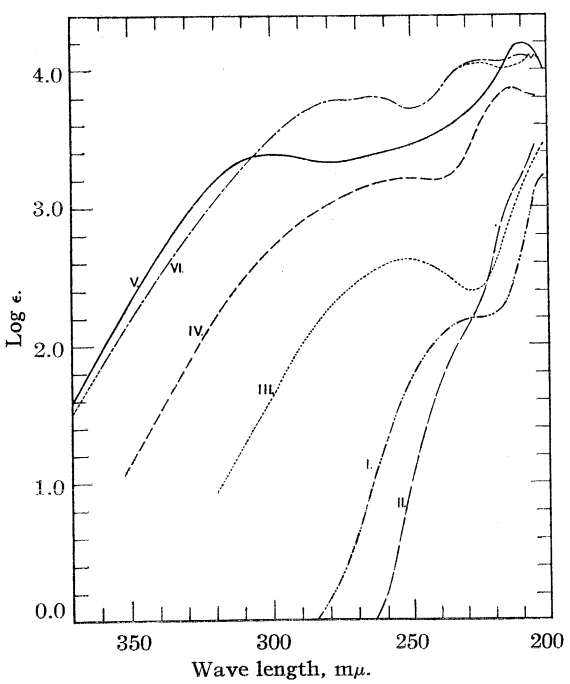

Fig. 1.—Curve I, *n*-hexadecyl mercaptan; II, *n*-hexadecyl sulfide; III, *n*-hexadecyl disulfide; IV, *n*-hexadecyl trisulfide; V, *n*-hexadecyl tetrasulfide; VI, sulfur ($S_8$) in hexane and alcohol (except dotted portion below 230 mμ showing deviation in alcohol).

The facts cited above lead one to expect that, in the disulfides and polysulfides, the groupings of linked sulfur atoms will behave optically somewhat like conjugated systems of carbon–carbon double bonds, as, for example, in the conjugated polyene hydrocarbons. That is, the peak of light absorption will increase in intensity and shift toward longer wave lengths as the number of conjugated sulfur atoms in the functional group increases. Some evidence of conjugation between sulfide groups and other functional groups containing double bonds has been noted in other connections in This Laboratory.[8]

Crystalline *n*-hexadecyl trisulfide and *n*-hexadecyl tetrasulfide[9] were chosen as particularly suitable reference compounds. Since these two compounds can be readily synthesized in good yields by straightforward methods and give the ordinary indications of homogeneity (sharpness and reproducibility of melting points and constancy of composition), there is little reason to doubt their true polysulfide nature and freedom from contamination with elementary sulfur. Furthermore, *n*-hexadecyl disulfide, *n*-hexadecyl sulfide, and *n*-hexadecyl mercaptan are all available and are well-defined, low-melting crystalline solids,[10] readily soluble in paraffinic solvents in which ultraviolet absorption spectra are relatively little complicated by solvent effects.

Figure 1 shows the absorption spectra of RSH (I) (R = $n$-$C_{16}H_{33}$), $R_2S$ (II), $R_2S_2$ (III), $R_2S_3$ (IV), $R_2S_4$ (V), and $S_8$ (VI) in hexane. The mercaptan and sulfide have spectra very similar to other simple alkyl compounds with these functional groups.[6,8] The mercaptan spectrum shows the typical shoulder at 225 mμ which has been noted with other mercaptans.[1] The absorption maxima for I and II lie just beyond the limits accessible to measurement with the instrument and solvent used. The disulfide (III) exhibits a fairly intense new peak at 252 mμ (log ε 2.63), an indication of conjugation between the unshared electrons on the two sulfur atoms.[11]

The trisulfide (IV) has two maxima: 251 mμ (log ε 3.22) and 213 mμ (log ε 3.87). The absorp-

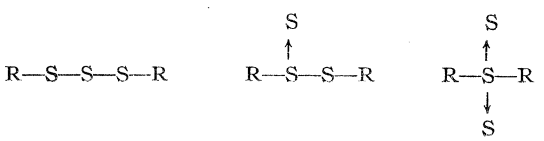
(11) Ethyl disulfide has an absorption band with a maximum at 249 mμ (log ε 2.63) (ref. 6e). Cystine has also been reported to exhibit a similar peak, Anslow and Foster, *J. Biol. Chem.*, **97**, 37 (1932).

tion is much more intense for the trisulfide than for the disulfide.[12]

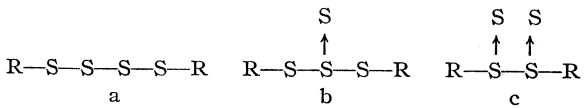
The tetrasulfide (V) shows two maxima: 300 mμ (log ε 3.39) and 209 mμ (log ε 4.19). The whole absorption curve for the tetrasulfide is more intense than that of the trisulfide, and the first peak is shifted markedly toward the visible region compared with the trisulfide.



The absorption spectrum of solutions of molecular sulfur is of interest not only to permit an evaluation of its contribution to the absorption of mixtures in which it may be present, but also because the ordinary $S_8$ molecule provides a structural model in which the mode of attachment of multiple units of sulfur atoms has been established by independent methods[13] and in which even the geometric relationships are well defined. The structure is considered to be a puckered eight-membered ring, as represented by formula VI.

(VI)

Curve VI of Fig. 1 shows the spectra of solutions of sulfur as determined in both hexane and ethyl alcohol. Curves in the two solvents are identical over a wide range, but differ slightly at short wave lengths. Several peaks and plateaus of high intensity are so broad and tend to merge to such an extent that the determination of the exact locations of the maxima is difficult. It may be noted that the absorption spectra of $S_8$ and of *n*-hexadecyl tetrasulfide have certain features in common: namely, both are nearly congruent from the visible region to approximately 320 mμ, and extinction values are of the same order of magnitude through the whole range investigated.



Several structures have been suggested for organic trisulfides (VIIabc)[3,4,5,14,15]; most authorities have favored the linear formulation (VIIa).[3,4]

VII

Recent studies of methyl trisulfide[15] by means of electron diffraction support the linear formulation.

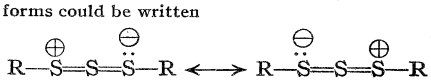
A number of possible structures can be written for tetrasulfides, but the three formulas most seriously considered have been VIIIabc.

VIII

In the conjugated diphenylpolyene series, $C_6H_5(CH{=}CH)_nC_6H_5$, a relationship has been found between the value of $n$ and $\lambda^2$ for the first absorption band.[16] It might be expected that chains of sulfur atoms connected linearly as in the series R–(–S–)$_n$R would show a regular shift of absorption maxima with increasing values of $n$, and that attachment of sulfur atoms along the chain in a non-linear fashion (as in VIIbc and VIIIbc) would be revealed by irregularities which could be correlated with structure.[17]

The correlation of structure with spectra in the polysulfide series is obviously very complicated, and many more compounds will need to be prepared before the relationships can be fully interpreted. It seems likely, for example, that steric relationships among the sulfur atoms of a polysulfide group may have an important influence upon the spectra. Zechmeister, LeRosen, Schroeder, Polgar and Pauling[18] have shown that in the carotenoid polyenes the stereochemical configurations have important, and predictable, influences upon the spectra. Similarly, in the polysulfides it may be expected that rigid polysulfide structures may have somewhat different spectra than acyclic polysulfides for which many stereochemical configurations are possible. The synthesis of other polysulfides, including the cyclic, is under investigation. Determinations of the spectra at lower temperatures may perhaps permit a sharper resolution of the absorption peaks.[19]

(12) That the trisulfide and disulfide should both have one peak at almost the same wave length (251–252 mμ) should probably not be considered particularly significant. The more intense peak of IV centering at 213 mμ has its foot superimposed upon the lower first absorption band, and this makes it difficult to estimate the location of the true center of the first absorption band. If merging of the broad bands did not occur to such an extent, it seems likely that the first band of the trisulfide would have a maximum somewhat nearer the visible region than the first band of the disulfide.



(13) Yost and Russell, "Systematic Inorganic Chemistry," Prentice–Hall, New York, N. Y., 1944, p. 277. Molecular extinction values were calculated on the basis of the molecular formula $S_8$ and it was assumed that the molecular state in solutions at room temperature is the same as in the crystalline state.

(15) Donohue and Schomaker, *J. Chem. Phys.*, **16**, 92 (1948).

(16) For an excellent recent discussion of this and other similar correlations of structure and spectra, *cf.*, Maccoll, *Quarterly Reviews of the Chemical Society (London)*, **1**, No. 1, 16–58 (1947), especially p. 45.

(17) The assumption of an analogy between the optical behavior of polyene chains and linear polysulfide chains implies that polarization can occur by a transfer of charge along the chain of sulfur atoms. Polarization of the molecule can occur if one sulfur atom accepts an extra pair of electrons from its adjoining neighbor (thus expanding its valence shell to ten electrons). For example, in a linear trisulfide the polar forms could be written

The non-linear structures of polysulfides are generally written with semipolar bonds between the chain sulfur and the extra sulfur atoms, implying a permanent polarization of the molecule; however, if expansion of the sulfur valence shell is possible, then a large number of resonance forms can be written for the non-linear as well as for the linear structures.

## Experimental

**Preparation and Purification of Compounds.**—*n*-Hexadecyl mercaptan purchased from the Connecticut Hard Rubber Company, m.p. 18°,[10b] was distilled at 0.6 mm., b.p. 135–140°. The middle cut was used for the spectrometric determination and for some of the other preparations described below. Analyses for carbon, hydrogen, and sulfur were satisfactory. ***n*-Hexadecyl sulfide** was prepared by the reaction of *n*-hexadecyl bromide[20] with sodium sulfide in alcohol; after recrystallization from 95% alcohol–hexane, colorless crystals, m.p. 58.2–58.5° (reported m.p. 57.5°[21]); analyses for carbon and hydrogen agreed with theory. ***n*-Hexadecyl disulfide** was prepared from *n*-hexadecyl mercaptan by oxidation with iodine in alcohol according to Collin *et al.*[10a]; recrystallization from acetone gave colorless needles, m.p. 55–55.5° (reported m.p. 54°[10a]). The sample for spectrometric analysis was recrystallized again from glacial acetic acid; analyses for carbon, hydrogen and sulfur agreed with the theoretical. ***n*-Hexadecyl trisulfide** was prepared from *n*-hexadecyl mercaptan and freshly redistilled sulfur dichloride according to the procedure of Clayton and Etzler[9]; recrystallization of the product from hexane–acetone gave colorless crystals, m.p. 42.0–42.6° (reported m.p. 41.2–41.9°[9]); analyses for carbon and hydrogen agreed with the theoretical. ***n*-Hexadecyl tetrasulfide** was prepared from *n*-hexadecyl mercaptan and sulfur monochloride according to the procedure of Clayton and Etzler[9]; recrystallization of the product three times from hexane–acetone gave a faintly yellow crystalline product, m.p. 36.8–37.2° (reported m.p. 35.9–36.5°[9]); analyses for carbon and hydrogen agreed with the theoretical. All preparations were repeated to verify the reproducibility of results. **Sulfur** (commercial, sublimed) was twice recrystallized from alcohol, m.p. 119° (capillary).

**Determination of Ultraviolet Absorption Spectra.**—The hexane used as a solvent in most of the determinations was purified by washing with 10% fuming sulfuric acid, followed by washing with aqueous sodium bicarbonate and water, then distillation through a Vigreux column. The spectrum of sulfur was determined in Commercial Solvents Gold Shield Absolute Alcohol as well as in hexane. Differences in the spectra in the two solvents were only observed at wave lengths below 230 mμ. Measurements were made in the Beckman Model DU Quartz Spectrophotometer in 1-cm. quartz cells. Values of log ε in the range 1–2 were measured at $10^{-2}$ *M* concentration, log ε 2–3 at $10^{-3}$ *M*, log ε 3–4 at $10^{-4}$ *M*, etc. Wave bands did not exceed 2.3 mμ. Most curves were checked on two different preparations of the same compound.

**Mixed Melting Point Determinations.**—It was of interest to determine whether mixtures of the various polysulfides would show depressions of melting point. For each of the several pairs of compounds, four simultaneous capillary melting point observations were made: specimens of each pure compound, a 2:1 mixture, and a 1:2 mixture of the two. The mixture of 1 disulfide: 2 trisulfide showed a 1°-depression below the m.p. of the pure trisulfide. The mixtures of the disulfide and tetrasulfide melted over wide ranges between the limits for the pure compounds. Mixtures of the trisulfide and tetrasulfide melted over ranges at intermediate values.

**Acknowledgment.**—Analyses of all compounds were made by Mrs. Sarah Miles Woods.

## Summary

The ultraviolet absorption spectra of *n*-hexadecyl mercaptan, *n*-hexadecyl sulfide, *n*-hexadecyl disulfide, *n*-hexadecyl trisulfide, and *n*-hexadecyl tetrasulfide were determined in hexane solution. The spectra of sulfur in hexane and in ethanol solutions were determined. The spectra of the polysulfides have been shown to vary markedly with the sulfur content of the functional group. Spectrometry may be useful in the qualitative identification and quantitative estimation of various organic polysulfides.

# The Synthesis of tris-(Hydroxymethyl)-methylnitramine and Other Compounds Related to tris-(Hydroxymethyl)-aminomethane[1]

BY JAMES CASON[2] AND FRANKLIN S. PROUT[2a]

In connection with studies on nitramines carried out in this country and Canada it became desirable to study the absorption spectra of an aliphatic nitramine and the isomeric nitrosohydroxylamine. The present communication describes the synthesis of such an isomeric pair. The study of the absorption spectra is reported separately by other authors.[3]

Although there have been prepared, in the aromatic series, nitramines isomeric with known nitrosohydroxylamines[4] there appears to be no report of the preparation and isolation in a pure condition of such an isomeric pair in the aliphatic series. In fact, there have been reported only a limited number of aliphatic nitrosohydroxylamines which are sufficiently stable to permit isolation in a pure state. tris-(Hydroxymethyl)-methylnitrosohydroxylamine has been prepared by Piloty and Ruff,[5] starting with tris-(hydroxymethyl)-nitromethane, and this preparation has been repeated by us with some modifications.

The method first investigated for the preparation of the previously unknown tris-(hydroxy-

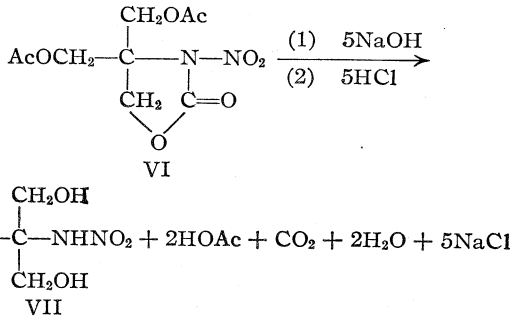
methyl)-methylnitramine (VII) involved nitration of tetraacetyl tris-(hydroxymethyl)-aminomethane (I), but this route was unsuccessful for



this amide resisted nitration by mixed acid, 98% nitric acid or nitric acid in acetic anhydride. The only product isolated from these attempted nitrations was starting material.

An attempt was also made to prepare the related tris-(nitroxymethyl)-methylnitramine, but it was found that nitration of N-acetyl-tris-(hydroxymethyl)-aminomethane (II) failed to affect the amide group; the only product isolated was N - acetyl - tris - (nitroxymethyl) - aminomethane. Two later attempts to obtain tris-(nitroxymethyl)-methylnitramine were also unsuccessful. The alkaline hydrolysis of 3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone,[6] as well as nitration of tris-(hydroxymethyl)-methylnitramine failed to yield any isolable product.

A successful synthesis of tris-(hydroxymethyl)-methylnitramine (VII) was finally worked out, starting with 4,4-bis-(hydroxymethyl)-oxazolidone[6] (IV). The steps involved are outlined in the accompanying chart.

(6) 4,4-bis-(Hydroxymethyl)-oxazolidone and 3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone were first prepared at Cornell University as a part of the investigation carried out under an OSRD contract and directed by Dr. A. T. Blomquist. The 3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone was obtained by Blomquist by nitration of the oxazolidone, IV, with mixed acid, while nitration with 98% nitric acid gave the 4,4-bis-(nitroxymethyl) derivative. Publication of this work is planned for the near future (private communication, 11-18-48, from A. T. Blomquist).

Nitration of 4,4-bis-(acetoxymethyl)-oxazolidone (V) with a mixed acid containing excess sulfur trioxide resulted in nitrolysis of the acetyl groups to give 3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone[6]; however, nitration with 98% nitric acid in acetic anhydride proceeded smoothly to give 3-nitro-4,4-bis-(acetoxymethyl)-oxazolidone (VI). Alkaline hydrolysis of the latter compound at room temperature gave a 77% yield of the desired tris - (hydroxymethyl) - methylnitramine (VII).

## Experimental[7]

**tris-(Hydroxymethyl)-methylhydroxylamine** was obtained only after some modification of the method of Piloty and Ruff.[5] In the best procedure, a solution of 10 g. of tris-(hydroxymethyl)-nitromethane (recrystallized from nitromethane, m. p. 158–162°, with gassing) and 45 g. of crystalline aluminum sulfate in 300 cc. of water was stirred at 0–2° while 360 g. of 2.5% sodium amalgam was added during forty-five minutes. The mixture was stirred an additional forty-five minutes at the same temperature. After removal of aluminum hydroxide and mercury by filtration, the filtrate was concentrated to dryness *in vacuo* at a bath temperature of 50–60°. The residue was extracted at 100° with one 50-cc. portion and three 25-cc. portions of butanol. On standing overnight in the refrigerator, there crystallized from this extract 3.2 g. (35.2%) of heavy blades, m. p. 139–140°, with softening at 128°. On concentrating the butanol filtrate *in vacuo* a slightly waxy second crop weighing 0.4 g. was obtained. This hydroxylamine is not hygroscopic in moist air and it reduces Fehling solution instantly in the cold.

The product obtained as above contains a trace of sulfate, for its aqueous solution gives a slight cloudiness with barium hydroxide; however, this should be no disadvantage for use in preparation of the nitrosohydroxylamine. Piloty and Ruff[5] recommend removing sulfate by crystallization from alcohol containing "enough" barium hydroxide; however, in our hands, this procedure gave a product of lower melting point.

**tris-(Hydroxymethyl)-methylnitrosohydroxylamine.**[5]—A solution of 1.00 g. of the above-described hydroxylamine in 15 cc. of 0.484 *N* hydrochloric acid was cooled in an ice–salt-bath and treated with 0.504 g. of sodium nitrite in 4 cc. of water. The mixture was left in the cooling-bath for five minutes then the water was removed *in vacuo* at a bath temperature of 50–60°. The residue was dried *in vacuo* for one hour at this temperature then extracted at 50° with butanol (20, 10, 5 cc.). The extract was concentrated *in vacuo* at a bath temperature of 55–60°, then allowed to stand overnight in the refrigerator. There was obtained 0.66 g. (54.5%) of small, white dense crystals, m. p. 123–138° with continuous gassing.

The substance burns with a flash of brown fumes and does not reduce Fehling solution in the cold. It shows no evidence of decomposition on warming briefly in butanol or ethanol to 80°. Approximate solubilities at room tem-

(7) All melting points corrected.

perature are 2.5 g. per 100 cc. in ethanol and 0.6 g. per 100 cc. in butanol. It is very soluble in water, but not hygroscopic in moist air. The melting point behavior was unchanged by additional crystallization from butanol or ethanol. Since Piloty and Ruff[5] give the melting point as 147°, two samples were analyzed; sample NB-I-50B was recrystallized four times, sample NB-I-51 was recrystallized once.

*Anal.* Calcd. for $C_4H_{10}O_5N_2$: C, 28.92; H, 6.07. Found: (Sample NB-I-51) C, 29.05; H, 6.51; (Sample NB-I-50B) C, 29.21; H, 6.28.

**Tetraacetyl tris-(Hydroxymethyl)-aminomethane[8] (I).**—To a mixture of 415 cc. of acetic anhydride and 1 g. of sodium acetate was added 121 g. of commercial tris-(hydroxymethyl)-aminomethane (m. p. 146–161°). The amine went into solution rapidly, with evolution of heat, and the mixture soon refluxed so violently that external cooling was necessary. After spontaneous refluxing had ceased (longer heating is unnecessary) acetic acid was removed *in vacuo* and the residue was treated with Norit in benzene and crystallized at 0° from 700 cc. of benzene. The product so obtained was bulky and soft, and removal of benzene on the filter was exceedingly difficult; weight, 179.3 g., m. p. 97–107°. This product was crystallized from 200 cc. of acetic acid-400 cc. of ether, then from 125 cc. of acetic acid–300 cc. of ether; yield of soft white needles, 107.8 g., m. p. 114.0–114.5° (literature,[8] 115°). By systematically working up the mother liquors there was obtained an additional 57.5 g., m. p. 114.0–114.5°; total yield, 56%.

When this substance was prepared from pure tris-(hydroxymethyl)-aminomethane (m. p. 170.4–171.8°) the yield was not greatly improved, but pure material was obtained after one crystallization. Sodium acetate may be omitted if the reaction mixture is heated on a steam-bath for several hours.

**N-Acetyl-tris-(hydroxymethyl)-aminomethane (II).**—Tetraacetyl tris-(hydroxymethyl)-aminomethane (72.3 g.) was dissolved at room temperature in 800 cc. of 0.9844 *N* sodium hydroxide. After this mixture had remained at room temperature for three hours there was added an amount of standard hydrochloric acid equivalent to the alkali used. Water was removed *in vacuo* and the residue was extracted at 50° with 300 cc. of ethanol in four portions. After addition of 200 cc. of nitromethane, filtration of precipitated salt and concentration to 300 cc. there crystallized 11.5 g. of monoacetyl derivative, II, m. p. 131.3–133.4°. From the mother liquor was obtained 8.26 g. of product, m. p. 130–134°, total yield, 48.4%. This substance crystallizes with considerable difficulty. A sample crystallized from nitromethane for analysis melted at 133.6–134.0°.

*Anal.* Calcd. for $C_6H_{13}O_4N$: C, 44.16; H, 8.03. Found: C, 44.28; H, 8.13.

Attempts to prepare this compound in other ways were unsuccessful. When an aqueous solution of tris-(hydroxymethyl)-aminomethane was treated at room temperature with one mole equivalent of acetic anhydride, practically no crystalline monoacetyl derivative could be isolated from the reaction mixture. When a sample of tetraacetyl tris-(hydroxymethyl)-aminomethane was boiled with absolute ethanol containing a trace of anhydrous hydrogen chloride the starting material was essentially unaffected, and when the amount of hydrogen chloride was increased the material recovered was the hydrochloride of tris-(hydroxymethyl)-aminomethane, m. p. 150.0–150.8° (gas). Täuber[9] gives the melting point of this substance as "about 149°."

**N-Acetyl-tris-(nitroxymethyl)-aminomethane (III).**—A 4.08-g. sample of monoacetyl compound, II, was added during ten minutes, at 5–9°, to a mixture of 12.6 g. of 98% nitric acid and 12.8 g. of acetic anhydride. After the mixture had been stirred for four hours at 15–20° it was poured on 75 g. of cracked ice and the precipitate was collected and washed with water. The product was treated with sodium bicarbonate in 50 cc. of acetone and precipitated with 150 cc. of water. The oil which separated was seeded and the resulting crystallizate collected and dried; yield 6.26 g. (80.8%): m. p. 89.6–91.0°. This substance is crystallized with much difficulty. According to the best method discovered, 0.50 g. of nitrate was dissolved in 50 cc. of acetone and the solution diluted with 200 cc. of water. The recovery of slender needles was 0.16 g., m. p. 90.3–90.6°. The substance decomposes slowly at room temperature and rapidly at 56°; it was dried at 35° *in vacuo* for two hours for analysis. The analytical values show that only three nitro groups entered the molecule.

*Anal.* Calcd. for $C_6H_{10}O_{10}N_4$: C, 24.17; H, 3.38. Found: C, 24.69; H, 3.49.

Nitration of II with mixed acid gave water-soluble products at elevated temperatures and a poor yield of the trinitroxy compound at lower temperatures.

**4,4-bis-(Hydroxymethyl)-oxazolidone (IV)** was prepared by a slight modification of the procedure described by Blomquist.[6] To a solution of 121 g. of tris-(hydroxymethyl)-aminomethane (recrystallized, m. p. 167.6–170.6°) in 200 cc. of water was added, during two hours, at 5–10°, 124.8 g. (15% excess) of ethyl chlorocarbonate. During the last half of this addition there was added concurrently 46 g. of sodium hydroxide in 400 cc. of water. After addition was complete the cooling bath was removed and stirring continued for two hours, then solvent was removed as completely as possible *in vacuo* at a bath temperature of 55–65°. The residue was extracted with 550 cc. of absolute ethanol, and the residue obtained after removal of ethanol *in vacuo* was crystallized from methanol. Additional crops of product were obtained by addition of butanone and concentration. The total yield of IV was 100.3 g. (68%) distributed in five crops of melting point varying from 107.9–109.2° to 93–104°. One additional crystallization gave essentially pure material from low-melting crops; the best sample melted at 109.5–110.7°.

When only one equivalent of ethyl chlorocarbonate was used the yield was lower and there was difficulty in completely separating small amounts of the less-soluble starting material.

**4,4-bis-(Acetoxymethyl)-oxazolidone (V).**—A mixture of 29.4 g. of 4,4-bis-(hydroxymethyl)-oxazolidone (IV), 44.8 g. of acetic anhydride and 0.2 g. of sodium acetate was heated under reflux for five minutes, then concentrated to a sirup *in vacuo*. The mixture was seeded[10] and allowed to stand overnight, then ground under 50 cc. of ether. There was collected 39.4 g. (85.4%) of nearly colorless product melting at 57–68°. Three crystallizations from ethanol gave hard irregular plates melting at 69.0–70.4°.

*Anal.* Calcd. for $C_9H_{13}NO_6$: C, 46.75; H, 5.67. Found: C, 47.00; H, 5.66.

**3-Nitro-4,4-bis-(acetoxymethyl)-oxazolidone (VI).**—To a mixture of 16.6 g. of 98% nitric acid and 13.3 g. of acetic anhydride there was added during ten minutes, at 3–8°, 16.9 g. of 4,4-bis-(acetoxymethyl)-oxazolidone (V) as a sirup (crystalline material had not been obtained at that time). After stirring for two hours at 20–25° the homogeneous mixture was poured on 150 g. of cracked ice. The white precipitate, after collecting and drying, weighed 9.3 g., m. p. 89.4–90.8°. After three crystallizations from methanol there was obtained 7.11 g. of heavy elongated prisms melting at 97.1–97.8°.

*Anal.* Calcd. for $C_9H_{12}N_2O_8$: C, 39.14; H, 4.38. Found: C, 38.81; H, 4.63.

When V was nitrated with a mixed acid containing 5% excess sulfur trioxide the acetyls were nitrolyzed to some extent and the only product isolated was a slightly impure sample of **3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone,**[6] m. p. 120.6–123.2°. A pure sample, prepared as de-

(8) Piloty and Ruff, *Ber.*, **30**, 2066 (1897).

(9) Täuber, *Z. Krystallographie und Mineralogie*, **33**, 87.

(10) During early runs, persistent and varied efforts failed to induce crystallization of this substance; however, a sample which had stood for several weeks at room temperature was found crystalline.

scribed by Blomquist for comparison, melted at 124.3–124.9°. The mixed m. p. was 121–124°.

When 3-nitro-4,4-bis-(nitroxymethyl)-oxazolidone was hydrolyzed as described below in the preparation of tris-(hydroxymethyl)-methylnitramine, no product could be isolated from the reaction mixture.

**tris-(Hydroxymethyl)-methylnitramine (VII).**—A 4.42-g. sample of the nitro derivative, VI, was stirred mechanically with 116.5 cc. of 0.9844 *N* sodium hydroxide for two hours, mild cooling being used at first to prevent the temperature from rising above 35°. The solid dissolved after about one hour. The solution was treated with an amount of standard hydrochloric acid exactly equivalent to the sodium hydroxide used, then concentrated to dryness *in vacuo* (bath, 50–65°). The crystalline residue was extracted at about 50° with 125 cc. of butanol in three portions (extraction at 100° with nitromethane caused considerable decomposition). After filtration of salt the butanol solution was concentrated to dryness *in vacuo* (bath, 53–65°), leaving 2.84 g. of crude nitramine containing some salt, m. p. 114–117° (gas). One crystallization from nitromethane gave 2.04 g. (77%) of material melting at 123–125°. After two additional crystallizations from nitromethane very large striated blades and plates were obtained, m. p. 124–126° (gas), varying somewhat with rate of heating. The analytical sample, Code No. IV-20, was ground and dried *in vacuo* at 80°.

*Anal.* Calcd. for $C_4H_{10}N_2O_5$: C, 28.92: H, 6.07; mol. wt., 166.1. Found: C, 29.00; H, 6.26; mol. wt., 165.3 (by titration).

This nitramine is very soluble in water, moderately soluble in alcohol and essentially insoluble in acetone and ether. It shows no evidence of decomposition during crystallization.

When tris-(hydroxymethyl)-methylnitramine was nitrated at −5°, using a slight excess of 98% nitric acid in acetic anhydride, there was evolution of gas during the reaction, and the water-insoluble product which was obtained crystallized very slowly. Attempted recrystallization caused further decomposition, and no pure product could be obtained.

## Summary

There has been prepared tris-(hydroxymethyl)-methylnitramine and the isomeric, previously known tris - (hydroxymethyl) - methylnitrosohydroxylamine. The preparation of several related compounds from tris-(hydroxymethyl)-aminomethane is also described.

# The Ultraviolet Absorption Spectra of tris-(Hydroxymethyl)-methylnitrosohydroxylamine, tris-(Hydroxymethyl)-methylnitramine, and their Salts[1,2]

BY MARVIN CARMACK AND J. J. LEAVITT[3]

The synthesis by Cason and Prout[4] of tris-(hydroxymethyl)-methylnitrosohydroxylamine (I) and its isomer, tris-(hydroxymethyl)-methylnitramine (II), has afforded us the opportunity

I

II

to investigate the ultraviolet absorption spectra of the primary nitramine and the isonitramine (nitrosohydroxylamine) chromophores in the rare, if not unique, situation in which both isomeric compounds are of the aliphatic series and isolable as reasonably stable crystalline compounds. In many of the more readily prepared nitrosohydroxylamine compounds, the presence of aromatic groups complicates the interpretation of the ultraviolet absorption spectra.

As was hoped, ultraviolet spectrometry proved useful in studying the nature of the functional groups in certain nitramines or isonitramines of ambiguous structure which have been reported in the literature, as for example, "methylenebisisonitramine," prepared by the Traube reaction.[2,5,6]

Kortüm and Finckh[7] have published the ultraviolet absorption spectra of nitramide and methylnitramine in dilute hydrochloric acid and of dimethylnitramine in water. They also reported the spectra of hyponitrous acid in dilute hydrochloric acid, and of sodium hyponitrite, nitrohydroxylamine, and methylnitrosohydroxylamine in dilute sodium hydroxide. The alkylnitramines were measured only in neutral or acidic solution, while methylnitrosohydroxylamine was, unfortunately, measured only in alkaline solution; hence, the spectra of the two types of isomeric compounds are not directly comparable, and it is difficult from the data of Kortüm and Finckh to evaluate the suitability of spectrometry as a means of distinguishing one functional group from the other.

The spectrometric curves for tris-(hydroxyl-

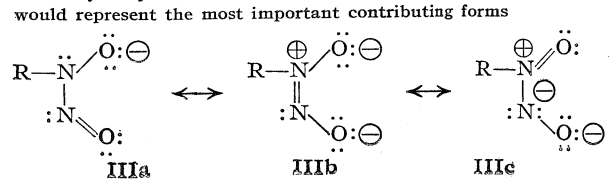
methyl)-methylnitrosohydroxylamine (I) in water and in 0.25 *N* sodium hydroxide solutions are shown in Fig. 1. Curves for tris-(hydroxymethyl)-methylnitramine (II) in water, in *N* sodium hydroxide, and in *N* hydrochloric acid are shown in Fig. 2. For comparison, curves for methylnitramine in *N* hydrochloric acid and for potassium methylnitramine in 0.5 *N* potassium hydroxide are shown in Fig. 3. Data on the extinction values at the absorption peaks are summarized in Table I.

TABLE I

ULTRAVIOLET ABSORPTION MAXIMA OF COMPOUNDS

| Compound and solvent | $\epsilon_{max.}$, mμ. | $\epsilon_{max.} \times 10^{-3}$ |
|---|---|---|
| tris-(Hydroxymethyl)-methylnitroso-hydroxylamine (I) | | |
| in water | 229 | 6.0 |
| in 0.25 *N* sodium hydroxide | 249 | 8.73 |
| tris-(Hydroxymethyl)-methyl-nitramine (II) | | |
| in water | 235 | 6.97 |
| in *N* sodium hydroxide | 236 | 8.07 |
| in *N* hydrochloric acid | 234 | 6.19 |
| Methylnitramine (potassium salt) | | |
| in *N* hydrochloric acid[8] | 230 | 7.01 |
| in *N* potassium hydroxide | 228.5 | 7.60 |



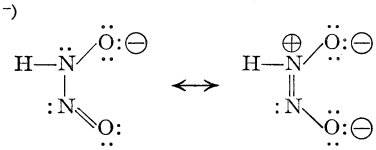
The spectra of the nitramines in water are very similar to the spectrum of tris-(hydroxymethyl)-methylnitrosohydroxylamine (I) in water. The differences in both the intensities and wave lengths of the absorption peaks are small and of the same order as those among homologous members of a series derived from one chromophore group.

A striking difference was observed between the nitramines and the isonitramine in alkaline solution. Upon the formation of the salt of the nitrosohydroxylamine (I) in alkali, it was noted that not only did the absorption peak increase in intensity, but the position of the maximum shifted 20 mμ toward the visible. In contrast, the nitramines showed only very slight shifts in the positions of their maxima although the extinction values at the maxima for the nitramines increased as the medium was varied from aqueous acid to water to dilute alkali.

The magnitude of the shift of the absorption peak for the isonitramine is sufficiently great to serve as a means of distinguishing the isonitramine (nitrosohydroxylamine) functional group from the nitramine.[9]

(8) Kortüm and Finckh (ref. 7) published a spectrum of methylnitramine in dilute hydrochloric acid, but the absorption maximum of their curve was apparently obtained by extrapolation.

(9) Kortüm and Finckh (ref. 7) proposed for the anion of methylnitrosohydroxylamine a resonating structure, of which IIIa and IIIb would represent the most important contributing forms

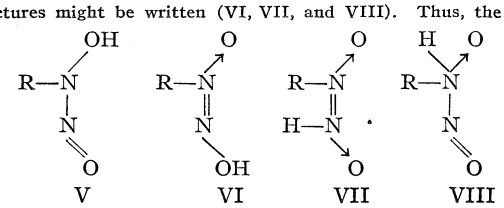


IIIa IIIb IIIc

## Experimental

**Materials.**—tris-(Hydroxymethyl)-methylnitrosohydroxylamine (I) was kindly supplied to us by Dr. James Cason[4] (his Sample No. NB-I-50B which had been recrystallized four times). When received in this Laboratory the sample had a well-defined crystalline appearance. The spectrum was determined immediately after receipt in order to minimize the possibility of deterioration upon storage. Solutions were freshly made up to appropriate concentrations immediately before being measured. Another sample of I (NB-I-51) gave similar results except that slightly lower extinction values were obtained at the maximum. tris-(Hydroxymethyl)-methylnitramine was also furnished to us by Dr. Cason (his Sample No. IV-20, m. p. 124–126°). The sample of potassium methylnitramine was provided through the courtesy of Dr. A. T. Blomquist, Cornell University.

**Ultraviolet Absorption Spectral Measurements.**—All spectrometric measurements were made on dilute aqueous solutions in 1-cm. quartz cells in the Beckman Quartz Spectrophotometer, Model DU.[10] Appropriate dilution, kept the readings within the range of 10–80% transmission. In the case of potassium methylnitramine, curves were determined in several concentrations of potassium hydroxide as well as in water alone. Although the curves were similar in appearance and location of the peak on the wave length scale, the value of $\epsilon_{max.}$ varied from 7.21 ×



These are analogous to the important resonance forms of the tautomeric structure favored by Kortüm and Finckh for the hyponitrite ion ($HN_2O_2^-$)

IVa IVb

They pointed out that the spectra of the hyponitrite ion and of methylnitrosohydroxylamine in alkaline solutions are very similar. It would be interesting to know whether hyponitrous acid and free methylnitrosohydroxylamine show similar spectra in neutral and acidic solutions and whether the magnitude of the shift on passing from neutral to basic medium is similar for hyponitrous acid and for the alkylnitrosohydroxylamines. Kortüm and Finckh did not extend their measurements of the solution of hyponitrous acid sufficiently far into the ultraviolet region to reach the absorption maximum, and they did not report the spectrum of the methylnitrosohydroxylamine in neutral or acidic solution.

For the free isonitramines, the general structural formula V is preferred because it does not involve a separation of charges; it is used to represent the crystalline compound prepared by Cason and Prout (I). It may be pointed out, however, that three other structures might be written (VI, VII, and VIII). Thus, the hydrogen atom could conceivably be attached to either of the oxygen atoms or either of the nitrogen atoms. Structure VII would be least probable, since it involves two positive charges on the adjacent nitrogen atoms. Kortüm and Finckh considered only the structure V. The possibility that a tautomeric equilibrium between two or more forms exists in solution must also be considered. In any case, only one resonating anion would be expected. The shift of the absorption peak upon formation of the salt from the isonitramine suggests that the distribution of electrical charges is different in the free parent isonitramine and in the salt anion.

V VI VII VIII

(10) We gratefully acknowledge the technical assistance of Mr. P. W. Wilcox and Mr. Joseph L. Ciminera of the Research Laboratory, Sharp and Dohme, Glenolden, Pennsylvania, in the determination of the absorption spectra.

Fig. 2.—Solid curve: tris-(hydroxymethyl)-methylnitramine in water; dash curve, same in *N* NaOH; dotted curve: same in *N* HCl.

Fig. 3.—Solid curve: methylnitramine in *N* HCl; dash curve, same in 0.5 *N* KOH.

$10^3$ in water to $7.60 \times 10^3$ in 0.5 *N* potassium hydroxide. No further increase of $\epsilon_{max.}$ was noted in *N* potassium hydroxide. The spectrum of free methylnitramine was obtained by dissolving potassium methylnitramine in a large excess of dilute hydrochloric acid.

## Summary

The ultraviolet absorption spectrum of tris-(hydroxymethyl) - methylnitrosohydroxylamine in neutral aqueous solution is similar in location and intensity to that of tris-(hydroxymethyl)-methylnitramine and methylnitramine in neutral, aqueous solution. In aqueous alkaline solution the absorption of the nitrosohydroxylamine is greatly intensified and the maximum shifts 20 mμ toward the visible region. The spectra of the alkylnitramines are intensified by conversion into the salts but the location of the maximum remains almost unchanged. This differing behavior in alkaline medium affords a means of distinguishing nitramines from isonitramines (nitrosohydroxylamines).

# The Separation of Choline Esterase, Mucoprotein, and Metal-Combining Protein into Subfractions of Human Plasma[1a,b,c]

BY D. M. SURGENOR, L. E. STRONG,[1d] H. L. TAYLOR,[1e] R. S. GORDON, JR., AND D. M. GIBSON[1f]

A system for the separation of the protein components of human plasma has been described in an earlier paper in this series.[2] The fractions so obtained contain groups of proteins of somewhat similar solubility characteristics, each of which is susceptible of further purification. Many of the components so isolated, either in

pure or concentrated form, have been found of physiological importance and some of them of clinical use. This was true of Fraction I which contains fibrinogen and the antihemophilic globulin[3]; of Fraction II which contains various antibodies, and of Fraction III which contains the isoagglutinins, prothrombin and the fibrinolytic enzyme precursor, plasminogen.[4]

Fraction IV, originally separated to render the albumin in Fraction V as pure as possible, has since been removed in two steps (2), Fraction IV-1 separated the $\alpha_1$-lipoprotein under conditions of lower ethanol concentration than were required to precipitate the whole Fraction IV. The remainder of this fraction, IV-4, contained those proteins soluble in 0.062 mole fraction (18 per cent.) ethanol[5] at *p*H 5.2 and $-5°$,—used for the precipitation of Fraction IV-1—and insoluble in 0.163 mole fraction (40%) ethanol at *p*H 5.8 at the same temperature. It comprised slightly more than 7% of the plasma proteins. In addition to a small amount of albumin which separated with this fraction, it was composed mainly of $\alpha_2$- and $\beta_1$-globulins. It has been routinely prepared free of pressor or depressor activity, and has been injected intravenously without untoward reactions.[6]

A number of labile components have also been recognized in Fraction IV-4. These include $\alpha_1$-lipoprotein, $\alpha_2$ carbohydrate-containing globulins, and hypertensinogen. It was early recognized that "precipitation of Fraction IV-4 by 0.163 mole fraction ethanol at *p*H 5.8 and $-5°$ led to the destruction of hypertensinogen and presumably of other labile components of the fraction without, however, destroying gross molecular structure."[7] Attempts to isolate certain of these components from Fraction IV-4 in their native states, particularly the various $\alpha$-globulins, have thus far met with only moderate success. The new method of fractionation now being developed should yield more satisfactory preparations of these and of other labile components of plasma.[8]

This communication is concerned with the separation of Fraction IV-4 of human plasma into subfractions in which have been concentrated certain of the more stable physiologically important components. These include plasma choline esterase and the $\beta_1$ metal-combining globulin.[9,10]

These subfractions have been used for certain clinical investigations,[11,12,13] and have been the starting materials for chemical studies, to be reported later, on the purification and crystallization of the metal-combining globulin[14] and on the further concentration and purification of plasma esterase.[15]

## II. Materials and Methods

Fraction IV-4 used in these studies came from three sources. The major part was from substandard or outdated dried plasma being fractionated in the interest of recovering albumin, $\gamma$-globulin, and other stable protein components of proven therapeutic or prophylactic value for distribution by the American Red Cross.[16] Some was prepared from fresh plasma at the Harvard Pilot Plant during the war. Finally, this fraction was made available from the fresh plasma fractionated at the Division of Biologic Laboratories, Massachusetts Department of Public Health, from blood collected by the American Red Cross.[17]

**Carbohydrate analyses** were performed by a modification by the method of Sørensen and Haugaard.[18] An equimolar mixture of galactose and mannose was used as the standard.[19] To 1 ml. of solution, containing 0.02 to 0.10 mg. of hexose, in a colorimeter cuvette, was added 5 ml. of 0.1% orcinol in 67 volume per cent. sulfuric acid. After heating for exactly ten minutes in an 80° bath, the tubes were chilled rapidly in an ice-bath. The solutions were kept in the dark and read within an hour against a protein-free blank in a Klett photoelectric colorimeter using Corning glass filters number 5031 and 3389 (420 to 580 m$\mu$). A series of standard tubes, containing varying amounts of the galactose–mannose standard, were always read at the same time as the unknowns.

**Hexoseamine** determinations were carried out by the method of Elson and Morgan,[20] as adapted by Rimington.[21] Glucoseamine was used as the standard.

**Metal-combining capacities** were measured by a modification of the method of Schade.[9,10] Determinations were carried out in *p*H 7.4 sodium diethyl barbiturate buffer of ionic strength 0.1, using a standard solution of ferrous ammonium sulfate (200 $\gamma$ Fe/ml.). The solutions were allowed to stand sixty minutes and their extinctions were read in the Beckman spectrophotometer against an iron-free blank at 460 m$\mu$.[22]

**Solubility studies** with plasma choline esterase were made with small sized aliquots of a standard solution of the enzyme, adjusted to the desired *p*H, ethanol concentration, and ionic strength; the total amount of protein in the system was the same throughout. After equilibration for twenty-four hours at the desired temperature, the precipitates were removed by centrifugation in a refrigerated angle centrifuge. The supernatant solutions were dried

from the frozen state to remove ethanol, and redissolved in water for analysis.[23]

Other methods and the equipment used in this Laboratory for the fractionation of proteins in ethanol–water mixtures of controlled *p*H, ionic strength, temperature, and protein concentration have been described elsewhere.[2]

We are glad to acknowledge the assistance of M. M. Hasson, B. J. Learned and W. O'Donnell during this investigation, as well as that of M. J. E. Budka for the electrophoretic analyses and C. G. Gordon and P. M. Baker, under the direction of J. L. Oncley, for the ultracentrifugal analyses.

## III. System of Fractionation

The conditions that have been found effective for the optimum separation of proteins from each other, in the five variable system here employed, have evolved slowly and are always subject to further modification. The lability of some of the components imposed limits on the conditions deemed acceptable. The precipitation of certain components in Fraction IV-4 rather than in Fraction IV-1 or V was considered evidence of protein–protein interactions. When purified, many of the proteins in Fraction IV-4 proved to be isoelectric and of low solubility near or below *p*H 5.0.

Electrophoretic analyses, assays for plasma esterase activity and metal-combining capacity were the principal analytical tools employed. Since a well-planned scheme of fractionation concentrates unknown, as well as known, components, it was hoped that an inclusive subfractionation of Fraction IV-4 would be obtained. This was indeed the case for several components for which no assay was carried out but which were later recognized in one or another subfraction. Because of the possible clinical utilization of some of these components, the number of subfractions was maintained as small as possible and those procedures were adopted which were suitable for large-scale processing.

**Fraction IV-5+6.**—When a solution of Fraction IV-4 was dialyzed against a buffer of low ionic strength, or diluted to 1% protein concentration (ionic strength 0.005) at 0°, a euglobulin precipitated. The minimum solubility of this precipitate, largely $\alpha_1$-lipoprotein, was near *p*H 5.0. This precipitate contained 85 to 90% of the lipid, measured as cholesterol, in Fraction IV-4. The supernatant solution contained albumin, $\alpha_2$- and $\beta_1$-globulins; all of the esterase and metal-combining activity.

Although all of the esterase could be precipitated from this solution at *p*H 5.2 by adding ethanol to a concentration of 0.062 mole fraction (18%), a large amount of albumin and $\beta_1$-globulin were precipitated as well. An attempt was therefore made to find conditions under which the albumin and $\beta_1$-globulin remained soluble while the esterase remained insoluble. On increasing the ionic strength at 0.062 mole fraction ethanol, the solubility of the impurities increased more rapidly than did the esterase. Moreover, on lowering the *p*H to 4.7, the impurities became more soluble. At a *p*H near *p*H 4.4, the esterase as well as the other proteins dissolved. This behavior was reminiscent of the principle[24] that acid to the isoelectric points of the proteins in a fraction, the tendency to interaction diminished and more satisfactory separations were achieved. Thus, at *p*H 4.7, ionic strength 0.02 and 0.062 mole fraction (18%) ethanol at −5°, the esterase was precipitated with a minimum of impurities.

Since the subsequent separation of the esterase involves many additional steps, considerable advantage was gained by proceeding directly to the conditions just described, for the precipitation of the esterase. A large subfraction, Fraction IV-5+6, was obtained, which contained the same components that were found in the earlier two subfractions. This reduced the number of steps and removed the limitation on protein concentration imposed by the low ionic strength necessary to precipitate the $\alpha_1$-lipoprotein, thus making it possible to use increased protein concentrations throughout.

**Fraction IV-5.**—In the subfractionation of Fraction IV-5+6 the lipoprotein was separated into Fraction IV-5 by employing the conditions previously found to precipitate this component: *p*H 4.9, and ionic strength 0.002 at 0°. The low ionic strength was attained at a protein concentration of 2.5%, instead of the 1% protein previously employed. The further treatment of Fraction IV-5+6 was intended to separate the plasma esterase, as well as to recover the serum albumins and $\beta_1$ metal-combining globulin in this fraction.

**Fraction IV-6.**—The solution from which Fraction IV-5 was separated was essentially free of lipid, measured as cholesterol. Solubility experiments on the protein remaining in the supernatant showed that the choline esterase had a minimum solubility near *p*H 4.9 (Fig. 1). At this *p*H, in 0.062 mole fraction (18%) ethanol, the solubility of the enzyme increased almost a thousand fold on increasing the ionic strength from 0.02 to 0.10. On lowering the *p*H, the inactive protein dissolved more readily than the esterase. At *p*H 4.4, ionic strength 0.02 and 0.062 mole fraction ethanol, all of the esterase was precipitated into Fraction IV-6 while a considerable fraction of the protein remained soluble.

**Fraction IV-7.**—The solution from which Fraction IV-5+6 separated consisted mainly of albumin and $\beta_1$-globulin. All of the protein in solution could be precipitated, without changing the *p*H or ionic strength, by raising the ethanol concentration to 0.163 mole fraction (40%). However, the $\beta_1$ metal-combining globulin could be precipitated in a smaller fraction (IV-7)

(23) We are indebted to Dr. Ralph W. Brauer, and, more recently, to Dr. Avram Goldstein for the plasma esterase assays which they kindly carried out in the Department of Pharmacology, Harvard Medical School.

(24) A. A. Green, THIS JOURNAL, **60**, 1108 (1938).

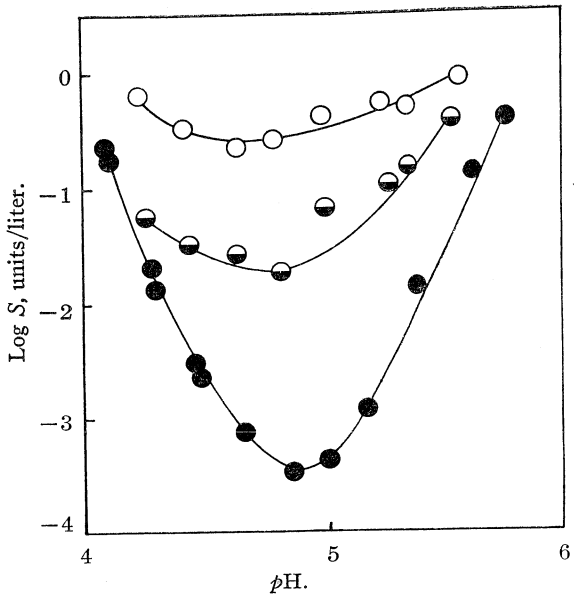

Fig. 1.—Solubility of plasma choline esterase in Fraction IV−5+6 in 0.062 mole fraction ethanol at −5°: ○, Γ/2 = 0.10; ◒, Γ/2 = 0.05; ●, Γ/2 = 0.02 [*cf.* footnote (a) of Table IV for definition of unit of enzyme activity].

formed at *p*H 5.9, ionic strength 0.09 and 0.163 mole fraction ethanol.

**Fraction IV-8.**—The albumin remaining in solution after removal of Fraction IV-7, could be precipitated, as Fraction IV-8, by lowering the *p*H to 4.9. This fraction contained only small amounts of globulins.

**Fraction IV-9.**—The solution, after the precipitation of Fraction IV-8, was essentially free of protein. That remaining in solution after precipitation of Fraction IV-6, was mainly albumin and $\beta_1$-globulin. These were precipitated together, as Fraction IV-9, by adjusting the *p*H to 5.2 and increasing the ethanol concentration to 0.091 mole fraction (25%) ethanol.

The detailed procedures for carrying out the separation of Fractions IV-5, IV-6, IV-7, IV-8 and IV-9 from Fraction IV-4 are given below. These have been tentatively recommended to the American Red Cross to make these fractions available for clinical studies.

### Subfractionation of Fraction IV-4

Fraction IV-4 separated from human plasma by method (6)[25] is the starting material for this preparation.[26] Each kg. of paste is suspended in 8.5 liters of water and ice. The resulting suspension is adjusted to *p*H 4.7, ionic strength 0.02 and 18% ethanol. This requires, for each liter of suspension, 26 millimoles of sodium acetate buffer diluted to 167 ml. with water, and 500 ml. of 53.3% ethanol. The buffer consists of the amount of *p*H 4 acetate buffer necessary to adjust the *p*H, together with sufficient *p*H 4.7 acetate buffer[27] so that the total amount of sodium acetate in the two buffers is 26 millimoles. The diluted buffers and then the ethanol should be added, with vigorous stirring, through capillary jets. The rate of addition should be 80–100 ml. per jet per minute.[28] During the addition of the ethanol the suspension should be kept at the freezing point until a temperature of −5° is reached, and then maintained at −5° throughout the remainder of the addition.

**Precipitate IV-5+6** is removed by centrifugation at −5°. The fraction may be further separated as described below, or dried from the frozen state. The latter is conveniently done after resuspending the paste in 2 or 3 volumes of water and ice.

The supernatant solution is brought to *p*H 5.9–6.0, ionic strength 0.09 and 40 per cent. ethanol. The *p*H is adjusted with sodium bicarbonate[29] and sodium chloride is added to make a total of 114 millimoles of sodium bicarbonate and sodium chloride for each liter of supernatant. The combined salts are added in 50 ml. of water, after which 437 ml. of 95% ethanol is introduced. The reagents are added through capillary jets, as before, but the rate of addition of the ethanol should be somewhat slower, *i. e.*, 40–50 ml. per jet per minute. The temperature is maintained at −5° throughout the addition.[30]

**Precipitate IV-7** is a concentrated source of the metal-combining globulin. The fraction is removed by centrifugation at −5°. It should be dissolved in 3 volumes of water and ice, and dried from the frozen state.

The albumin remaining in solution is precipitated by adjusting the *p*H to 4.9 with *p*H 4 sodium acetate buffer. The buffer should be adjusted with 95% ethanol so that it has an ethanol concentration of 40%. It should be added through capillary jets at the rate of 50 ml. per jet per minute, keeping the temperature constant at −5° and the ethanol concentration at 40%.

**Precipitate IV-8** is obtained by centrifuging at −5°. The paste should be redissolved in 3 volumes of ice and water, adjusted to *p*H 6.0–6.5, and dried from the frozen state. The supernatant solution may be discarded.

### Subfractionation of Fraction IV-5+6

The IV-5+6 paste[26] is resuspended in 9 volumes of ice and water.[31] This gives a protein concentration of 2.5 per cent., ionic strength 0.002 and 1% ethanol. The *p*H is adjusted with sodium bicarbonate to 4.9 and the suspension should be stirred at least two hours at 0°.

**Precipitate IV-5** is removed by centrifugation at 0° at a sufficiently slow rate to give a clear supernatant solution.[32] This fraction is largely $\alpha_1$-lipoprotein; when derived from dried plasma or dried fractions thereof, it is largely denatured. It may be resuspended in water and dried from the frozen state.

The solution is next brought to 18% ethanol, *p*H 4.4 and ionic strength 0.02. This requires 29 millimoles of ace-

(25) Ref. 2, p. 470.

(26) Storage at −5° of plasma esterase fractions in paste (containing ethanol) will generally result in loss of esterase activity in approximately a month. No appreciable loss of activity has been detected on storage of the dry powder. It is therefore advisable to use the wet paste immediately, or, if this is not possible, to dry the fraction from the frozen state and store the powder in the cold.

(27) W. C. Boyd, THIS JOURNAL, **67**, 1035 (1945).

(28) If dried Fraction IV-4 is used as the starting material, these same conditions will be attained by suspending each 300 g. of powder in 8.7 liters of water. Each liter will require 26 millimoles of the required buffers, diluted to 110 ml. with water, and 556 ml. of 53.3% ethanol.

(29) This is a difficult *p*H adjustment because of the solubility of carbon dioxide in the solution. Thorough equilibration is necessary. The *p*H should be determined with a sample which has been diluted with 3 volumes of 0.02 *M* NaCl without shaking or aerating the solution.

(30) Starting with 2 kg. of IV-4 paste, which is approximately the amount derived from 100 liters of plasma, the volume at this point in the procedure will be 40 liters.

(31) If dry powder is used, each 250 g. should be suspended in 10 liters of water at 0°. It is unnecessary to adjust the ethanol concentration.

(32) In certain cases, for example, in the preparation of the $\alpha_2$-mucoprotein, it is of advantage to clarify this solution. This can be done by suspending 0.25% of washed standard super-cel and filtering at 0° through Hormann type D-7 pads.

tate buffers, diluted to 50 ml., and 500 ml. of 53.3% ethanol for each liter of solution.[33] The buffers include the amount of *p*H 4 acetate buffer needed to lower the *p*H to 4.4 and enough *p*H 4.4 acetate buffer so that the total amount of sodium acetate in the two buffers is 29 millimoles. The diluted buffers and then the ethanol should be added through capillary jets at the rate of 80–100 ml. per jet per minute. During the addition of the ethanol the temperature should be kept at the freezing point until −5° is reached, and maintained at −5° thereafter. The suspension should be stirred at least two hours, and then centrifuged as soon as possible.[34]

**Precipitate IV-6** may be further subfractionated immediately, or resuspended in 2 volumes of ice and water, adjusted to *p*H 5 with sodium bicarbonate, and dried from the frozen state.

Finally, the supernatant solution is adjusted to *p*H 5.2 and 25% ethanol. This requires, for each liter, the necessary amount of sodium bicarbonate, diluted to 25 ml. with water, and 106 ml. of 95% ethanol. The bicarbonate and ethanol should be added through capillary jets as before, maintaining the temperature at −5° throughout.

**Precipitate IV-9** may be redissolved in 3 volumes of ice and water, and dried from the frozen state.

## IV. Distribution and Properties of Protein Components in Fraction IV-4 and its Subfractions

As in previous studies,[2,4] we have made use of chemical and physical measurements at our disposal to characterize the various components. The distribution of nitrogen and the actual yields of total protein have been determined by direct analysis of the separated subfractions and are given in Table I.

TABLE I

ESTIMATED DISTRIBUTION OF NITROGEN AND PROTEIN INTO SUBFRACTIONS OF FRACTION IV-4

| Fraction | Total nitrogen[a] | Per cent. of total protein | $\left(\frac{\text{g. protein}}{\text{g. nitrogen}}\right)$ |
|---|---|---|---|
| IV-4 | 100 | 100 | 7.1[b] |
| IV-5+6 | 59.8 | 61.8 | 7.3 |
| IV-7 | 14.8 | 13.8 | 6.6[c] |
| IV-8 | 14.0 | 12.4 | 6.3 |
| Supernatant soln. | 4.2 | 3.8 | 6.4 |
| Total | 92.8 | 91.8 | |

[a] Based on averages from direct analysis of precipitates in two runs. [b] From ref. 2, Table VII, p. 473 [c] Measurement made by J. L. Oncley, G. Scatchard and A. Brown, *J. Phys. and Coll. Chem.*, **51**, 184(1947).

From these data, and the results of the electrophoretic analyses,[35] the yields of the electrophoretic components in the subfractions have been calculated. The yields are presented in Tables II and III. The limitations in the quantitative interpretation of electrophoretic Schlieren diagrams, discussed in a previous paper in this series,[36] were quite apparent, especially in the determination of $\alpha$-globulins. Indeed, we have found the electrophoretic technique of but limited use in characterizing fractions containing high percentages of $\alpha_2$-globulins. The protein components of interest have been most readily followed during subfractionations by means of assays for lipid, carbohydrate, plasma esterase and iron-binding capacity. Results of certain experiments suggesting the distribution of lipoprotein, carbohydrate-rich proteins, plasma esterase and metal-combining globulin are reported in Table IV.

(33) If dry Fraction IV-5+6 were used, each liter of solution requires 535 ml. of 53.3% ethanol.

(34) Although serum esterase has proved to be among the more stable of the plasma proteins at acid *p*H, it is advisible to expose solutions of the enzyme to acid conditions for as short a time as possibe.

(35) Electrophoretic analyses have not been corrected for refractive index increments.

(36) S. H. Armstrong, Jr., M. J. E. Budka and K. C. Morrison, THIS JOURNAL, **69**, 416 (1947).

TABLE II

ESTIMATED DISTRIBUTION OF PROTEINS INTO SUBFRACTIONS OF FRACTION IV-4[a]

| Fraction | Albumin | $\alpha_1$ | $\alpha_2$ | $\beta_1$ | $\beta_2$ | Total |
|---|---|---|---|---|---|---|
| | Per cent. of subfraction | | | | | |
| IV-4[b] | 30 | 17 | 24 | 28 | 1 | 100 |
| IV-5+6 | 15 | 17 | 44 | 23 | 1 | 100 |
| IV-7 | 13 | 1 | 7 | 76 | 3 | 100 |
| IV-8 | 91 | 3 | 3 | 3 | | 100 |
| | Grams per liter of plasma recovered in subfractions | | | | | |
| IV-4[b] | 1.5 | 0.9 | 1.1 | 1.6 | 0.1 | 5.2 |
| IV-5+6 | 0.5 | 0.5 | 1.4 | 0.7 | 0.1 | 3.2 |
| IV-7 | 0.1 | <0.1 | <0.1 | 0.6 | <0.1 | 0.7 |
| IV-8 | 0.7 | <0.1 | <0.1 | <0.1 | 0 | 0.7 |
| Total | 1.3 | 0.5 | 1.4 | 1.3 | 0.1 | 4.6 |

[a] The strong interactions of the $\alpha$-globulins resulted in low apparent values for $\alpha_1$-globulins and correspondingly high apparent values for $\alpha_2$-globulins as determined from the Schlieren diagrams. [b] These values were obtained from three preparations of Fraction IV-4 used in this work, and have been used rather than the previously published values for Fraction IV-4 (ref. 2, Table IX, p. 479) in preparing this table, since the fraction obtained from outdated dried plasma or from fresh plasma in which acid citrate dextrose, "ACD," was used as the diluent, usually contained more albumin, and was therefore correspondingly larger in size, than Fraction IV-4 from fresh citrated plasma.

TABLE III

ESTIMATED DISTRIBUTION PROTEINS INTO SUBFRACTIONS OF FRACTION IV-5+6

| Fraction | Albumin | $\alpha_1$ | $\alpha_2$ | $\beta_1$ | $\beta_2$ | Total |
|---|---|---|---|---|---|---|
| IV-5+6 | 15 | 17 | 44 | 23 | 1 | 100 |
| IV-5 | 8 | 73 | 14 | 4 | 1 | 100 |
| IV-6 | 6 | 11 | 77 | 6 | | 100 |
| IV-9 | 30 | 0 | 28 | 41 | 1 | 100 |
| | Grams per liter of plasma recovered in subfractions | | | | | |
| IV-5+6 | 0.5 | 0.5 | 1.4 | 0.7 | 0.1 | 3.2 |
| IV-5 | <0.1 | 0.5 | 0.1 | <0.1 | <0.1 | 0.6 |
| IV-6 | 0.1 | 0.1 | 0.8 | <0.1 | 0 | 1.0 |
| IV-9 | 0.3 | 0 | 0.3 | 0.5 | <0.1 | 1.1 |
| Total | 0.4 | 0.6 | 1.2 | 0.5 | <0.1 | 2.7 |

**Fraction IV-5.**—The $\alpha_1$-lipoprotein separated in this fraction was largely denatured. Cholesterol determinations and qualitative observations, however, led to the conclusion that this component was probably identical with the $\alpha_1$-lipoprotein which separated into Fraction IV-1.

**Fraction IV-6.**—This complex fraction contained at least two carbohydrate-rich $\alpha_2$-globulins,

TABLE IV

ESTIMATED DISTRIBUTION OF CARBOHYDRATE, CHOLESTEROL, IRON-BINDING CAPACITY AND PLASMA CHOLINE ESTERASE IN SUBFRACTIONS

| Fraction | Carbohydrate, % | Cholesterol, % | Units plasma[a] esterase/g. | Iron-binding capacity, mg. Fe/g. |
|---|---|---|---|---|
| Plasma | (1.16)[b] | 2.3[b] | 1.5-2.0 | 0.04[c] |
| IV-4 | 2.9[b,d] | 1.7[b] | 20 | .30 |
| IV-5+6 | 3.1 | 2.1 | 32[e] | .24 |
| IV-5 | | 5.3 | | |
| IV-6 | 3.8 | | 45 | |
| IV-7 | 2.3 | <0.1 | <1 | .85 |
| IV-8 | 0.4 | <0.1 | 0 | .05 |
| IV-9 | 1.7 | | 1 | .44 |

[a] Assays for esterase activity were made on appropriate dilutions of the enzyme, by measuring in the Warburg apparatus, at 37°, the release of carbon dioxide from a solution of sodium bicarbonate buffered at *p*H 7.4 with carbon dioxide. Acetylcholine, 0.0805 molar, was used as the substrate. We have used the unit of esterase activity as that amount of enzyme which would split 1 millimole of acetylcholine per hour under the above conditions. [b] Values taken from Table VIII, ref. 2, p. 474. [c] Based on estimates of the amount of metal-combining protein in plasma. This agrees quite well with the value obtained by direct analysis of plasma. [d] Higher values have been obtained using the carbazole reaction, by F. B. Seibert, M. L. Pfaff and M. V. Seibert, *Arch. Biochem.*, **18**, 279 (1948). [e] Plasma esterase represents only a minor part of the protein in this fraction, and its properties cannot therefore be deduced from the properties of this fraction.

in addition to plasma choline esterase. From the results of studies now in progress[15] which indicate that the pure enzyme may have an activity of at least 15,000 times its activity in plasma, it has been estimated that less than 1 per cent. of the protein in the fraction was esterase.

**Fraction IV-7.**—The main component of this fraction was the metal-combining globulin, so designated because of certain *in vitro* evidence that it is capable of binding other metals as well as iron.[10,14,37] Subsequent purification and crystallization of this component[14] has proved that the $\beta_1$-globulin which separated with Fraction IV-4, and was further concentrated in Fraction IV-7, is indeed the component responsible for the iron-binding capacity of the serum.[9]

Of the impurities in Fraction IV-7, the $\alpha_2$-globulin, although rich in carbohydrate, has been distinguished from the $\alpha_2$-globulins of Fraction IV-6 by its ability to bind bilirubin. This property was not shared by the $\alpha_2$-globulins of Fraction IV-6.[38]

Fraction IV-7, rather than the crystallized $\beta_1$ metal-combining globulin obtained therefrom, has been recommended to the American Red Cross as the most convenient source of metal-combining globulin for clinical investigation.[10,12,13]

(37) This component has been called "siderophyllin" by Schade [A. L. Schade, R. W. Reinhart and H. Levy, *Arch. Biochem.*, **20**, 170 (1949)] and "transferrin" by Holmberg and Laurell (C. G. Holmberg and C.-B. Laurell, *Acta Chem. Scand.*, **I**, 944 (1947)).

(38) N. H. Martin, THIS JOURNAL, **71**, 1230 (1949).

**Fraction IV-8.**—Recovery of the albumins in Fraction IV-4 and their addition to those in Fraction V[2] represents an additional yield of 2%. The albumins in Fraction IV-8 were similar in ultracentrifugal behavior and in ability to bind hematin,[39] to the albumins separated into Fraction V. No differences between them have yet been observed.

## V. Studies with the $\alpha_2$-Mucoprotein

Protein-bound carbohydrate is distributed rather generally throughout the globulins in the plasma. Of the various components isolated from plasma, only the crystallized serum albumin was free of carbohydrate.[40] The highest concentration of bound carbohydrate was found in Fraction IV-4.[41]

The carbohydrate-rich proteins fall into two classes, the mucoproteins and the glycoproteins.[42] Examples of these are the mucoprotein fraction from guinea pig serum, associated with one of the components of complement,[43] and the glycoprotein from horse serum, associated with albumin.[44] Mucoproteins have been characterized by euglobulin properties, high viscosity in solution, and a tacky behavior when precipitated. Glycoproteins have often appeared to be pseudoglobulins, resembling the albumins in their solubility properties.

In the course of the studies with Fraction IV-4 we have recognized members of both classes of carbohydrate-rich proteins. These were largely separated, with the $\alpha_2$-globulins, into Fraction IV-6 by the procedures just described. The results of some studies with an $\alpha_2$-mucoprotein are outlined here; studies on the glycoproteins will be the subject of a later communication.

The mucoprotein has proved to be extremely labile under conditions of acid *p*H. Preparations derived from Fraction IV-6, which was precipitated at *p*H 4.4, were usually partially denatured, as evidenced by a large amount of fast-sedimenting, inhomogeneous material in the ultracentrifuge.[45] It therefore seemed necessary to prepare mucoprotein by means of separations which did not involve the use of acidities below *p*H 5. In this

(39) M. Rosenfeld, in preparation.

(40) E. J. Cohn, W. L. Hughes, Jr., and J. H. Weare, THIS JOURNAL, **69**, 1753 (1947).

(41) Ref. 2, Table VIII.

(42) The nature of the carbohydrate moiety has received considerable attention and the carbohydrate content has been the principal means of characterization. The presence of glucoseamine was early demonstrated by H. W. Bywaters [*Biochem. Z.*, **15**, 322 (1909)]. The evidence indicates a polysaccharide of the composition glucoseamine:mannose:galactose [C. Rimington, *Biochem. J.*, **34**, 931 (1940)]; ref. 19.

(43) L. Pillemer, E. E. Ecker, J. L. Oncley and E. J. Cohn, *J. Exp. Med.*, **74**, 297 (1941).

(44) T. L. McMeekin, THIS JOURNAL, **62**, 3393 (1940).

(45) It is difficult to decide, on the basis of ultracentrifugal behavior, whether a part of this denatured material was already present in the starting material because of the small amount that would have been present in Fraction IV-4.

way, it was hoped to obtain the native protein, although in lower yield and of less purity. Considerable difficulty was encountered in freeing the preparations of the euglobulin lipoprotein, as well as of the last traces of metal-combining globulin, which seemed to interact strongly with the mucoprotein.

## Experimental

Purified $\alpha_2$-mucoprotein was prepared by a series of separations involving varying conditions of *p*H, ionic strength, ethanol concentration, protein concentration and temperature. (1) Fraction IV-4 was resuspended and adjusted to *p*H 5.2, ionic strength 0.02, 18% ethanol, 2% protein and −5°. (2) The precipitate, which contained all the $\alpha_1$-lipoprotein, $\alpha_2$-globulins, together with some albumin and $\beta_1$ metal-combining globulin, was brought to *p*H 5.0, ionic strength 0.001, 1.5% protein and 0°. The euglobulin precipitate, largely lipoprotein, was discarded. (3) Crude mucoprotein was precipitated by adjusting the solution to *p*H 5.1, ionic strength 0.005, 10% ethanol and −3°. The esterase and more soluble $\alpha_2$-glycoproteins remained in solution under these conditions. (4) $\beta_1$ Metal-combining globulin was removed from the crude mucoprotein precipitate by resuspending and adjusting the conditions to *p*H 6.1, ionic strength 0.02, 19% ethanol, 1.2% protein and −5°. The mucoprotein, which remained soluble under these conditions, was reprecipitated (5) by returning to the first set of conditions: *p*H 5.2, ionic strength 0.02, 17% ethanol and −5°. The precipitate contained 6% of the protein from Fraction IV-4.

Further purification was effected (6) by reprecipitation of the mucoprotein at *p*H 5.1, ionic strength 0.003, 10% ethanol, 0.3% protein and −3°. (7) The precipitate was redissolved in water at a protein concentration of 0.5% and filtered through a Seitz type S-3 pad under pressure to remove the slight turbidity due to some residual lipoprotein in the preparation. The product was 82 per cent. $\alpha_2$-globulin by electrophoresis, the impurities being albumin (6%) $\alpha_1$-globulin (8%), and $\beta_1$-globulin (4%).

In the ultracentrifuge three poorly resolved components were observed: (a) about 10% sedimenting much like albumin and $\beta_1$ metal-combining globulin ($s$ = 4.5 to 5.5), (b) 15 to 25%, quite heterogeneous, sedimenting rapidly ($s$ = 12 to 20), and (c) the third and principal component (65 to 75 per cent.) sedimenting with $s$ = 6 to 9, depending on the protein concentration. The extrapolated value at infinite dilution was near $s$ = 11. This behavior is somewhat like that to be expected of a highly asymmetrical molecule, but more homogeneous preparations must be studied before this can be definitely proved.

The results of dry weight, nitrogen, and carbohydrate determinations are summarized in Table V. The hexose–hexoseamine ratio was close

TABLE V

PROPERTIES OF PURIFIED MUCOPROTEIN

| | |
|---|---|
| g. protein/g. nitrogen | 6.90 |
| g. hexose/g. protein | 0.0435 |
| g. hexoseamine/g. protein | 0.0284 |
| Hexose/hexoseamine | 1.53 |

to 3 to 2, instead of 2 to 1.[40] This may be due to the fact that our preparation was not pure.

The protein could be dried from the frozen state; it was insoluble in water and soluble in dilute sodium chloride, acetate, or bicarbonate. On boiling solutions up to 2% in concentration for four hours, there was no visible change. The protein was precipitated, however, with 7% trichloroacetic acid.

The mucoprotein had a marked accelerating effect on the sedimentation rate of erythrocytes which was accompanied by rouleau formation. Added to whole blood in concentrations of 0.5 g. per 100 ml., the mucoprotein increased the rate 2.5-fold over the control. Fibrinogen, which is the principal component affecting erythrocyte sedimentation rates,[46] produced a 5-fold acceleration in the same concentration. Other fractions tested, including Fraction IV-4, had no effect, or diminished the rate.

## Summary

Under controlled conditions of *p*H, temperature, ethanol, salt and protein concentrations, Fraction IV-4 of human plasma has been separated into a series of subfractions into which were concentrated plasma choline esterase, carbohydrate-rich $\alpha_2$-globulins, both glycoprotein and mucoprotein, the $\beta_1$-metal-combining globulin and albumins. These subfraction are of use in chemical physiological and clinical studies and as intermediates in the purification and crystallization of the various protein components.

# Preparation and Properties of Serum and Plasma Proteins. XXI. Interactions with Bilirubin[1,2]

BY NICHOLAS H. MARTIN[3]

Many of the small molecules circulating in the blood are "bound" to one or another of the protein components of the plasma. Among these is bilirubin, one of the intermediates of porphyrin metabolism. Bennhold,[4] using the electrophoretic techniques available to him in 1932, demonstrated that, in icteric serum, bilirubin migrated with the albumin fraction. Pedersen and Waldenström[5] made similar observations in the course of ultracentrifugal studies. Since then it has been assumed that the "bound" bilirubin in the blood serum was attached to the circulating albumins.[6]

In recent years a number of components of human plasma have been isolated in highly purified form. These include crystallized human serum albumins, a crystallized $\beta_1$ metal-combining globulin and electrophoretically pure $\gamma$-globulins. In addition, a number of $\alpha$-globulins and of other $\beta$-globulins have been concentrated in various fractions.[7] This investigation was undertaken to study the interactions of bilirubin with these proteins.

## Materials[8]

**Human Serum Albumin.**—Three different preparations were used. The first had been recrystallized five times from ethanol–water mixtures containing chloroform.[9] Another preparation had been recrystallized as a mercury compound.[10] The third preparation was made from crystallized serum albumin by guanidination of the free amino groups by reaction with methyl isourea, according to a modification of the method of Greenstein.[11] The modified, or guanidinated, preparation had approximately fifty-four of its amino groups replaced with guanidine groups.[12]

**Bovine serum albumin** was Armour's crystallized preparation.

**$\alpha_1$-Globulin.**—This globulin was concentrated from Fraction V-1 of human plasma. It was the component responsible for the indirect van den Bergh reaction[13] and, as isolated, already contained stably-bound bilirubin.[14]

**$\alpha_2$-Globulins.**—The first preparation was isolated from Fraction IV-6[15] and was 97% $\alpha_2$-globulin by electrophoresis. It contained approximately 6% carbohydrate. A second preparation was isolated from Fraction IV-7 and was 74% $\alpha_2$-globulin by electrophoresis. It was estimated to contain 3% carbohydrate.[16]

**$\beta_1$ Metal-Binding Globulin.**—This protein was purified from fraction IV-7 and crystallized from ethanol–water mixtures.[16]

**$\gamma$-Globulin** was 98% pure by electrophoresis.[17]

**Bilirubin** (Armour Laboratories) was isolated from ox bile. In chloroform, ethylene dichloride and acetone it had a well-defined absorption maximum at 450 m$\mu$ with a molecular extinction coefficient of 55,300. This is in good agreement with the value of 54,900 given by Heilmeyer.[18]

## Methods

Dissolved in 0.01 *N* sodium hydroxide at room temperature, the bilirubin had an ill-defined absorption maximum lying between 425 and 440 m$\mu$ whose height tended to decrease rapidly on standing. Preservation at 0° in the absence of light delayed but did not inhibit degradation. Advantage was taken of the ability of ascorbic acid to stabilize solutions of bilirubin.[19] Solutions were prepared by dissolving weighed amounts of bilirubin in 0.01 *N* sodium hydroxide at 0°, and immediately adding phosphate buffer containing sufficient ascorbate so that the final ratio of ascorbate to bilirubin was twenty to one. The extinction of solutions prepared in this manner decreased about 10% in forty-eight hours while the peak remained reasonably well defined at 430 to 435 m$\mu$ (Fig. 1). That ascorbic acid did not interfere with the interactions being studied was indicated by the fact that, within the experimental error, no difference was observed in the amount of bilirubin interacting with albumin in the presence or absence of ascorbate. Furthermore, in weight concentrations of ascorbate of from 5 to 30-fold the bilirubin concentration appeared to have no apparent effect on the extent of the interaction.

**Electrophoretic measurements** were carried out in the apparatus of Tiselius,[20] using the 11-cm. analytical cell. The electrophoretic migration of the protein solutions containing bilirubin was studied and in those fractions which were not homogeneous it was possible to observe with which component or components the bilirubin traveled, thus obtaining confirmatory evidence of the interaction observed by other techniques.

**Dialysis experiments** were carried out in two chambered systems across cellophane membranes. The solutions were kept at 0° in the absence of light and oxygen. Equilibration was aided by repeated inversion of the tubes. The outer chamber contained bilirubin dissolved in aqueous buffer, stabilized with ascorbate, as described, and in contact with solid bilirubin. The inner chamber contained albumin dissolved in the same buffer. A control experiment in which the inner chamber contained the buffer without protein, was run simultaneously. It was thus possible to compensate for losses of bilirubin due to its instability, as well as for losses in handling. Equilibrium was considered to be attained when the concentrations of bilirubin inside and outside the membranes were the same in the control experiment. Because of the instability of the bilirubin the experiments were not run longer than forty-eight hours. Attempts to avoid dialysis were unsuccessful due to difficulties in determining free and bound bilirubin directly.

***p*H measurements** were made with a glass electrode.

**Absorption spectra** were measured with a Beckman spectrophotometer using quartz cells.

## Results

### 1. Studies on the Interaction of Bilirubin with Serum Albumin

**a. Spectrophotometry.**—Within the range of concentration used in this work, bilirubin, either alone or in the presence of protein, was found to obey Beer's law. In aqueous phosphate buffer the molecular extinction coefficient at 435 to 440 mμ was 46,700, taking 584 as the molecular weight of bilirubin, and was independent of *p*H between *p*H 7.0 and *p*H 8.5. In the presence of crystallized human or bovine serum albumin the absorption maximum was displaced to 460 mμ (Fig. 1), while the extinction coefficient remained the same. The wave length of the maximum, and the extinction coefficient of bilirubin in the presence of albumin, were also independent of *p*H between *p*H 7.0 and 8.5. The characteristic shift in the absorption maximum of bilirubin, resulting from the addition of albumin, was taken as evidence of interaction. No such shift occurred when the albumin was replaced by γ-globulin.

**b. Electrophoresis.**—Further evidence of interaction was obtained when a solution of albumin to which bilirubin had been added was analyzed in the electrophoresis apparatus of Tiselius. The pigment was found to migrate in sharp coincidence with and at the same mobility as the albumin peak. In the presence of γ-globulin, no such clearly defined pigment boundary was observed. Attempts to follow the migration of the bilirubin in the absence of protein were unsuccessful.

**c. Dialysis Experiments.**—The results of dialysis studies with crystallized human serum albumin are summarized in Table I. Under these experimental conditions, and within the limits of *p*H and concentrations studied, it was found that between 2 and 3 moles of bilirubin interacted with each mole of albumin. Human serum albumin crystallized as the mercury compound behaved in the same manner. However, the guanidinated albumin was found to bind only approximately half a mole of bilirubin per mole.

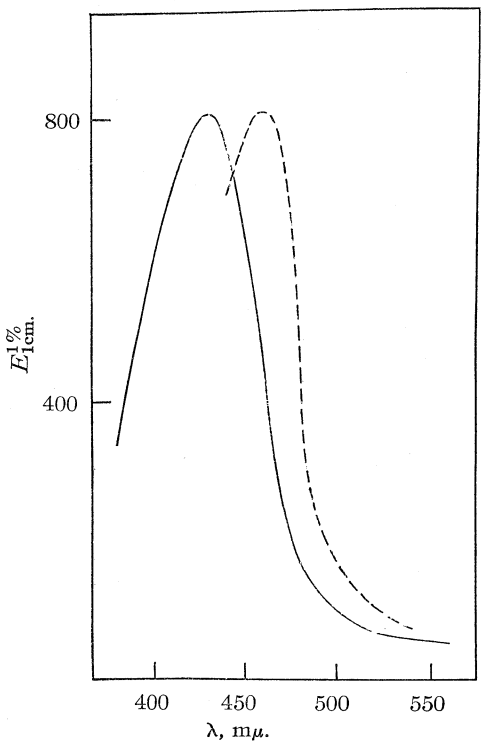

Fig. 1.—Absorption spectra of bilirubin alone and in the presence of excess albumin. *Solid line:* bilirubin, 1 mg./100 ml.; ascorbic acid 20 mg./100 ml. in *p*H 7.8, Γ/2 0.1 phosphate. *Dashed line:* Same in presence of 250 mg./100 ml. human serum albumin.

and containing 2 moles of bilirubin per mole of albumin was examined over a *p*H range of 8 to 3.5. The absorption maximum remained constant at 460 mμ betwen *p*H 8 and 5. Dissociation, as evidenced by a gradual return of the maximum to 435 mμ and precipitation of bilirubin, occurred near *p*H 4.5.[21] This is approximately the same range as was found by Klotz for the interactions of bovine serum albumin with methyl orange and azosulfathiazole.[22,23] Further, Stenhagen and Teorell have shown that albumin and "yellow pigment" migrated together in electrophoresis between *p*H 4.18 and 8.0.[24]

## 2. Studies on the Interaction of Bilirubin with the Serum Globulins

When the interaction of bilirubin with some of the globulin-containing fractions of human plasma was studied, it was observed that in certain cases more bilirubin was bound by the protein than could readily be accounted for by the amounts of albumin present in the fractions. This was confirmed, in the case of Fraction IV-7, by observing the electrophoretic behavior of the fraction in the presence of bilirubin. This experiment suggested that the bilirubin was bound to the $\alpha_2$-globulin, as well as to the albumin present in the fraction. The main component, $\beta_1$ metal-combining globulin, did not bind bilirubin under these conditions.

Accordingly, dialysis studies were made with a number of fractions rich in $\alpha$-, $\beta_1$- and $\gamma$-globulins. The results are given in Table II. Since the molecular weights of some of these components are not known, the data have been calculated on a gram basis. In the fourth column, the amount of bilirubin that would normally be bound to the albumin in the fraction has been calculated. The difference between this and the total bound bilirubin (column 3) has been taken as a measure of the binding capacity of the globulin components present. This involves the assumption that the albumin present in these fractions behaved normally with respect to its interaction with bilirubin. It does not preclude the possibility of other phenomena which might give rise to interactions with bilirubin.

The results indicate that neither $\gamma$-globulin nor the $\beta_1$ metal-combining globulin bind, if any, not more than traces of bilirubin. The $\alpha_1$-globulin from Fraction V-1 bound nearly four times as much bilirubin as would be anticipated from the amount of albumin present as impurity. Indeed, it is possible that the pure $\alpha_1$-globulin from this fraction may be capable of binding more bilirubin per gram than albumin. Of the $\alpha_2$-globulins studied, that isolated from Fraction IV-7 bound more bilirubin than the $\alpha_2$-globulin from Fraction IV-6.[25]

## Summary

From the present study it would appear that crystallized serum albumin forms a complex with bilirubin which is stable over a *p*H range including but extending well beyond physiological limits. The amount of this complex that formed was diminished when the free amino groups had been guanidinated by methyl isourea. Quantitative data suggest that, within the limits of bilirubin and protein concentration and in the range of *p*H used, the composition of the complex is of the order of 3 moles of bilirubin to 1 mole of albumin.

The studies on the interaction of bilirubin with fractions containing high proportions of $\alpha$-globulins suggest that complex formation can take place between $\alpha$-globulins and bilirubin. This is most marked with the $\alpha_1$-globulin isolated from Fraction V-1 but is evident with the $\alpha_2$-globulins isolated from Fractions IV-6 and IV-7 as well. The crystallized $\beta_1$ metal-combining globulin and the $\gamma$-globulin examined did not appear to interact with bilirubin to any significant extent.

BOSTON, MASS. RECEIVED[26] JULY 30, 1948

(21) It is possible that the dissociation of the complex was favored, at *p*H 4.5, by the extremely low solubility of bilirubin.

(25) Since this paper was completed we have learned of studies on the state of bilirubin in serum now being conducted by Dr. Ulrich Westphal at the University of Tübingen in Germany (French Zone). Dr. Westphal states: "Electrophoresis diagrams using the Philpot method (by courtesy of Dr. E. Wiedemann, Basel) demonstrate that bilirubin when added to human serum, is bound partly to the albumins, and partly to the $\alpha_2$ globulin fraction."

# Equilibria in Saturated Salt Solutions. IV. The Quaternary System $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75°

BY WILLIAM J. LIGHTFOOT AND CARL F. PRUTTON

In previous papers[1,2,3] the isotherms for the ternary systems at 35 and 75° and for the quaternary system at 35° were reported for the system $CaCl_2$–$MgCl_2$–KCl–$H_2O$.

## Experimental Method

The experimental methods used were identical with those employed in the earlier papers. Temperature at which solutions and solid phases were brought into equilibrium was 75 ± 0.02°. The three methods of identification for the solid phases employed in the earlier work[3] were used.

**The Quaternary System.**—The data for the quaternary system at 75° are given in Table I. In Fig. 1 the upper portion of the quaternary tetrahedral figure is shown schematically. The relative proportions of the saturation surfaces are indicated. The same characteristic of magnesium chloride solutions that was noted in the ternaries and quaternary at 35° is found here: carnallite remains almost insoluble in solutions saturated for $MgCl_2 \cdot 6H_2O$. Tachydrite solutions dissolve considerably more carnallite, particularly as the saturated solution becomes richer in calcium chloride. This ability of tachydrite solutions to dissolve more carnallite is more pronounced than at 35°. The presence of the field of a new compound, $2KCl \cdot CaCl_2 \cdot 2H_2O$, decreases the range of existence of carnallite appreciably.

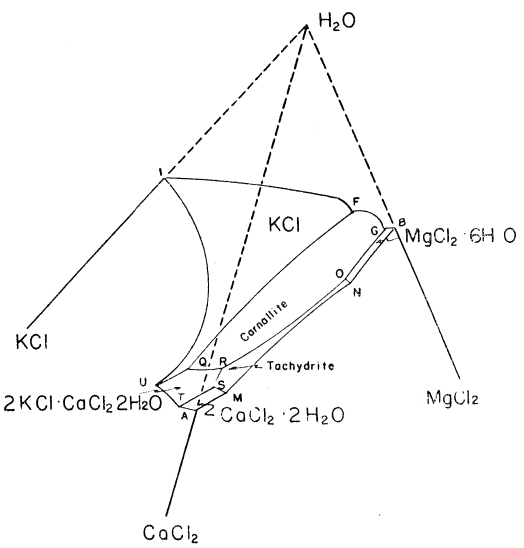

Fig. 1.—The system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75°, upper portion of tetrahedron.

The saturation surface of $MgCl_2 \cdot 6H_2O$ has been reduced so that it now covers a very small part of the diagram. The area of saturation of $CaCl_2 \cdot 2H_2O$ is the second smallest with tachydrite and $2KCl \cdot CaCl_2 \cdot 2H_2O$ coming next in size, each with about the same area. Again KCl and carnallite occupy the largest areas in the diagram. However, the field of carnallite no longer extends from one side almost to the other.

With the introduction of a new solid phase, $2KCl \cdot CaCl_2 \cdot 2H_2O$, the relationships in the quaternary diagram have been altered considerably. Where at lower temperatures, $CaCl_2 \cdot 4H_2O$ and carnallite were in equilibrium along a portion of the isotherm, the presence of the new phase completely separates $CaCl_2 \cdot 2H_2O$ from carnallite. No formation of a quaternary compound was found at 75°.

In Fig. 2 the quaternary isotherm has been projected on the $MgCl_2$–KCl–$H_2O$ plane. Points F, G, M, N, T, and U are the respective invariant points of the associated ternary systems. Area IFQU, is the saturation surface of KCl; FGORQ, that of carnallite, $KCl \cdot MgCl_2 \cdot 6H_2O$; NOGB, that of $MgCl_2 \cdot 6H_2O$; MNORS, that of tachydrite, $CaCl_2 \cdot 2MgCl_2 \cdot 12H_2O$; AMST, that of $CaCl_2 \cdot 2H_2O$; and RSTUQ, that of $2KCl \cdot CaCl_2 \cdot 2H_2O$.

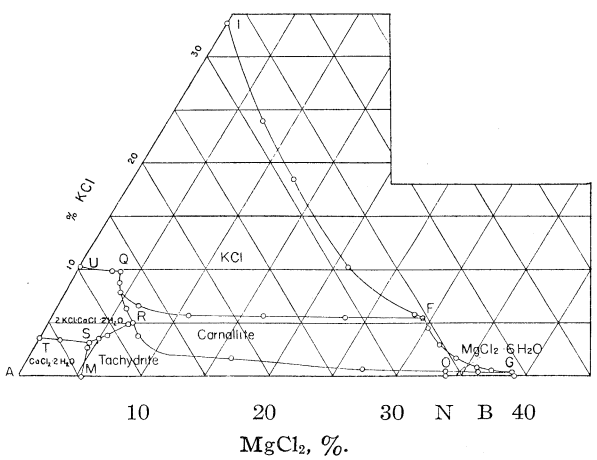

Fig. 2.—Equilibria in the quaternary system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75°, projection on the $MgCl_2$–KCl–$H_2O$ plane.

The curve FQ is the intersection of the KCl surface with the carnallite surface, and all points on it represent equilibrium between the two solid phases, KCl and carnallite, and saturated solution. GO represents solutions saturated with carnallite

| SR | 5.44 | 50.06 | 3.81 | | | | 9.17 | 84.40 | Tachydrite + $2KCl \cdot CaCl_2 \cdot 2H_2O$ |
| SR | 6.68 | 46.63 | 5.02 | | | | 11.45 | 79.94 | Tachydrite + $2KCl \cdot CaCl_2 \cdot 2H_2O$ |
| U | ... | 51.20 | 10.33 | | | | ... | 83.21 | KCl + $2KCl \cdot CaCl_2 \cdot 2H_2O$ |
| UQ | 2.71 | 47.32 | 9.84 | 1.49 | 39.94 | 32.06 | 4.53 | 79.04 | KCl + $2KCl \cdot CaCl_2 \cdot 2H_2O$ |
| N | 33.91 | 8.31 | ... | | | | 80.32 | 19.68 | Tachydrite + $MgCl_2 \cdot 6H_2O$ |

and $MgCl_2 \cdot 6H_2O$; RQ, carnallite and $2KCl \cdot CaCl_2 \cdot 2H_2O$; UQ, KCl and $2KCl \cdot CaCl_2 \cdot 2H_2O$; TS, $CaCl_2 \cdot 2H_2O$ and $2KCl \cdot CaCl_2 \cdot 2H_2O$; SR, tachydrite and $2KCl \cdot CaCl_2 \cdot 2H_2O$; MS, $CaCl_2 \cdot 2H_2O$ and tachydrite; and NO, $MgCl_2 \cdot 6H_2O$ and tachydrite.

There are four isothermal invariant points in the system, R, S, Q, and O. The three solid phases in equilibrium with saturated solution at each point are: at Q, KCl, carnallite and $2KCl \cdot CaCl_2 \cdot 2H_2O$; at S, $CaCl_2 \cdot 2H_2O$, tachydrite, and $2KCl \cdot CaCl \cdot 2H_2O$; and at O, $MgCl_2 \cdot 6H_2O$, tachydrite, and carnallite.

In Figs. 3 and 4, the quaternary relationships have been projected on the $CaCl_2$–KCl–$H_2O$ and the $CaCl_2$–$MgCl_2$–$H_2O$ planes respectively. In the projection on the $CaCl_2$–KCl–$H_2O$ face there appears to be an overlapping of the KCl and carnallite surfaces. This is due only to the method of projection. The saturation curves can be readily distinguished from one another. The projection on the $CaCl_2$–$MgCl_2$–$H_2O$ plane is perhaps the

clearest in that there is no overlapping or superimposing of the different curves.

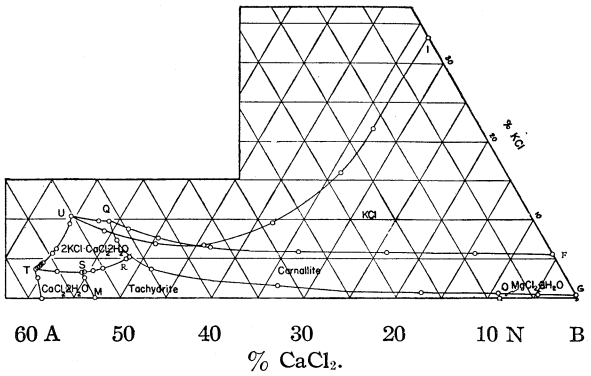

Fig. 3.—Equilibria in the system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75° projected on the $CaCl_2$–KCl–$H_2O$ plane.

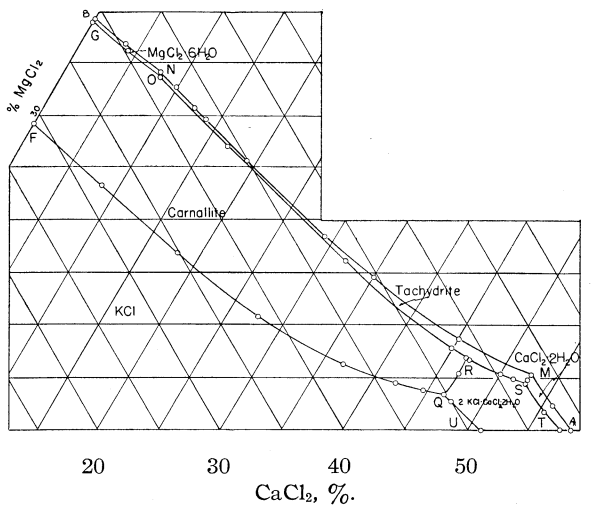

Fig. 4.—Equilibria in the quaternary system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75°, projection on the $CaCl_2$–$MgCl_2$–$H_2O$ plane.

The data on the quaternary system at 75° are given in Table I on a water free basis, and have been plotted in Figure 5, which gives the Jänecke projection. The coexistent solid phases are connected by straight lines, the triangles formed represent the three solid phases which are in equilibrium at the invariant points. The notations are consistent with those used in the other projections. Comparison with the similar type of diagram at 35° shows that all areas in general have increased except $MgCl_2 \cdot 6H_2O$. The main difference is that saturated solutions dissolve more KCl.

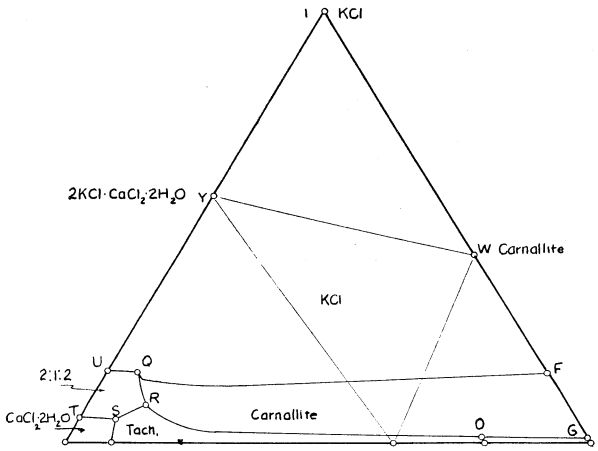

Fig. 5.—Quaternary system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75°, Jänecke projection.

## Summary

1. The isotherm for the quaternary system $CaCl_2$–$MgCl_2$–KCl–$H_2O$ at 75° has been determined.

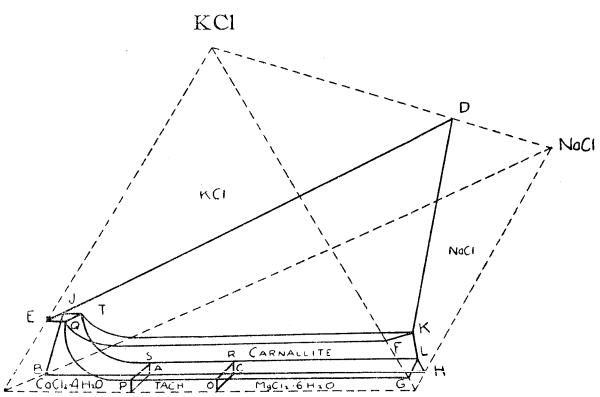
# Equilibria in Saturated Salt Solutions. V. The Quinary System $CaCl_2$–$MgCl_2$–KCl–NaCl–$H_2O$ at 35°

BY TED A. MEYER, CARL F. PRUTTON AND WILLIAM J. LIGHTFOOT



Invariant points in the quinary system $CaCl_2$–$MgCl_2$–KCl–NaCl–$H_2O$; in the quaternary systems $CaCl_2$–KCl–NaCl–$H_2O$, $MgCl_2$–KCl–NaCl–$H_2O$ and $CaCl_2$–$MgCl_2$–NaCl–$H_2O$; and in the ternary systems $CaCl_2$–NaCl–$H_2O$, $MgCl_2$–NaCl–$H_2O$ and KCl–NaCl–$H_2O$ were determined at 35° to supplement the existing data. Data for the remaining associated ternary systems and quaternary system are found in the papers of Lightfoot and Prutton.[1,2] Seidell[3] gives references to most of the other published data on these systems

## Experimental Method

Calcium chloride tetrahydrate was made by neutralizing C. P. hydrochloric acid with C. P. calcium carbonate and subsequent crystallization at 35°. Magnesium chloride hexahydrate was made by reaction of C. P. hydrochloric acid with distilled magnesium and the crystallization of the chloride at room temperature. A. C. S. grade potassium and sodium chlorides were used without further purification.

Samples of different over-all composition were made up for each invariant point, and it was possible to obtain analyses of fixed composition on these separate solutions that were within the limits for the experimental methods involved. Solid phases were checked by microscopic examination.

The samples were agitated three to five days in the usual manner in bottles in a thermostat maintained at 35 ± 0.02° to attain equilibrium. Each sample was seeded with the appropriate solid phase. Sampling and analytical methods for the determination of total chloride, calcium and potassium contents were identical with those used by Lightfoot and Prutton.[1] Magnesium was calculated by difference in all cases. Sodium was determined as uranyl zinc sodium acetate on a separate sample of saturated solution.

$CaCl_2$ $MgCl_2$

## Experimental Results

Table I gives the data for the quinary system $CaCl_2$–$MgCl_2$–KCl–NaCl–$H_2O$ at 35°. As it becomes increasingly difficult to graphically represent phase equilibria as the number of components increases, a schematic three dimensional figure probably offers the clearest conception of the relationships existing. In Fig. 1 the three dimensional model for the quinary system is shown schematically as a regular tetrahedron.

Each line forming the sides of the tetrahedron represents equilibria in the ternary system composed of the two salts at the ends of the line and water. Each face represents the equilibria in a given quaternary system. This last face is a projection by the Jänecke method of the equilibria in a quaternary tetrahedron on the base of the tetrahedron. Unfortunately in such a projection, there is no satisfactory method for representing water content of the saturated solutions and everything must be dealt with on a zero per cent. water basis. Each Jänecke projection of the quaternary systems forms the sides of the quinary tetrahedron. Equilibria in the quinary system are represented by points within the body of the tetrahedron.

A point on the line joining potassium chloride and magnesium chloride would represent a saturated solution of magnesium chloride and potassium chloride in equilibrium with one or two solid phases. At point F the two solid phases would be potassium chloride and carnallite, $KCl \cdot MgCl_2 \cdot 6H_2O$. At a point between F and G there would be only one solid phase, carnallite.

Within the area bounded by potassium chloride, F, K and D, a point would represent a saturated solution containing potassium chloride, magnesium chloride, and sodium chloride in equilibrium with potassium chloride as the solid phase. Along the line DK, the solid phases potassium chloride and sodium chloride would be present. At point K, a quaternary isothermal invariant point, the three phases, carnallite, potassium chloride and sodium chloride would exist. This same relationship holds true for the other quaternary faces.

In the quinary system, a point within the volume bounded by FGLKTQPOSR, the carnallite volume, would be a saturated solution containing potassium chloride, magnesium chloride, sodium chloride, calcium and chloride in equilibrium with one solid phase, carnallite. A point

| R | 17.50 | 27.10 | .21 | .26 | $MgCl_2 \cdot 6H_2O$ + carnallite + tachydrite + NaCl |
| S | 6.17 | 44.70 | .97 | .28 | $CaCl_2 \cdot 4H_2O\alpha$ + carnallite + tachydrite + NaCl |
| S | 6.21 | 44.72 | .97 | .28 | $CaCl_2 \cdot 4H_2O\alpha$ + carnallite + tachydrite + NaCl |

[a] Carnallite = $KCl \cdot MgCl_2 \cdot 6H_2O$. [b] Tachydrite = $CaCl_2 \cdot 2MgCl_2 \cdot 12H_2O$.

on the three dimensional surface within the tetrahedron bounded by FKTQ would have the solid phases, carnallite and potassium chloride. Along the line KT the solid phases would be carnallite, potassium chloride, and sodium chloride; along JT, $CaCl_2 \cdot 4H_2O\alpha$, potassium chloride, and sodium chloride; along QT, $CaCl_2 \cdot 4H_2O\alpha$, carnallite, and potassium chloride. These three lines join at point T, a quinary isothermal invariant point, where the four solid phases, carnallite, $CaCl_2 \cdot 4H_2O\alpha$, potassium chloride and sodium chloride are co-existent.

The same relationships can be reasoned for the other volumes, surfaces, lines and points in the quinary figure.

Literature values for the sodium chloride content of the invariant points of the systems studied are not in good agreement with each other and, in general, are higher than the values given in Table I. This might be explained by the fact that many of these investigations were carried out prior to the development of the zinc uranyl acetate method for sodium.

The most striking feature of the data of this investigation is the constancy of the sodium chloride values at the invariant points in which $CaCl_2 \cdot 4H_2O\alpha$ or $MgCl_2 \cdot 6H_2O$ appear as solid phases. These values range from 0.26 to 0.33%. Concentration of sodium chloride at other points is significantly higher.

## Summary

1. The isothermal invariant points in the quinary system $CaCl_2$–$MgCl_2$–KCl–NaCl–$H_2O$ were determined at 35°.

2. The isothermal invariant points in the quaternary systems $CaCl_2$–KCl–NaCl–$H_2O$ and $CaCl_2$–$MgCl_2$–NaCl–$H_2O$ were determined at 35°.

3. The isothermal invariant points in the ternary systems $CaCl_2$–NaCl–$H_2O$, $MgCl_2$–NaCl–$H_2O$ and KCl–NaCl–$H_2O$ were determined at 35°.

# The Photochemical Iodine-Sensitized *cis–trans* Isomerization of Dichloroethylene

BY ROSCOE G. DICKINSON,[1] RICHARD F. WALLIS[2] AND REUBEN E. WOOD[3]

The kinetics of a number of *cis–trans* isomerization reactions occurring in the presence of iodine can be interpreted in terms of a mechanism involving catalysis by iodine atoms.[4] We have studied the photochemical iodine-sensitized isomerization of *cis*- and *trans*-dichloroethylene and find that the kinetics of this reaction are compatible with such a mechanism.

**Acknowledgment.**—This study was begun and pursued by Dickinson and Wood during the academic year 1939–1940. The experiments made at that time were rate measurements on the above-named reaction carried out in decalin solutions. Fairly consistent results were obtained for specific rate constants and their temperature coefficients, and kinetics in agreement with those reported in this paper were indicated. However, side reactions involving the iodine occurred appreciably in the experiments in decalin solutions, as shown by decreases in concentration of free iodine during the runs; the results of those experiments could not, therefore, be interpreted in terms of the kinetics of the isomerization reaction so precisely and straightforwardly as should be possible with experiments involving no considerable side reactions.

During the academic year 1947–1948 new experiments were carried out the description and results of which are presented in this paper. The other two authors take responsibility for this publication but we have taken the liberty to include Professor Dickinson's name with ours in recognition of his proposal of and important contributions to this research.

## Experimental Details

**Apparatus.**—The work mentioned above showed that temperatures above 100° would be required to obtain convenient photochemical isomerization rates even with intense illumination. It also showed that the available intensity of illumination would have to be high in order to permit adequate exploration of temperature coefficients of rate constants and the effect of reduced light intensity, while operating in a temperature range below that at which thermal isomerization would be a factor seriously complicating the interpretation of the data. These two facts led to the choice of the radial illumination system[5] shown in Figs. 1 and 2. In this apparatus a cylindrical light source and a cylindrical reaction vessel are placed with axes at the conjugate foci of an elliptical reflector.

The light source selected was a 400-watt type A-H-1 mercury vapor lamp manufactured by the General Electric Company. This lamp has a convenient cylindrical shape and emits an intense light with the maximum of the spectral distribution curve located in the green. It has a glass envelope and emits practically no radiation of wavelengths shorter than 3200 Å. The mercury vapor pressure is a little over 1 atm. when the lamp is operating at full intensity, the arc appearing to be an almost white, pencil-like beam about 16 cm. long.

Although the lamp is designed for operation in open air, it was found necessary to have a light filter solution flowing around the lamp. This change in operating conditions did not, however, affect its performance materially. A pyrex glass tube about 8 cm. in diameter was placed around the lamp and held in position by rubber stoppers cut to size. Outlet and inlet tubes for the light filter solution were placed in the top and bottom stoppers, respectively. Cooling of the filter solution was effected by forcing it through a spiral condenser by means of an all-glass centrifugal pump. A thermometer was placed in the line so that the temperature of the filter solution leaving the lamp could be observed. The speed of the motor driving the pump was always adjusted so that the temperature shown by this thermometer remained at 68 ± 5°. This was done because the absorption spectrum of the filter is somewhat temperature dependent.

The elliptical reflector consisted of side, top, and bottom pieces made of chromium-plated brass. The side piece was bent into an elliptical shape and held in position by three brass templates. The top and bottom pieces were bolted to the upper and lower templates. The reflector was disassembled and dusted from time to time during the course of the research. No evidence of dulling or tarnishing appeared.

A brass tube directed toward the lamp was soldered into the wall of the reflector. An RCA Type 922 vacuum photocell was mounted in a light-tight box attached to the end of this brass tube. The photocell was connected in series with a 22.5-volt "B" battery and a microammeter (a suitably shunted and calibrated galvanometer was used in the experiments at reduced light intensity). The stated characteristics of this photocell and the light intensities involved were such that the current through the circuit should have been and is assumed to have been directly proportional to the light intensity. This system was used to observe the constancy of light intensity during runs and to evaluate the relative intensities in the various runs. Reduced intensities were obtained by wrapping a piece of blackened Monel metal wire cloth around the jacket of the lamp. Wire cloth screens of two different coarsenesses were used.

In "blank" runs, solutions of dichloroethylene containing no iodine were illuminated without filtration of the light other than that effected by the glass in the light path. A change in dielectric constant of the solutions equivalent to significant amounts of isomerization was observed in these runs. A light filter which would prevent photo-

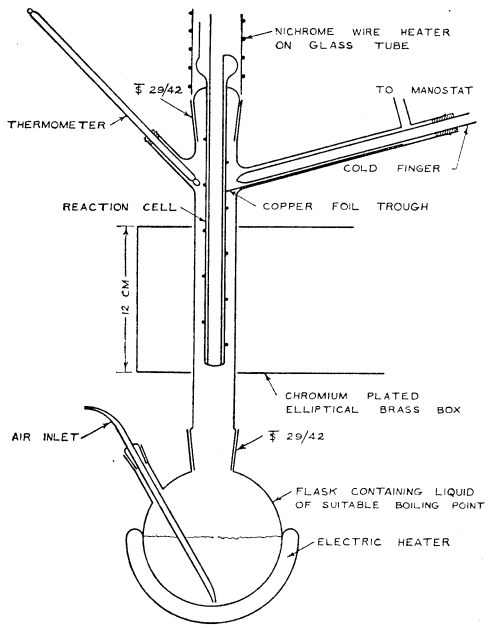

Fig. 2.—Vapor thermostat and reaction cell.

chemical reaction in the absence of iodine was sought and found. It is an aqueous solution of $^1/_2$ formula weight of cupric chloride and 1 formula weight of calcium chloride per liter of solution. Incidentally, a cupric sulfate solution was unsatisfactory; these two solutions differ significantly in absorption spectrum only in that the chloride solution absorbs more strongly in the violet and near-ultraviolet. *cis*- and *trans*-dichloroethylene and their benzene solutions were shown by means of a Beckman ultraviolet spectrophotometer to absorb weakly in the 3200 to 3700 Å. range.

The reaction cell is shown in Figs. 2 and 3. The high vapor pressures of the reaction solutions and the necessity for continuous measurement of their temperatures were principal factors influencing the design of the cell. Preliminary tests demonstrated that the cell, which was constructed of Pyrex glass tubing, could withstand an internal pressure of at least 8 atm. From a theoretical standpoint it was advantageous to have the solution in the form of a thin cylindrical lamina with axis passing through the focus of the elliptical reflector. A sheet of bright aluminum foil was wrapped around the thermometer as shown in Fig. 3 so that no radiation would fall directly on the thermometer and so that the light paths would represent as much vertical symmetry as possible.

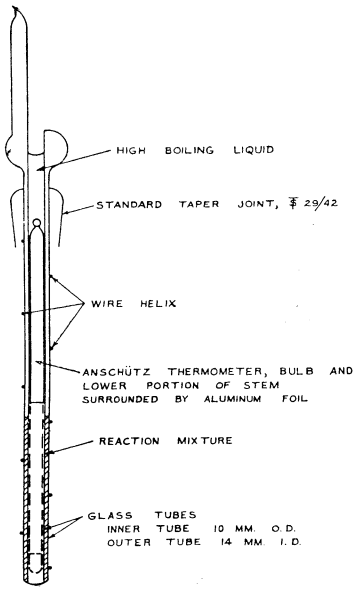

Fig. 3.—Reaction cell.

The method of thermostating the reaction solution is shown in Fig. 3. Because the cell was heated appreciably by the radiation focused on it, it was necessary to direct a flow of condensate over the outside of the cell by means of a copper foil trough and a wire helix wound on the cell. The condensate flowed smoothly over the glass; it seems probable that any inconstancy of light paths caused by irregularities of flow had a negligible effect on the rate measurement. The desired temperatures were obtained and maintained by suitable choice of the boiling liquid and by adjustment of the manostate controlling the boiling pressure. The temperature at the center of the reaction cell was measured by an Anschütz thermometer and was maintained constant within $\pm 0.2°$ during an experiment. The thermometer was immersed in decalin to ensure good thermal conduction to the inner wall of the reaction cell. The thermometer was calibrated at 100, 110 and 118° with boiling water, toluene, and acetic acid, respectively.

The temperature at the center of the reaction cell was consistently 4 or 5° higher than that of the thermostat vapor. This difference doubtless represents in part thermal gradients across the two cell walls and intervening solution, in part superheating of the condensate flowing over the outer wall. The thermal gradient across the inner wall would be expected to be smaller than that across the outer wall; it would be zero if all the radiation were absorbed before reaching the inner wall, neglecting heat conduction vertically through the inner wall to outside the illuminated zone. The thermal gradient in the bulk of the reaction solution, too, is probably small because of convection currents. So, in tabulations and calculations, we have treated the temperatures measured at the center of the reaction cell as the temperatures of the reaction solutions. We estimate the temperature uncertainties as follows: the true solution temperatures corresponding to calculated rate constants are not greater than, and are not more than 1° less than those recorded; the true differences in temperatures between runs, the basis of the activation energy calculation, are within a few tenths of a degree of those indicated by the recorded data.

To prevent the reaction mixture from refluxing from the upper part of the reaction vessel (outside the thermostat), this part of the reaction vessel was heated a little above the temperature of the thermostat by an electric heating coil wound on a slip-over glass tube. No condensate or iodine vapor was visible in this part of the reaction vessel once thermal equilibrium had been established. The portion of the reaction vessel extending above the reflecting

box was shielded from the direct rays of the lamp. Wood and Stevenson[6] obtained evidence that the rate of the thermal isomerization of the 1,2-dichloroethylenes catalyzed by iodine in the vapor phase is of the same order of magnitude as the rate in liquid solutions when comparable concentrations are used. From the foregoing considerations we believe that the isomerization in the vapor phase in this work was negligible.

As in previous work on the isomerization of the 1,2-dihaloethylenes,[4c,d,e] the analytical method was based on the difference in dielectric constant between the *cis* and *trans* isomer. The heterodyne circuit employed to measure dielectric constants was similar to that described by Hudson and Hobbs[7] and was operated at 1.7 megacycles. The liquid dielectric condenser (dielectric cell) is shown in Fig. 4. The amount of solution required to fill it was somewhat less than the 5 ml. used in the photo-chemical reaction cell. The gold-plated brass tubes were soldered to the glass members by applying a platinum film to the glass with a platinizing solution which is described by Strong.[8] The platinic chloride required was prepared by heating chloroplatinic acid at 110° until no more vapors were evolved. Water from a thermostat maintained at 24.7° was circulated around the dielectric cell while measurements were being made.

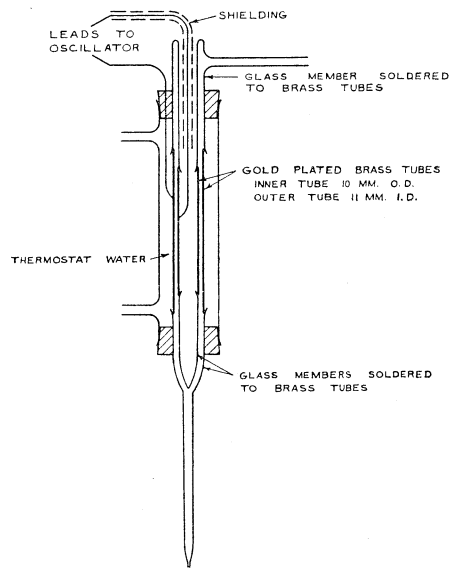

Fig. 4.—Dielectric cell.

**Chemical.**—It seemed desirable in the photochemical experiments to use one of the solvents which had been used in the thermal experiments.[4c] Decalin was tried first because its relatively low vapor pressure at convenient reaction temperatures would permit the use of flat-windowed photochemical reaction cells of conventional design. However, the earlier experiments as well as some carried out since this research was resumed indicate that in the decalin solutions there is a slow but appreciable side reaction. This may be a photochemical reaction between iodine and decalin itself or between iodine and impurities in the decalin which are not removed by reasonably careful purification.

Decalin was therefore abandoned and benzene was used as the solvent in all the isomerization experiments tabulated below. This more volatile solvent was permissible in the tubular reaction cell. Eastman Kodak Co. "White Label" benzene was cooled while being stirred, until about half frozen. The remaining liquid was poured off and discarded. The solid benzene thus obtained had a melting point of 5.5°. It was dried over anhydrous calcium chloride and distilled in an apparatus from which moisture was excluded. The solvent so prepared did not react with iodine under conditions corresponding to those of the isomerization experiments. The only evidence of any side reaction in the runs represented by the quantitative data reported here was the occasional appearance of a small ring of brownish coloration on the reaction vessel where the reaction solution meniscus had been.

*cis*- and *trans*-dichloroethylenes were obtained in 90–95% purity from the Columbia Organic Chemicals Company, and from the Westvaco Chlorine Products Company. The liquids were distilled through a packed column under an atmosphere of dry carbon dioxide. The boiling ranges of the final products were less than 0.1°. Exactly 10.00 mole per cent. solutions of the pure *cis*- and *trans*-dichloroethylenes in benzene were prepared by weighing and were stored under carbon dioxide in closed vessels designed to permit withdrawal of the solution without admission of air.

Merck "Reagent" grade iodine was sublimed from a mixture with Merck "Reagent" grade potassium iodide and was then resublimed. An 0.0602 mole per cent. iodine solution in benzene was prepared.

**Procedure.**—The following procedures were followed in the majority of the experimental runs; exceptions will be described below. Manipulations involved in filling and sealing the reaction cell were carried out under carbon dioxide to exclude oxygen. Between runs the reaction cell was filled with chromic acid cleaning solution to remove any materials which might influence the reaction. The chromic acid was removed by repeated washing with water and then twice with acetone. The residual solvent was pumped off.

Pure dry carbon dioxide was passed through the cell for a few minutes, after which the cell was stoppered and weighed. In the case of the runs with dilute iodine solutions, a suitable volume of benzene solution of iodine was pipetted into the cell which was then reweighed. Iodine crystals were added directly to the cell for the experiments with concentrated iodine solutions. In either case sufficient solution of one of the dichloroethylenes was next added to make a total of 5 ml. of reaction solution. A final weighing of the reaction cell was made, after which additional carbon dioxide was passed through the upper part of the cell to remove any vapors which might pyrolyze. The stream of carbon dioxide was not permitted to reach down to the reaction solution, however, so no fractionation of the latter is believed to have occurred; the results of blank experiments supported this assumption. The cell was then sealed off. At the start of these operations the mercury vapor lamp and the thermostat heater were turned on so that they would be at operating temperatures by the time everything else was ready to start the run.

The filled and sealed reaction cell was put into place in the apparatus and the starting time noted. Reference marks on both members of the ground glass joint supporting the cell made it possible to orient the cell in exactly the same manner for each run, a precaution which seemed advisable since the axis of the cell and that of the ground glass joint did not exactly coincide. The heater for the vapor portion of the cell was clamped into place. Thermal equilibrium was practically achieved within five minutes. Light intensity readings were taken at fifteen-minute intervals throughout the run. The run was concluded by turning off the light and removing the cell from the thermostat. When the solution had cooled it was transferred to a test-tube containing a clean coil of copper wire to remove iodine: this method of removing iodine had been shown[4c] not to produce isomerization.

After the solution had become free of iodine, its dielectric constant was measured and from it together with the knowledge of the total dichloroethylene concentration the concentrations of *cis*- and *trans*-dichloroethylene in it were

calculated. Such calculations were based on the assumption that, over the concentration ranges used, the dielectric constant is a linear function of the mole fractions of *cis*- and *trans*-dichloroethylene present in the solution. This assumption was tested and found valid for the two-component system comprising solutions of *cis*-dichloroethylene from 7 to 10 mole per cent. in benzene, it was also tested and found valid for the three-component system comprising benzene solutions of *cis*- and *trans*-dichloroethylene in which the total dichloroethylene concentration was kept at 10 mole per cent.

## Calculations

The conditions and results of the rate experiments are summarized in Tables I, II and III. The first part of this discussion will attempt to show how the specific rate constants, tabulated in the last column of each table, were calculated from the data, and to indicate how they are related to the interpretation of the results in terms of an iodine atom catalysis. The line of argument will be to derive, on the basis of the proposed mechanism, the equations for certain quantities ($k$'s) the values of which should be constant or should have a predicted dependence on the experimental parameters if the proposed mechanism is compatible with the data.

The proposed mechanism is[4]

$$C + I \rightleftarrows CI \qquad (1)$$

$$CI \rightleftarrows TI \qquad (2)$$

$$TI \rightleftarrows T + I \qquad (3)$$

where C and T represent the *cis* and *trans* isomers, respectively, I is atomic iodine, and CI and TI are complexes. On this basis one can write for the over-all reaction

$$-d(C)/dt = k_1(I)(C) - k_2(I)(T) \qquad (4)$$

in which $k_1$ and $k_2$ are specific rate constants for the forward and reverse *cis* to *trans* isomerization (note that $k_1$ and $k_2$ do not refer to reactions 1 and 2 above). This is an expression for the local rate of isomerization. In the case of photochemical experiments the rate will vary from place to place in the solution because of varying light intensity and consequently varying iodine atom concention (it is assumed that recombination of iodine atoms occurs before they have diffused appreciably). The over-all rate of isomerization will be the average local rate.

Because of the uniformity of C and T concentrations throughout the solution, which it is reasonable to assume because of the slowness of isomerization compared to probable stirring processes, the over-all isomerization rate should be given by

$$-\overline{d(C)/dt} = k_1\overline{(I)}(C) - k_2\overline{(I)}(T) \qquad (5)$$

Here $-\overline{d(C)/dt}$ represents the over-all net rate of conversion of *trans* to *cis* dichloroethylene, and $\overline{(I)}$ represents the average concentration of iodine atoms throughout the reaction solution.

If one now considers isomerization experiments of the kind reported here in which $\overline{(I)}$ remains essentially constant throughout a given experiment and which start with only the *cis* or only the *trans* isomer, equation (5) can be integrated. Representing by $\alpha$ the fraction of dichloroethylene in the *cis* form at the time $t$ and letting $K$ be the equilibrium constant $(trans)_{eq}/(cis)_{eq}$, the integration leads to the expressions for $k_1$

$$k_1 = -\frac{K}{t(I)(K+1)} \ln \frac{(K+1)\alpha - 1}{K} \qquad (6)$$

which applies to experiments in which the initial dichloroethylene is all *cis*, and

$$k_1 = -\frac{K}{t(I)(K+1)} \ln [1 - (K+1)\alpha] \qquad (7)$$

which applies to experiments in which the initial dichloroethylene is all *trans*. $k_2$ has been eliminated from these equations by $K = k_1/k_2$.

It remains to get expressions for $\overline{(I)}$ in terms of the experimental parameters. In addition to reactions 1, 2, and 3 one must consider processes by which iodine atoms are produced from molecular iodine and also the recombination of the atoms to form the molecule, *i. e.*

| | | |
|---|---|---|
| The photochemical dissociation | $I_2 + h\nu \longrightarrow 2I$ | (8) |
| The thermal dissociation | $I_2 \longrightarrow 2I$ | (9) |
| Recombination | $2I \longrightarrow I_2$ | (10) |

It is understood that energy and momentum requirements may be satisfied by particles not symbolized in these expressions. The usual treatment of rate expressions based on processes 1, 2, 3, 8, 9, and 10 leads to the following implicit expression for (I), the local steady-state iodine atom concentration

$$\phi i + k_9(I_2) = k_{10}(I)^2 \qquad (11)$$

where $\phi$ is the quantum yield for process 8, $i$ is the local rate of light absorption in einsteins liters$^{-1}$ seconds$^{-1}$, and $k_9$ and $k_{10}$ are the specific rate constants of processes 9 and 10, respectively.

The azimuthal variation of $i$ throughout the reaction vessel will not affect the form of rate expressions to be derived under the assumptions that the light enters and leaves the cell radially and that the isomer concentrations are at all times uniform throughout the solution. Therefore, since quantum yields are not calculated, it is not necessary to consider the azimuthal variation further.

The radial relations follow from applications of Beer's and Lambert's laws. Let $r$ be the distance from the axis of the reaction cell to the point in the solution where the rate of light absorption is $i$, and let $r_0$ and $r_1$ be the distances from the cell axis to the inner and outer boundaries of the solution, respectively. Let $\epsilon$ be a molal absorption coefficient of iodine for a particular wave length and let $I_0$ be the rate at which light enters the outer surface of the solution (in einsteins per second). It can be shown that the rate of light absorption per unit volume in a thin cylindrical shell of solution of radius $r$ is given by

$$i = \frac{I_0}{V}(I_2)\epsilon(r_1 - r_0)[\exp(-\epsilon(I_2)(r_1 - r)) + m\exp(-\epsilon(I_2)(r_1 + r - 2r_0))] \qquad (12)$$

In this equation $V$ is the total volume of the reaction solution, $m$ is a fraction which takes account of the loss of light which occurs at the aluminum reflectors. The derivation involves approximations which are good when $r_0$ is considerably larger than $r_1 - r_0$. These are thought to be satisfactory approximations for the cell used in this work.

A combination of equations 11 and 12 gives

$$(\mathrm{I}) = \sqrt{\frac{1}{k_{10}}\left\{k_9(\mathrm{I}_2) + \phi\left[\frac{I_0}{V}(\mathrm{I}_2)\epsilon(r_1 - r_0)\right][\exp(-\epsilon(\mathrm{I}_2)(r_1 - r)) + m\exp(-\epsilon(\mathrm{I}_2)(r_1 + r2 - r_0))]\right\}} \quad (13)$$

The average value of the iodine atom concentration, $\overline{(\mathrm{I})}$, is needed to evaluate the specific rate constant, $k_1$ (equation 7). Thus

$$\overline{(\mathrm{I})} = \frac{1}{r_1 - r_0}\int_{r_0}^{r_1}(\mathrm{I})\,dr \quad (14)$$

This expression for $\overline{(\mathrm{I})}$ can be integrated for several cases of interest. For the case of purely thermal isomerization $I_0$ is zero and only the first term under the radical sign in equation 13 remains, in this case $(\mathrm{I}) = \sqrt{k_9/k_{10}[(\mathrm{I}_2)]}$. On the other hand, the experiments reported here were carried out so that the rate of thermal isomerization should be small compared to the photochemical rate. The approximate evaluation of $\overline{(\mathrm{I})}$ for such experiments is done by neglecting the first (thermal) term in equation 13. In making this evaluation, it is convenient to treat separately two cases: the case in which the iodine concentration is low enough so that only a fairly small fraction of the incident light is absorbed in passing through the reaction solution, and the case in which the iodine concentration is high enough so that most of the light is absorbed in passing through the solution.

In the case of pale solutions in which the absorption of light approaches zero the sum of the exponential terms in equation 13 approaches $1 + m$ giving

$$\overline{(\mathrm{I})} = (\mathrm{I}) = \sqrt{\frac{\phi I_0(\mathrm{I}_2)\epsilon}{V}(r_1 - r_0)(1 + m)} \quad (15)$$

When this expression for $\overline{(\mathrm{I})}$ is put into equations 6 and 7 and constants are lumped together, expressions are obtained for $k_p$, the apparent pale solution photochemical specific rate constant for the *cis* and *trans* isomerization

$$k_p = -\frac{K}{t(K+1)\sqrt{I_0(\mathrm{I}_2)}}\ln\frac{(K+1)\alpha - 1}{K} \quad (16c)$$

equation 16c applying to experiments starting with *cis* and no *trans* isomer, and

$$k_p = -\frac{K}{t(K+1)\sqrt{I_0(\mathrm{I}_2)}}\ln[1 - (K+1)\alpha] \quad (16t)$$

equation 16t applying to experiments starting with *trans* and no *cis* isomer. By plotting values of $k_p$ against $(\mathrm{I}_2)$ and extrapolating to $(\mathrm{I}_2) = 0$ the best value of the true pale-solution photochemical specific rate constant should be obtained. It should be stated that since the thermal and photochemical rates both are proportional to $\sqrt{(\mathrm{I}_2)}$ in pale solutions, neglecting the thermal isomerization is as good an approximation for solutions having very small light absorption as for moderately absorbing solutions—a little better, in fact.

Although equations 16 have been derived for the case of monochromatic light, equations of the same form apply to polychromatic light provided that any variations of the intensity of incident light do not involve variation in the relative intensities of the various light components. Tables I and II show the pale solution results. In these tables the $k_p$'s are calculated from equations 16 where the $I_0$ values are in arbitrary units representing relative values as indicated by the photocell output. Most of these specific rate constants are plotted against the iodine concentration in Fig. 5. It can be seen that the $k_p$'s vary only a little with ten-fold variation in $(\mathrm{I}_2)$ and that their variation is in the direction that would be expected, in view of the approximations made in getting equations 16 from equation 13, if the reaction mechanism is indeed a simple iodine atom catalysis.

Equation 13 is also the starting point for the treatment of deep-colored solutions. In this case the second exponential term in that equation approaches zero. Then, still neglecting the thermal term and putting the residue of equation 13 into equation 14 and integrating, one gets

$$\overline{(\mathrm{I})} = \text{constant} \times \sqrt{I_0/(\mathrm{I}_2)} \quad (17)$$

On the basis of this equation, the photochemical rate in deep-colored solutions should vary inversely with $\sqrt{(\mathrm{I}_2)}$. Since the thermal rate should vary directly with $\sqrt{(\mathrm{I}_2)}$, in the very deep-colored solutions the thermal rate can become appreciable compared to the photochemical even though the temperature is such that this is not the case with paler solutions. The exact treatment of cases where both thermally and photochemically produced iodine atoms are present in effective quantities is complicated. However, if one makes the approximation that the photochemical reaction occurs appreciably only in a thin layer[9] on the outside of the reacting solution then convenient equations, equations 18c and 18t, can be derived for calculating the photochemical specific rate constant. Since at the temperatures and light intensities of these experiments the thermal isomerization has any relative importance only in the most deeply colored solutions, that approxi-

(9) A fuller discussion of this treatment as well as of a number of other aspects of this research can be found in a thesis entitled, "The Kinetics of the Photochemical Isomerization of Dichloroethylene Catalyzed by Iodine," submitted to the George Washington University in 1948 by Richard Fisher Wallis.

mation should be good where there is an appreciable thermal effect. Where there is no appreciable thermal effect expressions 18c and 18t for the photochemical specific rate constant reduce to just the forms that would follow from equation 17 without using the thin-layer assumption. Therefore, equations 18 may be used on all of the experiments with deep-colored solutions. In these equations, $\mathbf{k_p}$ is the photochemical specific rate constant in deep-colored solutions, $k_T$ is the thermal specific rate constant (called $k_1$ by Wood and Dickinson[4c]). Values for $k_T$ to use in equations 18 were calculated from the data of Wood and Dickinson.

$$\mathbf{k_p} = -\sqrt{\frac{(I_2)}{I_0}}\left\{\left[\frac{K}{t(K+1)}\ln\frac{(K+1)\alpha-1}{K}\right]-k_T\sqrt{(I_2)}\right\} \quad (18c)$$

$$\mathbf{k_p} = -\sqrt{\frac{(I_2)}{I_0}}\left\{\left[\frac{K}{t(K+1)}\ln\left[1-(K+1)\alpha\right]\right]-k_T\sqrt{(I_2)}\right\} \quad (18t)$$

Equation 18c applies to experiments in which the initial dichloroethylene is all *cis* and equation 18t to those in which it is all *trans*. Available data and the fact the polychromatic light was used do not permit a simple calculation of the numerical value to be expected for the ratio of the pale-solution photochemical specific rate constant, $k_p$, to the deep-colored-solution photochemical specific rate constant, $\mathbf{k_p}$.

## Results and Conclusions

The data and calculated $k_p$'s for the pale-solution experiments are presented in Tables I and II. In Fig. 5 these $k_p$'s (except those for the experiments to which footnotes a, b, and d of Table I refer) have been plotted against $(I_2)$. This graph shows that at a given temperature the $k_p$'s decrease by only about 10% with a tenfold increase in $(I_2)$. Both the comparative constancy of the $k_p$'s and the direction of their change with change in iodine concentration are, in the light of the preceding derivations, compatible with the proposed mechanism. It is to be noted that the light intensities as well as concentrations differed among the experiments the results of which are plotted. Table VII presents the data and calculated $k_p$'s for the experiments with deep-colored solutions. Again, the comparative constancy of the $k_p$'s with an eight-fold variation in $(I_2)$ is compatible with the proposed mechanism.

The numbers of the runs tabulated in Tables I, II and III indicate chronological order of the experiments. All of the isomerization experiments carried out except blanks and the preliminary experiments are included in these tables. It can be seen that the second, third and fourth runs gave low $k_p$'s. In these three cases the reaction cell had been rinsed with solvent but had not been cleaned with chromic acid before filling. In the first run and in all runs after the fourth a

soaking with chromic acid was part of the preparation of the cell.

Two other runs gave markedly low values of $k_p$, namely, runs 29 and 30 which are the first two of a series of eight in which the glass surface in contact with the reaction solution was approximately tripled by putting thin-walled glass tubing (melting-point tubes) into the solution space in the reaction vessel. This series of experiments was to test the homogeneity of the reaction, a test that seemed especially appropriate in view of the three anomalous results, mentioned in the preceding paragraph, which were obtained when the reaction vessel had not been vigorously cleaned. It seems most probable that the anomalous values obtained in runs 29 and 30 (as compared to all the other $k_p$'s in Table I and particularly as compared to the values from runs 31 through 36) like the $k_p$'s from runs 2, 3 and 4, involve faulty manipulation and are invalid. It is difficult to clean, rinse and dry thoroughly a set of capillary tubes entrapped and largely immobilized in a small reaction vessel such as we used. The only difference in technique between the earlier and later runs of the series 29 through 36 was in the care and extent of these operations. We did not feel justified in omitting runs 2, 3, 4, 29 and 30 from the tables because the probability of their invalidity is based on *a posteriori* considerations. But assuming them to be invalid, the agreement of the $k_p$'s from runs 31 through 36 with the other $k_p$'s in Table I is evidence that the reaction studied is homogeneous. It is not strange that the average value of $k_p$ in the experiments with capillary tubes should be a little different from the others. It is perhaps remarkable that it is so nearly the same since no correction was attempted for the disturbing effect that the capillary tubing would have on stirring processes and on the optical system..

Only two experiments remain to be mentioned specifically, runs 10 and 15. These were carried out to show that rigorous exclusion of oxygen had no appreciable effect on the rate of isomerization. In these experiments a solution of *cis*-dichloroethylene and iodine in benzene was put into the reaction vessel, part of the solution was boiled off, the remainder was frozen while being pumped on by a vacuum pump, and then the system was sealed off. The mixture was melted and part of the solution was poured into a side arm which was then sealed off, the rest of the solution in the sealed-off reaction cell being used in the isomerization run. The solution in the side arm was analyzed colorimetrically and by a dielectric constant measurement to determine the initial iodine and dichloroethylene concentrations in the reaction cell.

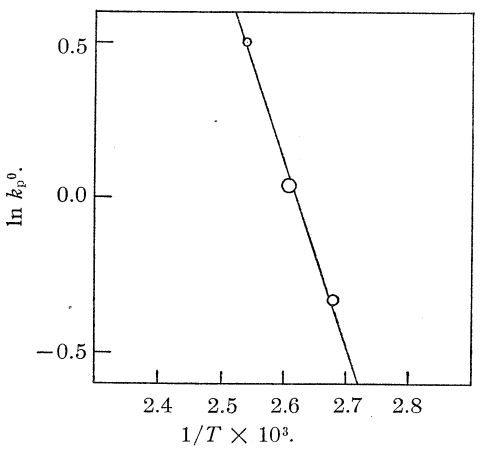

Fig. 6.—Temperature dependence of rate constants for pale iodine solutions.

In Fig. 6 in $k_p^0$ is plotted against $1/T$. $k_p^0$ is the experimental value of $k_p$ at the temperature in question extrapolated (Fig. 5) to zero iodine concentration. From the slope of this curve and a consideration of probable experimental errors the Arrhenius activation energy $Q_p$ of the photochemical iodine-sensitized isomerization can be estimated as $Q_p = 11{,}900 \pm 700$ cal. mole$^{-1}$ ($d \ln k_p^0/dT = Q_p/RT^2$). Wood and Dickinson[4c] give 31,200 cal. mole$^{-1}$ as the corresponding activation energy for the thermal iodine-catalyzed isomerization. The difference between these two quantities should be half the heat of dissociation of molecular iodine in these solutions. The difference is 19,300 cal. mole$^{-1}$. This is in good agreement with the value of 19,400 calculated by Dickinson and Lotzkar[4b] from the cinnamic acid isomerization data. Half the heat of dissociation of gaseous iodine, 18,100 cal. mole$^{-1}$ calculated[4b] from spectroscopic data may also be compared. The similarity of this last figure to the 19,300 calculated from the thermal and photochemical rate experiments would seem to constitute evidence favoring an atom catalysis as distinguished from some other mechanisms which might be proposed and which would be compatible with the other experimental

facts. Other evidence against the ion catalysis possibility is mentioned by Wood and Dickinson.

## Summary

The photochemical iodine-sensitized *cis–trans* isomerization of dichloroethylene in benzene solutions has been studied. Isomerization rates have been measured for various light intensities, iodine concentrations, temperatures, and area of glass surface in contact with the solution. The results indicate that the reaction is homogeneous under the experimental conditions and that a mechanism involving catalysis of the isomerization by iodine atoms is probable.

A value for the activation energy of this photochemical reaction has been calculated from the results of these experiments.

# Effect of Structure on Reactivity.[1] II. Influence of Solvents on Ammonolysis of Esters

BY MAXWELL GORDON,[2] JOHN G. MILLER AND ALLAN R. DAY

In the first investigation of this series[3] the electron release effects of alkyl and aryl groups in the ammonolysis of esters were studied. All of the reaction media employed contained about 18% water because it had been found that most esters will not react appreciably with ammonia in anhydrous dioxane or methanol over a period of several weeks at room temperature. The question of the effect of water on the ammonolysis of esters is subject to more difference of opinion[4] than any other phase of this work. On the basis of the references cited,[4] the work in this paper probably offers the first general method for the ammonolysis of esters in the absence of water.

From the earlier investigations and from the work in this laboratory, it may be stated that in general simple esters will not react with ammonia at a useful rate in anhydrous media. The notable effect of water on the rate of ammonolysis suggested that the use of hydroxylated organic solvents might also promote the ammonolysis of esters. Investigation of a series of such solvents has shown this assumption to be correct. Certain of the glycols and related compounds were found to be more effective than water. Furthermore, the results show the same qualitative structure–reactivity correlations as those reported in the first paper[3] for aqueous solutions.

## Experimental

The experimental method employed for ammonolysis in this investigation was identical with that used in the first paper of this series.[3] At this point in the work it became apparent that the choice of dioxane as a diluent was particularly fortunate, since it was found that ammonolysis proceeds more slowly in dioxane than in any other solvent tested. On this account dioxane could reasonably be used as a diluent in evaluating the catalytic effects of other solvents.

In addition to the compounds used in the previous work,[3] the following were employed: ethylene glycol, b.p. 72° at 1 mm., $n^{20}$D 1.4316; diethylene glycol, 101° at 1 mm., 1.4472 at 20°; trimethylene glycol, 88° at 1 mm., 1.4398 at 20°; ethylene glycol monomethyl ether, 43° at 20 mm., 1.4074 at 20°; diethylene glycol monomethyl ether, 68° at 1 mm., 1.4264 at 27°; glycerol, 1.4729 at 20°; propylene glycol, 65° at 1 mm., 1.4293 at 27°; ethylene glycol monoacetate, 61° at 1 mm., 1.4278 at 20°; 1,3-butanediol, 74° at 0.5 mm., 1.4410 at 20°; isobutylene glycol, 58° at 1 mm., 1.4350 at 20°. The anhydrous ammonia used was controlled with a steel needle valve and metered by means of a bubble counter.

## Results

The promoting effect of water on the ammonolysis of ethyl acetate was found to be dependent on its concentration. Thus with no water present there was no measurable ammonolysis in 400 hours, with 5 moles of water/l. the rate constant was 0.000220 l. mole$^{-1}$ hour$^{-1}$, with 10 moles of water/l., 0.000450, and with 20 moles of water/l., 0.000750. The concentration of ammonia was 0.809–1.172 moles/l. The lack of ammonolysis in the anhydrous diluent (dioxane) is notable. Further preliminary measurements revealed that other solvents similarly showed an increase in rate of ammonolysis beyond the point where the ammonia–catalyst ratio is 1:1. Other solvents tried were methanol, *t*-butanol, ethylene glycol and glycerol.

Because of the striking effects of the various

solvents used in the preliminary work and in view of the desirability of making the comparisons on the basis of the number of moles of solvent added, the experiments summarized in Table I were performed. Here, in the ammonolysis of methyl acetate, the data shown are for systems containing ten moles of water/l. in each case and five moles of additional solvent. In all instances the reaction mixtures were made up to volume with dioxane. The use of water was required because some of the solvents will not promote ammonolysis in the absence of water. The particular sample in which water was the additional solvent contained, of course, a total of fifteen moles of water/l.

In these experiments the rate constants were measured over rather long periods of time and, in general, showed a slight decrease as the reaction progressed, similar to the behavior reported in the previous investigation.[3] For comparison of the catalytic effects of the solvents, Table I lists the rate constants at the half-time in each case.

The order of listing in this table shows the relative catalytic effects of the solvents. Similar results were obtained in the ammonolysis of ethyl acetate, methyl benzoate and methyl lactate.

The values for per cent. ammonolysis for most of the experiments summarized in Table I are plotted against time in Fig. 1. Two of the curves 6 and 10, are important reference curves, the latter representing the behavior of the system containing the same constituents as all the rest, without any additional solvent, while the former shows the effect of additional water. Between these curves are found those of all the solvents which have a lower catalytic effect, mole for mole, than water. It is in these solvents that ammonolysis would not be expected to proceed appreciably in the absence of water. This conclusion was verified experimentally when ammonolysis failed to take place in anhydrous methanol or *t*-butanol.

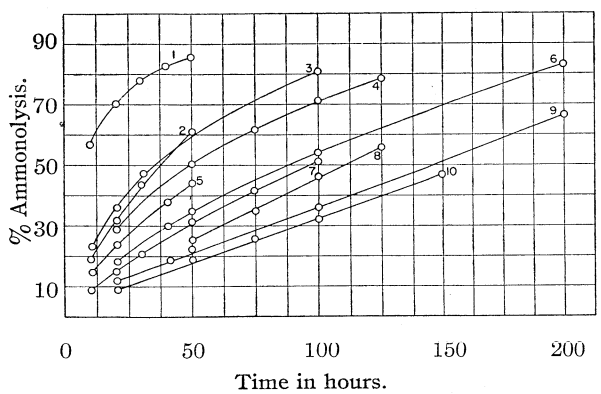

Fig. 1.—Effect of additional solvent on the ammonolysis of methyl acetate: 1, glycerol; 2, diethylene glycol; 3, ethylene glycol; 4, propylene glycol; 5, diethylene glycol monomethyl ether; 6, water (15 moles/l.): 7, ethylene glycol monoethyl ether; 8, *t*-butanol; 9, methanol; 10, water (10 moles/l.) All concentrations are 5 moles/l. with the exception of water.

TABLE I

EFFECT OF ADDITIONAL SOLVENT ON AMMONOLYSIS[a] OF METHYL ACETATE AT 30°

| Additional solvent | *k* | Additional solvent | *k* |
|---|---|---|---|
| None | 0.0014 | Water | 0.00391 |
| Methanol | .00172 | Diethylene glycol–monomethyl ether | .00527 |

| Isobutylene glycol | .0038 | | |

[a] Concentration of ester 0.7 mole/l., concentration of ammonia 2.463–2.537 moles/l.

Of course, ammonolysis of most esters would not be anticipated in anhydrous dioxane since replacement of a portion of dioxane by any of the other solvents tested resulted in an increase in rate, thus showing dioxane to be at the bottom of the scale of catalytic activity. Ethylene glycol monoethyl ether and trimethylene glycol lie below the level of water in catalytic activity, but are so close to it that they would be expected to promote ammonolysis in the absence of water. This conclusion was verified experimentally. All of the solvents corresponding to the curves above that of 15 moles of water/l. would be expected to promote ammonolysis readily in the absence of water, and this was found to be the case.

To corroborate the results shown in Table I and Fig. 1, the ammonolysis of methyl acetate was studied in the following anhydrous solvents at 30°: ethylene glycol, diethylene glycol, propylene glycol and trimethylene glycol. The concentration of ester was 0.7 mole/l. and that of the ammonia was 2.52 to 2.61 moles/l. Due to the high viscosity of these glycols, the experimental error was higher than in the experiments in which dioxane or alcohol diluent was used and the downward drift of the constants was slightly more pronounced. For this reason, only the values of the reaction constants measured at twenty hours reaction time are reported here: 0.0421, 0.0286, 0.0175, and 0.00216 l. mole$^{-1}$ hour$^{-1}$, respectively.

A more complete representation of the experiments is shown in Fig. 2 where the per cent. ammonolysis in each case is plotted over a period of time. This graph shows the variety of solvents in which ammonolysis can take place under anhydrous conditions. These results verify the prediction made in discussion of Table I, that solvents which exert a catalytic activity in the ammonolysis of esters equal to or greater than that of water would cause ammonolysis to proceed in

the absence of water. The relative catalytic effects of these anhydrous solvents follow the same order as that found with ten moles of water/l. present in each case.

The effect of sodium hydroxide on the ammonolysis of methyl acetate at 30° is shown by the two experiments reported in Table II. The concentration of sodium hydroxide was 0.07 mole/l. in one run, and the base was absent in the other. Ten moles of water/l. was present in each case. Dioxane was used as the diluent. The application of the second analytical method for ammonia described earlier[3] showed that about 50% of the ester was hydrolyzed. Without additional comment at this point, we note that the extent of hydrolysis prevents practical application of the use of sodium hydroxide in ammonolysis.

| *t*-Butyl lactate | .016 |

[a] Concentration of ester 0.7 mole/l., concentration of ammonia 2.458 moles/l. [b] Inserted for comparison with *n*-butyl lactate.

Table VI lists similar data, using the rate for methyl acetate as unity, for the ammonolysis of methyl esters of various acids in anhydrous ethylene glycol. It should be noted that in the case of methyl crotonate principally addition to the double bond, with very little ammonolysis, took place. These results confirm those obtained in aqueous dioxane solution.[3]

In the ammonolysis of four homologous series of esters in anhydrous ethylene glycol the same general effects were noted as were observed earlier in aqueous dioxane–ammonia solutions.[3] Of course, most of the esters ammonolyzed much

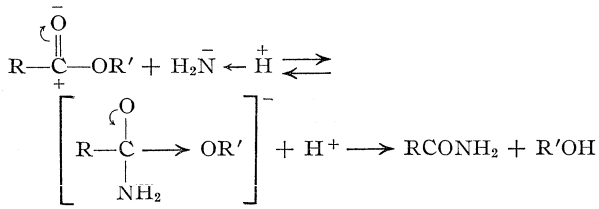
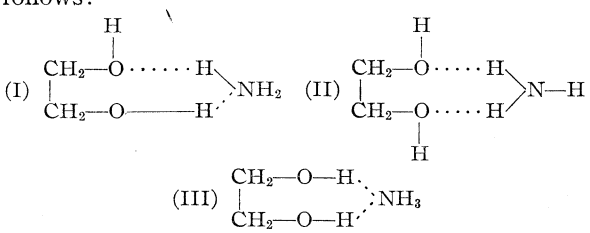
more rapidly in ethylene glycol solution than in aqueous dioxane. The only characteristic feature about the ammonolysis of esters in anhydrous ethylene glycol (Tables III, IV, V and VI) was the much smaller difference in reactivity between the different esters. While ammonolysis in anhydrous ethylene glycol has excellent possibilities for the preparation of amides, it should not be used in comparative studies without using a diluent such as dioxane to avoid the manipulative difficulties in working quantitatively with viscous solutions.



## Discussion

The mechanism of activation of the ammonia pictured earlier for water[3] is probably also in effect

with the alcohols. While the free amide ion is not postulated in any case, polarization of the hydrogen–nitrogen bond in the case of water and some of the other solvents is sufficient to make the ammonia molecule more reactive as a nucleophilic agent.



The effect of sodium hydroxide on the ammonolysis of methyl acetate (Table II) is strong evidence for the mechanism of ammonolysis involving addition of an amide ion, rather than molecular ammonia.

The presence of hydroxyl ions would favor the formation of amide ions and the precipitous initial rate of ammonolysis in sodium hydroxide solution bears this out. The rate constants drop off after 10% reaction. This would be expected from the low concentration of sodium hydroxide used and its consumption by the competing hydrolysis.

The catalysis by water and the other solvents continues increasingly even beyond the point where there is a 1:1 ratio of solvent to ammonia. This points to the association of only a fraction of the solvent molecules with ammonia. It is difficult, therefore, to assign a specific structure to the ammonia–solvent complex in most cases. However, for purposes of discussion of relative effects, a simple addition complex involving one molecule of ammonia and one of solvent will be considered.

In view of the results obtained for the ammonolysis of esters in various media a cyclic structure for the complex of ammonia with ethylene glycol, one of the most active of catalysts, seems probable. The three possible structures for this hydrogen-bonded complex are as follows:

In formula (I) for this complex the two hydrogen bonds are probably of unequal strength. Spectroscopic evidence has been found by Gordy[5] for this conclusion. In his studies Gordy used methanol containing a deuterium atom in the hydroxyl group, and he measured the shift in O–D infrared absorption as a result of hydrogen bonding to various compounds. From these data he concluded that the acceptor properties of the amine hydrogen are much weaker than those of the hydroxyl hydrogen. Huggins[6] has likewise emphasized the improbability of strong hydrogen bonds being formed through an amine hydrogen. From these investigations it is apparent that the N–H · · · · O bond is weaker than the N · · · · H–O bond in Formula I.

Formula II of the ammonia–ethylene glycol complex, although present in smaller amounts than Formula I due to its weak bonds, is probably the more active in ammonolysis because it contains two N–H · · · · O bonds which are the ones making a $NH_2^-$ ion available. However, a strong bond is not necessary to implement the mechanism of ammonolysis. All that is needed is an attractive force which will polarize the covalent nitrogen–hydrogen bond sufficiently. In form (II) both hydrogen–nitrogen bonds involved would be weakened somewhat, and it is statistically possible for fission of either bond to occur upon approach of the nitrogen to the carbonyl carbon of the ester.

In ammonolysis it is not necessary to postulate that the nitrogen–hydrogen bond breaks before the nitrogen–carbon bond is formed. These

(5) Gordy, *J. Chem. Phys.*, **7**, 93 (1939).

(6) Huggins, *J. Org. Chem.*, **1**, 407 (1936).

bonds could be broken and formed simultaneously,[7] after the nucleophilic center in the ammonia complex and the electrophilic center of the ester have approached one another through the action of electrostatic forces or by random motion.

An additional form of the ammonia–ethylene glycol complex may be drawn (III), but it was ruled out for two reasons: first, because it is difficult to see how it could contribute to the formation of potential amide ions and, second, because of the unlikelihood of two hydrogen bonds forming on a single nitrogen. In this connection Huggins[6] has stated that attempts to find two O–H $\cdots$ N bridges to the same nitrogen were unsuccessful.

The reasons for the postulate of a cyclic and not a linear hydrogen bonded ammonia–solvent complex are obvious from the data. The monohydric alcohols, for which no simple cyclic hydrogen bonded structure is possible, show a comparatively low order of catalytic activity. The 1,2-glycols and glycerol, on the other hand, exhibit an increase in catalytic effect that is far out of proportion to the additional molecular concentration of hydroxyl groups introduced. For example, the rate of ammonolysis of methyl acetate in the presence of 5 moles of ethylene glycol/l. is over five times the rate in a similar molecular concentration of methanol. The disproportionate increase in the catalytic activity of glycerol over ethylene glycol is probably due to the combination of inter- and intramolecular hydrogen bonded complexes with ammonia which are possible.

Trimethylene glycol, which differs from ethylene glycol only by one $CH_2$ group, has a catalytic activity only one-third that of ethylene glycol. Similarly 1,3-butanediol has a much lower order of catalytic activity than would be anticipated. In fact, on the basis of equivalent molecular concentrations of hydroxyl groups, the catalytic activity of these 1,3-glycols is of the order of magnitude of methanol. This phenomenon points very strongly to a structure like (II), containing a seven-membered ring, for the ethylene glycol–ammonia complex. A similar structure for trimethylene glycol or 1,3-butanediol would require an eight-membered ring, which is less likely on steric grounds. Wall and Claussen have stated,[8] on the basis of spectrographic evidence, that the most stable rings involving hydrogen bonds contain six or seven atoms, including the hydrogen. These numbers are greater by one than those usually given for rings involving only ordinary electron pair types of bonds.

Substitution of one of the hydrogens in ethylene glycol by an ethyl group reduced the catalytic activity in ammonolysis to one-third of the former value. The fact that ethylene glycol was three times as effective as ethylene glycol monoethyl ether indicates that the hydroxyl oxygen is much more effective in promoting hydrogen bonding, and hence ammonolysis, than the ether oxygen. Independent confirmation for these results was obtained by Gordy[9] from measurements of the shift in the infrared absorption spectra of hydroxyl groups. The shift in the oxygen–deuterium absorption maximum of $CH_3OD$ was more than twice as great in propylene glycol as in dioxane.

Gordy further stated that a cyclic ether is not as effective an electron donor solvent as an open chain ether. Errera[10] and Freymann[11] similarly commented on the comparatively low associating ability of dioxane. Their observations corroborate the results of this laboratory on the very low order of catalytic activity of dioxane. In this particular instance there is the additional steric factor which makes ring formation, involving the two ether oxygens of dioxane, improbable.

From all of the foregoing experiments we may generalize that the grouping –O–C–C–O– is the basic one involved in most of the pronounced catalytic effects noted in this study. If the groups attached to the terminal ends of the oxygens are hydrogens, the greatest activity is observed. Conversion of the hydroxyl oxygens to ether oxygens reduces the catalytic activity, particularly if the ether grouping is part of a ring. In diethylene glycol, which was found to have the same catalytic effect on ammonolysis as ethylene glycol, two hydroxyl groups are present, but they are separated by five atoms, the center one being an ether oxygen. In this molecule the possibility of bonding of ammonia to either half of the molecule increases its catalytic activity to the point where it equals that of ethylene glycol.

The catalytic activity of diethylene glycol monomethyl ether was about half that of diethylene glycol, showing again the reduced catalytic activity of the ether oxygen when compared with the hydroxyl oxygen. However, diethylene glycol monomethyl ether showed about 55% greater catalytic activity than ethylene glycol monoethyl ether, indicating that the ether oxygen must make some contribution, if a small one, to the catalytic activity of the solvent.

On the basis of the relative catalytic effects of methanol and *t*-butanol on the ammonolysis of esters, it might be anticipated that propylene glycol, containing a secondary alcohol group, would show a greater catalytic activity than ethylene glycol. A similar conclusion might be reached for the relative catalytic effects of trimethylene glycol and 1,3-butanediol, or ethylene glycol and isobutylene glycol.

In this Laboratory the catalytic effect of propylene glycol was found to be 40% less than that of ethylene glycol. Empirical confirmation for these

(11) Freymann, *Compt. rend.*, **204**, 41 (1937).

results can be obtained from the work of Gordy and Stanford[12] and Wall and Claussen.[8] These investigators found that there was no intramolecular hydrogen bonding in ethylene glycol, while in propylene glycol the internal association was noted in the shift in the oxygen–deuterium absorption band. Therefore these investigators concluded that ethylene glycol shows a greater proton attracting ability than propylene glycol.

Similarly, it was found in this Laboratory that ethylene glycol had greater catalytic activity in ammonolysis than isobutylene glycol, and it was ound that the effect of trimethylene glycol was greater than 1,3-butanediol. From all of these results on glycols a generalization is apparent. All symmetrical glycols have a greater catalytic activity in ammonolysis than the corresponding unsymmetrical glycols due to the presence of intramolecular hydrogen bonding in the latter. Thus: $CH_2OHCH_2OH > CH_3CHOHCH_2OH > (CH_3)_2COHCH_2OH$, and $CH_2OHCH_2CH_2OH > CH_3CHOHCH_2CH\ OH$. In other words, in unsymmetrical glycols the intramolecular hydrogen bonding results in a reduced over-all ability to associate with ammonia or other compounds. The more basic an atom, the more readily it acts as an acceptor for hydrogen; the more acidic the atom, the more readily it acts as a proton donor. Therefore in a glycol the greater the difference in electronegativities of the oxygens, the greater will be the intramolecular hydrogen bonding. The relative effects of ethylene glycol, propylene glycol, and isobutylene glycol, noted above, agree with these predictions. Wall and Claussen[8] postulated intramolecular hydrogen bonding in propylene glycol, in preference to intermolecular bonding, because of the small change in the frequency of hydroxyl absorption encountered upon dilution o' carbon tetrachloride solutions of propylene glycol.

Consideration was given the possibility that catalysis of the ammonolysis of esters by ethylene glycol takes place through ester interchange.

(1) $CH_3COOCH_3 + CH_2OHCH_2OH \longrightarrow CH_3COOCH_2CH_2OH + CH_3OH$

(2) $CH_3COOCH_2CH_2OH + NH_3 \longrightarrow CH_3CONH_2 + CH_2OHCH_2OH$

Demonstration that either of these two steps proceeds more slowly than the ammonolysis of methyl acetate in the presence of ethylene glycol rules out the mechanism involving ester interchange. The first of these steps was too difficult to study experimentally. The second step was followed experimentally, and the ammonolysis of β-hydroxyethyl acetate ($k = 0.00700$) was found to proceed more slowly than the ammonolysis of methyl acetate ($k = 0.0100$) in the presence of ethylene glycol. In addition, the ammonolysis of β-hydroxyethyl acetate was much slower in ethylene glycol than would be anticipated in comparison with other esters.

It should not be inferred from the above discussion that a sharp demarcation exists between those solvents which catalyze ammonolysis in the absence of water and those which do not. On the basis of experimental evidence the ammonolysis of all esters may be said to proceed in all solvents although the extent of reaction in some cases is too small to be measurable with any degree of accuracy. Justification for this statement is found in the behavior of phenyl acetate in various ammonia solutions. Phenyl acetate ammonolyzed completely in the presence of water in about half an hour. This ester was then shown to undergo ammonolysis almost completely in anhydrous dioxane or alcohol in about twenty-four hours. In comparison, the ammonolysis of methyl acetate takes place to the extent of only a few per cent. in anhydrous dioxane or alcohol over a period of three months. The magnitude of the experimental error involved in working with anhydrous solutions of alcohol or dioxane, particularly the latter, is so great that the results are of value in qualitative comparisons only. Experimental error in these cases is due to the low solubility o' ammonia in these solvents, and to the volatility of the solvents themselves.

**Acknowledgment.**—The authors wish to express their thanks to the following companies for supplying solvents used in this study: Carbide and Carbon Chemicals Corporation, Eastman Kodak Company, Shell Development Company, and Joseph E. Seagram and Sons, Inc.

## Summary

A general method has been developed for the ammonolysis of esters in the absence of water.

The catalytic effect of water and other solvents on the ammonolysis of esters has been found to increase with concentration, even beyond the point where the ammonia–catalyst ratio is 1:1.

The relative catalytic effects of solvents on the ammonolysis of esters has been investigated and the following order of reactivity was determined: glycerol > ethylene glycol, diethylene glycol > propylene glycol > diethylene glycol monomethyl ether > water > isobutylene glycol > ethylene glycol monoethyl ether > trimethylene glycol > 1,3-butanediol > *t*-butanol > methanol > dioxane.

A mechanism has been postulated for the ammonolysis of esters in various solvents.

# 1,4 Addition Reactions. III. The Addition of Cyclic Imides to α,β-Unsaturated Aldehydes. A Synthesis of β-Alanine Hydrochloride[1]

BY OWEN A. MOE AND DONALD T. WARNER

Previous publications[2,3] from this Laboratory have disclosed the 1,4 addition of malonate systems to acrolein. Since the 1,4 addition of imides to α,β-unsaturated aldehydes has not been reported, this paper describes the reaction of cyclic imides, such as phthalimide and succinimide with acrolein and alkyl substituted acroleins such as, methacrolein (α-methylacrolein) and crotonaldehyde.

The addition reactions involving phthalimide and acrolein, methacrolein and crotonaldehyde proceeded smoothly in the presence of a minute quantity of alkaline catalyst to yield the aldehydo compounds I, II and III, respectively. The adducts were characterized as the phenylhydrazones and the 2,4-dinitrophenylhydrazones.

Radde[4] attempted the preparation of phthalimidopropionaldehydes by the reduction of the corresponding acid chlorides. However, Radde observed that this reduction reaction was only applicable for the α-phthalimido acid chlorides and not for the β, γ and δ compounds.

The 1,4 addition of succinimide to acrolein, methacrolein and crotonaldehyde yielded the aldehydo compounds IV, V and VI, respectively.

The crude reaction products from the succinimide series were obtained in good yields, but they were liquids which resisted crystallization or distillation. Therefore, it was necessary to determine the proportion of the aldehydo compounds (1,4 addition products) by other methods. This was accomplished by means of derivative formation and reduction experiments. Some of the aldehydo derivatives were obtained in yields in excess of 80%. It was observed that the lowest yield of derivative occurred when crotonaldehyde was used as the unsaturated aldehyde.

If 1,2 addition had occurred, the presence of unsaturation in the reaction product could be readily determined by low pressure hydrogenation employing palladium on charcoal as the catalyst. In an experiment designed to determine this possibility (using methacrolein–succinimide reaction product) it was found that less than 5% of the theoretical amount of hydrogen had been consumed after one hour. However, when acetic acid, ethyl cyanoacetate and piperidine[5] were added to the same reaction mixture, and hydrogenation was resumed, 67% of the theoretical amount of hydrogen was taken up in one hour, indicating the predominant presence of the aldehydo compound.

The reduction of the crude α-methyl-β-succinimidopropionaldehyde in the presence of Raney nickel catalyst yielded 2-methyl-3-succinimido-1-propanol VII which in turn was characterized as the crystalline 3,5-dinitrobenzoate melting at 104–105°.

Oxidation by permanganate of β-phthalimidopropionaldehyde I yielded β-phthalimidopropionic acid VIII which was identical with an authentic sample. The substituted propionic acid was readily converted to β-alanine hydrochloride by means of acid hydrolysis.

Permanganate oxidation of β-succinimidopropionaldehyde IV yielded β-succinimidopropionic acid IX melting at 131–132°.

## Experimental

**β-Phthalimidopropionaldehyde, I.**—Phthalimide (44.1 g.) was added to an alcoholic solution containing 110 cc. of absolute ethanol and 0.15 g. of sodium. The resulting reaction mixture was stirred at room temperature and the greater portion of the phthalimide remained suspended in the reaction mixture. A solution containing 25 cc. of acrolein and 15 cc. of absolute ethanol was added dropwise over a twenty-minute period and the reaction temperature increased to 51°. The reaction mixture was stirred for an additional half hour when a substantially clear solution resulted. After standing overnight, the re-

action mixture was neutralized by the addition of the requisite quantity of glacial acetic acid. After filtration, the ethanol was removed by distillation under reduced pressure, yielding a viscous oil. Benzene (100 cc.) was added and the concentration *in vacuo* was repeated, yielding a semi-solid residue. The addition of benzene (100 cc.) yielded a pasty solid which was collected by filtration. Sixteen grams were obtained melting at 108–115°, and concentration of the filtrate yielded an additional quantity of solid which was not investigated further. Since this crude product proved difficult to purify by crystallization, a portion of it was placed in a round bottom flask and heated in an oil-bath under reduced pressure (15 mm.) until a clear melt was obtained. Fine needle-like crystals collected on the cool sides of the flask. These crystals melted at 119–120°.

*Anal.* Calcd. for $C_{11}H_9O_3N$: C, 65.02; H, 4.43; N, 6.90. Found: C, 65.20; H, 4.34; N, 7.03.

The phenylhydrazone melted at 121.5–122.5° after crystallization from ethanol.

*Anal.* Calcd. for $C_{17}H_{15}O_2N_3$: C, 69.60; H, 5.15; N, 14.33. Found: C, 69.41; H, 5.15; N, 14.73.

The 2,4-dinitrophenylhydrazone melted at 209–210° after crystallization from aqueous acetone.

*Anal.* Calcd. for $C_{17}H_{13}O_6N_5$: C, 53.26; H, 3.42; N, 18.28. Found: C, 53.24; H, 3.55; N, 18.33.

**α-Methyl-β-phthalimidopropionaldehyde.**—Phthalimide (14.7 g.) was suspended in an alcoholic solution consisting of 110 cc. of absolute ethanol and 0.04 g. of sodium. Methacrolein (7.4 g.) was added dropwise with no apparent increase in the reaction temperature. Reaction mixture was heated at 40–50° for a period of two hours when a substantially clear solution resulted. After neutralization, the ethanol was removed by concentration *in vacuo* and 21.3 g. of the reaction product resulted as an oil.

The crude phenylhydrazone was obtained in 80% yield and melted at 116–119°. An analytical sample was prepared by crystallization from ethanol and it melted at 119–121°.

*Anal.* Calcd. for $C_{18}H_{17}O_2N_3$: C, 70.35; H, 5.58; N, 13.68. Found: C, 69.88; H, 5.38; N, 13.63.

The crude 2,4-dinitrophenylhydrazone (70%) melted at 184–187°. An analytical sample which melted at 193–194° was prepared by crystallization from ethanol–acetone (50–50).

*Anal.* Calcd. for $C_{18}H_{15}O_6N_5$: N, 17.63. Found: N, 17.68.

**β-Methyl-β-phthalimidopropionaldehyde.**—This reaction was accomplished essentially as described in the previous case employing recrystallized phthalimide (29.4 g.) and freshly redistilled crotonaldehyde (15.66 g.). The reaction product (42 g.) was a brown pasty solid melting at 93–103°. A portion of this solid was recrystallized three times from Skelly C and melted at 105–108°.

*Anal.* Calcd. for $C_{12}H_{11}O_3N$: C, 66.36; H, 5.1; N, 6.4. Found: C, 66.62; H, 5.1; N, 6.6.

The crude phenylhydrazone (45%) melted at 98–100°. Purification by crystallization from ethanol yielded an analytical sample melting at 98–99°.

*Anal.* Calcd. for $C_{18}H_{17}O_2N_3$: C, 70.35; H, 5.58; N, 13.68. Found: C, 70.21; H, 5.60; N, 13.88.

The crude 2,4-dinitrophenylhydrazone (40%) melted at 170–172°. Recrystallization from acetone yielded an analytical sample melting at 180.5–181°.

*Anal.* Calcd. for $C_{18}H_{15}O_6N_5$: C, 54.4; H, 3.8; N, 17.6. Found: C, 54.63; H, 3.9; N, 17.84.

**β-Succinimidopropionaldehyde, II.**—Succinimide[6] (29.7 g.) was added to an alcoholic solution containing 50 cc. of absolute ethanol and 0.05 g. of sodium. The resulting suspension was cooled to 6° in an ice-bath. The cooling bath was removed and acrolein (16.8 g.) was added dropwise. The reaction temperature increased very rapidly to 31° and this temperature was maintained by varying the rate of addition of the acrolein. After the addition of the aldehyde was complete, the reaction mixture was stirred for an additional thirty-five minute period when a clear, water-white solution resulted. After standing for two and a half hours, the reaction mixture was neutralized with glacial acetic acid. Concentration *in vacuo* yielded a very viscous oil (44.3 g.) which resisted crystallization.

A portion of the crude aldehydo compound yielded a semicarbazone (75%) melting at 189–193°. An analytical sample was prepared by two crystallizations from aqueous ethanol and it melted at 201–202.5°.

*Anal.* Calcd. for $C_8H_{12}O_3N_4$: C, 45.3; H, 5.7; N, 26.4. Found: C, 45.34; H, 5.56; N, 26.64.

The *p*-nitrophenylhydrazone (61%) melted at 213–215°. After purification by crystallization from ethanol–acetone, it melted at 221–223°.

*Anal.* Calcd. for $C_{13}H_{14}O_4N_4$: C, 53.8; H, 4.8; N, 19.3. Found: C, 53.5; H, 4.8; N, 19.45.

The 2,4-dinitrophenylhydrazone (60% crude) melted at 183.5–184.5° after crystallization from 50 volume % ethanol–acetone solution.

*Anal.* Calcd. for $C_{13}H_{13}O_6N_5$: C, 46.56; H, 3.9; N, 20.89. Found: C, 47.05; H, 4.34; N, 20.68.

**α-Methyl-β-succinimidopropionaldehyde, V.**—Succinimide (9.9 g.) was added to an alcoholic solution containing 55 cc. of absolute ethanol and 0.05 g. of sodium. Methacrolein (7.04 g.) was added dropwise and the reaction temperature increased from 20 to 31°. The resulting clear reaction mixture was stirred for three hours and then neutralized with glacial acetic acid. Concentration *in vacuo* yielded 15.8 g. of an oily product which resisted crystallization.

The 2,4-dinitrophenylhydrazone which was obtained in 86% yield melted at 196.5–197° after crystallization from acetone.

*Anal.* Calcd. for $C_{14}H_{15}O_6N_5$: C, 48.13; H, 4.32. Found: C, 48.52; H, 4.59.

The *p*-nitrophenylhydrazone (80%) melted at 184–185° after crystallization from acetone.

*Anal.* Calcd. for $C_{14}H_{16}O_4N_4$: C, 55.26; H, 5.3; N, 18.42. Found: C, 55.22; H, 5.3; N, 18.42.

**Low Pressure Reduction of Reaction Product, V.**—The above crude reaction product (15.4 g.) was dissolved in 60 cc. of ethanol. Palladium on charcoal (0.5 g.) was added and the reduction was carried out at initial pressure of 32.5 pounds of hydrogen. After one hour, less than 5% of the theoretical amount of hydrogen had been consumed. The attempted reduction was interrupted at this point and 1 cc. of glacial acetic acid, 11.3 g. of ethyl cyanoacetate and 0.4 g. of piperidine were added. The reduction was again resumed at 32 pounds pressure. After one hour, 67% of the theoretical amount of hydrogen had been consumed. No attempt was made to characterize this simultaneous condensation–reduction product.

**2-Methyl-3-succinimido-1-propanol, VII.**—The crude β-methyl-β-succinimidopropionaldehyde (12.5 g.) was dissolved in 75 cc. of absolute ethanol. Raney nickel catalyst was added and the reduction was carried out at 70–80° at an initial pressure of 800 pounds of hydrogen. When the reduction was complete, the catalyst was removed by filtration and the filtrate was concentrated *in vacuo*. A light yellow viscous oil resulted. The crude carbinol (1.9 g.) was mixed with 3,5-dinitrobenzoylchloride in a conventional manner. The resulting 3,5-dinitrobenzoate (0.93 g.) melted at 104–105° after crystallization from ethanol.

*Anal.* Calcd. for $C_{15}H_{15}O_8N_3$: C, 49.32; H, 4.14; N, 11.50. Found: C, 49.84; H, 4.23; N, 11.76.

**β-Methyl-β-succinimidopropionaldehyde, VI.**—This reaction was accomplished essentially as described in the

(6) The 1,4 addition reactions involving Eastman Kodak Co. White Label succinimide did not proceed under the reaction conditions described. This may be due possibly to the presence of acidic components; hence recrystallized succinimide was employed in all experiments.

previous case employing recrystallized succinimide (7.7 g.) and freshly redistilled crotonaldehyde (5.8 g.) and the reaction temperature increased from 28 to 34°. Concentration *in vacuo* yielded 12.8 g. of crude reaction product.

The crude aldehydo compound was converted to the 2,4-dinitrophenylhydrazone (40%) which melted at 165–166° after crystallization from an ethyl acetate–acetone solution.

*Anal.* Calcd. for $C_{14}H_{15}O_6N_5$: C, 48.13; H, 4.32; N, 20.06. Found: C, 48.35; H, 4.38; N, 20.32.

**Preparation of β-Succinimidopropionic Acid, IX.**—The crude β-succinimidopropionaldehyde (15.5 g., viscous oil) was dissolved in 30 cc. of warm water. Approximately 1.5 cc. of 10% aqueous sodium hydroxide solution was added, and the resulting solution was cooled to 8°. An aqueous solution of potassium permanganate consisting of 300 cc. of water and 10.5 g. of permanganate was added in portions. The temperature increased rapidly to 14° but was maintained at approximately 10° by continued cooling. After the oxidation was complete, the manganese dioxide was removed by filtration, and the excess permanganate was destroyed with dilute sodium bisulfite solution. The clear reaction solution was concentrated *in vacuo* yielding a viscous oil. The residual oil was extracted with ether, and after drying over anhydrous sodium sulfate the ether was removed by distillation. The residual oil rapidly crystallized on cooling and the crystalline product melted at 124–128°. Further extraction of the syrup with ethyl acetate gave additional crude product. The total yield (2.15 g.) was low. Recrystallization from absolute ethanol yielded needle-like crystals melting at 131–132°.

*Anal.* Calcd. for $C_7H_9O_4N$: C, 49.12; H, 5.30; N, 8.18; neut. equiv., 171. Found: C, 49.03; H, 5.34; N, 8.00; neut. equiv., 177.

**Conversion of β-Phthalimidopropionaldehyde to β-Alanine Hydrochloride.**—The crude β-phthalimidopropionaldehyde I was oxidized by permanganate essentially as discussed in the previous case. Concentration *in vacuo* yielded a white crystalline material which was collected by filtration, washed with water and dried. The N-phthalyl-β-alanine VIII thus obtained melted at 139–141°. Recrystallization from absolute ethanol increased the melting point to 141–142°. When the N-phthalyl-β-alanine was recrystallized from water, it melted at 149.5–151°. The melting point of the N-phthalyl-β-alanine was not depressed when mixed with an authentic sample.[7]

Two and five-tenths grams of the recrystallized N-phthalyl-β-alanine was refluxed with 25 cc. of 20% hydrochloric acid for a period of eighteen hours. Upon cooling, the phthalic acid crystallized from the reaction solution, and after filtration the filtrate was evaporated *in vacuo* to yield a crystalline residue. Recrystallization from isopropyl alcohol yielded β-alanine hydrochloride (0.51 g.) as fine needles melting at 120–121.5°. An additional crystallization increased the melting point to 121.5–123°.

## Summary

1. The 1,4 addition of cyclic imides, such as phthalimide and succinimide, to acrolein, methacrolein and crotonaldehyde has been described.

2. A new synthesis of β-alanine, using β-phthalimidopropionaldehyde as the starting material, has been described.

# Furan and Tetrahydrofuran Derivatives. X.[1] The Synthesis of the Sulfonic Acid Analogs of Oxybiotin and Homoöxybiotin

BY KLAUS HOFMANN, ANNA BRIDGWATER AND A. E. AXELROD[2]

In connection with our studies on the relationships of chemical structure and biological activity in the biotin and oxybiotin series,[3] it seemed desirable to replace the carboxyl group in *dl*-oxybiotin (I) by a sulfonic acid moiety and to test the biological activity of the resulting compound. Recently we have shown that *dl*-homoöxybiotin (II) has the ability to antagonize the growth-promoting effects of *dl*-oxybiotin for yeast. It was of interest to determine whether the sulfonic acid analog (IV) would possess greater antagonistic potency than homoöxybiotin (II). This communication describes the synthesis of the two sulfonic acids (III and IV). A brief account of the biological activities of these acids and of several of the intermediates obtained during their preparation will also be presented.

| (IV) | 5 | $SO_3H$ |

The methods used to prepare *dl*-hexahydro-2-oxo-4-(4-hydroxybutyl)-1-furo-(3,4)-imidazole (XIII), the key intermediate in the synthesis of III, were those recently developed in this Laboratory for the preparation of similar compounds.[3,4,5,6] Starting material for the present study was 2-furanpropanol (V)[3] which was transformed into 2-furanpropyl chloride (VI) by a modification of the procedure of Gilman.[7] This chloride, on treatment with potassium cyanide followed by hydrolysis, was converted into 2-furanbutyric acid (VII), which was then esterified. The resulting ethyl 2-furanbutyrate (VIII), upon reduction with sodium and alcohol, yielded the desired 2-furanbutanol (IX). Condensation of IX with diethylacetylenedicarboxylate, followed by partial hydrogenation and thermal decomposi-

(1) A preliminary report of some of the work herein described has appeared in THIS JOURNAL, **69**, 1550 (1947).

tion,[4,8] gave 3,4-dicarbethoxy-2-furanbutanol which was transformed into 3,4-dicarboxy-2-furanbutanol (XI) by alkaline hydrolysis. The acetate of XI, by a modified Curtius degradation,[6] was converted into 3,4-dicarbethoxyamino-2-furanbutanol (XII).

It should be noted that the transformation of a tri-substituted furan such as XII into the corresponding tetrahydro derivative creates three assymetric carbon atoms within the molecule, and four racemic 3,4-diamino-2-tetrahydrofuranbutanols may theoretically be expected. Stereochemically this situation parallels that of the 3,4-dicarbethoxyamino-2-tetrahydrofuranpentanols.[9] Catalytic hydrogenation of XII resulted in the formation of a mixture of reduction products, which were separated into an ether-soluble and an ether-insoluble fraction. The ether-insoluble material, containing the desired *cis*-3,4-dicarbethoxyamino-2-tetrahydrofuranbutanol, upon treatment with barium hydroxide[5] yielded a hexahydro-2-oxo-4-(4-hydroxybutyl)-1-furo-(3,4)-imidazole (XIII) which on the basis of evidence presented below has the same spatial configuration as *dl*-oxybiotin (I).

Treatment of XIII with thionyl chloride[3] gave the corresponding chloride (XIV), which upon reaction with potassium cyanide and hydrolysis was transformed into *dl*-oxybiotin (I). Therefore, derivatives which are prepared from XIII by modification of the side chain also have the same stereochemical configuration as *dl*-oxybiotin. Condensation in absolute alcohol of the chloride (XIV) with sodiobenzylmercaptide gave the benzyl thioether (XV), which upon reduction with sodium and alcohol was converted into the mercaptobutanol (XVI). Attempts to cleave the thioether (XV) with sodium in liquid ammonia failed, probably because of the insolubility of the compound in the liquid ammonia. Oxidation with dilute barium permanganate of the mercaptobutanol (XVI) gave the desired sulfonic acid (III) in excellent yield. Oxidation of XVI with bromine according to Levene[10] gave the same sulfonic acid in poor yields.

A similar series of reactions was used in the preparation of the sulfonic acid (IV). *dl*-Hexahydro-2-oxo-4-(5-chloropentyl)-1-furo(3,4)-imidazole (XVII),[3] through the benzyl thioether (XVIII), was converted into the mercaptopentanol (XIX), which on oxidation with barium permanganate yielded the desired sulfonic acid (IV). Both sulfonic acids were characterized in the form of their crystalline barium salts.

The microbiological activity of compounds III, IV, XV, XVI, XVIII and XIX was determined with *Lactobacillus arabinosus* and *Saccharomyces cerevisiae* as the test organisms. In conformity with earlier observations which showed that the substitution of carboxyl groups by sulfonic acid groups in biologically active molecules led to antagonists, the sulfonic acid analog of oxybiotin (III) was also found to possess antagonistic activity against *d*-biotin and *dl*-oxybiotin (molar-inhi-

(8) Hofmann, THIS JOURNAL, **66**, 51 (1944).

bition ratio[11] toward *d*-biotin and *dl*-oxybiotin for *S. cerevisiae* = 1,500,000 and 16,000, respectively).

Two intermediates in the synthesis of the sulfonic acid (III), namely, the benzyl thioether (XV) and the mercaptobutanol (XVI), proved to be rather active antagonists. Thus, compound XV possessed a molar-inhibition ratio toward *d*-biotin and *dl*-oxybiotin of 740,000 and 9,300, respectively, when *S. cerevisiae* was used as the test organism.

In contrast to *dl*-homoöxybiotin (II), which is an effective oxybiotin antagonist for yeast, the corresponding sulfonic acid analog (IV) possessed slight growth-stimulating activity both for *L. arabinosus* and *S. cerevisiae*. Compounds XVIII and XIX also had stimulatory activity for *L. arabinosus*. They were inhibitory, however, when tested with *S. cerevisiae*.

A complete description of the biological activities of the above compounds, especially their inhibitory action toward pathogenic organisms, will be published elsewhere.

## Experimental[12,13]

**2-Furanbutyric Acid (VII).**—To a three-neck flask, equipped with a dropping funnel and a stirrer with a mercury seal, were added 300 g. of 2-furanpropanol (V)[3] and 312 g. of dimethylaniline. The flask was cooled in an ice–salt-bath, and 306 g. of thionyl chloride in 180 cc. of dry chloroform was added dropwise with stirring. The inside temperature was kept at 0–10° throughout the operation. The mixture was stirred for one hour, poured on crushed ice, and extracted with chloroform. The chloroform extracts were washed with 2 *N* hydrochloric acid, water and 2 *N* potassium carbonate, and were dried over sodium sulfate. The solvent was removed *in vacuo*, and the residue on distillation yielded 218 g. (63% of the theoretical yield) of 2-furanpropyl chloride (VI) as a colorless liquid which boiled at 80–92° at 13 mm. To a solution of 71 g. of (VI) in 700 cc. of 95% alcohol, 36 g. of potassium cyanide dissolved in 75 cc. of water were added, and the mixture refluxed for twenty-two hours. The solution was concentrated to one-third of its volume, 215 cc. of 5 *N* potassium hydroxide was added, and refluxing was continued for nine hours. Most of the alcohol was removed by distillation and the solution was extracted with ether. It was then acidified with 18 *N* sulfuric acid to congo red and re-extracted with ether. The ether extracts were washed with water, dried over sodium sulfate, and the ether removed on the steam-bath. The residue, on distillation, yielded 46 g. (60% of the theoretical yield) of 2-furanbutyric acid as a colorless liquid which boiled at 94–117° at 0.03 mm.

*Anal.* Calcd. for $C_8H_{10}O_3$: C, 62.31; H, 6.54. Found: C, 62.53; H, 6.71.

**Anilide of 2-Furanbutyric Acid.**—A mixture of 3.0 g. of the above acid and 6.0 g. of freshly distilled aniline was heated to 170–175° for seventeen hours. The anilide was isolated in the usual manner, and was sublimed at 140° and 0.02 mm. Recrystallization of the sublimate from a mixture of petroleum ether and ether yielded shiny white crystals which melted at 62–64°.

*Anal.* Calcd. for $C_{14}H_{15}O_2N$: C, 73.31; H, 6.59; N, 6.11. Found: C, 72.81; H, 6.90; N, 6.03.

**2-Furanbutanol (IX).**—The furanbutyric acid (VII) (175 g.) was esterified with cold ethanolic hydrochloric acid and the ester isolated in the usual manner; 179 g. (87% of the theoretical yield) of ethyl 2-furanbutyrate (VIII), which boiled at 119–122° and 23 mm. was obtained. The ester (VIII) (60 g.) was reduced with sodium and ethanol as described previously,[4] and 36 g. (78% of the theoretical yield) of 2-furanbutanol was obtained as a colorless liquid which boiled at 115–117° at 18 mm.

*Anal.* Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.62. Found: C, 68.50; H, 8.25.

**α-Naphthylurethan of 2-Furanbutanol.**—This derivative was prepared in the usual manner and following recrystallization from a mixture of petroleum ether (b. p. 30–60°) and ether melted at 71–73°.

*Anal.* Calcd. for $C_{19}H_{19}O_3N$: C, 73.80; H, 6.19; N, 4.53. Found: C, 73.82; H, 6.16; N, 4.71.

**3,4-Dicarboxy-2-furanbutanol (XI).**—Fifty grams of 2-furanbutanol (IX) and 67 g. of diethylacetylene dicarboxylate were heated on the steam-bath overnight. The cooled mixture was dissolved in 300 cc. of ethyl acetate and hydrogenated at room temperature and atmospheric pressure in the presence of 8 g. of a palladium-on-barium sulfate catalyst[14] until one mole of hydrogen had been absorbed. The catalyst was removed by filtration, the ethyl acetate was evaporated *in vacuo*, and the residue heated to 190–200° at 16 mm. until the evolution of ethylene had ceased, and distilled *in vacuo;* 86.8 g. (86% of the theoretical yield), of 3,4-dicarbethoxy-2-furanbutanol (X) was obtained, which boiled at 156–161° at 0.02 mm. Saponification of the above material with a mixture of 500 cc. of methanol and 250 cc. of 5 *N* potassium hydroxide followed by acidification gave 67.3 g. (96% of the theoretical yield) of 3,4-dicarboxy-2-furanbutanol (XI) which was recrystallized from a mixture of methanol and ethyl acetate; m. p. 126–127°.

*Anal.* Calcd. for $C_{10}H_{12}O_6$: C, 52.63; H, 5.31. Found: C, 52.59; H, 5.54.

**3,4-Dicarboxy-2-furanbutanol Acetate.**—To 57.5 g. of 3,4-dicarboxy-2-furanbutanol (XI) in 235 cc. of dry pyridine was added slowly 150 cc. of acetic anhydride. After standing overnight, the solvents were removed *in vacuo*, the residue was dissolved in ethyl acetate, and the solution washed with 2 *N* hydrochloric acid and water, and extracted with several portions of 10% sodium bicarbonate. The combined bicarbonate extracts were acidified with concentrated hydrochloric acid to congo red and the desired compound re-extracted with ethyl acetate. The combined ethyl acetate extracts were washed with water, dried over sodium sulfate, and the solvent removed *in vacuo*. The crystalline residue of 3,4-dicarboxy-2-furanbutanol acetate was repeatedly washed with petroleum ether (b. p. 30–60°) and dried over phosphorus pentoxide; 61.3 g. (90% of the theoretical yield) of crystals was obtained, which upon recrystallization from ether melted at 89–90°.

*Anal.* Calcd. for $C_{12}H_{14}O_7$: C, 53.35; H, 5.22. Found: C, 53.04; H, 4.99.

**3,4-Dicarbethoxyamino-2-furanbutanol (XII).**—To a suspension of 50 g. of the above acetate in 250 cc. of dry ether was added, in small amounts, with cooling and shaking, a total of 87 g. of phosphorus pentachloride. Shaking was continued until most of the phosphorus pentachloride had disappeared, and the ether was removed *in vacuo* at a bath temperature of 95–100°. Dry benzene (100 cc.) was added to the residue with subsequent removal, and this procedure was repeated twice more. The residue was dissolved in 500 cc. of ether and stirred vigorously in an ice-bath for two hours with a solution of 48 g. of sodium azide in 130 cc. of water. The ether layer was separated, the aqueous layer reëxtracted with fresh ether, and the combined ether extracts washed with 10% sodium bicarbonate and water and finally dried over freshly desiccated sodium sulfate. The dried solution was filtered through a fluted

(11) The ratio of the molar concentration of the antagonist to that of *d*-biotin or *dl*-oxybiotin, at which *complete* inhibition of growth results.

(12) All melting points are corrected.

(13) The microanalyses were performed in our Microanalytical Laboratory by Mr. George L. Stragand.

(14) Schmidt, *Ber.*, **52**, 409 (1919).

filter filled with sodium sulfate, and the ether was removed *in vacuo* at a bath temperature of 20°. The resulting oily azide was dissolved in 500 cc. of absolute alcohol and decomposed under nitrogen as described in a previous communication.[15] The resulting solution was cooled to 0° and 370 cc. of *N* sodium hydroxide was added with stirring. After standing overnight the alcohol was removed *in vacuo*, the residue was diluted with water and extracted with ether. The ether extracts were washed with three 100-cc. portions of water, dried over sodium sulfate, and the solvent evaporated on the steam-bath. The oily residue crystallized on standing and gave 30 g. (52% of the theoretical yield) of ether-washed crystals which melted at 77–79°. No further purification was necessary for the next step. A sample for analysis was recrystallized from ether.

*Anal.* Calcd. for $C_{14}H_{22}O_6N_2$: C, 53.49; H, 7.05; N, 8.90. Found: C, 53.31; H, 6.75; N, 9.26.

***dl*-Hexahydro-2-oxo-4-(4-hydroxybutyl)-1-furo-(3,4)-imidazole (XIII).**—A solution of 50 g. of (XII) in 800 cc. of glacial acetic acid was hydrogenated at room temperature and atmospheric pressure in the presence of 75 g. of a palladium-on-barium sulfate catalyst[14] until 2 moles of hydrogen had been absorbed (reaction complete in approximately two hours). The catalyst was removed by filtration, the glacial acetic acid was evaporated *in vacuo*, and the residual oil dissolved in 100 cc. of ether. Washing of the ethereal solution with 100 cc. of 10% sodium bicarbonate resulted in the separation of an oily layer which contained the desired *cis* isomer of 3,4-dicarbethoxyamino-2-tetrahydrofuranbutanol. This oil was separated, dissolved in ethyl acetate, the solution dried over sodium sulfate, and the ethyl acetate removed *in vacuo*. A 10% solution of $Ba(OH)_2 \cdot 8H_2O$ (2.8 liters) was added to the residue and the mixture stirred at 90° for four hours. Isolation in the usual manner[3,6] gave 12 g. of crystals of XIII (37% of the theoretical yield) which upon recrystallization from dioxane melted at 156–157°.

*Anal.* Calcd. for $C_9H_{16}O_3N_2$: C, 53.98; H, 8.05; N, 13.99. Found: C, 54.12; H, 7.81; N, 13.80.

***dl*-Hexahydro-2-oxo-4-(4-chlorobutyl)-1-furo-(3,4)-imidazole (XIV).**—The butanol (XIII) (2 g.) was placed in a round-bottomed flask surrounded with ice, 5 cc. of ice-cold thionyl chloride was added at once and the solution was kept at room temperature for approximately twelve hours. The reaction product was isolated in the usual manner[3] and recrystallized from ethyl acetate; 1.33 g. (61% of the theoretical yield) of prisms melting at 124–126° was obtained.

*Anal.* Calcd. for $C_9H_{15}O_2N_2Cl$: C, 49.38; H, 6.90; N, 12.80; Cl, 16.22. Found: C, 49.16; H, 6.84; N, 12.54; Cl, 16.27.

***dl*-Oxybiotin (I).**—To a solution of 3.5 g. of the above chloride (XIV) in 100 cc. of 95% alcohol a solution of 2 g. of potassium cyanide in 4 cc. of water was added, and the mixture refluxed for twenty-four hours. The solvents were removed *in vacuo*, 1 *N* sodium hydroxide (100 cc.) was added to the residue, and refluxing continued for twelve hours. A slow stream of carbon dioxide was passed into the solution for thirty minutes and the resulting precipitate of silica removed by filtration through a layer of Filter-Cel. The clear filtrate was concentrated to a small volume *in vacuo* and was then acidified to congo red with concentrated hydrochloric acid. The resulting *dl*-oxybiotin (2.1 g.) (69% of the theoretical yield) was purified by crystallization from water. The compound was by mixed melting point and biological activity identical with *dl*-oxybiotin prepared by another method.[6]

***dl*-Hexahydro-2-oxo-4-(4-benzylthiobutyl)-1-furo-(3,4)-imidazole (XV).**—A stock solution of sodiobenzylmercaptide was prepared by dissolving 1.2 g. of sodium in a mixture of 19 cc. of absolute ethanol and 6 cc. of benzyl mercaptan.

To a solution of 442 mg. of the chloride (XIV) in 10 cc. of absolute ethanol 1.1 cc. of the above sodiobenzylmercaptide solution was added, and the mixture refluxed for two hours. The ethanol was removed *in vacuo*, the residue dissolved in ethyl acetate, and the solution washed with several portions of water, dried over sodium sulfate, and the ethyl acetate removed *in vacuo*. The oily residue solidified on standing, and the crystals were washed with ether and purified by recrystallization from dilute methanol; 410 mg. (66% of the theoretical yield) of silky needles were obtained which melted at 76–79°.

*Anal.* Calcd. for $C_{16}H_{22}O_2N_2S$: C, 62.73; H, 7.24; N, 9.14; S, 10.46. Found: C, 62.54; H, 6.96; N, 9.31; S, 10.32.

**Sulfone of XV.**—To a solution of 100 mg. of (XV) in 2 cc. of glacial acetic acid, 1 cc. of 30% hydrogen peroxide (Superoxol) was added, and the mixture kept at room temperature for twelve hours. The solvents were removed and the crystalline residue dried over potassium hydroxide *in vacuo*. Recrystallization of the substance from absolute ethanol gave 90 mg. (82% of the theoretical yield) of prisms melting at 189–190°.

*Anal.* Calcd. for $C_{16}H_{22}O_4N_2S$: C, 56.80; H, 6.55; N, 8.27; S, 9.48. Found: C, 57.03; H, 6.64; N, 7.95; S, 9.22.

Recrystallization of the sulfone from aqueous methanol gave needles of the half hydrate melting at 95–100°.

*Anal.* Calcd. for $C_{16}H_{22}O_4N_2S \cdot {}^1/_2H_2O$: C, 55.32; H, 6.62. Found: C, 55.11; H, 6.64.

***dl*-Hexahydro-2-oxo-1-furo-(3,4)-imidazole-4-(4-butane Sulfonic Acid) (III).**—To 4 g. of sodium which was placed in a round-bottomed flask, a solution of 500 mg. of the above thioether (XV) in 50 cc. of absolute ethanol was added at once and the mixture refluxed until all of the sodium had dissolved. Absolute alcohol (200 cc.) was then added and carbon dioxide was passed into the solution for one hour. The sodium carbonate was removed by filtration and the filter cake was repeatedly washed with absolute ethanol. The combined filtrate and washings were evaporated to dryness *in vacuo* in a stream of carbon dioxide, and the residue extracted with three 25-cc. portions of hot ethyl acetate. The combined ethyl acetate extracts were filtered and evaporated to dryness *in vacuo* under carbon dioxide. The resulting crystalline *dl*-hexahydro-2-oxo-4-(4-mercaptobutyl)-1-furo-(3,4)-imidazole (XVI), 185 mg. (52% of the theoretical yield), was used for the next step without further purification. The compound gave a strong nitroprusside test. To a solution of the above thiopentanol (XVI) (390 mg.) in 39 cc. of water which was cooled in an ice-bath, a 0.01 *M* solution of barium permanganate was added slowly with stirring until the pink color remained for twenty minutes. (Approximately 174 cc. of the solution was required.) The mixture was heated on the steam-bath, and 2 cc. of methanol was added in order to decompose the excess of permanganate. The manganese dioxide was removed by filtration and the clear filtrate was concentrated to dryness *in vacuo*. The crystalline residue was suspended in hot 95% alcohol and water was added until all of the barium salt had dissolved. Upon the addition of more hot 95% alcohol, the barium salt of the sulfonic acid crystallized; 485 mg. (81% of the theoretical yield) of colorless needles were obtained, which were purified by recrystallization from dilute ethanol.

*Anal.* Calcd. for $C_9H_{15}O_5N_2SBa/2$: C, 32.53; H, 4.55; N, 8.44: S, 9.66; Ba, 20.69. Found: C, 32.58; H, 4.74; N, 8.18; S, 9.43; Ba, 20.33.

***dl*-Hexahydro-2-oxo-4-(5-benzylthiopentyl)-1-furo-(3,4)-imidazole (XVIII).**—To a solution of 538 mg. of *dl*-hexahydro-2-oxo-4-(5-chloropentyl)-1-furo(3,4)imidazole (XVII)[3] in 5 cc. of absolute ethanol, 1.3 cc. of the above-mentioned sodiobenzylmercaptide solution was added and the mixture was refluxed for two hours. The benzyl thioether was isolated as described for the preparation of the lower homolog (XV). Recrystallization from dilute methanol yielded 639 mg. (86% of the theoretical yield) of needles which melted at 66–68°.

*Anal.* Calcd. for $C_{17}H_{24}O_2N_2S$: C, 63.73; H, 7.55;

(15) Hofmann and Bridgwater, THIS JOURNAL, **67**, 738 (1945).

N, 8.74; S, 10.00. Found: C, 63.24; H, 7.36; N, 8.89; S, 10.30.

**Sulfone of (XVIII).**—A sample of the thioether (XVIII) (200 mg.) was oxidized with Superoxol as described for the preparation of the lower homolog. Recrystallization from methanol gave 190 mg. (87% of the theoretical yield) of needles melting at 169–170°.

*Anal.* Calcd. for $C_{17}H_{24}O_4N_2S$: C, 57.95; H, 6.86; N, 7.94; S, 9.10. Found: C, 57.79; H, 6.59; N, 7.93; S, 9.17.

***dl*-Hexahydro-2-oxo-4-(5-mercaptopentyl)-1-furo-(3,4)-imidazole (XIX).**—Five hundred milligrams of the above thioether (XVIII) were cleaved with sodium in absolute ethanol as described for the lower homolog (XV); 250 mg. (70% of the theoretical yield) of the desired material, m. p. 92–94°, was obtained which was purified by recrystallization from ethyl acetate. The substance gave a strong nitroprusside test.

*Anal.* Calcd. for $C_{10}H_{18}O_2N_2S$: C, 52.15; H, 7.88; N, 12.15; S, 13.90. Found: C, 52.35; H, 7.58; N, 11.82; S, 14.67.

***dl*-Hexahydro-2-oxo-1-furo-(3,4)-imidazole-4-(5-pentane Sulfonic Acid) (IV).**—To an ice-cold solution of 200 mg. of the above thiopentanol (XIX) in 10 cc. of water and 1 cc. of acetone, a 0.01 *M* solution of barium permanganate was slowly added with stirring until the solution remained pink for thirty minutes (approximately 76 cc.). The excess of permanganate was destroyed by the addition of 2 cc. of methanol and heating on the steam-bath, and the solution was filtered and concentrated to dryness *in vacuo*. The residue was dissolved in a small amount of water, acetone was added until the solution became cloudy and the barium salt of the sulfonic acid crystallized out. Two hundred fifteen milligrams (71% of the theoretical yield) of the crystalline salt was obtained. The compound was purified by recrystallization from dilute acetone.

*Anal.* Calcd. for $C_{10}H_{17}O_5N_2SBa/2$: C, 34.70; H, 4.95; N, 8.09; S, 9.27; Ba, 19.86. Found: C, 34.37; H, 5.20; N, 8.14, S, 9.30; Ba, 19.60.

## Summary

1. The sulfonic acid analogs of oxybiotin and homoöxybiotin have been prepared.

3. These compounds, as well as several intermediates in their synthesis, were capable of antagonizing the growth-promoting activity of biotin and oxybiotin for several microörganisms.

# Condensation of Acetylenes. Acetylene and Alkyl Carbonates

BY W. J. CROXALL AND H. J. SCHNEIDER

Although alkyl carbonates in the presence of strong bases have been successfully used to introduce the carbalkoxy group into the anions of esters,[1,2,3] ketones[4] and nitriles[5,6] there appears to be no record of the acylation of an acetylene with an alkyl carbonate. This paper describes the results obtained with acetylene and alkyl carbonates.

Preliminary work demonstrated that when ethyl carbonate in the presence of alcohol-free sodium ethoxide was contacted with acetylene at 80° and two to five psi gage pressure, absorption of acetylene occurred over a period of six to eight hours. After neutralization with aqueous acetic acid, distillation of the reaction mixture gave two fractions. The main fraction was a mixture of ethyl β-ethoxyacrylate (I) and ethyl β,β-diethoxypropionate (II). The higher boiling fraction was mostly ethyl α,α-diethoxysuccinate (IV) containing a small amount of ethyl ethoxymaleate (III). The over-all reaction may be represented schematically as follows:

Excess of ester was found to give higher yields of the products and when a twenty to one molar ratio of ethyl carbonate to sodium ethoxide was used, the yields (calculated as mole per cent.) varied between 55–60% based on the ethyl carbonate and acetylene and 175–200% based on the sodium ethoxide. Lower ratios of carbonate to ethoxide gave progressively poorer yields so that when a two to one ratio was used only traces of the products were obtained along with a large amount of non-distillable residue.

Further investigation showed that basic agents other than sodium ethoxide (Method A) were suitable as condensation agents. Sodium acetylide (Method C), disodium acetylide (Method D), and benzyltrimethylammonium ethoxide (Method E) were successfully employed in this reaction with various alkyl carbonates. Table I lists the experiments using these agents with various alkyl carbonates. In all the experiments the yield values

based on the condensation agents were over one hundred per cent. indicating the reaction to be catalytic. Table II lists the physical constants of the products obtained from the various alkyl carbonates.

With sodium alkoxide, a reaction temperature of 80–85° was found to be preferable. Lower temperatures gave slow rates of acetylene absorption, whereas higher temperatures, while increasing the absorption rate, decreased the yields due to nondistillable residues. The initial rate of acetylene absorption with the sodium alkoxides was slow and did not increase appreciably for two to four hours, after which the rate increased and a slightly exothermic reaction occurred over a two-hour period. The rate then became increasingly slow. However, the addition of 0.125 to 0.25 mole of ethyl β-ethoxyacrylate per mole of alkoxide (Method B) to the carbonate, before pressurizing with acetylene, eliminated this induction period so that the absorption of acetylene started immediately. Of all the agents used, sodium alkoxides in general gave the poorest yields.

Mono and disodium acetylide were more active agents than the sodium alkoxides. Reaction with acetylene occurred exothermically at 30–45°, the yields were higher and the amount of the alkyl dialkoxysuccinate fraction was larger than when alkoxides were used. Considerable care was necessary in using these materials with various carbonates; on one occasion when allyl carbonate was mixed with monosodium acetylide, a violent explosion occurred.

Benzyltrimethylammonium methoxide and ethoxide were prepared as alcoholic solutions from benzyltrimethylammonium chloride and the corresponding sodium alkoxide.[7] They were isolated from these solutions by filtration and evaporation under reduced pressure as viscous liquids whose compositions corresponded to equimolecular ratios of quaternary alkoxide to alcohol. Yields were highest with these agents, reaction with acetylene occurring rapidly at room temperature.

The condensation of alkyl carbonates with acetylene is thought to proceed through a series of acid-base type reactions which may be represented by the following ionic mechanisms

(7) Meisenheimer, *Ann.*, **397**, 295 (1913).

The first step is the establishment of an equilibrium between acetylene and acetylide ion. It is probable that the equilibrium favors the products on the left-hand side due to (a) the solubility of acetylene in the alkyl carbonate[8] and (b) the stronger acidity of alcohol as compared to acetylene.[9] However, any acetylide ion formed in this equilibrium reacts (see Method C) according to the second step with the alkyl carbonate to give an intermediate ionic complex which releases an alkoxide ion to form an alkyl propiolate. The postulated ionic complex is similar to that advanced by Hauser and Renfrow for the Claisen condensation of esters.[10]

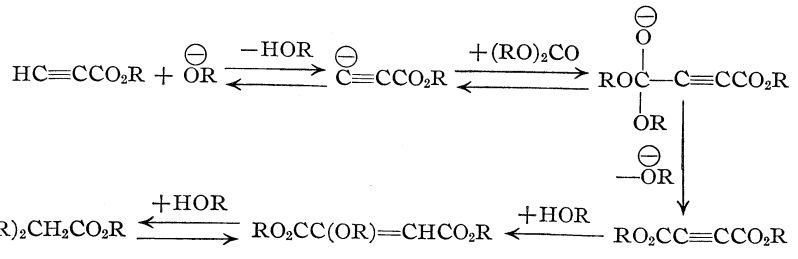
The third step is the addition of alcohol to the alkyl propiolate to give alkyl alkoxyacrylate and alkyl dialkoxypropionate.[11] Although in none of the experiments was it possible to isolate propiolates, their transitory existence seems likely. Their known reactivity with alcohols in the presence of basic catalysts suggests that they immediately react to form the alcohol adducts, namely, the alkoxyacrylate and dialkoxypropionate.[11]

It is therefore evident that in this mechanism the driving force which is capable of shifting the initial equilibrium between acetylene and acetylide ion is represented by the last step in which the alkyl propiolate is converted to the alkyl alkoxyacrylate and the alkyl dialkoxypropionate. The equilibrium existing between acrylate and propionate is undoubtedly in favor of the propionate since only small amounts of acrylate are isolated. That the last step affects the initial equilibrium is partially demonstrated in Method B where alkyl alkoxyacrylate is added to the alkyl carbonate at the beginning of the condensation. In this case, reaction with acetylene starts immediately and no induction period occurs. This procedure presumably removes alcohol in the initial equilibrium to give the alkyl dialkoxypropionate, and allows the formation of acetylide ion.

A possible route for the formation of alkyl alkoxymaleate and alkyl dialkoxysuccinate is indicated in the next formulas.

In this mechanism the alkyl propiolate first undergoes an acid-base exchange and then a series of reactions similar to those outlined for the acrylate and propionate, the intermediate in this case being the alkyl acetylenedicarboxylate. As in the proposed mechanism for the acrylate and propionate, no intermediate acetylenedicarboxylic ester was isolated but only the alcohol addition products of this ester.[11,12]

With disodium acetylide (Method D) it is thought that an initial attack by two molecules of



(8) The amount of acetylene required to saturate ethyl carbonate at 40° and five psi gage pressure was found to be 0.5%.

(9) Nieuwland and Vogt, "The Chemistry of Acetylene," Reinhold Publishing Corp., New York City, 1945, state on page 45, . . . the oxyradicals of alcohols and phenols appear to be capable of displacing the ethynyl group. . . .

alkyl carbonate produces an intermediate doubly charged ionic complex which releases two alkoxide ions to give directly the acetylenedicarboxylic ester. Further condensation with acetylene would then follow the routes indicated above for acrylate-propionate and maleate-succinate formation.

**Acknowledgment.**—The authors wish to thank Dr. R. Connor for his helpful suggestions and encouragement. The analyses were carried out under the direction of Dr. E. L. Stanley and Mr. C. W. Nash.

## Experimental

**Materials.**—Methyl carbonate was obtained from Pittsburgh Plate Glass Company, Columbia Chemicals Division, and the ethyl carbonate was obtained from U. S. Industrial Chemicals, Inc. Both carbonates were fractionated before use. The higher alkyl carbonates were prepared by alcoholysis of ethyl carbonate with the appropriate alcohol using sodium ethoxide as a catalyst.

**Acetylene and Ethyl Carbonate with Sodium Ethoxide.**—Method A—The general procedure herein described is representative of all the condensations carried out with acetylene. The others differ only in the type of condensation agent used.

In a 5-liter, 3-necked flask, equipped with a reflux condenser and a gas tight stainless steel stirrer whose blades scraped the bottom of the flask, was placed 800 g. of anhydrous ethanol. While stirring, 57.5 g. (2.5 moles) of clean sodium cut in quarter-inch cubes was added over a period of one hour. The excess ethanol was removed by distillation under vacuum to give white powdered sodium ethoxide. The vacuum was broken by admitting dry nitrogen and 2950 g. (25 moles) of diethyl carbonate was added. In order to remove the last traces of ethanol from the ethoxide–ethyl carbonate mixture, distillation under reduced pressure was continued until a total of 1134 g. of distillate was obtained which consisted of 898 g. of ethyl carbonate and 236 g. of ethanol. Additional ethyl carbonate, 898 g., was then added to the flask so that the final charge was 25 moles of carbonate to 2.5 moles of ethoxide. The flask was then equipped with a thermometer, a gas inlet tube extending below the surface of the liquid and a gas outlet tube which was connected to an open end mercury manometer. With stirring, the mixture was heated to 80°, and acetylene which had been washed with water and concd. sulfuric acid and dried with soda lime was pressed in at five psi gage pressure. The absorption of acetylene was very slow at the start and did not increase appreciably for three hours, at which point the absorption rate began to increase and heating was not necessary. The temperature was held at 80–85° by periodic cooling. A total of 192 g. (7.37 moles) of acetylene was absorbed in seven hours. During the last two hours, the absorption rate was very slow and heating was necessary to maintain the temperature at 80°. The mixture was cooled to room temperature and 653 g. (2.5 moles) of aqueous 23% acetic acid was added. The upper oil layer was separated, the aqueous layer extracted with ether and the extract combined with the oil layer. Distillation through a short packed column, after removal of ether, ethanol and 1620 g. (14 moles) of ethyl carbonate, gave (a) 915 g. of material b. p. 63–65° (2 mm.) and (b) 25 g. of material b. p. 65–110° (2 mm.). There was 223 g. of nondistillable residue.

Fraction (a) had a saponification equivalent of 182. Treatment of a portion of this fraction with a 1% solution of sodium in ethanol gave ethyl $\beta,\beta$-diethoxypropionate, b. p. 65° (2 mm.); $n^{25}D$ 1.4108[13]; saponification equivalent 192 (calcd. 190).

*Anal.* Calcd. for $C_9H_{18}O_4$: C, 56.86; H, 9.46. Found: C, 56.90; H, 9.91.

Distillation of a part of fraction (a) from 0.5% of sodium bisulfate gave ethanol and ethyl $\beta$-ethoxyacrylate, b. p. 60° (1.8 mm.); $n^{20}D$ 1.4471; saponification equivalent 145 (calcd. 144).[14]

*Anal.* Calcd. for $C_7H_{12}O_3$: C, 58.33; H, 8.33. Found: C, 57.96; H, 8.50.

Therefore, from the original saponification equivalent (182), fraction (a) was 87% ethyl $\beta,\beta$-diethoxypropionate and 13% ethyl $\beta$-ethoxyacrylate. These percentages check those obtained from a known index of refraction–composition graph. The yield of the propionate–acrylate fraction calculated on a mole per cent. basis was 50.0% on the carbonate consumed, 69.9% on the acetylene and 200% on the sodium ethoxide.

From 600 g. of fraction (b), obtained from a number of runs, there was obtained on fractionation through a two-foot glass helices packed column, 74 g. of ethyl $\beta,\beta$-diethoxypropionate, $n^{20}D$ 1.4106; 9 g. of an intermediate fraction, b. p. 65° (2 mm.) −85° (0.1 mm.), $n^{20}D$ 1.4195; 377 g. of ethyl $\alpha,\alpha$-diethoxysuccinate, b. p. 85° (0.1 mm.), $n^{20}D$ 1.4305, saponification equivalent 131.5 (calcd. 131) and 106 g. of a higher fraction, b. p. 85° (0.1 mm.) to 98° (0.5 mm.).

*Anal.* Calcd. for $C_{12}H_{22}O_6$: C, 54.96; H, 8.39. Found: C, 54.95; H, 8.11.

The ethyl $\alpha,\alpha$-diethoxysuccinate was characterized by hydrolysis with aqueous hydrochloric acid to ethyl oxalacetate according to the method of Michael and Bucher.[12] Treatment of the crude oxalacetate with a copper acetate solution gave the copper salt of ethyl oxalacetate which on recrystallization from anhydrous ethanol formed fine needles, m. p. 156°.[15]

The higher boiling material (106 g.) was refractionated to give 45 g. of ethyl ethoxymaleate, b. p. 97–98° (0.5 mm.); $n^{20}D$ 1.4562; saponification equivalent 108 (calcd. 108).

*Anal.* Calcd. for $C_{10}H_{16}O_5$: C, 55.55; H, 7.39. Found: C, 55.59; H, 7.27.

The ethyl ethoxymaleate was characterized by hydrogenation over Raney nickel at 30° and 1500 psi gage pressure to ethyl ethoxysuccinate, b. p. 92–93° (2 mm.); $n^{20}D$ 1.4217[16]; saponification equivalent 108 (calcd. 109).

*Anal.* Calcd. for $C_{10}H_{18}O_5$: C, 55.05; H, 8.25. Found: C, 55.01; H, 8.00.

**Acetylene and Ethyl Carbonate with Sodium Ethoxide and Ethyl $\beta$-Ethoxyacrylate.**—Method B—In a similar experiment there was added before the introduction of acetylene, 0.25 mole of ethyl $\beta$-ethoxyacrylate. On heating to 80° and pressurizing to five psi gage with acetylene, the absorption of acetylene started immediately, heating was discontinued and periodic cooling was necessary to

maintain the temperature at 80–85°. Over a period of three hours, 4 moles of acetylene was absorbed.

**Acetylene and Ethyl Carbonate with Monosodium Acetylide.**—Method C—Sodium acetylide (0.54 mole) was prepared in liquid ammonia according to the method of Hennion.[17] The liquid ammonia was allowed to evaporate and the last traces were removed by warming under reduced pressure. Rapidly there was added, with stirring and cooling, 1350 g (15.0 moles) of methyl carbonate.[18] The carbonate–acetylide suspension was warmed to 40° and acetylene was pressed in at five psi gage pressure. The absorption of acetylene started immediately and cooling was necessary to maintain the temperature below 45°. A total of 49 g. (1.93 mole) of acetylene was absorbed in four hours.

**Acetylene and Ethyl Carbonate with Disodium Acetylide.**—Method D—To 0.25 mole of disodium acetylide[19] there was added cautiously 590 g. (5 moles) of ethyl carbonate.[18] Acetylene was pressed in at five psi gage pressure until a total of 29.5 g. (1.1 mole) of acetylene had been absorbed in two hours. The temperature was maintained at 35–40°.

**Acetylene and Ethyl Carbonate with Benzyltrimethylammonium Ethoxide.**—Method E—Benzyltrimethylammonium ethoxide was prepared in a manner similar to the method used by Meisenheimer[7] for the preparation of tetramethylammonium ethoxide. From 238 g. (0.43 mole) of a 35.2% ethanolic solution of benzyltrimethylammonium ethoxide there was obtained by evaporation at 40° under reduced pressure (5–1 mm.), 103 g. of the ethoxide containing an equivalent of ethanol. To this was added 1520 g. (12.9 moles) of ethyl carbonate and then 65 g. (2.5 moles) of acetylene over a period of two hours while a temperature of 40–45° was maintained by cooling.

(17) Hennion, *Proc. Indiana Acad. of Sci.*, **47**, 116 (1938).

(18) Unless sufficient agitation was maintained and adequate cooling provided, violent exothermic reactions occurred at this stage. In one case when dipotassium acetylide was used a violent explosion occurred.

## Summary

1. Acetylene condenses with alkyl carbonates in the presence of basic condensation agents to produce alkyl $\beta$-alkoxyacrylates, alkyl $\beta,\beta$-dialkoxypropionates, alkyl alkoxymaleates and alkyl $\alpha,\alpha$-dialkoxysuccinates.

2. A mechanism has been proposed to account for the course of this reaction.

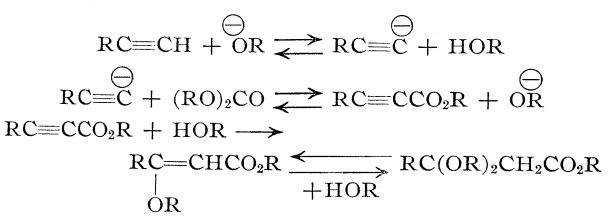
# Condensation of Acetylenes with Esters. Mono Substituted Acetylenes and Alkyl Carbonates[1]

BY W. J. CROXALL AND MARIAN F. FEGLEY



The nature of the products obtained from acetylene and alkyl carbonates[1] suggested that similar results might be obtained with substituted acetylenes. Our first experiments involved sodium phenylacetylide and ethyl carbonate and it was found that when these reactants were used in equimolecular amounts intractable oils were obtained as reported earlier by Nightingale and Wadsworth.[2] However when ethyl carbonate in the presence of a basic condensation agent such as sodium phenylacetylide was treated with phenylacetylene, there was formed in good yield ethyl β-phenyl-β-ethoxyacrylate and ethyl β-phenyl-β,β-diethoxypropionate. The yield data indicated that sodium phenylacetylide functioned as a catalyst. Sodium ethoxide and benzyltrimethylammonium ethoxide were also used successfully as the basic condensation agents for this reaction in place of sodium phenylacetylide. Extension of this work to methyl carbonate gave the corresponding methyl analogs. The over-all reaction may be represented as

Similar results were obtained with an alkeneyne. Ethyl carbonate and 2-methyl-1-butene-3-yne in the presence of either sodium ethoxide or benzyltrimethylammonium ethoxide gave three fractions on distillation. The first fraction was shown to be a mixture consisting chiefly of 2-methyl-3-ethoxy-4-carbethoxy-1,3-butadiene (I) containing a small amount of 2-methyl-3,3-diethoxy-4-carbethoxy-1-butene (II). This mixture when heated with a catalytic amount of sodium bisulfate gave ethanol and the pure butadiene ester (I) which was hydrogenated to the known 2-methyl-3-ethoxy-4-carbethoxybutane (III).[3] The second fraction was the butene ester (II) which on acid hydrolysis produced methyl isopropenyl ketone. Distillation of the ester (II) from a trace of sodium bisulfate gave the butadiene ester (I) and ethanol. Butene ester (II) gave on hydrogenation 2-methyl-3,3-diethoxy-4-carbethoxybutane (IV) which on acid hydrolysis yielded methyl isopropyl ketone. The third fraction was a high boiling oil which could not be distilled without decomposition. It was not characterized.

These reactions are thought to proceed throug a mechanism similar to that advanced for acety - ene and alkyl carbonates[1] and may be represented in a condensed form as

It is to be noted that this mechanism requires that the acetylene possess at least one acetylenic hydrogen atom. Actually, experiment showed that methylphenylacetylene gave no reaction.

**Acknowledgment.**—We wish to thank Dr. R. Connor for his advice and assistance. The analyses were carried out under the direction of Dr. E. L. Stanley and Mr. C. W. Nash. Miss R. Lookabaugh carried out the preparation of a number of intermediates used in this work and Mr. H. J. Schneider performed the experiment on methylphenylacetylene.

## Experimental

**Phenylacetylene with Methyl and Ethyl Carbonates.**—In a 1-liter, 3-necked flask equipped with a Hershberg stirrer, a dropping funnel and a soda lime tube there was prepared 0.5 mole of sodamide[4] in liquid ammonia. To the sodamide in liquid ammonia was added 51 g. (0.5 mole) of phenylacetylene, the ammonia allowed to evaporate at

(1) For the first paper of this series, see Croxall and Schneider, THIS JOURNAL, **70**, 1257 (1948).

room temperature and the last traces removed at the water pump. The flask was then equipped with a reflux condenser topped with a soda lime tube and with vigorous stirring and cooling there was added 590 g. (5 moles) of ethyl carbonate. After the exothermic reaction had subsided, the mixture was heated to 80° and 204 g. (2 moles) of phenylacetylene was added over a one-hour period, the temperature being maintained at 70–80° by periodic cooling. After being heated for ten hours at 65–75°, the reaction mixture was cooled to room temperature and neutralized with 130 g. of aqueous 23% acetic acid. The oil layer was separated, washed with 200 ml. of water, dried over anhydrous potassium carbonate and distilled through a short packed column. After removal of ethanol and 265 g. of ethyl carbonate there was obtained (a) 75 g. of material b. p. 135° (2 mm.); $n^{20}D$ 1.5202 and (b) 370 g. of material b. p. 135–148° (2 mm.); $n^{20}D$ 1.5274. Both fractions *a* and *b* were carefully refractionated to give pure ethyl β-phenyl-β-ethoxyacrylate, b. p. 101–102.5° (0.4 mm.); $n^{20}D$ 1.5320[5]; saponification equivalent 216 (calcd. 220) and ethyl β-phenyl-β,β-diethoxypropionate, b. p. 86–89° (0.24 mm.); $n^{20}D$ 1.4920[6]; saponification equivalent 253 (calcd. 266). From the saponification equivalents, the combined fractions *a* and *b* correspond to 93% ethyl β-phenyl-β-ethoxyacrylate and 7% ethyl β-phenyl-β,β-diethoxypropionate. The yield of acrylate–propionate mixture was 73% based on the ethyl carbonate consumed, 80% on phenylacetylene and 400% on sodium.

In a similar experiment in which sodium ethoxide was substituted for sodium phenylacetylide, there was obtained 64% of the acrylate and 36% of the propionate. The yield was 46% based on the ethyl carbonate consumed, 76% on phenylacetylene and 152% on sodium ethoxide.

From a condensation reaction maintaned at 30–40°, methyl carbonate (1.9 moles), phenylacetylene (0.5 mole) and 0.2 mole of benzyltrimethylammonium methoxide (containing an equivalent of methanol)[1] there was obtained 38% methyl-β-phenyl-β-methoxyacrylate,[5,7] b. p. 101° (0.25 mm.); $n^{20}D$ 1.5507; saponification equivalent 192 (calcd. 192) and 62% methyl β-phenyl-β,β-dimethoxypropionate,[6] b. p. 85–88° (1 mm.); $n^{20}D$ 1.4997; saponification equivalent 213 (calcd. 224). The yield was 63% based on the methyl carbonate consumed, 80% on phenylacetylene and 208% on benzyltrimethylammonium methoxide.

**2-Methyl-1-butene-3-yne with Ethyl Carbonate.**—To 1.5 moles of sodium ethoxide and 1414 g. (12 moles) of ethyl carbonate in a 2-liter, 3-necked flask equipped with a dropping funnel, a gas-tight stainless steel stirrer whose blades scraped the bottom of the flask and a reflux condenser which was connected to an open end mercury manometer, there was added 204 g. (3.1 moles) of 2-methyl-1-butene-3-yne[8] over a period of four hours, the temperature being maintained at 70–80°. The mixture was heated at the above temperature six additional hours, cooled and neutralized with aqueous 23% acetic acid. Fractionation of the organic layer through a short packed column gave after removing ethanol and 866 g. (7.3 moles) of ethyl carbonate, (a) 189 g. of material, b. p. 73–80.5° (2 mm.); $n^{20}D$ 1.4490–1.4527, 34 g. of an intermediate fraction, b. p. 80.5–100° (2 mm.) and (b) 216 g. (30%) of a constant boiling fraction, b. p. 100–103° (1 mm.); $n^{20}D$ 1.4520, which proved to be 2-methyl-3,3-diethoxy-4-carbethoxy-1-butene (II). *Anal.* Calcd. for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63. Found: C, 62.61; H, 9.53. There was also obtained 90 g. of a higher boiling material, b. p. 91–195° (1–4 mm.) which distilled with decomposition and was discarded.

In a similar experiment in which the condensation was carried out at 30–45°, there was obtained from 14 moles of ethyl carbonate, 3.8 moles of 2-methyl-1-butene-3-yne and 0.9 mole of benzyltrimethylammonium ethoxide (containing an equivalent of ethanol),[1] 1289 g. (10.9 moles) of unreacted ethyl carbonate, 289 g. of fraction *a*, 108 g. of fraction *b* and 170 g. of the high boiling fraction.

**2-Methyl-3-ethoxy-4-carbethoxy-1,3-butadiene (I).**—All attempts to fractionate cut *a* to obtain a pure compound were unsuccessful. However, by fractionating a toluene (100 g.) solution of fraction *a* (50 g.) in the presence of sodium bisulfate (0.25 g.) there was obtained 32 g. of an ethanol–toluene mixture, b. p. 76–110° (9.36% ethanol by hydroxyl determination) and 41 g. of the pure butadiene ester (I), b. p. 65–66° (1.7 mm.); $n^{20}D$ 1.4690; saponification equivalent 185 (calcd. 190).

*Anal.* Calcd. for $C_{10}H_{16}O_3$: C, 65.18; H, 8.75. Found: C, 65.06; H, 8.74.

**2-Methyl-3-ethoxy-4-carbethoxybutane (III).**—In a high pressure hydrogenation bomb was placed 66 g. (0.36 mole) of (I) and 4 g. of Raney nickel. This mixture was treated with hydrogen at 1300 psi and 70–78° to give 56 g. of the butane ester (II), b. p. 81–81.5° (10 mm.); $n^{20}D$ 1.4175; saponification equivalent 189 (calcd. 188).[3]

**2-Methyl-3,3-diethoxy-4-carbethoxy-1-butene (II).**—The pure butene ester (II) (fraction *b*) was characterized as follows. To 32 g. (0.14 mole) was added 23 ml. of aqueous 15% hydrochloric acid and 24 ml. of 95% ethanol. The mixture was allowed to stand ninety hours, refluxed for thirty minutes, cooled, neutralized with potassium carbonate, extracted with ether and dried over anhydrous potassium carbonate. After removing ether, fractionation gave 20 g. of an ethanol-water azeotrope, b. p. 76–78°, 14 g. of an intermediate fraction, b. p. 78–94° and 24 g. of crude methyl isopropenyl ketone, b. p. 94–99°. These last two fractions gave a semicarbazone which on recrystallization from ethanol-water melted at 173.5–175°. A mixed melting point with an authentic sample of the semicarbazone was 172.5–174°.

Fractionation of 30 g. (0.13 mole) of (II) and 50 g. of toluene in the presence of 0.5 g. of sodium bisulfate gave 11 g. of an ethanol–toluene fraction, b. p. 76–110° (98% yield of ethanol by hydroxyl determination) and 20 g. of the butadiene ester (I), b. p. 102° (12 mm.); $n^{20}D$ 1.4688.

**2-Methyl-3,3-diethoxy-4-carbethoxybutane (IV).**—Hydrogenation of 40 g. (0.17 mole) of the butene ester (II) dissolved in 80 ml. of ethanol over 20 g. of Raney nickel at 1300 psi and 80° gave 31 g. of the butane ester (IV), b. p. 85–87° (1 mm.); $n^{20}D$ 1.4308.

*Anal.* Calcd. for $C_{12}H_{24}O_4$: C, 62.04; H, 10.41. Found: C, 62.25; H, 10.38.

Acid hydrolysis of this ester gave methyl isopropyl ketone whose 2,4-dinitrophenylhydrazone melted at 116–117° and did not depress an authentic sample.

## Summary

1. Phenylacetylene condenses with alkyl carbonates in the presence of basic condensation agents to produce alkyl β-phenyl-β-alkoxyacrylates ($C_6H_5C(OR)=CHCO_2R$) and alkyl β-phenyl-β,β-dialkoxypropionates ($C_6H_5C(OR)_2CH_2CO_2R$).

2. 2-Methyl-1-butene-3-yne condenses with ethyl carbonate under similar conditions to give chiefly 2-methyl-3-ethoxy-4-carbethoxy-1,3-butadiene ($CH_2=C(CH_3)C(OC_2H_5)=CHCO_2C_2H_5$) and 2-methyl-3,3-diethoxy-1-butene ($CH_2=C(CH_3)C(OC_2H_5)_2CH_2CO_2C_2H_5$).

# The Gattermann–Koch Reaction. The Formylation of Isopropylbenzene under Pressure

BY NATHAN N. CROUNSE[1]

Although a description of the high pressure formylation of benzene utilizing the Gattermann–Koch reaction is available,[2] there are only patent reports[3,4,5] on the pressure formylation of an alkylbenzene. The high pressure formylation of isopropylbenzene and the side reactions have been studied. The reaction of isopropylbenzene and carbon monoxide under pressure with aluminum chloride and hydrogen chloride as catalysts gives chiefly *p*-isopropylbenzaldehyde, small amounts of benzaldehyde and 2,4-diiospropylbenzaldehyde.

The addition of hydrogen chloride was found necessary, and since water is also required,[2,6] it was attempted to add them as hydrochloric acid. The yield of *p*-isopropylbenzaldehyde was increased from 33% when only dry hydrogen chloride was used to 37% with no decrease in the time of absorption of carbon monoxide. To distribute water evenly on the aluminum chloride, twenty-mesh aluminum chloride was raked occasionally in the open air for two hours.[7] This treatment decreased the time of absorption from seven to three hours, and raised the yield to 45%.

The role of benzene, the solvent in the formylation,[8] has never been analyzed. The amount of benzene used can affect the yield of 2,4-diisopropylbenzaldehyde, formation of which could occur through the reactions shown.

The first reaction is known.[9] The diisopropylbenzenes must then be formylated according to the second equation since no diisopropylbenzenes are isolated from the reaction. The first reaction is reversible,[10] hence increasing the amount of benzene should reduce the yield of diisopropylbenzenes and preserve the isopropylbenzene. Increasing the amount of benzene 50% raised the yield of *p*-isopropylbenzaldehyde from 45 to 54%.

The effect of excess aluminum chloride on formylation has been shown.[2,11] A considerable excess of aluminum chloride utilized all the isopropylbenzene without increasing the yield of *p*-isopropylbenzaldehyde. By dropping the ratio of aluminum chloride to isopropylbenzene from 1.31 to 1.10, the yield of *p*-isopropylbenzaldehyde rose from 54 to 60%.

The formation of 2,4-diisopropylbenzaldehyde could also have been effected by alkylation of *p*-isopropylbenzaldehyde with isopropylbenzene and aluminum chloride. *p*-Isopropylbenzaldehyde can be alkylated with isopropyl chloride and aluminum chloride.[5] However, simulating formylation conditions but omitting carbon monoxide yielded neither a diisopropylbenzaldehyde nor benzaldehyde.

The lower boiling by-product of the reaction was benzaldehyde which could be formed by dealkylation of *p*-isopropylbenzaldehyde. *p*-Isopropylbenzaldehyde, benzene, aluminum chloride, and hydrogen chloride were processed together, but only the starting materials were recovered. Hence the benzaldehyde is formed probably by the action of carbon monoxide on benzene.

The higher boiling by-product, an aldehyde, was assumed to be 2,4-diisopropylbenzaldehyde, previously mentioned without proof of structure.[5] Its structure was determined here by oxidation to 2,4-diisopropylbenzoic acid, and characterization of the latter as its amide through mixed melting points.[12] The aldehyde was also characterized as a 2,4-dinitrophenylhydrazone. The formation of 2,4-diisopropylbenzaldehyde is in accord with the observation made when *m*- and *p*-xylenes are formylated to give 2,4-dimethylbenzaldehyde.[8,13,14]

As in the case of benzene[2] cuprous chloride was found unnecessary as a carrier for high pressure formylation.

A pressure of 500 p. s. i. was used here. However, when the same conditions were used at 30 p. s. i., no carbon monoxide was absorbed in seven hours. The poor agitation of the rocking autoclave may be more noticeable at low pressure than at high.

## Procedures

**p-Isopropylbenzaldehyde.**—To a mixture of 210 g. (1.75 moles) of isopropylbenzene and 315 g. (4.05 moles) of benzene saturated with hydrogen chloride in a lead-lined rocking autoclave,[15] was added 255 g. (1.92 moles) of aluminum chloride (technical) which previously had been ground to pass 20-mesh and exposed in a one-inch layer to air for two hours with frequent stirring. The autoclave was then purged with carbon monoxide (commercial) from a cylinder and carbon monoxide added to a pressure of 500 p. s. i. at 25–30°. After the pressure dropped to 300 p. s. i., it was again raised to 500 p. s. i. This was repeated until no drop occurred (two and one-half hours) whereafter the pressure was maintained for an hour longer.

The reaction mixture was poured onto 2500 g. of ice acidified with 5 cc. of concentrated hydrochloric acid and separated. The oil layer was washed with 500-cc. portions of water and 5% sodium carbonate solution, and filtered to break the emulsion. After separation the oil layer was washed twice with 500-cc. portions of water.

The oil was charged to a round-bottom flask headed by a 36-inch fractionating column packed with glass helices. Distillation was continued under atmospheric pressure until the pot temperature reached 131°, the distillate being benzene. Then, under a vacuum of 135 mm., 40.5 g. of isopropylbenzene (b. p. 95° at 135 mm.) were recovered. Distillation at 35 mm. gave 11 g. of benzaldehyde (b. p. 83–88° at 35 mm.) contaminated with a small amount of isopropylbenzene, 126 g. of *p*-isopropylbenzaldehyde (b. p. 131–135° at 35 mm.), 60.3% yield based on the recovered isopropylbenzene, and 25 g. of 2,4-diisopropylbenzaldehyde. A residue of about 25 g. remained.

The *p*-isopropylbenzaldehyde reduced Tollens reagent. Oxidation with alkaline potassium permanganate gave *p*-isopropylbenzoic acid, m. p. 115°.[16] Calcd.: neut. equiv., 164. Found: neut. equiv., 162.

Benzaldehyde was characterized as its phenylhydrazone, m. p. 156°. A mixed melting point with an authentic specimen suffered no depression.

The higher boiling aldehyde was redistilled. Fifteen g. was recovered: $n^{20}D$ 1.5241, $d^{20}_4$ 0.9461, b. p. 127° (13 mm.).

*Anal.* Calcd. for $C_{13}H_{18}O$: C, 82.10; H, 9.47. Found: C, 82.14; H, 9.45.

**Oxidation of Diisopropylbenzaldehyde.**—Oxidation of diisopropylbenzaldehyde with alkaline potassium permanganate gave low yields of 2,4-diisopropylbenzoic acid, m. p. 107–107.5°.[17] Calcd.: neut. equiv., 206. Found: neut. equiv., 204. Newton[12] records a melting point of 107.5–108.5°.

**2,4-Diisopropylbenzamide.**—Half a gram of the above acid was treated with an excess of thionyl chloride[18] and then converted to the amide; melting point 156.5°. A mixed melting point with a sample prepared by Newton's[12] method showed no depression.

**2,4-Dinitrophenylhydrazone of 2,4-Diisopropylbenzaldehyde.**—One gram of 2,4-diisopropylbenzaldehyde was treated with 2 g. of 2,4-dinitrophenylhydrazine in alcohol.[19] The yield of red needles, m. p. 156.5–157.5°, was 2.5 g. (90% yield). The product was dissolved in 20 cc. of cold benzene. Addition of 15 cc. of low boiling petroleum caused the precipitation of 2.2 g. of tiny red needles, m. p. 156.5–157.5°.

*Anal.* Calcd. for $C_{19}H_{22}O_4N_4$: N, 15.20. Found: N, 15.00.

**Attempted Alkylation of *p*-Isopropylbenzaldehyde with Isopropylbenzene.**—To a mixture of 225 g. of benzene and 74 g. of isopropylbenzene, saturated with hydrogen chloride, 80 g. of aluminum chloride was added and then 74 g. of *p*-isopropylbenzaldehyde in forty-five minutes at 24–27°. After stirring for two hours, the mixture was poured onto 800 g. of ice and separated. The oil layer was washed with water, 5% sodium carbonate solution, and again with water. Distillation through a 3-ft. column packed with helices gave benzene, isopropylbenzene, and *p*-isopropylbenzaldehyde in 90% recoveries. The small residue showed no evidence of 2,4-diisopropylbenzaldehyde.

**Attempted Dealkylation of *p*-Isopropylbenzaldehyde.**—The conditions of the experiment recorded above were repeated omitting the 74 g. of isopropylbenzene. Only the starting materials were recovered.

## Summary

A study has been made of some factors in the pressure formylation of isopropylbenzene. The structure and mode of formation of the by-products of the reaction have been discussed.

CINCINNATI, OHIO RECEIVED DECEMBER 10, 1948

(15) American Instrument Company, Silver Springs, Md.; lead-lined at Hilton-Davis.

(16) Meyer, *J. prakt. Chem.*, [2] **34**, 100 (1886), reports the melting point as 116–117°.

(17) Niedzielski and Nord, *J. Org. Chem.*, **8**, 147 (1943). These authors report the formation of diisopropylbenzaldehydes through application of the Gattermann reaction to both isopropylbenzene and *m*-diisopropylbenzene. The corresponding acids melt at 186° and 190°, respectively; the 2,4-dinitrophenylhydrazones melt at 133° and 143°.

# The Analgesic Activity of Some Benzoxazolone Derivatives[1]

BY W. J. CLOSE, BURRIS D. TIFFANY AND M. A. SPIELMAN

Lespagnol and his co-workers[2] were the first to indicate that compounds of the benzoxazolone type may affect the central nervous system. Inasmuch as benzoxazolone is structurally related to 2,4-oxazolidinedione which forms the nucleus of a number of compounds with analgesic and anticonvulsant activity,[3] it seemed desirable to make an extensive search among benzoxazolone derivatives for possible therapeutic application.

The compounds included in this study were N-alkyl, N-acyl, and N-dialkylaminoalkyl derivatives of benzoxazolone and various nuclear substituted derivatives. It was found that a majority of these compounds are capable of inducing mild analgesia in animals.

The preparation of the benzoxazolones required the use of various *o*-aminophenols (II) as intermediates. These were prepared generally through nitration of the corresponding phenol (I), followed by catalytic reduction. In certain cases it was considered more expedient to couple the phenol with benzenediazonium chloride and to reduce the resulting azo derivative chemically. Most of the aminophenols were very sensitive to air oxidation; these were isolated and used in the form of their hydrochlorides.

Usually, the *o*-aminophenol salts were converted to benzoxazolone derivatives (III) by fusion with urea. Though this reaction represents one of the oldest methods of making benzoxazolones,[4] it has received little attention,[5] possibly because it was associated with a poor yield. We have found, however, that yields of 76–90% can be obtained by moderating the temperature and time of reaction. In one case (5,6-dimethylbenzoxazolone) the urea fusion technique failed to give satisfactory yields and the less convenient phosgene method was employed. 6-Chlorobenzoxazolone was prepared in good yield directly from benzoxazolone by chlorination.

The alkylation of the parent benzoxazolones to produce N-substituted derivatives (IV) required considerable experimentation to secure satisfactory results. The use of an alkyl halide in methanolic potassium hydroxide as suggested in the literature[6] usually gave very low yields. By substituting the higher-boiling Cellosolve (glycol monoethyl ether) for methanol, yields of 62–76% were obtained except when secondary halides were used. Somewhat higher yields (generally 80–95% for normal halides) could be obtained by the use of Cellosolve as the solvent and its sodium alkoxide as the basic condensing agent; this method was used for approximately half of the preparations.

Acylation of the benzoxazolones was accomplished easily by treatment of the compound or its sodium salt with acetic anhydride.

## Experimental[7]

### Preparation of Substituted Phenols

***p*-Propylphenol.**—*p*-Propylanisole[8] (289 g.) was demethylated by refluxing three days with a mixture of 450 cc. of 48% hydrobromic acid and 450 cc. of acetic acid into which dry hydrogen bromide was bubbled during the first two hours of reaction. The yield of product was 245 g. (93%); b. p. 79–80° (0.75 mm.).[8]

***p*-Amylphenol.**—The following modification of the procedure of Sandulesco and Girard,[9] using a large excess of aluminum chloride, was found to give a three-fold increase in the amount of the desired *p*-hydroxyvalerophenone: Seventy-two grams of phenol dissolved in 144 cc. of nitrobenzene was added to 205 g. of aluminum chloride in 400 cc. of nitrobenzene at 10–12° with stirring. The mixture was treated with 85 g. of valeryl chloride by dropwise addition at 5–10° with stirring. After standing overnight the mixture was poured onto ice and concentrated hydrochloric acid, the layers were separated, and the nitrobenzene layer was extracted with dilute sodium hydroxide. The oil obtained by neutralizing the basic extract was taken up in ether and fractionated to give 108 g. (87%) of the *p*-isomer; b. p. 150–160° (0.6 to 0.8 mm.).

The ketone was reduced by the Clemmensen procedure to give an 85% yield of *p*-amylphenol boiling at 103–107° (1.4 mm.).[10]

### Preparation of Substituted ortho-Aminophenols

**2-Amino-4-methylphenol.**—2-Nitro-4-methylphenol[11] was dissolved in absolute alcohol and reduced with Raney nickel at 75° under a hydrogen pressure of 1000 pounds. After removal of the catalyst by filtration and evaporation of the solvent, the basic residue was treated with a slight excess of alcoholic hydrogen chloride. Anhydrous ether was then added to precipitate the hydrochloride in 90% yield; m. p. 222–224° (dec.).[12]

**2-Amino-4-propylphenol.**—A modification of the Baranger[11] procedure gave 83% of 2-nitro-4-propylphenol; b. p. 92–96° (0.85 mm.); $n^{25}D$ 1.5574.

*Anal.*[13] Calcd. for $C_9H_{11}NO_3$: N, 7.7. Found: N, 7.7.

Catalytic reduction as described above gave 98% of the aminopropylphenol hydrochloride; m. p. 245–252° (dec.).

*Anal.* Calcd. for $C_9H_{13}NO \cdot HCl$: N, 7.5. Found: N, 7.6.

**2-Amino-4-amylphenol.**—A solution of 51 cc. of concentrated nitric acid in 100 cc. acetic acid was cooled to −10° and 65 g. of *p*-amylphenol dissolved in 65 cc. of acetic acid was added with stirring over a period of two hours. The temperature was maintained below −5° during the addition. The reaction mixture was immediately poured into a mixture of ice and 160 g. of 10% sodium hydroxide, and extracted with benzene. The benzene extract was steam distilled and the oil so obtained was distilled to give 61.8 g. (75%) of 2-nitro-4-amylphenol; b. p. 100–105° (0.5 mm.); $n^{25}D$ 1.5253.

*Anal.* Calcd. for $C_{11}H_{15}NO_3$: N, 6.7. Found: N, 6.9.

The nitro derivative was reduced as described above to give 84% of the hydrochloride which melted at 194° after recrystallization from alcohol.

*Anal.* Calcd. for $C_{11}H_{17}NO \cdot HCl$: N, 6.5. Found: 6.5.

The free base, obtained by neutralization of the hydrochloride and recrystallization from petroleum ether, melted at 128°.

*Anal.* Calcd. for $C_{11}H_{17}NO$: N, 7.8. Found: N, 8.0.

**2-Amino-4,5-dimethylphenol.**—2-Benzeneazo-4,5-dimethylphenol[14] was reduced by sodium hydrosulfite in basic solution to give 77% of aminophenol melting at 171–175°.[15]

**2-Amino-4-methoxyphenol.**—One mole of diazotized aniline was added over a period of 1.5 hours to a solution of 124 g. of hydroquinone monomethyl ether dissolved in 1200 cc. of water containing 120 g. of sodium hydroxide. The temperature was maintained at −5 to 0° during the addition. The mixture was filtered, and the filtrate acidified to yield 202 g. (89%) of 2-benzeneazo-4-methoxyphenol; m. p. 69–72°. A pure sample was prepared as dark red needles from alcohol; m. p. 72.5–73.5°.

*Anal.* Calcd. for $C_{13}H_{12}N_2O_2$: N, 12.3. Found: N, 12.5.

The azo derivative was reduced by dissolving 100 g. in 1 l. of water containing 100 g. of sodium hydroxide. The solution was warmed on the steam-bath and sodium hydrosulfite was added in portions with stirring until the color was discharged. The aniline formed was extracted with ether; neutralization of the basic solution precipitated the aminophenol which was filtered rapidly, pressed as dry as possible on the filter plate, and immediately triturated with ethereal hydrogen chloride to give 57.5 g.; m. p. 205–212° (dec.). An additional 7.8 g., m. p. 197–205°, isolated from the aqueous filtrate by ether extraction and precipitation with ethereal hydrogen chloride brought the yield to 85%. The hydrochloride could be recrystallized only with considerable loss. An analytically pure sample was obtained from alcohol, using Norit. The m. p. was 210–213° (dec., pyrex tube evacuated to 0.5 mm.). Roberts and co-workers[16] reported a m. p. of 171° for the product obtained by the reduction of 2-nitro-4-methoxyphenol.

*Anal.* Calcd. for $C_7H_9NO_2 \cdot HCl$: N, 8.0. Found: N, 7.8.

### Preparation of Parent Benzoxazolones

The urea-fusion method (Method A), which was used for the preparation of most of the parent compounds, is illustrated by the preparation of 5-propylbenzoxazolone. Benzoxazolones not prepared by fusion with urea were synthesized as described below. The properties of all the compounds are given in the accompanying table.

**Method A. 5-Propylbenzoxazolone.**—2-Amino-4-propylphenol (470 g.) was intimately mixed with 300 g. of urea and heated in an oil-bath at 180° for two hours. The reaction mixture was cooled somewhat and acidulated water was added. The oil which separated was taken up in ether, concentrated and distilled. The product (348 g., 79%) boiled at 180–182° (0.8 mm.) and solidified in the receiver.

**5,6-Dimethylbenzoxazolone.**—A suspension of 34.2 g. of 2-amino-4,5-dimethylphenol and 59 g. of anhydrous potassium acetate in 600 cc. of ethyl acetate was treated dropwise with 30 g. of phosgene in 400 cc. of ethyl acetate with vigorous stirring. After refluxing briefly, water was added and the ethyl acetate layer separated. After washing with water and 5% hydrochloric acid, the solvent was removed. The residue of crude product was best purified by dissolving in boiling 10% NaOH and cooling in ice. The sodium salt which precipitated was suspended in water and acidified. By reworking the basic filtrate, a total of 27.6 g. (68%) of material melting at 173–177° was obtained.

**6-Chlorobenzoxazolone.**—Benzoxazolone (50 g.) was dissolved in 500 cc. of acetic acid, cooled in ice, and treated with 32 cc. of sulfuryl chloride with stirring. After standing overnight at room temperature, the solution was warmed on the steam-bath for one hour, cooled, and poured into water. A total of 51.3 g. (81%), m. p. 189–194°, was obtained.

The position of the chloro group was demonstrated by cleavage of the oxazolone ring with sodium hydroxide to give a chloroaminophenol. Purification of the product gave prismatic needles, m. p. 152–154° (dec.). The melting point was undepressed when mixed with a sample of 2-amino-5-chlorophenol, m. p. 152–154°, prepared according to Theilacker.[17]

### Alkylation of Benzoxazolones

The following examples illustrate the two general methods used to convert the parent benzoxazolones into N-substituted derivatives. The accompanying table lists the compounds prepared by these methods together with their properties.

**Method B. 3-*iso*-Amyl-5-propylbenzoxazolone.**—5-Propylbenzoxazolone (6.2 g.) was dissolved in 60 cc. of 0.84 *N* KOH in Cellosolve. *iso*-Amyl iodide[18] (9.3 cc.) was added and the mixture was refluxed for six hours. The liquid was decanted from the precipitate of potassium iodide and concentrated under reduced pressure. The residue was taken up in benzene and water; the benzene layer was separated and washed with 5% sodium hydroxide and water. After removal of the benzene, the product was distilled to give 5.7 g. (66%); b. p. 148–150° (0.8 mm.).

**Method C. 3-Amyl-5-methoxybenzoxazolone.**—A small flask was fitted with a reflux condenser, stirrer, dropping funnel, and short gas inlet tube. A slow stream of nitrogen was passed through the inlet tube during the course of reaction. Thirty cc. of Cellosolve (purified by distillation from sodium dissolved in Cellosolve) was introduced into the flask, and 1.6 g. of sodium was dissolved

in the solvent. 5-Methoxybenzoxazolone (9.9 g.) was stirred into the solution, followed by 9.6 cc. of *n*-amyl bromide.[18] The solution was refluxed for one hour, then retreated with 0.69 g. of sodium dissolved in 10 cc. of Cellosolve (solution prepared under nitrogen) and 4.8 cc. of bromide. Refluxing was continued for one hour.

The reaction mixture was acidified with acetic acid and concentrated under reduced pressure. The residue was treated with ether and water. The separated ether layer was washed with water, 5% sodium hydroxide, 5% hydrochloric acid, and water. The ether was removed and the residue was distilled to give 13.0 g. (92%); b. p. 166–174° (1.0 mm.).

### Acylation of Parent Benzoxazolones

N-Acetyl derivatives of two benzoxazolones were prepared (see table). The following procedure gave the best results.

**3-Acetyl-5-methoxybenzoxazolone.**—A solution of 1.6 g. of sodium in 50 cc. of methanol was prepared and 9.9 g. of

5-methoxybenzoxazolone was added. The solvent was removed under reduced pressure and the dry solid residue was treated with 25 cc. of acetic anhydride. The mixture was swirled thoroughly and allowed to stand for ten minutes, after which it was poured into water. The product was filtered to give 11.8 g. (95%); m. p. 100–103°.

### Pharmacologic Evaluation

The compounds were tested for analgesic activity in dogs by a modification of the method of Andrews and Workman.[19] These determinations were carried out by Dr. R. K. Richards and Mr. K. E. Kueter of our laboratories to whom we express our thanks. Doses of 100–200 mg./kg. were used, at which level toxic symptoms rarely appeared. Several of the derivatives raised the pain threshold 10–20%; a few 20–30%. The best compounds, therefore, have an activity comparable to that of aspirin, which gives a 15–20% increase in 100 mg./kg. doses. They are much weaker analgesics than Demerol, which is capable of raising the pain threshold 30–40% in 15 mg./kg. quantities. Pharmacologic data for all of the benzoxazolones tested are included in the table.

(19) Andrews and Workman, *J. Pharmacol.*, **73**, 99 (1941).

## Summary

1. The synthesis of approximately forty N-alkyl, N-acyl, and N-dialkylaminoalkyl derivatives of benzoxazolone and nuclear substituted benzoxazolones is described.

2. About two-thirds of the derivatives induced mild analgesia in dogs.

# Streptomycin. XII. Streptamine Isomers from *meso*-Inositol

BY A. E. O. MENZEL,[1] M. MOORE AND O. WINTERSTEINER

In 1915 Griffin and Nelson,[2] in a study of the action of acetyl bromide on *meso*-inositol, obtained besides other products two isomeric dibromotetraacetoxycyclohexanes, melting at 225 and 130°, respectively, which Müller[3] had previously prepared from *meso*-inositol in a slightly different manner. In the absence of information on the position of the bromine atoms the higher-melting isomer was arbitrarily termed α-, and the lower melting isomer, β-. Soon after the structure of streptamine had been established,[4,5] we began an investigation of the aminolysis of these compounds and of the corresponding dibromotetrols (of which only the β-isomer had been previously described[2]), in the hope to arrive, if not at streptamine itself, at some isomers of it. While Griffin and Nelson were unable to effect amination of the β-dibromotetraacetoxycyclohexane by treatment with liquid ammonia at room temperature, we found that both the α- and the β-dibromotetrol reacted with aqueous ammonia at 100° with the formation of diamines. The crude products were isolated as picrates, which in both cases could be separated into a methanol-soluble fraction (I) and a much smaller methanol-insoluble fraction (II). The four picrate fractions were purified by recrystallization and converted to dihydrochlorides. The two pairs of diamines thus obtained are designated here for convenient reference as α- and β-diamines I, and α- and β-diamines II, the Greek letters signifying derivation from the corresponding dibromotetrol isomers, and the Roman numerals derivation from the methanol-soluble and methanol-insoluble picrate fraction, respectively. They were converted into suitable acyl derivatives for comparison with each other and with streptamine.

As could be anticipated from the properties of the salts and acyl derivatives of streptamine, the crystal shape and melting point data were of limited value as criteria for establishing identity or non-identity because the new compounds were generally microcrystalline and melted or decomposed over a considerable range. This was for instance the case with the dipicrates, sulfates, N,N′-diacetates and hexaacetates of α-diamine I and β-diamine I, respectively. Notwithstanding these limitations the picrates, sulfates and hexaacetates showed such close correspondence of their properties that identity of the parent diamines was at first suspected. Subsequently, however, certain differences in melting point behavior were observed with the N,N′-diacetates and the hexabenzoates. Particularly with the latter pair these discrepancies could not be dismissed as being due to accidental causes, because both compounds, in contradistinction to the acetyl derivatives, exhibited fairly well-defined melting points. Thus, while the β-hexabenzoate melted at 262–263°, it was not possible to raise the melting point of the α-hexabenzoate beyond 252–255°, and a small but distinct depression (251–253°) was observed in mixture. Furthermore, the X-ray diffraction patterns[6] of the two compounds were quite dissimilar, but the significance of this finding is not quite clear in view of the fact that the pattern given by the α-hexabenzoate raised some doubt as to its completely crystalline character (*cf.* Experimental). Nevertheless, we believe that the weight of the evidence is against identity, and that α-di-

amine I and β-diamine I should be considered as separate entities. It was not vital for the purpose of this investigation to establish this point more conclusively.

There can be little doubt that neither of the isomers is identical with streptamine, since the N,N′-diacetates, hexaacetates and hexabenzoate of the latter all exhibit much higher melting points than the corresponding derivatives of the two diamines.

The dihydrochlorides of both isomers consumed, as expected, 6 moles of periodic acid while the N,N′-diacetates consumed 2 moles. This parallels the results obtained with streptamine and its N,N′-diacyl derivatives.[4,5] The amino groups in either diamine could therefore be in 1,3- or 1,4-position to each other.

The dihydrochlorides of α-diamine II and β-diamine II could be secured in small amounts only, since the yields of the purified methanol-insoluble picrates were poor and in some runs insignificant. Of acyl derivatives only the N,N′-diacetates were prepared. Both products melted sharply at 268–269° after slight sintering at 265°, and did not depress each other's melting point, whereas admixture of streptamine N,N′-diacetate gave a marked depression. It is therefore highly probable that these two diamines are identical. Identity with either of the diamines I is excluded not only by the different melting point properties of the dihydrochlorides and N,N′-diacetates of the latter, but also by the results obtained by the periodic acid method. The dihydrochlorides of the "α-" as well as of the "β-" diamine II consumed the expected 6 moles, but the N,N′-diacetates consumed 3 moles, indicating that the amino groups occupy vicinal positions. The fact that the isomeric α- and β-dibromotetrols give rise to the same diamine must be ascribed to the formation, in the initial phase of the amination reaction, of a common intermediate, *i. e.*, an epoxide.

The investigation had to be discontinued at this point for extraneous reasons so that no effort could be made to obtain further information on the structure of the diamines I and of the isomeric dibromotetrols. It might be mentioned in this connection that the application of the periodate method to the bromine compounds gave a definitive result only with the β-isomer, which in slow reaction consumed 3 moles of periodic acid and hence appears to carry the bromine atoms at adjoining carbon atoms. In the case of the α-dibromotetrol the oxidative attack was evidently complicated by side reactions. Consumption came to a standstill at 4 moles whereas no more than 3 moles could be consumed if the oxidation were confined to glycol groupings.

## Experimental

**α- and β-Dibromotetrahydroxycyclohexane.**—*meso*-Inositol was subjected to the reaction with acetyl bromide as described by Griffin and Nelson.[2] For the separation of the reaction products we followed in general their procedure of fractional crystallization, and were able to isolate most of the compounds reported by them, *e. g.*, α-dibromotetraacetoxycyclohexane, m. p. 222–223°[7]; β-dibromotetraacetoxycyclohexane, m. p. 128–129°; monobromopentaacetoxycyclohexane, m. p. 240–241°; dibromodiacetoxydihydroxycyclohexane, m. p. 220–222°; and β-dibromocyclohexanetetrol m. p. 214–216°. However, the yields of these compounds, as well as the proportion of the two dibromotetraacetoxy isomers, varied markedly from run to run. The purification of the α-isomer was greatly facilitated by chromatographing the crude product in benzene solution on aluminum oxide. For instance, the sirupy reaction product obtained from 50 g. of *meso*-inositol was taken up in hot absolute ethanol (1.4 l.). The resulting crystalline mass was filtered off from the hot solution, washed and dried (19.5 g.), then dissolved in benzene and chromatographed on a column (35 × 480 mm.) of acetic acid-washed alumina. Continued washing with benzene (2.1 l.) eluted crystalline material, which on recrystallization from ethyl acetate–ethanol (1:9) yielded slightly impure α-dibromotetraacetoxycyclohexane, m. p. 218–222° (10.9 g.). Subsequent elution with benzene–ethanol (9:1) removed from the column the chief contaminant of this fraction, monobromopentaacetylcyclohexane. The original alcoholic mother liquor on concentration yielded a second crop of crystals consisting mainly of β-dibromotetraacetoxycyclohexane (after recrystallization 10.4 g., m. p. 126–128°). A third crop of crystals obtained from this mother liquor was treated with hot chloroform. From the chloroform-insoluble fraction crude dibromodiacetoxydihydroxycyclohexane (9.2 g.) was isolated, while the chloroform-soluble fraction afforded an additional amount (1 g.) of α-dibromotetraacetoxycyclohexane m. p. 219–221°. The identity of the purified preparations was in all cases confirmed by analysis.

It was found preferable to secure **β-dibromocyclohexanetetrol** by acid hydrolysis of its tetraacetate rather than by direct isolation. A solution of the tetraacetate in about 20 parts of a 1:1 mixture consisting of ethanol and 2 *N* hydrochloric acid was boiled on the steam-bath for five hours and then concentrated to a small volume *in vacuo*. The excess hydrochloric acid was removed by twice repeating the distillation after the addition of absolute ethanol. The residue was taken up in warm ethanol, and the tetrol was precipitated by the addition of excess ether. After recrystallization from acetone it melted at 214–216° (dec.) after softening at 210°, yield, 58–65%.

*Anal.* Calcd. for $C_6H_{10}O_4Br_2$: C, 23.55; H, 3.29; Br, 52.2. Found: C, 23.14; H, 3.50; Br, 51.9.

The hitherto undescribed **α-dibromocyclohexanetetrol** was prepared from the tetraacetate in the same manner. The crude product was triturated with dry ether, and the insoluble part recrystallized from methanol–benzene or ethyl acetate–chloroform; prisms, m. p. 186–188°. The melting point of a mixture with the β-isomer was 175–180°. The solubility properties were similar to those of the β-isomer (readily soluble in water, moderately in methanol or ethanol, sparingly in acetone, insoluble in benzene and chloroform).

*Anal.* Calcd. for $C_6H_{10}O_4Br_2$: C, 23.55; H, 3.29; Br, 52.2. Found: C, 23.42; H, 3.59; Br, 51.9.

**Amination of Dibromotetrols.**—One gram portions of the tetrols were dissolved in concentrated aqueous ammonia (50 cc.), and the solutions heated in pressure bottles on the steam-bath for fifteen hours. (This ratio of tetrol to ammonia was retained from preliminary experiments, and could probably be decreased considerably.) After cooling the contents of several bottles were combined, and the excess ammonia was removed by repeated distillation *in vacuo* with water. The final aqueous solution was lyophilized, yielding the crude dihydrobromide as an amorphous white hygroscopic mass. Attempts to crystallize these products were unsuccessful.

It might be mentioned that other methods of amination previously explored had proved ineffective. Thus β-

(7) All melting points were taken in the capillary and are corrected for stem exposure.

dibromotetraacetoxycyclohexane was recovered unchanged after treatment with potassium phthalimide at 165° in the bomb tube, or at 100° in the presence of xylene or amyl alcohol, nor would this compound react with sodium amide in boiling xylene. On standing for a week in alcoholic ammonia partial amination occurred, but only a small amount of picrate was obtained.

**Isolation of Diamines as Picrates.**—The crude dihydrobromide (525 mg., 1.54 millimole) from α-dibromocyclohexanetetrol was dissolved in water (3 cc.), and a saturated solution of picric acid in absolute ethanol (7.2 cc., about 3 millimoles) was added. Since only a small amount of precipitate appeared within an hour, the solution was concentrated at room temperature to *ca.* 6 cc. and allowed to stand in the refrigerator overnight. The resulting microcrystalline precipitate was collected by centrifuging, washed with 50% ethanol and dried (600 mg.). The product was suspended in dry methanol (3 cc.), and the mixture was centrifuged after short boiling while still warm. The insoluble part was subjected to the same treatment with 1 cc. of methanol. On addition of benzene (12 cc.) to the combined supernatants and standing clumpy aggregates separated out on the walls of the vessel (322 mg.). Recrystallization from the same solvents yielded **α-diamine I dipicrate** in form of indistinctly crystalline particles. A somewhat better-looking preparation (microscopic rods) could be obtained from warm *t*-amyl alcohol containing a small amount of water and chilling; m. p. 235–236° (dec.) after sintering and darkening from about 210° on (block preheated to 180°). With some preparations a somewhat higher decomposition point (240–242°) was observed. The picrate is fairly readily soluble in water (difference from diamine II dipicrate) and methanol, and sparingly soluble in ethanol and dioxane.

*Anal.* Calcd. for $C_{18}H_{20}O_{18}N_8$: C, 33.97; H, 3.17; N, 17.6. Found: C, 33.93; H, 3.64; N, 17.0.

**A picrolonate,** which is probably that of α-diamine I, was prepared from the same dihydrobromide; hair-like needles from methanol–water, m. p. 265° after sintering and darkening from 235° on.

*Anal.* Calcd. for $C_{26}H_{30}O_{14}N_{10}\cdot H_2O$: C, 43.10; H, 4.45; N, 19.3. Found: C, 43.36; H, 4.51; N, 20.0.

The methanol-insoluble fraction (31 mg.) of the mixed picrate was recrystallized twice from hot water. **Diamine II dipicrate** was obtained as small prisms melting gradually with decomposition at 260–290° after darkening at about 235°.

*Anal.* Calcd. for $C_{18}H_{20}O_{18}N_8$: C, 33.97; H, 3.17; N, 17.6. Found: C, 34.03; H, 3.55; N, 17.4.

Essentially the same procedure was used with the dihydrobromide prepared from β-dibromocyclohexanetetrol. For example, to a solution of the dihydrobromide (4.75 g.) in water (40 cc.) picric acid (6.65 g.) in ethanol (75 cc.) was added. After concentration to about 50 cc. the solution was chilled; and the precipitate (7.2 g., m. p. 155–220°) collected after one hour. For removal of the picric acid present the product was extracted with cold benzene, and the residue leached with methanol (150 cc.). After filtering off of the insoluble portion and concentration of the filtrate to 50 cc. benzene (250 cc.) was added. The solution on standing at 4° deposited 1.9 g. of **β-diamine I dipicrate** in form of indistinctly crystalline aggregates. The recrystallized product was indistinguishable in appearance and melting point from α-diamine I dipicrate (m. p. 240–242° (dec.) after darkening and sintering beginning at 207°). There was no depression of the melting point in mixture.

*Anal.* Calcd. for $C_{18}H_{20}O_{18}N_8$: C, 33.97; H, 3.17; N, 17.6. Found: C, 33.71; H, 3.35; N, 17.8.

The methanol-insoluble fraction (187 mg.) was recrystallized twice from water, yielding 107 mg. of diamine II dipicrate. The product showed the same melting point behavior as the diamine II dipicrate prepared from the α-tetrol.

*Anal.* Calcd. for $C_{18}H_{20}O_{18}N_8$: C, 33.97; H, 3.17; N, 17.6. Found: C, 34.27; H, 3.66; N, 17.8.

**Salts and Acyl Derivatives of α-Diamine I.**—α-Diamine I dipicrate (1.62 g.) was decomposed in the usual way with dilute hydrochloric acid and toluene–benzene. The lyophilized material from the aqueous phase (628 mg.) was dissolved in dry methanol and precipitated with ether. The dihydrochloride was obtained as an amorphous, hygroscopic, white product which started sintering at 90° but showed no definite melting point up to 180°. The analytical sample was dried at 78° *in vacuo*.

*Anal.* Calcd. for $C_6H_{14}O_4N_2\cdot 2HCl$: Cl, 28.2. Found: Cl, 28.2.

The **sulfate** was prepared from the dihydrochloride by double decomposition with one molar equivalent of silver sulfate. It was purified by dissolving it in a small volume of warm water and adding excess methanol; microscopic prisms, which darken from 260° on, and undergo pronounced decomposition from 285° to 340° without melting completely. The salt differs from streptamine sulfate by its crystal shape and its much higher solubility in water.

*Anal.* Calcd. for $C_6H_{14}O_4N_2\cdot H_2SO_4$: N, 10.14; S, 11.6. Found: N, 10.14; S, 11.2.

For the preparation of the **N,N'-diacetate** a mixture of the dihydrochloride (100 mg.), silver acetate (133 mg.), acetic anhydride (1.2 cc.) and dry methanol (0.9 cc.) was shaken for 2.5 hours, allowed to stand overnight and then heated on the steam-bath for five minutes. The silver chloride was filtered off from the warm solution and washed with hot water (10 cc.). A few drops of 1 *N* HCl were added to the filtrate for the removal of dissolved silver and the filtered solution was concentrated *in vacuo* to a small volume. On addition of ethanol (2 cc.) and standing in the refrigerator a precipitate formed, which was recrystallized twice by dissolving it in the minimal volume of hot methanol and adding excess ethanol. The purified product (69 mg.) consisted of small rods melting without decomposition at 210–212°. The analytical sample was dried at 155° *in vacuo* and then melted at 213–215°.

*Anal.* Calcd. for $C_{10}H_{18}O_6N_2$: C, 45.79; H, 6.92; N, 10.68. Found: C, 45.75; H, 7.12; N, 10.42.

The **hexaacetate** was prepared by boiling a mixture of the sulfate (26 mg.), anhydrous sodium acetate (22 mg.), and acetic anhydride (2 cc.) under reflux for one hour. The acetic anhydride was removed by vacuum distillation and the residue was extracted several times with chloroform. The product obtained by evaporating the filtered chloroform extract (40 mg.) was sublimed at 140–150° (0.07 mm.). The sublimate consisted of microscopic rods (23 mg.) melting to a viscous droplet at 142–146° with meniscus formation at 177°. The analysis of this and another preparation was not quite satisfactory.

*Anal.* Calcd. for $C_{18}H_{26}O_{10}N_2$: C, 50.23; H, 6.09; $COCH_3$, 60.0. Found: C, 49.31; H, 5.88; $COCH_3$, 56.5.

For the preparation of the **hexabenzoate** a mixture of the dihydrochloride (199 mg.), pyridine (2.5 cc.) and benzoyl chloride (1 cc.) was heated just to boiling. After cooling the mixture was poured into ice water, acidified with hydrochloric acid, and extracted with chloroform. The extract was washed with bicarbonate solution and water, dried and evaporated. The residue was triturated with warm ether, and the insoluble portion (472 mg.) recrystallized twice from chloroform–ether. Small rods (408 mg.), melting without decomposition at 252–255°. On drying for the analysis at 155° *in vacuo* the melting point remained unchanged.

*Anal.* Calcd. for $C_{48}H_{38}O_{10}N_2$: C, 71.81; H, 4.77. Found: C, 71.86; H, 4.85.

**Salts and Acyl Derivatives of β-Diamine I.**—In general the same procedures were used as in the case of α-diamine I.

The **dihydrochloride** was obtained from the dipicrate in 72% yield, amorphous, gradually decomposed with effervescence after sintering at about 95°. The material was dried for analysis at 78° *in vacuo*.

*Anal.* Calcd. for $C_6H_{14}O_4N_2\cdot 2HCl$: C, 28.70; H, 6.42. Found: C, 28.63; H, 6.51.

**Sulfate**: microscopic prisms, darken above 280°, no m. p. up to 340°.

*Anal.* Calcd. for $C_6H_{14}O_4N_2 \cdot H_2SO_4$: C, 26.12; H, 5.84; N, 10.14. Found: C, 25.80; H, 6.10; N, 9.84.

The **N,N'-diacetate** was prepared from the dihydrochloride (101 mg.) with acetic anhydride (0.12 cc.) and methanol (0.9 cc.) as described for the α-diamine. The crude product was thrice recrystallized from methanol–ethanol, yielding small prisms (42 mg.) which started sintering at 194° and then gradually decomposed over the range 208–245°. This behavior is in marked contrast to that of the α-diamine I N,N'-diacetate (see above). A mixture of the two compounds melted over the same range as the α-isomer. The analytical sample was dried at 150° *in vacuo*.

*Anal.* Calcd. for $C_{10}H_{18}O_6N_2$: C, 45.79; H, 6.92; N, 10.68. Found: C, 46.14; H, 6.99; N, 10.57.

The **hexaacetate** was prepared from the dihydrochloride (213 mg.) with sodium acetate (145 mg.) and acetic anhydride (14 cc.) as described for the α-isomer. Like the latter, it could be sublimed in a high vacuum, but the bulk of the material was in this case purified by precipitation from chloroform or dioxane with dry ether. The final product was not distinctly crystalline. The melting point properties were similar to those of the α-isomer (liquefication at 145–149°, meniscus at 170°). A mixture of the isomers showed the same behavior. The compound was dried for analysis at 110° (2 mm.).

*Anal.* Calcd. for $C_{18}H_{26}O_{10}N_2$: C, 50.23; H, 6.09; N, 6.51; 6 $COCH_3$, 60.0. Found: C, 49.83; H, 6.17; N, 6.26; $COCH_3$, 58.6.

The **hexabenzoate** was prepared from 206 mg. of the dihydrochloride and worked up as described for the α-isomer. The residue from the chloroform extract was for the most part soluble in ether (difference from α-isomer). Accordingly the ether-soluble part was recrystallized from chloroform–hexane, and then twice from benzene–hexane, from which it separated in well-defined, short needles, melting without decomposition at 262–263° (block preheated to 230°). The melting point of mixtures with the α-isomer (m. p. 252–255°) was found to be 251–253° in repeated determinations. Admixture of a small amount of streptamine hexabenzoate (m. p. 314–316°) to the β-hexabenzoate depressed the melting point of the latter to 258–260°. The analytical sample was dried at 110° (2 mm.).

*Anal.* Calcd. for $C_{48}H_{38}O_{10}N_2$: C, 71.80; H, 4.77; N, 3.49. Found: C, 71.88; H, 5.04; N, 3.47.

The X-ray diffraction diagram[6] showed the following characteristics (letters in brackets denote intensities, *i. e.*, very strong, strong, medium, faint, very faint): 12.00 (v. s.), 10.10 (m.), 8.70 (f.), 7.45 (v. f.), 6.18 (f.), 5.65 (f.), 5.12 (v. f.), 4.85 (s.), 4.62 (s.), 4.33 (s.), 3.93 (m.), 3.54 (f.), 3.41 (f.), 3.24 (f.), 3.08 (f.), 2.73 (f.), 2.38 (v. v. f.), 2.17 (v. v. f.), 2.05 (v. v. f.), 2.02 (v. v. f.), 1.95 (v. v. f.), 12.70 (s.). On the pattern of the α-diamine I hexabenzoate Dr. G. L. Clark comments as follows:

"The pattern is distinguished by only one sharp crystalline interference which corresponds with the innermost, most intense diffraction line of the preceding sample. In addition, there is a broad outer halo which appears to result from the overlapping of several of the ill-defined lines which appear completely resolved for the β-hexabenzoate. This means, therefore, that this second sample is very imperfectly crystalline and that the molecules in the solid have only one direction in which there is anything like a regular arrangement, this corresponding to the longest interplanar spacing. This very diffuse pattern would not eliminate the possibility of an admixture of more than one compound, and it cannot be interpreted as conclusive evidence either that the compound is the same or different from the well-crystallized β-hexabenzoate even granted that there is an approximate (12.0 and 12.7 å.) correspondence in this longest interplanar spacing. This at least is evidence that one of the molecular dimensions must be common to the two materials."

**Diamine II.**—Diamine II dipicrate (83 mg.) prepared from the β-dibromotetrol was dissolved in hot water (10 cc.). After the addition of 2 *N* hydrochloric acid (0.75 cc.) the solution was extracted with toluene and then with benzene. The residue of the lyophilized phase (165 mg.) was purified by dissolving it in warm methanol and concentrating to a small volume. Repetition of the procedure yielded the **dihydrochloride** (22 mg.) as a well-particulated, possibly microcrystalline precipitate which in the capillary started darkening at about 220° but did not liquefy up to 300°. The analytical sample was dried at 110° (2 mm.).

*Anal.* Calcd. for $C_6H_{14}O_4N_2 \cdot 2HCl$: C, 28.70; H, 6.42. Found: C, 28.84; H, 6.65.

A sample prepared *via* the dipicrate from the α-dibromotetrol behaved similarly.

For the preparation of the **N,N-diacetate** the "α"-dihydrochloride (64 mg.) was acetylated with methanol (2.9 cc.), silver acetate (85 mg.) and acetic anhydride (0.18 cc.). After refluxing for five minutes the mixture was worked up as described for the α-diamine I N,N'-diacetate, except that excess ether was added to the aqueous-ethanolic solution of the crude product to complete the precipitation (63 mg.). Recrystallized twice from methanol–ethanol the diacetate formed long needles melting at 268–269° after some sintering at 265°. The preparation derived from the β-dibromotetrol behaved identically, as did the mixture of the two samples. The desiccator-dry specimens contained one mole of water, which was removed by drying at 150° *in vacuo*.

*Anal.* Calcd. for $C_{10}H_{18}O_6N_2$: C, 45.79; H, 6.92; N, 10.68. Found: (a) from α-tetrol: C, 45.61; H, 6.97; N, 10.80; (b) from β-tetrol: C, 45.60; H, 6.91.

Streptamine N,N'-diacetate was prepared as in the above instances by selective N-acetylation instead of by alkaline hydrolysis of the hexaacetate.[4] Its melting point (282–283°) was depressed to 242–262° by admixture of diamine II N,N'-diacetate.

**Periodate Titration.**—Accurately weighed 4–8 mg. samples of the compounds were dissolved in 10 cc. of potassium periodate solution containing 0.0128 atom of available oxygen per cc. One-cc. aliquots were withdrawn at suitable intervals, and after the addition of sulfuric acid, sodium acetate and potassium iodide, titrated with 0.01 *N* thiosulfate solution. The results are expressed in moles of periodate per mole of substance, the figures in parentheses denoting the reaction time in hours.

α-Diamine I dihydrochloride: 4.21 (0.75), 5.76 (3.25), 6.05 (22).
α-Diamine I N,N'-diacetate: 0.43 (1.0), 1.32 (6), 1.97 (23), 1.95 (30).
β-Diamine I dihydrochloride: 4.39 (0.5), 6.11 (21), 6.05 (26).
β-Diamine I N,N'-diacetate: 0.09 (0.5), 1.97 (21), 1.99 (26).
"α"-Diamine II dihydrochloride: 4.82 (0.5), 6.01 (2.5), 6.09 (24).
"α"-Diamine II N,N'-diacetate: 0.64 (0.5), 1.51 (2.5), 2.93 (24), 2.96 (44).
"β"-Diamine II N,N'-diacetate: 0.36 (0.33), 3.00 (22), 2.99 (70).
α-Dibromotetrol: 1.11 (23), 1.46 (46), 2.79 (69), 3.46 (94), 3.96 (144), 4.01 (192).
β-Dibromotetrol: 1.53 (23), 2.30 (46), 2.76 (70), 2.88 (94), 3.02 (118), 3.02 (192).

The analyses were performed by Mr. J. F. Alicino and his assistants.

## Summary

The two isomeric dibromotetraacetoxycyclohexanes ("α"- and "β") which Griffin and Nelson[1] had obtained by treatment of *meso*-inositol with acetyl bromide were hydrolyzed to the corresponding free tetrols. Amination of the dibromotetrols

with aqueous ammonia afforded a mixture of diaminocyclohexanetetrols which were isolated and separated as the picrates.

The main product from the α-dibromotetrol (α-diamine I) was converted into suitable acyl derivatives and compared with the main product from the β-dibromotetrol (β-diamine I) and its derivatives. Though in many respects similar, the two diamines appear to be different chemical entities. Their N,N′-diacetyl derivatives both consumed two moles of periodate indicating that the parent diamines could be either 1,3- or 1,4-diaminocyclohexanetetrols. Identity with streptamine is excluded in either case by the properties of the acyl derivatives.

In addition both dibromotetrols yielded small amounts of an identical diaminocyclohexanetetrol (diamine II). The N,N′-diacetyl derivative consumed three moles of periodate and hence must carry the acetamido groups in vicinal ring positions.

# Ultrasonic Investigation of Molecular Properties of Liquids. V. Inorganic Halides[1]

BY ALFRED WEISSLER

The relation between sound velocity and molecular structure has been studied[2] in several series of organic liquids, but thus far not in inorganic liquids. A group of compounds which seemed especially suitable for this purpose consists of the Group IV tetrahalides. Their molecules may be considered as approximately spherical, so that they are easier to treat theoretically and thus furnish an approach to a better understanding of the liquid state. Because of this, their physical and thermodynamic properties have been studied for many years by Hildebrand[3] and co-workers.

A two-fold aim motivated the present work: (a) comparison of inorganic and organic liquids with respect to sound velocity, and (b) determining further properties of the interesting tetrahalides referred to above. Several thermodynamic quantities may be calculated from the measured velocity of sound in a liquid.

In addition to $CCl_4$, $SiCl_4$, $TiCl_4$, $GeCl_4$ and $SnCl_4$, some of the Group V halides were included here, specifically, $PCl_3$, $PBr_3$, $POCl_3$, $AsCl_3$ and $SbCl_5$.

## Experimental

The ten liquids were procured from commercial sources. Each was purified by fractional distillation (the fraction retained had a boiling-range of 0.5°) shortly before use, and protected as well as possible from deterioration due to moisture. The liquids were handled only under conditions of low atmospheric humidity.

Sound velocities at 30° were measured by means of the three-megacycle ultrasonic interferometer already described,[2] which requires only 10 ml. of sample. In order to minimize contamination of these reactive liquids, all interior surfaces were gold-plated and the usual nickel diaphragm at the floor of the cell was replaced by tantalum.

Densities, heat capacities and coefficients of thermal expansion at 30° were obtained from the "International Critical Tables" and Landolt–Börnstein tables.

## Results and Discussion

The velocity of sound in each of these inorganic halides is given in Table I; the probable accuracy is ±0.1%. These values lie in the range from about 760 to 1000 meters per second, which is somewhat lower than for most other liquids, including the organic halides. Figure 1 shows that no regular change of sound velocity in the tetrachlorides occurs as the atomic number of the central atom increases. In the Group V halides also, there is no consistent trend with molecular weight.

**Molar Sound Velocity.**—Because it is an additive function[4,5] of the chemical bonds in the molecule, the molar sound velocity is useful in correlating molecular structure with sound velocity. It is defined, so as to be empirically almost temperature-independent, as the molar volume times the cube root of sound velocity.[6]

From the values of molar sound velocity listed in Table I, the bond increment characteristic of each bond present in these compounds was obtained by simple arithmetic. For example, the value for $SiCl_4$ was divided by 4 in order to find the Si–Cl increment, while that for $PBr_3$ was divided by 3 to get the P–Br increment. Table II contains the figures so derived, which again fail to vary regularly with atomic number of the central atom, in either Group IV or Group V.

TABLE I

PROPERTIES OF INORGANIC HALIDES AT 30°

| Compound | Sound velocity, meters/sec. | Density, g./ml. | Molar sound velocity | Adiabatic compressibility ($10^{-12}$ cm.²/dyne) | Coefficient of thermal expansion | Heat capacity, joule/g. | Isothermal compressibility ($10^{-12}$ cm.²/dyne) | Ratio of specific heats | Thermal pressure coefficient, $10^6$ dyne/cm.² deg. | Energy-volume coefficient, $10^6$ dyne/cm.² |
|---|---|---|---|---|---|---|---|---|---|---|
| $CCl_4$ | 905.8 | 1.5746 | 945.4 | 77.40 | $1.240 \times 10^{-3}$ | 0.866 | 111.6 | 1.44 | 11.11 | 3367 |
| $SiCl_4$ | 766.2 | 1.4622 | 1063.2 | 116.50 | 1.438 | .837 | 167.7 | 1.44 | 8.57 | 2598 |
| $TiCl_4$ | 977.5 | 1.7078 | 1102.6 | 61.28 | 1.045 | .804 | 85.4 | 1.39 | 12.24 | 3708 |
| $GeCl_4$ | 768.6 | 1.8533 | 1059.8 | 91.34 | 1.273 | .699[a] | 129.3 | 1.42 | 9.85 | 2984 |
| $SnCl_4$ | 782.3 | 2.2004 | 1090.9 | 74.26 | 1.178 | .619 | 105.2 | 1.42 | 11.20 | 3394 |
| $PCl_3$ | 944.1 | 1.5567 | 831.3 | 72.07 | 1.207 | .876 | 104.4 | 1.45 | 11.56 | 3504 |
| $PBr_3$ | 916.7 | 2.8513 | 922.4 | 41.74 | 0.858 | | | | | |
| $POCl_3$ | 969.3 | 1.6564 | 916.5 | 64.26 | | | | | | |
| $AsCl_3$ | 1006.7 | 2.1392 | 884.5 | 46.13 | 1.040 | .737 | 66.9 | 1.45 | 15.55 | 4712 |
| $SbCl_5$ | 912.3 | 2.331 | 1244.3 | 51.54 | | | | | | |

[a] Estimated by interpolation.

**Compressibility.**—The adiabatic compressibility $K_{ad}$ is related to the velocity of sound $v$ and the density $d$ by the equation

$$K_{ad} = 1/v^2d \qquad (1)$$

Adiabatic compressibilities computed from (1) are listed in Table I. $SiCl_4$ is by far the most compressible of these liquids, in agreement with its known low boiling point and low internal pressure, while $PBr_3$ is the least compressible.

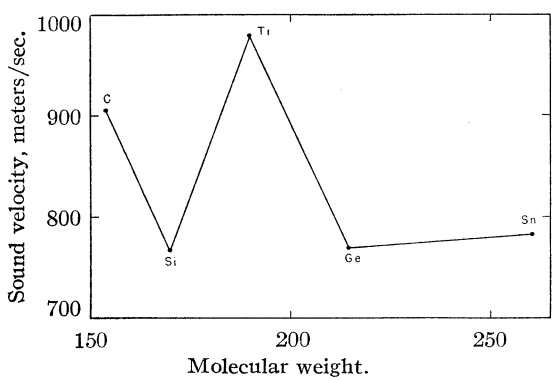

Fig. 1.—Sound velocity in liquid tetrachlorides.

A plot of $K_{ad}$ for the tetrachlorides (solid line, Fig. 2) shows an irregular variation with molecular weight. This is in sharp contrast to the organic halides (for example, methylene chloride, bromide, and iodide) where each increase in molecular weight causes a considerable decrease in compressibility.[5,7]

Freezing points of the tetrachlorides are also plotted in Fig. 2 (broken line) using an inverted temperature scale. The remarkable similarity between the two curves suggests that the same forces which determine compressibility also fix the freezing temperature, for each of these liquids. This may be thought of in the following way. The greater the space between molecules, the greater the compressibility—also, the greater the cooling necessary to bring the molecules sufficiently close together so that their mutual attractive forces become strong enough to freeze the molecules into the solid lattice.

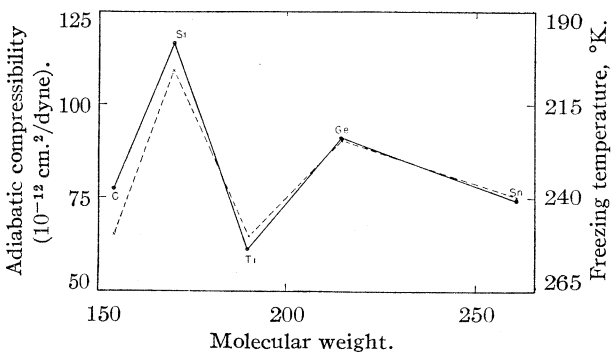

Fig. 2.—Adiabatic compressibility (solid line) and freezing temperature (broken line) of liquid tetrachlorides.

From the adiabatic compressibility plus the heat capacity $c_p$, coefficient of thermal expansion $\alpha$, temperature $T$, and density $d$, the isothermal compressibility may be calculated using the equation

$$K_{is} = K_{ad} + T\,\alpha^2/c_p d \qquad (2)$$

Table I gives the values (where available) for $c_p$, $d$, and $\alpha$, as well as the isothermal compressibilities calculated therefrom for seven of the liquids.

Of thermodynamic interest is the fact that the ratio of isothermal to adiabatic compressibility is equal to the ratio of specific heats $\gamma$. The values for $\gamma$ shown in Table I are as usual considerably higher than those for the same molecules in the gaseous state: thus, 1.44 for liquid $CCl_4$ compared to 1.18 (theoretical) for the gas. For $TiCl_4$, $\gamma$ is appreciably lower than for the other tetrahalides, possibly as a result of the greater ionic character of its bonds.

**Thermal Pressure and Energy–Volume Coefficients.**—The thermal pressure coefficient $(\partial P/\partial T)_V$ is related to the isothermal compressi-

(7) Bergmann, "Der Ultraschall," 3rd ed., Edwards Brothers, Ann Arbor, Mich., 1944, p. 183.

bility in that their product is equal to the coefficient of thermal expansion[8]

$$\left(\frac{\partial P}{\partial T}\right)_V \cdot \frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \frac{-1}{V}\left(\frac{\partial V}{\partial T}\right)_P \qquad (3)$$

Values for $(\partial P/\partial T)_V$ computed from this equation are listed in Table I, which shows that $SiCl_4$ has the lowest and $AsCl_3$ the highest. Comparison with the thermal pressure coefficients previously obtained by direct measurement[9] for four of these liquids indicates fairly good agreement; uncertainty in the specific heats probably accounts for much of whatever differences exist.

A thermodynamic equation of state applicable to all substances is

$$(\partial E/\partial V)_T = T(\partial P/\partial T)_V - P \qquad (4)$$

which makes it possible to calculate the important coefficient for the variation of energy with volume, $(\partial E/\partial V)_T$. For a liquid, this quantity is also called the internal pressure (dimensions of energy/volume are equivalent to pressure) because it is a measure of the attractions and repulsions of the molecules. These energy–volume coefficients obtained from equation (4), taking $P$ as atmospheric pressure ($1.013 \times 10^6$ dynes/cm.$^2$), are given in Table I. Again there is no monotonic variation with molecular weight.

(9) Hildebrand and Carter, THIS JOURNAL, **54**, 3592 (1932).

**Estimation of Heat Capacity.**—The heat capacity $c_P$ may be estimated by means of equation (2), if the other quantities are known. This may be illustrated in the case of $PBr_3$. Assuming as an approximation that $\gamma$ for this compound is 1.45, the same as for $PCl_3$ and $AsCl_3$, we find that the heat capacity at 30° is 0.417 joule/gram, with a presumable accuracy of a few per cent.

TABLE II

BOND INCREMENTS FOR MOLAR SOUND VELOCITY

| Bond | Increment | Bond | Increment |
|---|---|---|---|
| C–Cl | 236 | P–Cl | 277 |
| Si–Cl | 266 | P–Br | 307 |
| Ti–Cl | 276 | P=O | 85 |
| Ge–Cl | 265 | As–Cl | 295 |
| Sn–Cl | 273 | Sb–Cl | 249 |

**Acknowledgment.**—It is a pleasure to acknowledge the many helpful suggestions made by Dr. G. R. Ringo during the course of this work.

## Summary

The velocity of sound at 30° in ten inorganic halides has been determined; on the average, it is lower than in the organic halides. Such properties as compressibility, ratio of specific heats, and the energy–volume coefficient have been computed from the sound velocities. There is no systematic variation with molecular weight in any of these properties.

# Resolution of the Dissociation Constants of Citric Acid at 0 to 50°, and Determination of Certain Related Thermodynamic Functions[1]

BY ROGER G. BATES AND GLADYS D. PINCHING

The development of exact electromotive-force methods[2,3] has brought about a considerable extension of our knowledge of the thermodynamics of weak electrolytes in recent years. In general, these experimental procedures, based upon electromotive-force measurements of cells without liquid junction, have been applied only to systems the composition of which can be completely expressed in terms of stoichiometric concentrations, the water equilibrium, and a single step in the dissociation of the weak electrolyte. If two or more acids or acidic groups are partially neutralized in the same range of hydrogen-ion concentrations, as is often the case with organic polybasic acids, the composition of the mixture may be quite difficult to establish. For this reason little attention has been directed to the resolution, by thermodynamic methods, of the dissociation constants of dibasic acids for which $K_1/K_2$ is less than 1000.

Separation of the constants for three overlapping equilibria is even more laborious. For citric acid, $K_1/K_2$ and $K_2/K_3$ are both about 44 at 25°. Existing values[4,5,6] of the thermodynamic constants for this acid were derived from electromotive-force measurements of cells with liquid junction. The analysis of the data rests in each instance upon a computation of the hydrogen-ion concentration or activity. Consequently, an assumption regarding the potential at the liquid junction must be introduced.

In spite of the interest that attaches to the thermodynamics of such a three-step dissociation process, no determination of the constants of a tribasic acid, with or without overlapping, has

heretofore been made by methods free of the uncertainties of a liquid junction. The changes of entropy and of heat capacity accompanying dissociation are computed from the first and second derivatives, respectively, of electromotive force (or log $K$) with temperature. Hence, these functions can be established accurately only from a multifarious series of measurements over a range of temperatures.

The three dissociation constants of citric acid have therefore been determined at intervals of 5° from 0 to 50° by measurement of the electromotive force of hydrogen–silver chloride cells without liquid junction. The changes of free energy, heat content, entropy and heat capacity accompanying the acidic dissociation of one mole of citric acid or one gram ion of primary or secondary citrate ion in the standard state at 0 to 50° have been calculated.

## Method of Resolution

All of the cells are represented by the following scheme

Pt; $H_2$(g), citrate buffer solution, KCl, AgCl(s); Ag

Each value of the electromotive force of this cell for a solution of known chloride concentration furnishes a measure of $-\log (f_H f_{Cl} m_H)$, where $m$ is molality and $f$ is the activity coefficient on the molal scale. For convenience, this experimental quantity has been termed $pw$H.[7] The

$$pw\mathrm{H} \equiv -\log (f_H f_{Cl} m_H) = \frac{(E - E^0)\mathbf{F}}{2.3026\ RT} + \log m_{Cl} \quad (1)$$

value of $E^0$ in int. v. has been determined by Harned and Ehlers,[8] and 2.3026 $RT/\mathbf{F}$ in the same units has been tabulated in an earlier publication from this Bureau.[9]

The buffer solutions in the range of $p$H governed principally by the third dissociation equilibrium were prepared from tertiary potassium citrate and secondary potassium citrate. In order to minimize corrections for the second dissociation step, the salts were combined in the molal ratio 3:1. The advantage of a similar preponderance of free citric acid over primary potassium citrate for the determination of the first constant is offset by the enhanced correction for hydrogen ion, and for this reason a molal ratio of unity was selected. The $K_2$ correction is therefore more important in the determination of $K_1$ than of $K_3$, although only two equilibria need be considered in each instance.

The compositions of mixtures of primary and secondary citrates, on the other hand, can be expressed completely only in terms of all three steps in the dissociation of the acid, namely[10]

$$H_3Ci + H_2O \rightleftharpoons H_2Ci^- + H_3O^+; \quad K_1 \quad (2a)$$
$$H_2Ci^- + H_2O \rightleftharpoons HCi^= + H_3O^+; \quad K_2 \quad (2b)$$
$$HCi^= + H_2O \rightleftharpoons Ci^{\equiv} + H_3O^+; \quad K_3 \quad (2c)$$

Hence, no pair of constants can be evaluated by simple simultaneous solution of two formal equations derived exclusively from data corresponding to the three regions where the buffer capacity is highest. One of the authors has recently shown,[11] however, that the resolution of the constants for overlapping equilibria can be materially simplified with the aid of electromotive-force data for buffer solutions composed simply of a single acid salt (with added chloride). In this way a second equation can be written in terms of $K_1$ and $K_2$ (or $K_2$ and $K_3$) with at most a relatively minor correction for a third equilibrium.

It is therefore possible to obtain the first and second constants from an analysis of only two sets of data and, by a similar procedure, also the second and third constants. In practice, the equations are most conveniently solved by the method of approximations. The concentrations of secondary and tertiary citrates were so chosen that the influence of $K_2$ on the third constant was kept relatively small. It was found by trial that $pK_2$ need be known only within 0.03 to yield a value of $pK_3$ accurate to 0.001 unit. For the same accuracy in $pK_1$, it is necessary to know $pK_2$ to the nearest 0.01 unit. Somewhat larger errors are inherent in the value of $pK_2$ derived in this way, however, for the electromotive force of the cells containing the acid salt depends upon the product of two constants.[11] It follows, then, that the equations for overlapping are of limited usefulness in determining $K_2$ accurately, although they are a material aid in resolving the constants, for they permit the first and third equilibria readily to be freed of the influence of the second. With a knowledge of $K_1$ and $K_3$, however, $K_2$ can be determined by conventional methods.

The buffer solutions studied are conveniently grouped into five series: (1) mixtures of citric acid and potassium dihydrogen citrate, (2) potassium dihydrogen citrate, (3) mixtures of potassium dihydrogen citrate and dipotassium hydrogen citrate, (4) dipotassium hydrogen citrate, and (5) mixtures of dipotassium hydrogen citrate and tripotassium citrate. Potassium chloride was added to each solution. The number of solutions studied in each of these five series was respectively, 19, 25, 10, 5 and 25.

**Series 1.**—For systems governed principally by the first dissociation equilibrium, such as

(7) R. G. Bates, *Chem. Rev.*, **42**, 1 (1948).

(8) H. S. Harned and R. W. Ehlers, THIS JOURNAL, **55**, 2179 (1933). The determination of $E^0$ from these data has also been examined by H. S. Harned and D. D. Wright, *ibid.*, **55**, 4849 (1933), and by W. J. Hamer, J. O. Burton and S. F. Acree, *J. Research Natl. Bur. Standards*, **24**, 269 (1940).

(9) G. G. Manov, R. G. Bates, W. J. Hamer and S. F. Acree, THIS JOURNAL, **65**, 1765 (1943).

(10) In these equations, Ci is written for citrate, and $K$ is the thermodynamic dissociation constant. For simplicity, H will be written for hydronium ion, and the charges will be omitted from the symbols for this ion and for chloride ion. The activity of water does not depart greatly from unity in the dilute solutions, and it will therefore be omitted from the equations. As usual, $pK \equiv -\log K$.

(11) R. G. Bates, THIS JOURNAL, **70**, 1579 (1948).

those of series 1, it is convenient to write the relationship between $pw\mathrm{H}$ and $pK_1$ in the form

$$pK_1 = pw\mathrm{H} + \log \frac{m_{\mathrm{H_3Ci}}}{m_{\mathrm{H_2Ci^-}}} + \log \frac{f_{\mathrm{H_3Ci}} f_{\mathrm{Cl}}}{f_{\mathrm{H_2Ci^-}}} \quad (3)$$

The concentration term, $m_{\mathrm{H_3Ci}}/m_{\mathrm{H_2Ci^-}}$, can be expressed in terms of $m$ (the stoichiometric molality of citric acid and of primary potassium citrate), $m_{\mathrm{H}}$, and $m_{\mathrm{HCi^=}}$ by consideration of the equilibria that fix the compositions of the solutions of series 1. If the Debye–Hückel equation[12] is assumed, the last term of equation (3) disappears at low ionic strengths. Hence, the "apparent" first constant, $K_1'$, which becomes equal to the thermodynamic $K_1$ at zero ionic strength, is given by

$$pK_1' = pw\mathrm{H} + \log \frac{m - m_{\mathrm{H}} + m_{\mathrm{HCi^=}}}{m + m_{\mathrm{H}} - 2m_{\mathrm{HCi^=}}} \quad (4)$$

The apparent hydrogen-ion concentration, $m_{\mathrm{H}}$, which approaches the true hydrogen-ion concentration at low ionic strengths, was obtained from $pw\mathrm{H}$ by substitution of the Debye–Hückel equation for the activity coefficients of hydrogen and chloride ions

$$-\log m_{\mathrm{H}} = pw\mathrm{H} + \log f_{\mathrm{H}} f_{\mathrm{Cl}} = pw\mathrm{H} - \frac{2A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (5)$$

The constants $A$ and $B$ depend upon the temperature[9]; $a^*$ is the ion-size parameter. The ionic strength, $\mu$, of the mixtures of series 1 is

$$\mu = m + m_{\mathrm{H}} + m_{\mathrm{HCi^=}} + m_{\mathrm{KCl}} \quad (6)$$

The necessary correction for the molality of secondary citrate ion, $m_{\mathrm{HCi^-}}$, is made only with an estimate of $K_2$

$$m_{\mathrm{HCi^=}} = m_{\mathrm{H_2Ci^-}} \text{ (antilog } pw\mathrm{H}) \, K_2/f^2 \quad (7)$$

The activity coefficient, $f^{\mathrm{n}}$, was computed here and in other steps of the calculations by the Debye–Hückel equation[12]

$$\log f^{\mathrm{n}} = \frac{-nA\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (8)$$

**Series 2.**—The value of $(K_1K_2)'$, the apparent product of $K_1$ and $K_2$, is related to the electromotive force of the cells containing primary potassium citrate and potassium chloride by the following equation[13]

$$-\tfrac{1}{2}\log (K_1K_2)' = pw\mathrm{H} - \tfrac{1}{2}\log \frac{m_{\mathrm{H_3Ci}} + m_{\mathrm{H}} - m_{\mathrm{Ci^{\equiv}}}}{m_{\mathrm{H_3Ci}}} + \frac{A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (9)$$

The true $K_1K_2$ is obtained by extrapolation of apparent values to zero ionic strength, where the last term of the equation is zero. In writing equation (9), the activity coefficient of the molecular acid has been assumed to be unity, and that of each ionic species has been represented by the Debye–Hückel formula.

The second term on the right of equation (9) changes but slightly with relatively large alterations in the estimated molality of free citric acid. Consequently it can be obtained readily with sufficient accuracy by the approximation[11]

$$\frac{m_{\mathrm{H_3Ci}} + m_{\mathrm{H}} - m_{\mathrm{Ci^{\equiv}}}}{m_{\mathrm{H_3Ci}}} \approx \frac{mx + m_{\mathrm{H}} - 2m_{\mathrm{Ci^{\equiv}}}}{mx - m_{\mathrm{H}}} \quad (10)$$

where $m$ is the molality of potassium dihydrogen citrate and $x$ is a function of the concentration dissociation constants, $k_{\mathrm{n}}$

$$x \equiv \frac{2(k_2/k_1)^{1/2}}{1 + 2(k_2/k_1)^{1/2}} \quad (11)$$

These concentration constants are related to the thermodynamic constants, $K_{\mathrm{n}}$, by the following expression

$$k_{\mathrm{n}} = K_{\mathrm{n}}/f^{2n} \quad (12)$$

The activity coefficient, $f^n$, is obtained by equation (8).

The concentration of hydrogen ion in equation (10) is small compared with $m_{\mathrm{H_3Ci}}$. Its approximate value is derived from $pw\mathrm{H}$ by equation (5). The concentration of citrate ion, $m_{\mathrm{Ci^{\equiv}}}$, in primary citrate solutions of molality, $m$, not exceeding 0.1 is less than 1% of $m_{\mathrm{H_3Ci}}$. Hence, this molality is a correction of secondary importance in equation (10) and can be estimated with sufficient accuracy if the approximate magnitude of $K_3$ is known

$$m_{\mathrm{Ci^{\equiv}}} = \frac{K_3 m_{\mathrm{HCi^=}}}{f^6 m_{\mathrm{H}}} \approx \frac{K_3(mx + m_{\mathrm{H}})}{2f^6 m_{\mathrm{H}}} \quad (13)$$

In order to estimate $m_{\mathrm{H}}$ and $m_{\mathrm{HCi^=}}$, as well as to perform the extrapolation, the ionic strength was calculated by

$$\mu = m(1 + 0.5x) + 1.5m_{\mathrm{H}} + 2.5m_{\mathrm{Ci^{\equiv}}} + m_{\mathrm{KCl}} \quad (14)$$

It has been shown[11] that the choice of $a^*$ in equations (5) and (8) has a negligible influence upon $K_1K_2$ in the limit of zero ionic strength, provided the same value is used in both equations.

**Series 3.**—In a buffer mixture composed of primary and secondary potassium citrates and potassium chloride, each at a molality $m$, the second dissociation constant is given by

$$pK_2 = pw\mathrm{H} + \log \frac{m_{\mathrm{H_2Ci^-}}}{m_{\mathrm{HCi^=}}} + \log \frac{f_{\mathrm{H_2Ci^-}} f_{\mathrm{Cl}}}{f_{\mathrm{HCi^=}}} \quad (15)$$

The second term on the right can be written in terms of $m$ and the actual concentrations of free citric acid and of tertiary ion in the buffer solutions. Likewise, the activity-coefficient term can be expressed by the Debye–Hückel equation, and the second constant can be obtained in the usual manner by extrapolation to zero ionic strength of apparent values, $pK_2'$, defined by

$$pK_2' = pw\mathrm{H} + \log \frac{m - 2m_{\mathrm{H_3Ci}} + m_{\mathrm{Ci^{\equiv}}}}{m + m_{\mathrm{H_3Ci}} - 2m_{\mathrm{Ci^{\equiv}}}} + \frac{2A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (16)$$

The ionic strengths of the buffer solutions of series 3 are given by

$$\mu = 5m + 0.5m_{\mathrm{H}} + m_{\mathrm{H_3Ci}} + m_{\mathrm{Ci^{\equiv}}} \quad (17)$$

The values of $m_{\mathrm{H_3Ci}}$ and of $m_{\mathrm{Ci^{\equiv}}}$ are readily obtained, when $K_1$ and $K_3$ have been determined,

(12) P. Debye and E. Hückel, *Physik. Z.*, **24**, 185 (1923).

(13) Compare Case IV of ref. 11.

with sufficient accuracy by a short series of approximations

$$m_{H_3Ci} = f^2 m_H (m - 2m_{H_3Ci} + m_{Ci^{\equiv}})/K_1 \quad (18)$$

$$m_{Ci^{\equiv}} = K_3(m + m_{H_3Ci} - 2m_{Ci^{\equiv}})/(f^6 m_H) \quad (19)$$

The concentration of hydrogen ion is obtained as before by equation (5).

**Series 4.**—The electromotive force of the cells containing mixtures of secondary potassium citrate and potassium chloride, each at molality $m$, is related to $(K_2K_3)'$, the apparent value of $K_2K_3$, by the equation [14]

$$-{}^1/_2 \log (K_2K_3)' = pwH - {}^1/_2 \log \frac{m_{H_2Ci^-} + m_H + 2m_{H_3Ci}}{m_{H_2Ci^-}} + \frac{3A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (20)$$

The second term on the right of equation (20) is readily obtained by

$$\frac{m_{H_2Ci^-} + m_H + 2m_{H_3Ci}}{m_{H_2Ci^-}} \approx \frac{my + m_H + 2m_{H_3Ci}}{my - m_H - 2m_{H_3Ci}} \quad (21)$$

where

$$y \equiv \frac{2(k_3/k_2)^{1/2}}{1 + 2(k_3/k_2)^{1/2}} \quad (22)$$

The concentration constants, $k_n$, are obtained by equations (8) and (12), and $m_H$ by equation (5). The choice of $a^*$ in equations (5) and (8) has a negligible effect upon the second term on the right of formula (20). The molality of citric acid, $m_{H_3Ci}$, amounts to only 4% of $my$. It is calculated with sufficient accuracy by the approximate formula

$$m_{H_3Ci} \approx \frac{f^2 m_H (my - m_H)}{2K_1} \quad (23)$$

Finally, the ionic strengths of the solutions of series 4 are given by

$$\mu = m(4 + 0.5y) + 2.5m_H + 2m_{H_3Ci} \quad (24)$$

**Series 5.**—The principal equilibrium in mixtures of secondary potassium citrate ($m_1$), tertiary potassium citrate ($m_2$), and potassium chloride is (2c). The third constant is given by

$$pK_3 = pwH - \log \frac{m_{Ci^{\equiv}}}{m_{HCi^{=}}} + \log \frac{f_{Cl} f_{HCi^{=}}}{f_{Ci^{\equiv}}} \quad (25)$$

The concentration of hydrogen ion in these solutions is so small that it can be neglected entirely. Consideration of the second and third dissociation steps, equilibria (2b) and (2c), leads to the equality

$$\frac{m_{Ci^{\equiv}}}{m_{HCi^{=}}} = \frac{m_2 + m_{H_2Ci^-}}{m_1 - 2m_{H_2Ci^-}} \quad (26)$$

Hence, when the activity coefficients are expressed by the Debye–Hückel equation, the following extrapolation formula is obtained.

$$pK_3' = pwH - \log \frac{m_2 + m_{H_2Ci^-}}{m_1 - 2m_{H_2Ci^-}} + \frac{4A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (27)$$

The molality of the primary anion, $m_{H_2Ci^-}$, is but 1.5% of $m_1$ for mixtures of series 5, in which $= 3m_1$. It was evaluated by equation (7) with substitution of $m_1$ for $m_{iCH^-}$. The ionic strength is given by

$$\mu = 3m_1 + 6m_2 + m_{H_2Ci^-} + m_{KCl} \quad (28)$$

The problem of resolving the three constants was approached in the following manner. Inasmuch as the precise determination of any one of the constants requires a knowledge of at least one of the others, it was first necessary to ascertain the accuracy with which these other constants must necessarily be estimated to allow $pK$ to be established with an accuracy of 0.001. As indicated earlier in this paper, $pK_2$ need be known to 0.01 unit for the accurate determination of $pK_1$ and to 0.03 unit for the calculation of $pK_3$ from the measurements of series 5. As a point of departure, $pK_2$ was taken as 4.76, the value at 25° found by Bjerrum and Unmack.[6] Values for the first and third constants were then obtained by analysis of the data for solutions of series 1 and series 5. With these, values of $K_1K_2$ and of $K_2K_3$, from which a new $K_2$ could be derived, were obtained from the measurements of series 2 and series 4 and the calculation of $pK_1$ and $pK_3$ repeated. A third approximation was usually unnecessary. Finally, with $pK_1$ and $pK_3$ already established, the values of $pK_2$ derived from series 2 and series 4 were supplemented by a calculation of $pK_2$ from the measurements with solutions of series 3. Approximation methods were used in establishing the ionic and molecular concentrations and the ionic strength for each solution.

## Experimental

**Anhydrous Citric Acid.**—Anhydrous citric acid of special purity was obtained through the courtesy of Chas. Pfizer & Co., Inc. Samples of the acid were titrated with a carbonate-free solution of sodium hydroxide to the blue color of thymol blue. The acid was found to have a neutralization value of 100.03 ± 0.05%.

**Tripotassium citrate monohydrate** of reagent grade was crystallized twice from water. Before the first crystallization, the saturated solution of the salt was adjusted to $p$H 8.8 to 9.0 by the addition of small amounts of a solution of potassium hydroxide. The salt was dried at 110°. The weight of ash obtained when three 5-g. samples were heated in a muffle furnace at 800° averaged 100.04% of the theoretical, with a mean deviation of 0.06.

**Potassium dihydrogen citrate** was prepared by mixing aqueous solutions of citric acid and tripotassium citrate monohydrate in the correct proportions and crystallizing. The salt was dried in a vacuum at a temperature below 80°[15] and was analyzed by titration with standard alkali to the thymol blue end-point and by differential electrometric titration. Some difficulty was experienced in obtaining primary salt of the correct composition by repeated crystallization from water or by precipitation from an aqueous solution with ethanol. One sample of salt used appeared to contain about 0.3 mole % of citric acid. Corrections for this amount of free acid were applied to the experimental data.

**Dipotassium hydrogen citrate** could not conveniently be crystallized from water. Solutions of this salt were therefore prepared as required from solutions of citric acid and of the tertiary salt.

**Potassium chloride** was purified and fused in an atmos-

[a] Each e. m. f. value is the average result of 2 cells (4 pairs of electrodes). Of 193 such measurements, 128 differed by 0.1 mv. or less, 46 by 0.1 to 0.2 mv. and 19 by more than 0.2 mv.

phere of nitrogen as described by the authors in an earlier publication.[16]

Air was removed from each cell solution by bubbling nitrogen through each solution flask for at least two hours. An air-free technique was used in filling the cells. Measurements at the 11 temperatures extended over a period of three days. The cells showed remarkable stability, however, and often resumed their initial values of electromotive force within a few hundredths of a millivolt at the conclusion of the series. The average change during this time was about 0.1 mv.

Two constant-temperature water-baths and two potentiometers were used. Temperatures were measured with a platinum resistance thermometer and with a calibrated mercury thermometer. The standards of electromotive force were two saturated Weston cells maintained in a temperature-controlled box of the type described by Mueller and Stimson.[17] The cells had been calibrated recently by this Bureau. Other details concerning the experimental methods are described elsewhere.[18]

## Results

The electromotive force of the cells containing solutions of series 1, 3 and 5, corrected as usual to 1 atm. partial pressure of hydrogen, is listed in Table I. The electromotive force of cells containing 25 solutions of potassium dihydrogen citrate of molality $m$ in 0.01 $m$ potassium chloride (series 2) was found to be a linear function of log $m$ at each temperature

$$E_t = a + b \log m \qquad (29)$$

The constants of equation (29) are given in Table II, together with the mean difference, $\Delta$, between observed and calculated values of the electromotive force. Five solutions were studied in series 4 to demonstrate, by comparison with the results from series 2, the internal consistency of the equations for overlapping. The data obtained at 25° are listed in Table III.

The determination of $pK_1$ is portrayed in Fig. 1, where $pK_1'$ at 25° computed from the measurements of series 1 is plotted as a function of the ionic strength. The curve at the bottom represents the value of $pK_1'$ obtained by equation (4) when $m_{HCi^=}$, which embodies the correction for the second dissociation step, is omitted.

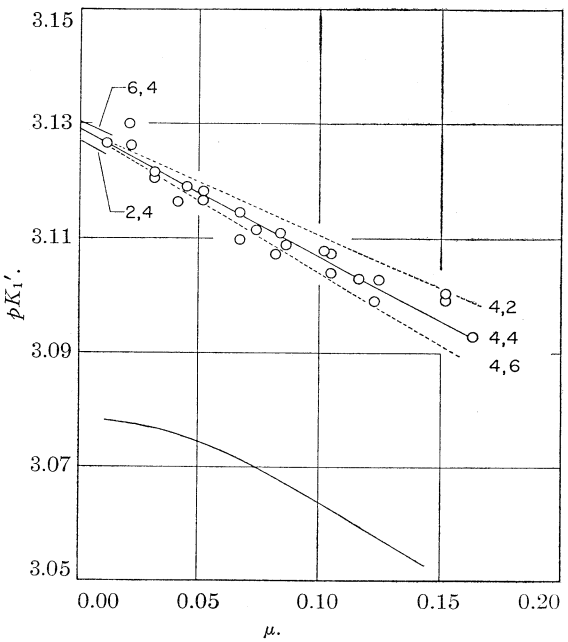

Fig. 1.—Determination of $pK_1$ from data of series 1.

Two numbers appear beside each of the upper curves of Fig. 1. The first of these represents the value of $a^*$ chosen for the computation of $m_H$ by equation (5), and the second is the value used to obtain $m_{HCi^=}$ by equations (7) and (8). Unfortunately, the first acidic dissociation is so strong that some uncertainty is introduced in the final $pK_1$ by the arbitrary choice of $a^*$ for the computation of the hydrogen-ion concentration by equation (5). Nevertheless, the value of $a^*$ used to compute the $K_2$ correction by equations (7) and (8) is of little concern, for the lines converge satisfactorily when the correction for the second dissociation step is made with different values of $a^*$, provided that $a^*$ of equation (5) does not vary. The three different intercepts at zero ionic strength show, however, that the value of $pK_1$ determined by extrapolation is dependent upon the value of $a^*$ chosen to compute the hydrogen-ion correction. When $a^*$ is changed from 4 to 6 or 2, $pK_1$ is, respectively, raised or lowered by 0.001 to 0.002. A value of 4 was used in the calculation at each temperature. It is therefore impossible to consider $pK_1$ more accurate than $\pm 0.003$. Inasmuch as the estimation of $m_H$ or $m_{OH}$ in a buffer solution from the electromotive force necessarily requires an assumption regarding activity coefficients, the accuracy of this electromotive-force method diminishes some-

what when $pK$ is less than 3 or greater than 11.[19]

The extrapolation of data obtained with the solutions in series 2 (mixtures of primary potassium citrate and potassium chloride) is shown in Fig. 2. The choice of $a^*$ in formulas (5) and (8) has, within reasonable limits, a negligible effect on the second term on the right of equation (9). The value of $a^*$ in equation (9) is chosen to yield a straight-line extrapolation. A value of 3 was found best suited to this purpose at each temperature, and, for convenience, this value was also used in equations (5) and (8).

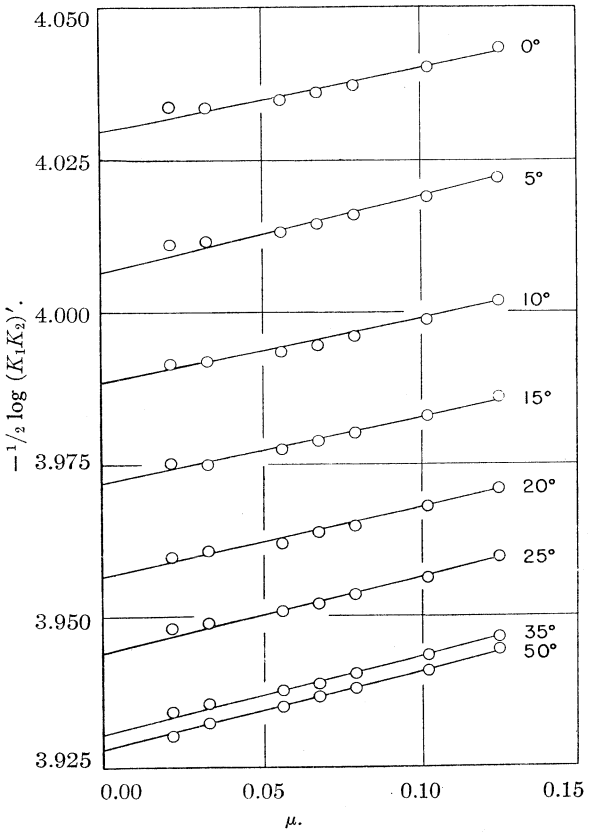

Fig. 2.—Determination of $K_1K_2$ from data of series 2.

Figure 3 is a plot of $pK_2'$, derived from the measurements of series 3 by equation (16), as a function of ionic strength at 25°. The extrapolation was made most conveniently, as the figure shows, with the use of $a^* = 6$ in equation (16). Inasmuch as the curves converged satisfactorily at zero ionic strength when different values of $a^*$ were used in equation (8) to compute the activity coefficients of formulas (18) and (19), $a^*$ was taken as 6 also in equation (8).

(19) In the analysis of some unpublished data, the senior author has found the extrapolated value of $pK$ for the first step in the dissociation of phosphoric acid to be altered by nearly 0.03 when $a^*$ used to compute $m_H$ is changed from 2 to 6. $pK_1$ is 2.12: L. F. Nims, THIS JOURNAL, **56**, 1110 (1934). A similar but much less pronounced effect has been reported by W. J. Hamer, G. D. Pinching, and S. F. Acree, *J. Research Natl. Bur. Standards*, **35**, 539 (1945), for *o*-phthalic acid, a weaker acid than phosphoric.

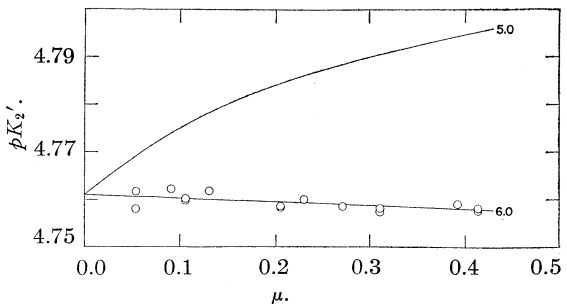

Fig. 3.—Determination of $pK_2$ from data of series 3. Number beside each curve indicates the value of $a^*$ used.

The essential agreement of $pK_2$ values calculated by the equations for overlapping from the measurements of series 8 and of series 4 is demonstrated in Fig. 4. These curves show, as well, the consistency of the results for $pK_1$ and $pK_3$ at this temperature, for the open circles were derived from $-\frac{1}{2}\log(K_1K_2)'$ of equation (9) together with $pK_1$, whereas the dots were obtained from $-\frac{1}{2}\log(K_2K_3)'$ of equation (20), together with $pK_3$. Curves a, b, and c correspond to 4.2, 4.7, and 5.2, respectively, for $a^*$ in formula (20), and d, e, and f were calculated by formula (9) with the use of 2, 3, and 4, respectively, for $a^*$. The value of $a^*$ in equations (5) and (8) is without appreciable effect on the concentration term of formula (20). Hence 4.7, the value yielding the best extrapolation of the data of series 4, was employed.

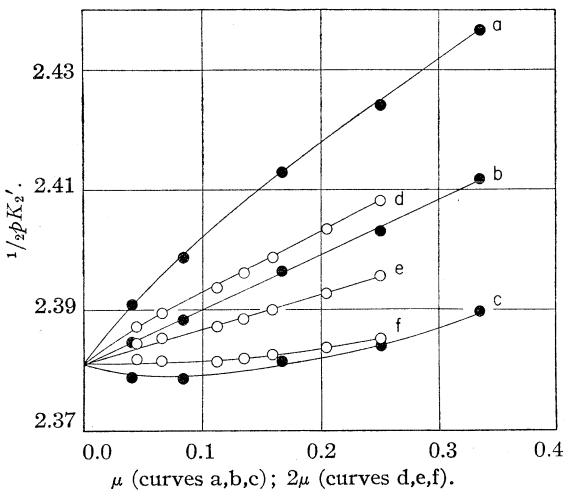

Fig. 4.—Determination of $pK_2$ from data of series 2 (curves d, e, and f) and of series 4 (curves a, b, and c).

The determination of $pK_3$ at 25* from an analysis of the results for buffer solutions of series 5 is illustrated in Fig. 5. The effect of a change of $a^*$ in equation (27) upon the extrapolation is indicated by the positions of the three solid lines labeled 5.6, 6.0 and 6.4. These were calculated from the data of series 5a, whereas series 5b yielded $pK_3'$ values represented by the dots, for

TABLE IV

[a] 4.761 was also obtained from Series 4.

$a^* = 6.0$. The dashed line shows the course of the extrapolation of series 5a solutions when the correction for $K_2$ ($m_{H_2Ci^-}$ in formula (27)) is ignored. It is apparent that employment of a three-fold excess of tertiary salt over secondary salt has effectively reduced the magnitude of the correction. If $a^*$ in equation (8) is changed from 4 to 6, the second term on the right of formula (27) undergoes a change amounting to 0.0023 for an ionic strength of 0.45. Nevertheless, the differences disappear in the extrapolation to zero ionic strength.

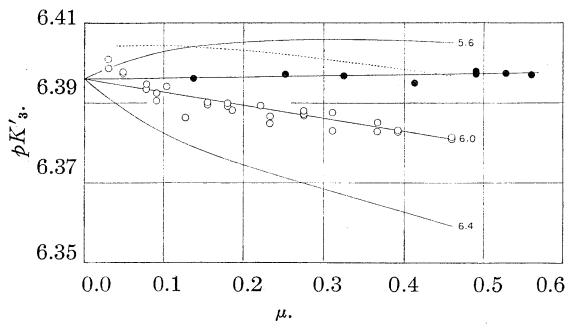

Fig. 5.—Determination of $pK_3$ from data of series 5a (open circles and curved lines) and of series 5b (dots).

The experimental points at the two lowest ionic strengths are seen to lie somewhat above the curves used for extrapolation. The departures correspond to 0.16, 0.20, 0.22, and 0.36 mv. and are, with one exception, only slightly larger than the estimated experimental error. If these data in dilute solutions are correct, the plots of $pK_3'$ with respect to ionic strength would have to depart from the paths predicted by the Hückel equation[20] and followed at the higher concentrations. For $a^*$ less than 5.8, these curves would have points of inflection at ionic strengths near 0.05 that cannot be justified in terms of the Hückel equation alone. The influence of the higher terms of the Debye–Hückel theory[21] upon the last term of equation (25) is large and could cause a rapid change in slope at concentrations below the lowest studied in this investigation. Unfortunately, the effect of higher terms at ionic strengths above 0.1 cannot readily be ascertained, and it is impossible to say whether the linearity of the plot between 0.05 and 0.57$\mu$ is consistent with a pronounced change of slope below $\mu = 0.05$.

The negative logarithms of the constants for the three steps in the dissociation of citric acid at the 11 temperatures are summarized in Table IV and plotted as a function of temperature in Fig. 6. The characteristic minimum in $pK$ is shifted to lower temperatures as the strength of the acidic group decreases. The values of $pK$ at 18, 25 and 37° are compared in Table V with earlier determinations based upon electromotive-force measurements of cells with liquid junction. The agreement among the values of

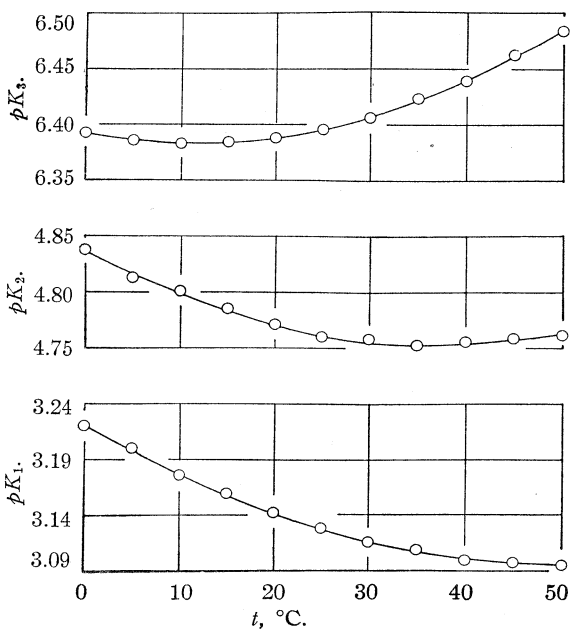

Fig. 6.—$pK_1$, $pK_2$ and $pK_3$ plotted as a function of temperature.

(20) E. Hückel, *Physik. Z.*, **26**, 93 (1925). This equation differs from (8) by inclusion of a term linear in ionic strength.

(21) T. H. Gronwall, V. K. LaMer and K. Sandved, *ibid.*, **29**, 358 (1928); V. K. LaMer, T. H. Gronwall and L. J. Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

$pK_2$ and among three of the four values of $pK_3$ is satisfactory, but $pK_1$ obtained from cells with liquid junction is lower by 0.05 to 0.07 than that found in this investigation.

TABLE V

COMPARISON OF $pK$ WITH THAT DERIVED FROM THE E. M. F. OF CELLS WITH LIQUID JUNCTION

| | Method | $t$, °C. | $pK_1$ | $pK_2$ | $pK_3$ |
|---|---|---|---|---|---|
| Simms[4] | Cells with l. j. | 25 | 3.08 | 4.74 | 6.26 |
| Kolthoff and Bosch[5] | Cells with l. j. | 18 | 3.075 | 4.752 | 6.407 |
| Bjerrum and Unmack[6] | Cells with l. j. | 18 | 3.087 | 4.769 | 6.398 |
| | | 25 | 3.057 | 4.759 | 6.400 |
| | | 37 | 3.042 | 4.747 | 6.424 |

| | | 37 | 3.105 | 4.750 | 6.429 |

## Thermodynamic Functions

The values of $pK_1$, $pK_2$ and $pK_3$ listed in Table IV were fitted by the method of least squares to an equation of the form[22]

$$-\log K_n = A/T + B + CT \qquad (30)$$

where $T$ is the temperature on the Kelvin scale (°C. + 273.16). The constants of equation (30) are given in Table VI. The average difference between the "observed" $pK_1$ at the 11 temperatures and the corresponding values calculated by equation (30) is 0.0010. For $pK_2$ and $pK_3$ the differences are, respectively, 0.0009 and 0.0007.[23]

TABLE VI

CONSTANTS OF EQUATION (30)

| Dissociation step | $A$ | $B$ | $C$ |
|---|---|---|---|
| 1 | 1255.6 | −4.5635 | 0.011673 |
| 2 | 1585.2 | −5.4460 | .016399 |
| 3 | 1814.9 | −6.3664 | .022389 |

The molal changes of free energy, $\Delta F^0$, of heat content, $\Delta H^0$, of entropy, $\Delta S^0$, and of heat capacity, $\Delta C_p^0$ that accompany each of the dissociation processes in the standard state are readily derived from the constants of equation (30).

$$\Delta F^0 = 2.3026\,R(A + BT + CT^2) \qquad (31)$$
$$\Delta H^0 = 2.3026\,R(A - CT^2) \qquad (32)$$
$$\Delta S^0 = 2.3026\,R(-B - 2CT) \qquad (33)$$
$$\Delta C_p^0 = 2.3026\,R(-2CT) \qquad (34)$$

where $R$, the gas constant, is 8.3127 int. j. deg.$^{-1}$ mole$^{-1}$. These thermodynamic quantities are summarized in Table VII.

The molal entropy change at 25° for the first step in the dissociation is −11.0 cal. deg.$^{-1}$, −19.8 for the second step, and −32.0 for the third.

(22) H. S. Harned and R. A. Robinson, *Trans. Faraday Soc.*, **36**, 973 (1940).

(23) The first and third constants can be represented by the equation $-\log K_n = A/T + B + C \log T$ with average differences of 0.0018 and 0.0012, respectively, between "observed" and calculated $-\log K_n$. Inasmuch as equation (30) gave a better fit of the dissociation constants, it was used to calculate the thermodynamic functions. The differences between the thermodynamic quantities derived from the two equations are not large at 25° but are considerably greater at the extremes of the temperature range.

| 35 | 37,883 | −5,957 | −142.3 | −264 |
| 40 | 38,604 | −7,288 | −146.6 | −268 |
| 45 | 39,348 | −8,641 | −150.8 | −273 |
| 50 | 40,114 | −10,015 | −155.1 | −277 |

The values for the first two steps are somewhat smaller than those found for other weak acids of the same electric type.[24] These functions have not heretofore been determined for a third dissociation step by methods free of the uncertainties of the liquid junction. However, $\Delta F^0$, $\Delta H^0$ and $\Delta S^0$ for all three steps in the dissociation of phosphoric and citric acids can be derived from the data for hydrogen–calomel cells with liquid junction at 18, 25 and 37° reported by Bjerrum and Unmack.[6] For the third group of phosphoric acid, $\Delta S^0$ is found to be approximately −35 cal. deg.$^{-1}$ mole$^{-1}$ at 27.5°, or about the same as for the third group of citric acid. The thermodynamic functions for the dissociation of citric acid were computed from the data of Bjerrum and Unmack and are compared in Table

(24) H. S. Harned and B. B. Owen, *Chem. Rev.*, **25**, 31 (1939).

VIII with those found in this investigation. The two sets of values are in good agreement. For these purposes, values in calories were obtained by dividing the number of int. j. by the conversion factor 4.1833.

TABLE VIII

COMPARISON OF THERMODYNAMIC FUNCTIONS AT 25°

| | $\Delta F^0$, cal. mole$^{-1}$ | $\Delta H^0$, cal. mole$^{-1}$ | $\Delta S^0$, cal. deg.$^{-1}$ mole$^{-1}$ |
|---|---|---|---|
| Bjerrum and Unmack, Step 1 | 4170 | 940[a] | −11 |
| Step 2 | 6492 | 408[a] | −20 |
| Step 3 | 8731 | −754[a] | −32 |
| This investigation, Step 1 | 4268 | 997 | −11.0 |
| Step 2 | 6491 | 583 | −19.8 |
| Step 3 | 8726 | −803 | −32.0 |

[a] Calculated from values at 27.5° with the use of $\Delta C_p^0$ found in this investigation.

It is possible to compare $\Delta C_p^0$ given in Table VII with that derived from the temperature coefficients of heats of dilution determined by Richards and Mair[25] and from the heat capacity measurements of Richards and Gucker[26] at 18°. From these data, Rossini[27] has evaluated the partial molal heat capacities of citric acid and of the three sodium citrates at infinite dilution. By combination of these with the partial molal heat capacities of hydrochloric acid and sodium chloride, also at infinite dilution,[28] $\Delta C_p^0$ for each dissociation step can be computed. The results are summarized in Table IX. The sum of $\Delta C_p^0$ for the three steps, given in the last line, represents $\Delta C_p^0$ for the process: $H_3Ci = 3H^+ + Ci^{\equiv}$. The agreement can be considered satisfactory, inasmuch as the calorimetric results may be in error by 5 cal.[27] and the E.m.f. determination by an amount at least as large.

TABLE IX

$\Delta C_p^0$ FOR THE DISSOCIATION OF CITRIC ACID AT 18°, IN CAL. DEG.$^{-1}$

| | Calorimetric | E. m. f., mv. |
|---|---|---|
| Step 1 | −41 | −31 |
| Step 2 | −37 | −44 |
| Step 3 | −54 | −60 |
| Process: $H_3Ci = 3H^+ + Ci^{\equiv}$ | −132 | −135 |

Coulombic forces are probably responsible for a considerable part of the change of $\Delta C_p^0$ from step 1 to step 3, for there is no marked change in chemical type. Consequently, the apparent irregularity of the results given in the second column of Table IX seems of doubtful significance. The calorimetric data for citric acid used in computing these results have not been corrected for acidic dissociation, nor have the detailed compositions of the citrate salt solutions been considered in obtaining the heat capacities at infinite dilution. However, these corrections have only a small effect upon the partial molal heat capacities of the salts at infinite dilution. On the other hand, the correction for acidic dissociation alters the value for citric acid itself by 5 to 10 cal., but the magnitude and direction of the change are such as to make more pronounced the irregularity in $\Delta C_p^0$ for the three dissociation steps, although the sum remains in good agreement with the results of the present investigation.

## Summary

The three dissociation constants of citric acid have been determined at intervals of 5° from 0 to 50° from measurements of the electromotive force of hydrogen–silver chloride cells without liquid junction. The resolution was accomplished by analysis of data for 84 buffer solutions grouped into five series, as follows: (1) mixtures of citric acid and primary potassium citrate, (2) primary potassium citrate, (3) mixtures of primary and secondary potassium citrates, (4) secondary potassium citrate, and (5) mixtures of secondary and tertiary potassium citrates. The changes of free energy, heat content, entropy, and heat capacity associated with the dissociation reactions in the standard state have been calculated from the dissociation constants at the eleven temperatures.

# Rates and Temperature Coefficients in the Hydrolysis of some Aliphatic Esters with a Cation Exchange Resin as the Catalyst[1]

BY VERNON C. HASKELL AND LOUIS P. HAMMETT

It has been noted recently[2] that acidic cation exchangers such as sulfonated coal and resinous exchangers containing sulfonic acid groups are effective as catalysts for various acid-catalyzed reactions. The practical advantages of an acidic catalyst which can be separated quickly and easily from a reactive solution are obvious. From the theoretical point of view this example of heterogeneous catalysis in which the number of active sites on the catalyst can be measured with some certainty possesses considerable interest. A comparison of the kinetics of a reaction catalyzed by a solid acid and by an acid in solution should for instance provide useful information about the mechanism of the heterogeneous process.

The acid-catalyzed hydrolysis of esters in 70% acetone, studied previously by others,[3] was selected for this work; the kinetics of the homogeneous reaction are of the first order in ester concentration, the reaction is easy to follow by titrating the carboxylic acid with standard alkali solution, and the rates are of conveniently measurable magnitude at room temperature. The solid-catalyzed reaction has an advantage that the catalyst acid need not be titrated if the carboxylic acid can be rinsed from the solid rapidly.

## Experimental

The esters used in the rate experiments were fractionated in a thirty-inch column of glass helices, the fractions retained in each case boiling in a range of not more than 0.2°. The following are the esters used with their sources, boiling points (uncor.) at atmospheric pressure, and saponification analyses: methyl acetate, 56.3°, 100.2%; ethyl acetate, Mallinckrodt, 76.6°, 99.5%; ethyl *n*-butyrate, Eimer and Amend, 121.0°, 100.5%; ethyl *n*-caproate, Eastman Kodak, 165.4°, 99.4%. U.S.P. grade acetone was boiled with alkaline permanganate and was fractionated in the above column, the fraction retained boiling over a range of not more than 0.2°.

Sulfonated coal and two synthetic resin cation exchangers were examined as possible catalysts. The resinous exchanger selected[4] was chosen not for its efficiency as a catalyst but because its exchange capacity could be measured within limits of ±0.3% by a simple titration with standard alkali. In contrast the attempts to titrate the other exchangers gave end-points which were neither sharp nor reproducible. Moreover the selected exchanger had a high exchange capacity (3.95 to 4.32 meq. per g. depending on the moisture content) and was available in the form of spherical particles which could be separated into narrow fractions with standard sieves giving samples of easily calculated external area. Fractions taken between 40 and 45 mesh sieves (average diameter 0.38 mm.) and between 80 and 100 mesh sieves (average diameter 0.16 mm.) were used in subsequent rate experiments.

Rate experiments were carried out in thermoregulated water-baths, the temperatures being 12.5, 25.0 and 37.5° with an estimated ±0.02° error. The 25.0 and 37.5° baths were of the conventional type. The 12.5° bath was as described elsewhere.[5]

The solid-catalyzed reactions were done with individual samples of acidic cation exchanger and proportionate volumes of reacting solution in sealed tubes of 12-mm. Pyrex tubing 10 to 15 cm. long. A shaker was designed to provide continuous agitation by tumbling the tubes over at about 30 r. p. m. A study of the effect of agitation showed that with this degree of agitation the rate of hydrolysis of methyl acetate was insensitive to the shaking rate.

Parallel experiments were performed with hydrochloric acid and the acidic cation exchanger respectively as catalysts. In the solid-catalyzed runs, six portions of exchanger weighing between 0.3 and 0.4 g. were delivered into the sample tubes described above. A reaction mixture was prepared from 70 ml. of acetone, 2 ml. of ester (except that 4 ml. of ethyl *n*-caproate was used) added from a volumetric pipet which was calibrated for each ester, and distilled water to make 100 ml. of solution. After agitation the solution was measured from a 10-ml. buret into the sample tubes in the proportion of 10 ml. of liquid per gram of catalyst. The tubes were immersed in ice water, sealed, and introduced into the shaker in the water-bath, the instant of introduction into the bath being taken as zero time. The tubes were broken at appropriate time intervals, the solid was separated by suction filtration through glass wool, and was rinsed with 75 to 100 ml. of distilled water over a period of about five minutes, and the solution with rinsings was analyzed for acid. Tests with acetic acid solutions showed that such rinsing recovered 99.8% of the acid. With the other acids, the reproducibility of the results was taken as evidence of the adequacy of the rinsing process. A 10-ml. buret was used for titration of the acid produced by the reaction and a correction was applied for the amount of base required to achieve a slightly pink shade with phenolphthalein in distilled water.

Measurements of exchange capacity were obtained from samples of catalyst which had been used in the rate experiment. After the rinse with distilled water the sample of exchange resin was transferred to an erlenmeyer flask and was mixed with 25 ml. of water and about 2 g. of solid sodium chloride. The acid was titrated to a phenolphthalein end-point with standard sodium hydroxide. The addition of an excess of sodium hydroxide and back-titration with standard hydrochloric acid gave agreeing results. The exchange capacity of the resin was the same before and after use as catalyst.

The experiments with hydrochloric acid as the catalyst were performed in 50 or 100 ml. volumetric flasks having glass stoppers. The reaction mixture was made up from 70 ml. of purified acetone, 10.00 ml. of 4.405 *N* hydrochloric acid and 2 ml. of ester (or 4 ml. of ethyl *n*-caproate) and distilled water to the 100-ml. mark. These were made up at 25° and were then transferred to the thermostat having the temperature desired. The change in

volume was noted and the correction for change in concentration applied. The instant of addition of ester was taken as zero time but the initial point was not used except in experiments at 25°. In Fig. 1 the result of this technique is shown. The line for the hydrogen chloride-catalyzed hydrolysis of methyl acetate does not go through the origin. This does not affect the value of the specific rate which is obtained from the slope of the line.

## Calculations

The values of $k'$, the specific rate of the hydrolysis, were obtained by least squares methods from the slope of the plot of $\ln a/(a - x)$ against time, using points between zero and half-complete reaction. Here $a$ is the concentration of organic acid which would be obtained if the reaction were complete, calculated from the composition of the original reaction mixture, and $x$ is the concentration at time $t$. In the region used for the calculation these plots were linear within the precision of the measurements for both resin and hydrogen chloride-catalyzed reactions.

The $k'$ values were approximately proportional to the concentration of catalyst acid in the homogeneous reaction; they were found to be very closely proportional to the ratio of quantity of resin to volume of solution in the heterogeneous one. Therefore a rate constant $k$ was calculated in the former case by dividing $k'$ by the concentration of catalyst acid, and in the latter case by dividing $k'$ by the ratio of the number of moles of exchangeable acid in the resin to the volume of the solution. Since the $k$ values thus obtained depended somewhat on the concentration of hydrochloric acid and on the initial concentration of ester the same concentration of a given ester was used in both homogeneous and heterogeneous reactions and a correction was applied for the small difference in acid concentrations between the two systems.

The energies of activation $E$ were calculated using the equation

$$E = 2.303\ R\ \frac{T_1T_2}{T_1 - T_2} \log \frac{k_1}{k_2} \qquad (2)$$

$k_1$ being the rate constant at temperature $T_1$.

Relative entropies of activation were obtained from the expression[6]

$$\Delta\Delta S^{\ddagger} = 2.303\ R\ \frac{\Delta(T \log k_r/k_a)}{\Delta T} \qquad (3)$$

$k_r$ and $k_a$ being rate constants for the same ester with the resinous catalyst and hydrochloric acid respectively at temperature $T$.

## Results

The effect of agitation on the resin-catalyzed hydrolysis of methyl acetate in 70% acetone was studied by subjecting four similar samples of heterogeneous reaction mixture to different degrees of agitation. The results are given in Table I. The time of reaction was five hours. The relatively small difference between the amounts of acid production in the third and fourth samples showed that the limiting rate of reaction was being approached.

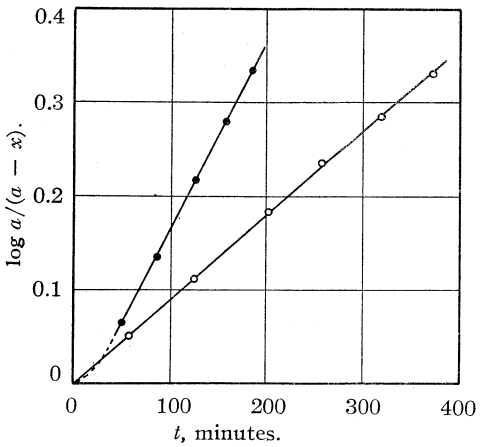

Fig. 1.—Hydrolysis of methyl acetate in 70% acetone at 37.5°: ● catalyst: 0.4350 $N$ HCl (started at 25°, then transferred to 37.5° bath); O catalyst: 1.000 g. resin (4.30 meg. $H_3O^+$/g.) in 10.33 ml. of solution.

TABLE I

THE EFFECT OF AGITATION IN THE HYDROLYSIS OF METHYL ACETATE WITH AN ACIDIC EXCHANGE RESIN AS THE CATALYST

| Sample | $n$ (Half-minute shaking periods per hour) | Vol. of NaOH (per g. catalyst) |
|---|---|---|
| 1 | 0.2 | 9.50 |
| 2 | 1 | 14.72 |
| 3 | 4 | 16.08 |
| 4 | 120 (continuous shaking) | 17.02 |

The effect of varying the ratio of exchange resin to solution was studied in order to determine the order of the reaction with respect to the solid catalyst. Six samples of resin were weighed and were delivered into separate glass tubes. A solution of ethyl acetate in 70% acetone was prepared and was added to the samples of exchange resin in such proportions that the weight of resin per unit volume of solution varied regularly. The sample tubes were sealed, introduced into the 25° bath

TABLE II

THE EFFECT OF WT. RESIN/VOL. SOLUTION ON THE SPECIFIC RATE OF HYDROLYSIS OF ETHYL ACETATE IN 70% ACETONE AT 25°

Exchange capacity of resin: 4.23 meq. $H_3O^+$/g. Calculated titer for complete reaction of 10 ml. solution: $a$ = 34.38 ml. of 0.05877 $N$ NaOH solution. Blank on 100 ml. distilled $H_2O$, 0.06 ml.

| Wt. resin, g. $W$ | Vol. soln., ml. $V$ | Vol. NaOH, ml. | $\log \frac{a}{a - x}$ | $10^5k'V/W$ |
|---|---|---|---|---|
| 0.122 | 3.67 | 2.30 | 0.0850 | 6.48 |
| .196 | 2.94 | 3.36 | .1718 | 6.53 |
| .2885 | 2.88 | 4.48 | .2560 | 6.49 |
| .404 | 3.03 | 5.69 | .3376 | 6.41 |
| .521 | 3.13 | 6.80 | .4274 | 6.50 |
| .597 | 2.985 | 7.20 | .5168 | 6.55 |

and were shaken continuously for 1515 minutes. Titration of the acid formed and substitution of the results into the integrated first order rate equation gave the data of Table II.

These results indicate that the specific rate of the resin-catalyzed reaction is proportional to the "concentration" of resin.

Preliminary experiments were performed to elucidate the effect of surface area of the catalyst resin on the rate of ester hydrolysis. For equal weights of samples the resin passing between 80 and 100 mesh sieves had 2.4 times the geometrical area ($4\pi r^2$) of the 40 to 45 mesh material. The rate constants obtained with the same liquid mixture of a given ester were as shown in Table III.

TABLE III

THE EFFECT OF PARTICLE SIZE ON THE RATE OF THE EXCHANGER-CATALYZED HYDROLYSIS OF ESTERS

| Ester | $10^6k$ 40–45 mesh | $10^6k$ 80–100 mesh | % Difference |
|---|---|---|---|
| Ethyl acetate | 14.8 | 15.4 | +4.1 |
| Ethyl *n*-butyrate | 2.27 | 2.42 | +6.3 |
| Ethyl *n*-caproate | 0.74 | 0.77 | +4.4 |

Subsequent rate experiments were done with 40 to 45 mesh particles only.

Figure 1 is a graph of data from two representative rate experiments. The slopes of the best straight lines obtained by least squares calculation were $1.98 \times 10^{-3}$ and $8.86 \times 10^{-4}$ for the hydrogen chloride- and resin-catalyzed reactions, respectively, and the corresponding rate constants were $1.75 \times 10^{-4}$ l. mol.$^{-1}$ sec.$^{-1}$ and $8.18 \times 10^{-5}$ l. mol.$^{-1}$ sec.$^{-1}$.

The rate data obtained at 25° are summarized in Table IV. The units for the $k$ values of Tables IV and V are l. mol.$^{-1}$ sec.$^{-1}$. Each rate experiment used in calculating catalyst efficiency and heats of activation was performed in duplicate.

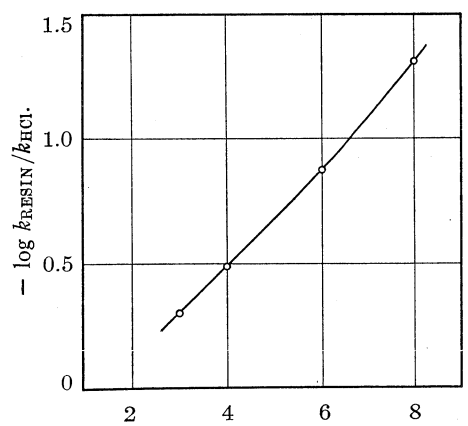

Fig. 2.—Efficiency of exchange resin compared with HCl as a catalyst, as a function of the chain length of the ester hydrolyzed in 70% acetone. Points in increasing order are for methyl acetate, ethyl acetate, ethyl *n*-butyrate and ethyl *n*-caproate.

TABLE IV

RATE CONSTANTS AT 25° FOR HYDROGEN CHLORIDE AND RESIN-CATALYZED HYDROLYSIS OF ESTERS

| Ester | $c_{ester}$, mol./l | $k_{HCl} \times 10^5$ | $k_{HCl} \times 10^5$ (cor.)[a] | $k_{Resin} \times 10^5$ | $k_{Resin}/k_{HCl}$ |
|---|---|---|---|---|---|
| | $c_{HCl}$: 0.4405 mol./l. | | | | |
| Methyl acetate | 0.2483 | 5.45 | 5.41 | 2.70 | |
| | | 5.44 | 5.40 | 2.74 | 0.502 |
| Ethyl acetate | 0.2020 | 4.61 | 4.58 | 1.49 | |
| | | 4.66 | 4.63 | 1.51 | 0.326 |
| Ethyl *n*-butyrate | 0.1504 | 1.92 | 1.91 | 0.255 | |
| | | 1.91 | 1.90 | 0.256 | 0.134 |
| Ethyl *n*-caproate | 0.2401 | 1.53 | 1.52 | 0.0741 | |
| | | 1.53 | 1.52 | 0.0749 | 0.0490 |

[a] The correction was necessary because the acidity of the hydrogen chloride-catalyzed experiments was 6% higher than that of the resin-catalyzed experiments. A 16% decrease in $c_{HCl}$ lowered the rate constant for the hydrolysis of methyl acetate 2.2%. When account is taken of the moisture content of the exchange resin the concentration of water in the reaction mixture containing resin is greater than that in the reaction mixture containing hydrochloric acid by a factor of 1.08. No correction was applied. Because of this and because of possible medium effects associated with the solid catalyst more significance is attached to the variations of the $k$-ratios with the size of the ester molecules than to the actual values of the $k$-ratios.

Figure 2 shows the variation of the efficiency of the solid catalyst with the length of the ester molecule.

Methyl acetate and ethyl *n*-butyrate were hydrolyzed at 37.5° and at 12.5° and the heats and entropies of activation were calculated. The results are shown in Table V.

TABLE V

RATE CONSTANTS, ENERGIES AND ENTROPIES OF ACTIVATION FOR THE HYDROLYSIS OF METHYL ACETATE AND ETHYL *n*-BUTYRATE IN 70% ACETONE

| | Methyl acetate | | Ethyl *n*-butyrate | |
|---|---|---|---|---|
| | Exchange resin | HCl | Exchange resin | HCl |
| $10^5k_{12.5}$ | 0.881 | 1.59 | 0.0866 | 0.577 |
| | 0.881 | 1.57 | 0.0863 | 0.586 |
| $10^5k_{25}$ | 2.70 | 5.45 | 0.255 | 1.92 |
| | 2.74 | 5.44 | 0.256 | 1.91 |
| $10^5k_{37.5}$ | 8.15 | 17.3 | 0.722 | 5.96 |
| | 8.18 | 17.5 | 0.718 | 5.93 |
| $E_{25-12.5}$[a] | 15,300 | 16,800 | 14,700 | 16,100 |
| $E_{37.5-25}$ | 16,200 | 17,100 | 15,200 | 16,700 |
| $\Delta\Delta S^{\ddagger}_{25-12.5}$[b] | −6.5 | | −9.0 | |
| $\Delta\Delta S^{\ddagger}_{37.5-25}$ | −4.5 | | −8.9 | |

[a] Calories. [b] $\Delta\Delta S^{\ddagger} = \Delta S^{\ddagger}_{Resin} - \Delta S^{\ddagger}_{HCl}$ (cal./deg.).

**An Absorption Experiment.**—When the air-dry exchange resin was mixed with 70% acetone there was 40% increase in the apparent volume of the resin. It was of interest to determine if there was selective absorption of the components of solutions of fatty acids in 70% acetone.

Solutions of caproic acid and of acetic acid in 70% acetone were prepared; these were mixed with the exchange resin in the proportion of 25 ml. of solution to 10 g. of air-dry resin. After agitation and settling of the solid, 1-ml. samples of

the supernatant liquid were removed, added to 50 ml. of distilled water, and titrated with standard alkali in the presence of phenolphthalein. Blanks of 1 ml. from 70% acetone in contact with resin required 0.10 ml. of 0.05185 $N$ alkali for neutralization just after mixing and 0.14 ml. after ten days in contact with the resin. Table VI shows the results.

TABLE VI

CONCENTRATION OF ACID BEFORE ($C_{Acid}$) AND AFTER ($C'_{Acid}$) ABSORPTION OF AQUEOUS ACETONE SOLUTIONS OF CARBOXYLIC ACIDS BY AN EXCHANGE RESIN

"Concentration" of resin: 0.40 g. per ml. of solution

| Acid solution | $C_{Acid}$ | $C'_{Acid}$ | Increase, % |
|---|---|---|---|
| Caproic acid | 0.312 | 0.383 | 22.8 |
| Acetic acid | .353 | .410 | 16.2 |

These results show that the solvent is absorbed in preference to the acid in the case of caproic acid and acetic acid, and that acetic acid is absorbed to a greater degree than caproic acid.

## Errors

At 25° the average deviation of the mean of the $k$ values is ±0.2% for hydrogen chloride-catalyzed experiments and ±0.5% for resin-catalyzed experiments. Residual errors in temperature, concentration of ester, concentration of hydrochloric acid and other factors are expected to increase the precision measure in the $k$ values to ±1% for both hydrogen chloride and resin-catalyzed reactions.

The precision measure for energies of activation is ±200 calories per gram mole, and the precision measure for relative entropies of activation is ±1 calorie per degree.

## Discussion

Whatever the detailed mechanism of the catalysis of hydrolysis by strong aqueous acids, there is every reason to suppose it to be the same for the resin, a strong acid of essentially infinite molecular weight, as for the homogeneous acid. It involves therefore for both a positively charged transition state in which a proton has been transferred to the ester molecule from the oxonium ion of the acid. If, as the present results indicate, diffusion rates are fast enough so that the chemical process is rate determining, the difference in rate between heterogeneous and homogeneous cases depends upon the fact that, in the former, both the oxonium ion and the charged transition state are restricted by electostatic forces to the immediate neighborhood of the negatively charged $RSO_3^-$ groups in the resin. More specifically the ratio $k_{resin}/k_{HCl}$ is determined by the difference

$$F^{\ddagger}_{resin} - F^{\ddagger}_{HCl} - F^{\circ}_{resin} + F^{\circ}_{HCl}$$

in which the $F^{\ddagger}$'s are the standard free energies of the transition states for the resin and hydrogen chloride cases and the $F^{\circ}$'s are the standard free energies of oxonium ion in the resin system and in the hydrochloric acid solution, respectively.

This quantity is observed to be positive in the cases studied and increases rapidly and nearly linearly (Fig. 2) with increasing chain length of the ester molecule. The positive free energy difference results from negative values of the corresponding heat content and entropy differences, the latter being therefore predominant in effect. The heat content difference of about −1.3 kcal. is little if any affected by chain length, the entropy difference changes from −5.5 cal./deg. with methyl acetate to −9.0 with ethyl $n$-butyrate. It appears therefore that the major factor in the effects observed is the loss in internal entropy of the ester molecule accompanying its fixation on the skeleton of the resin catalyst in the formation of the transition state. This conclusion is consistent with the fact that the longer chain ester, having more internal entropy, loses more in the formation of the transition state. Translational entropies, on the other hand, and all effects which depend on the electrical charge of the transition state should to a first approximation cancel out between the transition state and the oxonium ion.

This interpretation of the kinetic results is related to the one given by Barrer[7] for the equilibrium in the absorption of hydrocarbons by zeolites. It is supported by the results reported in Table VI which show that the longer chain molecule caproic acid is less strongly absorbed by the ion exchange resin than the shorter chain molecule acetic acid.

Effects of this sort may very well be important in the general problem of heterogeneous catalysis and in that of enzyme action, although there is no exact correspondence, either qualitative or quantitative, between the net effect observed in these cases and those reported here for the exchange resin catalysis. Thus the energy of activation for the catalysis by yeast saccharase of the inversion of saccharose near the optimum $p$H is 17 kcal. less than for the hydrochloric acid catalyzed reaction,[8] and low temperature coefficients have also been observed[9,10] for other enzyme catalyzed reactions. Further the efficiency of pancreatic lipase in the hydrolysis of esters in water increases with chain length from ethyl acetate to ethyl $n$-butyrate.[10]

It appears however that the balance of conflicting effects may lead to considerable difference in the behavior of the catalysis by an ion exchange resin according to the particular resin used and the medium. Thus Thomas and Davies[11] have reported that the resin Amberlite IR-100 is more efficient than hydrochloric acid for the hydrolysis of aliphatic esters in water and that its efficiency increases with increasing chain length. And Levesque and Craig[12] using Amberlite IR-100 for the

esterification of oleic acid with *n*-butanol obtained specific rates very nearly proportional to the external area of the resin particle employed, indicating that only acid groups near the exterior of the particles are active catalytically. The present results on the effect of particle size of resin, obtained with much smaller molecules, also indicate a superiority of the external acid groups, but one which is of almost negligible total effect. One might attribute this effect to the intrusion of diffusion into the interior of the particle as a significant factor in the control of the over-all rate except that the effect of particle size is unchanged by a change in the size of the reacting molecule which produces a large change in the over-all rate.

## Summary

A method in which reproducible rate constants can be obtained has been developed for following the hydrolysis of esters in 70% acetone with a cation exchange resin as the catalyst. A comparison of the catalytic effect of the exchange resin with that of hydrochloric acid showed that the free energy of activation relative to the hydrogen chloride-catalyzed reaction increased almost linearly with the chain length of the ester in the series methyl acetate, ethyl acetate, ethyl *n*-butyrate, ethyl *n*-caproate at 25°.

Measurements of the temperature coefficients of the rates of hydrolysis of methyl acetate and of ethyl *n*-butyrate showed that the lower rates with the exchange resin were accompanied by lower entropies of activation and lower heats of activation than with hydrochloric acid, the former effect being strongly dependent on the chain length of the ester, the latter relatively independent.

The major factor determining these effects appears to be the loss in internal entropy of the ester molecule which accompanies its fixation on the skeleton of the resin catalyst in the formation of the transition state.

# Absorption Spectra of Some Double Salts Containing Bivalent Cobalt[1]

BY MELVIN L. SCHULTZ[2]

The absorption spectra of crystals of five double salts of cobaltous chloride all containing the tetrahedral $CoCl_4^{--}$ ion have been shown[3] to consist, at room temperature, of a large number of relatively narrow bands. The details of these spectra were found to be almost completely independent of the identity of the cation and therefore it was concluded that the absorption was characteristic of the complex ion.

Prominent among the wave number differences of adjacent bands in these spectra is one of approximately 370 cm.$^{-1}$. This frequency was identified tentatively as one of the characteristic frequencies of the $CoCl_4^{--}$ ion. The validity of this interpretation has, in the present work, been investigated by studying the spectra of two salts, $(PyH)_2CoBr_4$ and $(QuH)_2CoBr_4$,[4] containing the corresponding bromo- complex ion. Substitution of one halogen for another would be expected to lead to changes in frequency differences if the structure of the spectrum is determined by the coupling of vibrations of the complex with electronic transitions.

Such an effect has, in fact, been observed by Brode and Morton[5] for solutions of cobaltous halides in concentrated aqueous solutions of the corresponding hydrogen halides.[6] They found decreasing separations of bands in passing from the chloride to the bromide and to the iodide. Their analysis is subject to some uncertainty, however, since the absorption bands of the solutions are broad and incompletely resolved. The comparison in the case of the crystals is much more clear cut since the bands are considerably sharper and therefore more completely resolved. The expected frequency shifts have been found for many, but not all, of the bands in the spectra of the crystals.

Confirmation of the hypothesis that the detailed structure of the spectra of these complexes of bivalent cobalt is determined essentially by the configuration of the complex ion was obtained by studying the absorption spectrum of crystals of $2(en\ H_2)Cl_2 \cdot CoCl_2$.[7] Although the structure of the complex ion in this compound has not been determined, the coördination number of cobalt is probably six[8] with probably an octahedral arrangement of chloride ions about the central co-

(1) The spectra described here were photographed in 1943 while the author was a member of the staff of Illinois Institute of Technology. The plates obtained were measured and the present paper was written after the author became associated with RCA Laboratories.

balt ion. Although the spectrum of this salt shows the same general arrangement of groups of bands as do the tetrahalide complexes, the detailed structure of the groups is completely different.

## Experimental

The experimental methods employed were, with some modifications, those previously described.[3] The double salts used were prepared according to published methods.[8,9] In each case, the composition of the preparation was established by the determination of halogen by precipitation and weighing as silver halide.

When large single crystals of the double salts could be obtained these were mounted in Canada balsam between microscope slides and cover glasses. For $(en\ H_2)_2CoCl_6$ which could not be obtained as large crystals or for very thin absorbing layers of the bromides, the micro crystals were suspended in Canada balsam and mounted between slides. In this manner, the transparency of the preparations was increased and, in addition, the crystals were protected from attack by water vapor in the atmosphere. In the case of $(QuH)_2CoBr_4$, crystals obtained from hydrobromic acid solution and material prepared by recrystallization from ethyl alcohol solution gave identical spectra.

The wave lengths of the band maxima were determined from microphotometer tracings, made with a Leeds and Northrup recording microphotometer, of the comparison spectra produced by either a copper arc or a neon discharge tube and of the absorption spectra. Except for the very weak or very diffuse bands, the uncertainties in the wave numbers calculated from the measured wave lengths are about 10 cm.$^{-1}$. In the extreme red where the dispersion of the spectrograph was small, the uncertainty is somewhat greater.

## Results and Discussion

The wave numbers and estimated relative intensities of the observed band maxima for the two bromides are listed in Table I. Except for differences in the region between 18,100 cm.$^{-1}$ and 20,300 cm.$^{-1}$ and for the very weak doublet at 25,300 cm.$^{-1}$, which was observed for $(PyH)_2CoBr_4$ but not for $(QuH)_2CoBr_4$, there is a complete correspondence between the two spectra. The differences in wave lengths of corresponding bands are small and are of the same order of magnitude as the uncertainties in the determination of the band positions. The differences between the two spectra mentioned above represent the only effects of the identity of the cation within the portion of the spectrum studied. A similar situation was observed in the spectra of the chlorides where the specific cation effects appeared between 19,200 cm.$^{-1}$ and 20,600 cm.$^{-1}$.

In order to facilitate comparison of the bromide and chloride spectra, the slight differences among the spectra of the individual salts with a common anion have been neglected and a composite chloride and a composite bromide spectrum have been obtained by averaging wave number values and intensities of corresponding bands. These composite spectra are summarized in Table II and are illustrated in Fig. 1. For convenience, the bands have been numbered consecutively beginning with the one of longest wave length and, in addition, have been classified into groups designated by Roman numerals. In the figure, the band centers are represented by the positions of the vertices of the triangles representing the bands, the relative intensities by the altitudes of the triangles and the approximate band widths by the lengths of their bases. The solid triangles represent bands whose positions are independent of the identity of the cation while the open triangles represent those which are not. For comparison with the tetrahalide spectra, that portion of the spectrum of $(en\ H_2)_2CoCl_6$ which was photographed is also illustrated in the figure. The wave numbers and relative intensities of the bands in this spectrum are listed in Table III.

It is apparent from an examination of Fig. 1, that Groups I and II of the two tetrahalide spectra are essentially identical except for a shift of about 700 cm.$^{-1}$ of the entire bromide spectrum to the red relative to that of the chloride; for small differences in the spacing of the bands and for

This band observed only for [a] $(PyH)_2CoBr_4$. [b] $(QuH)_2CoBr_4$. [c] $Cs_3CoCl_5$, $(PyH)_2CoCl_4$, and $(QuH)_2CoCl_4 \cdot H_2O$. [d] All of the tetrachloride double salts except $Cs_2CoCl_4$.

some differences in relative intensities. The groups lying at higher frequencies show more pronounced differences but nevertheless, the correspondence between the two spectra is sufficiently close to justify the conclusion that both spectra are due to absorbing groups having the same configuration.

[a] Short wave length edge of unresolved group.

On the other hand, the spectrum of $(en\ H_2)_2CoCl_6$ is distinctly different. For it, Groups II and IV are similar in structure (which is not the case for the tetrahalides) and consist of doublets with an average separation of 426 ± 14 cm.$^{-1}$ and with similar relative intensities within each doublet. In each group the less intense doublet occurs displaced to the long wave length side of the more intense one. This displacement is 814 cm.$^{-1}$ in Group II and 970 cm.$^{-1}$ in Group IV.

The comparative sharpness of most of the bands in these spectra suggests that for the transitions responsible for the observed absorption both the initial and final states are rather effectively shielded from perturbing effects of surrounding ions. The absorption is probably due to an unpaired electron in one of the 3d orbitals of the cobalt ion and the shielding is provided by the electron clouds of the coördinated halide ions. The complexity of the spectra may be due to the multiplet nature of the energy levels of the cobalt ion or to the coupling of vibrations characteristic of the complex with the electronic transitions or possibly to both. If vibrational structure is present, then, as has been pointed out above, substitution of one halogen by another should give rise to changes in the characteristic frequencies. The direction and magnitude of such changes will be determined both by the masses of the halide ions and by the force constants of the cobalt–halogen bonds. Examination of Table II and Fig. 1 reveals that a number of intervals between adjacent bands in Groups I and II are smaller in the spectrum of the bromide than in the spectrum of the chloride. This is to be expected if vibrational structure is present and if the force constants of the Co–Br and Co–Cl bonds are not very different in magnitude.

All of the bands, with the exception of number 7, in these two groups can be represented by the energy level diagrams shown in Fig. 2 in which the transitions representing observed bands are indicated by arrows numbered to correspond to Table II. The ground state consists of two levels separated by 263 cm.$^{-1}$ for the bromide and by 346 cm.$^{-1}$ for the chloride. The excited states are also doublets separated by about 600 cm.$^{-1}$ for the

bromide and by about 800 cm.$^{-1}$ for the chloride. The comparison between wave numbers calculated from the term values shown in the figure and the observed wave numbers of these bands is made in Table IV. For the bromide the average difference between calculated and observed values is 12 cm.$^{-1}$ while for the chloride it is 17 cm.$^{-1}$.

Although no attempt to give a complete interpretation of this energy level diagram will be made, the separation in the ground state will be identified tentatively as the totally symmetric valence vibration of the tetrahedral $CoX_4^{--}$ complex. The magnitude of the observed frequencies is about that to be expected for such an assignment. For example, for several tetrahalides of elements of the fourth group of the Periodic Table, the values of the frequency in question range from 220 cm.$^{-1}$ to 265 cm.$^{-1}$ for the bromides and from 367 cm.$^{-1}$ to 459 cm.$^{-1}$ for the chlorides.[10]

If this assignment is correct and if it be assumed that the vibration may be represented by a simple harmonic force function, the force constants, calculated from the above frequencies, for the Co–X bond in these complexes are $3.25 \times 10^5$ dynes/cm. and $2.50 \times 10^5$ dynes/cm. for the bromide and chloride, respectively. Since the force constant can be taken as being roughly proportional to the dissociation energy of the bond,[11] it may be concluded that in these complexes, the Co–Br bond is stronger than the Co–Cl bond.

From these relative bond strengths, certain conclusions regarding the nature of the binding may be drawn. If ion–ion attractive forces alone were responsible for the binding, the Co–Cl bond would be expected to be stronger than the Co–Br bond since the interionic distance is smaller for the former than for the latter. Clearly, then, other forces must be operative in order to account for the observed relative magnitudes of the bond energies. These are presumably ion-induced dipole forces between the cobalt ion and the dipoles produced by polarization of the halide ions in the field of the cobalt ion. Since the polarizability of the

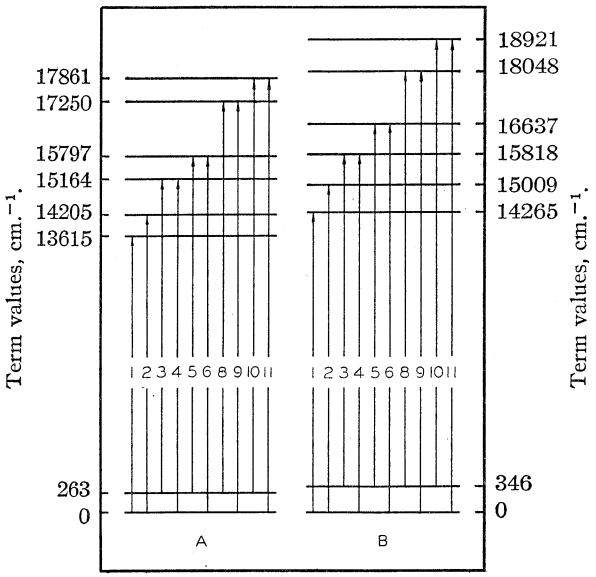

Fig. 2.—Energy level diagram: A, $CoBr_4^{--}$; B, $CoCl_4^{--}$.

bromide ion is larger than that of the chloride ion, this type of force will make a larger contribution in the case of the Co–Br bond than in that of the Co–Cl bond. The ratio of the polarizabilities of the bromide and chloride ions is 1.40[12] while the ratio of the force constants for the complex ions is 1.30. The contribution of the ion–ion forces to the binding is reflected in the smaller value of the latter ratio as compared with the former.

Additional evidence that the binding is not purely of ion–ion type is obtained from a consideration of the interionic distance for the $CoCl_4^{--}$ complex ion. From an analysis of X-ray diffraction measurements upon $Cs_3CoCl_5$,[13] the Co–Cl distance in the complex ion has been found to be 2.34 Å. The sum of the ionic radii[14] for $Co^{++}$ and $Cl^-$ is 2.53 Å. Since the experimental distance is significantly smaller than this sum, a considerable deformation of the electron distribution of the chloride ion is indicated.

The question as to whether the observed relative intensities of the bands agree with those to be expected may now be considered. Since the population of the higher level in the ground state relative to that of the lower is determined by a Boltzmann factor, the intensities of bands originating in the upper level ought to be smaller than that of those from the lower. This condition is satisfied for all of the pairs of bands except numbers 5 and 6 for both the bromide and chloride. Since band 6 occurs at the short wave length edge of Group I where the continuous background absorption is falling very rapidly with decreasing wave length, the estimated relative intensities of bands 5 and 6 may well be in error. It must be emphasized that

the relative intensities reported here are based on visual estimates of blackening of the photographic plate at the band maxima. No account of deviations from linearity of the characteristic curve of the plate or of the effect of the appreciable width and overlapping of the absorption bands has been taken in making the estimates. Therefore the discrepancy in the relative intensities mentioned above cannot be considered to be a serious objection to the suggested interpretation of the spectra; at least not until accurate intensity measurements are made and until the changes of relative intensities with changes of temperature of the absorbing crystals are investigated.

## Summary

1. The room temperature absorption spectra of crystals of pyridinium tetrabromocobaltate(II), quinolinium tetrabromocobaltate(II) and ethylenediaminium hexachlorocobaltate(II) have been photographed.

2. The spectra of pyridinium tetrabromocobaltate(II) and quinolinium tetrabromocobaltate(II) were found to be essentially identical and to bear a very close resemblance to the previously observed spectra of similar double salts containing the tetrahedral tetrachlorocobaltate(II) ion. Therefore the bromides may be assumed to contain the tetrahedral tetrabromocobaltate(II) ion. The spectrum of ethylenediaminium hexachlorocobaltate(II) is distinctly different.

3. A vibration frequency of the tetrahedral complex ions has been identified from an analysis of the tetrahalide spectra. From the magnitude of this frequency, the force constants of the cobalt–bromine and cobalt–chlorine bonds have been determined.

# The Preparation of the Six *n*-Octynoic Acids[1,2]

BY MELVIN S. NEWMAN AND JOHN H. WOTIZ[3]

In this paper are described the syntheses of the six *n*-octynoic acids and of many intermediates. This work was undertaken with a multiple purpose: (1) to add to our knowledge of the reactivity of the acetylenic function in acids having the triple bond at varying distances from the carboxyl group; (2) to study various methods of synthesis for such acids; (3) to obtain information about the odors of the methyl esters. Inasmuch as the synthetic problems consumed most of our efforts, the first objective must remain for future study. It was deemed of interest to investigate the odors of the methyl esters of these acids because of the commercial use of methyl heptynecarboxylate in perfumery. The odors have been evaluated by men skilled in the art and are described as follows.[4]

$HC{\equiv}C(CH_2)_5COOCH_3$, very green but sharp, chemical, fatty, unpleasant; $CH_3C{\equiv}C(CH_2)_4COOCH_3$, reseda-like, fatty, weak, green seaweed; $CH_3CH_2C{\equiv}C(CH_2)_3COOCH_3$, leafy, cucumber-like, something like talia, sweet, violet; $CH_3(CH_2)_2C{\equiv}C(CH_2)_2COOCH_3$, cucumber-like but sharp, chemical, somewhat fruity; $CH_3(CH_2)_3C{\equiv}CCH_2COOCH_3$, something like fresh cut grass, but crude and fatty.

The synthetic methods used are described below and are summarized in a series of charts. Since many bifunctional acetylenic intermediates of either rare or previously non-existent types were prepared, we prefer to discuss the preparation of these compounds according to the functional group other than the triple bond. In this way the scope and limitations of the methods of synthesis will be emphasized.

## Alkynes and Alkynols

The required 1-alkynes were prepared in high yields by known procedures.[5] 2-Alkyn-1-ols were made in high yield by condensation of 1-alkynylmagnesium bromides with gaseous formadehyde[6] while 3-alkyn-1-ols were prepared in poor yield by the reaction of acetylenic organometallic reagents with ethylene oxide.[7]

## Acetylenic Halides

One useful method for preparation of halogenated acetylenes involved the reaction of alkynylsodium in liquid ammonia with polymethylene chlorobromides.[8] This reaction failed with ethylene

(8) In a paper which appeared while this manuscript was in preparation, Ahmad and Strong, THIS JOURNAL, **70**, 1699 (1948), mention a 36% yield of 1-chloro-5-decyne from 1-chloro-4-iodobutane and 1-hexynylsodium.

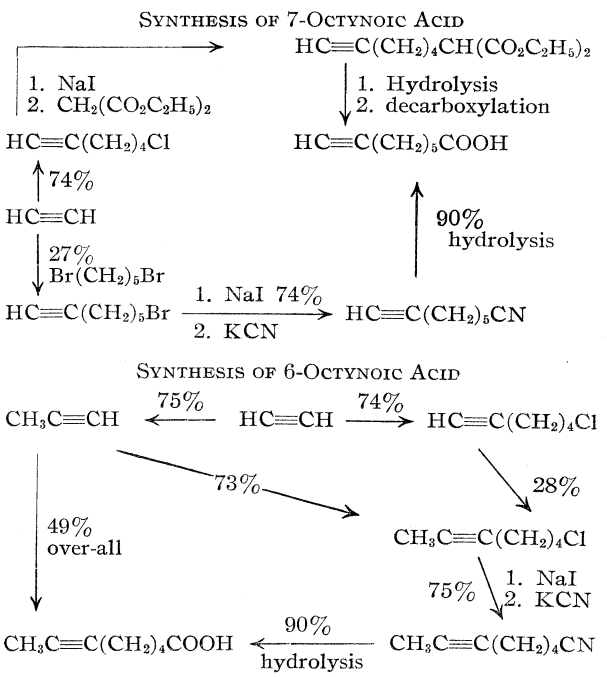
chlorobromide. The condensation of 1-pentynylmagnesium bromide with β-chloroethyl *p*-toluenesulfonate[9] yielded 1-chloro-3-heptyne in 38% yield. This halide was also prepared in 72% yield from the corresponding alcohol, but, because of poor yields in preparation of the required alcohol, this route to 4-octynoic acid was not the best.

Since it was difficult to get a pure sample (required for infrared spectroscopy) of 1-chloro-5-heptyne from the reaction between propynylsodium and 1-chloro-4-bromobutane[10] we attempted to prepare this intermediate by alkylating 1-chloro-5-hexyne with methyl bromide in liquid ammonia. In a similar manner, and for a similar reason, 1-chloro-4-heptyne was prepared by alkylating 1-chloro-4-pentyne with ethyl bromide. It is interesting to note that in each of these alkylations, small quantities of a terminal alkyne, possibly 1-chloro-6-heptyne, were found. This impurity was removed by a treatment with potassium iodomercurate reagent (see experimental). The presence of an acetylenic hydrogen in the distilled reaction products was first suspected when the infrared absorption spectra were examined.[11]

Another method which proved useful for the preparation of acetylenic halides involved replacement of the hydroxyl group of acetylenic alcohols. The behavior of 2-heptyn-1-ol with thionyl chloride and phosphorus tribromide is especially noteworthy. The 1-chloro-2-heptyne thus prepared only reacted with alcoholic silver nitrate on standing and warming whereas the 1-bromo-2-heptyne reacted immediately. The chloro compound could not be brought to react with magnesium even by the "entrainment" method,[12] whereas the bromo compound reacted with such ease that coupling occurred predominantly. However, by using a special high dilution technique recently developed[13] a 98% yield of organomagnesium derivative was obtained from the bromide. A mixture of acids, whose composition is now under investigation, was isolated on carbonation of this derivative.

Examples of an acetylenic–allenic isomerism, $R—C\equiv C–CH_2X \rightleftarrows RCX=C=CH_2$, are described by Johnson.[14] It may be that we were dealing with a similar isomerism. Further work on these halides is being done by one of us (J. H. W.).

## Acetylenic Nitriles



Acetylenic halides having at least three methylene groups between the halogen and the triple bond were best converted into the cyanides *via* the iodides by standard procedures. However, neither 1-chloro-2-heptyne nor 1-bromo-2-heptyne yielded the corresponding iodide or cyanide in this way. Only by heating the bromide in anhydrous medium with cuprous cyanide at 150–160° could the nitrile be obtained. The yield by this method was excellent. It is interesting to note that attempts to prepare $NCCH_2C\equiv CCH_2CN$ from the chloride or bromide were unsuccessful.[15]

Similar difficulties were met in attempting to prepare nitriles from 1-halo-3-heptynes. However, since the corresponding acid could easily be prepared by the malonic ester synthesis from 1-bromo-2-hexyne no intensive study of this reaction was made.

## Acetylenic Acids

Except for 1-cyano-3-heptyne the hydrolysis of acetylenic nitriles proceeded very well by refluxing in aqueous alcoholic alkali until the evolution of ammonia ceased. 1-Cyano-3-heptyne was converted into the corresponding ester by heating with alcoholic hydrogen chloride followed by alkaline hydrolysis of the ester thus produced. Several other methods of hydrolysis were tried without success. 4- and 5-octynoic acids were prepared by decarboxylation of the corresponding malonic acids. 2-Octynoic acid was prepared by carbonation of 1-heptynyl sodium.[16]

The structures of the isomeric *n*-octynoic acids

SYNTHESIS OF 5-OCTYNOIC ACID

SYNTHESIS OF 4-OCTYNOIC ACID

SYNTHESIS OF 3-OCTYNOIC ACID

were established by ozonization and by hydrogenation to *n*-octanoic acid. Comparison with the latter of the various samples was effected through the amide.

## Experimental[17]

**Tetramethylene Chlorobromide.**—A fairly rapid stream of hydrogen chloride (cylinder) was passed into a heated mixture of 1 g. of aluminum chloride, 3 cc. of water, and 720 g. (10 moles) of tetrahydrofuran (du Pont). When the temperature levelled off at 105° the heater was removed and hydrogen chloride was introduced until the reaction mixture returned to room temperature. This crude mixture was added slowly to 2 kg. (7.4 moles) of phosphorus tribromide with stirring and ice cooling. After all had been added, the mixture was heated on a steam-bath for one hour and cooled. The upper layer was washed, dried, and rectified to yield 2.13 kg. (62%) of tetramethylene chlorobromide, b. p. 80–82° at 30 mm.

**Pentamethylene Chlorobromide.**—5-Chloroamyl acetate, b. p. 82–84° at 2 mm., was prepared in 93% yield from 430 g. (5 moles) of tetrahydropyran (du Pont), 429 g. (5.5 moles) of acetyl chloride, and 40 g. of freshly fused zinc chloride.[18] A mixture of this ester (329 g., 2 moles), 320 g. of methanol, and 5 g. of *p*-toluenesulfonic acid was rectified until 180 g. of the methanol–methyl acetate azeotrope, b. p. 54°, had been collected. The remaining solvent was removed under reduced pressure at *room temperature*. The residue was reacted with phosphorus tribromide (271 g.) as in the case of tetramethylene chlorohydrin (above) to yield 325 g. (88% over-all) of pentamethylene chlorobromide, b. p. 92–93° at 20 mm., $n^{25}D$ 1.4815.

*Anal.* Calcd. for $C_5H_{10}ClBr$: C, 32.3; H, 5.4. Found: C, 32.8, 32.9; H, 5.4, 5.3.

**2-Heptyn-1-ol.**—A solution of 82 g. (1 mole) of 1-hexyne in 300 cc. of dry ether was added slowly to 1.1 moles of ethylmagnesium bromide in 300 cc. of ether. After refluxing for six hours the mixture was cooled (nitrogen atmosphere). Gaseous formaldehyde was introduced (at a rate to maintain gentle refluxing) by passing dry nitrogen through a flask containing paraformaldehyde (dried over phosphorus pentoxide for at least two weeks) and heated by a bath at 180°. The exothermic reaction ceased when about one equivalent of formaldehyde had been introduced. On working up in the usual manner 92 g. (82%) of 2-heptyn-1-ol, b. p. 113–16° at 56 mm., was obtained.[6] Larger runs gave yields 5 to 10% smaller.

**2-Hexyn-1-ol.**—By a procedure similar to that described above, 2 moles of 1-pentyne yielded 140 g. (71%) of 2-hexyn-1-ol, b. p. 87–89° at 58 mm.

*Anal.* Calcd. for $C_6H_{10}O$: C, 73.4; H, 10.2. Found: C, 73.2, 73.3; H, 10.2, 10.3.

The 3,5-dinitrobenzoate, prepared in high yield, melted at 64–65°.

*Anal.* Calcd. for $C_{13}H_{12}O_6N_2$: C, 53.4; H, 4.1; N, 9.6. Found: C, 53.6, 53.3; H, 4.1, 4.4; N, 9.5, 9.2.

**3-Hexyn-1-ol.**—This compound,[19] prepared in 48% yield from 1-butynylsodium and ethylene oxide in liquid ammonia[5b] boiled at 160–170°. On redistillation almost all of it boiled at 161°. The 3,5-dinitrobenzoate melted at 72–73°, in agreement with Takei.[19]

*Anal.* Calcd. for $C_{13}H_{12}O_6N_2$: C, 53.4; H, 4.1; N, 9.6. Found: C, 53.1, 53.1; H, 4.1, 4.2; N, 9.3, 9.3.

**3-Heptyn-1-ol.**—This compound (Table II) was prepared in 30% yield from 1-pentynylsodium and ethylene oxide in liquid ammonia.[5b] The yield was about the same when prepared from 1-pentynylmagnesium bromide and ethylene oxide. In the latter case, enough 1-pentyne could be recovered to raise the yield to 45% (based on pentyne consumed). No attempt to recover pentyne was made in the liquid ammonia run.

**3-Octyn-1-ol (Table II).**—Using the liquid ammonia procedure[5b] 164 g. of 1-hexyne yielded 53 g. (21%) of 3-octyn-1-ol, b. p. 105–106° at 25 mm. The yield was 37% if based on hexyne consumed (70 g. recovered).

**4-Heptyn-1-ol, 5-Heptyn-1-ol and 6-Heptyn-1-ol (Table II).**—The corresponding chloroalkynes were converted through the iodides to the acetates by heating with potassium acetate in absolute alcohol. After hydrolysis the alcohols were separated from unreacted halide by conversion to the benzoates, distillation, and saponification. No yields for these steps are available because of uncertain purity of starting halides.

**1-Chloroacetylenic Compounds (Table II).**—To a mixture of sodium acetylide (5 moles) in 3 l. of liquid ammonia[5b] was added 858 g. (5 moles) of tetramethylene chlorobromide during four hours and the whole stirred under reflux for seven hours. After most of the ammonia had evaporated (eight hours) 2 l. of water was added slowly. The organic layer was taken into ether, washed with dilute acid and water, and dried. Rectification yielded 430 g. (74%) of 1-chloro-5-hexyne, b. p. 143–144°. In a similar way 1-chloro-6-heptyne (70% yield) and 1-chloro-5-heptyne (73% yield) were prepared from the reaction of sodium acetylide with pentamethylene chlorobromide and of propynyl sodium with tetramethylene chlorobromide. The yield of 1-chloro-4-heptyne by this method was about 30%. Improvement by adding 1-butynylsodium to trimethylene chlorobromide was not achieved.

**1-Chloro-4-heptyne.**—To a solution of 205 g. of 1-chloro-4-pentyne in 2 l. of liquid ammonia was added 78

[a] Boiling points represent middle cuts taken for analyses; melting points are usually over a one degree range, the upper limit being that recorded. Duplicate analyses were obtained for almost every sample. To save space, only the best analysis is included in this table. [b] These boiling points were observed with different vacuum systems and flasks and hence are not directly comparable. [c] Known compounds; properties listed for comparison. [d] Reported by Toussaint and Wenzke, THIS JOURNAL, **57**, 668 (1935), without analysis. [e] Ellis and Reid, *ibid.*, **54**, 1678 (1932). [f] Adamson and Kenner, *J. Chem. Soc.*, 287 (1935). [g] Heilbron, "Dictionary of Organic Compounds," Vol. I, p. 473. [h] McCusker and Vogt, THIS JOURNAL, **59**, 1307 (1937). [i] Our values. Heilbron (footnote *g*) p. 296, gives b. p. 70.6° at 19 mm. and $n^{25}D$ 1.4480. [j] Moureu and Lazennec, *Bull. soc. chim.*, [3] **35**, 524 (1906). [k] Footnote *g*, page 393. [l] Boiling points taken in same apparatus, hence comparable. [m] Footnote *g*, p. 393. [n] Moureu and Delange, *Bull. soc. chim.*, [3] **29**, 655 (1903). [o] The 3,5-dinitrobenzoates were prepared in 90% yields by heating with pure 3,5-dinitrobenzoyl chloride until evolution of hydrogen chloride slackened. The products were isolated and recrystallized to constant melting point from petroleum ether (b. p. 30–60°) and benzene. Mixed melting points between the various derivatives all gave large depressions. [p] Values in parentheses are calculated. [q] Of the alcohols, ROH.

g. of sodium amide. After stirring for thirty minutes 218 g. of ethyl bromide was added during three hours. By rectification of this reaction product there was obtained 35 g. (17%) of crude 1-chloro-4-pentyne, b. p. 110–112°, and 45 g. (17%) of crude 1-chloro-4-heptyne, b. p. 163–165°. When the infrared absorption spectrum[11] of this fraction showed the presence of a terminal acetylenic function, 19 g. was treated with a mercuric iodide, reagent[20] until no further precipitate formed. The white solid was collected and recrystallized to a melting point of 66–67°. Analysis showed 48.6% carbon and 4.7% hydrogen, which did not indicate any compound to be expected. The excess mercury reagent was removed by precipitating with 1-hexyne and on rectification 4 g. of a pure sample of 1-chloro-4-heptyne (Table II) was obtained.

**1-Chloro-5-heptyne (Table II).**—By a procedure similar to that used above, there was obtained 50 g. (38%) of crude 1-chloro-5-heptyne, b. p. 173–174°, by treating 116 g. of 1-chloro-5-hexyne with sodium amide and then methyl bromide. Purification of this entire fraction as above yielded 25 g. of pure 1-chloro-5-heptyne. The mercury derivative[20] obtained in this case (4 g.) melted at 76–77° and contained 48.9% of carbon and 4.8% of hydrogen.

**1-Chloro-3-heptyne (Table II).**—1-Chloro-3-heptyne, b. p. 71–75° at 30 mm., b. p. 90–93° at 70 mm., was prepared in 38% yield (calculated on 1-pentyne) essentially as described by Johnson for a similar reaction.[9] This chloride was also prepared in 72% yield from a reaction between thionyl chloride, pyridine, and 3-heptyn-1-ol by the procedure described below, except that a glass stirrer was used.

**1-Chloro-2-heptyne (Table II).**—In the best of several experiments a solution of 112 g. (1 mole) of 2-heptyn-1-ol and 78 g. (1 mole) of dry pyridine in 100 cc. of dry ether was added to a solution of 131 g. (1.1 mole) of thionyl chloride (obtained from the Columbia Chemical Division of the Pittsburgh Plate Glass Company) in 100 cc. of dry ether at such a rate as to maintain refluxing. After the addition was complete ether (about 150 cc.) was distilled until the inside temperature was 80°. Then 13 g. more of thionyl chloride was added and the stirring and heating continued for an hour. The chromel (nickel and chromium alloy) wire stirrer had completely dissolved and the mixture was green. We do not know whether this happening aided or harmed the reaction. The mixture was treated with 500 cc. of cold water and the ether layer was separated, washed with sodium carbonate solution and water, and was dried over calcium chloride. After a rapid vacuum distillation the product was redistilled to yield 100 g. (77%) of 1-chloro-2-heptyne, b. p. 73° at 24 mm. This product gave a precipitate with alcoholic silver nitrate only on warming or long standing.

**1-Bromo-2-heptyne (Table II).**—To a solution of 310 g. (2.75 mole) of 2-heptyn-1-ol and 5 g. of pyridine in 800 cc. of dry ether was added 271 g. (1 mole) of phosphorus tribromide at a rate to maintain refluxing. After heating and stirring for an additional two hours the mixture was cooled and the upper layer poured on ice. The organic matter was taken into ether, washed with sodium carbonate and saturated sodium chloride, and was dried over calcium chloride. The crude mixture remaining after removal of the ether was rapidly vacuum distilled to remove high boiling material and then rectified to yield 340 g. (72%) of 1-bromo-2-heptyne, b. p. 104–105° at 56 mm., and 55 g. (7%) of a hydrogen bromide addition compound presumably 1,3-dibromo-2-heptene, b. p. 112° at 25 mm., 70° at 2 mm., $n^{25}D$ 1.5172.

*Anal.* Calcd. for $C_7H_{12}Br_2$: C, 32.8; H, 4.7. Found: C, 33.3, 33.7; H, 4.8, 4.5.

Repetition of the above reaction under slightly modified conditions gave yields in the range of 60 to 70%. None of the desired product was obtained when one equivalent of pyridine was used.

In a manner similar to the above, 2-hexyn-1-ol was con-

(20) Johnson and McEwen, THIS JOURNAL, **48**, 469 (1926).

verted into 1-bromo-2-hexyne, b. p. 97–98° at 80 mm., $n^{25}D$ 1.4884, in 63% yield.

*Anal.* Calcd. for $C_6H_9Br$: C, 44.7; H, 5.6; Br, 49.7. Found: C, 44.4; H, 5.8; Br, 50.2.

The hydrogen bromide addition product (12% yield) formed here, probably 1,3-dibromo-2-hexene, had a boiling point of 100° at 25 mm., or 62° at 2 mm. and $n^{25}D$ 1.5235.

*Anal.* Calcd. for $C_6H_{10}Br_2$: C, 29.9; H, 4.1. Found: C, 30.4, 30.1; H, 4.3, 4.4.

Both 1-bromo-2-heptyne and 1-bromo-2-hexyne gave immediate precipitates when added to alcoholic silver nitrate.

The yield in the conversion of 3-heptyn-1-ol to 1-bromo-3-heptyne (Table II) by this method was considerably less (crude, 41%).

**1-Bromo-6-heptyne.**—A suspension of 3.2 mole of sodium acetylide in 1.5 l. of liquid ammonia was added during one hour to a stirred mixture of 1050 g. (4.6 mole) of pentamethylene dibromide, 500 cc. of dry ether, and 1 l. of ammonia. The addition was accomplished through a tube dipping into the bottom of the sodium acetylide flask and leading into the other. The rate of addition was controlled by partial release of the ammonia pressure in the acetylide flask as needed. The last amounts of acetylide were transferred by using three 50-cc. portions of ammonia for washing. After stirring for two more hours, the product was isolated as usual as a colorless oil, b. p. 80–100° at 20 min. in 27% yield. On redistillation, pure 1-bromo-6-heptyne of b. p. of 92° at 20 min., $n^{25}D$ 1.4750, was obtained with little loss.

*Anal.* Calcd. for $C_7H_{11}Br$: C, 48.0; H, 6.3. Found: C, 48.8, 48.5; H, 6.5, 6.6.

**1,2,3-Tribromo-2-heptene.**—Because of difficulties met with in the attempted conversion of 1-bromo-2-heptyne to the corresponding cyanide, we thought it might prove useful to add bromine to the triple bond and remove it later. However, we never attempted to do the latter. By adding 80 g. of bromine in 80 cc. of carbon tetrachloride to 56 g. of 2-heptyn-1-ol in 75 cc. of carbon tetrachloride at 0° and waiting until decolorization after adding each drop, there was obtained 110 g. (81%) of 2,3-dibromo-2-hepten-1-ol, b. p. 113–115° at 4 mm.

*Anal.* Calcd for $C_7H_{12}OBr_2$: C, 30.9; H, 4.4. Found: C, 30.8, 30.6; H, 4.5, 4.8.

The 3,5-dinitrobenzoate melted at 84–85°.

*Anal.* Calcd. for $C_{14}H_{14}O_6Br_2N_2$: C, 36.1; H, 3.0; N, 6.0. Found: C, 36.3; H, 3.0; N, 6.1.

By the procedure described above, this alcohol was converted into 1,2,3-tribromo-2-heptene, b. p. 112–114° at 4 mm., 96° at 2 mm., $n^{25}D$ 1.5540, in 87% yield.

*Anal.* Calcd. for $C_7H_{11}Br_3$: C, 25.1; H, 3.2. Found: C, 25.3, 25.4; H, 3.7, 3.6.

**3,4-Dibromo-3-octen-1-ol.**—In a similar way, 3-octyn-1-ol was converted into its dibromide, b. p. 111–113° at 2 mm. *Anal.* Calcd. for $C_8H_{14}OBr_2$: C, 33.5; H, 4.9. Found: C, 33.5, 33.8; H, 5.2, 5.3. The 3,5-dinitrobenzoate melted at 85–86°. *Anal.* Calcd. for $C_{15}H_{16}O_6Br_2N_2$: C, 37.5; H, 3.3; N, 5.8. Found: C, 37.4, 37.2; H, 3.5, 3.7; N, 6.3, 6.2. No further useful experiments with these bromine addition products were performed.

**1-Iodo-5-hexyne.**—Crude 1-chloro-5-hexyne prepared as described above was converted into 1-iodo-5-hexyne, b. p. 94–95° at 35 mm., $n^{25}D$ 1.5286, in 82% yield by refluxing with an excess of sodium iodide in acetone for twenty hours.

*Anal.* Calcd. for $C_6H_9I$: C, 34.4; H, 4.3. Found: C, 35.3; H, 4.4.

**1-Cyano-6-heptyne (Table II).**—A mixture of 120 g. of 1-bromo-6-heptyne, 65 g. of potassium cyanide, 120 cc. of water, and 300 cc. of acetone was stirred and refluxed for forty-eight hours after which 250 cc. of mixed solvent was distilled. After suitable treatment the residue yielded 60 g. (74%) of 1-cyano-6-heptyne as a colorless liquid, b. p. 90–92° at 6 mm.

Similarly, 1-cyano-5-heptyne (Table II) b. p. 88–95° at 5 mm. was prepared from 1-iodo-5-heptyne (prepared from 1-chloro-5-heptyne as above described), the over-all yield from chloro compound being 75%. Likewise, 1-chloro-4-heptyne was converted (Table II) directly into 1-cyano-4-heptyne, b. p. 110–112° at 29 mm., in 82% yield.

**1-Cyano-2-heptyne (Table II).**—In the best of many experiments, a mixture of 70 g. of 1-bromo-2-heptyne, 45 g. of carefully dried cuprous cyanide, and 40 cc. of xylene was stirred and heated by a salt-bath at 160° until the inside temperature reached 157°. The temperature of the bath was lowered to 145° and the reaction proceeded exothermically for about thirty minutes during which time the inside temperature was not allowed to exceed 165°. After cooling the mixture was extracted thoroughly with benzene, all solids being removed by filtration. On distillation there was obtained 44 g. (92%) of nitrile, b. p. 123–126° at 56 mm. In other trials, the yields varied from 0 to 90%. Careful regulation of the temperature of the reaction mixture seems to be most important. Attempts to combine either the chloride or bromide with aqueous solutions of potassium cyanide were always fruitless.

**1-Cyano-3-heptyne (Table II).**—This nitrile was prepared from the corresponding acid via the amide and dehydration of the latter with phosphorus pentoxide. The yield on the last step was 50%.

**5-,6- and 7-Octynoic Acid (Table II).**—The corresponding nitriles were hydrolyzed to the acids in about 90% yields by refluxing with an excess of 10% potassium hydroxide solution until the evolution of ammonia ceased.

**3-Octynoic acid (Table II).**—A stream of hydrogen chloride (tank) was passed into solution of 140 g. of 1-cyano-2-heptyne in 250 cc. of methanol and 25 cc. of water until it refluxed and later fell to 30°. The precipitated ammonium chloride was collected and the filtrate was concentrated. The crude ester was further hydrolyzed with alcoholic alkali to yield 120 g. (74%) of acid, b. p. 120–130° at 6 mm.

One attempt at hydrolysis involving shaking 6 g. of the cyanide with 20 cc. of concentrated hydrochloric acid for four days at room temperature yielded 3 g. (34%) of a product, b. p. 148 at 4 mm., m. p. 54–55° after crystallization from petroleum ether (b. p. 30–60°), which was presumably the amide of 4-chloro-3-octenoic acid.

*Anal.* Calcd. for $C_8H_{14}ONCl$: C, 54.9; H, 7.9; N, 8.0. Found: C, 54.9; H, 7.8; N, 8.1.

When the hydrolysis with concentrated hydrochloric acid was carried out at 80° for twelve hours, 8 g. (46%) of a chloro acid, presumably 4-chloro-3-octenoic acid, b. p. 125–126° at 3 mm., was obtained. The neutral equivalent was 177, 178; calculated for $C_8H_{13}O_2Cl$, 176.5.

When a mixture of 6 g. of 1-cyano-2-heptyne, 5 g. of concentrated sulfuric acid, and 2 cc. of water was heated and stirred at 60° for two days little reaction had occurred. An additional 10 cc. of 6 *N* sulfuric acid was added and the heating and stirring continued for one day. The organic matter was then isolated and heated with aqueous potassium hydroxide until a homogeneous solution was obtained. The acid fraction after vacuum distillation and crystallization from petroleum ether (b. p. 30–60°) amounted to 4 g., m. p. 53–54°, neutral equivalent, 157. Calcd. for $C_8H_{14}O_3$, 156. This acid was thus 4-ketoöctanoic acid.[21]

Because of the difficulty in hydrolyzing 1-cyano-2-heptyne, it was brominated, as described for 1,2,3-tribromo-2-heptene, to yield 50% of the expected 1-cyano-2,3-dibromo-2-heptene, b. p. 118 at 4 mm.

*Anal.* Calcd. for $C_7H_{11}NBr_2$: N, 4.9. Found: N, 4.4.

Hydrolysis of this compound was likewise incomplete as heating 14 g. with 20 cc. of concentrated sulfuric acid to 80° for fifteen minutes, followed by standing at room temperature for three hours yielded only 7 g. (47%) of the amide of 3,4-dibromo-3-octenoic acid, m. p. 130–131°.

*Anal.* Calcd. for $C_8H_{13}ONBr_2$: C, 32.1; H, 4.3; N, 4.7. Found: C, 32.2; H, 4.5; N, 5.0.

(21) Blaise and Koehler, *Compt. rend.*, **148**, 489 (1909).

**4-Octynoic acid (Table II).**—In a typical malonic ester synthesis 280 g. (1.74 mole) of 1-bromo-2-hexyne was added to a solution of 1.5 l. of absolute alcohol, the sodium ethoxide prepared from 41.5 g. (1.8 mole) of sodium, and 320 g. (2 mole) of ethyl malonate. After refluxing for eight hours the product was treated as usual to yield 240 g. (57%) of ethyl 2-hexynylmalonate, b. p. 134–134° at 5 mm., and 75 g. (13%) of ethyl di-(2-hexynyl)-malonate, b. p. 168–170° at 5 mm., $n^{25}D$ 1.4600.

*Anal.* Calcd. for $C_{13}H_{20}O_4$: C, 65.0; H, 8.3. Found: C, 65.3, 65.2; H, 8.2, 8.2. Calcd. for $C_{19}H_{28}O_4$: C, 71.2; H, 8.7. Found: C, 71.2, 71.3; H, 8.8, 8.7.

In another experiment partial saponification occurred during isolation of the products from the reaction mixture and there was isolated a small amount of ethyl di-(2-hexynyl)-acetate, b. p. 135–137° at 3 mm.

*Anal.* Calcd. for $C_{16}H_{24}O_2$: C, 77.4; H, 9.7. Found: C, 77.0, 77.0; H, 9.7, 9.8.

On alkaline hydrolysis 2-hexynylmalonic acid, m. p. 109–110° with dec., and di-(2-hexynyl)-malonic acid, m. p. 138–139° with dec., were obtained. The neutralization equivalents were 92, 91 (theory, 92) and 131, 131 (theory, 132), respectively.

*Anal.* Calcd. for $C_9H_{12}O_4$: C, 58.9; H, 6.5. Found: C, 59.0, 59.0; H, 6.6, 6.7. Calcd. for $C_{15}H_{20}O_4$: C, 68.2; H, 7.6. Found: C, 68.4, 68.5; H, 7.6, 7.6.

Heating at 150 to 170° until the evolution of carbon dioxide ceased afforded 4-octynoic acid in 93% over-all yield from ester. The di-2-hexynylacetic acid was not isolated as such but was converted into the amide, m. p. 63–64°.

*Anal.* Calcd. for $C_{14}H_{21}ON$: C, 76.8; H, 9.6; N, 6.4. Found: C, 76.9, 77.0; H, 10.1, 10.1; N, 6.5, 6.5.

**2-Octynoic Acid.**—In a manner similar to the above, ethyl 2-heptynylmalonate, b. p. 146 at 5 mm., was prepared in 66% yield.

*Anal.* Calcd. for $C_{14}H_{22}O_4$: C, 66.1; H, 8.7. Found: C, 64.9; H, 8.5.[22]

(22) The remaining malonic ester was saponified before the poor analytical result was obtained, hence we were unable to secure a good analysis.

On hydrolysis 2-heptynylmalonic acid, m. p. 93–94°, neutral equivalent 99 (theory, 99), was obtained.

*Anal.* Calcd. for $C_{10}H_{14}O_4$: C, 60.6; H, 7.1. Found: C, 59.9, 59.5; H, 7.1, 7.3.

**Preparation of Methyl Esters.**—The acetylenic acids were obtained in over 90% yields after refluxing for twelve hours in an excess of methanol containing small amounts of *p*-toluenesulfonic acid.

**Ozonization of Octynoic Acids.**—The octynoic acids were oxidized in acetic acid in an ozonizer of the Henne–Perilstein type[23] using a flow rate of 23 l. of oxygen, containing 1 g. of ozone, per hour. Only the dibasic acid fractions were isolated. The acids were checked by melting point and neutralization equivalent. The yields from solutions of about 4 g. of acids in 50 cc. of acetic acid (ozonized for four hours at room temperature) were as follows: 7-octynoic acid, 46% pimelic acid; 6-octynoic acid, 52% adipic acid; 5-octynoic acid, 71% glutaric acid; 4-octynoic acid, 67% succinic acid; and 3-octynoic acid, 80% malonic acid. No attempt to isolate maximum amounts of these dibasic acids was made.

**Hydrogenation of Octynoic Acids.**—The octynoic acids, 0.8 to 1.4 g., were dissolved in 20 cc. of pure ethyl alcohol and reduced over 0.20 g. of Adams platinum catalyst in a quantitative manner using an apparatus similar to that described by Joshel.[24] In each case almost exactly the theoretical amount of hydrogen was absorbed in times which varied from 150 to 300 minutes. 5-Octynoic acid was hydrogenated on a larger scale in a shaking device (Parr Instrument Company). In each case the saturated acid, obtained in almost theoretical yield, proved to be *n*-octanoic acid. Comparison was always effected by means of the amide, m. p. and mixed m. p., 103–104°.

## Summary

The synthesis of 7-, 6-, 5-, 4- and 3-octynoic acids and the preparation and chemical behavior of many of the new acetylenic intermediates are described.

# Native Lignin. II. Native Aspen Lignin[1,2]

BY M. A. BUCHANAN, F. E. BRAUNS AND R. L. LEAF, JR.

The isolation of native lignin fractions from black spruce and western hemlock has been described by Brauns.[3] These two preparations represent softwood (gymnosperm) lignin and are similar in nature. It is well known that hardwood (angiosperm) lignin differs from softwood lignin in that the former contains a greater amount of methoxyl and is built up of both syringyl and guaiacyl nuclei, whereas only the latter are found in softwood lignins. In recent years, the hardwoods have become increasingly important as a source of wood pulp. Consequently, it was of interest to isolate and investigate the native lignin fraction from a typical hardwood.

Native aspen lignin was isolated by means of neutral ethanol under conditions designed to prevent any change in the lignin during its isolation and purification. The crude lignin contained 17.6% methoxyl, which agrees with the value of 17.5% reported by Lovell and Hibbert[4] for a lignin preparation extracted from aspen with neutral alcohol. These investigators separated their product into three fractions by a fractional distribution between water, methanol, chloroform and carbon tetrachloride. They obtained one fraction having a methoxyl content of 18.4%, but apparently did not investigate their lignin further.

(1) For paper I of this series see F. E. Brauns, THIS JOURNAL, **61**, 2120–2127 (1939).

(2) Presented before the Division of Cellulose Chemistry at the 114th meeting of The American Chemical Society, Portland, Oregon, September 13–16, 1948.

(3) F. E. Brauns, *J. Org. Chem.*, **10**, 211–215 (1945).

(4) E. L. Lovell and H. Hibbert, THIS JOURNAL, **63**, 2070–2073 (1941).

Purification of the crude native aspen lignin by repeated precipitations into water and into ether increased the methoxyl content to a constant value of 19.5%. The purified lignin on treatment with 72% sulfuric acid under the conditions of the lignin determination gave approximately 90% of a "Klason lignin." The composition corresponds very well with those normally obtained from Klason lignin isolated directly from hardwoods.[5] The isolated native aspen lignin, therefore, undergoes changes similar to those produced in native spruce lignin on treatment with 72% sulfuric acid. The exact nature of these changes is not known, but they may involve loss of some fragment of the lignin molecule, in addition to loss of water as a result of condensation.

Treatment of the purified native aspen lignin with methanol containing hydrogen chloride resulted in a product having a methoxyl content slightly higher than the value (25.6%) reported by Harris[6] for methanol lignin prepared directly from aspenwood.

Methylation of the purified native aspen lignin with diazomethane indicates the introduction of 1.5 methoxyl groups per six methoxyl groups originally present. On the other hand, diazomethylation of the methanol native aspen lignin introduced one additional methoxyl group. Under these conditions, diazomethane methylates only acidic hydroxyl groups. Methanol in the presence of hydrogen chloride methylates carboxyl groups and forms acetals with aldehydic or ketonic carbonyl groups and, therefore, the above results indicate the presence of one phenolic group per six methoxyl groups in the original aspen lignin. The additional 0.5 methoxyl group introduced by diazomethane may represent the methylation of one enolic group per 12 original methoxyl groups. However, the methoxyl content of the methanol derivative suggests that there may be as many as 2.5 carbonyl groups per 12 original methoxyl groups.

Complete methylation of the diazomethane-methylated native aspen lignin and acetylation of the original lignin suggests that it contains six hydroxyl groups. However, *p*-toluenesulfonyl chloride reacts with one or two less groups than does acetic anhydride under similar conditions.

A spruce lignin building unit containing four methoxyl groups has been postulated which agrees very well with the analytical results of a number of derivatives.[1] Attempts to postulate a similar unit for aspen lignin have not been entirely satisfactory. If one assumes a unit of aspen lignin containing six methoxyl groups, the unit weight is calculated to be approximately 950 on the basis of the methoxyl content of the native aspen lignin. The carbon and hydrogen data suggest that a unit of this size contains 50 carbon, 56 hydrogen, and 18 oxygen atoms. This combination corresponds to a unit weight of 945. Calculated values for a unit of this size are compared with the observed values in Table I. The data for the original native aspen lignin, as well as those for the completely methylated and acetylated products, agree rather well with the calculated values. However, the diazomethane-methylated material, the methanol lignin, and the phenylhydrazine reaction product do not correspond to the introduction of an integral number of groups. This suggests that either the true unit is a multiple of 945 or that the native aspen lignin is not homogeneous. If the lignin is non-homogeneous, any attempts to derive a unit weight can represent only an average composition of the material. Hence, the 945 unit is only tentative in nature and may require revision when more data are available.

**Absorption Spectra.**—Methylation of the native aspen lignin reduces the absorption in the visible range by a factor of about four (Fig. 1). Ultraviolet absorption spectra were determined by means of a Beckman Model DU spectrophotometer. The results, expressed as specific extinction (optical density/concentration in grams per liter), are shown in Fig. 2. Methylation has but little effect on the absorption in the ultraviolet region. The native aspen lignin differs from spruce lignin in that it does not have a well-defined maximum at about 280 mmu. It does show a slight inflection at 275 mmu but does not have the minimum at approximately 260 mmu. The aspen lignin curve may be composed of the same general absorption bands which are responsible for the spruce lignin curve. If this is true, the bands are broadened sufficiently to remove the characteristic maximum and minimum.

Patterson and Hibbert[7] likewise found a broadening of the absorption bands in the case of certain hardwood lignin products obtained by the ethanolysis of maplewood.

The infrared spectrum of native aspen lignin has been determined and will be reported later. Its general nature is similar to that reported for native spruce lignin.[8]

## Experimental

**Isolation of Native Aspen Lignin.**—A 17-year old aspen (*Populus tremuloides*) tree having a butt diameter of 5.25 inches was felled shortly after leafing. The wood was immediately converted into sawdust. A 59-pound portion of sawdust (containing 50.6% moisture and 2.4% ethanol-soluble material) was extracted with 95% ethanol at room temperature. One to two gallons of the alcoholic extract was removed from the bottom of the percolator per day, which was then replenished with fresh ethanol. After three weeks, approximately half of the original

ethanol-soluble material had been removed from the sawdust and the extraction was discontinued. The alcoholic solutions were concentrated under reduced pressure to a volume of 3 liters. This removed the alcohol and caused precipitation of considerable water-insoluble material.

[a] Methylated in dioxane solution to constant methoxyl content. [b] N. A. L. methylated with dimethyl sulfate. [c] Prepared according to Brauns.[1] [d] Number of groups introduced by diazomethane. [e] N. A. L. treated with 2.5 parts *p*-toluenesulfonyl chloride and 15 parts pyridine for 24 hours at room temperature. [f] N. A. L. treated with 72% sulfuric acid under conditions of the lignin determination; yield 90%.

The aqueous mixture was extracted directly with ether, which removed 179.1 g. of ether-soluble material.

The extracted mixture was filtered and the moist precipitate dissolved in dioxane.[9] The resulting solution was dehydrated by distilling under reduced pressure with fresh dioxane. The dry dioxane solution was adjusted to approximately 10% solids and was added dropwise (in small portions) with vigorous stirring to 30 volumes of anhydrous ether. The precipitated product was washed thoroughly with low boiling petroleum ether to remove all traces of ethyl ether. This crude product contained 17.6% methoxyl. It was purified by reprecipitating from a 10% solution in 1:1 methanol–acetone into 10 volumes of water. Eighty per cent. of the material was recovered as a water-insoluble product which, after an additional precipitation into ether, contained 19.2% methoxyl. The yield at this stage was 87.7 g. or 0.7% of the original wood (oven-dry basis). After three additional precipitations into ether, the product contained 19.5% methoxyl (ash-free basis) and 0.12% ash. Additional precipitations into water or into ether did not change the methoxyl content. The analysis of this and other derivatives is given in Table I.

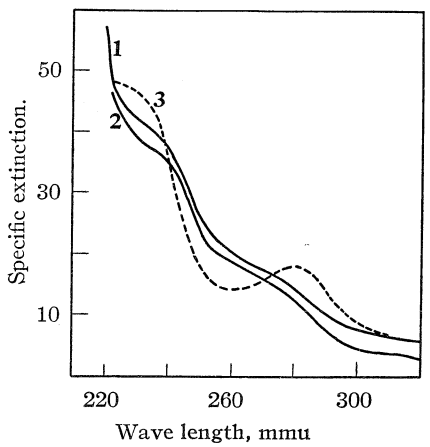

Fig. 2.—Ultraviolet absorption spectra of dioxane solutions: 1, aspen native lignin (concn. 0.021 g./l.); 2, diazomethane-methylated aspen, native lignin (concn. 0.021, g./l.); 3, spruce native lignin[10] (concn. 0.03 g./l.).

**Acknowledgment.**—The authors are indebted to the Analytical Department of The Institute of Paper Chemistry for some of the analyses reported in this paper.

## Summary

A native hardwood lignin has been isolated from aspenwood. After purification, the product contains 19.5% methoxyl. On treatment with 72% sulfuric acid, using the Klason procedure, the methoxyl content is increased to 20.4%. A unit of native aspen lignin containing six methoxyl groups also contains six hydroxyl groups, one of which is phenolic in nature. The ultraviolet absorption spectrum of the aspen lignin differs from that of softwood lignins in that no well-defined maximum is present.

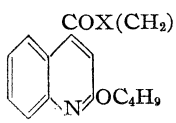
# Sulfur-Containing Amines. VII.[1] Local Anesthetics. II

BY R. O. CLINTON, U. J. SALVADOR AND S. C. LASKOWSKI

A logical extension of local anesthetic type compounds derived from the 4-aminobenzoyl nucleus and sulfur-containing amines[2] is to analogous types containing other parent nuclei. Gilman, *et al.*,[3] have shown, in a correlation of therapeutic activity with aromaticity, that the dialkylaminoalkyl esters of cinnamic acid are more effective than the corresponding benzoate esters; this observation has been extended by McElvain[4] to a series of methylpiperidinoalkyl benzoates and cinnamates. In the latter series it was shown that activity was highest with the cinnamates; however, in general, toxicity was found to increase proportionally. It is also interesting to note in this connection that Gardner, *et al.*,[5] have succeeded in lowering toxicity with retention of activity in the cinnamate series, through the use of esters containing the terminal morpholine group.

The present report describes a representative series of benzoates (I), benzamides (II–III), cinnamates (IV), cinnamamides (V, VI) and 2-butyloxycinchonyl derivatives (VII, VIII) derived from



$COX(CH_2)_nS(CH_2)_mNR_2$

I, X = O
II, X = NH
III, X = $NC_2H_5$

$CH{=}CHCOX(CH_2)_nS(CH_2)_mNR_2$

IV, X = O
V, X = NH
VI, X = $NC_2H_5$

$COX(CH_2)_nS(CH_2)_mNR_2$

VII, X = O
VIII, X = NH

certain of the sulfur-containing amines previously reported,[6] with the purpose of ascertaining whether the high therapeutic index associated with the related 4-aminobenzoyl types[2] could be extended to non-aminated nuclei. Compounds of types VII and VIII were of especial interest, since they contain the parent nucleus of the very active but very toxic substance, Dibucaine.

All of the above compounds were prepared by standard procedures with little difficulty. The pharmacological results will be reported upon by Dr. T. J. Becker and Dr. F. P. Luduena of these Laboratories at a later date. In general, it may be stated here that most of the compounds were of a low order of activity.

## Experimental[7]

**Esters and Amides, I–VI.**—The esters were prepared from a slight excess of acid chloride and the appropriate alcohol[6] in cold dry benzene, and the amides from an excess of acid chloride and the amine[6] in chloroform–water mixture in the presence of sodium bicarbonate, with due precautions to avoid decomposition of the amines.[2] In general the bases were isolated in the usual manner and purified by washing with dilute sodium hydroxide solution. In certain cases distillation was necessary to provide bases suitable for conversion to salts. The yields varied from 80–95%.

# A Family of Long-Acting Depressors[1,2]

BY RICHARD BALTZLY, JOHANNES S. BUCK,[3] EDWIN J. DE BEER AND FREDERICK J. WEBB[4]

Some years ago Ide and Buck[5] prepared a number of N-methyltetrahydro*iso*quinolines by the cyclization of the appropriate N-methylphenethylamines with formalin and hydrochloric acid. A pharmacological study was performed by Fassett and Hjort,[6] who found all but one member of this group to be weak pressors or depressors with transient action, while 6-ethoxy-N-methyltetrahydro*iso*quinoline was an extremely potent depressor with a long period of action. While correlation of physiological action with chemical structure is on essentially an empirical basis at present, such correlation within classes of related compounds usually is fairly good. It was therefore felt that the physiological results cast grave doubt on the purity and identity of this sample of 6-ethoxy-N-methyltetrahydro*iso*quinoilne.

An authentic specimen of 6-ethoxy-2-methyltetrahydro*iso*quinoline hydrochloride was prepared by an alternative route.[7] The new sample had none of the remarkable physiological activity of the older specimen. Further fractionation of material prepared according to the formalin procedure afforded a sample more nearly resembling the authentic (new) specimen. De-ethylation of the original material also yielded a sample of 6-hydroxy-N-methyl tetrahydro*iso*quinoline hydrochloride identical with an authentic specimen of this substance. It was thus evident that the Ide and Buck material was preponderantly 6-ethoxy-N-methyl tetrahydro*iso*quinoline hydrochloride contaminated by a small amount of a highly potent depressor substance whose physical properties and composition were not markedly different from those of the major component.

A number of formalin cyclizations of 3-ethoxyphenethylmethylamine followed by attempts to fractionate the reaction products gave rather irregular results. Usually such preparations, like the original one, produced strong, lasting depression of blood pressure when administered intravenously to anesthetized dogs in doses of 1 mg./kg. body weight. One specimen, a chloroform-insoluble hydrochloride obtained by successive precipitations from chloroform solution by ethyl acetate, was about four times as active.

Serious progress in elucidating the nature of the unknown depressor was not made until a change in the amine under study was effected. Cyclization of a phenethylamine to a tetrahydroisoquinoline by the formalin–hydrochloric acid procedure is effective only when there is an activating group para to the cyclization-point. Ortho and para methoxyphenethylmethylamines are not cyclized by this method. When these amines were treated by the usual procedure, however, the products were by far the most active depressors so far obtained. It was now possible to secure a fall in the blood-pressure of 100 mm. of mercury lasting for an hour or more with doses of the

order of 0.1 mg./kg. body weight.[8] This indicated that the depressor type was not a tetrahydro*iso*quinoline.

Two main possibilities remained: cross-linking between nitrogen atoms by formaldehyde, and formation of methylene links between aromatic nuclei. The first possibility was eliminated when it was found that hordenine methyl ether and its metho-chloride both yielded preparations of maximum potency. It was therefore probable that the depressor type was formed by the sort of reaction shown in Chart I.

CHART I

I

wherein X might be Cl or OH and Z and Z′ could be H or $CH_2OH$ or $CH_2Cl$. The conditions of the reaction are essentially those of a mild chloromethylation and formation of a condensation polymer as indicated in Chart I is not at all surprising.

The optimum conditions for the condensation were found to be when the formalin was approximately equimolecular with the amine, when the hydrochloric acid was about 6*N*, and when heating was continued for about four hours on the steam-bath. The products so obtained were light colored glasses when dried thoroughly. They exhibited the usual amine-hydrochloride solubilities and could be ground to powders under ether. Precipitation from absolute ethanolic solution by ethyl acetate and ether under controlled conditions gave filterable powders that appeared granular to gross inspection and which were not clearly crystalline or non-crystalline under the microscope. Such powders, however, were incapable of seeding out more material from solutions in alcohol brought to the point of turbidity by addition of ether, and undoubtedly were not truly crystalline. Further fractionation revealed a variety of components.

When a "Standard Preparation" from *p*-methoxyphenethylmethylamine was dissolved in water, perchloric acid and ammonium perchlorate were added and the solution was refrigerated, a solid perchlorate separated. This material, doubtfully crystalline to start with, became definitely crystalline on recrystallization from water and could be transformed to a crystalline hydrochloride. This hydrochloride had a composition consistent with that of a "dimer" (I, $n = 0$, $Z = Z' = H$). The base corresponding gave a molecular weight in agreement with this formulation. The "dimer" base distils at about 120° at 0.5 $\mu$ pressure. On the basis of the amounts of perchlorate isolable about a third of the "standard preparation" is "dimer." This material is nearly inactive physiologically giving a weak depression of short duration.

After removal of the "dimer" as its perchlorate, partial basifications followed by extraction with ether and later ether–ethyl acetate mixtures produced a series of base fractions. All were oils and were increasingly viscous and diminishingly soluble in ether as the basification proceeded. The more ether-soluble fractions gave "molecular weights" about right for a "trimer," the less ether-soluble fractions were probably more highly polymerized; their Rast values were about right for the "tetramer." In high vacuum the "trimer fraction" was partially distillable, perhaps with some decomposition. The distillate (boiling around 200° at 0.3 $\mu$ pressure) was highly active; it left a residue on redistillation. It is not clear whether this residue consists of higher molecular material initially present or produced by further condensation during the distillation. Some of these residues proved to be reactive on testing, but some were too insoluble for investigation.

The above experiments indicated that the physiological activity was associated with trimeric and tetrameric condensation products. Attempts at crystallizing such fractions were not successful and further fractionation appeared required. The most fruitful results were obtained by the use of Craig's method of counter-current distribution[9] on the product from the condensation

(8) We have not been able to improve on this potency. Some fractions obtained subsequently were undoubtedly more homogeneous and probably more potent. Unfortunately, the physiological assay will not differentiate clearly between preparations whose activity is in the ratio of 3:2. As will be seen this is about the greatest ratio of potencies that could be expected between a pure component and a total reaction mixture of this type.

(9) Craig, *J. Biol. Chem.*, **155**, 519 (1944); Craig, Golumbic, Mighton and Titus, *ibid.*, **161**, 321 (1945); Williamson and Craig, *ibid.*, **168**, 687 (1947).

of *p*-methoxyphenethyldimethylamine with formaldehyde. This polymer is perhaps less active than that from the corresponding secondary amine but appeared more suitable for investigation. An eight-plate fractionation between 50% benzene–hexane and 75% methanol–water yielded two fractions. The more hydrophobic of these, which contained about two-thirds of the active material, was presumably free of hydroxymethyl groups since it gave no gas in a Zerewitinoff machine. The more hydrophilic fraction could be separated further by a repeated distribution using 55% methanol as the lower phase. The separation was only approximate but indicates the presence of low polymers having one hydroxymethyl group and of another type having two. All of these fractions were highly potent, and equally potent within the limits of accuracy of the physiological assay. So far, however, no active fraction has yielded crystalline salts. It is to be expected that molecules of this type would not crystallize readily and failure to crystallize them is not in itself proof of non-homogeneity but their physical properties taken together with the analytical data seem to indicate that separation had been made only between types, not between species.[10]

Condensations between formaldehyde and amines with shorter side chains resulted in qualitatively similar products. Those from *p*-methoxybenzylmethylamine and *p*-methoxybenzyldimethylamine were somewhat less potent and more toxic. The proportion of dimer was higher and the general state of polymerization appeared to be lower. This would be anticipated on the general principles of aromatic substitution since a cationic group only one stage removed from a benzene ring is well known to interfere appreciably with substitution.[11]

Condensation products of the same general type were also obtained from *o*-anisidine. The polymeric aromatic bases had no depressor action but the derived methiodides were fairly potent. This would seem to show that activity is dependent on the presence of groups that would be cationic under physiological conditions and suggests that a molecule of the approximate dimensions of a "trimer" and possessing two or three properly spaced cationic groups should exhibit strong depressor action. Experiments in this direction have been in progress and will be reported separately.

## Experimental

**Physiological Testing.**—Since evaluation of the chemical work was at all times dependent on physiological assay a few remarks about the methods used and their interpretation are desirable even though the pharmacology of these depressors is to be reported elsewhere. In Table I are shown typical results selected from the very large number available. The preparations tested are identified by code numbers referring to the section "Chemical Manipulations."

TABLE I

POTENCIES OF TYPICAL DEPRESSOR PREPARATIONS

| Specimen (Code number) | Potency | Specimen (Code number) | Potency |
|---|---|---|---|
| IV-132 | ++ | GC-60 | + |
| Q-190C | +++ | GC-55 | + |
| M-25 | ++ | GC-125 I | ++++ |
| M-27 | ++ | GC-125 II | ++++ |
| GD-6 | + | GC-69A | ++++ |
| GC-142-1 | + | GC-69B | ++++ |
| GC-142-2 | ++ | GC-131-2 | ++++ |
| GC-142-3 | +++ | GC-131-3 | ++++ |
| GC-142-4 | ++++ | GC-132-8 | ++++ |
| GC-142-5 | +++ | M-124 res. | ++++ |
| M-96 | +++ | GC-114 | ++++ |
| GC-81 II | ++++ | GC-114 II | ++++ |
| M-118 | ++++ | GC-104 II | + |
| M-114 | ++++ | GC-110 | +++ |

Assay was carried out by injecting aqueous solutions intravenously into anesthetized dogs in the usual set-up for observation of blood pressure. In the earlier period of this work chief attention was given to discovering the minimum effective dose for the preparation used. This led to irregularities since relatively few animals could be tested and individual variations in sensitivity were considerable. It was later decided to administer standard doses (usually 0.4 mg./kg.) of the more potent preparations and to evaluate the response by the magnitude and duration of depression. Such methods might distinguish one preparation from another of twice the potency but smaller differences are not detected with certainty.

Potency is indicated in Table I by the notations ++++, +++, etc. The maximum potency is ascribed to preparations that in doses of 0.02–0.05 mg./kg. body weight lowered the blood pressure by about 30 mm. (of mercury) and whose effect lasted at least fifteen minutes *or*, by the later method of testing, gave depressions of 90 mm. or more lasting at least one hour in doses of 0.1–0.4 mg./kg. Preparations giving only short depressions (five to ten minutes) of small amplitude in doses of 1 mg./kg. are indicated with +. The notations +++ and ++ show samples of intermediate activity.

**Chemical Preparations.**—Sample IV-132 was the original specimen of "6-ethoxy-2-methyltetrahydroisoquinoline hydrochloride."[5]

Q-190-C was prepared from a repeat preparation of IV-132 by repeated solution in chloroform and precipitation with ether. Q-190-C represented a final, chloroform-insoluble fraction.

**Standard Preparations.**—For these preparations the base was suspended in water and the whole chilled in ice. An exact equivalent of formalin solution was added followed by sufficient concentrated hydrochloric acid to make the final concentration 6 *N*. (As an example, 12.4 g. of N-methylhomoanisylamine was suspended in 15 cc. of water and 5.85 cc. of formalin solution added slowly, followed by 30 cc. of cold concentrated hydrochloric acid.) The flask was then covered with a watch-glass and heated on the steam-bath for four hours. All preparations subsequently identified as "standard preparation" were subjected to this treatment. GC-142-1 received one hour of heating, GC-142-2 two hours and the other GC-142 samples the number of hours indicated by the last digits. It will be observed that GC-142-4 was the most potent. A minor variation was to extract the amine-formaldehyde reaction mixture with ether before adding acid, to evapo-

(10) The occurrence of methylene substitution in positions other than those ortho to the methoxyl groups, while doubtless of minor quantitative importance, is to be expected and would add to the complexity of the polymer mixture, while presumably having little influence on the physiological properties.

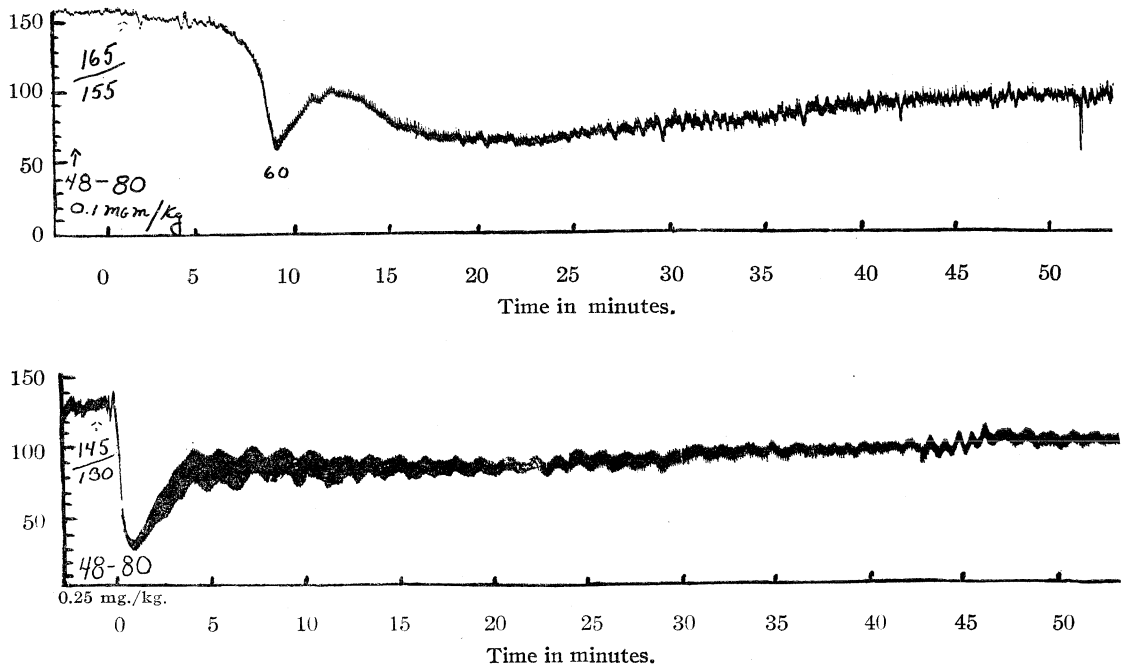

Fig. 1.—Blood pressure tracings for "Standard Preparations." The vertical scale indicates pressure in mm.

rate the ether and heat with acid as before. The products so obtained were not distinguishable from those previously described and the term "standard preparation" is intended to cover both. After completion of the heating period, the solution was evaporated *in vacuo* on the steam-bath and the residue was dissolved in a minimum of absolute ethanol (about 40 cc. for the quantity previously quoted). To the hot ethanolic solution was added an equal volume of ethyl acetate and the solution, which set to a jelly on cooling, was refrigerated overnight. About two volumes of anhydrous ether were then stirred in whereby the jelly was broken up to a colorless suspension of granular appearance. This was filtered rapidly, washed with anhydrous ether and dried *in vacuo*. Figure 1 shows typical blood pressure tracings with a "standard preparation" from *p*-methoxyphenethylmethylamine administered in two dose levels as indicated.

M-25 was a "standard preparation" from 3,4-dimethoxyphenethylmethylamine, M-27 from 2,3-dimethoxyphenethylmethylamine, GD-6 from hordenine. M-96 was a "standard preparation" from hordenine methyl ether and M-118 from hordenine methyl ether methochloride. The five samples GC-142-1 through GC-142-5 were obtained from *p*-methoxyphenethylmethylamine as previously indicated. M-114 was prepared from *o*-methoxyphenethyldimethylamine, GC-114 from *p*-methoxybenzylmethylamine, and GC-104 II from *o*-anisidine. GC-110 was the quaternary salt formed by the methylation of GC-104 II with methyl iodide in methanol (in the presence of sodium carbonate).

### Isolation of "Dimers"

**GC-60 from *p*-Methoxyphenethylmethylamine.**—This was prepared by a variation of the "standard preparation" using perchloric acid instead of hydrochloric. To 6.4 g. of base was added 3.0 cc. of formalin and 20 cc. of 20% perchloric acid in the cold. The mixture was heated two hours on the steam-bath and placed in the refrigerator. The gummy solid that separated was crystallized twice from water giving 3.7 g. of a colorless micro crystalline powder. The perchlorate was converted to the base and transformed to the hydrochloride which melted at 261–262° (m. p. not raised by four recrystallizations from ethanol-ether mixtures).

*Anal.* Calcd. for $C_{21}H_{32}Cl_2N_2O_2$: C, 60.69; H, 7.77 Calcd. for $C_{32}H_{49}Cl_3N_3O_3$: C, 60.9; H, 7.84. Found: C, 60.91; H, 7.30.

The base was again liberated from its salt and was distilled at 0.4 $\mu$ pressure, bath temperature, 125–130°. By the Rast method the base showed a molecular weight of 329 (calcd. for $C_{21}H_{30}N_2O_2$, 342). On reconversion to the hydrochloride the m. p. was 264–265°.

**GC-55 from 4-Methoxy-3-methylphenethyldimethylamine.**—This amine was condensed with formalin and hydrochloric acid in the expectation that the "dimer" would be obtained to the virtual exclusion of other material. Actually, considerable amounts of more highly polymerized bases were formed (as shown by distillation of the base in high vacuum). The presumed "dimer" was isolated in poor yield from the reaction mixture by repeated crystallizations from ethanol–ether mixtures, m. p. 221–222°.

*Anal.* Calcd. for $C_{25}H_{40}Cl_2N_2O_2$: C, 63.66; H, 8.56. Calcd. for $C_{36}H_{57}Cl_3N_3O_3$: C, 63.88; H, 8.61. Found: C, 63.47; H, 8.51.

The analysis fits either a "dimer" or a "trimer," but in view of the failure to obtain any "trimer" crystalline that possibility appears remote. Some of the starting amine was recovered from the reaction mixture but since its hydrochloride melts at 181–182°, the 221–222° material is clearly a condensation product.

**GC-125-I and GC-125-II.**—These were products from an attempt to conduct a condensation so as to favor formation of a "trimer." Four grams of formalin solution, 9.65 g. of 4-methoxy-3-methylphenethyldimethylamine and 48 g. of concentrated hydrochloric acid were held at 30–40° for two hours during which time a current of hydrogen chloride was passed through the solution. The reaction mixture was then evaporated *in vacuo*. It was hoped that at this stage the main constituent would be a mono-chloromethyl derivative. To the residue from evaporation was then added 5.4 g. of *p*-methoxyphenethyldimethylamine hydrochloride and 10 cc. of concentrated hydrochloric acid and the solution was heated on the steam-bath for seven hours. The reaction mixture was again taken down *in vacuo*, redissolved in water and basified. GC-125-I was the fraction of base soluble in ether while GC-125-II was insoluble in ether but soluble in

ethyl acetate. The former fraction, as a base, had a "molecular weight" of 520 (Rast method). Both fractions were tested as hydrochlorides.

**GC-114-II.**—A portion (275 mg.) of base from the "standard preparation" with *p*-methoxyphenethylmethylamine (GC-114) was subjected to distillation up to 130° at 0.3 μ pressure. There distilled 115 mg. of oil giving a "molecular weight" of 244 (calcd. for "dimer," 314). The residue (GC-114-II), weighed 140 mg. and showed a "molecular weight" of 496 (calcd. for "trimer," 477).

**Counter-current Distribution.**—A "standard preparation" from hordenine methyl ether was largely freed of "dimer" by partial basification of its aqueous solution and solvent extraction. Fraction GC-81-II represented about 70% of the original preparation, about 25% being in the "dimer" fraction first removed. Two 1-g. portions of GC-81-II were separately subjected to distributions by the Craig method (using separatory funnels) between 50-50 benzene-hexane and 75% aqueous methanol (120 cc. of each solvent mixture in each funnel). On completion of an "eight-plate" distribution (with Tube 0 containing the initial upper layer and Tube 8 the final lower layer) the contents of each funnel was evaporated separately. The evaporation residues from the tubes in Run 2 were as follows: Tube 0, 50 mg.; Tube 1, 155 mg.; Tube 2, 205 mg.; Tube 3, 170 mg.; Tube 4, 110 mg.; Tube 5, 60 mg.; Tube 6, 65 mg.; Tube 7, 100 mg.; Tube 8, 110 mg. It was evident that about two-thirds of the material was contained in Tubes 0–4, inclusive, and that a separate hydrophilic component was concentrated in Tubes 7–8. Run 1 was an almost exact duplicate, but Tube 8 was lost by an accident.

The combined contents of Tubes 1–3 of the two runs amounting to 1.08 g. was redistributed and now gave a curve indicating homogeneity (Tubes 6, 7 and 8 contained 30, 15 and 20 mg., respectively). The contents of Tubes 2 and 3, transformed into hydrochlorides, were tested as GC-131-2 and GC-131-3. GC-131-2 gave no gas in the Zerewitinoff machine.

The combined contents of Tube 7 of Run 1, Tubes 7 and 8 of Run 2 and Tubes 7 and 8 of a third similar run, totaling 490 mg. was redistributed in the same fashion. The contents of Tubes 0–8 were as follows: Tube 0, 15 mg.; Tube 1, 5 mg.; Tube 2, 5 mg.; Tube 3, 10 mg.; Tube 4, 10 mg.; Tube 5, 35 mg.; Tube 7, 80 mg.; Tube 7, 155 mg.; Tube 8, 185 mg. The contents of Tube 8 was analyzed (as the base).

*Anal.* Calcd. for $C_{37}H_{55}N_3O_5$ (trimer with two hydroxy methyl groups): C, 71.40; H, 8.84; m. wt., 621. Found: C, 72.18; H, 8.72; m. wt., 630.

In a Zerewitinoff machine 14.77 mg. gave 1.20 cc. of gas at 25° and 771 mm. = 1.12 cc. at 0° and 760 mm. Calcd. for m. wt. 621 and two active hydrogen atoms: 1.07 cc. The remainder of this sample was dissolved in dilute hydrochloric acid and tested as GC-132-8.

One-tenth g. of fraction GC-131-2 was distilled as base, three fractions being taken. The first, boiling up to 175° at 0.2 μ weighed 40 mg. and gave a "molecular weight" of 296. Distillation was continued on the residue but nothing came over below 195°. A total of 25 mg. distilled, mainly at 208°. This showed a "molecular weight" of 572. (Calcd. for "trimer" with no hydroxy methyl groups, 561.) The residue weighed 25 mg. and showed a "molecular weight" of 557. It seems likely that the material suffered some decomposition.

Several larger distributions having been made, several terminal fractions amounting to 655 mg. were united and redistributed between 50-50 benzene–hexane and 55% aqueous methanol. The contents of Tubes 0–8 were as follows: Tube 0, 135 mg.; Tube 1, 95 mg.; Tube 2, 70 mg.; Tube 3, 75 mg.; Tube 4, 55 mg.; Tube 5, 40 mg.; Tube 6, 50 mg.; Tube 7, 45 mg.; Tube 8, 90 mg. The contents of Tube 0 gave a "molecular weight" of 746 (in camphor). The "tetramer" with one hydroxy methyl group would have mol. wt., 782. 27.8 mg. in the Zerewitinoff machine gave 0.61 cc. of gas (reduced to 0° and 760 mm.). Calcd. for mol. wt. of 782 with one active hydrogen, gas = 0.80 cc.

The contents of Tube 8 was not sufficiently soluble in camphor for a molecular weight determination. In borneol (observed mol. m. p. depression 33°; lit. value, 35.6°) the "molecular weight" was 567 (or 612 using the literature m. p. depression). A "trimer" with two hydroxy methyl groups would have mol. wt. = 621. In the Zerewitinoff machine 25.6 mg. gave 1.57 cc. of gas (reduced to 0° and 760 mm.). Calcd. for "trimer" with two active hydrogens, 1.85 cc.

**Acknowledgment.**—The authors wish to express their gratitude to Mr. Samuel Blackman, who performed the microanalyses, and to Mr. Lloyd Wnuck for assistance in preparing the blood pressure tracings.

## Summary

1. The condensation of formaldehyde with alkoxyphenalkylamines in the presence of acid results in mixtures of low-polymeric bases that have been only partially separated into their constituents.

2. Those polymers having three or four residues of the parent amine joined by methylene groups between the rings have a pronounced and enduring effect in lowering the blood pressure.

3. Evidence is presented that some of these polymers have one or two hydroxy methyl groups attached (presumably to the terminal rings). Presence or absence of these groups is not critical to the effect on the blood pressure.

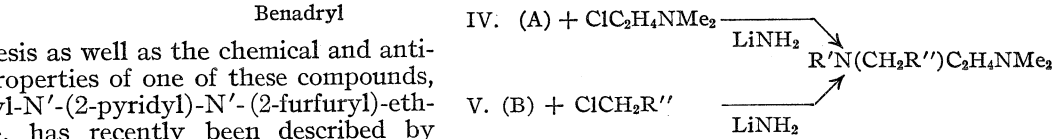
# Antihistaminics. I. Some Ethylene Diamines and an Aminoether

BY JOHN H. BIEL

In the course of a search for new antihistaminic agents we have investigated the effect of substituting chloro and methoxy as well as various heterocyclic groups into different moieties of compounds possessing antihistaminic activity. With one exception the compounds prepared conformed to the general formula

where R′ was a substituted or unsubstituted phenyl, 2-pyridyl or 2-pyrimidyl radical, R″ was a phenyl, substituted phenyl, 2-thienyl or 2-furyl radical and R‴ was a methyl or isopropyl group. In addition we prepared a furan analog of "Benadryl"

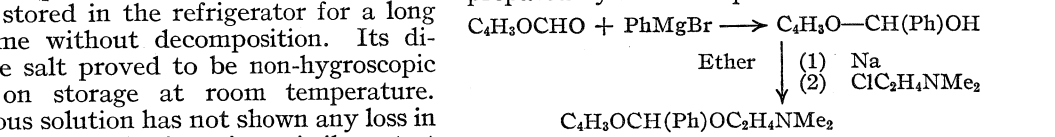
$C_4H_3OCH(Ph)OC_2H_4NMe_2$, $(Ph)_2CHOC_2H_4NMe_2$ (Benadryl)



The synthesis as well as the chemical and antihistaminic properties of one of these compounds, N,N-dimethyl-N′-(2-pyridyl)-N′-(2-furfuryl)-ethylenediamine, has recently been described by Vaughan and Anderson.[1] The authors reported a 15% yield of the purified base which was described to be quite unstable even at temperatures of −80° and to polymerize in the presence of mineral acids. We prepared the pure tertiary amine in 54% yield by condensing N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine[2] with freshly distilled 2-furfuryl chloride[3] in the presence of lithium amide (procedure V). The light yellow oil could be stored in the refrigerator for a long period of time without decomposition. Its dihydrochloride salt proved to be non-hygroscopic and stable on storage at room temperature. Its 1% aqueous solution has not shown any loss in antihistaminic activity in the guinea pig ileum test after being stored in the refrigerator for a considerable length of time.

The intermediate secondary amines of the pyridine and pyrimidine series (R″ = phenyl or substituted phenyl) were prepared by condensing 2-aminopyridine, 2-aminopyrimidine or their substituted derivatives with either the appropriate araldehyde in the presence of formic acid[4] (method I) or with the corresponding chloromethyl compound in toluene using lithium amide as the condensing agent (method II).

The intermediate secondary ethylenediamines $R'NHC_2H_4NMe_2$ (R′ = 2-pyridyl, 2-pyrimidyl, phenyl or substituted phenyl) were obtained by treating the primary amine with β-dimethylaminoethyl chloride in the presence of either anhydrous potassium carbonate[5,6] or lithium amide[6] according to general methods described in the literature (method III).



The tertiary amines were obtained by the alkylation of (A) by method IV or the aralkylation of (B) by method V using lithium amide in dry toluene as the condensing agent

They were then converted to water soluble salts in which form they were evaluated pharmacologically. The N-isopropyl analog of "Pyribenzamine" did not form a solid derivative. For the purpose of pharmacological testing the base was dissolved in dilute acetic acid and the *p*H of the aqueous solution adjusted to 6.8.

The furan analog of "Benadryl" was readily prepared by standard procedures.

The tertiary amino ether proved to be quite unstable in the presence of mineral acids, but in dilute acetic acid solution it was stable long enough to be tested pharmacologically.

The physical properties and analytical data of the secondary and tertiary amines are summarized in Tables I and II, respectively. The data on the antihistaminic activities are to be found in Table II. For the synthesis of the tertiary amines procedure IV was used except where it is otherwise indicated.

Preliminary *in vitro* studies on the isolated guinea pig ileum strip indicate the furyl isosteres of "Pyribenzamine" (PBZ), N,N-Dimethyl-N′-(2-pyridyl)-N′-benzylethylenediamine, and "Antergan," N,N-dimethyl-N′-phenyl-N′-benzyl-

[a] Prepared according to procedure V. [b] R‴ = methyl, except where otherwise indicated. [c] Vaughan and Anderson, THIS JOURNAL, **70**, 2607 (1948). [d] Viaud, *Produits Pharmaceutiques*, **2**, 53 (1947). [e] $n^{30}D$ 1.5485. [f] R‴ = isopropyl. [g] Bisuccinate. [h] Average per cent. by which a bath concentration of 0.00009375 micrograms/cc. of antihistaminic reduced guinea pig ileum response to a histamine base concentration of 0.024 microgram/cc. [i] Acute toxicity, intravenous to rats. [j] For the purpose of pharmacological testing the base was dissolved in dilute acetic acid and the *p*H of the aqueous solution adjusted to 6.8. [k] Dihydrochloride. [l] Pyribenzamine.

ethylenediamine, to be the most potent histamine antagonists of this series. They proved to be approximately twice as active as PBZ. The acute toxicities were comparable to those of the parent compounds.[7] The antihistaminic activity of these two compounds has been described previously by other authors. Viaud[8] reported the furyl analog (2803 R.P.) of PBZ (2750 R.P.) to be less active than "Antergan" (2339 R.P.) or less than one-half as active as PBZ in the ileum test, but equal in activity to PBZ in the histamine aerosol test. Vaughan and Anderson[1] found its activity to be "comparable to PBZ when tested in guinea pigs by the histamine aerosol technique or the intravenous injection of histamine." Viaud[8] described the antihistaminic activity of the furyl analog (2349 R.P.) of "Antergan" to be equal to that of the parent compound in the ileum test.

Methoxyl or isopropyl substitution in the para-position of the phenyl ring of the furyl isostere of "Antergan" resulted in an appreciable lowering of activity, coupled with an increase of acute toxicity in the case of the isopropyl derivative.

The furyl isostere of "Benadryl," β-dimethylaminoethyl benzhydryl ether, proved to be about 80% as active as PBZ, and less than twice as "Benadryl," however, the true evaluation of this drug was hampered by deterioration in aqueous solution.

Winter[9] reported the antihistaminic activity of "Benadryl" to be about sixty per cent. that of PBZ in the ileum test. Other investigators[10] described it to be only 20% that of PBZ in the same test.

The introduction of chlorine in the pyridine ring almost doubled the activity of the unsubstituted analog (PBZ), while the toxicity was only slightly elevated. A similar observation was made by Clapp and associates[11] who reported that the introduction of chlorine in the thiophene ring (Chlorothen) of "Thenylene," N,N-dimethyl-N′-(2-pyridyl-N′-(2-thienylmethyl)-ethylenediamine, doubled the activity of that compound and decreased its acute toxicity by one-half.

A simultaneous introduction of chlorine and methoxyl in the pyridine and phenyl ring, respectively, resulted in decreased activity, but also

an appreciable lowering of acute toxicity. A *p*-isopropoxy substituent in the benzyl moiety of PBZ markedly enhanced the antihistaminic activity and lowered the acute toxicity of the parent compound. A similar effect was obtained following the introduction of a para-methoxy group in the same position (Neo-Antergan) as reported by Viaud[8] (2786 R.P.) and Winter.[9] An ethoxy group[8] (2843 R.P.), however, did not seem to bring about any change in activity.

The thienyl isostere of "Hetramine," N,N-dimethyl-N′-(2-pyrimidyl)-N′-benzylethylenediamine, produced a compound of very low activity. Thienyl isosteres of PBZ[10,12] and "Antergan[8,13,14] were reported to be less potent antihistaminics than their corresponding parent compounds.

Introduction of a methoxyl group in the pyrimidine ring of "Hetramine" afforded a compound with an activity and acute toxicity comparable to PBZ. Substitution of N-methyl by N-isopropyl in PBZ resulted in a decrease in activity and increase in acute toxicity. A similar observation was made by Viaud[8] concerning the activity of the N,N-diethyl analog (2323 R.P.) of PBZ.

Of the compounds tested the furyl analogs of "Pyribenzamine" and "Antergan" deserve particular attention: the first, because of its high activity and fair toxicity, the second, because of its high activity and particularly low toxicity.

## Experimental

2-Thienyl chloride,[15] 2-(β-dimethylaminoethyl)-aminopyrimidine,[16] 2-(β-dimethylaminoethyl)-aminopyridine,[2] 2-furfuryl chloride,[3] 2-amino-4-methoxypyrimidine,[16] 2-amino-5-chloropyridine,[17], *p*-nitrocumene,[18] β-dimethylaminoethyl chloride hydrochloride[19] and phenyl isopropyl ether[20] were obtained by methods described in the literature.

**Substituted Aniline Derivatives.**—These compounds were readily prepared by the catalytic reduction of their respective nitro compounds. In a typical experiment 36.0 g. (0.22 mole) of *p*-nitrocumene was dissolved in 75 cc. of absolute alcohol and hydrogenated over 0.15 g. of Adams platinum oxide catalyst at four atmospheres of hydrogen. The catalyst was filtered off, the filtrate concentrated *in vacuo* and 26.8 g. (91%) of primary amine collected, b. p. 60–61° (0.3 mm.).[21]

**β-Isopropylaminoethanol.**—To a mixture of 307 g. (5.20 mole) of isopropylamine,[22] 18.0 g. (1.0 mole) of water and 8.6 g. (approximately 0.1 mole) of concentrated hydrochloric acid there was added with stirring from a Dry Ice–acetone jacketed dropping funnel 76.8 g. (1.74 mole) of ethylene oxide over a period of three and a half hours. The temperature of the reaction mixture gradually rose to 51° during the course of the addition. After all the ethylene oxide had been added the mixture was refluxed for another twelve hours, fractionated and 137 g. (76%) of product collected, b. p. 169–171°.[23]

**β-(N-Methyl-N-isopropyl)-aminoethanol.—Method A:** To a mixture of 113 g. (1.10 mole) of isopropylaminoethanol, 152 g. (1.10 mole) of anhydrous potassium carbonate and 200 cc. of benzene was added 156 g. (1.10 mole) of methyl iodide with vigorous mechanical stirring over a period of six hours. Stirring and refluxing was continued for another three hours, the reaction mixture filtered and the precipitate dissolved in water. The aqueous solution was then made strongly alkaline with solid sodium hydroxide, extracted with benzene and the benzene extracts combined with the filtrate. The benzene was removed and the residual liquid distilled at 67–70° (13–14 mm.); yield, 46.0 g. (36%).

*Anal.* Calcd. for $C_6H_{15}NO$: N, 11.97. Found: N, 12.19.

**Method B:** A solution of 10.0 g. (0.10 mole) of β-isopropylaminoethanol, 13.1 g. (0.25 mole) of 88% formic acid and 8.9 g. (0.11 mole) of 37% formaldehyde was refluxed for twenty-four hours. The reaction mixture was cooled, 5.0 g. of concentrated hydrochloric acid added to it and the resulting solution distilled until the temperature of the distillation had reached 110°. To the residual liquid was added 10 cc. of water, the aqueous solution made strongly alkaline with potassium hydroxide pellets and subjected to vacuum distillation. After saturation of the distillate with solid sodium hydroxide it was extracted repeatedly with ether, the ether extracts dried over potassium carbonate and distilled. The product was collected at 161–162°; yield, 8.0 g. (68%).

*Anal.* Calcd. for $C_6H_{15}NO$: N, 11.97. Found: N, 11.70.

**β-(N-Methyl-N-isopropyl)-aminoethyl Chloride.**—To a solution of 46.1 g. (0.40 mole) of methylisopropylaminoethanol in 225 cc. of chloroform at 0° was added 47.0 g. (0.40 mole) of thionyl chloride with stirring at room temperature for thirty minutes and it was then allowed to reflux for three hours. Chloroform was removed, the residue taken up in 100 cc. of water, the aqueous solution made strongly alkaline with 40% sodium hydroxide and then quickly extracted with ether. The ether extract was dried over potassium carbonate, the ether distilled and 34.0 g. (63%) of the chloro-amine collected at 72–74° (40 mm.). On standing at room temperature the free base quickly changed to a white, crystalline solid—presumably its dimerized quaternary salt—and, therefore, had to be used immediately for any subsequent reaction.

***p*-Chloromethylphenyl Isopropyl Ether.**—The compound was prepared according to the directions described by Sommelet and Marszak[24] for the chloromethylation of anisole. From 50.0 g. (0.37 mole) of phenyl isopropyl ether there was obtained 35.0 g. (51%) of the desired product, b. p. 85–87° (0.3–0.4 mm.) and 16.0 g. of unreacted starting material. The yield based on the amount of starting material reacted was 76%.

*Anal.* Calcd. for $C_{10}H_{13}ClO$: Cl, 19.24. Found: Cl, 18.80.

**Procedure I. N-(*p*-Methoxybenzyl)-2-amino-5-chloropyridine.**—From 24.0 g. (0.19 mole) of 2-amino-5-chloropyridine, 25.4 g. (0.19 mole) of *p*-anisaldehyde (Eastman Kodak Co.) and 47 cc. of 90% formic acid there was obtained 17.0 g. (36%) of the desired product, m. p. 154–156°. This material was pure enough to be used in any subsequent reactions. A small amount recrystallized from isopropyl alcohol melted at 158–159°.

**Procedure II. N-(*p*-Isopropoxybenzyl)-2-aminopyridine.**—To 20.0 g. (0.19 mole) of 2-aminopyridine in 100 cc. of dry toluene was added 4.4 g (0.19 mole) of lithium amide and the resulting mixture slowly heated to reflux with stirring. Refluxing and stirring was continued for three hours. The reaction mixture was then allowed to

cool to 60° and 35.0 g. (0.19 mole) of *p*-chloromethylphenyl isopropyl ether in 50 cc. of toluene added dropwise. The temperature of the reaction mixture rose to 87° during the addition. Stirring and heating at 80–90° was continued for three hours. The cooled reaction mixture was then shaken repeatedly with 100-cc. portions of a dilute hydrochloric acid solution (60 cc. of concd. acid and 250 cc. of water). Three layers appeared; the two lower layers were separated and made alkaline with solid potassium hydroxide. The water insoluble oil was extracted with ether and the ether dried over potassium carbonate. After removal of the ether the residue was distilled *in vacuo* through a modified, vacuum-jacketed Claisen head. The product was collected at 194–202° (0.3–0.4 mm.) and 26.0 g. of a viscous, yellow oil obtained which soon solidified to a white semisolid mass. This was recrystallized from 80 cc. of Skelly B and 6 cc. of isopropyl alcohol and 13.1 g. (28.5%) of a white, crystalline precipitate obtained; m. p. 101–102°. A small amount was again recrystallized from a mixture of Skelly B and isopropyl alcohol; m. p. 101–102°.

**Procedure III. N-β-Dimethylaminoethyl-*p*-isopropylaniline.**—A mixture of 53.0 g. (0.39 mole) of *p*-isopropylaniline, 29.0 g. (0.21 mole) of β-dimethylaminoethyl chloride hydrochloride, 54.0 g. (0.39 mole) of anhydrous potassium carbonate and 200 cc. of dry toluene was refluxed with stirring for twenty-one hours, and worked up in the usual manner. The residual liquid was fractionated through a 10″ vacuum-jacketed Vigreux column and two fractions were collected, one at 96–97° (6 mm.), 23.0 g. of recovered *p*-isopropylaniline and the other at 113–115° (0.2 mm.); 32.5 g. (a 74% yield, based on recovered material, of the desired product).

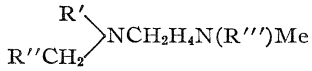
**Procedure IV. N,N-Dimethyl-N′-(2-pyridyl)-N′-(*p*-isopropoxybenzyl)-ethylenediamine Monohydrochloride.**—To 2.1 g. (0.09 mole) of lithium amide in 100 cc. of dry toluene was added 22.0 g. (0.09 mole) of N-(*p*-isopropoxybenzyl)-2-aminopyridine. The mixture was stirred and refluxed for three hours, cooled and 10.8 g. (0.10 mole) of β-dimethylaminoethyl chloride in 50 cc. of dry toluene added. Stirring and refluxing were continued for eighteen hours. The mixture was allowed to cool and was then extracted several times with dilute hydrochloric acid solution. The *p*H of the aqueous phase was adjusted to 6.8 with concentrated ammonium hydroxide solution and a small amount of unreacted starting material filtered off. The filtrate was made strongly alkaline with solid potassium hydroxide and extracted several times with ether. The combined ether extracts were dried over potassium carbonate, the ether removed, the residual oil distilled through a modified, vacuum jacketed Claisen head and 18.0 g. (64%) of desired product collected, b. p. 192–193° (0.190 mm.). The yield based on actual starting material reacted was 77%.

The **monohydrochloride** was obtained by adding an equivalent amount of 3.3 *N* ethereal hydrochloric acid to the base in dry isopropyl alcohol. The white, crystalline solid melted at 151–152°.

**Procedure V. N,N-Dimethyl-N′-(*p*-methoxyphenyl)-N′-(2-furfuryl)-ethylenediamine Monohydrochloride.**—A mixture of 33.0 g. (0.17 mole) N,N-dimethyl-N′-(*p*-methoxyphenyl)-ethylenediamine, 3.9 g. (0.17 mole) of lithium amide and 100 cc. of dry toluene was stirred and refluxed for two hours, cooled to room temperature and 19.8 g. (0.17 mole) freshly distilled furfuryl chloride in an equal weight of dry toluene added with stirring at such a rate as to keep the temperature of the reaction mixture at 60–70°. Stirring was then continued for three hours at 50–60°, the reaction mixture cooled, washed with water and the toluene removed by distillation *in vacuo*. The residue was fractionated through a 2″ Vigreux column and 24.0 g. (63%) of product collected, b. p. 137–139° (0.030 mm.).

The **monohydrochloride** was prepared in the manner described under procedure IV, m. p. 125–126°.

The **bisuccinate** was prepared by the addition of 1.18 g. (0.01 mole) of succinic acid dissolved in 10 cc. of hot isopropyl alcohol to 2.75 g. (0.01 mole) of the base in 10 cc. of anhydrous ether. After scratching and cooling for several minutes crystallization finally started. The white, crystalline material was filtered, washed with 1:1 dry ether:dry isopropyl alcohol; yield, 3.6 g. (92%), m. p. 96–97°.



**Phenyl-2-furylmethyl β-Dimethylaminoethyl Ether.**—To a suspension of phenylmagnesium bromide freshly prepared from 2.5 g. (0.10 mole) of magnesium and 20.0 g. (0.10 mole) of bromobenzene in 50 cc. of anhydrous ether was added 9.1 g. (0.10 mole) of freshly distilled furfural[25] in 50 cc. of anhydrous ether with cooling and stirring over a period of fifteen minutes. Refluxing and stirring were continued for another two hours. A saturated solution of ammonium chloride (17 g.) was then added slowly with stirring. At the completion of the addition the finely divided solid had set to a stiff mass. The ethereal solution was readily decanted, the precipitate washed twice with fresh ether and the combined ether layers were dried over Drierite. The ethereal solution was then concentrated to a volume of 50 cc. and added to 2.0 g. (0.087 mole) of bird-shot sodium suspended in 100 cc. of dry toluene. The mixture was stirred at 60° for three hours, when no more hydrogen was evolved. A solution of 10.8 g. (0.10 mole) of β-dimethylaminoethyl chloride in 100 cc. of dry toluene was then added and the resulting mixture stirred and refluxed for sixteen hours in such a manner as to allow the ether to distil off, in order to raise the temperature of the reaction mixture. The reaction mixture was cooled, washed with water and the toluene distilled *in vacuo*. The oily residue was poured into 50 cc. of water and the *p*H of the aqueous solution adjusted to 6.0 by the addition of 22 cc. of 2.4 *N* hydrochloric acid. The aqueous mixture was extracted with ether to remove any water insoluble material and was then made strongly alkaline with potassium hydroxide solution, extracted with ether and the ether layer dried over potassium carbonate. After removal of the ether 9.5 g. (39%) of a clear, yellow oil were obtained, b. p. 100–102° (0.035 mm.). The oil could be stored in the refrigerator over many months, but was quite unstable in the presence of mineral acids. Any attempts to form a solid salt with either organic or inorganic acids failed. For the purpose of testing the compound pharmacologically it was dissolved in dilute acetic acid solution and the *p*H adjusted to 6.8. However, this solution deteriorated on standing.

*Anal.* Calcd. for $C_{15}H_{19}NO_2$: C, 73.40; H, 7.75. Found: C, 73.52; H, 7.58.

**Acknowledgment.**—We are indebted to Messrs. P. Nuhfer and O. Torstveit of the Biology Division for supplying the pharmacological data, to Mr. E. Schwarz for preparing some of the intermediates, and to Mr. E. Curschmann for the analytical data. We wish to thank Dr. H. L. Daiell for his continued interest throughout the course of this project.

## Summary

Eight new and two previously reported ethylenediamine derivatives have been synthesized in

which R′ is a substituted or unsubstituted phenyl, 2-pyridyl or 2-pyrimidyl radical, R″ is a phenyl, substituted phenyl, 2-thienyl or 2-furyl radical, and R‴ is a methyl or isopropyl group. A furan analog of "Benadryl" also has been prepared. Some of these compounds were found to be potent antihistaminic agents. The relationship between chemical structure and antihistaminic activity has been discussed briefly.

# The Reaction of Amides with Isocyanates

BY PAUL F. WILEY

The reaction of amides with isocyanates was discovered in 1884 by Kühn,[1,2] who found that amides reacted as shown

$$RCONH_2 + R'NCO \longrightarrow RCONHCONHR'$$

Although experiments were limited it appeared that R and R' could be either aliphatic or aromatic. It was observed that some N-substituted amides, such as acetanilide, gave a reaction of the above type, but others reacted in a much more complex manner. The reaction has never been investigated extensively and has been reported infrequently until its recent use in the preparation and curing of polymers.[3,4] Some employment of the reaction has been made occasionally in the preparation of aroylarylureas,[5,6,7,8,9,10] and a very similar reaction, the reaction of urea derivatives with isocyanates, has been studied.[11,12,13]

The purpose of the present study was to investigate optimum conditions for the reaction of amides with isocyanates and to extend the reaction to other amides and isocyanates. The isocyanates used were ethyl, phenyl and α-naphthyl, and of these only phenyl isocyanate was studied extensively. The amides used and optimum conditions are shown in Table I and the Experimental. The most generally useful solvent was found to be toluene, and it was used in all experiments listed in Table I except where indicated that no solvent was used.

It was found that inclusion of aluminum chloride and stannic chloride in the reaction mixtures caused a marked decrease in yields. Triethylamine had no discernible effect on yields when included.

A totally unexpected result appeared when phenyl isothiocyanate was allowed to react with acetamide or benzamide. The reactions in both cases required prolonged heating without solvents, and the resultant products were acetanilide and benzanilide. Low yields of about 10% were obtained in both cases. This result can be readily explained only by the operation of a different mechanism than prevails in the case of isocyanates. Apparently the nitrogen atom of the isothiocyanate molecule reacts with the carbonyl carbon atom of the amide followed by the expulsion of the elements of thiocyanic acid.

This reaction of amides with isocyanates would be a very convenient one to use in the preparation of derivatives of unsubstituted amides for identification purposes.

TABLE I

| Amide | Isocyanate | Time in hours | Yield, % |
|---|---|---|---|
| Benzamide | Phenyl | 18 | 86 |
| Acetamide | Phenyl | 18 | 89 |
| Nicotinamide | Phenyl | 12 | 94 |
| *p*-Nitrobenzamide | Phenyl | 24 | 95 |

## Experimental[14]

The experiments recorded here are representative of those used throughout this study. At least one of the methods recorded is illustrative of and applicable to all the pairs of reactants studied. New compounds not discussed in connection with their preparation are listed in Table II with analytical data. The isocyanates and amides used with the exception of diethylaminoacetamide and β,β-diphenylbutyramide were commercial products. Diethylaminoacetamide was prepared by the method of Einhorn and Hamburger.[15]

**β,β-Diphenylbutyramide.**—A solution of 17.9 g. (0.075 mole) of β,β-diphenylbutyric acid in 44.6 g. (0.375 mole) of thionyl chloride was refluxed for one hour. The excess thionyl chloride was removed by evaporation under re-

duced pressure. A cold solution of the residue in 200 cc. of dry benzene was stirred while ammonia was bubbled in until reaction appeared to be complete. The reaction mixture was filtered, and the filter cake was triturated with water and again isolated by filtration. The dried solid obtained was dissolved in 500 cc. of benzene, and the benzene solution was filtered. The filtrate was concentrated until crystals appeared. Cooling gave 11.7 g. (65%) of amide, m. p. 103–105°. Three recrystallizations from benzene gave a sample with no higher melting point.

*Anal.* Calcd. for $C_{16}H_{17}NO$: N, 5.85. Found: N, 5.25.

**1-Benzoyl-3-phenylurea.**—(a) With Solvent: A solution of 12.1 g. (0.1 mole) of benzamide and 11.9 g. (0.1 mole) of phenyl isocyanate in 200 cc. of dry toluene was refluxed for twenty-four hours. The cooled reaction mixture deposited a crystalline product which was removed by filtration and dried. The crude product weighed 24.0 g. and melted at 193–198°. Recrystallization from 135 cc. of dioxane gave 21.5 g. (89%) of 1-benzoyl-3-phenylurea, m. p. 203–204° (lit. 204°). (b) Without Solvent:—A mixture of 12.1 g. (0.1 mole) of benzamide and 11.9 g. (0.1 mole) of phenyl isocyanate was heated slowly to about 115°. At this temperature a vigorous reaction began, and the temperature mounted rapidly to 185°. External heating was stopped when the reaction began to occur vigorously. The mixture became almost completely liquid while the temperature was climbing rapidly, but at about 185° solidification began. The cooled reaction mixture was crystallized from dioxane to give 19.8 g. (82%) of 1-benzoyl-3-phenylurea, m. p. 203–204°.

**1-Benzoyl-3-ethylurea.**—A solution of 7.1 g. (0.1 mole) of ethyl isocyanate and 12.1 g. (0.1 mole) of benzamide in 150 cc. of dry toluene was refluxed for eighteen hours. When the reaction mixture was refrigerated, a crystalline precipitate formed. This precipitate proved to be 4.5 g. of benzamide, m. p. 120–124° and no depression in melting point upon admixture with benzamide. Evaporation of the toluene solution under reduced pressure left a white residue. This residue was recrystallized three times from alcohol. The final product was 7.3 g. of white needle-like crystals, m. p. 112–114° (lit. 114–115°); yield 38%.

**1-Butyryl-3-ethylurea.**—A mixture of 8.7 g. (0.1 mole) of butyramide and 7.1 g. (0.1 mole) of ethyl isocyanate was dissolved in 100 cc. of dry toluene. The solution was refluxed for twenty-four hours, cooled and filtered. The solvent was removed from the filtrate by evaporation under reduced pressure. Two recrystallizations of the residue from alcohol gave 4.0 g. (25%) of 1-butyryl-3-ethylurea, m. p. 98.5–100°, crystallizing in irregular oblong plates.

*Anal.* Calcd. for $C_7H_{14}N_2O_2$: N, 17.72. Found: N, 17.79.

**Phenyl Isothiocyanate and Benzamide.**—A mixture of 12.1 g. (0.1 mole) of benzamide and 13.5 g. (0.1 mole) of phenyl isothiocyanate was heated at a temperature of 180–190° for four hours. The reaction mixture was recrystallized four times from alcohol. The only product isolated was 2.9 g. of a light tan solid melting at 149–153°. Several more recrystallizations from alcohol gave a cream colored product melting at 157–159°. The melting point of a mixture with benzanilide (m. p. 160°) was 158–160°.

*Anal.* Calcd. for $C_{12}H_{11}NO$: C, 77.84; H, 5.95; N, 7.56. Found: C, 78.18; H, 5.74; N, 7.34.

**Phenyl Isothiocyanate and Acetamide.**—A mixture of 13.5 g. (0.1 mole) of phenyl isothiocyanate and 5.9 g. (0.1 mole) of acetamide was heated at 180–190° for four hours. Cooling gave a dark brown liquid which had no isothiocyanate odor or lachrymatory properties but did smell strongly of hydrogen sulfide. The residue was dissolved in an equal volume of absolute alcohol and cooled. The precipitate which formed was removed and recrystallized from alcohol. There was obtained 2.3 g. of acetanilide melting at 110–112°. The mixed melting point with authentic acetanilide (m. p. 113–115°) was 112–114°.

## Summary

1. The reaction of isocyanates with unsubstituted amides to give acylaryl- or alkylureas has been found to be quite general. The effects on the reaction of temperature, solvent, time, catalysts, and different types of amides and isocyanates have been studied.

2. Phenyl isothiocyanate has been found to react with amides only under severe conditions giving anilides.

# Hydrogen Bonding in Some 4-Substituted Cyclohexanols

BY E. E. PICKETT AND H. E. UNGNADE

The spectroscopic evidence for hydrogen bonding in liquid alcohols has been studied extensively. In pure liquid alcohols there is a broad intense absorption band peaked between 2.95 and 3.00$\mu$ attributed to associated molecules, which decreases in intensity with dilution in an inert solvent, and a sharper band appears at 2.75$\mu$, arising from single molecules.

Fox and Martin[1] resolved the association band of certain alcohols into two components. They suggested that the shorter wave length component is due to dimers and the longer wave length component is due to higher polymers. In the dimer form no single molecule serves as both donor and acceptor of hydrogen and the OH stretching force constant thus differs from that of the higher polymer.

In a study of several of the isomeric hexanols[2] it was found that the formation of polymers higher than dimers was inhibited in all of those isomers which contained the structures —C(R)—C—OH or —C(R)—OH.

With the *cis* and *trans* 4-phenyl and cyclohexylcyclohexanols at hand,[3] the question arose as to whether differences in steric inhibition of hydrogen bonding could be detected spectroscopically in such compounds. On the basis of viscosity and molecular weight determinations, the *cis* alcohols are thought to be less associated than the *trans* alcohols, but the 4-substituents are less effective than the 2-substituents in preventing association.[4]

## Experimental

The samples were prepared and purified in an earlier investigation by one of us.[3] Optical properties, melting point diagrams, and other properties have been determined for these compounds and they are believed to be of high purity. Solutions of them were made up to the desired molarities in purified carbon tetrachloride. A single 1.00 mm. absorption cell, refillable without dismantling, was used for all samples. The concentration range employed was imposed by the solubility of the samples or by the cell thickness. Point-by-point per cent. transmission measurements were made against air, at constant slit width, in the range 2.68 to 3.20$\mu$ at every 0.02$\mu$ interval by means of a Beckman IR-2 spectrophotometer. Recorder tracings indicated that this measurement interval was acceptable. The spectra are presented in Fig. 1. The curve marked $CCl_4$ shows the transmission of the cell filled with pure carbon tetrachloride.

## Discussion

All of the four compounds exhibit hydrogen bonded absorption regions, 2.8–3.2$\mu$, which increase in intensity with increasing concentration more rapidly than the free OH bands, at 2.75$\mu$. Beer's law "fails" for both types of bands, the deviations being negative for the free OH band and positive for the association band. However, the extinction *versus* concentration curves of both band types are nearly straight above 0.10 molar concentration.

The associated OH absorption regions quite obviously consist of two chief components in each case, centered at about 2.87 and 2.97$\mu$. The former of these may be taken as the dimer component and the latter as the polymer component. At low concentrations the dimer component is more intense than the polymer, the latter being almost absent at the concentration 0.05 molar. The intensity of the polymer component then increases more rapidly than that of the dimer. This behavior seems consistent with the interpretation of these components as being due to dimer and polymer aggregates in solution.

It is apparent that the *trans* forms show somewhat greater hydrogen bonded OH absorption than the corresponding *cis* isomers at similar concentration, as was anticipated, indicating some steric inhibition to intermolecular association in the latter. At a given concentration, the intensity of the dimer component of each *trans* isomer is only slightly greater than that of the corresponding *cis* isomer, while the intensity of the polymer component is considerably greater in the former than in the latter. This suggests that the formation of the polymers is more sensitive to steric interference than is the formation of the dimers.

Moreover, in the spectra of the two *cis* isomers, the intensity of the association band relative to that of the free OH band is somewhat greater for the 4-phenyl than for the 4-cyclohexyl derivative, at each similar concentration, to an extent larger than can be accounted for entirely by the slightly higher molar concentrations of the former, perhaps indicating that the 4-cyclohexyl group is a bit more effective in preventing association than the 4-phenyl group. This effect is of course not observed in the *trans* isomers: the intensities of both the association and the free OH bands are greater for the *trans*-phenyl than for the *trans*-cyclohexyl derivative of similar concentration, and to about the same extent in each band.

## Summary

The infrared spectra between 2.7 and 3.2$\mu$ of carbon tetrachloride solutions of *cis*- and *trans*-4-phenyl and 4-cyclohexylcyclohexanols were measured in the concentration range 0.05 to 0.5 molar. The *trans* isomers exhibit greater intermolecular association than the *cis* isomers. The 4-cyclohexyl group produces slightly greater interference with association than the 4-phenyl group. Certain other conclusions are obtained from the data.

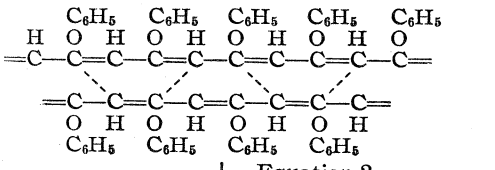
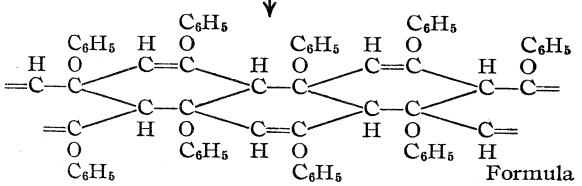
# Acetylenic Ethers. V.[1] The Polymerization of Phenoxyacetylene



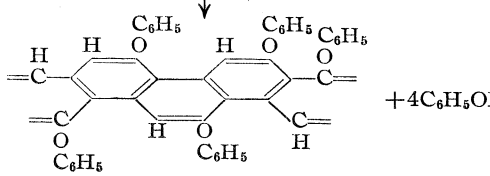
BY THOMAS L. JACOBS AND WILLIAM PENN TUTTLE, JR.[2]

The polymerization of acetylenic compounds other than acetylene itself has been investigated in only a few instances[3] although the literature occasionally contains a reference to the changes which these compounds undergo when heated, and a few substituted acetylenes are known to polymerize readily at room temperature or below.[4,5,6,7] Among the latter, acetylenic ethers of the type ROC≡CH appear to offer several advantages for a more careful study of the process.



Phenoxyacetylene polymerizes spontaneously at a moderate rate at room temperature to give first a deep red liquid and finally a hard, shiny, brittle, black solid. The change was shown to be a true polymerization by powdering this solid and extracting it with benzene in which it is partially soluble. The insoluble residue had the same composition as the monomer. The reaction appears to occur in two stages, involving first a chain reaction to give a linear, conjugated polyene and next a cross-linking step in which the conjugation is broken. The second reaction probably begins soon after the first linear chains are formed and insolubility occurs well before all of the monomer is consumed. It is suggested that the cross-linking may occur by a Diels–Alder reaction and that the polymerization may be represented by the equations shown.

Equation 1 Formula I



Equation 2

Formula II

Equation 3

The first stage in the polymerization may be followed by observing the rate of disappearance of monomer. Methods of analysis involving the acetylenic hydrogen of phenoxyacetylene or other properties such as ultraviolet absorption were not readily adapted to the problem, and the determination finally was made by finding the molecular weights cryoscopically of samples polymerized under various conditions. This method was used by Taylor and Vernon[8] to follow the photopolymerization of styrene and vinyl acetate in benzene solution. It was found that the polymers themselves as precipitated from benzene by petroleum ether had molecular weights of 3000 to 8000 so that, within the experimental error, the lowering of the freezing point of benzene by a small sample of partly polymerized phenoxyacetylene was due entirely to monomer. Tables I and II record the data obtained at 25 and 40°. The percentage of polymerization of each sample was readily calculated, and also the rate constants for the gross reaction. A first order rate equation fits the data slightly better than a second order one, but the reaction could not be followed much beyond 50% completion due to insolubility of the polymer and no choice between first and second order kinetics could be made (see Fig. 1). The values of the rate constants are

| | $k$ at 25° | $k$ at 40° |
|---|---|---|
| First order | $0.34 \times 10^{-6}$ sec.$^{-1}$ | $2.2 \times 10^{-6}$ sec.$^{-1}$ |
| Second order | $0.41 \times 10^{-6}$ sec.$^{-1}$ wt. fraction$^{-1}$ | $2.6 \times 10^{-6}$ sec.$^{-1}$ wt. fraction$^{-1}$ |

From the first order values, the temperature coefficient for the over-all reaction of producing the linear polymer is found to be 4.3 per 10° between 25 and 40° and the total energy of activation is 23 kcal. per mole of monomer. It is interesting that styrene gives a value of 23.5 kcal. from specific rates determined at 100.5° and 132°.[9,10] The

cross-linking reaction made it difficult to get information about the constancy of chain length.

Although no attempts were made to determine the heat of polymerization of phenoxyacetylene, a considerable amount of heat is evolved in the reaction. Samples of monomer in an air-bath produced heat faster than it was conducted away at temperatures of 55° or above, and sealed samples could seldom be polymerized above 80° without exploding violently. Larger samples exploded as low as 65°.

Tables I and II also contain the results of a preliminary study on the influence on the polymerization of typical catalysts and inhibitors for vinyl monomers. Most of these were ineffective in the concentrations used. Among substances expected to promote ionic polymerization only cadmium iodide produced a change, and even with it the catalysis was erratic in a series of qualitative experiments. The polymer obtained appeared to be different from that formed in the absence of the catalyst. Stannic chloride and aluminum chloride gave no qualitative evidence of catalytic action, but were not tested quantitatively. *p*-Toluenesulfonic acid may have been without effect because it added to the triple bond.

Iodine was tried because it is a powerful catalyst for the polymerization of vinyl ethers.[11] Since it is known to add to phenoxyacetylene,[12] the failure to observe catalysis is not surprising. The experiment with metallic sodium was noteworthy because when care was taken to bring the phenoxyacetylene into contact with the bright metallic surface under an inert atmosphere and with care-

ful exclusion of moisture, even the expected reaction of the acetylenic hydrogen with the metal failed to occur and the surface remained clean and bright throughout the experiment. In other experiments when a piece of sodium was mashed under phenoxyacetylene, the metal dissolved but there was no evidence that the polymerization was catalyzed.

The experiments with benzoyl peroxide and phenylazotriphenylmethane give very little evidence about the influence of free radicals on the polymerization because, at the temperature used, the rate of production of radicals was probably so small that it was negligible. If one assumes that the rate of decomposition of benzoyl peroxide in phenoxyacetylene is about the same as in benzene, styrene, phenetole, and diphenyl ether, and calculates the rate of formation of radicals by the first order process,[13] it is found that at 25° with the concentration used, no more than one or two chains in a thousand could be started by radicals resulting from the decomposition of benzoyl peroxide even if these were 100% effective. The rate of radical formation in phenylazotriphenylmethane is not known, but the compound is an effective catalyst for styrene polymerization at 50°[14] although the evolution of nitrogen is not observed below 55°.[15] Since the rate of thermal chain initiation appears to be about 10,000 times greater for phenoxyacetylene than for styrene at 25 or 40°, it is not surprising that most of the catalysts which are commonly used with the latter are ineffective with the former. Phenyl α-naphthylamine which merely destroys peroxides should be without action on the polymerization as was observed. Cupric acetate, commonly used to inhibit the polymerization of vinyl acetate, is quite insoluble in phenoxyacetylene which may account for its lack of inhibiting action. Further experiments are planned on the effect of more powerful inhibitors and of compounds that decompose to give radicals at lower temperatures.

Absorption spectra give considerable information on the structure of the polymer and the course of the polymerization. Studies were made on samples polymerized for various periods and on polymers isolated by precipitation Typical curves are shown in Figs. 2 and 3. Phenoxyacetylene does not absorb above 3000 Å. (Fig. 4) and the absorption by the polymers at longer wave lengths is believed to be due to a conjugated system of double bonds as suggested above. It is somewhat surprising to find a maximum in the absorption curve of a polymer only once reprecipitated (A, Fig. 2). A number of reprecipitations produced only slight sharpening of this maximum (A, Fig. 3). This may indicate that the conjugated chains are somewhat uniform in length, but

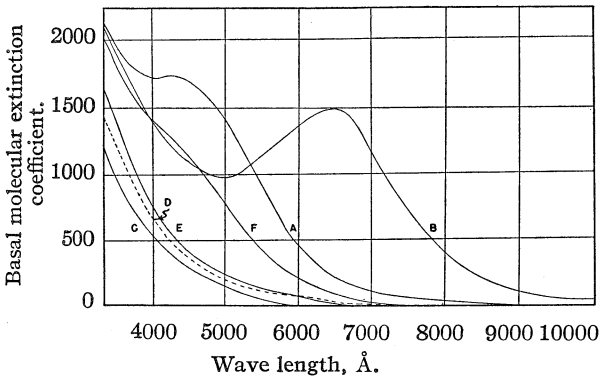

Fig. 2.—Absorption spectra of polyphenoxyacetylene in benzene: A, polymer 2, 0.029 g./l.; B, solution used for A plus 40.0 g. trichloroacetic acid/l.; C, solution used for A after standing 62 days at 25°; D, solution used for C plus 40.0 g. trichloroacetic acid/l.; E, solution used for B after standing 62 days at 25°; F, polymer 4.

in the absence of suitable model systems the evidence is uncertain. If one assumes that a straight line represents the plot of the squares of the wave lengths of the absorption maxima of a series of compounds indicated by Formula I against the number of double bonds ($n$), that the slope is the same as for the corresponding plot for the α,ω-diphenylpolyenes,[16] and that the value of the 2250 Å. band of phenyl vinyl ether (B, Fig. 4) may be taken for $n = 1$, then the 4600 Å. maximum in Curve A, Fig. 3 corresponds to about 10 conjugated double bonds. The effect of phenoxyl groups placed either alternately along the chain as shown in Formula I, or at random, cannot be predicted quantitatively, but such groups would be expected to increase the wave length ab-

sorbed.[17] Further uncertainty arises from lack of knowledge of the steric arrangement of the chain.[18] However, the value of 10 is not unreasonable. If the degree of polymerization were 40 corresponding to a molecular weight of 4700, it would take only one cross link per molecule to reduce the conjugation on the average to 10 double bonds, since each cross link that breaks the conjugation effects the absorbing system by a factor 4. Lack of material prevented determination of the molecular weight of the five-hour polymer, but a six-day polymer gave a cryoscopic molecular weight of 8100 and it is probable that considerable cross linking had already occurred in this sample. The polymers show some absorption out to 9000 Å. and beyond, which corresponds to 46 or more conjugated double bonds on the assumptions indicated.

It was found that polymers isolated after brief polymerization absorbed at longer wave lengths than later polymers and that the absorption in the visible of the early polymers decreased greatly when their solutions were allowed to stand for long periods. This change is represented by the difference between Curves A and C in Fig. 2 and indicates clearly that a secondary reaction involving decrease in conjugation has occurred. In ether solution the decrease was even more marked. The absorption at 4300 and 3850 Å. of an ether solution containing $1.49 \times 10^{-4}$ basal moles of polymer 4 per liter changed from basal molecular extinction coefficients of 2060 and 1900 to 30 and 152, respectively, on standing at room temperature in the dark for 202 days. At the end of this experiment the solution appeared visually to be completely colorless.

The early polymers behaved like linear, conjugated systems, giving a deep blue color with antimony trichloride in chloroform (Curve B, Fig. 3), bromine (violet) and stannic chloride (violet). This behavior is similar to that of positive ethylenes[19,20] such as 1,1-di-(*p*-dimethylaminophenyl)-ethylene, and can be interpreted similarly as due to the formation of a resonating positive ion in which the positive charge is distributed among the oxygens of the phenoxyl groups and the alternate carbons along the chain.

and other resonance forms.

These formulas are drawn with the monomer units arranged head-to-tail, which permits the maximum participation of the oxygen atoms in the resonance, but there is as yet no evidence for such arrangement in these polymers and the participation of part of the oxygens, which could occur in random or other arrangements, might account for the colors produced. As with the positive ethylenes, highly colored solids could be obtained in certain instances (bromine or stannic chloride) by adding the reagent to the polymer in a non-polar solvent such as carbon tetrachloride. The solid could be redissolved by adding ethanol to the reaction mixture, although this solvent would not dissolve the original polymer. This behavior would be expected of a polar salt of the type suggested.

The color produced by acids was readily discharged by even such weakly basic compounds as diethyl ether. Relatively large amounts of less basic compounds like phenyl vinyl ether or phenetole were required to discharge the color and diphenyl ether had no influence on the phenomenon. Pyridine discharged the color instantly and an insoluble pyridinium salt soon precipitated. Further evidence that the color produced by acids was due to transfer of a proton to the polymer, was obtained by studying the color change with a number of acids. The intensity of the color produced (as determined visually) was greater, the greater the dissociation of the acid, as indicated in Table III. Acetic acid not only failed to alter the color of the polymer solution, but in large amounts discharged the color produced by stronger acids.

(17) Bowden, Braude and Jones, *J. Chem. Soc.*, 948 (1946). In this paper it is shown that the effect of alkoxyl and similar groups is less when placed in cross-conjugation, but that it is in the same direction. Additional unpublished results from the same group on alkoxy and aryloxy dienoic and trienoic acids support this generalization. We wish to thank Dr. Ernest A. Braude for his assistance and suggestions in the interpretation of the absorption spectra of the polymers.

TABLE III

| Acid | Dissociation constant in water at 25° | Color produced on polymer in chloroform or benzene |
|---|---|---|
| Trichloracetic | Strong acid | Bright blue |
| Maleic | $1.5 \times 10^{-2}$ | Bluish green |
| Malonic | $1.61 \times 10^{-3}$ | Olive |
| Chloroacetic | $1.55 \times 10^{-3}$ | Olive |
| *dl*-Malic | $4 \times 10^{-4}$ | Slight darkening (in chloroform) |
| α-Naphthoic | $2 \times 10^{-4}$ | Reddish color |
| Benzoic | $6.6 \times 10^{-5}$ | of polymer |
| Acetic | $1.86 \times 10^{-5}$ | unchanged |

The maximum in the absorption spectrum of the colored solution produced with antimony trichloride (Curve B, Fig. 3) is at nearly the same wave length as that produced similarly with Vitamin A (617 mm.).[21] This corresponds to five double bonds in the absorbing ion,[22] but since the carotenoids with larger conjugated chains absorb at lower wave lengths,[21] possibly due to coördination with more than one molecule of antimony trichloride,[22] and since no information on the effect of phenoxyl groups is available, it is not possible to correlate the maximum with chain length in our system. The maximum is surprisingly distinct for a polymer system, however, and again suggests some uniformity in the chain length of the absorbing system.

The secondary reaction of cross-linking must involve the double bonds of the polyene polymer, and results in loss of the conjugation. The cross-linked material no longer gives colors with acids, antimony trichloride, etc., as is shown in Curve D, Fig. 2. The colors produced by these reagents on the early polymers fade fairly quickly and cannot be restored by more reagent. This fading occurs much more rapidly than the simple solutions of polymer lose their power to give the colors, which suggests that these reagents catalyze the cross-linking reaction.

Further evidence for the cross-linking reaction is obtained by chromatography. A sample of phenoxyacetylene polymerized for six days at 25° could be separated by adsorption from benzene solution onto magnesium oxide into a strongly held, dark red material and a weakly held, yellow substance. Complete separation of these bands was attained by elution of the yellow material with benzene and of the red with alcohol–benzene. Absorption curves showed that the latter absorbed more strongly, but insufficient material was at hand for isolation of the polymers and the value of the extinction coefficients were therefore not known. It was found that the precipitated, early polymer was absorbed strongly like the dark red material and could be eluted similarly. Its absorption spectrum (Curve A, Fig. 2) was only slightly changed by the adsorption.

(22) Meunier, *Compt. rend.*, **221**, 64 (1945); *Bull. soc. chim.*, **13**, 73 (1946).

The physical properties of the polymers gave evidence that the secondary reaction was a true cross-linking. Early, precipitated polymers had sintering points as low as 90° while late polymers obtained by bulk polymerization at 65–75° did not sinter at 400°. Intermediate polymers sintered at intermediate temperatures. These polymers were thermosetting, and could not be remelted after heating. Under controlled conditions the thermosetting did not involve decomposition, and the products were very brittle. The thermosetting polymers were poor cements, having low adhesive and cohesive strengths. Attempts to draw threads from the "melts" led only to exceedingly brittle fibers. All of these properties are consistent with a structure made up of cross-linked relatively short chains.

It was found that the cross-linked polymers lost phenol when heated under reduced pressure to 200°. The amount of phenol liberated corresponded to 46% of the phenoxyl groups present, and no more was obtained by heating to above 400°. The polymerization probably did not involve substitution in the ring of the remaining phenoxyl groups, since fusion of the dephenolated polymer with alkali gave a moderate yield of phenol based on phenoxyls still remaining. It was found that the soluble polymers also lost phenol when heated in benzene solution. The ready loss of phenol is easily interpreted if the cross-linking is assumed to occur by a Diels–Alder reaction (Equation 2). The product of such a cross-linking would be a hydroaromatic compound that could aromatize by losing phenol (Equation 3). In bulk or precipitated polymers the cross-linking would be expected to occur at random, leaving considerable portions of the linear, conjugated system unchanged. In solution the cross-linking might occur in a more regular fashion to produce a polycyclic hydroaromatic compound such as is shown in Formula II. Such a change requires the loss of just 50% of the phenoxyl groups. These polymers would absorb much less at the longer wave lengths than would a cross-linked polymer produced by bulk polymerization. The absorption spectra are in agreement with this interpretation.

The primary polymerization to form the linear, conjugated polyene appears on the basis of absorption spectra to be a chain reaction, and this may involve a free radical mechanism. The failure of the usual free radical catalysts to influence the polymerization is explained by the high rate of thermal initiation relative to the rates of production of free radicals by the catalysts. Solvents slow down the polymerization very markedly, and long exposure of an ether solution of phenoxyacetylene to sunlight gave a polymer that appeared to contain fragments of the ether molecule. This is most readily interpreted on the basis of a free radical mechanism. It seems clear that an ionic mechanism is also possible for the polymerization since cadmium iodide acts as a catalyst.

The investigation is being extended to establish the course of the reaction more exactly.

The polymerization of acetylenic compounds in general is relatively complex, and on the basis of the extensive work on acetylene itself probably takes place in several ways.[3] It has been suggested[23] that conversion of acetylene to cuprene occurs by primary formation of a conjugated linear polyene which cross links at once. Cuprene is believed to have an aromatic or partially aromatic structure,[24,25] and analyses indicate that some hydrogen has been lost during the reaction. This suggests that under these special conditions acetylene may behave like phenoxyacetylene. Other readily polymerized acetylenes are now being investigated to determine how general this mode of reaction may be.

## Experimental Part

**Phenoxyacetylene** was prepared as described earlier[12] and was redistilled at least twice before use. Care was taken to exclude moisture at all times; the distillate was collected in a receiver cooled in solid carbon dioxide, and the samples sealed off under reduced pressure and stored without allowing them to warm up. The following physical constants are more accurate than those reported earlier[12]: b. p. 61.5–61.8° (25 mm.); $d^{20}_4$ 1.0114; $n^{20}D$ 1.5171 $MR_D$ obsd. 35.34, calcd. 35.12; $d^{25}_4$ 1.0088; $n^{25}D$ 1.5143. The density and refractive index did not change perceptibly in the course of an hour although the samples darkened markedly.

**The rate of polymerization and the effect of catalysts** were found by polymerizing 0.3-g. samples in thin-walled bulbs of 0.5 to 1 ml. capacity. Carefully cleaned, dry Pyrex glass tubing which had been rinsed with ammonia and repeatedly with distilled water was used in making the bulbs and care was taken to exclude moisture. However, soft glass bulbs or less carefully cleaned Pyrex gave the same results. The purified phenoxyacetylene sample was allowed to warm up to room temperature before opening, and the liquid transferred to the bulbs with a micropipet. The bulbs were then cooled in solid carbon dioxide and sealed. Catalysts were added to the bulb before the acetylene was introduced. The sealed bulbs were weighed to determine the exact amount of phenoxyacetylene and the samples polymerized by immersion in a thermostatted bath at 25 or 40°.

The depression of the freezing point of pure benzene by the samples was determined in the usual Beckmann apparatus modified to exclude moisture and using a carefully standardized rate of cooling which gave reproducible values. In each case the freezing point of the pure benzene was determined, the bulb carefully dried and broken in the benzene and the freezing point depression determined at once. The results are summarized in Tables I and II.

**Cross-linked Polyphenoxyacetylene Polymer 1.**—Phenoxyacetylene (8 g.) was sealed in glass under 20 mm. pressure and polymerized at 40° for forty-eight hours to a thick red fluid. The temperature was then increased to 60° for twenty-one hours, slowly raised to 75° during five hours and maintained at 75° for nineteen hours longer. After cooling, the glass was broken away leaving a hard, brittle, shiny, ebony-black solid which had a faint odor of phenoxyacetylene. The mass was homogeneous and contained no bubbles. It broke with conchoidal fracture. Pieces barely floated in carbon disulfide, indicating a density of about 1.26. Chips of the material colored chloroform and carbon disulfide, but otherwise were unaltered even on prolonged standing, remaining hard and brittle. Carbon tetrachloride, alcohol, 15% aqueous sodium hydroxide and 10% sulfuric acid exerted no visible effect over a long period of time. Concd. sulfuric acid attacked the solid only slowly. The polymer was ground in a mortar, giving a dark brown powder.

*Anal.* Calcd. for $(C_8H_6O)_x$: C, 81.35; H, 5.08. Found: C, 81.61; H, 4.83.

The powder was exhaustively extracted with benzene in a Soxhlet extractor. The soluble portion, 39%, was almost entirely polymer; a trace of phenoxyacetylene (odor) was recovered by heating under reduced pressure, and as the temperature was raised to 370° at 1 mm. a crystalline material (35% of the weight of the soluble portion) was collected in a receiver cooled in Dry Ice. Phenol was separated from this distillate by extraction with 5% sodium hydroxide, and determined as usual.[26] It made up 85% of the weight of the distillate, and was identified by conversion to tribromophenol, m. p. and mixed m. p. 93.0–93.5° The neutral material (50 mg.) in the distillate was a dark oil with a faint odor of phenoxyacetylene. It was not identified.

The insoluble portion from the benzene extraction of the original polymer had the composition of phenoxyacetylene.

*Anal.* Found: C, 81.31; H, 5.38.

It was heated at 1 mm. in an all-glass apparatus with a U-tube receiver cooled in solid carbon dioxide; at 200° a distillate collected, and no further change was observed as the temperature was raised to 400° and maintained there for some time. The total distillate amounted to 44% of the initial weight of polymer (1 g.) and 84% of the distillate was phenol (by titration[26]) which corresponds to 46.4% of the phenoxyls present in the polymer. The rest of the distillate was an oil with a pleasant, fruity (almost cinnamon-like) odor which was a mixture and could not be identified.

The powder remaining in the flask was dark brown and inert to reheating to 400°. It absorbed air readily and was burned with difficulty.

To show that the phenoxyl groups remaining in the polymer were unsubstituted, 0.21 g. of the dephenolated powder was added to 14 g. of molten potassium hydroxide (C. P. 85% alkali plus 0.6 ml. of water) at 250°. The fusion was continued for fifteen minutes at 300–350° which gave a homogeneous melt. It was poured onto ice and phenol isolated and determined as usual. The yield was 0.04 g. which corresponds to 25% of the phenoxyls which should still remain on the dephenolated polymer. The rest of the fusion product was an alkali soluble, dark brown resin which may have resulted in part from phenol. Although the yield of phenol was not high, it is as good as could be expected under the conditions of the experiment and furnishes some evidence that the original polymerization did not involve substitution of the phenoxyl groups.

**Early Polyphenoxyacetylene.**—Quantitative precipitation of the polymers could not be achieved due to their solubility in phenoxyacetylene or in the large amounts of solvent required to remove the monomer, and to their tarry nature while even traces of the monomer remained. Petroleum ether (b. p. 30–60°) was the most effective precipitating solvent and in reprecipitations and fractionation the polymer was dissolved in a little benzene and 4 to 8 volumes of petroleum ether added. Due to the tendency of the powders to acquire an electric charge, it was necessary to avoid rubbing or scratching of vessel walls, and a centrifuge technique proved far superior to filtration, which was used at first.

**Polymer 2.**—Only 20 mg. of a reddish brown powder was obtained after a single precipitation from 25.6 g. of phenoxyacetylene allowed to polymerize for five hours at 25°. The first order rate constant shows that 160 mg. should have been obtained. Losses were due to solubility and to mechanical difficulties in the filtration technique used. The polymer had sintering point 90° m. p. 110–115°.

**Polymer 3** was obtained from 45.3 g. of phenoxyacetylene which was allowed to polymerize for five hours at 25°

and reprecipitated eight times using a centrifuge technique. The yield was 80 mg. or 30% of the weight calculated to have been formed (from the first order rate constant, the polymerization should be 0.61% complete); sintering point, 86–87°, m. p. 103–107°. No molecular weight determinations were carried out because of the small amounts of material available.

**Polymer 4** was prepared from 19.2 g. of phenoxyacetylene by polymerization at 25° for six days and reprecipitated once (filtration technique); yield, 2.05 g.; sintering point, 113°; mol. wt. 8100 (cryoscopic determination in benzene).

*Anal.*[27] Calcd. for $(C_8H_6O)_x$: C, 81.35; H, 5.08; C/H ratio, 16.0. Found: C, 78.30, 78.07; H, 4.83, 4.95; C/H ratio 16.0.

The low values are believed to be due to adsorption of air by the powder. The combustion left no residue, and the polymer contained no halogen. When the polymer was placed under dibutyl ether, in which it was insoluble, or dissolved in benzene, a continuous stream of bubbles was produced. No bubbles could be obtained similarly from polymer 1.

A micro Zerewitinoff determination[27] on the polymer gave 1 active H for 17 phenoxyacetylene units and 1 mole of methylmagnesium iodide adding for 2.5 moles of phenoxyacetylene. The presence of adsorbed air accounts for much of the Grignard reagent addition and may have vitiated the active hydrogen determination as well.

**Polymer 5** was obtained from 12.3 g. of phenoxyacetylene by polymerization at 40° for seventy-four hours. After 1 reprecipitation the yield was 3.75 g.; sintering point, 125°, mol. wt. 2900 (cryoscopic determination in benzene).

**Absorption Spectra.**—An older Beckmann Photoelectric Spectrophotometer, Model D, was used to determine the curves given in Fig. 2 while the newer model DV equipped with fused silica cells was employed for all other curves given. The polymers were insoluble in ethanol or hexane; benzene was used when working with the older instrument and chloroform or ether with the new. All solvents were redistilled through a 2-ft. column packed with helices. When carefully purified chloroform free from alcohol was stored, it decomposed even when under nitrogen in the dark and soon produced a slight acid color reaction with the early polymers. This purified chloroform was therefore used only to make up a standard antimony trichloride solution. For other spectra a redistilled chloroform containing a little alcohol was employed; it did not give an acid reaction with the early polymers even after standing for some time in the dark. Chloroform is opaque to ultraviolet light below 2420 Å., but was used because it is the most suitable solvent for the antimony trichloride color reaction.

The antimony trichloride solution was made up with freshly purified chloroform and kept under nitrogen in the dark. Its concentration was 17.6 g./l. and exactly 1 ml. was added to the dilute polymer solution in chloroform in making up the final 10 ml. dilution for the spectrophotometer. This amount of antimony trichloride was approximately twice that needed to give a strong blue color with polymer 4. The intense blue color (Curve B, Fig. 3) did not fade perceptibly in one or two hours, but the solution was nearly colorless in one or two days. The stock solution did not absorb in the range 3350–12000 Å., but below 3300 Å. absorption increased and the solution was opaque at 2810 Å. In the curves with antimony trichloride present, the stock solution was used in the reference cell of the spectrophotometer.

$\epsilon$, the basal molecular extinction coefficient, is obtained as usual except that concentration is expressed in basal moles (weight of polymer per liter divided by the molecular weight of the monomer, 118).

It was shown with polymer 3 in benzene that Beer's law is closely obeyed over a three-fold change in concentrations. Thus with concentrations of $0.720 \times 10^{-4}$, $1.44 \times 10^{-4}$ and $2.16 \times 10^{-4}$ basal moles/l. $\epsilon$ at 4400 Å. was 2180, 2190 and 2170, respectively, and at 3850 Å. $\epsilon$ was 2010, 2040, and 2010, respectively.

The absorption spectra of phenoxyacetylene and phenyl vinyl ether were of interest for study of the polymer absorptions. Phenetole and diphenyl ether were also measured for comparison. Ethanol (96%) was used as the solvent because in general it is more satisfactory than chloroform. The curve for phenetole in methanol or hexane is very similar[28] but was not extended to show the maximum at 2205 Å. Our curve for diphenyl ether agrees with spectra in the literature.[29,30,31]

The phenoxyacetylene used for the measurement was a carefully purified sample which was dissolved very quickly in the solvent and contained so little polymer that there was no measurable absorption at 4000 Å. The phenetole, phenyl vinyl ether and diphenyl ether were purified by distillation under reduced pressure through a 30-cm. Podbielniak-type column and had the following physical properties.

Diphenyl ether: b. p. 114° (8 mm.), m. p. 27–27.4°. Values from 26 to 29° are recorded in the literature.

Phenyl vinyl ether: b. p. 112° (200 mm.), $n^{15}D$ 1.5255, $n^{20}D$ 1.5226, $n^{25}D$ 1.5198. Chalmers[32] found $n^{20}D$ 1.5226.

Phenetole: b. p. 105° (100 mm.), $n^{18.8}D$ 1.5087. The literature[33] records $n^{18.8}D$ 1.5084.

**Polymerization in Solution: Polymer 6.**—Eight grams of phenoxyacetylene in 75 ml. of anhydrous ether was sealed in Pyrex glass under reduced pressure and allowed to polymerize for seven months in the open air exposed to sunlight. The resulting solution was reddish yellow and contained a small amount of a light colored, flocculent precipitate. A control sample kept in the dark was similar in color but homogeneous. The main sample contained 0.0072 g. of phenol per g. of phenoxyacetylene, the control only 0.002 g. Ether was removed under reduced pressure and phenoxyacetylene recovered from the main sample by distillation in a molecular still at room temperature with pressures finally as low as $5 \times 10^{-4}$ mm. The recovery of phenoxyacetylene was 61%; after extraction of phenol and redistillation, this phenoxyacetylene polymerized at the usual rate. The dark red sirup in the molecular still was dissolved in benzene and precipitated with petroleum ether as a very light, buff-colored powder. Two reprecipitations left 0.22 g. of polymer, sintering point 115–120°, m. p. 145–210° with thermosetting at 210°.

*Anal.* Calcd. for $(C_8H_6O)_x$: C, 81.35; H, 5.08. Found: C, 77.24, 77.06; H, 6.33, 6.36; ethoxyl, 5.11, 5.20.

The material was not hygroscopic and burned smoothly. Its absorption in chloroform was lower than any of the cross-linked polymers (Curve D, Fig. 3, in which it was assumed to have the composition of polyphenoxyacetylene for the purposes of calculating the extinction coefficients). It gave no color reactions with antimony trichloride, bromine or trichloroacetic acid.

The mother liquors from the precipitation contained more distillable by-products than could be obtained from the products of ordinary polymerization. These were oils that could not be purified or identified.

## Summary

Phenoxyacetylene polymerizes spontaneously at room temperature and above by a two stage process. The first step is a chain reaction believed to yield a linear, conjugated polyene which then undergoes cross-linking. The rate of disappearance of monomer could not be followed beyond

50% reaction and no choice between first and second order kinetics could be made. A preliminary study of the effect on the reaction, of several of the common catalysts and inhibitors for vinyl polymerization showed that only cadmium iodide was effective. Thermal initiation appears to be so rapid that the usual free radical catalysts have negligible effect, and the question of free radical initiations can be answered only by examining more active radical-producing substances. Early polymers isolated by precipitation have absorption spectra indicating a conjugated, polyene structure, and give color reactions with strong acids, metallic salts and bromine easily explained on this basis. Cross-linking involves breaking of the conjugation of the chain as indicated by decreased absorption, and the cross-linked polymers readily lose up to 46% of their phenoxyl content on heating. This suggests that the cross-linking may occur by a Diels–Alder reaction and that the hydroaromatic structure so produced is aromatized by loss of phenol. The early polymers are thermosetting and can be separated from later, cross-linked polymers chromatographically. Solvents greatly retard the polymerization and some indication that the primary reaction may involve free radicals was obtained by carrying out the reaction in ether which produced a polymer containing fragments of the ether molecule.

# Raman Frequencies of *n*-Paraffin Molecules

BY SAN-ICHIRO MIZUSHIMA AND TAKEHIKO SIMANOUTI

## I. Intramolecular Rotation

The experimental results of Raman effect, infrared absorption, dipole moment and electron diffraction made for ethylene dihalides by Mizushima, Morino, Watanabe, Simanouti, and others in our Laboratory[1] has shown that there are three potential minima in one complete rotation about a carbon single bond as axis (Fig. 1). These three potential minima correspond to one *trans* form (T) in which two halogen atoms are at the farthest distance apart and two *gauche* forms (G and G′) obtainable from the *trans* form by internal rotation of $\pm 120°$ (see Fig. 2). The energy difference between the *trans* and the *gauche* minima amounts to 1 kcal./mole (1.2 kcal. for ethylene dichloride and 1.3 kcal. for ethylene dibromide), from which the equilibrium isomeric ratio in the gaseous state can readily be calculated, but this ratio becomes naturally different in the liquid state owing to the intermolecular effect. In the solid state the intermolecular force (*i. e.*, crystal force) plays such a predominant role as to make only the *trans* form stable, which is most clearly seen from the disappearance of Raman lines assigned to *gauche* form on solidification.[2]

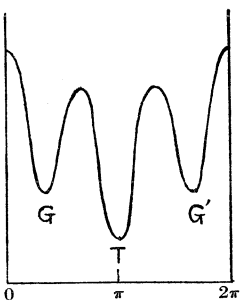

Fig. 1.—Intramolecular potential curve of ethylene dihalides $XH_2C–CH_2X$.

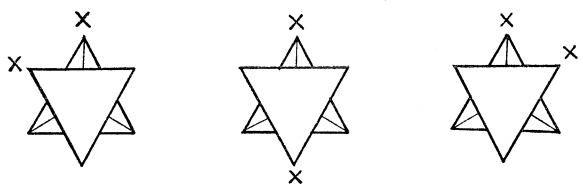

Fig. 2.—Molecular forms corresponding to the three potential minima.

## II. Raman Spectra of *n*-Paraffins in the Liquid and Solid States

The change of Raman spectra of *n*-paraffins on solidification observed by Mizushima, Okazaki, Morino, Takeda and Nakamura in our Laboratory (see Table I) can readily be explained, if we assume quite similarly the existence of only one molecular form in the solid state and of several forms in the liquid state. It is seen from the calculation of normal frequency similar to that made for ethylene dihalide that the only one molecular form realized in solid butane is the *trans* form.[3] It is, therefore, quite reasonable to assume that the molecular form of *n*-paraffin in general is the extended zigzag configuration in which four consecutive $CH_2$-groups form the *trans* configuration. This is also compatible with the results of X-ray investigation made by Müller[4] and Bunn[5] for long chain paraffins. Let us explain in the following the Raman frequencies observed for solid paraffins on the basis of this molecular model.

In Table I we see that in the lower frequency region there was observed only one Raman line for each solid paraffin and its frequency is inversely

proportional to the number of carbon atoms when it is greater than five. This would be explained simply, if we approximate the extended carbon chain by a continuous rod and assign the said Raman line to its longitudinal motion whose frequency is given by

$$\nu = \frac{1}{2l}\sqrt{\frac{E}{\rho}} \qquad (1)$$

where $E$ is Young's modulus, $\rho$ the density, $l$ the length of the rod. This relation means that the frequency is inversely proportional to the length of the chain or to the number of carbon atoms. Putting the observed frequencies into $\nu$ of Eq. (1), we obtain a value of $E$ ($34 \times 10^{11}$ dynes/sq. cm.) comparable to that of diamond ($55 \times 10^{11}$ dynes/sq. cm.). This is quite reasonable, since this value of $E$ refers to the carbon chain connected by covalency just as in the case of diamond, but not to the solid paraffins whose molecules are connected by van der Waals forces.

The calculation of skeletal modes of vibration was made by Kirkwood,[6] and by somewhat different method by Thomas, Whitcomb and Nielsen[7] and by Barriol.[8] Kirkwood's formulation will be used here with, however, a modification in the potential function, since the simple valence force formula used by Kirkwood cannot explain the quantitative feature of our problem.

As in the case of our previous calculation[3] for ethylene dihalide we assume the potential function of the form

$$V = K'r_0 \sum_n (\Delta r_n) + \frac{1}{2}K \sum_n (\Delta r_n)^2 + H'r_0 \sum_n (r_0 \Delta\alpha_n) + \frac{1}{2}H \sum_n (r_0\,\Delta\alpha_n)^2 + F' \sum_n q_0\,(\Delta q_n) + \frac{1}{2}F \sum_n (\Delta q_n)^2 \qquad (2)$$

where the significance of the force constants $K$, $H$, $F$, etc., and of the increments in atomic distances $\Delta r_n$ and $\Delta q_n$ and in bond angles $\Delta\alpha_n$ is clear from Fig. 3. Eliminating $q$'s through the relation $q_n^2 = r_n^2 + r_{n+1}^2 - 2r_n r_{n+1}\cos\alpha_n$, we can set up the equations of motion as

$$\ddot{\xi}_n + \frac{K+2F'(1+\cos\alpha_0)}{m}\left[\sin^2\left(\frac{\alpha_0}{2}\right)(2\xi_n - \xi_{n+1} - \xi_{n-1}) + (-1)^n \sin\frac{\alpha_0}{2}\cos\frac{\alpha_0}{2}(\eta_{n+1} - \eta_{n-1})\right] + \frac{H}{m}\left[\cos^2\left(\frac{\alpha_0}{2}\right)(2\xi_n - \xi_{n+2} - \xi_{n-2}) + (-1)^n \sin\frac{\alpha_0}{2}\cos\frac{\alpha_0}{2}(2\eta_{-1} - 2\eta_{n+1} + \eta_{n+2} - \eta_{n-2})\right] + \frac{F}{m}[2\xi_n - \xi_{n+2} - \xi_{n-2}] = 0$$

$$\ddot{\eta}_n + \frac{K+2F'(1+\cos\alpha_0)}{m}\left[\cos^2\left(\frac{\alpha_0}{2}\right)(2\eta_n - \eta_{n+1} - \eta_{n-1}) + (-1)^n \sin\frac{\alpha_0}{2}\cos\frac{\alpha_0}{2}(\xi_{n+1} - \xi_{n-1})\right] + \frac{H}{m}\left[\sin^2\left(\frac{\alpha_0}{2}\right)(6\eta_n - 4\eta_{n+1} - 4\eta_{n-1} + \eta_{n+2} + \eta_{n-2}) - (-1)^n \sin\frac{\alpha_0}{2}\cos\frac{\alpha_0}{2}(2\xi_{n+1} - 2\xi_{n-1} + \xi_{n+2} - \xi_{n-2})\right] - \frac{F'}{m}[6\eta_n - 4\eta_{n+1} - 4\eta_{n-1} + \eta_{n+2} + \eta_{n-2}] = 0$$

where $\xi$ is the displacement from equilibrium along the length of the chain, $\eta$ the displacement perpendicular to the chain (see Fig. 3), and $m$ the mass of $CH_2$-group.

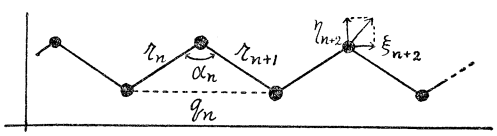

Fig. 3.—Coördinates of the extended chain.

Let $N$ be the number of carbon atoms in the chain. We have then $2N$ such equations of motion, the particular solutions of which are of the form

$$\xi_n = Ae^{i(\omega t + n\lambda)},\ \eta_n = (-1)^n Be^{i(\omega t + n\lambda)}$$

where the amplitudes $A$ and $B$ satisfy the equations.

$$\left.\begin{aligned}(\kappa_{11} - \omega^2)A + i\kappa_{12}B &= 0\\ -i\kappa_{12}A + (\kappa_{22} - \omega^2)B &= 0\end{aligned}\right\} \qquad (3)$$

$$m\kappa_{11} = (1-\cos\lambda)[\{K + 2F'(1+\cos\alpha_0)\}(1-\cos\alpha_0) + 2H(1+\cos\alpha_0)(1+\cos\lambda) + 4F(1+\cos\lambda)]$$

$$m\kappa_{22} = (1+\cos\lambda)[\{K + 2F'(1+\cos\alpha_0)\}(1+\cos\alpha_0) + 2H(1-\cos\alpha_0)(1+\cos\lambda) - 4F'(1+\cos\lambda)]$$

$$m\kappa_{12} = \sin\lambda\,[-\{K + 2F'(1+\cos\alpha_0)\}\sin\alpha_0 + 2H\sin\alpha_0(1+\cos\lambda)]$$

The values of $\omega^2$ corresponding to non-trivial solutions of Eq. (3) satisfy the secular equation

$$\begin{vmatrix}\kappa_{11} - \omega^2 & i\kappa_{12}\\ -i\kappa_{12} & \kappa_{22} - \omega^2\end{vmatrix} = 0 \qquad (4)$$

Since an integral number of half wave length must be completed within the molecule,[9] we have

$$\left.\begin{aligned}\lambda &= \pi l/N\\ l &= 0, 1, 2, \ldots, N-1\end{aligned}\right\} \qquad (5)$$

(6) Kirkwood, *J. Chem. Phys.*, **7**, 506 (1939).

(7) Thomas and Whitcomb, *Phys. Rev.*, **56**, 383 (1939); Whitcomb, Nielsen, and Thomas, *J. Chem. Phys.*, **8**, 143 (1940).

(8) Barriol, *J. phys. rad.*, **10**, 215 (1939).

(9) Instead of Eq. (5) Kirkwood put $\lambda = 2\pi l/N$, which is not correct as pointed out by Pitzer, *J. Chem. Phys.*, **8**, 711 (1940).

By the examination of the character of motion associated with each mode of vibration we see that the two vibrations of $l = 1$ appear in the Raman spectrum as strong lines.[10] One of them corresponds to the symmetric deformation vibration and the other to the symmetric valency vibration. It is evident that the former is assigned to the said Raman line of the lowest frequency and the latter to the line observed at about 900 cm.$^{-1}$. As the values of force constants and equilibrium angle we shall use the following reasonable ones:

$$\left.\begin{aligned} K &= 4.0 \times 10^5 \text{ dynes/cm.} \\ H &= 0.11 \times 10^5 \text{ dynes/cm.} \\ F &= 0.96 \times 10^5 \text{ dynes/cm.} \\ F' &= 0 \\ \alpha_0 &= \text{tetrahedral angle} \end{aligned}\right\} \quad (6)$$

With these molecular constants we can calculate the two frequencies stated above as shown in Table II. The agreement with the observed and the calculated frequencies is satisfactory.[11]

TABLE II

THE CALCULATED AND OBSERVED SKELETAL FREQUENCIES (IN CM.$^{-1}$) OF *n*-PARAFFIN MOLECULES IN THE EXTENDED FORM[a]

| Number of carbon atoms in a molecule | Deformation frequency Calcd. | Obs. | Valency frequency Calcd. | Obs. |
|---|---|---|---|---|
| 4 | 432 | 425 | 835 | 837 |
| 5 | 402 | 406 | 851 | 869 |
| 6 | 369 | 373 | 893 | 898 |
| 7 | 325 | 311 | 890 | 905 |
| 8 | 289 | 283 | 888 | 899 |
| 9 | 259 | 249 | 888 | 888 |
| 10 | 235 | 231 | 887 | 886 |
| 12 | 198 | 194 | 887 | 892 |
| 16 | 150 | 150 | 887 | 888 |

[a] The frequencies of *n*-butane and *n*-pentane have been calculated similarly to those of dichloroethane.[3] The values of force constants was put equal to those of the long chain paraffins except that of the end group $CH_3$–$CH_2$ for which $K$ was put equal to $3.2 \times 10^5$ dynes/cm.

We want to add a few words about the spectra in the liquid state. As already stated they have many more lines than the spectra observed in the solid state (see Table I), which is due to the fact that several rotational isomers co-exist with one another in the liquid state. It is very interesting that the lines observed in the solid state remain very strong in the liquid state for low homologs, while the strong line at 150 cm.$^{-1}$ of solid cetane, $C_{16}H_{34}$, escaped detection in the liquid state. This means that for lower homologs the extended molecular form is abundant in the liquid state, while for cetane this is almost absent in that state. This would have something to do with the idea proposed by Eyring[12] that the long chain molecules act in segments in the liquid state.

(10) This is consistent with Pitzer's assignment (*J. Chem. Phys.*, **8**, 711 (1940)), but our calculated frequencies are different from those of Pitzer who used the same potential function as Kirkwood.

(11) In Eq. (6) we put $F' = 0$. This means that only the quadratic terms were taken into account in our numerical calculation. Hence the difference of the present calculation from the previous ones results from the last term in potential function (2).

## III. Intramolecular Rotation of Highly Elastic Substances

We shall take this opportunity to make a short discussion on high elasticity. This property of rubber-like polymers has been considered to be due to the chain structure of their molecules, but all the substances with chain molecules do not show high elasticity. For instance polyisobutylene, $-C(CH_3)_2-CH_2-C(CH_3)_2-CH_2-$, shows highly elastic properties even at considerably lower temperature, while a simpler hydrocarbon polyethylene does not show this property at ordinary temperature.

We consider that such a difference can be explained readily from the result of our study stated in I. A unit structure of these two polymers corresponds, respectively, to 2,2-dimethylbutane, $CH-C(CH_3)_2-CH-CH_3$, (polyisobutylene) and to *n*-butane, $CH_3-CH_2-CH_2-CH_3$, (polyethylene). In the former case the three stable molecular forms are identical and, therefore, have the same energy, while in the latter case the *trans* form has a lower energy than the *gauche* forms. From this fact it immediately follows that the molecular chain of polyisobutylene can be folded more easily than that of polyethylene and hence the former substance shows high elasticity at a lower temperature than the latter.

It seems that high elasticity at lower temperature is observed for a substance whose molecule has at least two potential minima of practically the same energy. In the case of carbon chain such an intramolecular potential will be realized by the existence of side chain, which is quite consistent with our experience. If, however, we consider that the energy difference between the *trans* and the *gauche* forms of *n*-butane amounts only to about 1 kcal./mole, the straight carbon chain will have considerable probability to be folded at a slightly higher temperature. This would be the reason why polyethylene shows elastic property at a temperature higher than about 120°.

## Summary

The disappearance of many Raman lines of *n*-paraffins on solidification has been explained by considering only one molecular form in the solid state and several ones in the liquid state. The molecular form in the solid state has been shown to be the extended form for which the calculation of normal vibrations has been made. A short discussion on high elasticity has been added.

# Studies of Sulfonates. X.[1] Sodium Triisopropylbenzenesulfonate as a Colloidal Electrolyte[2,3]

BY GORDON R. SHUCK[4,5] AND E. C. LINGAFELTER

The colloidal electrolyte behavior of several sodium *n*-alkylbenzene-*p*-sulfonates has been previously reported.[6] It seemed of interest to compare the behavior of a polyalkylbenzene sulfonate, since the effective length of the molecule could be considerably decreased while maintaining a hydrocarbon residue of considerable molecular weight. The compounds which we have prepared and studied are triisopropylbenzenesulfonic acid and its sodium salt. These may be compared with the sodium *n*-octylbenzene-*p*-sulfonate,[6] which differs in molecular weight by that of one methylene group only.

The critical concentration for micelle formation has been determined from solubility and electrical conductance measurements and by the use of the dye, pinacyanol chloride.[7]

## Experimental

**Preparation of Compounds.**—Triisopropylbenzene and tetraisopropylbenzene were prepared by the repeated alkylation of cumene (Eastman Kodak Co. white label) with isopropyl alcohol and sulfuric acid under reflux conditions. The alkylation procedure consisted of the slow addition of the sulfuric acid to a boiling solution of hydrocarbon and isopropyl alcohol. Using this method, the mole ratio and acid concentration found to give the greatest yield of alkylated product with minimum loss due to sulfonation was 1 mole hydrocarbon:1 mole isopropyl alcohol:1.2 moles 98% sulfuric acid. After each alkylation, the hydrocarbons were separated from the acid in a separatory funnel, washed with water and finally with 10% aqueous sodium hydroxide to remove sulfonic acids, and dried with calcium chloride. The final alkylated product was fractionated in an 18-inch helices-packed column at about 15 mm. pressure to separate the mono-, di- and triisopropylbenzenes, and the tetraisopropylbenzene was distilled from the residue in a special distillation apparatus. The tetraisopropylbenzene was further purified by three recrystallizations from isopropyl alcohol. From 1 liter of cumene there was obtained 650 ml. of triisopropylbenzene (boiling range 230–240° at 760 mm.) and 260 g. of tetraisopropylbenzene (m. p. 117.5°). Francis[8] gives the following data: 1,2,4-triisopropylbenzene, b. p. 244°; 1,3,5-triisopropylbenzene, b. p. 238°; 1,2,4,5-tetraisopropylbenzene, m. p. 118.4° Newton[9] reports that the triisopropylbenzene prepared by sulfuric acid alkylation consists of 84% 1,2,4-triisopropylbenzene and 16% 1,3,5-triisopropylbenzene. No serious attempt was made to separate these isomers, although our triisopropylbenzene fraction was fractionated at a slow rate several times, the first portion being discarded each time. Therefore our final product was probably quite largely 1,2,4-triisopropylbenzene, but almost certainly contained some 1,3,5-triisopropylbenzene.

100 ml. of triisopropylbenzene was dissolved in 300 ml. of carbon tetrachloride and agitated with 100 ml. of fuming sulfuric acid (15% free $SO_3$) for fifteen minutes. The layers were then separated, the carbon tetrachloride was evaporated off and the residue taken up in water. The aqueous solution was neutralized with sodium hydroxide and upon cooling yielded crystals of sodium triisopropylbenzenesulfonate.

Tetraisopropylbenzene was also sulfonated by the same method, yielding a product identical with that obtained from the triisopropylbenzene. The identity of the two substances is shown by a comparison of powder patterns of the sodium salts (see Table I). The product of the sulfonation of tetraisopropylbenzene was further shown to be triisopropylbenzenesulfonic acid by three additional experiments: (1) hydrolysis of the compound in boiling dilute sulfuric acid yielded a hydrocarbon boiling at 235–240°; (2) the equivalent weight of the solid hydrate, determined by titration with 0.1 *N* NaOH, was found to be 299.5 (calculated for triisopropylbenzenesulfonic acid monohydrate, 302.5); (3) the barium salt was prepared and analyzed for barium by precipitation of barium sulfate (found 19.50% Ba, calculated for barium triisopropylbenzenesulfonate 19.51% Ba). Newton[10] also found that the sulfonic acids formed from 1,2,4-triisopropylbenzene and 1,2,4,5-tetraisopropylbenzene by the action of chlorosulfonic acid were identical. Thus our product consists of a mixture of the isomeric triisopropylbenzenesulfonic acids.

The solubility of sodium triisopropylbenzenesulfonate in water was determined at intervals over the range 10 to 49°. Two large test-tubes, each containing 30 ml. of water and excess solid were placed in a water thermostat regulated to ±0.05° and stirred mechanically for two hours. One of the solutions had been heated above the bath temperature to obtain complete solution, while the other had been made up below the bath temperature. Thus, agreement between the results from the two solutions indicated that equilibrium had been established. After the excess solid had settled, samples were pipetted from the solutions by means of a pipet whose tip was covered with filter paper. The samples were discharged into weighing bottles, evaporated to dryness, and weighed again. The results of the solubility determination are given in Fig. 1.

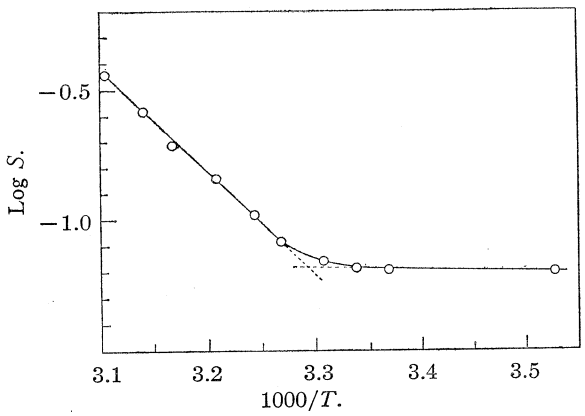

Fig. 1.—Solubility of sodium triisopropylbenzene-sulfonate in water (moles per 1000 g. of water).

The electrolytic conductance of aqueous solutions of sodium triisopropylbenzenesulfonate and of triisopropylbenzenesulfonic acid were measured using the bridge and cells previously described.[11] The cells were replatinized and their constants redetermined before use. The results are given in Figs. 2 and 3.

The critical concentration of the sodium salt was determined to be 0.061 *M* at 50° by the use of the dye pinacyanol chloride.[7]

## Discussion of Results

The solubility and pinacyanol chloride results with sodium triisopropylbenzenesulfonate and the conductance of the acid clearly indicate that these substances behave as colloidal electrolytes. The absence of any marked discontinuity in the conductance curve of the sodium salt illustrates the danger of basing conclusions on one property alone.

The values obtained for the critical concentration from the several properties seem to agree as well as corresponding results for other colloidal electrolytes. The values for the sodium salt are 0.065 *M* (from solubility) and 0.061 *M* (from the pinacyanol chloride method), while the value for the acid is 0.055 *M* (from the equivalent conductance). In particular, it may be pointed out that a comparison of the data of Wright, Abbott, Sivertz and Tartar[11] with those of McBain, Dye and Johnston[12] show the critical concentrations of the alkane-sulfonic acids to be slightly less than those of the sodium alkane-sulfonates.

(11) Wright, Abbott, Sivertz and Tartar, THIS JOURNAL, **61**, 549 (1939).

(12) McBain, Dye and Johnston, *ibid.*, **61**, 3210 (1939).

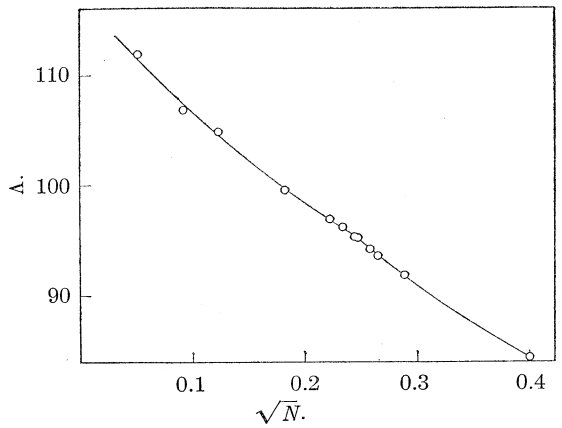

Fig. 2.—Equivalent conductance of aqueous solutions of sodium triisopropylbenzenesulfonate at 50°.

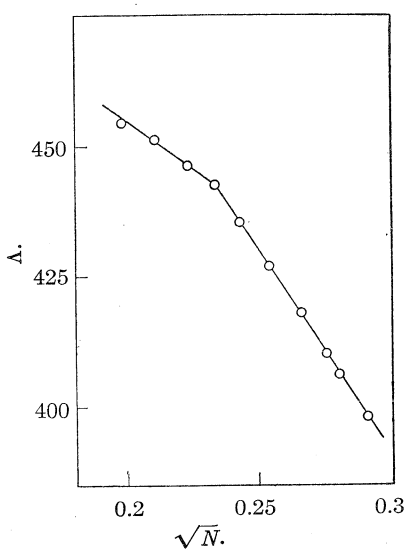

Fig. 3.—Equivalent conductance of aqueous solutions of triisopropylbenzenesulfonic acid at 50°.

The average value for the sodium salt, 0.063 *M*, may be compared with the value for sodium *n*-octylbenzene-*p*-sulfonate, 0.013 *M*.[6] Thus, although the triisopropylbenzenesulfonate ion contains one more carbon atom, it does not aggregate until a higher concentration is reached. This indicates the importance of the shape of the molecule in determining the tendency toward micelle formation, agreeing with the observation of Hartley[13] that branching of the hydrocarbon portion increases the critical concentration. It does not seem possible at present to decide whether this effect is a consequence of the efficiency of packing in the micelle, the size of the micelle, or the interfacial free energy of the unassociated ion.

Furthermore, the observation that the conductance of the sodium salt does not decrease at the critical concentration indicates that the fraction of gegenions attached to the micelles is smaller

(13) Hartley, *Trans. Far. Soc.*, **37**, 130 (1941).

than is the case for the long-chain compounds. This may be due to the greater distance between charges on the surface of the micelle, or to a smaller aggregation number.

## Summary

1. Triisopropylbenzenesulfonic acid has been prepared by the sulfonation of triisopropylbenzene and of tetraisopropylbenzene.

2. Triisopropylbenzenesulfonic acid and its sodium salt have been shown to be colloidal electrolytes, with critical concentrations of 0.055 and 0.063 *M*, respectively.

3. The comparison of these compounds with sodium *n*-octylbenzene-*p*-sulfonate illustrates the importance of molecular shape as well as size in determining the tendency toward aggregation.

4. The conductance of the sodium salt shows no discontinuity at the critical concentration, indicating a relatively small fraction of attached gegenions.

# Transference Numbers of Dodecylammonium Chloride in Water–Organic Solvent Systems

BY A. W. RALSTON AND A. E. BRAKE

Dodecylammonium chloride is a typical cationic colloidal electrolyte and the equivalent conductivity of its aqueous solutions shows an abrupt drop at $1.44 \times 10^{-2}$ molar[1] at which concentration it undergoes a transition from an ordinary to a colloidal electrolyte. It has been shown recently[2] that the addition of organic solvents such as acetone, methyl or ethyl alcohol or acetonitrile to aqueous solutions of dodecylammonium chloride increases the concentration of colloidal electrolyte at the critical point. As the concentration of organic addend is increased the conductivity curves of dodecylammonium chloride are no longer characteristic of those of a colloidal electrolyte and resemble those of an ordinary electrolyte. This decreased tendency toward association has been attributed to the decreased ionizing powers and dielectric properties of the mixed solvent, the latter factor increasing the effectiveness of the repulsion of similarly charged ions. When the equivalent conductivities of various concentrations of dodecylammonium chloride are plotted against the mole per cent. of organic addend the effect of the organic addend is seen to vary greatly depending upon whether the concentration of colloidal electrolyte is more or less than the critical concentration. At concentrations lower than critical the conductivity falls to a minimum and then rises smoothly as the composition of the solvent approaches that of the pure organic addend. On the other hand, the conductivity curves for concentrations higher than the critical concentration rise quite sharply to a maximum and then gradually decrease as the mole percentage of organic addend is increased. It has been postulated that these maxima occur at those points which represent a transition of the dodecylammonium chloride from a colloidal to an ordinary electrolyte. Since it is well established that at concentrations beyond the critical point the transference number of the associated ion exhibits a characteristic, sharp rise, it is apparent that transference data would be of great assistance in the interpretation of the effect of organic addends upon the colloidal behavior of dodecylammonium chloride. This present paper presents transference data upon dodecylammonium chloride in two of the water–organic solvent systems studied; namely, water–methanol and water–acetonitrile, and correlates these data with the conductometric behavior of these systems.

## Experimental

**Apparatus.**—The Washburn cell[3] employed in earlier transference experiments in these laboratories[4] was again employed for a portion of the work herein reported.

Comparable results were obtained in a smaller apparatus designed to economize amine salt and to avoid complications of changing solution density. This cell consisted of three U-tubes sealed together, having a uniform internal diameter of 15 mm. and a mean total length of 80 cm., and required only 150 ml. of solution. The cell was provided with glass stopcocks at the bottom of each U-tube and with vent tubes at the top. The electrodes were helices of 18 gage, pure silver wire (15 turns of 1 cm. diameter). A silver surface for the anode and a silver chloride surface for the cathode were produced electrolytically. Two silver coulometers of the Kohlrausch type were employed. Observations and initial adjustment of current were made with the usual resistances and meters. Constant temperature of 30° was obtained by the use of a large air bath having temperature control to ±0.05°.

**Materials.**—The dodecylammonium chloride employed in these studies has been previously described.[1] The solutions were made with freshly prepared conductivity water, dried and redistilled acetonitrile and C. P. absolute methanol.

**Procedure.**—Experiments in the Washburn cell were conducted in the manner previously described.[4]

In the smaller cell the silver anode was washed repeatedly in distilled water and dried by burning off methanol before use. The silver-chloride cathode, also washed, was suspended in the solution to be electrolyzed with occasional stirring for a day prior to its use. This permitted the establishment of the initial concentration of dodecylammonium chloride in the pores of the cathode surface.

(3) Washburn, THIS JOURNAL, **31**, 322 (1909).

(4) Hoerr and Ralston, *ibid.*, **65**, 976 (1943).

After the completion of the electrolysis the stopcocks at the bottom of each U-tube were carefully opened, thus dividing the solution into three portions, namely, anode, cathode and middle.

**Electrode Reactions.**—The usual electrode reactions, the formation of silver chloride at the anode and the reduction of silver chloride to free silver at the cathode were observed.

The formation of a complex salt between silver chloride and dodecylammonium chloride at the anode resulted in a poorly adhering deposit which clouded the solution in this compartment. It is necessary to include the dodecylammonium chloride contained both in the electrode itself and in the detached material in the analytical results in order to obtain check results for the content of amine salt in the anode and cathode compartments. This procedure is much preferable to employing a correction such as that recently discussed by Hale and De Vries.[5] At the cathode the reduction of silver chloride to free silver in the presence of the colloidal electrolyte resulted in the production of a colloidal silver sol as evidenced by the development of a yellow color in these solutions. Both these effects were greatly reduced as the amount of organic solvent increased and they were not observed in those mixtures which were rich in organic solvent.

**Analyses.**—The concentration of dodecylammonium ion was determined by steam distillation of the amine and its titration with standard acid.[6] As stated previously, it was necessary to decompose the silver chloride–dodecylammonium chloride in order to obtain satisfactory analytical values. The chloride ion was determined gravimetrically as silver chloride after removal of the dodecylammonium ion. In the experiments with acetonitrile it was necessary to remove the acetonitrile by distillation of its azeotrope from the amine salt solution before satisfactory analytical results could be obtained.

Agreement between the analyses of the original solution and the middle portion was better than 1% for all results reported. The transference numbers in aqueous solution were reproducible within ±0.02 unit. In mixtures rich in organic solvent the analyses were in better agreement (±0.2%) and the transference numbers in methanol were reproducible within ±0.003 unit.

## Results and Discussion

The cationic transference numbers at 30° of dodecylammonium chloride plotted against the mole percentage of methanol in the solvent are shown in Fig. 1. Two concentrations of dodecylammonium chloride were studied, 0.1 molar which is materially greater than the critical concentration and 0.01 molar which is less. At the concentration greater than the critical concentration increase in the percentage of methanol is attended by a very rapid decrease in $T_c$, the value reaching a minimum at approximately thirty mole per cent. of methanol and then slowing rising. The conductometric work, to which reference has previously been made,[2] showed that a maximum value in the equivalent conductivity of dodecylammonium chloride in methanol–water mixtures occurs at about thirty mole per cent. methanol. The rapid drop to a minimum in the transference number of the dodecylammonium ion and its subsequent rise presents further evidence of the transition of dodecylammonium chloride from a colloidal to an ordinary electrolyte as the composition of the solvent goes from pure water to pure methanol. This transition is apparently completed in the neighborhood of the minimum in the $T_c$ curve. The rise in the transference numbers after the minimum can be attributed to the reduction in the viscosity of the solvent as its composition approaches pure methanol. Decrease in the viscosity of the solvent should have a greater relative effect upon the large dodecylammonium ion than upon the smaller chloride ion.

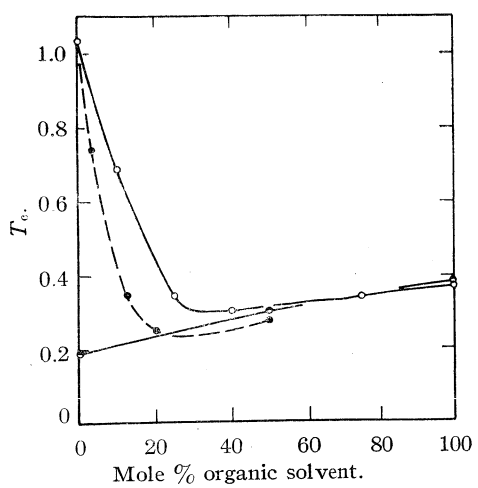

Fig. 1.—Transference numbers of dodecylammonium chloride in methanol–water and acetonitrile–water at 30°: ○, 0.1 *M* in methanol–water; ●, 0.1 *M* in acetonitrile–water; ◒, 0.01 *M* in methanol–water.

The transference numbers for the dodecylammonium ion in 0.01 molar dodecylammonium chloride show a gradual rise as the composition of the solvent goes from pure water to pure methanol. The values in the water-rich mixtures do not exhibit the abnormal behavior shown by the higher concentration of amine salt when the dodecylammonium chloride functions as a colloidal electrolyte. The increase in the value $T_c$ is explainable on the basis of decreased solvation of the dodecylammonium ion coupled with viscosity changes in the solvent. It is of interest to note that in the methanol-rich solvents the values of $T_c$ for 0.1 and 0.01 molar dodecylammonium chloride are similar and are in marked contrast with the rise to abnormally high values obtained in aqueous solutions in this concentration range.

Figure 1 also shows the transference numbers of the dodecylammonium ion in several acetonitrile–water mixtures. The decrease in the values of $T_c$ is somewhat more abrupt than in the methanol–water solvents and the minimum occurs at a lower value of $T_c$ and at a somewhat lower concentration of organic addend. It has been previously observed[2] that the addition of acetonitrile brings about a more rapid transition of this amine salt from a colloidal to an ordinary electrolyte than does the addition of methanol. A maximum in the equivalent conductivity curve was observed in the neighborhood of fifteen per cent. acetonitrile a value in approximate agreement with the minimum in the $T_c$ values.

(5) Hale and De Vries, THIS JOURNAL, **70**, 2473 (1948).

(6) Ralston and Hoerr, *Ind. Eng. Chem., Anal. Ed.*, **16**, 459 (1944).

The values of $\Lambda_c$ plotted against the solvent composition are shown in Fig. 2. It is significant that the values for 0.1 molar dodecylammonium chloride in those solvent compositions in which it functions as a colloidal electrolyte are identical for similar molar concentrations of methanol and acetonitrile. This suggests that the results described in this paper for methanol–water and acetonitrile–water systems may constitute examples of a general effect which may be encountered with other organic solvent–water systems. The values of $\Lambda_c$, unlike those of $T_c$, are of course greater for the lower concentration of amine salt in methanol–water mixtures under those conditions where the amine salt functions as an ordinary electrolyte.

The numerical values of $T_c$, $\Lambda_c$, $T_a$ and $\Lambda_a$ at 30° are shown in Table I.

TABLE I

| Mole % $CH_3OH$ | $T_c$ | $\Lambda_c$[a] | $T_a$ | $\Lambda_a$[a] |
|---|---|---|---|---|
| | $C_{12}H_{25}NH_3Cl$, 0.10 *M* | | | |
| 0 | 1.033 | 40.3 | −0.027 | .. |
| 10.0 | 0.689 | 27.6 | +0.325 | 13.0 |
| 25.0 | .343 | 15.1 | .663 | 29.2 |
| 40.0 | .302 | 13.0 | .723 | 28.9 |
| 75.0 | .345 | 15.2 | .673 | 29.6 |
| 100.0 | .369 | 18.5 | .665 | 30.9 |
| | $C_{12}H_{25}NH_3Cl$, 0.01 *M* | | | |
| 0 | 0.189 | 19.3 | 0.814 | 83.0 |
| 50 | .301 | 15.9 | .725 | 38.4 |

| | $C_{12}H_{25}NH_3Cl$, 0.10 *M* | | | |
| $CH_3CN$ | | | | |
| 3.66 | 0.738 | 36.9 | 0.316 | 15.8 |
| 12.5 | .346 | 25.3 | .656 | 47.8 |
| 20.0 | .250 | 17.5 | .719 | 50.3 |
| 50.0 | .275 | 15.1 | .725 | 39.8 |

[a] The ionic conductances were computed from data of reference.[2]

The negative value of $T_a$ for dodecylammonium chloride in pure water is noteworthy. A value of 0.13 for $T_a$ at 30° has previously been reported.[4] The low value is explainable on the basis of solubilization of the undissociated amine salt by the micelles.

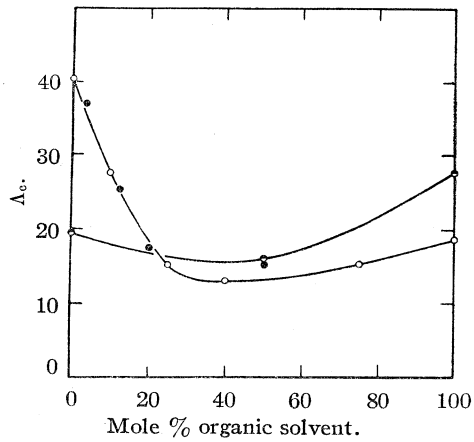

Fig. 2.—Cationic conductances of dodecylammonium chloride in methanol–water and acetonitrile–water at 30°: ○, 0.1 *M* in methanol–water; ●, 0.1 *M* in acetonitrile–water; ◓, 0.01 *M* in methanol–water.

Above forty mole per cent. methanol the values of $\Lambda_a$ for 0.1 molar dodecylammonium chloride are in close agreement with those of Longsworth and MacInnes[7] for 0.05 molar lithium chloride and sodium chloride in similar methanol–water mixtures. This is further evidence of the normal behavior of dodecylammonium chloride in methanol-rich solvents. Below forty mole per cent. methanol the values are widely divergent owing to association of the colloidal electrolyte.

## Summary

The values of $T_c$, $T_a$, $\Lambda_c$ and $\Lambda_a$ for dodecylammonium chloride in methanol–water and acetonitrile–water mixtures at 30° have been determined or derived.

At 0.10 *M* the transference numbers indicate a transition of dodecylammonium chloride from a colloidal to an ordinary electrolyte as the percentage of organic addend is increased.

# Reaction Heats of Organic Fluorine Compounds. I. Apparatus and the Heat of Chlorination of Tetrafluoroethylene[1]

BY J. R. LACHER, J. J. MCKINLEY, C. M. SNOW, L. MICHEL, G. NELSON AND J. D. PARK

Since the pioneering work of Swarts[2] very few thermochemical data on organic fluorine compounds have been obtained. Wartenberg and Schütte,[3] using elemental fluorine, measured the heat of formation of carbon tetrafluoride. However, since higher fluorides of carbon were probably formed in the reaction, the actual value for the heat may be greater than that reported. In the case of organic chlorine and bromine compounds the situation is not much better. Kistiakowsky and co-workers[4] have measured the heat of chlorination of ethylene and the heats of bromination of several simple olefins. The heats of combustion of some chloro derivatives of benzene have been measured recently by Hubbard, Knowlton and Huffman,[5] and by L. Smith.[5a]

Thermochemical data are necessary for the thermodynamic and statistical calculations of equilibrium constants. They give valuable information concerning the nature of a chemical bond and are useful in the design of process equipment. Accordingly a long range program is being undertaken to measure directly the heats of vapor phase reactions of organic halogen compounds. The calorimeter constructed for this purpose possesses the flow characteristics of the one described by Kistiakowsky and co-workers[6] but it operates at constant temperature in a manner similar to those described by Kraus,[7] Tong and Kenyon[8] and Coon and Daniels.[9]

The operation of the calorimeter is simple in principle and is essentially one of substitution. The gaseous reactants are led into a catalyst chamber where the reaction takes place, and the products pass through a heat exchanger out to a collecting system. A volatile liquid surrounding the heat exchanger absorbs the heat of reaction. At the same time nitrogen is bubbled through this liquid thereby removing heat by vaporization at such a rate as to maintain the temperature constant. When equilibrium has been established on the catalyst, the flow of reactants is stopped and direct electrical heating substituted for that due to the reaction, the nitrogen flow remaining constant. The electrical energy required is then equal to that produced by the reaction. From the rate of energy input and the rate of formation of product, the heat of reaction can be calculated.

**Apparatus.**—The essential parts of the calorimeter are shown in Fig. 1. The reaction chamber was machined from a cylinder of monel metal 1″ × 10″. The chamber is charged with catalyst through a cap at the bottom which is soldered in place. The reactants are led into the catalyst chamber through two concentric tubes and mix at the top of the catalyst bed. The products are taken from the bottom and led through a heat exchanger made of six feet of $^1/_4$″ copper tubing and thence to the collecting system. This chamber and accessories were suspended from a circular brass plate so that they could be immersed in a 960-ml. wide-mouth dewar flask. This dewar contained chlorobenzene and the heat of reaction was transferred to it. In order to remove heat from the system, dry nitrogen was bubbled through the chlorobenzene and was dispersed by means of a size B fritted glass distributor. The metal-to-glass joint was below the liquid level in the dewar. The waste nitrogen and chlorobenzene were led out through a $^1/_2$″ thin-walled brass tube. The upper part served as a condenser to return most of the chlorobenzene.

A bare nichrome heater, made of number 32 wire and having a resistance of 42 ohms, was fastened to the glass distributor tube. The potential and current leads were led out through the nitrogen line. The heating current was supplied by four lead storage batteries in series. During a run the batteries were charged at a slightly lower rate than the power requirement.[10] In this way very constant currents were obtained. The electrical energy input was obtained by measuring the e. m. f. across a standard resistance in series with the heater and also the potential drop across the heater. A Rubicon type B potentiometer and high sensitivity galvanometer were used for these measurements. In case of the potential drop across the heater, a voltage divider was necessary.

A 12-junction copper–constantan thermel was used to measure the temperature differential between the chlorobenzene and the oil-bath in which the whole assembly was immersed. One end of the thermel was located in a well made of telescopic iron tubing and extending about midway into the

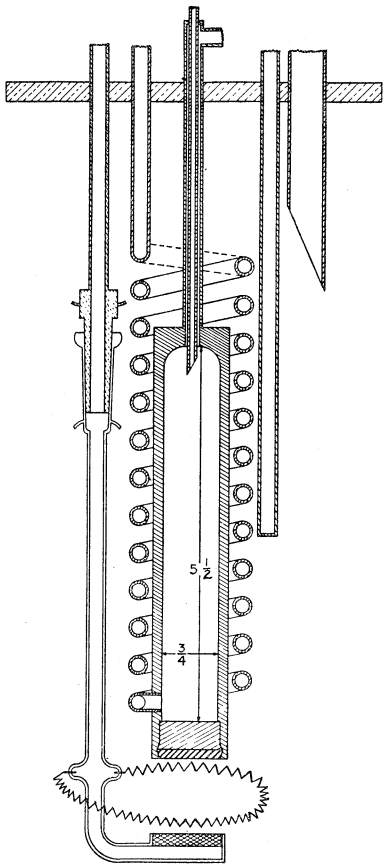

Fig. 1.

chlorobenzene (shown in Fig. 1). The other end was located in the surrounding oil-bath. By means of a suitable switching arrangement, the e. m. f. of the thermel could be read on a potentiometer or placed directly on the high sensitivity galvanometer or on a Rubicon photoelectric galvanometer depending on the sensitivity required. When the reacting system had reached a steady state during a run, the e. m. f. of the thermel would fluctuate about zero.

The 960 ml. wide-mouth dewar containing the chlorobenzene was tightly contained in a brass cylinder as shown diagrammatically in Fig. 2. The dewar rested on a platform supported by three stiff metal springs. The bottom plate of the brass cylinder was fitted with a $^3/_4$" pipe flange and a pipe extension in order that the assembly could be supported from the bottom of the thermostat. The top plate held the catalyst chamber and auxiliary equipment. It was tightly bolted on using sheet gaskets. The gases entering the calorimeter were brought to temperature by passing them through heat exchangers made of $^1/_4$" copper tubing immersed in the oil thermostat.

The thermostat consisted of a cubical iron tank containing 110 gallons of lubricating oil. It was thoroughly insulated with "Sil-o-cell" brick and is designed for operation up to 200°. Continuous

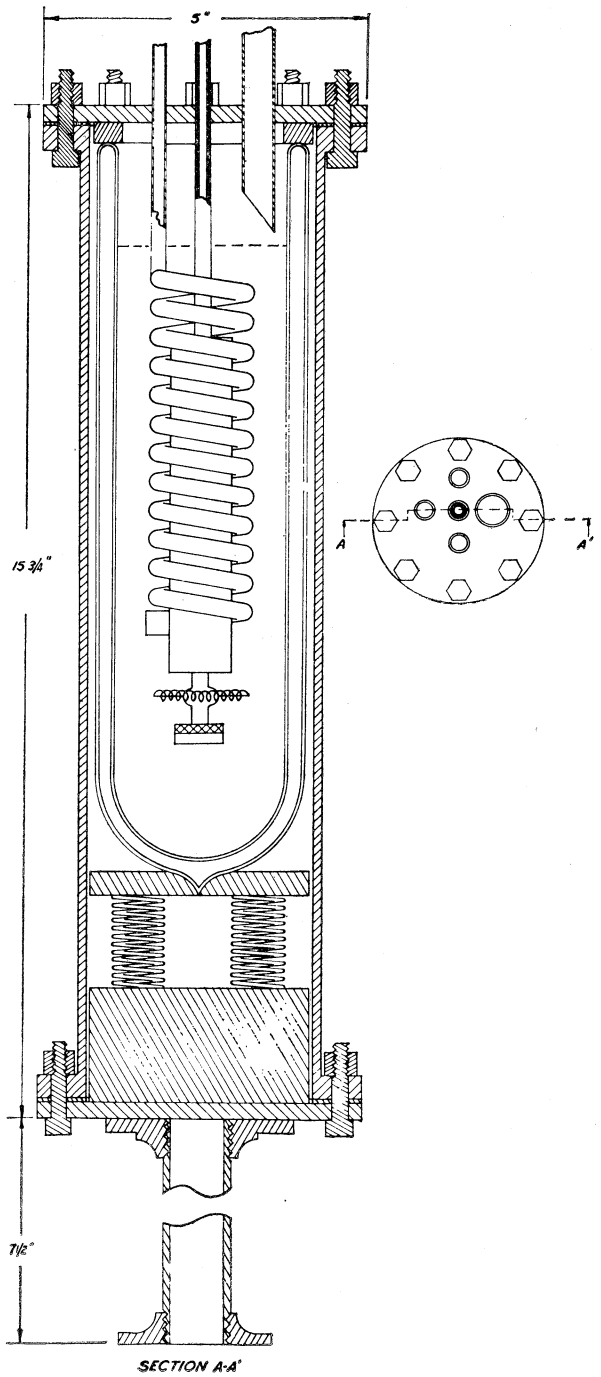

Fig. 2.

heating was supplied by nichrome elements evenly spaced in the top, bottom and sides of the thermostat. Intermediate heating was obtained by four nichrome immersion heaters. These surround the propeller shafts located in each of the four corner "wells" in the tank. The temperature was controlled by a d. c. bridge-photoelectric cell system. The temperature sensing element was a thermister (type D 169,604), developed by the Bell Telephone

Laboratories and formed one arm of the bridge. When the heating current was on, a reversible "Telechron" increased the voltage of the "Variac" controlling the heaters. On the other hand, when this current was off, this voltage was slowly decreased. The system sought a condition where the current was on half the time. A 25-ohm platinum resistance thermometer and Mueller bridge were used to measure temperatures. No gradients could be measured in the bath while operating at 80° and temperature fluctuations were less than 0.001° over a period of several hours.

The flow rate of the nitrogen used to cool the chlorobenzene was carefully controlled. Nitrogen from a commercial cylinder was supplied to a Moore[11] "Nullmatic" pressure regulator at a pressure of six pounds by means of a standard reducing valve. It then passed to an adjustable head overflow tower, buffer tank and through an ordinary capillary flow meter. Several manometers were included in the line for observation of back pressures. It was necessary only to maintain a constant nitrogen flow once the catalyst had reached a steady state and while the electrical energy balance was being made. A differential of more than 100 mm. across the flow meter could be held constant to 0.2 mm. during the course of a run.

## Experimental

**Hydrogenation of Cyclohexene.**—The cyclohexene was prepared from commercial cyclohexanol after the methods of Kistiakowsky, *et al.*,[12] and Coleman and Johnstone.[13] The crude cyclohexene obtained was distilled twice in a vacuum-jacketed column packed with glass helices, having a total condensation head and a variable magnetic takeoff. The middle fraction consisting of 60% of the crude material was used. The refractive index, $n^{20}D$ 1.4466, of this product was in close agreement with that of Kistiakowsky.[11] The catalyst used for hydrogenation was platinum black on asbestos found satisfactory by Kistiakowsky[11] and prepared by the method of Shiels.[14]

The hydrogen, from a commercial cylinder, was led through heated copper and a "Drierite" and "Ascarite" tower. It then passed through a Moore pressure regulator, Moore constant flow regulator, precatalyst chamber and to a valve system whereby it could be sent either directly to the calorimeter or to a gas-saturating device containing cyclohexene. In this cyclohexene bubbler, the hydrogen becomes partially saturated. The temperature was so controlled that hydrogen was in excess when the mixture was led to the calorimeter. The amount of cyclohexane formed was determined by condensing it from the excess hydrogen and weighing the product. In order to test the effectiveness of the collecting system used, the hydrogen stream was saturated with cyclohexane in auxiliary experiments. The amount of cyclohexane recovered was compared with that removed by the hydrogen from a weighed sample. The results, shown in Table I, indicate that the per cent. loss decreases with increasing size of the sample. We were not able to recover quantitatively all of the cyclohexane, due apparently to a small initial loss by entrainment which was stopped when the glass wool in the trap became matted with crystals of cyclohexane.

TABLE I

RECOVERY OF CYCLOHEXANE FROM A HYDROGEN STREAM

| Grams of cyclohexane | | |
|---|---|---|
| Lost from saturator | Condensed in collector | Loss, % |
| 2.998 | 2.930 | 2.3 |
| 3.352 | 3.290 | 1.8 |
| 5.144 | 5.134 | 0.2 |
| 6.334 | 6.296 | 0.6 |

In making a calorimetric run, hydrogen was first passed through the calorimeter and collecting system to flush out air. An arbitrary flow of nitrogen through the chlorobenzene was chosen and sufficient electrical energy supplied to establish isothermal conditions. The amount of energy required was independent of the flow rate of hydrogen through the system. After a balance was obtained, the electrical heating was discontinued and the hydrogen was sent to the cyclohexene bubbler. The rate of reaction on the catalyst was adjusted to again give isothermal conditions. After collecting a sample, the flow of reactants was stopped and the electrical energy required for the same nitrogen flow was again measured. The final results obtained are shown in Table II. The second column gives the time during which the product was collected. The weight was increased steadily from 2.8 g. in sample 1 to 6.6 g. in sample 5. The amount of cyclohexane formed in moles per minute was obtained from the weight of the sample collected and the time. Owing to the fact that complete conversion of the cyclohexene did not occur on the catalyst, a correction was applied. The amount of cyclohexene present in the product was determined by measurement of refractive index. The catalyst slowly lost activity during these runs and the conversion which was initially 99% fell to 93%. The heat of hydrogenation in calories per mole was obtained by dividing the heat input in calories per minute by the rate of formation of cyclohexane in moles per minute. The per cent. deviations in the values so obtained from that found by Kistiakowsky[12] are shown in the last column. It is apparent that, if a sufficiently large sample is collected, the results agree to within a per cent. Since this is the accuracy desired, it was not thought worthwhile to improve the collecting system further.

TABLE II

HYDROGENATION OF CYCLOHEXENE AT 78°

| Run | Sampling time, min. | Cyclohexane formed[a] moles/min. $\times 10^{+4}$ | Energy input cal./min. | $-\Delta H_{351°}$, cal./mole | % Deviation from 28,592 |

[a] Corrected for unreacted cyclohexene.

**Heat of Formation of Hydrogen Chloride.**—Commercial hydrogen was purified by passing it over calcium chloride, hot copper gauze, and phosphorus pentoxide before entering the "Nullmatic" pressure regulating valve. This resulted in water-free hydrogen at the exit of the valve. The gas then went through a flow meter, a pre-catalyst chamber (palladium-on-carbon) and directly to the calorimeter. It was found, on treating this hydrogen with chlorine, that considerable amounts of water were discharged from the calorimeter indicating that either the hydrogen or chlorine contained oxygen which reacted in the palladium–carbon catalyst chamber. When two precatalyst chambers were installed in the hydrogen line and followed by three phosphorus pentoxide-drying tubes, very little, if any, water was formed in the main catalyst chamber.

Earlier work in this Laboratory showed that commercial

chlorine must be purified by a low temperature distillation before it could be used in calorimetric studies. Chlorine[15] from Matheson gave satisfactory results without further purification and was used in all experiments reported here. The cylinder was maintained at 0° to minimize pressure fluctuations. The chlorine was dried over phosphorus pentoxide and run through a suitable series of needle valves, constant pressure overflow tower to a capillary glass tube flow-meter. Several manometers were in the line to indicate back pressures. From the flow-meter, the chlorine could be sent either directly to the calorimeter or to a potassium hydroxide absorption tower.

The catalyst was prepared on "Columbia" activated carbon sized to pass a no. 6 and be retained on no. 20 screens. A suspension of $PdCl_2 \cdot 2H_2O$ in carbon tetrachloride was poured over the carbon (10% by weight of the chloride based on carbon was used). The solvent was removed by heating at 120° and hydrogen was used to reduce palladium chloride to palladium at the same temperature. The catalyst was then heated to 200° *in vacuo* for three hours. Upon cooling, nitrogen was admitted and the catalyst transferred to the calorimeter.

In making a run the flow rates of hydrogen and chlorine were arbitrarily chosen with hydrogen being in excess. The heat of reaction was removed by adjusting the nitrogen flow. One and one-half to two hours were required for an isothermal balance. After the balance had been obtained, the exit flow was sent through a collecting tower of 6 *N* potassium iodide to determine the amount of unreacted chlorine. The flow of chlorine was then directed from the calorimeter to a waste line and the hydrogen flow continued through the catalyst chamber for ten to fifteen minutes, electrical energy being substituted for that produced by the reaction. The hydrogen flow was then shut off and the nitrogen flow balanced with electrical energy. The chlorine was then sent through a collecting tower of 3 *N* potassium hydroxide for a definite time to determine the input of chlorine to the calorimeter. The same chlorine flow was used throughout. The amount of chlorine in the sample was determined, after reduction with hydrogen peroxide, by adding an excess of silver nitrate and back-titrating with potassium thiocyanate in the usual way. The analytical procedure was shown to average 0.2% low by analyzing weighed samples of chlorine dissolved in potassium hydroxide.

The results obtained are shown in Table III. Only those runs are included which were carried out after the installation of two pre-catalyst chambers and phosphorus pentoxide drying towers in the hydrogen line. Rossini[16] burned hydrogen and chlorine at constant pressure in a flame calorimeter and obtained heats of formation of HCl(g) to be 22,063 and 22,060 calories per mole at 25 and 18°, respectively. From heat capacity data, the heat of reaction is estimated to be −22,120 calories at 90°. The per cent. deviation of the values listed in Table III from this are given in the last column. The agreement is better than one per cent.

| 6.481 | 3.770 | 97.99 | 16.4164 | 22,246 | + .6 |

**Chlorination of Tetrafluoroethylene.**—Matheson chlorine was used in all experiments. The tetrafluoroethylene,[17] taken from a cylinder, was passed through a purification train consisting of concentrated sulfuric acid, 10% sodium hydroxide, water, and a calcium chloride drying tower followed by phosphorus pentoxide. An ordinary capillary glass flow meter indicated the flow and the gas was then sent directly to the calorimeter.

The catalyst used was 10% by weight of ferric chloride on "Columbia" activated carbon. The carbon was sized to go through no. 6 and retained on no. 20 screens. It was then activated by heating under vacuum at 250°, cooled and mixed with iron powder obtained by reduction. After charging it in the calorimeter, the iron was converted to the chloride by passing chlorine through the chamber for several hours. When no further reaction took place, as indicated by the heat generated, the conversion was assumed to be complete. Antimony chloride catalyst, prepared in the same way, will quantitatively chlorinate the tetrafluorethylene at room temperature.

In making a run, the olefin was used in excess and the amount of reaction was taken as being equal to the amount of chlorine consumed. If the catalyst was active and if the reactants were sufficiently pure, neither chlorine nor hydrogen chloride could be detected in the product gases with fresh starch–potassium iodide and moist litmus paper. Since the carbon catalyst adsorbs considerable amounts of the gases in reaching a steady state, the flows of both reactants were carefully controlled. In starting a run, the flow of olefin and chlorine were arbitrarily set and the ni-

trogen flow adjusted to give isothermal conditions at a steady state. This meant that the energy balance was obtained only at the end of the run. While this energy balance was being taken, the chlorine was directed to the potassium hydroxide tower and a sample collected at the same flow rate as used in the reaction. The amount of chlorine in the sample was determined as described previously.

The products resulting while the calorimeter was at a steady state were condensed in a trap at −80°. Infrared absorption spectra[18] were taken on the first, middle and last fraction of the sample. By comparing the curves so obtained with those given by the pure olefin and dichloride, it was shown that no appreciable amounts of disproportionation or degradation reactions took place on the catalyst. The curves for the pure materials are given in Figs. 3a and 3b.

The data obtained on the chlorination of tetrafluoroethylene are summarized in Table IV. The results are quite reproducible and show that the heat of chlorination of this olefin is considerably greater than that of ethylene which is 43,600 calories.[3]

TABLE IV

HEAT OF CHLORINATION OF TETRAFLUOROETHYLENE AT 90°

| Run no. | Olefin flow, moles/min. × $10^{+4}$ | Chlorine flow, moles/min. × $10^{4}$ | Energy rate, cal./min. | $-\Delta H$, cal./mole |
|---|---|---|---|---|
| 29 | 7.60 | 5.101 | 29.22 | 57,283 |
| 30[a] | 8.25 | 5.77 | 33.04 | 57,262 |
| 31 | 9.04 | 6.071 | 34.86 | 57,420 |
| 32 | 6.93 | 6.109 | 35.02 | 57,325 |

[a] The chlorine flow was read off the flow meter in this case rather than being determined by direct analysis.

(18) The instrument is a model 12B manufactured by the Perkin-Elmer Corporation of Glennbrook, Conn.

**Acknowledgment.**—This work was made possible by a grant from the Research Corporation of New York. A special grant from the Regents of the University of Colorado made possible the purchasing of the infrared spectrometer. We wish to thank Mr. C. Walden and K. Lea for assistance in operating the calorimeter and infrared spectrometer. Mr. D. K. Vail assisted in the preparation of some of the compounds used and Mrs. C. M. Snow carried out the analysis for chlorine. Mr. E. Holderby constructed the calorimeter proper and most of the accessories in the shops of the University of Colorado.

## Summary

An isothermal constant-flow calorimeter is described which is suitable for measuring heats of vapor phase reactions at temperatures up to 90°. By measuring the heat of hydrogenation of cyclohexene and the heat of formation of hydrogen chloride and comparing the results obtained with data existing in the literature, the calorimeter was shown to give heats of reactions to an accuracy of one per cent. The vapor phase heat of chlorination of tetrafluoroethylene was measured to be $\Delta H = -57{,}322 \pm 200$ calories per mole at 90°.

# Reaction Heats of Organic Fluorine Compounds. II. The Vapor Phase Heats of Chlorination of Some Simple Fluoroölefins[1,2]

BY J. R. LACHER, J. J. MCKINLEY, C. WALDEN, K. LEA AND J. D. PARK

In the first paper of this series[2] an isothermal constant flow calorimeter was described. The performance of the equipment was determined by measuring the heat of hydrogenation of cyclohexene and the heat of formation of gaseous hydrogen chloride. New data on the vapor phase chlorination of tetrafluoroethylene were also presented. The present paper deals with the vapor phase heats of chlorination of trifluorochloroethylene, 1,1-dichloro-2,2-difluoroethylene, perfluoropropene and perfluorocyclobutene.

**Preparation of Compounds.**—The trifluorochloroethylene[3] was purified by a low temperature distillation in a vacuum-jacketed column packed with glass helices using a magnetic take-off head and a reflux ratio greater than 5 to 1. The still head was cooled by circulating a carbon tetrachloride–chloroform–Dry Ice mixture from a reservoir at such a rate as to maintain about a 20° differential between the still head and the boiling point of the olefin. A forecut was discarded and the center fraction having a boiling point variation of less than 0.1° was collected and stored in a steel cylinder for subsequent use. The infrared absorption spectrum is shown in Fig. 1a. Using auxiliary equipment, a sample of the chlorine adduct of trifluorochloroethylene was prepared. A flow system identical with that used in the calorimeter was employed and the chlorination was carried out in the presence of ferric chloride–impregnated carbon catalyst previously described. After distillation, the product, 1,1,2-trifluoro-1,2,2-trichloroethane, gave an absorption spectrum as shown in Fig. 1b. The isomer of this compound,[3] 1,1,1-trifluoro-2,2,2-trichloroethane, gives an absorption spectrum as shown in Fig. 1c. By studying the spectrum of the product formed in an actual calorimetric run, it was concluded that little or no disproportionation occurred on the catalyst. However, if the olefin was not pure, the absorption spectrum of the calorimeter product was not a combination of those shown in Figs. 1a and 1b. Instead, anomalous absorption peaks appeared at 6.50 and 11.77 $\mu$, hydrochloric acid was in the effluent gases and the heat of reaction was low. The trouble was overcome by scrubbing the olefin in the purification train described in Paper I of this series.[2] The 1,1-dichloro-2,2-difluoroethylene and perfluoropropene[3] were passed through the purification train and then sent directly to the calorimeter. The infrared absorption spectra of 1,1-dichloro-2,2-difluoroethylene and its chlorine adduct, 1,1,1,2-tetrachloro-2,2-

difluoroethane, are given in Figs. 2a and 2b, respectively. The absorption spectra of perfluoropropene and its chlorine adduct are given in Figs. 3a and 3b, respectively.

The perfluorocyclobutene was prepared[4] by dimerization of trifluorochloroethylene followed by subsequent removal of two chlorine atoms by alcoholic zinc.[5] The olefin was purified by distillation in a modified Podbielniak column packed with glass helices using a reflux ratio of about 15 to 1. The forecut was discarded and the center cut, having a boiling point constant to 0.1°, was collected and stored in a steel cylinder for subsequent use. The olefin was also sent through the scrubbing train before entering the calorimeter. The infrared absorption spectrum is shown in Fig. 4a. The absorption spectrum and freezing point of the chlorine adduct depend on how the material is prepared.[6] The absorption spectrum of the compound produced by catalytic chlorination at 90° is shown in Fig. 4b and is probably a mixture of *cis–trans* isomers.

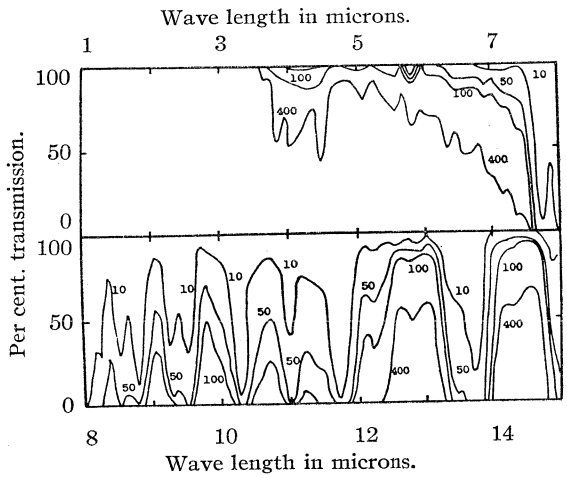

Fig. 3B.—Infrared absorption spectrogram of $CF_3$—$CFCl$—$CF_2Cl$ gas in 10-cm. cell and ind. mm. pressure.

**Experimental Results.**—The procedure used in making a run was similar to that described in Paper I[2] for the chlorination of tetrafluoroethylene. The chlorine was mixed in the catalyst chamber with an excess of olefin. The product gases were tested for unreacted chlorine and the presence of hydrogen chloride. They were found to be absent. In the case of trifluorochloroethylene some difficulty was experienced in obtaining products free of hydrogen chloride and with perfluorocyclobutene a high olefin to chlorine ratio was necessary to ensure complete reaction.

New reagents were used in the scrubbing train whenever the olefin was changed; a new catalyst, however, was not always used. The products of a previous run were thoroughly removed by displacement with dry nitrogen until no organic fluorine compounds could be detected in the effluent. The catalyst chamber was then evacuated for several hours and the system then filled with nitrogen.

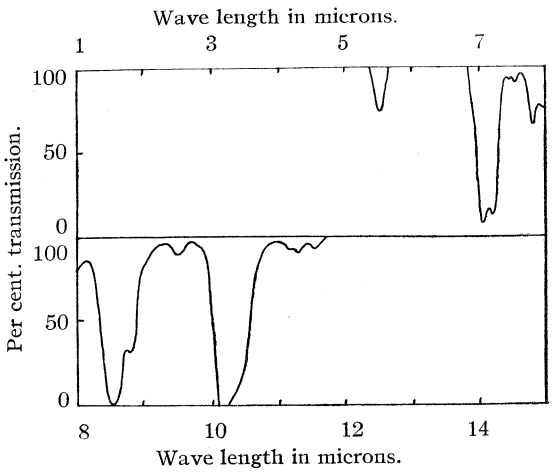

Fig. 4A.—Infrared absorption spectrogram of $CF_2{=}CF{-}CF{=}CF_2$ gas at 10 mm. pressure, room temperature and in 10-cm. cell.

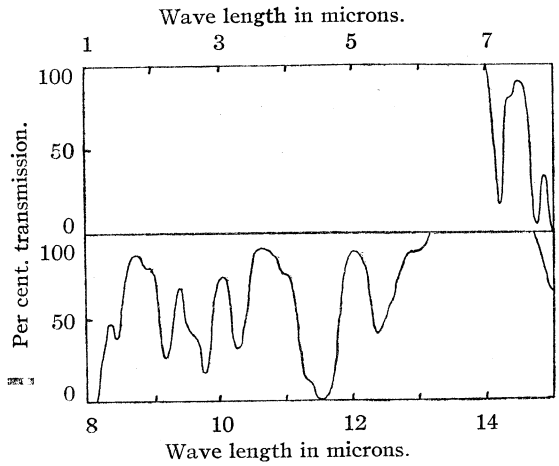

Fig. 4B.—Infrared absorption spectrogram of $CF_2{=}CFCl{-}CFCl{-}CF_2$ gas at 11 mm. pressure, in 10-cm. cell at room temperature, thermal chlorination.

After the catalyst had reached a steady state, the products were collected for thirty minutes or more in a Dry Ice-trap and reserved for infrared analysis. Two separate series of infrared spectra were obtained from each of the runs. The first was obtained by drawing off at $-80°$ a vapor sample into the absorption cell. This sample was run at several pressures necessary to obtain absorption peaks. This foreshot was rich in olefin and should have contained the low boiling impurities, if present. The second series of spectra were run after distilling off most of the olefin and then taking a sample. This tail fraction consisted mainly of the chlorine adduct and should have any high boiling impurities, if present. The analysis was again carried out at several pressures. Slight amounts of impurities would be detected at the higher pressure runs and the low pressure anal-

ysis served to identify the olefin and chlorine adduct. A comparison of the spectra so obtained with those shown by the purified olefin and chlorine adduct showed the presence of no new bands. Since some of the bands given by fluorocarbons are very intense, we believe that any undesirable side reactions, if they took place at all, were less than 0.2%.

The results obtained on chlorinating the four olefins at 90° are summarized in Table I. All of the experiments are reported except in the case of trifluorochloroethylene. Many experiments using this compound served merely in developing the technique of handling the calorimeter, purification method for the olefin and the method of analysis for the chlorine sample. In this case only the last three runs are included. It is believed that the average values for the vapor phase heats of chlorination are reliable to about 1%.

## Discussion of Results

The vapor phase heats of chlorination obtained to date are summarized in Table II. Also included in the table is the heat of chlorination of ethylene as determined by Kistiakowsky and coworkers.[7] It is apparent that for this series of reactions there are strong deviations from the additivity rule. The heat of chlorination of tetrafluoroethylene is 20 kcal. greater than that of perfluorocyclobutene. When one fluorine in tetrafluoroethylene is replaced by chlorine, the reaction heat drops 8.5 kcal. When two are replaced on the same carbon, the heat drops by 16.2 kcal. or just twice. If the fluorine in tetrafluoroethylene is replaced by a $CF_3$–group, the heat drops by 10.1 kcal. and the $CF_3$– group has a greater effect than a chlorine atom. In this case, one of the added chlorine atoms is on a carbon containing a $CF_3$– group and a fluorine atom and is, therefore, "secondary." When chlorine adds to perfluorocyclobutene, both the chlorine atoms go into secondary positions. The lowering of the heat is 19.9 kcal. or just twice that shown by perfluoropropene. Systematic generalizations concerning the deviations from the additivity rule will, of course, have to wait upon further experimentation.

TABLE II

VAPOR PHASE HEATS OF CHLORINATION

| Compound | $-\Delta H_{363}$, cal./mole |
|---|---|
| $CF_2{=}CF_2$ | 57,323 |
| $CF_2{=}CFCl$ | 48,815 |
| $CF_2{=}CCl_2$ | 41,076 |
| $CF_2{=}CF{-}CF_3$ | 47,149 |
| $\begin{matrix} CF_2{-}CF \\ \vert \quad \Vert \\ CF_2{-}CF \end{matrix}$ | 37,376 |
| $CH_2{=}CH_2$[a] | 43,600 |

[a] Reference 7.

The calorimetric studies of Swarts[8] show that rather large deviations from the additivity rule are to be expected. For the series ethyl alcohol, monofluoroethanol and difluoroethanol, his data show that 9 kcal. more heat is liberated when a second hydrogen is replaced by fluorine than obtains for the first one. The difference in stability of the –CHF– and $-CF_2-$ groups is accounted for by thermochemical data. The same is true for the reactions studied here.

**Acknowledgment.**—This work was made possible by a grant from the Research Corporation of New York.

## Summary

The vapor phase heats of chlorination of trifluorochloroethylene, 1,1-dichloro-2,2-difluoroethylene, perfluoropropene and perfluorocyclobutene have been measured at 90°. The heats of these reactions deviate strongly from the additivity rule.

# The Volatilization of Beryllium Oxide in the Presence of Water

BY CLYDE A. HUTCHISON, JR.,[1a] AND JOHN G. MALM

## Introduction

It has been noted by many observers[1b] in connection with the use of beryllium oxide as a refractory that: (a) under certain conditions it is quite volatile at temperatures as low as 1800° as evidenced by weight losses; (b) that firing of beryllium oxide produces relatively rapid vapor phase transfer at temperatures as low as 1500° as shown by changes in individual crystals; (c) that beryllium oxide condenses in the cooler portion of furnaces with maximum temperatures not in excess of 1800°. Similar phenomena were noted in this Laboratory[2] under conditions involving the presence of water in the vapor phase. The data of Erway and Seifert,[3] however, showed equilibrium vapor pressures of beryllium oxide too low to account for the observed rates of volatilization ($3.2 \times 10^{-8}$ mm. at 1500° and $1.5 \times 10^{-4}$ mm. at 1800°). Their vapor pressure data are also inconsistent with the phenomena mentioned in (a), (b) and (c). We have performed experiments showing that the volatilization is due to the presence of water in the gas in contact with the beryllium oxide. A reaction with the water results in the formation of a volatile compound which condenses at lower temperatures with decomposition to beryllium oxide. Previous studies on the BeO–$H_2O$ system in a lower temperature range have been made by HaldunTerem[4] and Hackspill and Kieffer.[5]

## Experimental Description

Pure beryllium oxide half cylinders weighing ~2 g. and ~19 mm. in diameter and ~8 mm. in altitude, of density 2.38 g. cc.$^{-1}$ were prepared by bisecting fired pellets made from a pressed dry paste by adding 0.5 cc. of 6 *M* nitric acid to 5 g. of 200-mesh Brush high fired beryllium oxide powder. This beryllium oxide powder was of high purity. Spectrographic analyses on the samples taken gave these results in p.p.m.

| Fe | Mg | Mn | Si |
|---|---|---|---|
| 50 | 50 | <2 | <500 |

More extensive spectrographic analyses on a similar sample of beryllium powder gave the results shown, in p.p.m.

| Ag | Ba | Ca | Cd | Co | Cr | Cu |
|---|---|---|---|---|---|---|
| <10 | <100 | 100 | 0.5 | <10 | <10 | 50 |
| Fe | Li | Mg | Mn | Na | Ni | |
| 400 | <20 | 100 | 5 | 300 | <100 | |
| Pb | Si | Sn | Ti | V | Sb | |
| 10 | 100 | <10 | 100 | <500 | <200 | |

The pellets were fired at 1650° for one hour. When such samples were placed in a platinum boat in a mullite tube and water at ~1 atm. passed through the tube, the per cent. weight losses listed in Table I were observed in the temperature range 1483–1528°.

TABLE I

| Time, hours | 4.13 | 6.80 | 10.80 | 15.05 |
|---|---|---|---|---|
| Weight loss, % | 1.7 | 5.6 | 10.3 | 13.3 |

Condensation of beryllium oxide crystals in the form of a white cotton-like mass in the cooler portion of the tube and on the downstream side of the sample was observed. This material was shown to be nearly pure beryllium oxide by X-ray examination by W. H. Zachariasen.

Similar experiments were then performed with nitrogen–hydrogen mixtures passing over the sample at ~1 atm. and in stagnant air with no measurable volatilization of the beryllium oxide.

In a series of similar experiments[6] with water at 1 atm. the effect of temperature (shown in Table II) was observed when the water was passed over the samples at a rate of 0.11 mole min.$^{-1}$ in a tube of 3.6 cm. inside diameter.

TABLE II

| Temperature, °C. | 1000 | 1250 | 1400 | 1500 | 1550 |
|---|---|---|---|---|---|
| BeO lost in 2.5 hr., % | 0.01 | 0.19 | 0.66 | 1.58 | 2.24 |

Similar experiments performed with samples of magnesia and beryl resulted in no measurable volatilization.

## Conclusions

1. The presence of water vapor in contact with beryllium oxide results in its relatively rapid volatilization at temperatures at which the vapor pressure of beryllium oxide is too low to account for the observed rates.

2. Reaction of water with beryllium oxide results in the formation of a volatile compound at temperatures of 1250° or greater. This volatile substance condenses with decomposition to beryllium oxide.

The reported observations (a, b and c) may be

# The Distillation of Mixtures Containing Diborane and the Identification of Two Azeotropes

BY LEWIS V. MCCARTY[1]

Depending upon the method of manufacture diborane may be contaminated with hydrogen halides, boron halides and ethane. Thus in Schlesinger's[2] and Stock's[3] methods of preparation hydrogen chloride and boron trichloride, and hydrogen bromide and boron tribromide are possible contaminants. In Schlesinger's later preparation[4] ethane might also contaminate the diborane. In other reactions described by Hurd[5] boron trifluoride as well as boron trichloride and hydrogen chloride may be impurities. A knowledge of the various possible mixtures of diborane with these materials becomes important both for the purification of diborane and the analytical distillation of the products of the reactions.

## Experimental

**Apparatus.**—The apparatus used to perform the distillations was the Automatic Recording Low Temperature Fractional Distillation Apparatus, Hyd Robot Model, Serial No. H 576, manufactured by the Podbielniak Centrifugal Super Contactor Company. The entering stopcock of the "Super Cool" column was attached to a vacuum line that was equipped with bulbs of known volume. This part of the system was not thermostated, and all measurements of the gases entered into the column were made at room temperature. All values reported in the tables, however, have been reduced to 0° and 760 mm. Samples were mixed in the column by entering each gas separately. No van der Waals corrections were applied to any of the gases. The time under total reflux was ordinarily about thirty minutes to one hour long.

**Chemical Analysis.**—In Expt. 1 of Table I a chemical analysis was made for hydrogen chloride. This was accomplished by freezing a known volume of the gases into a sample bulb and then expanding through two bubblers of distilled water. A slow stream of dry nitrogen was used to prevent water from sucking back into the sampling bulb. The water was analyzed for hydrogen chloride by titration with a sodium hydroxide solution to a methyl orange end-point.

**Materials.**—The hydrogen chloride and diborane used in Expt. I, Table I, were distilled and only the middle cuts were saved. All boron trichloride was distilled prior to use. The diborane, ethane and boron trifluoride of Tables III and IV were distilled before use. All other hydrogen chloride and diborane as well as the hydrogen bromide came from tanks in which the impurities were known to be mainly gases not condensable in liquid nitrogen. Accordingly, the purification procedure for these samples was to freeze some gas into a bulb in liquid nitrogen, and then pump on the bulb.

## Results

**The System Hydrogen Chloride–Diborane.**—A few preliminary runs (not reported here) with rather impure materials served to indicate that an azeotrope was formed having the approximate composition 26–30% hydrogen chloride and 70–74% diborane. This material boiled at about −94° at 760 mm., 1.5° lower than the value for diborane, −92.5°.

In order to get an accurate value for the composition of the azeotrope at 760 mm., samples of distilled hydrogen chloride and diborane were used in Expt. 1 of Table I. It will be noticed that in this experiment the difference between the total volume of gas used and that found is only 2 cc. in 4,934. This is fortuitous as will be found by an inspection of other data in this and subsequent tables. Sometimes less and sometimes more gas was found than was originally used. This is attributed to solution and possibly reaction in some cases with the stopcock grease of the Podbielniak apparatus. Apiezon L was the lubricant used. In making calculations on azeotrope composition, it is convenient to have the total volumes found agree with the total volumes used. If there is a discrepancy, it is assumed to be due to the causes mentioned, and the volumes found are pro-rated with an appropriate factor to bring them into agreement with the volumes used. It is then a simple matter to make the azeotrope composition calculations. The value for the azeotrope at 755 mm. was found to be 29.9% hydrogen chloride on a molar basis. When 1984 cc. of the azeotrope at S.T.P. was analyzed for hydrogen chloride in water solution,[6] 0.957 g. of hydrogen chloride was found. This corresponds to 29.6 mole per cent. in the azeotrope.

Experiments 2, 3 and 4 of Table I are determinations of the azeotrope composition at a lower pressure (205–208 mm.). The average of the three determinations of the composition is 26.2% hydrogen chloride and 73.8% diborane. The boiling point of the azeotrope at 207 mm. is about −114.5°, whereas for pure diborane at 207 mm. the boiling point is −113°.

TABLE I

THE SYSTEM HCl–$B_2H_6$

| Expt. | HCl used, cc. | $B_2H_6$ used, cc. | Azeotrope found, cc. | B. p. of azeotrope, °C. | HCl found, cc. | B. p. of HCl, °C. | Dist. pres., mm. | % in azeotrope HCl | % in azeotrope $B_2H_6$ |
|---|---|---|---|---|---|---|---|---|---|
| 1[b] | 2470 | 2464 | 3513 | − 94 | 1419 | − 85 | 755 | 29.9[a] | 70.1 |
| 2[c] | 939 | 1142 | 1523 | −115.5 | 512 | −106 | 205 | 26.7 | 73.3 |
| 3[b] | 1106 | 1242 | 1646 | −114.5 | 674 | −105.5 | 207 | 25.5 | 74.5 |
| 4[b] | 1004 | 1244 | 1666 | −114.5 | 554 | −105.5 | 208 | 26.3 | 73.7 |

[a] 1984 cc. of azeotrope analyzed for hydrochloric acid by solution in water and titration, 29.6% of hydrochloric acid on a molar basis. [b] HCl entered into column first. [c] $B_2H_6$ entered into column first.

**The System Boron Trichloride–Diborane.**—Data for the single experiments on this system are: cc. $B_2H_6$ used, 1262; cc. $B_2H_6$ found, 1280 b. p. −93.5°, 750 mm.; cc. $BCl_3$ used, 1173; cc. $BCl_3$ found, 1183, b. p. +11.5°, 750 mm. The data on the gas found as compared to that put into the distillation column checks sufficiently closely so that an azeotrope probably does not exist.

**The System Hydrogen Chloride–Boron Chloride.**—Although this system does not include diborane, it was considered important because of the ternary system which follows: cc. HCl used, 1274; cc. HCl found, 1271, b. p. −85.5° 754 mm.; cc. $BCl_3$ used, 934; cc. $BCl_3$ found, 945, b. p. +11.5°, 754 mm. Somewhat more $BCl_3$ was found than used to make up the sample, but the amount is within the experimental error.

**The System Hydrogen Chloride–Diborane–Boron Trichloride.**—The data for this ternary system are: cc. $BCl_3$ used, 1208; cc. $BCl_3$ found, 1228, b.p. +12.5°, 752 mm.; cc. $B_2H_6$ used, 1249; cc.* azeotrope found, 1782, b.p. −95.5°, 752 mm.; cc. HCl used, 1246; cc. HCl found, 713, b.p. −85.5°, 752 mm. (*Composition from these data, 29.9% HCl, 70.1% $B_2H_6$.) There was slightly more boron trichloride found than used, but again this is most likely to be experimental error. It does not apparently form a ternary azeotrope with the other components, nor does it influence the composition of the hydrogen chloride–diborane azeotrope.

| 5[b] | 618 | 590 | 127 | 116 | −120.5 | −117.5 | 99 |
| 6[b] | 740 | 744 | 132 | 114 | −121.5 | 118.5 | 100 |

[a] $C_2H_6$ entered into column first. [b] $B_2H_6$ entered into column first.

**The System Hydrogen Bromide–Diborane.**—The conclusion drawn from the data presented in Table II is that no azeotrope exists at the pressures studied. The system is somewhat difficult to study because of the relatively high melting point of the hydrogen bromide, −86°.

**The System Diborane–Ethane.**—Table III presents the data for the distillation of known samples of diborane–ethane. Experiment 1 does not show very good agreement between the amount of materials used and found in the analysis. This was blamed on insufficient reflux time rather than on the formation of an azeotrope. Accordingly, two hours of reflux time was allowed before taking off any gas from the top of the distillation column in all other experiments. There does not seem to be any general trend dependent upon which liquid, ethane or diborane, wets the packing of the column first. There does not seem to be any trend dependent upon the size of the sample or the ratio of diborane to ethane. The conclusion drawn is that there is no azeotrope in the system.

**The System Diborane–Boron Trifluoride.**—For the experiments of Table IV a total reflux time of two hours was allowed before any gas was taken off the top of the distillation column. As can be seen from the data the composition of the azeotrope formed is reasonably constant regardless of which material is in excess or entered into the column first. The average of the three

values determined is 41.6% diborane and 58.4% boron trifluoride, and the boiling point at atmospheric pressure is about −106°.

## Summary

The systems $HCl-B_2H_6$, $B_2H_6-BCl_3$, $HCl-BCl_3$, $HCl-B_2H_6-BCl_3$, $HBr-B_2H_6$, $B_2H_6-C_2H_6-C_2H_6$ and $B_2H_6-BF_3$ have been studied.

An azeotrope containing 70.1% $B_2H_6$ and 29.9% HCl and boiling at −94° at atmospheric pressure has been identified. The presence of $BCl_3$ does not affect the $HCl-B_2H_6$ azeotrope.

An azeotrope containing 41.6% $B_2H_6$ and 58.4% $BF_3$ and boiling at −106° at atmospheric pressure has been identified.

None of the other systems studied show azeotrope formation.

# Ultraviolet Absorption Spectra of Nicotine, Nornicotine and Some of Their Derivatives

BY MARGARET L. SWAIN, ABNER EISNER, C. F. WOODWARD AND B. A. BRICE

Nicotine and its analog, nornicotine, and the myosmines and nicotyrines derived from them as dehydrogenation products, represent interesting examples of series of compounds possessing progressively increasing conjugated unsaturation of the cyclic type. Characteristic and similar ultraviolet absorption spectra for the two parent compounds and for the pairs of analogs obtained at each successive dehydrogenation step may therefore be expected. Such spectra determined on preparations of high purity should be useful as a means of further characterizing the compounds, provide a test of the correctness of assigned structures, and furnish a possible method of assay and analysis. Although the increasing practical importance of nicotine has prompted an intensive study of the chemistry of the alkaloid and its derivatives during recent years, no spectroscopic studies using modern photoelectric instruments have been reported. The only available absorption curves are those for nicotine published by Purvis[2] and Dobbie and Fox[3] and others during the early years of the century. A systematic determination of the ultraviolet spectra of pure preparations of nicotine, nornicotine, their dehydrogenated derivatives, and a few related compounds has therefore been carried out.

The wave length positions of the clearly defined maxima and minima occurring in the spectra of the compounds in a number of solvents and the specific extinction coefficients at these maxima and minima are listed in Table I. Molecular extinction coefficients at the maxima are also listed to permit comparison on a molar basis. Absorption curves for all the compounds in 95% ethanol solution and for representative compounds in acidified 95% ethanol are shown in Figs. 1 to 9.

(1) One of the Laboratories of the Bureau of Agricultural and Industrial Chemistry Agricultural Research Administration, United States Department of Agriculture. Article not copyrighted.

(2) Purvis, *J. Chem. Soc.*, **97**, 1035 (1910).

(3) Dobbie and Fox, *ibid.*, **103**, 1193 (1913).

As might be expected, the absorption curves of nicotine (A, Fig. 1) and nornicotine (A, Fig. 5) are almost identical in shape and in position of maxima and minima. The observed difference in specific extinction coefficients is apparently entirely due to the diluent effect of the methyl group occurring on the pyrrolidine ring of nicotine; on a molecular basis the extinction coefficients are nearly identical. The spectra of nicotine and nornicotine show the close relationship to the ultraviolet spectrum of pyridine (A, Fig. 2) that was to be expected. Differences between the curves of the alkaloids and that of pyridine, namely, a bathochromic shift of about 5 mμ in the position of the chief maximum, an elevation in molecular extinction coefficient, and a loss in fine structure, are of the kind to be anticipated as a result of substitution of the pyrrolidine ring on the pyridine nucleus. Addition of acid produces similar exaltations of the absorption maxima, depressions of the minima, and loss of fine structure in nicotine (B, Fig. 1) and nornicotine (A, Fig. 7) as it does in pyridine (B, Fig. 2).

Introduction of an additional double bond in conjugation with the pyridine ring as in myosmine (B, Fig. 5) results in a further shift of the pyridine absorption to longer wave lengths, accompanied by the appearance of a new strong, structureless band at 234 mμ. Presumably this latter band represents the bathochromic shifting through conjugation of the pyridine absorption normally lying below 200 mμ. An ever greater shift toward the red is exhibited in the spectrum of metanicotine (A, Fig. 4), in which the pyrrolidine ring has been opened and the introduced unsaturation conjugated with the pyridine nucleus occurs in an open chain. As is generally the case, the conjugation of ring and open chain unsaturation possessed by metanicotine also produces a substantially higher intensity of absorption than does the equivalent ring to ring conjugated unsaturation of myosmine. The spectrum of the comparison compound, 3-vinylpyridine (A, Fig. 6),

TABLE I

[a] Specific extinction coefficient, $k$, is the spectral density of a solution of thickness 1 cm. and concentration 1 g. per liter compared with 1 cm. of solvent. [b] Molecular extinction coefficient, $\epsilon$, is equal to $kM$, where $M$ is the molecular weight. [c] 95% ethanol containing 0.045 mole of hydrochloric acid per liter. [d] 0.045 molar hydrochloric acid. [e] Chief maximum and minimum, respectively.

which possesses the ring to open chain type of conjugation, therefore resembles that of metanicotine in location and intensity of absorption maxima more closely than it does that of myosmine.

The spectrum obtained on introduction of a >C=O group in conjugation with the pyridine nucleus, as exemplified by the comparison compound 3-pyridyl methyl ketone (B, Fig. 6), is similar to that obtained on introduction of >C=C< conjugation. No gross differences are found, therefore, between the spectrum of myosmine in neohexane and that in water, in which it exists at least in part in a hydrolyzed ketonic form. The changes produced in the spectra of compounds containing the pyridine nucleus conjugated with >C=C< and those containing the pyridine nucleus conjugated with >C=O on acidification are, however, markedly different. Thus the spectra of metanicotine (B, Fig. 8) and vinylpyridine (A, Fig. 9) on acidification undergo bathochromic shifts resulting in each case in a displacement of the two original bands by 7 to 10 mμ and the appearance of a new strong band at about 220 mμ. Acidification of pyridyl methyl ketone (B, Fig. 9) and myosmine (A, Fig. 8) on the contrary leads to hypsochromic shifting of the two original maxima, with an increase in intensity of the longer wave length band and a decrease in the intensity of the other.

A spectral curve similar to that of myosmine was expected from its methylated analog, "N-methylmyosmine," whose structure had been chemically established by Späth, Wibaut and Kesztler[4] as 1-methyl-2-(3-pyridyl)-2,3-pyrroline.

Wave length, mμ.

"N-Methylmyosmine" (B, Fig. 4) as prepared by the accepted method of partially hydrogenating nicotyrine, however, had an absorption curve essentially identical with that of nicotine rather than with that of myosmine. Apparently in this compound no conjugation of the pyridine nucleus with a double bond in the dehydrogenated pyrrolidine ring exists. Some evidence for the existence of a greater degree of non-conjugated unsaturation than that occurring in nicotine is indicated by the heightened end absorption encountered in the neighborhood of 210 mμ. The observed results can be explained if it is assumed that in the preparation of "N-methylmyosmine" by the partial hydrogenation of nicotyrine, the hydrogen is added 1,4 rather than 1,2. The product of 1,4 addition would be a compound having a double bond in the 3,4 position of the methylpyrroline ring and possessing the observed absorption characteristics. The spectroscopic results suggest that further chemical studies should be made.

The absorption curves of nicotyrine (C, Fig. 4) and nornicotyrine (C, Fig. 5), both of which contain a pyrrole ring in conjugation with the pyridine nucleus, are similar in shape and in the wave length positions of maxima and minima. Conjugation of the pyridine nucleus with a doubly conjugated system results in further shifting of the absorption toward the red and complete loss of the fine structure associated with the pyridine ring. The large differences in the extinction coefficients at the maxima observed between nicotyrine and nornicotyrine are probably to be expected, since in these compounds the methyl substituent differentiating nicotine and nornicotine is intimately associated with the chromophore. Acidification of these compounds, for example (B, Fig. 7), leads to further bathochromic shifts in absorption, accompanied by an increase in intensity, particularly of the low wave length band.

In benzoylmyosmine the hydrogen of the secondary amine group of myosmine has been replaced by the benzoyl group, but the added aromatic unsaturation is not in conjugation with the myosmine chromophore. The observed spectrum (B, Fig. 3) is related to that of myosmine but is modified by the additive and interacting effects of the two absorbing groups. A similar effect is encountered in the spectrum of 3-pyridyl-ω-benzamido ketone (A, Fig. 3), which contains isolated pyridyl ketone and benzoyl chromophores.

The observed ultraviolet absorption spectra of nicotine, nornicotine and those of their derivatives which possess additional conjugated unsaturation are characteristic and intense enough to afford a means of identification and characterization of these compounds and to provide a rapid method for the assay of crude preparations. Detection and determination of the more highly unsaturated compounds in nicotine or nornicotine preparations are possible, although not extremely sensitive. Satisfactory analysis of partially purified fractions such as those obtained in the pyrolysis of nicotine should, however, be possible. Ultraviolet spectrophotometry cannot be used to distinguish between nicotine and nornicotine or between the various dehydrogenated derivatives possessing equivalent degrees of conjugated unsaturation.

The impossibility of distinguishing between nicotine and nornicotine is a drawback common to both ultraviolet spectrophotometry and the chemical precipitation method generally used for the determination of nicotine. Determination of nicotine by ultraviolet spectrophotometry in solutions or concentrates derived from natural products which contain both alkaloids but are essentially free of other interfering absorbers may therefore be expected to yield results in agreement with those obtained by the chemical method. Preliminary tests have shown that this expectation is realized and that generally good agreement exists between the percentages of nicotine found by the two methods. The results of a study now in progress to determine the applicability of the spectrophotometric method to the estimation of nicotine in a variety of sample types will be published shortly.

## Experimental

The spectra were obtained with a Beckman Model DU Spectrophotometer with slit widths corresponding to approximately 1.5 mμ in the 260 mμ region and to 2 mμ in the 230 mμ region for all solvents and for all compounds with the exception of pyridine. Narrowing of the slit was without measureable effect on the location or intensity of the absorption maxima and minima except in the case of pyridine. For determinations on this compound, the narrowest possible slit, corresponding to about 0.6 mμ at 256 mμ, was used. The undenatured 95% ethanol possessed sufficient transparency for use without further purification; the neohexane was purified to suitable transparency by percolation through silica gel. Ethanol was generally acidified by the addition of 3.75 ml. of concentrated hydrochloric acid per liter of solution; higher concentrations exerted no further effect on the spectra of any of the compounds with the exception of pyridine. For the determination of pyridine, the acid concentration used to provide an excess over that required to exert the maximum effect on the spectrum was about 0.2 *M*.

In general, commercial nicotine and some of the fractions derived from it on pyrolysis served as starting materials for the preparation of the pure compounds. Whenever possible, the bases were purified by recrystallizing the picric acid derivatives until further recrystallization did not raise the melting point. The recrystallized base picrates were decomposed by addition of 10% hydrochloric acid, the precipitated picric acid was filtered off, and any small residual amounts of picric acid were removed by extraction of the filtrate with ether. The filtrates were then made strongly alkaline with sodium hydroxide, and the free bases were recovered from them by successive extractions with ether. The ether extracts were dried over anhydrous sodium carbonate, the ether was evaporated off, and the free bases which were left at residues were distilled under reduced pressure in a nitrogen atmosphere. Departures from this scheme of purification were necessary for bases like nicotyrine, whose monopicrates are not readily decomposed by 10% hydrochloric acid. The procedures used in these cases are described in the notes on the preparation of the individual bases which follow.

**Nicotine.**—The commercially available material, rated as 99% alkaloid, was steam distilled through a fractionat-

ing column to separate it from nornicotine. The steam volatile product was purified by the general method described above. The recrystallized picrate had a melting point of 224–225°, and the boiling point of the free base recovered from it was 93.2° (2 mm.) and $n^{25}D$ 1.5278.

*dl*-**Nornicotine.**—A sample of myosmine obtained from the pyrolysis of nicotine[5] was hydrogenated to nornicotine, with palladous oxide as catalyst.[6] The *dl*-nornicotine was recovered from the mixture as picrate and purified by the general procedure. The recrystallized picrate had a melting point of 193° and yielded a free base boiling at 91.5° (0.4 mm.) and having $n^{25}D$ 1.5469.

**"N-Methylmyosmine" (Dihydronicotyrine).**—Nicotyrine (see below) was subjected to the zinc–hydrochloric acid reduction procedure of Wibaut and Hackman.[7] The resulting dihydronicotyrine was recovered as the dipicrate and purified in the usual manner. The recrystallized dipicrate had a melting point of 162–163° and yielded a free base boiling at 99° (2.3 mm.) and having $n^{25.5}D$ 1.5358.

**Myosmine.**—This base was prepared from a freshly distilled myosmine fraction obtained on pyrolysis of nicotine. The general scheme of purification was employed to secure the pure base. The recrystallized dipicrate had a melting point of 184–185° and the free base recovered from it boiled at 118° (3.2 mm.).

**Nicotyrine.**—A distilled fraction of nicotyrine obtained by the catalytic dehydrogenation of nicotine over nickel-impregnated bauxite served as a source of the crude base. Nicotyrine monopicrate is not readily decomposed by cold 10% hydrochloric acid. A new compound, nicotyrine tartrate dihydrate, which is more easily decomposable was used in the purification of the base. After recrystallizing from water and drying in a vacuum desiccator, a sample of nicotyrine tartrate[8] melted at 105–106° and had the analysis: C, 48.61; H, 5.88; N, 8.10; calcd. for $C_{10}H_{10}N_2 \cdot H_2C_4H_4O_6 \cdot 2H_2O$: C, 48.84; H, 5.81; N, 8.14.

Nicotyrine tartrate was prepared by treating nicotyrine with an equal weight of tartaric acid dissolved in the least amount of hot 95% ethanol. The precipitated product after five recrystallizations from 95% ethanol, had a melting point of 105–106°. The purified nicotyrine tartrate was dissolved in water and the solution made strongly alkaline with sodium hydroxide to liberate the base, which was then extracted with ether; b. p. 117° (1.2 mm.), $n^{24.5}D$ 1.6138.

**Nornicotyrine.**—The base was prepared from pure myosmine by catalytic dehydrogenation with palladium black.[9] Since nornicotyrine picrate is not readily decomposed by the usual method, an alternative procedure suggested by Burger[10] for obtaining the free base from its picrate was tried. In this modification, lithium hydroxide is used as the alkali, so that any remaining picric acid is supposedly present in the aqueous phase as the soluble lithium salt during extraction of the liberated base with ether. However, poor results were obtained on application of this procedure to the recovery of nornicotyrine from its picrate. Nornicotyrine was therefore purified by recrystallization of the base itself from a benzene–petroleum ether mixture. The purified base so obtained had a melting point of 99–101°.

**Metanicotine.**—Metanicotine was prepared by Löffler and Kober's[11] modification of Pinner's[12] original method with one change, namely, the unreacted nicotine was removed by fractional vacuum distillation from the final product rather than from the N-methylbenzoyl-3-pyridylchlorobutylamine in the early stages of the preparation. The product so obtained gave a picrate which, after several recrystallizations, had a melting point of 170–171° instead of 163°, as reported by Pinner. The metanicotine was further characterized by catalytic reduction to dihydrometanicotine, as described by LaForge.[13] The base recovered from the recrystallized picrate had a boiling point of 141° (3.7 mm.) and $n^{25}D$ 1.5540.

**N-Benzoylmyosmine and 3-Pyridyl-ω-benzamidopropyl Ketone.**—These compounds were prepared by the same methods and possessed the same constants as those described in an earlier paper.[6]

**3-Vinylpyridine.**—The starting material for this base was a crude vinylpyridine obtained as one of the low-boiling pyridine-base fractions from the pyrolysis of nicotine. The base was purified as the picrate by the general method. The recrystallized picrate had a melting point of 144° and yielded a base having a boiling point of 162° and $n^{25}D$ 1.5370.

**3-Pyridyl Methyl Ketone.**—This ketone was prepared by the method described by LaForge[13]; b. p. 217–221°, $n^{25}D$ 1.5250.

## Summary

The ultraviolet absorption spectra of nicotine, nornicotine, and some of their derivatives have been determined in a number of solvents and found to bear the expected relationship to the spectrum of pyridine. Progressive hyperchromic and bathochromic effects were exhibited by the increasingly unsaturated members of the series derived from each of the parent compounds by dehydrogenation, with the exception of "N-methylmyosmine," which had a spectrum incompatible with the structure assigned to it. A few potential applications of the spectra to problems of analysis and assay are suggested.

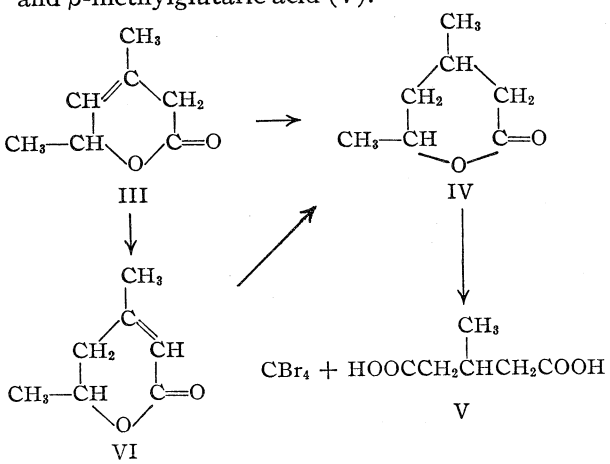
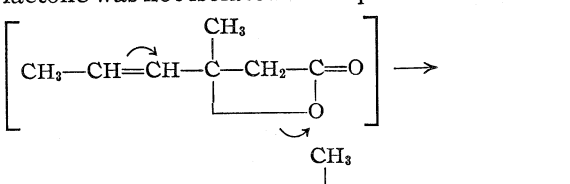
# The Reaction of Ketene with Unsaturated Ketones

BY FRANK G. YOUNG



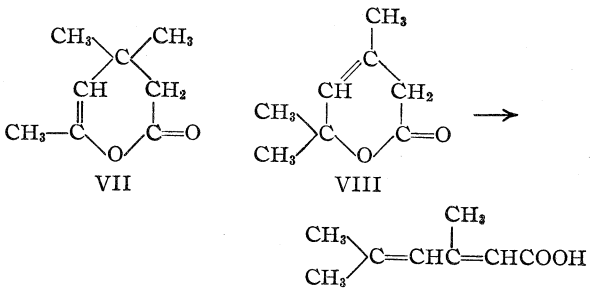
Recent patents have described the reaction of ketene with saturated aldehydes and ketones giving $\beta$-lactones[1] and $\alpha,\beta$-unsaturated acids.[2] The reaction of vinyl methyl ketone with ketene was described in patents[3,4] by Hopff and Rapp. This reaction was carried out in absence of catalyst and the product was described as a $\gamma,\delta$-unsaturated lactone (I) which was easily hydrolyzed, by water or aqueous alkali, to a $\delta$-keto acid (II). The over-all equation



I II

proposed[3] presumably involves a 1,4-addition of ketene to the unsaturated system.

Because of the widespread physiological activity of unsaturated lactones,[5] it was of interest to determine if $\beta$-alkyl vinyl methyl ketones would undergo similar condensation with ketene. In contrast to its reaction with vinyl methyl ketone, no reaction between ketene and $\beta$-alkyl vinyl methyl ketones could be produced in the absence of a catalyst, but a trace of boron trifluoride or other acidic agent afforded rapid reaction and good yields of unsaturated lactones. The lactone isolated, after neutralization of catalyst, from the condensation of ketene and ethylidene acetone was not of type I, since it remained unchanged on treatment with boiling water, and saponification with aqueous alkalies followed by acidification of the cold solution, produced the same substance as that originally isolated. Presumably the intermediate product of the acidification was an unsaturated acid, which under the experimental conditions rapidly isomerized to the lactone. This eliminated the possibility of a $\beta$-lactone and indicated that the unsaturation was not in the $\gamma,\delta$-position, an observation which was supported by its mode of hydrogenation,[6] and confirmed by reaction with iodine bromide.[7,8,9,10] Distinction among $\Delta^{\alpha,\beta}$, unconjugated, and enol-lactones can be made using this reagent.[7] Since the lactone required approximately one mole of halogen per mole, the $\beta,\gamma$-position of the double bond was indicated. The $\delta$-lactone structure of the molecule (III) was proved by hydrogenation to a saturated lactone (IV), which upon oxidation with alkaline hypobromite solution gave carbon tetrabromide and $\beta$-methylglutaric acid (V).



The production of a $\Delta^{\beta,\gamma}$ rather than a $\Delta^{\gamma,\delta}$ enol-lactone indicated that 1,4-addition of ketene to the ene-one system, $-C=C-C=O$ could not represent the true reaction mechanism. An alternative mechanism involving 1,2-addition of ketene to the carbonyl group of the ketone, producing an intermediate unsatured $\beta$-lactone, analogous to the mechanism proposed for the reaction of ketene with saturated aldehydes,[1] is postulated. The $\beta$-lactone was not isolated in the present work.

The electron-donating effect of the $\gamma$-double bond would be expected to enhance the instability of the $\beta$-lactone ring, and the formation of a doubly unsaturated acid by $\beta$-displacement. The methylsorbic acid would then rapidly equilibrate with its isomeric $\delta$-lactone (III).

Addition of ketene to ethylidene acetone by either of these mechanisms would produce an unsaturated δ-lactone, differing only in the location of the double bond. Support for the latter mechanism was found in the reaction of mesityl oxide and ketene. In this case reaction by 1,4-addition should yield VII, but VIII was formed as proved by its conversion to β,δ-dimethylsorbic acid.

VII VIII

Lactone III may be converted quantitatively to the $\Delta^{\alpha,\beta}$-isomer (VI) by heating it with a trace of an alkaline catalyst. This lactone is unreactive toward the iodine monobromide reagent, and on hydrogenation yields a saturated lactone identical with IV.

Spectrographic examination of the lactones III and VI in *n*-heptane shows a much more intense ultraviolet absorption below 220 mμ for VI, but the distinct maximum at 265 mμ, characteristic of the carbonyl group, is much weakened. Longer wave lengths are about equally absorbed by the two lactones. Molecular extinction values are 115 at 240 mμ, 130 at 265 mμ, 68 at 280 mμ, and 5 at 300 mμ for III; and $\epsilon$ = 267, 108, 60, and 10 at corresponding values for VI. The lactone III is readily soluble to the extent of 5% by volume in *n*-heptane, but VI is less than 2% soluble in the same solvent.

## Experimental[11]

**β-Methyl-$\Delta^{\beta,\gamma}$-δ-hexenolactone (III).**—Into a solution of 800 g. (10.0 moles) of dry ethylidene acetone in 715 g. of anhydrous ether maintained at 0° by external cooling, there was diffused simultaneously 240 g. (5.7 moles) of ketene at the rate of 168 g. per hour and 10 g. of boron trifluoride at the rate of 6.6 g. per hour. Enough 0.5 *N* sodium hydroxide solution to destroy the catalyst was then added. The lower aqueous layer was separated and discarded. After removal of the ether, the residue from the upper layer was distilled. There was obtained 404 g. of unreacted ethylidene acetone and 467 g. (95% based on the ketone consumed) of the unsaturated lactone (III), b. p. 85° (5 mm.); sp. gr. $^{20}_{15.6}$ 1.043; $n^{30}D$ 1.4640. *Anal.* Calcd. for $C_7H_{10}O_2$: C, 66.6; H, 8.0; sapn. equiv., 126.2. Found: C, 66.4; H, 8.0; sapn. equiv., 126.0.

**Saponification of β-Methyl-$\Delta^{\beta,\gamma}$-δ-hexenolactone (III).**—Eighty-seven grams of the lactone was stirred with 350 ml. of 10% aq. sodium hydroxide at 20° until solution was complete. The clear solution was acidified with 75 ml. of concentrated hydrochloric acid, and the oil which separated was distilled, b. p. 85° (5 mm.); sp. gr. $^{20}_{15.6}$ 1.042; $n^{30}D$ 1.4640, identical in all respects with the original lactone (III).

**Reaction of β-Methyl-$\Delta^{\beta,\gamma}$-δ-hexenolactone (III) with Iodine Bromide Reagent.**—The iodine number was determined by the usual Hanus procedure[12] using the modifications suggested by Cavallito and Haskell.[7]

*Anal.* 0.1103 g. (III) required 9.40 ml. of 0.1001 *N* IBr = 1.07 moles of halogen per mole.

**β-Methyl-δ-hexanolactone (IV).**—Fifteen hundred grams of the unsaturated lactone (III) was hydrogenated at 50° and 1000 p. s. i. hydrogen in the presence of 15 g. of Raney nickel. The catalyst was filtered off and the filtrate was washed several times with 10% sodium bicarbonate solution to remove the small amount of β-methylcaproic acid formed by hydrogenolysis of the lactone ring. The neutral material was dried and distilled, b. p. 83–86° (3 mm.); sp. gr. $^{30}_{15.6}$ 1.020; $n^{30}D$ 1.4437. *Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.6; H, 9.4; sapn. equiv., 128.2. Found: C, 65.4; H, 9.4; sapn. equiv., 128.1. Iodoform test positive. The yield was 1250 g. (82%).

**Oxidation of β-Methyl-δ-hexanolactone (IV).**—Six and one-half grams of the saturated lactone (IV) was added to a solution of 40 g. of bromine and 20 g. of sodium hydroxide in 400 ml. water. During twelve hours standing at room temperature a heavy liquid separated which was soon converted to a white crystalline solid. The material (9.0 g., 70% of the theoretical) was filtered off and identified as carbon tetrabromide by its m. p. of 90.1°. The filtrate was extracted with ether, acidified with hydrochloric acid and re-extracted with ether. After removal of the solvent, the residue of 5 g. was distilled at 0.5 mm., 140° bath temperature. The distillate crystallized, m. p. 87–89°, undepressed by admixture with an authentic sample of β-methylglutaric acid (V).

**β-Methyl-$\Delta^{\alpha,\beta}$-δ-hexenolactone (VI).**—Seven hundred eighty-two grams of III and 3.7 g. (0.5%) of anhydrous potassium carbonate were heated together by means of an oil-bath to a temperature of 118°. A mild exothermic reaction set in and the temperature rose to 130° with the bath removed. The mixture was allowed to cool to 115°, and maintained at that temperature for fifteen minutes by replacing the oil-bath. Distillation gave a fraction of 743 g. (94%), b. p. 105° (5 mm.); sp. gr. $^{20}_{15.6}$ 1.045; $n^{30}D$ 1.4746. *Anal.* Calcd. for $C_7H_{10}O_2$: C, 66.6; H, 8.0; sapn. equiv., 126.2. Found: C, 66.6; H, 8.0; sapn. equiv., 126.2. 1.9094 g. required 1.02 ml. of 0.1001 *N* IBr = 0.0067 mole of halogen per mole.

**Hydrogenation of β-Methyl-$\Delta^{\alpha,\beta}$-δ-hexenolactone (VI).**—Two hundred fifty-two grams (2 moles) of the lactone (VI) and 6.5 g. of Raney nickel in 400 ml. of dioxane were shaken at 80–100° and 800 p. s. i. of hydrogen until the uptake was completed. Distillation of the filtered material gave 250 g. of a liquid b. p. 84–85° (3 mm.); sp. gr. $^{30}_{15.6}$ 1.020; $n^{30}D$ 1.4437; *Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.6; H, 9.4; sapn. equiv., 128.2. Found: C, 65.5; H, 9.3; sapn. equiv., 128.2, identical in all respects with IV previously prepared.

A sample of each of the two saturated lactones from the different sources, III and VI, dissolved in cold aqueous sodium hydroxide and treated with *p*-bromophenacyl bromide, gave identical *p*-bromophenacyl esters m. p. 139–140°, undepressed when mixed.

Thirteen grams of the saturated lactone prepared from VI was oxidized with excess aqueous sodium hypobromite solution. Twelve grams of carbon tetrabromide m. p. 90.1° was collected after standing for twenty-four hours. The filtrate was acidified with hydrochloric acid and freed from bromine with a little sodium bisulfite. Extraction with ether and evaporation gave 10 g. of an acid m. p. 87°; undepressed when mixed with authentic β-methylglutaric acid or the acid from the oxidation of the saturated lactone derived from (III). *Anal.* Calcd.: neut. equiv., 73.1. Found: neut. equiv., 73.7.

**Reaction of Mesityl Oxide with Ketene.**—Into a well-agitated solution of 1 g. of boron trifluoride diethyl etherate in 479 g. of mesityl oxide, 185 g. of ketene was introduced over a period of two hours at 0–10°. The catalyst was destroyed by stirring with an excess of dilute (2%) sodium hydroxide solution at this temperature. Distilla-

(11) All m. p. are corrected and b. p. uncorrected.

(12) Scott, "Standard Methods of Chemical Analysis," D. Van Nostrand Co., New York, N. Y., 1922, p. 1166.

tion of the organic layer gave 133 g. of unreacted mesityl oxide, and 396 g. (80%) of β,δ-dimethyl-Δβ,γ-δ-hexenolactone (VIII) b. p. 92–93° (2 mm.); sp. gr. $^{20}_{15.6}$ 1.012; $n^{30}D$ 1.4600. *Anal.* Calcd. for $C_8H_{12}O_2$: C, 68.6; H, 8.6; sapn. equiv., 140.3. Found: C, 68.5; H, 8.5; sapn. equiv., 140.0.

**β,δ-Dimethylsorbic Acid.**—Fifty grams of VIII was refluxed eight hours with 100 ml. of 50% sodium hydroxide solution. The clear solution was cooled to 10° and strongly acidified. β,δ-Dimethylsorbic acid crystallized and was filtered off (24 g., 48%), m. p. 94–95°, undepressed by admixture with authentic material. By extraction of the filtrate with ether 25 g. of reformed VIII was isolated.

**β-Methyl-Δβ,γ-δ-octenolactone (IX).**—One hundred and nine grams of ketene was introduced at 10° into a solution of 291 g. of butylidene acetone dissolved in 800 ml. of ether containing 4 g. of boron trifluoride. The catalyst was destroyed with sodium hydroxide as previously described. Distillation gave 73 g. unreacted ketone and 298 g. (99%) of IX, b. p. 111° (3.5 mm.); sp. gr. $^{20}_{15.6}$ 1.002; $n^{30}D$ 1.4660. *Anal.* Calcd. for $C_9H_{14}O_2$: C, 70.0; H, 9.2; sapn. equiv., 154.2. Found: C, 70.1; H, 9.2; sapn. equiv., 154.2.

## Summary

β,γ-Unsaturated δ-lactones were readily obtained by the reaction of ketene with β-alkyl vinyl methyl ketones in the presence of boron trifluoride.

The β,γ-unsaturated lactones were transformed quantitatively to α,β-unsaturated lactones by heating with potassium carbonate.

The mechanism for the condensation reaction is discussed.

# *m*-Diarylbenzenes

BY G. FORREST WOODS AND FRED T. REED

The reaction of the monoethyl ether of dihydroresorcinol with organo-metallic reagents[1] gives rise to a series of *m*-diarylbenzenes.

An earlier communication[2] described the preparation of V, VI and VIII. The present study describes the preparation of VII, IX and X, these syntheses being summarized in the flow sheet.

The intermediate dienes were not isolated and identified in all cases, since they undergo oxidation very readily, presumably to the aromatic compounds. In practice, the dienes were treated directly without purification with palladium–charcoal to effect aromatization. 1-Phenyl-3-(3-xenyl)-benzene, VII, was best prepared by the reaction of IV with 3-xenylmagnesium bromide rather than by the alternate route since a Wurtz type of reaction in the preparation of 3-xenylmagnesium bromide gives VII as a product. Substance VII, obtained by either procedure, corresponds in properties with those reported by Bowden[3] for 1-phenyl-3-(3-xenyl)-benzene prepared by the treatment of 3-xenyl iodide with copper powder. Substance IX was best prepared by treating II with 3-xenylmagnesium bromide rather than by the alternate method. Substance X could be prepared only by the one series of reactions indicated.

The authors wish to acknowledge that this work was supported in part by a contract from the Office of Naval Research.

## Experimental

**Preparation of 3-Xenyl Bromide.**—The synthesis of 3-xenyl bromide, first attempted without success by the Gomberg–Bachmann[4] reaction, was realized by the method of Huber, *et al.*,[5] modified by extracting the deamination reaction mixture with ether and obtaining crude 3-xenyl bromide by distillation of this extract. A solution prepared by adding an approximately equal volume of 30–60° petroleum ether to the crude 3-xenyl bromide was passed through a chromatographic column packed with activated alumina, resulting in an effective removal of colored impurities. The resulting solution was distilled, yielding

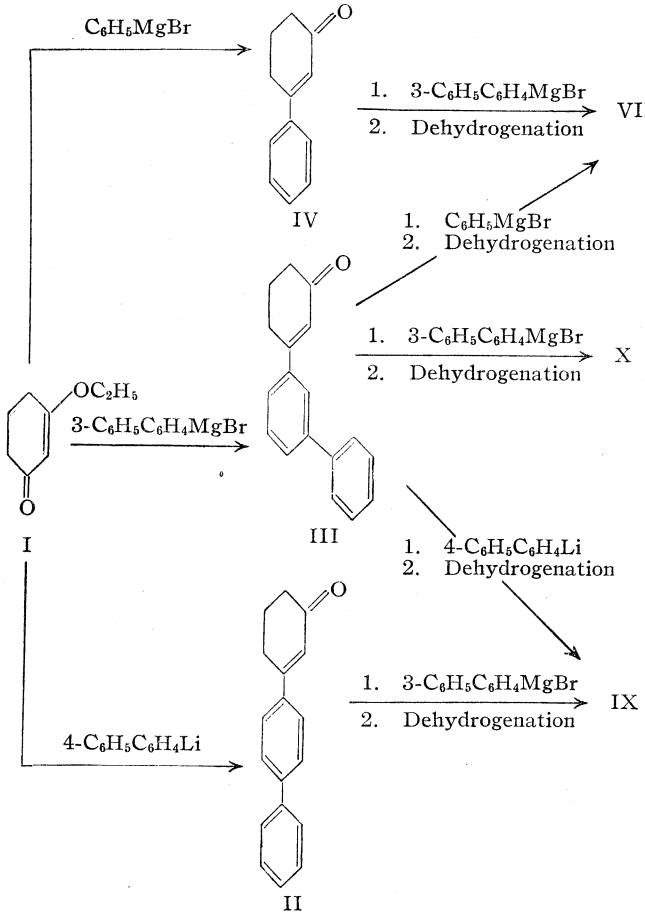

CHART I

water white 3-xenyl bromide boiling at 113–115° at 0.1 mm. Physical constants agreed with those reported by Huber, *et al.*, and yields were about the same.

Since this work dealt in part with positional isomerism, the identity of the above product was determined as follows: Fifteen grams of the 3-xenyl bromide was converted to the Grignard reagent by reaction with 1.6 g. of magnesium in 35 ml. of dry ether. This was poured into a mixture of dry ice and ether and then acidified with 150 ml. of 10% sulfuric acid. After washing the ether layer with 20% sulfuric acid, it was extracted with a 25% solution of potassium hydroxide. Acidification of the alkaline extract gave 9 g. of crude 3-xenylcarboxylic acid, melting at 150–3°, a 70% yield.

**Preparation of 1-Phenyl-3-(3-xenyl)-benzene (VII).**—(A) A solution of 92 g. of monoethyl ether of dihydroresorcinol[1] (I) in dry ether (100 ml.) was added to a solution of 3-xenylmagnesium bromide prepared from 3-xenyl bromide (142.6 g.) and magnesium (14.8 g.) in dry ether (250 ml.) in the usual manner. The resulting mixture was hydrolyzed with 10% sulfuric acid (about 100 ml.) and steam-distilled until no organic material was observed in the distillate. The residue was extracted with ether, washed with sodium bicarbonate solution and with water, and dried over magnesium sulfate. After removal of solvent the residue was distilled in a Hickman apparatus using a high vacuum diffusion pump. An extremely viscous, slightly colored distillate (70 g.) of 3-(3-xenyl)-$\Delta^2$-cyclohexenone (III) was obtained. Attempts to crystallize this compound were without success.

The red 2,4-dinitrophenylhydrazone of this compound was prepared, m. p. 210–211°. *Anal.* Calcd. for $C_{24}H_{20}O_4N_4$: C, 67.28; H, 4.71. Found: C, 67.81; H, 4.68.

The intermediate compound 1-(3-xenyl)-3-phenylcyclohexediene-1,3 was prepared by the addition of 3-(3-xenyl)-$\Delta^2$-cyclohexenone (III) (25 g.) in dry ether (20 ml.) to a solution (40 ml.) of phenylmagnesium bromide prepared from bromobenzene (25 g.) and magnesium (3.3 g.) in the usual manner. The resulting mixture was hydrolyzed with 10% sulfuric acid (about 50 ml.) and the impurities removed in part by steam-distillation. The gummy residue, washed several times by water using decantation, was extracted with ether, and dried over magnesium sulfate. After removal of the solvent, the residue was distilled in the Hickman apparatus as before. 1-(3-Xenyl)-3-phenylcyclohexediene-1,3 (22.7 g.), a highly viscous substance was obtained, which did not crystallize.

This substance (7.7 g.) was dehydrogenated[1] by treatment with 5% palladinized charcoal (4 g.) in refluxing *p*-cymene (25 ml.) for three hours. Most of the cymene was removed by distillation and to the residue was added 100 ml. of ethyl alcohol. The catalyst was removed by filtration of the hot solution. Cooling of the filtrate yielded 3.43 g. of 1-phenyl-3-(3-xenyl)-benzene (VII) which melted at 85.5–86.0°[6] after recrystallization from ethyl alcohol. *Anal.* Calcd. for $C_{24}H_{18}$: C, 94.07; H, 5.91. Found: C, 93.63; H, 6.05.

(B) Employing the method of Woods and Tucker,[1] 3-phenyl-$\Delta^2$-cyclohexenone (IV) was prepared.

A solution of this substance (9.7 g.) in dry ether (30 ml.) was added to 40 ml. of dry ether solution of 3-xenylmagnesium bromide prepared from 3-xenyl bromide (16.3 g.) and magnesium (1.58 g.). The Grignard complex thus formed was isolated by rapid filtration and then hydrolyzed with 10% sulfuric acid. The mixture obtained was extracted with ether and the extract washed with sodium bicarbonate solution and with water and dried over magnesium sulfate. After filtration, the ether was permitted to evaporate and there remained a viscous residue composed principally of 1-phenyl-3-(3-xenyl)-cyclohexadiene-1,3. No further attempt at isolation or purification was made.

A portion of this material (about 2 g.) was aromatized and the product (about 1 g.) isolated exactly as described in (A). The 1-phenyl-3-(3-xenyl)-benzene (VII) thus obtained melted at 84.5–85.0° and showed no depression in melting point when mixed with an equal portion of the product obtained by procedure (A).

**Preparation of 1-(4-xenyl)-3-(3-xenyl)-benzene (IX).**—(A) 3-(4-Xenyl)-$\Delta^2$-cyclohexenone (II) was prepared as described by Woods and Tucker.[2]

To a solution of 3-xenylmagnesium bromide, prepared from 3-xenyl bromide (25 g.) and magnesium (2 g.) in dry ether (40 ml.), was added 3-(4-xenyl)-$\Delta^2$-cyclohexenone (II) (15.0 g.) as finely divided solid. After the reaction was complete, the reaction vessel was chilled in a salt–ice bath to precipitate the Grignard complex. The complex was isolated by filtration and hydrolyzed with cold 10% sulfuric acid (about 50 ml.). The hydrolysis mixture was extracted with benzene and the solution washed with water and sodium bicarbonate solution and finally dried over magnesium sulfate. After removal of a portion of the benzene, a precipitate was obtained upon chilling. Recrystallization of this solid from ethyl alcohol yielded 1-(4-xenyl)-3-(3-xenyl)-cyclohexadiene-1,3 (9.6 g.), melting at 148–149°. *Anal.* Calcd. for $C_{30}H_{24}$: C, 93.70; H, 6.29. Found: C, 93.35; H, 6.48.

This compound (2.4 g.) was dehydrogenated by the same procedure as before using *p*-cymene (25 ml.) and 5% palladinized charcoal (0.5 g.). Benzene was added to the dehydrogenation mixture and the catalyst removed by filtration. Upon addition of an equal volume of ethyl alcohol crystals of 1-(4-xenyl)-3-(3-xenyl)-benzene (IX)

(6) Bowden reports a melting point of 86° for this compound (*cf.* ref. 3).

(1.89 g.) were obtained. These were recrystallized from an equal mixture of benzene and alcohol, m. p. 155.0–155.5°. *Anal.* Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80. Found: C, 94.57; H, 5.67.

(B) 3-(3-Xenyl)-$\Delta^2$-cyclohexenone (III) was prepared as described above.

A 40-ml. dry ether solution of the substance (17.6 g.) was added to a 40-ml. dry ether solution of 4-xenyllithium, prepared from 4-xenyl bromide (35.0 g.) and lithium (0.76 g.). Hydrolysis of the complex formed was effected as before with 10% sulfuric acid (50 ml.) and the resulting mixture was steam-distilled until there was no further appearance of organic material in the distillate. The residue was extracted with benzene, the extract being then washed successively with sodium bicarbonate solution and with water and finally dried over magnesium sulfate. This was filtered and the solvent allowed to evaporate. The resulting residue of 1-(3-xenyl)-3-(4-xenyl)-cyclohexediene-1,3 was not purified further.

This crude product (3.60 g.) was aromatized as described in procedure A, and the residue taken up in benzene. After filtration and addition of about four times the volume of ethyl alcohol, crystals of 1-(4-xenyl)-3-(3-xenyl)-benzene (IX) were obtained which upon recrystallization from an equal mixture of benzene and ethyl alcohol melted at 153–154°. Mixed melting point with the product obtained by procedure A showed no depression.

**Preparation of 1,3-Di-(3-xenyl)-benzene (X).**—A Grignard solution prepared in dry ether (40 ml.) from 3-xenyl bromide (30.3 g.) and magnesium (3.2 g.) was treated with a dry ether solution (20 ml.) of 3-(3-xenyl)-$\Delta^2$-cyclohexenone (III). The Grignard complex was isolated as before by rapid filtration of the chilled ether reaction mixture. The precipitate obtained was hydrolyzed with cold 10% sulfuric acid and then extracted with ether. The extract was washed with water and sodium bicarbonate solution and dried over magnesium sulfate. After removal of the solvent, distillation of the residue in the Hickmann apparatus yielded a very viscous yellow liquid (11.36 g.). Attempts to crystallize this material were unsuccessful.

Dehydrogenation of this substance was accomplished as before, by adding dropwise the 1,3-di-(3-xenyl)-cyclohexediene-1,3 (7.55 g.) to a refluxing mixture of 5% palladinized charcoal (4 g.) in *p*-cymene (25 ml.). The reaction mixture was worked up as before using ethyl alcohol, but crystallization from this solution yielded an oil. A portion of this oil was dissolved in benzene–petroleum ether (30–60°) and, upon cooling, crystalline material precipitated, which upon recrystallization from benzene and petroleum ether, yielded 1,3-di-(3-xenyl)-benzene, melting at 97–98°. *Anal.* Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80. Found: C, 94.60; H, 5.89.

## Summary

The reaction of the monoethyl ether of dihydroresorcinol with organo-metallic reagents has been extended to include the preparation of 1-phenyl-3-(3-xenyl)-benzene, 1-(4-xenyl)-3-(3-xenyl)-benzene and 1,3-di-(3-xenyl)-benzene.

# Condensations of Esters by Diisopropylaminomagnesium Bromide and Certain Related Reagents[1]

BY FREDERICK C. FROSTICK, JR., AND CHARLES R. HAUSER

Dialkylaminomagnesium bromides may react with esters either at the $\alpha$-hydrogen, effecting their condensations, or at the carbonyl carbon to form the corresponding N,N-dialkylamide, thus

$$RCH_2CO_2C_2H_5 + R'_2NMgBr \begin{cases} \longrightarrow (RCHCO_2C_2H_5)MgBr \xrightarrow{RCH_2CO_2C_2H_5} RCH_2COCHRCO_2C_2H_5 \\ \longrightarrow RCH_2CONR'_2 \end{cases}$$

Diethylaminomagnesium bromide has recently been shown[2] to effect the self-condensation of ethyl phenylacetate, *t*-butyl acetate and certain other esters but not ethyl *i*-valerate and ethyl *i*-butyrate with which the amide is presumably formed. This reagent self-condensed ethyl *n*-butyrate, but the condensation product was contaminated with the amide. The condensation product from ethyl propionate was reported free of the amide, but later work has shown that this condensation product also is generally contaminated with the amide.[3]

In the present investigation, diisopropylaminomagnesium bromide has been found to be a more suitable condensing agent than diethylaminomagnesium bromide. The diisopropyl reagent effects in good yield the self-condensation not only of the straight chain esters, ethyl propionate, ethyl *n*-butyrate and methyl laurate, but also that of the branched chain esters, ethyl *i*-valerate and ethyl *i*-butyrate, which are known to be more difficult to condense. The results are summarized in Table I. The yields have been based on the diisopropylaminomagnesium bromide since a 10% excess of the ester was employed; however, the yields would be approximately the same if they were based on the ester used minus that recovered. The condensation products were shown by the sodium fusion test for nitrogen to be free from the amide with the exception of that from ethyl *i*-valerate when the reaction time was twenty hours; in this case, secondary reactions appeared to have occurred. The products obtained when the reac-

(2) Hauser and Walker, *ibid.*, **69**, 295 (1947).

(3) In a private communication, Dr. Robert W. Holley of the State College of Washington, Pullman, Washington, has stated that the condensation product he obtained from ethyl propionate using diethylaminomagnesium bromide was contaminated with the amide. We have similarly found that this condensation product is contaminated with the amide (as detected by the sodium fusion test) when the reaction is carried out for either one-half hour or for four hours.

tion time was four hours were converted by ketonic cleavage to the corresponding ketones which were obtained in good yields. With ethyl diethylacetate, diisopropylaminomagnesium bromide gave, after a reaction time of two and one-half hours, a mixture containing nitrogen. An attempt to self-condense ethyl diphenylacetate with this reagent failed even after twenty hours, 55% of the original ester being recovered. However, the magnesium enolate of ethyl diphenylacetate was evidently formed since, on treatment of the reaction mixture with benzoyl chloride after one-half hour, ethyl benzoyldiphenylacetate was obtained in 38% yield.

$$(C_6H_5)_2CHCO_2C_2H_5 \xrightarrow{[(CH_3)_2CH]_2NMgBr} [(C_6H_5)_2CCO_2C_2H_5]MgBr \xrightarrow{C_6H_5COCl} C_6H_5COC(C_6H_5)_2CO_2C_2H_5$$

The present method for self-condensing esters is conveniently carried out and the condensing agent, diisopropylaminomagnesium bromide, is readily prepared from standardized ethylmagnesium bromide and diisopropylamine which is available commercially. Diisopropylaminomagnesium bromide is particularly suitable for the self-condensations of ethyl *i*-valerate and ethyl *i*-butyrate which are not condensed by sodium alkoxides. Although sodium hydride[4] self-condenses ethyl *i*-valerate, and sodium[5] and potassium triphenylmethide[6] and mesitylmagnesium bromide[7] self-condense both ethyl *i*-valerate and ethyl *i*-butyrate, diisopropylaminomagnesium bromide is probably more convenient to use.

Certain esters have also been condensed by means of dicyclohexylaminomagnesium bromide and di-*n*-butylaminomagnesium bromide. With the dicyclohexyl reagent, both ethyl *n*-butyrate and ethyl *i*-valerate were self-condensed to form β-keto esters which were free from the amide. However, the yields were somewhat lower than those obtained with the diisopropyl reagent. Moreover, working up the reaction mixture is more convenient with the diisopropyl reagent than with the dicyclohexyl reagent. With the di-*n*-butyl reagent, some amide formation appeared to occur along with the self-condensation of ethyl *i*-valerate since the condensation product gave a positive test for nitrogen.

These results indicate that, as the complexity of the basic reagent is increased, the α-hydrogen reaction of an ester is favored over the reaction at the carbonyl carbon. Similarly, the relatively complex mesitylmagnesium bromide[7] and sodium[5] and potassium triphenylmethides[6] react with the α-hydrogen of ethyl *i*-valerate or ethyl *i*-butyrate effecting self-condensation whereas simpler basic reagents such as methyl or ethyl magnesium bromide[8] and sodium amide[9] appear to react mainly at the carbonyl carbon of the ester.

In these Claisen condensations by dialkylaminomagnesium bromides, the magnesium cation as well as the dialkylamino anion (both of which are present at least potentially) appears to be involved in the mechanism.[2] However, the magnesium appears to influence mainly the rate of the reaction[2] whereas the basic anion may influence both the rate and the equilibrium. Actually, the condensation has been possible only when a sufficiently weaker base is formed.[10] A study of these factors is in progress.

## Experimental

**Self-condensations of Esters by Diisopropylaminomagnesium Bromide.**—In a 500-ml., three-necked flask equipped with a mercury-sealed stirrer, dropping funnel and reflux condenser (having a drying tube), was placed the appropriate quantity (0.2–0.4 mole) of standardized[11] ethylmagnesium bromide in ether solution. To the stirred mixture was added an equivalent number of moles of dry diisopropylamine in 50 ml. of dry ether at such a rate that the ether refluxed and stirring was continued for fifteen to thirty minutes to complete the formation of the diisopropylaminomagnesium bromide.[12] The ester (molar equivalent plus 10% excess) in 100 ml. of dry ether was added at such a rate that the ether refluxed gently. This addition required about one-half hour. In most cases, stirring was continued at room temperature (25–30°) for a longer period.

The reaction mixture was poured with stirring onto 300 g. of crushed ice mixed with 40–70 ml. of concentrated hydrochloric acid and the flask rinsed with some of the solution. After acidification, the ether phase was separated and the aqueous layer extracted twice with ether. The combined ether solution was washed with water, 10% sodium bicarbonate solution, and again with water, dried over Drierite, and the solvent distilled from a steam-bath. The residue was distilled *in vacuo* or recrystallized. Approximately 10–15% of the original ester was recovered in a low-boiling fraction obtained before the product distilled. The products were tested qualitatively for nitrogen by the sodium fusion method,[13] and certain of them were subjected to ketonic cleavage in the presence of acid.[14] The results are summarized in Table I.

With ethyl diethylacetate (b. p. 148.7–150°, 26.9 g., 0.187 mole), there was obtained, after a total reaction time of two and one-half hours, 9.5 g. (35% recovery) of the ester, b. p. 147–151°, and 13.8 g. of material boiling at 110–132° at 11 mm. which gave a positive test for nitrogen.

With ethyl diphenylacetate (m. p. 59.0–59.5°),[15] after refluxing on a steam cone for five hours and standing at room temperature for fifteen hours, 55% of the ester (m. p. 57–58°, mixed m. p. 57–59°) was recovered.

TABLE I

SELF-CONDENSATIONS OF ESTERS BY DIISOPROPYLAMINOMAGNESIUM BROMIDE

| Ester, ethyl | Reaction time, hr.[a] | β-Keto ester | B. p., °C., uncor. | Mm. | Yield, % |
|---|---|---|---|---|---|
| Propionate | 4 | Ethyl α-*n*-propionylpropionate[b] | 92.5–94 | 19[j] | 73[c] |
| *n*-Butyrate | 1 | Ethyl α-*n*-butyryl-*n*-butyrate[b] | 101.5–104.5 | 11.5 | 65 |
| *n*-Butyrate | 4 | Ethyl α-*n*-butyryl-*n*-butyrate[b] | 102–104.5 | 12[k] | 66[d] |
| *i*-Butyrate | 1.3 | Ethyl α-*i*-butyryl-*i*-butyrate[b] | 88–92.5 | 15 | 48 |
| *i*-Butyrate | 2 | Ethyl α-*i*-butyryl-*i*-butyrate[b] | 90.5–93.5 | 15 | 55 |
| *i*-Butyrate | 4 | Ethyl α-*i*-butyryl-*i*-butyrate[b] | 91.5–94.5 | 15[l] | 55[e] |
| *i*-Valerate | 1 | Ethyl α-*i*-valeryl-*i*-valerate[b] | 117–118.5 | 15 | 61 |
| *i*-Valerate | 4 | Ethyl α-*i*-valeryl-*i*-valerate[b] | 116–118 | 14[m] | 71[f] |
| *i*-Valerate | 20 | Ethyl α-*i*-valeryl-*i*-valerate | 110–118 | 15 | (55)[h] |
| Laurate (methyl) | 4 | Methyl α-lauryl-laurate[b,i] | 37–39[n] | M. p. | 92[g] |

[a] Reaction time includes one-half hour for adding the ester and one-half hour on a steam-bath; additional time was at room temperature (25–30°). [b] Product gave a negative test for nitrogen. [c] Ketonic cleavage gave a 41% yield of diethyl ketone, b. p. 98–102°; m. p. of semicarbazone, 138–139° (ref. 13a, p. 240). [d] Ketonic cleavage gave an 84% yield of di-*n*-propyl ketone, b. p. 135–143°; m. p. of semicarbazone, 131–132° (ref. 13a, p. 240). [e] Ketonic cleavage gave a 68% yield of diisopropyl ketone, b. p. 120–125°; m. p. of 2,4-dinitrophenylhydrazone, 94–95° (ref. 13b, p. 262). [f] Ketonic cleavage gave a 69% yield of diisobutyl ketone, b. p. 163–166; m. p. of 2,4-dinitrophenylhydrazone, 91–92° (ref. 13a, p. 240). [g] Ketonic cleavage gave an 88% yield of laurone, m. p. 68–69° (ref. 13b, p. 264). [h] Product gave a positive test for nitrogen. [i] Product recrystallized from methanol at −5° after all traces of ether had been removed under vacuum. [j] Reported b. p. 92–93° at 20 mm. [Dieckmann and Kron, *Ber.*, **41**, 1269 (1908)]. [k] See ref. 17. [l] Hudson and Hauser, THIS JOURNAL, **63**, 3159 (1941). [m] Reported b. p. 118–119° at 15 mm. (see ref. 6). [n] Reported m. p. 38–40° [Hansley, U. S. Patent 2,158,071 (1939)].

**Benzoylation of Ethyl Diphenylacetate.**—To a solution of 0.227 mole of diisopropylaminomagnesium bromide in ether was added slowly 43.0 g. (0.179 mole) of ethyl diphenylacetate (m. p. 57–59°)[15] dissolved in 150 ml. of dry ether. The reaction mixture was refluxed on a steam cone for ten minutes during which time a thick cream-colored precipitate was formed. After stirring an additional thirty minutes, 35.0 g. (0.250 mole) of benzoyl chloride was added and the resulting mixture stirred for thirty minutes. The reaction mixture was poured with stirring onto 50 ml. of concentrated hydrochloric acid and 500 ml. crushed ice. The ether phase was separated and the white solid left with the aqueous phase was dissolved in ether after several extractions with this solvent. The combined ether solution was washed with water, dried with Drierite and the solvent distilled. The residue was treated with hydriodic acid and glacial acetic acid according to the procedure described previously.[16] There was obtained 23.1 g. (38% yield) of ethyl benzoyldiphenylacetate, m. p. 146–147.5°; a mixed melting point with a known sample, m. p. 147–148°,[16] was 146–148°.

**Self-condensations of Esters by Other Dialkylaminomagnesium Bromides.**—Dicyclohexylaminomagnesium bromide and di-*n*-butylaminomagnesium bromide were prepared by the action of ethylmagnesium bromide on equivalent amounts of dicyclohexylamine and di-*n*-butylamine, respectively. With the latter amine, the reaction mixture was refluxed for about one hour.

In the usual manner, ethyl *n*-butyrate was self-condensed by the dicyclohexyl reagent for one hour (total time) to form ethyl α-*n*-butyryl-*n*-butyrate, b. p. 103–106° at 12 mm. (reported b. p. 102–103° at 12 mm.)[17] in 46% yield. Ethyl *i*-valerate was self-condensed by this reagent for four hours to form ethyl α-*i*-valeryl-*i*-valerate, b. p. 116–118° at 14 mm. (reported b. p. 118–119° at 15 mm.)[6] in 55% yield. In these cases, approximately six liters of water was required to dissolve the aminomagnesium halide complex formed on pouring the reaction mixture onto the acid. Tests for nitrogen on these condensation products were negative.

Ethyl *i*-valerate was treated with di-*n*-butylaminomagnesium bromide for three hours to form a product boiling at 126–144° at 14 mm. which gave a positive test for nitrogen.

**Acknowledgment.**—The authors wish to thank the Shell Chemical Corporation, New York, N. Y., for the diisopropylamine, Monsanto Chemical Company, Charlotte, N. C., for the dicyclohexylamine, and Sharples Chemicals, Inc., New York, N. Y., for the di-*n*-butylamine.

## Summary

1. Diisopropylaminomagnesium bromide effects satisfactorily the self-condensation of various esters including ethyl *i*-butyrate and ethyl *i*-valerate.

2. This reagent converts ethyl diphenylacetate to its magnesium enolate which has been benzoylated.

3. Certain esters have been condensed by dicyclohexylaminomagnesium bromide and by di-*n*-butylaminomagnesium bromide.

4. Comparisons have been made between various basic reagents in their reactions with esters where attack may occur at the α-hydrogen or at the carbonyl carbon atom.

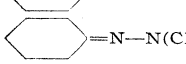
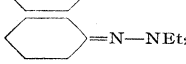
# The Wolff–Kishner Reduction. I. The Preparation and Properties of N-Alkyl- and N,N-Dialkylhydrazones

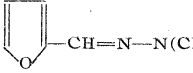
BY DAVID TODD

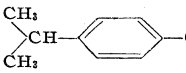
The Wolff–Kishner reduction of a carbonyl group to a methylene group by decomposition of a hydrazone, azine or semicarbazone in the presence of an alkaline catalyst or platinum has recently been shown to be practicable for large-scale operations[1] and, in the absence of solvent, not to require the fairly high temperatures commonly employed.[2] It seems of interest to investigate the mechanism of the reaction with a view to widening its scope. As a first step, the effect of alkali on N-alkyl- and N,N-dialkylhydrazones was investigated.[3] In this paper the preparation of these substituted hydrazones is described.

Very few N-alkylated hydrazones are known. Of the compounds of this class reported in this paper only the methylhydrazone and diethylhydrazone of benzaldehyde, and the methylhydrazone of *p*-nitrobenzaldehyde are in the literature. A preparation of benzaldehyde methylhydrazone was claimed by Harries and Haga,[4] but their product was a high-melting solid whereas one would expect that the compound should be an oil of lower boiling point (because of less hydrogen bonding) than the liquid benzaldehyde hydrazone. In this paper the isolation of the methylhydrazone of the expected physical properties is described. The diethylhydrazones of benzaldehyde and *p*-nitrobenzaldehyde were prepared by Brady and McHugh.[5] Hurd and Spence[6] have reported the preparation of several oily diethylhydrazones without giving details or properties.









It was found that the hydrazones could be readily prepared by refluxing the appropriate carbonyl compound with an aqueous-alcoholic solution of the free alkylhydrazine. The latter was prepared by distilling to dryness an alkaline solution of a salt of the hydrazine. The hydrazones could also be prepared by refluxing an ether or benzene solution of the hydrazine with the carbonyl compound. In this case the hydrazine solution was prepared by solvent extraction of a cold basic solution of the hydrazine salt. The hydrazones were generally liquids, and almost all could be characterized as the picrate, styphnate, or N-nitroso derivative (in the case of monoalkylhydrazones). Furfural methylhydrazone was rapidly decomposed by picric acid in dry benzene, but the N-nitroso derivative was easily prepared. Cyclohexanone diethylhydrazone gave only a small yield of the styphnate in dry benzene while the picrate would not come out at all.

The ultraviolet absorption spectra of the hydrazone, methylhydrazone, dimethylhydrazone and diethylhydrazone of benzaldehyde are given in Fig. 1.

The molecular refractions of these materials were determined and found to show some remarkably high exaltations when the literature values for hydrazone nitrogen atomic refractivities were employed to calculate the molecular refractions.

It has been found[7] that for a series of four monoalkylhydrazones of aliphatic carbonyl compounds the calculated molecular refractions could be made to fit the observed values by assigning (1) to the C=N link the normal C=C bond refractivity of 1.733 units, (2) to the double-bonded nitrogen the normal secondary amine nitrogen value of 2.65 units, and (3) to the other nitrogen the normal primary amine nitrogen value of 2.45 units. These values were used to calculate the molecular refractions in Table I.

[a] M. p. (by immersion) is 10–12°. This compound is completely hydrolyzed by fifteen minutes contact with cold 5% HCl. [b] This material was not hydrolyzed after fifteen minutes contact with cold 5% HCl. [c] It is necessary to work up the reaction mixture immediately to avoid polymerization of the product. The compound is very sensitive to air oxidation. [d] Turns green on storage. [e] In ethanol this picrate is rapidly converted to the picrate of dimethylhydrazine, m. p. 140–142.5° dec. *Anal.* Calcd. for $C_8H_{11}N_5O_7$: C, 33.22; H, 3.83. Found: C, 33.06; H, 3.96.

It will be observed that in the cyclohexanone series no appreciable exaltation is found. In the benzaldehyde and furfural series the exaltations are not only unusually high but increase sharply with increased molecular weight.

The abnormalities in both the spectroscopic and refraction data are probably best explained by the existence of contributing resonance forms, typified by  in the case of the aromatic and furfural hydrazones. It would be expected that an increase in the number of alkyl groups on the terminal nitrogen of the hydrazones of aromatic carbonyl compounds would favor the increased participation of these resonance forms because of the electron-donating nature of the alkyl groups. It will be observed in Fig. 1 that the bathochromic shift of the maximum amounts to about 10 millimicrons as one passes from benzaldehyde methylhydrazone to the dimethylhydrazone. This is large in comparison with the almost negligible shift that occurs when such a change in structure does not alter the resonating character of the molecule.

Similarly it is well known that the stabilization of resonance forms leads to abnormal exaltations of molecular refractivities.[8] It is not at all clear why the *p*-isopropylbenzaldehyde hydrazones should show identical exaltations; they would be expected to show the same changes as the benzaldehyde series, though the exaltations should be of a lower order of magnitude because of the resonance-damping effect of the isopropyl group.

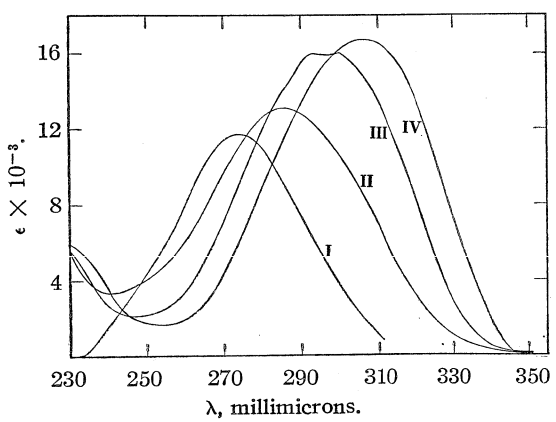

Fig. 1.—I, Benzaldehyde hydrazone; II, benzaldehyde methylhydrazone; III, benzaldehyde dimethylhydrazone; IV, benzaldehyde diethylhydrazone.

## Experimental

The two general methods for preparing the alkylhydrazones are described in detail for the preparation of benzaldehyde methylhydrazone. In Table II will be found the data on the preparation and properties of all the hydrazones prepared in this work.

**Benzaldehyde Methylhydrazone: Method (a).**—Twenty-one and six-tenths grams (0.15 mole) of methylhydrazine sulfate was dissolved in 25 ml. of warm water and dropped slowly from a separatory funnel into excess aqueous sodium hydroxide. The free hydrazine was distilled off, and several more portions of water added to the damp salt cake and distilled off. To the distillate was added about 25 ml. of ethanol and 15.9 g. (0.15 mole) of benzaldehyde, and the mixture heated on the steam-bath for three hours. The ethanol was removed *in vacuo*, the residual solution extracted with ether, the ether solution washed and dried, and the ether removed. The residual oil was distilled at 20 mm. After a small forerun had been removed the product came over at 129–133° as a pale yellow oil of characteristic camphoraceous-basic odor.

| Picrate[d] | 124–125 dec. | 367 | 367 | 42.51 | 42.15 | 3.57 | 3.65 | | |
| Picrate[d] | 140–145 dec. | 395 | 402 | | | | | | |
| Styphnate | 135–136 dec. | 205.6 | 207.5 | 43.80 | 43.63 | 4.17 | 3.74 | | |
| Picrate[e] | 124–125 dec. | | | 45.53 | 45.21 | 5.19 | 5.06 | | |
| Styphnate | 137–140 dec. | 192.5 | 193 | | | | | | |
| Styphnate | 135–138 dec. | 206.5 | 211.5 | 46.48 | 46.78 | 5.62 | 5.10 | | |

The yield was 13.85 g. (69%). (If the alcohol–water solution of the product is allowed to stand at room temperature for several days the yield is far lower and a large amount of non-distillable polymer is formed.)

**Method (b).**—To 20 ml. of cold 50% sodium hydroxide in an ice-bath was added 14.4 g. (0.10 mole) of finely powdered methylhydrazine sulfate. The mixture was well stirred until the pale yellow hydrazine salt had dissolved; a heavy white precipitate of sodium sulfate came down during this period. The suspension was extracted twice with 50-ml. portions of ether, and the ether solution dried over potassium hydroxide pellets for an hour. To the filtered ether solution was added 10.6 g. (0.10 mole) of benzaldehyde; a mildly exothermic reaction set in immediately. The solution was refluxed one half hour, washed twice with 40% sodium bisulfite, with water, and dried over sodium hydroxide. After removal of the ether the product was distilled at 18 mm.; b. p. is 130–131°: yield is 10.03 g. (75%). The material was redistilled *in vacuo* for purification. The boiling point is 133° at 20 mm. (130–131° at 18 mm., 118–119° at 8 mm.); $n^{21.5}D$ 1.6053; $d^{21.5}_4$ 1.0305; $MR_{obs}$ 44.86; $MR_{calcd.}$ 42.38. (This material was found to be quite stable to cold 5% hydrochloric acid for half an hour or so at least. This fact was made use of several times to separate the hydrazone from unchanged benzaldehyde.)

**Picrate.**—To a solution of 2.29 g. of picric acid in warm benzene was added a benzene solution of 1.34 g. of benzaldehyde methylhydrazone. The yellow precipitate that formed was filtered and recrystallized from benzene; m. p. 133–133.5° (dec.).

Harries and Haga reported that benzaldehyde methylhydrazone was a colorless crystalline solid, m. p. 179°.

**The N-nitroso derivative** was prepared by refluxing a mixture of 5.36 g. of freshly-distilled benzaldehyde methylhydrazone with 9.36 g. of isoamyl nitrite in 50 ml. of hexane for two hours. The solution was cooled to −20° and two crops of pale yellow crystals totalling 2.25 g. (35% yield) were obtained. Two recrystallizations of this material from ethanol–water gave massive pale yellow prisms, m. p. 73.0–73.5°. This material gives a strong Liebermann nitroso test.

An attempt was made to prepare the N-acetate by the method employed by Brady and McHugh[4] to prepare the N-acetate of *p*-nitrobenzaldehyde methylhydrazone. Only unreacted starting material was recovered from the reaction mixture.

## Summary

The preparation and physical properties of the methyl-, dimethyl- and diethylhydrazones of benzaldehyde, *p*-isopropylbenzaldehyde, furfural and cyclohexanone are reported.

# The Wolff–Kishner Reduction. II. The Effect of Alkali on N-Substituted Hydrazones

BY DAVID TODD

The net change in the Wolff–Kishner reduction is a shift of two hydrogen atoms from nitrogen to carbon and simultaneous loss of a molecule of nitrogen

$$R_2C{=}N{-}NH_2 \longrightarrow R_2CH_2 + N_2$$

That monoalkylhydrazones might undergo the same reaction with loss of $N_2$ and formation of a new carbon–carbon bond would seem not unlikely in view of the fact that alkylpyrazolines, when heated to 230° in the presence of potassium hydroxide and platinum, have been found to lose nitrogen with the formation of a cyclopropane ring

A glance at the formula of the above pyrazoline will show that such compounds are cyclic N-alkylhydrazones. By the same analogy, since N-substituted pyrazolines are stable to hot alkali, it would be expected that dialkylhydrazones would also be stable.

The observed facts are in good accord with expectations. Three methylhydrazones have been found to lose close to the theoretical amount of nitrogen under the influence of hot alkali. Benzaldehyde methylhydrazone lost nitrogen in the presence of potassium hydroxide and platinum at 220–230°. Among the products of the reaction there were identified ethylbenzene (about 10% yield), benzoic acid and stilbene. When *p*-isopropylbenzaldehyde methylhydrazone was treated in a similar fashion, a 25% yield of *p*-ethylisopropylbenzene was obtained, as well as a small amount of *p*-isopropylbenzoic acid. No diisopropylstilbene could be detected. The *p*-ethylisopropylbenzene was identified by conversion to 2-ethyl-5-isopropylbenzenesulfonamide. The structure of the latter was proved by oxidation to the known 3-sulfonamido-4-ethylbenzoic acid.

Furfural methylhydrazone lost nitrogen at 170–190° in the presence of alkali and platinum but no products could be isolated from the reaction mixture.

Cyclohexanone methylhydrazone distilled unchanged from alkali and platinum at about 200°, but when the mixture of reagents was heated in a sealed tube at 250° there was obtained a colorless crystalline product of unknown structure. It is apparently a tertiary amine of the empirical formula $C_9H_{15}N$. There was no methylcyclohexane detected.

The dimethyl and diethylhydrazones of benzaldehyde, *p*-isopropylbenzaldehyde and furfural were all stable to alkali at 250°. The dialkylhydrazones of cyclohexanone, however, were largely decomposed to tarry products under these conditions.

## Discussion of Results

The fact that some N-monoalkylhydrazones, but not N,N-dialkylhydrazones, can be made to lose nitrogen in the presence of hot alkali with the formation of a product analogous to that formed in the Wolff–Kishner reduction of simple hydrazones makes it appear plausible that these processes go by a similar mechanism at least in the absence of solvent. It has been suggested[1] that the Wolff–Kishner reduction proceeds by a preliminary shift of the double bond to form a diimine, which then loses nitrogen in the manner characteristic of compounds containing the N=N linkage

$$R{-}CH{=}N{-}NH_2 \xrightarrow{OH^-} RCH_2{-}N{=}N{-}H \longrightarrow RCH_3 + N_2$$

Balandin and Vaskevitch[2] have reported kinetic data on the decomposition of cyclohexanone hydrazone that indicate an intermediate is formed in the process, and suggest that the only reasonable intermediate is the diimine.

If this mechanism is applied to the decomposition of benzaldehyde methylhydrazone it is difficult to avoid the conclusion that the diimine decomposes into two free radicals and a molecule of nitrogen. The free radicals then combine with each other to form ethylbenzene. The three steps in the reaction are then

$$C_6H_5CH{=}N{-}N(H)CH_3 \rightleftharpoons C_6H_5CH_2{-}N{=}N{-}CH_3 \quad (1)$$

$$C_6H_5CH_2{-}N{=}N{-}CH_3 \longrightarrow C_6H_5CH_2\cdot + CH_3\cdot + N_2 \quad (2)$$

$$C_6H_5CH_2\cdot + CH_3\cdot \longrightarrow C_6H_5CH_2CH_3 \quad (3)$$

There is a considerable amount of evidence that points to the existence of the reversible reaction (1).[3] The hydrazone is evidently always favored in this equilibrium though there are cases known in which the diimine form exhibits considerable stability. Phenyl ethyl diimine can be distilled at

(1) Gattermann and Wieland, "Laboratory Methods of Organic Chemistry," New York, N. Y., 1938, p. 384.

(2) Balandin and Vaskevitch, *J. Gen. Chem. U.S.S.R.*, **6**, 1878 (1936); [*C. A.*, **31**, 4575 (1938)].

(3) Sidgwick, "Organic Chemistry of Nitrogen," Oxford University Press, New York, N. Y., 1937, p. 432.

180° without isomerizing to acetaldehyde phenylhydrazone, and is stable to dilute alkali.[4] Phenyl benzyl diimine and dibenzyl diimine have been prepared, and are converted to the corresponding hydrazones by the action of either acid or base.[5] Surprisingly enough, diisopropyl diimine is so stable that the action of alkali at 180° for three to five hours converts it only partially into the hydrazone form.[6] It is evident that not only are the diimine forms characterized by considerable stability, but that alkali is a catalyst for the diimine-hydrazone equilibrium.

The evidence for step (2) is equally impressive. The thermal decomposition of dimethyl diimine in the gas phase into nitrogen and ethane at 275 to 320° has been carefully studied,[7] and shown to proceed almost certainly by a free radical mechanism.[8] Substitution of the hydrogens of one or both methyls in dimethyl diimine by alkyl groups leads to a slight decrease in thermal stability of the compound, whereas substitution by aromatic groups leads to a far more pronounced decrease in thermal stability. Thus, the temperatures of roughly comparable rates of decomposition are: dimethyl diimine, 320°; methyl isopropyl diimine, 300°[9]; diisopropyl diimine, 280°[10]; dibenzyl diimine,[5] 160–170°. It would then be expected that methyl benzyl diimine formed by isomerization of benzaldehyde methylhydrazone, would decompose at a temperature between 170° and 280°. The observed temperature is 220–230°.

If the reaction proceeds by a free radical mechanism, it could be expected that the particles might recombine partly with themselves and partly with each other. Therefore a search was made for dibenzyl among the reaction products of the benzaldehyde methylhydrazone decomposition but none could be detected. It was thought likely that the small amount of stilbene formed in the reaction might have arisen by platinum dehydrogenation of dibenzyl produced. But dibenzyl was found to be completely stable under the reaction conditions, and the formation of stilbene remains unexplained. However Wolff[3] found some symmetrical tetraphenylethane among the reaction products when benzophenone phenylhydrazone was heated with sodium ethoxide at 190° or slowly distilled in the absence of alkali. In this case the relatively high stability of the diphenylmethyl radical can explain the formation of this product though it is difficult to see why triphenylmethane was not also formed.

Similarly, it seems highly likely that the thermal decomposition of pyrazolines proceeds by initial isomerization to the $\Delta'$-form, which loses nitrogen to form a di-free radical. This becomes stabilized by forming a cyclopropane derivative. Further work on appropriately substituted pyrazolines is now in progress.

## Experimental

**Attempted Alkaline Decomposition of the Dialkylhydrazones.**—The procedure used involved simply heating the compound in question, with a pellet of sodium or potassium hydroxide and a small platinum spiral, in a Woods metal bath to 250° for about half an hour. The apparatus was connected with a gas buret.

The dimethyl- and diethylhydrazones of benzaldehyde, *p*-isopropylbenzaldehyde and furfural were all found to be stable under the above conditions. There was little or no net evolution of gas and the hydrazones could be recovered virtually quantitatively, as shown by the boiling points, indices of refraction, and preparation of solid derivatives.

Because of their low boiling point, the dimethyl- and diethylhydrazones of cyclohexanone had to be heated in sealed tubes. Considerable pressure had developed when the tubes were cooled and opened, and a strong amine odor was evident. In both cases very little dialkylhydrazone could be recovered from the dark tarry mass, and it was evident that almost complete decomposition had occurred.

**Alkaline Decomposition of Benzaldehyde Methylhydrazone.**—In a 50-ml. modified Claisen flask equipped with a receiver and connected to a gas buret were placed 5.0 g. of the hydrazone, a pellet of sodium hydroxide and several pieces of platinized porous plate. The flask was heated in a Woods metal-bath. Gas began to evolve rapidly at 235° (bath temp.). The bath was heated to 254° and maintained there for one-half hour, when gas evolution had virtually ceased. The gas evolved corresponded to 83% of the theoretical amount of nitrogen expected.

In the receiver there was found a mixture of two liquids. This turned out to consist of a few drops of methylhydrazine and 0.5 g. of ethylbenzene. The former was identified by its rapid positive Fehling test and conversion to the picrate. The ethylbenzene was removed with a pipet, washed with 1 ml. of water, dried over potassium carbonate. The material has b. p. (micro) 137°, $n^{20}D$ 1.4943 (ethylbenzene has b. p. 136.2, $n^{20}D$ 1.4959). Several hundred milligrams of this material was converted to 2,4-diacetaminoethylbenzene,[11] m. p. 223–225° (no depression with an authentic specimen of m. p. 224–227°).

The residue in the flask was taken up in ether, washed with water and 5% hydrochloric acid and dried. (From the aqueous washings there was recovered a little benzoic acid.) The ether residue was distilled at 16 mm. to give 0.3 g. of material coming over below 100° (odor of benzaldehyde, positive DNP test), 0.73 g. of a fraction boiling at 160–180° (A), and 0.60 g. of a fraction of b. p. 213° (B). The residue weighed 0.88 g.

Fraction A was partially crystalline. After seven crystallizations from ethanol–water there was isolated about 20 mg. of slightly impure stilbene, m. p. 116–121°, mixed m. p. with stilbene (m. p. 120–124°) showed no depression.

*Anal.* Calcd. for $C_{14}H_{12}$: C, 93.29; H, 6.71. Found: C, 93.17; H, 7.27.

Fraction B was almost entirely crystalline, but was evidently a mixture since it could not be obtained crystalline from ethanol–water. The ethanol solution on treatment with trinitrobenzene gave a yellow precipitate that after two more crystallizations gave yellow needles, m. p. 110.0–111.5°. The analysis indicates this compound is still impure.

*Anal.* Found: C, 38.04; H, 2.11.

**Alkaline Decomposition of *p*-Isopropylbenzaldehyde Methylhydrazone.**—The decomposition was carried out as described in the previous case. From 13.4 g. of the hydrazone there was obtained 119% of the theoretical amount of gas. A sample of this gas was cooled to −193°

(11) Ipatieff and Schmerling, THIS JOURNAL, **59**, 1056 (1937).

and pumped off with a mercury pump. No significant portion of the gas remained after this treatment. Evidently no detectable amount of ethane is formed in the reaction.

The distillate produced during the reaction was combined with the few drops of material that could be distilled *in vacuo* (bath to 180°), worked up in ether as usual and finally distilled from sodium. There was obtained 2.8 g. (25%) of *p*-ethylisopropylbenzene. Micro b. p. is 194°, $n^{23}D$ 1.4858, $d^{23}_4$ 0.8530 (the literature values are: b. p. 196°, $n^{16}D$ 1.4928, $d^{16}_4$ 0.8606); $MR_{obs}$ 49.90; $MR_{calcd.}$ 49.40.

**2-Ethyl-5-isopropylbenzenesulfonanilide.**—One gram of the hydrocarbon was dissolved in 5 ml. of chloroform, cooled to 0°, and while stirred in an ice-bath was treated dropwise with 5 ml. of chlorosulfonic acid. The solution was held at 0° for ten minutes, allowed to warm to room temperature and poured on ice. The chloroform solution was separated, washed and dried. One-half of the chloroform solution of sulfonyl chloride was evaporated to dryness and to the oil was added 2 ml. of aniline. The solution was boiled for two minutes, and the product was worked up by extraction from ether with 1% of sodium hydroxide. There was obtained 0.74 g. (72%) of the crude anilide of m. p. 104–107°. Crystallization from ethanol–water gave the pure material as tiny serrated needles melting constantly at 108.0–109.0°.

The same material was prepared from authentic hydrocarbon. It had the same melting point and a mixture of the two showed no melting point depression.

This material is probably identical with the compound (position of sulfonanilide group unknown), prepared by Klages and Keil,[12] reported to melt at 110°.

The position of the entering sulfonyl chloride group was demonstrated as follows:

Authentic *p*-ethylisopropylbenzene was treated as described above, and the chloroform solution of the acid chloride was divided into two parts. One of these was converted to the anilide as described. The other was evaporated, heated with ammonium carbonate on the steam-bath for one-half hour, the solid washed well with cold water, and the residue crystallized from ethanol to give 64% of crude 2-ethyl-5-isopropylbenzenesulfonamide. Two crystallizations from ethanol gave a product melting at 69.0–70.5°.

*Anal.* Calcd. for $C_{11}H_{17}NO_2S$: C, 58.12; H, 7.54. Found: C, 58.11; H, 6.92.

**3-Sulfonamido-4-ethylbenzoic acid.**—Two-tenths of a gram of the above sulfonamide was refluxed with 1.2 g. of potassium dichromate, 1 ml. of concentrated sulfuric acid, and 3 ml. of water for four hours. The acid fraction was crystallized from ethanol–water several times to give the pure acid which has a constant, though wide, melting range. It begins to soften at 235°, and melts at 248–257°, mostly at 253–257°. Widman[13] reported that this compound melted at 259–260°.

An authentic specimen of this material was prepared by the same series of reactions applied to *p*-diethylbenzene. The acid so formed was obtained as colorless needles that begin to soften at about 235°, and melts at 248–259°, mostly at 253–259°. A mixture of the two materials shows exactly the same melting characteristics.

**Alkaline Decomposition of Furfural Methylhydrazone.**—This material was decomposed in the usual way. It was found that the decomposition temperature was considerably lower than in the other cases. At about 140° the compound begins a very rapid evolution of gas. The temperature was carried up to 200° to ensure complete reaction. There was collected 91% of the theoretical volume of gas.

On working up the reaction mixture nothing but tar could be obtained. Evidently little or no ethylfuran was formed.

**Alkaline Decomposition of Cyclohexanone Methylhydrazone.**—This material was found to distill unchanged at about 200° from potassium hydroxide and platinum. The hydrazone (3.45 g.) one pellet of potassium hydroxide and a platinum spiral were heated in a sealed tube at 250° for two hours. On being cooled the tube's contents were found to be a solid mass of crystals. On being worked up this material was found to contain no trace of methylcyclohexane. The solid material was crystallized from ethanol to give 0.40 g. of colorless plates, m. p. 88.0–89.5°. A second crop of 0.39 g. of less pure material was obtained. Recrystallization of the first crop from ethanol gives platelets of m. p. 90.5–91.0°.

*Anal.* Found: C, 81.90, 81.57; H, 9.63, 9.51; N, 7.95, 8.32. Calcd. for $C_{11}H_{15}N$: C, 81.9; H, 9.3; N, 8.8.

This material is a very weak base (soluble in 6 *N* HCl, insoluble in 1.3 *N* HCl), and is probably a tertiary amine (forms no derivative in the Hinsberg process). It does not form a picrate or a chloroplatinate.

## Summary

The stability of some N-alkyl and N,N-dialkylhydrazones to alkali has been investigated. The results indicate that the decomposition of monoalkylhydrazones, of unsubstituted hydrazones, and of pyrazolines may all proceed by the same mechanism in the absence of solvent: *i. e.*, preliminary isomerization of the hydrazone to the diimine, and loss of nitrogen from the diimine to give two free radicals (a di-free radical in the case of pyrazolines) that rapidly combine to give the observed products.

# Morphine Studies. The Synthesis of a Tetralin–Piperidine Fused-Ring System[1]

BY E. C. HORNING AND R. U. SCHOCK, JR.[2]

One of the chief problems connected with the synthesis of morphine derivatives and morphine analogs lies in the synthesis of bridged-ring piperidine systems similar to that in morphine. This problem has been studied in a number of laboratories, and several methods have been found suitable for the preparation of certain types of analogs. A bicyclic system, containing a piperidine ring bridged at appropriate points, has been described recently by Cronyn.[3] Another bicyclic system involving a bridged-piperidine structure, in which the nitrogen was present in a quaternary salt group, was obtained by Barltrop,[4] and the method of synthesis was extended to the preparation of a tetralin analog. The synthesis of a compound (morphan) containing the carbon skeleton of morphine was recently announced by Grewe,[5] although experimental details of this work are lacking.

We have been interested in the preparation of certain tetralin analogs of morphine,[6] and in the course of the work it was necessary to investigate the problem of obtaining a tetralin–piperidine fused-ring system. At the same time, it was hoped that the investigation might result in a method sufficiently general to allow further application to the preparation of a synthetic tetrahydrodesoxycodeine. The work described here includes a study of two methods aimed at a ring system of the required sort.

The starting compound, 2,3-dimethoxyphenylacetonitrile, was alkylated with β-ethoxyethyl methanesulfonate to provide α-(2,3-dimethoxyphenyl)-γ-ethoxybutyronitrile (I). Addition of acrylonitrile led to the dinitrile II; this was converted into methyl γ-(2,3-dimethoxyphenyl)-γ-cyano-ε-ethoxycaproate (III) by means of hydrogen chloride in methanol. Formylation of the ester III with ethyl formate and sodium methoxide, followed by cyclization of the formyl derivative (IV) with sulfuric–phosphoric acids, gave the dihydronaphthalene derivative (V). Hydrolysis of the ester group, followed by hydrogenation with palladium–carbon catalyst in acetic acid, resulted in the tetralin derivative VI. The acid group was then transformed into the urethan group of compound VII through a method somewhat similar to that employed earlier,[6] except that ethanol was used during the Curtius rearrangement. Through the action of 48% hydrobromic acid under reflux, the crude urethan was converted into an amine hydrobromide (VIII). The structure of this intermediate was evident from the results of cyclization experiments; preliminary trials aimed at isolating a pure sample of this salt were not successful, and in later experiments solutions of the salt were used directly for cyclization after clarification with decolorizing carbon. There are six functional group reactions, including cleavage of three ether groups, hydrolysis of the cyano group, and hydrolysis-decarboxylation of the ester group, which occur at this point.

Cyclization of the intermediate was best carried out in aqueous solution in the presence of sodium acetate at *p*H 5. The resulting product was isolated as a crystalline acetyl derivative by acetylation in a solution maintained at *p*H 7–8 with sodium bicarbonate. The crystalline product was obtained in pure form without difficulty, and analytical data indicated that the empirical formula corresponded to a diacetyl derivative (IXb). The acetylation of only one phenol group in the parent compound, IXa, under acetylation conditions, is not without analogy in the morphine series. At the same time, the possibility that cyclization might have occurred to yield a chroman, with subsequent acetylation to provide the diacetyl derivative X, was also present. Freshly prepared solutions of the product gave an azo dye when treated with diazotized aniline or diazotized sulfanilic acid; this indicates the presence of a free phenolic group. The alternate assumption, that the compound is a chroman in which the acetyl group is hydrolyzed on contact with aqueous alkali, followed by *o*-coupling, appears far less probable.

A second method of synthesis was carried to the point indicated in the accompanying figure. It was hoped that the nitrosoketone could be reduced by the methods of Rosenmund[7] and Kindler.[7] Unfortunately, the nitrosation gave as a product an unstable oil from which very little crystalline material could be isolated.

The application of reaction methods leading to the formation of a tetralin–piperidine system are of particular interest in connection with a synthesis of tetrahydrodesoxycodeine. A useful precursor, 2-(2′,3′,-dimethoxyphenyl)-2-(β-ethoxyethyl)-cyclohexanone, has been prepared,[8] and work in this direction is under way.

## Experimental

All melting points are corrected.

**α-(2,3-Dimethoxyphenyl)-γ-ethoxybutyronitrile (I).**—Sodamide was prepared from the reaction of 12.7 g. of sodium (0.55 mole) and 400 ml. of liquid ammonia in the presence of a trace of ferric nitrate.[9] A solution of 88.5 g. (0.50 mole) of 2,3-dimethoxyphenylacetonitrile in 100 ml. of dry benzene and 100 ml. of dry ether was added to the suspension of sodamide in liquid ammonia. The suspension was stirred for one hour or until the ammonia evaporated. Then, with vigorous stirring, a mixture of 92.4 g. (0.55 mole) of β-ethoxyethyl methanesulfonate[10] and 100 ml. of dry ether was added at such a rate that the heat of reaction maintained the mixture at gentle reflux. After heating under reflux for one hour, the mixture was cooled and diluted with 500 ml. of water. The layers were separated and the aqueous phase extracted once with 100 ml. of ether. The combined organic solutions were washed successively with 5% sodium hydroxide solution, 5% hydrochloric acid and with water. The extract was dried over magnesium sulfate, the solvents removed by distillation and the residue fractionated through a short Vigreux column. The fraction boiling at 131–140° (0.4 mm.) was collected. The yield of nearly colorless product was 105.2 g. (84%).

*Anal.* Calcd. for $C_{14}H_{19}O_3N$: C, 67.45; H, 7.68. Found: C, 67.48; H, 7.63.

**α-(β-Ethoxyethyl)-α-(2,3-dimethoxyphenyl)-glutaronitrile (II).**—The procedure followed was essentially that described by Bruson[11] for the cyanoethylation of phenylacetonitrile. A solution of 105.2 g. of the nitrile I in 90 ml. of *t*-butyl alcohol was heated to 40° and then, with stirring, the dropwise addition of a solution of 24 g. of acrylonitrile in 30 ml. of *t*-butyl alcohol was started. After the addition of a few drops, 2 ml. of a 30% aqueous solution of benzyltrimethylammonium hydroxide was added, and the temperature maintained at 40–45° by occasional external cooling. Another 2-ml. portion of catalyst was introduced after half the acrylonitrile was added. When the temperature no longer rose spontaneously, the solution was heated for one hour at 40–45° and allowed to stand overnight. The dark solution was acidified with dilute hydrochloric acid and diluted with 250 ml. of cold water. The layers were separated with the aid of ether and the aqueous layer extracted once with 50 ml. of ether. The combined extracts were washed with water and dried over magnesium sulfate. Distillation of the residue remaining after evaporation of

(11) Bruson and Riener, *ibid.*, **65**, 25 (1943).

the solvent yielded 108.5 g. (85%) of a colorless viscous oil boiling at 171–178° (0.3 mm.).

*Anal.* Calcd. for $C_{17}H_{22}O_3N_2$: C, 67.53; H, 7.33. Found: C, 67.68; H, 7.24.

**Methyl γ-(2,3-Dimethoxyphenyl)-γ-cyano-ε-ethoxycaproate (III).**—A solution of 108.5 g. of the dinitrile II in 400 ml. of absolute methanol was treated with a stream of dry hydrogen chloride for thirty minutes. The mixture was heated gently under reflux for one hour, and then approximately one-half the alcohol was removed in a current of air. Dilution of the cooled residue with water produced an oil which was separated by three 100-ml. portions of ether. The extract was washed with water, once with 50 ml. of saturated sodium bicarbonate solution and dried over magnesium sulfate. Evaporation of the solvent left a colorless residue which was distilled at reduced pressure. The fraction boiling at 176–180° (0.5 mm.) was collected; the yield was 104.7 g. (87%).

*Anal.* Calcd. for $C_{18}H_{25}O_5N$: C, 64.46; H, 7.51. Found: C, 64.51; H, 7.37.

**γ-(2,3-Dimethoxyphenyl)-γ-cyano-ε-ethoxycaproic Acid (XI).**—The ester-nitrile was hydrolyzed with aqueous alkali. It was found that greater yields were obtained if the intermediate ester was not distilled, but was saponified immediately after distillation of the solvent ether. Thus, the methyl ester obtained from 70.0 g. of the dinitrile II was boiled under reflux for two and one-half hours with a solution of 18 g. of sodium hydroxide in a mixture of 400 ml. of water and 10 ml. of ethanol. Upon acidification of the cooled alkaline solution with dilute hydrochloric acid, a colorless oil precipitated which was separated with two 75-ml. portions of ether. The extract was dried over magnesium sulfate and the ether distilled, leaving 72.7 g. (97%) of an oily residue. The product, γ-(2,3-dimethoxyphenyl)-γ-cyano-ε-ethoxycaproic acid XI, did not crystallize on standing and was not purified further. Derivatives prepared for characterization could not be crystallized.

**1-Cyano-1-(β-ethoxyethyl)-7,8-dimethoxy-1,2,3,4-tetrahydro-3-naphthoic Acid (VI). A. Formylation.**—Sodium methoxide was prepared from 4.6 g. of sodium (0.2 mole) and absolute methanol. Then, at room temperature, a solution of 33.5 g. of the nitrile-ester III (0.1 mole) and 14.8 g. of ethyl formate (0.2 mole) in 100 ml. of dry ether was added to a vigorously stirred suspension of the sodium methoxide in 100 ml. of dry ether. After one and one-half hours, an additional 0.2 mole of ethyl formate was added and the stirring continued for another hour, at which time all suspended material was in solution. The solution was allowed to stand for fifteen hours; then 200 ml. of cold water was added and the layers separated. The aqueous layer was washed once with 50 ml. of ether and this extract combined with the original organic layer. From this ether solution there was obtained 5.6 g. of unchanged III which was pure enough for further use. The aqueous layer was acidified with dilute acetic acid and extracted with two 75-ml. portions of ether. The extract was washed once with 50 ml. of saturated sodium bicarbonate solution, dried, and the solvent evaporated. There was obtained 29.2 g. of the formyl derivative, as a pale yellow oil. The yield was 80% or 97% based on unrecovered nitrile-ester.

**B. Cyclization.**—A solution of 64.7 g. of the formyl derivative in 60 ml. of glacial acetic acid was added to a mixture of 175 ml. of 85% phosphoric acid and 45 ml. of concentrated sulfuric acid, keeping the temperature below 0°. The solution was allowed to stand at −5° for thirty minutes and 1.5 hours at room temperature. Pouring upon ice produced a viscous gum which was separated with three 100-ml. portions of ether. The extract was washed once with 75 ml. of 5% sodium hydroxide solution and then concentrated. The residue was heated under reflux for one and one-half hours with a solution of 16 g. of sodium hydroxide in 600 ml. of water and 20 ml. of ethanol. Acidification of the hot solution produced a gum which crystallized after standing twenty-four hours in an ice-chest. The dried crystalline **1-cyano-1-(β-ethoxyethyl)-7,8-dimethoxy-3,4-dihydro-3-naphthoic acid** melted at 165–166° and weighed 55.2 g. (93%). Recrystallization from dilute acetic acid raised the melting point to 167–168°.

*Anal.* Calcd. for $C_{18}H_{21}O_5N$: C, 65.24; H, 6.39. Found: C, 65.31; H, 6.35.

**C. Reduction.**—A solution of 17.0 g. of the acid in 150 ml. of glacial acetic acid was hydrogenated in a low-pressure apparatus in the presence of 5% palladium–carbon catalyst at 65°. The catalyst was removed by filtration and the filtrate concentrated in a current of air on a steam cone. The crystalline residue was fractionally crystallized from dilute acetic acid in an effort to isolate each of two possible diastereoisomers. The melting points of three crops (*ca.* 129–131°) were almost the same, and the filtrates yielded a compound which was apparently identical with that obtained in the first three crops but less pure. It is believed that one isomer is formed exclusively. Recrystallization raised the melting point to 131–132°. The yield of VI was 17.0 g.

*Anal.* Calcd. for $C_{18}H_{23}O_5N$: C, 64.84; H, 6.95. Found: C, 64.75; H, 6.76.

**Conversion of VI to 1-Carboxy-3,1-acetyliminoethano-7-acetoxy-8-hydroxy-1,2,3,4-tetrahydronaphthalene (IXb).**—A mixture of 2 ml. of thionyl chloride and 1.65 g. of VI was allowed to stand overnight. The excess thionyl chloride was removed at 50° at the water pump and the residual acid chloride taken up in 25 ml. of dry reagent-grade acetone. The solution was chilled in an ice-bath, and a solution of 0.73 g. of sodium azide in 2 ml. of water was added with vigorous stirring. After fifteen minutes the mixture was diluted with 75 ml. of cold water and the crude azide separated with three 25-ml. portions of ether. The extracts were washed once with saturated sodium bicarbonate solution and dried for fifteen minutes over magnesium sulfate. To the ether extract was added 25 ml. of absolute ethanol and the solution slowly distilled on a steam cone through a short column. The residue of the **ethyl urethan** weighed 1.8 g. (95%). The residue was then boiled vigorously under reflux with 20 ml. of 48% hydrobromic acid for four hours, allowing the initial volatile products of reaction to escape from the reflux condenser. The dark solution was diluted with 50 ml. of hot water, treated with carbon and the colorless filtrate made slightly alkaline with solid sodium bicarbonate. Dilute hydrochloric acid was then added until the filtrate was acid. The acidified filtrate was boiled under reflux with 5.0 g. of sodium acetate trihydrate for 1.5 hours; the addition of sodium acetate brought the *p*H to approximately 5. The cooled solution was then treated with 2 ml. of acetic anhydride and solid sodium bicarbonate was added with stirring to keep the mixture alkaline (*p*H 7–8). After fifteen minutes, a further 2-ml. portion of acetic anhydride was added. After an additional fifteen minutes, the solution was acidified with dilute hydrochloric acid and extracted with four 25-ml. portions of chloroform. The combined extracts were dried over magnesium sulfate and evaporated, leaving a crystalline residue weighing 1.50 g. This material was purified by recrystallization from dilute acetic acid. The melting point of the pure compound varied from 258 to 262° (dec.) depending upon the rate of heating of the bath.

*Anal.* Calcd. for $C_{17}H_{19}O_6N$: C, 61.25; H, 5.74; N, 4.22. Found: C, 61.21; H, 5.68; N, 4.26.

Structure IXb, with the phenolic hydroxyl group acetylated (*viz.*, $C_{19}H_{21}O_7N$) requires: C, 60.79; H, 5.64; N, 3.73.

The presence of a phenolic group in this product was indicated by the addition of either diazotized sulfanilic acid or diazotized aniline to a freshly prepared alkaline solution of the compound; a deep orange color resulted. A small amount of the azo dye from diazotized *p*-nitroaniline was isolated in solid form, but it proved difficult to purify and was not characterized further.

**4-Cyano-4-(β-ethoxyethyl)-5,6-dimethoxytetralone-1 (XII).**—A solution of 63.0 g. of crude γ-(2,3-dimethoxyphenyl)-γ-cyano-ε-ethoxycaproic acid (XI) in 50 ml. of

absolute ether was treated with 30 ml. of thionyl chloride and three drops of pyridine. After standing for fifteen hours, the volatile constituents were removed at 50° at the water pump; 5 ml. of dry benzene was added and the operation repeated. The residue was dissolved in 600 ml. of dry thiophene-free benzene and chilled until the solvent began to crystallize. Then a solution of 40 ml. of stannic chloride in 40 ml. of benzene was added rapidly with shaking and the mixture allowed to stand in the ice-bath for fifteen minutes. The yellow complex was destroyed by pouring upon a mixture of 50 ml. of ether, 100 ml. of concentrated hydrochloric acid, and ice. The organic layer was then separated and washed successively with 5% hydrochloric acid, water, 5% sodium hydroxide solution, and finally with water. Drying, followed by evaporation of the solvent, left an oil which was distilled at reduced pressure. The fraction boiling at 192–198° (0.4 mm.) was collected as product; the yield was 42.2 g. (71%). The pale yellow oil solidified on standing and melted at 67–68° after recrystallization from cyclohexane–petroleum ether.

*Anal.* Calcd. for $C_{17}H_{21}O_4N$: C, 67.30; H, 6.98. Found: C, 67.14; H, 6.89.

**Nitrosation of the Tetralone XII.**—Various conditions and methods were tried without good results. Nitrosation with an ester of nitrous acid in the presence of dry hydrogen chloride produced only resinous products. In the presence of sodium alkoxides with either freshly prepared butyl or isopropyl nitrite, small amounts of the desired oximinoketone XIII were obtained. The yields in all cases were too low to warrant continuance of the synthesis along this path. The following procedure is an example of a successful experiment. A solution of 1.5 g. (0.005 mole) of XII and 0.23 g. of sodium in 50 ml. of absolute ethanol was prepared. Then, 1.5 g. (0.0075 mole) of freshly prepared *n*-butyl nitrite was added, and the mixture was allowed to stand at 5° for two days. The alcohol solution was diluted with an equal volume of cold water and extracted twice with 30-ml. portions of ether. The aqueous layer was acidified with diluted hydrochloric acid and extracted three times with 30-ml. portions of ether. Drying, followed by evaporation of the solvent, left 1.5 g. of a red oil which partially solidified on standing. Trituration with ether provided 0.15 g. of pale yellow **2-nitroso-4-cyano-4-(β-ethoxyethyl)-5,6-dimethoxytetralone-1 (XIII)** which melted with darkening at 154–155° after three recrystallizations from ethyl acetate–petroleum ether.

*Anal.* Calcd. for $C_{17}H_{20}O_5N_2$: C, 61.43; H, 6.07. Found: C, 61.33; H, 5.81.

## Summary

A method leading to a compound containing a fused-ring tetralin–piperidine system, similar to part of the morphine ring system, has been developed.

# The Preparation of the $C_{10}$ Monocyclic Aromatic Hydrocarbons

BY S. F. BIRCH, R. A. DEAN, F. A. FIDLER AND R. A. LOWRY

## Introduction

A comparatively elaborate program has been carried out over a number of years to produce a supply of hydrocarbons in a high degree of purity required in connection with spectroscopic analysis and other analytical problems. Although interest in the aromatic series at first centered primarily round the hydrocarbons in the $C_6$ to $C_9$ range, it was later found desirable to include the $C_{10}$ compounds. At the time this work was commenced, no source of these hydrocarbons was available, and the physical data reported in the literature were extremely scanty and contradictory.

The present paper describes in general the methods and techniques employed in these laboratories for their preparation. Possibly its chief interest is on account of the steps taken at each stage to ensure that the intermediate compounds were satisfactorily purified before proceeding to the next step in the synthesis. Particular emphasis was placed on the determinations of the physical constants and purities of the intermediates at all stages of their purification and as a result the densities, refractive indices and freezing points of many compounds of known purity are recorded for the first time. At any point at which an intermediate proved relatively impure, it was possible to continue purification until a satisfactory product had been obtained. Only when a following stage permitted the easier separation of impurities was the synthesis continued without satisfactory purification being attained. Thus in some cases it was more satisfactory to purify the carboxylic acid than the nitrile from which it was obtained.

The scale of the preparation was based upon a quantity of 1500 to 2000 ml. of final hydrocarbon in a satisfactory state for purification. This quantity is appreciably smaller than that generally made available to Rossini and his co-workers for purification at the National Bureau of Standards and it would have been desirable to increase this quantity two- or three-fold. Unfortunately, the effort necessary for preparations on this scale was not available. It was felt, however, that taking considerable care in the purification of the intermediates would in great measure offset the smaller quantity of hydrocarbon available for final treatment.

The methods chosen as being most satisfactory were made as general as possible so that they would be applicable to the preparation of more than one hydrocarbon. By so doing, not only was the working out of new techniques largely avoided but the same apparatus could frequently be employed for a number of preparations. Routes were selected which enabled readily avail-

able and easily purified starting materials to be employed for the synthesis. Thus it will be observed that amines formed the most common class of starting materials, since these can readily be purified in bulk by crystallization of their salts or acyl derivatives.

Care was taken to avoid reactions in which the possibility of isomerization was likely to occur at any stage or in which impurities separated only with difficulty from the final products, would be formed. Thus, the Friedel–Crafts method for preparing substituted ketones, *e.g.*, *p*-ethylacetophenone from acetyl chloride and ethylbenzene with aluminium chloride, was avoided, since previous experience had shown that this reaction tends to produce a mixture of isomers. Also, an early batch of *n*-butylbenzene was prepared by the Wurtz–Fittig reaction using bromobenzene and *n*-butyl bromide. The purification of the hydrocarbon obtained by this method proved so difficult, owing to the presence of halogen compounds in the product, and the yield was so poor, that this reaction was avoided in further syntheses. The low yield obtained in this reaction is in agreement with the findings of Karabinos, Serijan and Gibbons[1]. Still another reaction which was avoided was that exemplified by the Grignard condensation of benzylmagnesium chloride and diethyl sulfate for the production of *n*-propylbenzene. This preparation had been carried out several years ago in these laboratories but the purification of the hydrocarbon proved extremely difficult with the columns then available. At the time, this was assumed to be due to halogen substitution in the benzene ring but a recent publication[2] has shown that in this reaction, a certain amount of rearrangement occurs giving *p*-ethyltoluene as well as *n*-propylbenzene.

A further point which influenced the choice of route was that, as far as possible, the stages involved should be adaptable to relatively large-scale laboratory operation. Thus the reactions which were found to be most applicable and were repeatedly used included the diazo reaction, Grignard condensations, ketonization by passage of mixed acids over a thoria catalyst and Clemmensen reductions.

## Experimental

For simplicity, since more than one hydrocarbon was often prepared by the same route, the general method adopted is described once only and details of physical properties and yields of intermediates are quoted for each individual hydrocarbon. Thus the route

Amine ⟶ Nitrile ⟶ Acid ⟶ Ketone ⟶ Hydrocarbon

was used for *p*-diethylbenzene, 1,2-dimethyl-3-ethylbenzene, 1,2-dimethyl-4-ethylbenzene, and 1,4-dimethyl-2-ethylbenzene while the route

Amine ⟶ Nitrile ⟶ Ketone ⟶ Hydrocarbon

was employed for *o*-diethylbenzene, 1,3-dimethyl-4-ethylbenzene, 1,3-dimethyl-5-ethylbenzene and the three methyl-*n*-propylbenzenes.

**Conversion of Amines to Ketones via Nitriles and Acids.**—The procedures used for the conversion of the various toluidines, xylidines and ethylanilines to their corresponding ketones through the nitriles and carboxylic acids followed very closely on those described in Organic Syntheses.[3] The hydrolysis of the nitriles to carboxylic acids by 75% sulfuric acid worked perfectly satisfactorily in all the cases tried except for *m*-2-xylonitrile. When this nitrile was heated with the acid, the only recoverable product was *m*-xylene.

Since pumice was unobtainable when much of the work was carried out (1942), the thoria catalyst used for the conversion of the carboxylic acids into substituted acetophenones was supported on unglazed porcelain (approximately 0.25 inch). Furthermore, owing to the low solubility of many of the acids in glacial acetic acid, it was necessary to increase the mole ratio of acetic acid to carboxylic acid to 8 to 1. Even so, in certain instances it was essential to provide the dropping funnel with a heating jacket in order to prevent crystallization and subsequent blockage. A reaction tube 48 inches long and 1.5 inches in diameter, and holding approximately 500 ml. of the impregnated unglazed porcelain, was employed. With a new batch of catalyst it was found that no more than about 500 to 600 ml. of the mixed acids could be put through the reactor tube in eight hours, otherwise a considerable portion passed through unchanged. However, when the catalyst had been in use for several days, the rate could be almost doubled. The most satisfactory method of arranging the processing and regeneration was to carry out the ketonization during the day and regenerate the catalyst each night by drawing through air at a temperature of between 500 and 550°.

**Reaction of Nitriles with Alkylmagnesium Halides.**—In the production of an arylalkyl ketone from a nitrile and a Grignard reagent, it has been observed that the best yield is obtained by the use of an aryl nitrile and aliphatic Grignard rather than an aromatic Grignard and alkyl nitrile.[4] The procedure adopted for the Grignard condensations described here was based on a private communication received from Dr. G. Baddeley.

A quantity of methylmagnesium (or ethylmagnesium) chloride was prepared in the usual manner by passing methyl (or ethyl) chloride into a stirred suspension of magnesium turnings in absolute ether. The nitrile (1 mole to each 1.2 moles of Grignard) was then added with stirring over a period of one hour. During the addition, the reaction product became yellow but no temperature rise was observed.

After stirring for seventeen to twenty hours, the magnesium complex was decomposed to the ketimine by pouring on to crushed ice and the precipitated magnesium compounds were dissolved by the subsequent addition of dilute sulfuric acid. During this process, the ethereal layer changed in color giving a green solution. The combined aqueous and ethereal layers were heated on a steam-bath for one and a quarter hours during which time the ether distilled off and the ketimine was hydrolyzed to give an upper layer of ketone.[5]

The ketone was separated off, the aqueous layer extracted with ether and the combined ketone and extract dried. After removal of the solvent the residue was distilled under reduced pressure.

**Clemmensen Reduction of the Ketones to Hydrocarbons.**—The method which was found most satisfactory and which gave good yields of hydrocarbons from the ketones was the modification of the Clemmensen reduction described by Brady and Day.[6]

(4) Baddeley, *J. Chem. Soc.*, **147**, 232 (1944).

(5) An evolution of ammonia at this stage indicated that an insufficient quantity of acid had been used and that more should be added.

(6) Brady and Day, *J. Chem. Soc.*, **137**, 114 (1934).

**Purification.**—In almost all cases the purification of the hydrocarbons obtained in the last stages of the syntheses comprised refluxing over sodium for several hours, distilling to as small a residue as possible and fractionating in 50- or 100-plate columns. Recently, the 100-plate columns have been modified to operate at reduced pressures and, as a result, some of the higher boiling aromatic hydrocarbons have been fractionated at 50 mm. or 100 mm. instead of at 760 mm. From these distillations, the final "best" samples were obtained by bulking fractions of constant boiling point and constant refractive index. In a number of cases, freezing points of individual fractions were used as an additional check.

### Tetramethylbenzenes

**1,2,4,5-Tetramethylbenzene (Durene).**—The alkylation of a mixed coal-tar *meta/para*-xylene cut was carried out as described by Smith.[7] The yield of tetramethylbenzenes obtained from a number of runs varied from 8.3% to 43% based on the xylene taken while the yield of crude durene varied from 2% up to 15.3%. The average yield of tetramethylbenzene cut from nine thirty mole runs was 17% theoretical.

Cooling the mixture to −10° brought about the crystallization of the durene, which was filtered off and crystallized three times from ethanol and finally from benzene. The mother liquors were used for the preparation of prehnitene and isodurene (see below). The yield of pure durene (no. 1129) from 28.6 kilograms of xylene was 1470 g.

**1,2,3,4-Tetramethylbenzene (Prehnitene).**—The experimental procedure for the conversion of durene and isodurene sulfonic acids by the Jacobsen reaction into prehnitene sulfonic acid varied slightly from that given in "Organic Reactions."[8] It was found that the reaction between the acid and hydrocarbon was too violent to allow shaking in a separating funnel, and consequently the sulfonation was carried out in a wide-mouthed bottle with efficient stirring. The starting material for this preparation was the mother liquors from the tetramethylbenzenes, obtained by the alkylation of xylenes, after filtration of the durene.

The prehnitene sulfonic acid from 750 g. of hydrocarbon was hydrolyzed by dissolving in 2 liters of water and allowing this aqueous solution to drip into sulfuric acid (600 ml. of 96% acid and 400 ml. of water) which was maintained at 140–150°. During the hydrolysis, a stream of super-heated steam was blown through the reaction mixture, the prehnitene thus being steam distilled over as rapidly as formed. The yield of crude prehnitene thus obtained was 1564 g. from 2350 g. of mixed durene–isodurene. Final purification was effected by distillation in a 100-plate column at 48 mm. pressure.

**1,2,3,5-Tetramethylbenzene (Isodurene): First Method, via Bromomesitylene.**[9]—The bromination of mesitylene proceeded satisfactorily and the crude bromocompound, which was obtained in 75 to 80% yields, was fractionated in a 20-plate column under reduced pressure. The fractions, which were bulked together, boiled at 135.5° at 50 mm. pressure and had a constant refractive index $n^{20}D$ of 1.5520.

Reaction of the Grignard compound of the bromomesitylene with dimethyl sulfate[9] gave a 55% yield of crude isodurene (600 g.) which on fractionation in a 50-plate column at 36 mm. pressure gave 308 g. of hydrocarbon. The purity of this hydrocarbon as indicated by its freezing point was 99.8% by weight.

**Second Method, by Alkylation of Xylene.**—The mother liquors, after filtration of crude durene from the tetramethylbenzene fractions, were twice fractionated in a 100-plate column at 100 mm. pressure.

TABLE I

PHYSICAL CONSTANTS OF DURENE, PREHNITENE AND ISODURENE

| | | Durene no. 1129 | Prehnitene no. 1130 | Isodurene: From bromomesitylene no. 1131 | Isodurene: By fractionation no. 1134 |

### Ethylxylenes

#### 1,3-Dimethyl-4-ethylbenzene

***m*-4-Xylidine (1,3-Dimethyl-4-aminobenzene): 2,4-Dimethylbenzonitrile.**—Approximately 15 kilograms of technical *m*-4-xylidine acetate was crystallized once from petroleum ether which served to remove most of the attached oil. The amine was then regenerated from the acetate, distilled at 30 mm. pressure and converted to the hydrochloride. Crystallization of this salt from 5% hydrochloric acid gave a final material (7,931 g.) of melting point 161–162°. The yield of nitrile from the hydrochloride *via* the Sandmeyer reaction was 52.4%.

**2,4-Dimethylacetophenone.**—The product from the Grignard reaction contained a mixture of the ketone and unchanged nitrile and these proved very difficult to separate by distillation. However, trial Clemmensen reductions on the mixture indicated that although the ketone was reduced to hydrocarbon, the nitrile remained unaffected. Consequently the whole of the mixture (2,473 g.) was reduced and the reaction product distilled at a pressure of 140 mm. The hydrocarbon boiled at 130° at this pressure and the residue which remained consisted almost entirely of unreacted nitrile.

#### 1,2-Dimethyl-4-ethylbenzene

**4-Nitro-*o*-xylene. (1,2-Dimethyl-4-nitrobenzene).**—*o*-Xylene (19,150 g., purity 99.92%) was nitrated according to the method of Emerson and Smith.[10] The crude nitroxylenes (21,622 g.) were fractionated in a 7-ft. all-glass helix-packed column under reduced pressure when the 3-nitro compound (11,020 g.) was taken overhead and the 4-nitro-*o*-xylene left as a residue. The latter was distilled from a Claisen flask at 12 mm. pressure, the distillate solidifying on cooling. Final purification was effected by crystallization from ethanol, the recrystallized 4-nitro-compound weighing 8,122 g.

***o*-4-Xylidine (1,2-Dimethyl-4-aminobenzene).**—Reduction of the nitro compound was carried out with hydrogen in a stirred autoclave using a Raney nickel catalyst, the pressure employed being 1500 lb. per sq. in. As soon as the reaction commenced, usually at 90 to 100°, the temperature rose very rapidly due to the strongly exothermic nature of the reaction, and the external heating was stopped. By regulation of the hydrogen pressure and the rate of stirring, the temperature was maintained at 150 ± 2°.[11] Before the amine solidified, the product was removed from the autoclave, steam distilled and then distilled under reduced pressure. Crystallization of the crude amine from 60–80° petroleum ether gave 4,930 g. of purified *o*-4-xylidine.

**3,4-Dimethylbenzonitrile: 3,4-Dimethylbenzoic Acid.**—The Sandmeyer reaction on *o*-4-xylidine gave a 43.5% yield of nitrile (2,015 g.) and hydrolysis of this material gave a 70% yield of acid melting at 164°.

(10) Emerson and Smith, THIS JOURNAL, **62**, 141 (1940).

(11) It is important that the temperature is not allowed to fall below 145° whilst the hydrogenation is proceeding otherwise the reaction rate slows down considerably and can only be raised again with difficulty.

**3,4-Dimethylacetophenone.**—The acetic acid solution of the 3,4-dimethylbenzoic acid (150 g. in 500 ml. of acetic acid) was maintained at a temperature of approximately 60° to avoid crystallization of the xylic acid. The pure ketone (906 g.), obtained from 1,560 g. of acid, had the physical properties given in Table II.

### 1,3-Dimethyl-5-ethylbenzene

***m*-5-Xylidine (1,3-Dimethyl-5-aminobenzene).**—The most satisfactory method for the preparation of this amine was by the direct amination of 1,3,5-xylenol. Amination of this xylenol, with ammonia and ammonium chloride under pressure, had previously been studied by Morgan and Pratt[12] who found that treatment with ammonia alone at 350° for eight hours gave a 20% yield of the required xylidine.

Various catalysts have been recommended to increase the production of *m*-5-xylidine, chiefly chlorides of such metals as zinc, iron, etc., but a preliminary experiment using ferric chloride (5% by weight) yielded mostly the secondary base and very little xylidine. To avoid formation of the secondary amine, it was therefore decided to use no catalyst at all but merely to heat the xylenol with ammonia, recover the unchanged starting material from the base and reaminate.

The aminations were kindly carried out by Dr. Hardy at the Chemical Research Laboratory, Teddington, England, in an 18-liter autoclave equipped with a stirrer. Commercially "pure" 1,3,5-xylenol (6,530 g.) and liquid ammonia (2,025 g.) were weighed into an autoclave and stirring was commenced whilst cold and continued throughout the warming up period. The time taken to reach the reaction temperature of 350° was approximately six hours and at this temperature the pressure was of the order of 200 to 250 atmospheres. The autoclave was maintained at 350 to 360° for eight hours and was then allowed to cool. At the end of each run, the excess of ammonia was blown to waste and the autoclave flushed out with a current of air.

The crude product was dissolved in 60–80° petroleum ether at 35 to 40°, and washed several times with dilute hydrochloric acid until all the amine had been extracted. The acid extracts were neutralized with caustic soda and the amine, which was recovered by steam distillation, was distilled under reduced pressure. Approximately 25% of the amination product was recovered as crude xylidine. The unchanged xylenol crystallized out from the petroleum ether solution on cooling and was filtered off.

A further batch of xylidine was prepared employing only xylenol recovered from the earlier runs. On working up the product, it was discovered that the yield of xylidine had increased to 70 to 75%, the weight of crude xylidine obtained from 7,138 g. of xylenol being 4,900 g. This increased yield of amine obtained indicated that the recovered xylenol must have contained some material which was capable of catalyzing the amination reaction.[13]

The crude *sym*-xylidine (11,400 g.) was converted to the formyl-derivative, which was crystallized from methanol to constant melting point (76%). The final amine (9,274 g.) was obtained by steam distilling the pure formxylidide (11,680 g.) from caustic soda solution.

**3,5-Dimethylbenzonitrile.**—The yield of nitrile based on amine was 45% of the theoretical.

**3,5-Dimethylacetophenone.**—A preliminary experiment was carried out using the conditions employed for the *m*-4-xylonitrile, but the yield of ketone was only of the order of 50%. In addition to the expected ketone, a small amount of yellow solid separated during the decomposition of the ketimine. Analysis showed this material to be trixylyldiazine produced from two molecules of nitrile and one of ketimine. It was found that the best method of carrying out the Grignard reaction on symmetrical xylonitrile was to use a considerable excess of methylmagnesium iodide over that theoretically required. Using a 2.5 to 1 mole ratio of Grignard to nitrile, the yield of ketone was 63%. The yield of ethylxylene from the ketone was 82%. A high-boiling residue, obtained from the fractionation of the crude hydrocarbon, was shown to contain a solid hydrocarbon (m. p. 277.5°) believed to be trixylylbenzene.

### 1,4-Dimethyl-2-ethylbenzene

***p*-Xylidine (1,4-Dimethyl-2-aminobenzene): 2,5-Dimethylbenzonitrile.**—The hydrochloride of this base was obtained by crystallization of a batch of commercial *p*-xylidine hydrochloride (as obtained by treatment of coal-tar xylidines with hydrochloric acid) from dilute hydrochloric acid. The free base regenerated from the hydrochloride (m. p. 223°) had the physical properties shown in Table II. The yield of nitrile from amine in this case was only 38%.

Although the purity of this nitrile was only 96.0%, no further purification was attempted since it was considered that this could be most satisfactorily carried out at the next stage.

**2,5-Dimethylbenzoic Acid.**—Hydrolysis of the nitrile (2,600 g.) by the standard procedure gave 2,5-dimethylbenzoic acid, which was crystallized to a constant melting point of 132°.

**2,5-Dimethylacetophenone.**—Ketonization of the above acid with acetic acid over thoria produced 2,5-dimethylacetophenone in 69% yield

### 1,2-Dimethyl-3-ethylbenzene

***o*-3-Xylidine (1,2-Dimethyl-3-aminobenzene): 2,3-Dimethylbenzonitrile.**—This was obtained by reduction of 3-nitro-*o*-xylene, the preparation of which has already been described, with hydrogen in the presence of Raney nickel under conditions similar to those used for *o*-4-xylidine. Purification of the amine was effected through its sulfate, the *o*-3-xylidine sulfate being much less soluble in water than the *o*-4-salt.[14] The amine was regenerated from the purified sulfate for the diazotization and Sandmeyer reaction. The yield of nitrile from amine was 27%.

Again, further purification was considered easier at the next stage of the synthesis.

**2,3-Dimethylbenzoic Acid.**—The yield of xylic acid, which was purified to a constant melting point of 143.5°, was 68% based on the nitrile.

**2,3-Dimethylacetophenone.**—The ketone was prepared in the usual way by passage of *o*-3-xylic acid with acetic acid over thoria.

### 1,3-Dimethyl-2-ethylbenzene

***m*-2-Xylidine (1,3-Dimethyl-2-aminobenzene).**—When the preparation of this amine was commenced, it was realized that the most satisfactory method would have been by the nitration of pure *m*-xylene, separation of the 2-nitro-*m*-xylene and 4-nitro-*m*-xylene by fractionation, followed by reduction of the former in a manner similar to that employed for the *o*-xylidines.[15] Unfortunately, at the time, an insufficient supply of pure *m*-xylene was available and the raw material used was a commercially available xylidine mixture even though it was known that the desired amine was present only to a small extent in this product and was contaminated with isomeric amines derived from ethylbenzene, *o*-xylene and *p*-xylene. The separation of *m*-2-xylidine from this mixture was however, relatively easily if tediously effected.

A quantity (80 gallons) of "Xylidine residues," which is the material obtained from coal-tar xylidines after removal of the bulk of the *m*-4- and *p*-xylidines as acetate and hydrochloride respectively, was made available through the kindness of Imperial Chemical Industries, Ltd. (Dyestuffs Division). The method of separation adopted was also suggested by I. C. I. and depended on the isolation of

(12) Morgan and Pratt, *J. Soc. Chem. Ind.*, **51**, 283(T) (1932).

(13) Further work on this process has since been carried out and is covered in British Patent Application No. 17,719/46.

(14) The solubility of *o*-3-xylidine sulfate was approximately 200 g. in 3-liters of water at the boiling point.

(15) A report describing German work on the nitration of *m*-xylene and the separation of the nitro-*m*-xylenes at Leverkusen has recently been issued (British Intelligence Objectives Subcommittee Final Report 1146, Published by H. M. Stationery Office, London, 1947).

[a] M. p. of formyl derivative 102°. [b] Determinations of the physical constants on the six ethylxylenes, whose preparations are described here, were kindly carried out by Dr. Rossini at the National Bureau of Standards and these are included together with the values obtained at Sunbury.

the *m*-2-xylidine as the nitrate after a preliminary treatment of the residues with sulfuric acid.

The crude amine was purified through its formyl derivative. The total amount of xylidine residues treated was 311 kg. from which 9,510 g. of *m*-2-formxylidide of melting point 164° was obtained. The amine was regenerated in the usual manner by steam distillation in the presence of caustic soda whereby 6,990 g. of *m*-2-xylidine was obtained from 8,750 g. of formyl compound.

While the above work on the isolation of *m*-2-xylidine from the residues was proceeding, it was decided to investigate whether any individual xylidines could be separated from this material by means of fractionation alone. It was found that it was possible by distillation of the residues at a pressure of 10 mm. in a 20-plate column to obtain a low boiling fraction rich in *m*-2-xylidine and a high boiling fraction rich in *o*-4-xylidine. Further work along these lines is given in British Patent Application 15,840/46.

It was found that neither of the schemes already described for going from the amine to the hydrocarbon could be applied to the 1,3-dimethyl-2-ethylbenzene. Using the Grignard technique, no reaction occurred with *m*-2-xylonitrile and the latter was recovered completely unchanged. An attempt was also made to prepare the carboxylic acid from the nitrile but it was found, rather surprisingly, that on hydrolysis the —CN group was eliminated and the only product recoverable was *m*-xylene. The method finally adopted was the conversion of the amine to the iodo compound which in turn was treated with magnesium, the Grignard compound thus formed being then treated with diethyl sulfate.

**2,6-Dimethyliodobenzene.**—The method adopted for the conversion of the amine to the iodo compound was based on that of Hickinbottom.[16] Diazotization of the amine was carried out in the presence of sulfuric acid and the diazo solution reacted with potassium iodide solution at 0°. After allowing to stand overnight, the product was worked up in the usual manner. Fractionation of the crude iodoxylene gave a final material (5857 g. from 6137 g. of *m*-2-xylidine) which was used for the Grignard reaction. Physical properties of 2,6-dimethyliodobenzene; b. p. 102.3° (14 mm.); f. p. + 11.2°; $n^{20}D$ 1.6035; $d^{20}$ 1.6518; estimated purity 99.6% by wt.

**1,3-Dimethyl-2-ethylbenzene.**—The iodoxylene was converted to the magnesium compound which in turn was treated with diethyl sulfate. The crude hydrocarbon obtained from this reaction was given a purification by reflux-

(16) Hickinbottom, "Reaction of Organic Compounds," Longmans-Green, London, 1936, p. 341.

ing for one hour with alcoholic soda followed by steam distillation. Fractionation in a 40-plate column gave a material boiling at 188° and having a refractive index of 1.5110. Further purification of the hydrocarbon, which was yellow in color, was effected by stirring with 20% caustic potash for two hours followed by sodium treatment and fractionation.

### Diethylbenzenes

#### *o*-Diethylbenzene

***o*-Nitroethylbenzene.**—Ethylbenzene was nitrated according to the method of Cline and Reid.[17] The crude nitration product was distilled under reduced pressure from an oil-bath, care being taken that the temperature of the liquid did not exceed 150°. The isomeric nitro compounds were then fractionated in a 7-ft. glass helix-packed column under reduced pressure. Fractions containing the *o*-nitroethylbenzene from several distillations boiling at 119° at 19 mm. were bulked and refractionated, fractions of the distillate of constant refractive index being bulked prior to reduction. Nitration of 12 kg. of ethylbenzene produced 12,104 g. of crude nitroethylbenzenes from which was isolated 4,650 g. of the pure *ortho* isomer.

***o*-Ethylaniline.**—The reduction of the nitroethylbenzene was carried out under conditions similar to those employed for the reduction of the nitro-*o*-xylenes.

***o*-Ethylacetophenone.**—Trial runs indicated that reaction of *o*-ethylbenzonitrile with an excess of methylmagnesium iodide gave a product which was a mixture of ketone and unchanged nitrile in approximately equal proportions and these two compounds proved to be separable by vacuum fractionation. The procedure therefore adopted was to treat the whole of the nitrile with methylmagnesium iodide and separate the unchanged nitrile by fractionation. The latter then reacted further until the final yield of ketone based on reacted nitrile was 62% of the theoretical.

#### *m*-Diethylbenzene

**Fractionation of Commercial Diethylbenzene.**—A commercial diethylbenzene cut, which was kindly given by the Distillers Co., Ltd., was fractionated in a 100-plate column and the fractions boiling between 180.6 and 181.5° and having refractive indices of 1.4954 or 1.4955 were bulked, refluxed with sodium and refractionated. Separation of the *o*- and *p*-isomers from this material could not be effected by fractionation owing to the similarity in their boiling points.

#### *p*-Diethylbenzene

***p*-Nitroethylbenzene.**—The *p*-nitroethylbenzene was obtained with the *ortho* derivative in the product from the nitration of ethylbenzene, this isomer distilling at 125° at 12 mm. Attempts to isolate the *meta* isomer from the intermediate boiling fractions failed. From the 12 kg. of ethylbenzene which was nitrated, the final yield of *p*-nitroethylbenzene was 4,750 g.

***p*-Ethylaniline.**—The amine obtained by the catalytic reduction of the above nitro compound appeared from its freezing point to be relatively impure (92.5%) and further purification was effected through its acetyl derivative (m. p. 89.5° to 90.5°).

***p*-Ethylbenzoic Acid.**—The *p*-ethylbenzoic acid, which was obtained on hydrolysis of the nitrile, was crystallized to a constant melting point of 112°. The yield of pure acid based on nitrile was 85% theoretical.

***p*-Ethylacetophenone.**—*p*-Ethylbenzoic acid and glacial acetic acid (300 g. per liter of acetic acid) were passed over a thoria catalyst at 450° and the resulting product was fractionated in a 25-plate column at a pressure of 20 mm.

### Methyl-*n*-Propylbenzenes

**Methylpropiophenones.**—The three ketones were prepared from the corresponding nitriles and ethylmagnesium chloride using the procedure already described. The reaction was usually carried out in 12-liter flasks, 350 g. of the nitrile being added to the Grignard reagent from 168 g. of magnesium in 3-liters of ether. The crude ketones were fractionated at reduced pressures from which fractions of constant refractive index and constant boiling point were bulked.

(17) Cline and Reid, THIS JOURNAL, **49**, 3150 (1927).

### Methylisopropylbenzenes (Cymenes)

***o*- and *m*-Cymenes.**—These two isomers were synthesized by identical routes. The toluic acids, obtained from the toluidines *via* the nitriles, were converted to the acid chlorides which in turn were converted to the tertiary alcohols by reaction with methylmagnesium chloride. These reactions were carried out in 10-liter cylindrical copper pots. The products, after working up in the usual way, were mixtures of the olefins and alcohols. Dehydration was completed by distillation at atmospheric pressure through a column packed with short lengths of glass tubing.

***m*-Isopropenyltoluene.**—B. p. 184°; $n^{20}D$ 1.5321, yield 81%.

***o*-Isopropenyltoluene.**—B. p. 170–171°; yield, 79.5%.

The olefins were hydrogenated in an autoclave using a Raney nickel catalyst. Reaction commenced at room

fluxing with 10% by weight of powdered sulfur; (2) treatment with small amounts of sulfuric acid followed by chlorosulfonic acid and an alkali wash; (3) shaking for three hours with potassium permanganate solution; (4) refluxing for five hours over sodium.

Fractions of constant refractive index ($n^{20}D$) were bulked to give 1,013 g. of "best" *p*-cymene.

**Second Method, from Camphor.**—A quantity of *p*-cymene was prepared from camphor and phosphorus pentoxide.[19] The yield of purified material was poor (30%) and the product rather impure.

### Butylbenzenes

***n*-Butylbenzene: First Method, *n*-Butyrophenone.**—*n*-Butyrophenone was prepared in the usual manner by the reaction of *n*-butyryl chloride and benzene in the presence of aluminium chloride. Properties of ketone: b. p. 142° at 50 mm., 128° at 27 mm., $n^{20}D$ 1.5198–1.5199.

The hydrocarbon obtained by reduction of the ketone was extremely sensitive to oxidation by air and had to be freshly distilled before the physical constants were determined.

**Second Method, Bromobenzene.**—The product from the reaction of bromobenzene and *n*-butyl bromide[20] was obtained in poor yield and was of low purity.[21]

**Isobutylbenzene.**—Isobutyrophenone was prepared from isobutyryl chloride and benzene as for *n*-butyrophenone. The pure ketone, which was obtained by fractionation of the product at 50 mm. pressure, amounted to 1,653 g. Properties of ketone; b. p. 131.0° at 50 mm.; $n^{20}D$ 1.5176.

***s*-Butylbenzene: First Method, by Alkylation.**—The conditions used for the alkylation of benzene with 2-butanol were those given by Meyer and Bernhauer.[22] The yield of crude *s*-butylbenzene (1,710 g.) on benzene taken was 52% of the theoretical.

Purification was effected by vigorous stirring with concentrated sulfuric acid (1% by volume of 96% acid) followed by removal of the acid, neutralization with sodium hydroxide solution, refluxing with sodium and finally fractionation.

The purity of the hydrocarbon could not be estimated accurately owing to the peculiar shape of the freezing curve but it was not less than 99.75%. The fact that only one isomer is formed by this method of alkylation confirms the findings of both Meyer and Bernhauer and of Nightingale and Smith.[23]

**Second Method, Methylethylphenylcarbinol.**—This carbinol was obtained in 85% yield from acetophenone and

(23) Nightingale and Smith, THIS JOURNAL, **61**, 101 (1939).

ethylmagnesium chloride. Properties of carbinol: b. p. 140° at 25 mm.; $n^{20}D$ 1.5198.

The carbinol was dehydrated over activated alumina at 300–350°, and the olefin hydrogenated as for *o*- and *m*-cymenes.

***t*-Butylbenzene: First Method, by Alkylation.**—*t*-Butyl chloride (1.108 g.) was added to a stirred mixture of benzene (5.320 g.) and powdered anhydrous aluminum chloride over a period of two hours. Stirring was continued for a further thirty minutes after which the hydrocarbon was decanted from the catalyst and worked up in the usual manner. The residue in the flask was used as catalyst for eleven similar runs with addition of 20 g. of fresh aluminium chloride in between each batch.

A total quantity of 11 gallons of fractionated hydrocarbon was prepared.

**Second Method. By Disproportionation of *p*-Di-*t*-Butylbenzene and Benzene.**—The conditions used for this reaction were those described by Ipatieff and Corson,[24] approximately 2 kg. of *t*-butylbenzene being prepared by this method. The yield of final hydrocarbon was 85% based on *p*-di-*t*-butylbenzene initially taken.

**Acknowledgment.**—The authors wish to express their indebtedness to Miss D. Macken, Messrs. G. J. Curteis, E. A. Johnson, D. T. McAllan, W. S. Nathan, W. J. Oldham and C. L. Walters who were responsible for a considerable amount of the experimental work.

## Summary

Selected methods for the preparation of the twenty-two monocyclic $C_{10}$ aromatic hydrocarbons are described. Selection was based upon readily available starting materials, which could be conveniently purified, and upon reactions easy to carry out on a relatively large scale. Excepting where a required hydrocarbon could be readily separated from a commercially available material by fractionation, *e.g.*, *m*-diethylbenzene, syntheses have been chosen to avoid the presence of impurities in the final hydrocarbon which would prove difficult to separate.

Physical constants have been determined on the hydrocarbons and on most of the amines, nitriles, ketones and nitro compounds which were obtained as intermediates in the syntheses.

# Interaction of Homologous Alkyl Sulfates with Bovine Serum Albumin

BY FRED KARUSH[1] AND MARTIN SONENBERG

The study of the structure of the protein molecule as it exists in aqueous solution meets formidable difficulties not only because of the complexity of the structure but also because of the absence of any really direct and general experimental method. It is true, of course, that important structural information has come and more will undoubtedly follow from X-ray diffraction investigations with protein crystals and that much of this knowledge can be carried over to the dissolved molecule. However, it is still an open question whether the diffraction method can disclose the fine details of protein structure, particularly those associated with the configuration of side chains. These elements of structure are undoubtedly of crucial significance in the determination of specificity. In any case, it would appear that the environment of the protein molecule in the crystal is sufficiently different from that in solution that significant limits on the extrapolation from solid to solution must be imposed. It seems very likely that distinctive structural properties would accrue to the protein molecule in the transition from the crystalline to the dissolved state.

One experimental approach which offers promise of obtaining information which can be interpreted in terms of protein configuration is the study of complex formation of protein with small organic ions or molecules of known structure. In the specialized field of immunochemistry this method has been intensively employed[2] and has led to considerable clarification with regard to the problem of serological specificity. It is particularly applicable to the study of serum albumins since these proteins are able to combine reversibly with a great variety of compounds of known structure, in particular, organic anions.[3–7]

In the investigation described here we have studied the reversible binding by bovine serum albumin of an homologous series of straight chain alkyl sulfates. These compounds offer the possibility of distinguishing between polar and nonpolar contributions to the binding. The work was conducted with a view to obtaining the maximum amount of thermodynamic information about the binding process. Earlier studies[8] of the interaction of serum albumin and alkyl sulfates, as well as other synthetic detergents, have involved much higher concentrations of detergent

than employed here. As a result the interpretation of the data in terms of the binding properties of the native protein has been complicated by micelle formation and, in many cases, denaturation.

## Experimental

**Materials.**—The serum albumin used was crystallized bovine serum albumin obtained from Armour & Co. The actual protein content of the powdered material was determined by Kjeldahl analysis using a value of 16.07%[9] for nitrogen. The particular lot of albumin used in these experiments contained 94.5% protein.

The alkyl sulfates ($C_nH_{2n+1}SO_4Na$) employed, sodium dodecyl, sodium decyl and sodium octyl sulfates, were specially purified samples generously supplied by the Fine Chemicals Division of E. I. du Pont de Nemours and Co. The purity of the dodecyl sulfate was checked by determining the additional acidity developed after acid hydrolysis. Accurately weighed samples of about 0.3 g. were placed in Pyrex test-tubes with 5 ml. of 0.1 *N* HCl and 2 ml. of water. The tubes were sealed and kept at 110° for forty-eight hours. After cooling and solidification of the dodecyl alcohol, the aqueous phase was quantitatively transferred and titrated. A value of 99.7% for the purity of the dodecyl sulfate was thus obtained. Other samples of these three materials from the same source have also been analyzed[10] for sodium and on this basis calculated to be practically 100% alkyl sulfate.

**Dialysis Method.**—The binding of alkyl sulfates by albumin was determined by equilibrium dialysis. All the experiments were conducted at *p*H 6.1 with a final buffer concentration of 0.025 *M* phosphate. This concentration was selected so as to be just large enough to render the Donnan correction negligible within the range of protein concentration employed, namely, 0.05 to 0.5%, and permit a maximum free alkyl sulfate concentration. The latter is limited by the salting-out effect of the buffer salt.

The dialysis was carried out with 20 ml. of protein solution in 0.05 *M* phosphate contained in a bag of Visking sausage casing. This bag was placed in a large test-tube with 20 ml. of a solution of alkyl sulfate free of buffer and the tube stoppered with a serum cap. All the phosphate was placed in the protein solution to allow larger initial concentrations of the alkyl sulfate to be used than would be possible if the original sulfate solution were made up in 0.025 *M* phosphate. The tubes were placed on a rocker, with a capacity of 24 tubes, in a horizontal position and gently rocked at a frequency of 1 or 2 cycles per minute. If the bag is prepared so that it is taut and an air bubble is enclosed and if an air space is provided inside the tube, very efficient mixing, both inside and outside the bag, takes place. With this arrangement at room temperature, equilibrium is attained in four hours or less and at low temperature (2°) overnight rocking is more than adequate.

To ensure maximum accuracy protein concentrations were selected so that the concentration of bound anion, wherever feasible, would be two to three times that anticipated for the free anion at equilibrium. This precaution avoids the situation in which the calculation of the amount of bound anion depends on a small difference between two large numbers. The initial outside concentrations of alkyl sulfate were chosen in such a way that the resulting equilibrium values of free anion when plotted as described below would be fairly evenly distributed over the range encompassed by the plot.

Equilibrium controls consisting of alkyl sulfate outside and buffer inside the bag were frequently included in the experiments. In addition the possibility that loss of alkyl sulfate might occur, either by adsorption or chemical reaction, was investigated. It was found that no significant adsorption took place in the range of anion concentration of interest, namely, $10^{-3}$ to $10^{-5}$ *M*. Fortunately also, chemical losses were negligible for these dilute solutions when subjected to room temperature for not more than several hours and to low temperature for not more than two days. It is worth noting, however, that longer exposure at room temperature, say, twenty-four to forty-eight hours, usually led to detectable loss of alkyl sulfate, particularly with the very dilute solutions.

In order to calculate the values of the thermodynamic functions $\Delta H$ and $\Delta S$ for the binding process, experiments were conducted at room temperature (25–28°) and at low temperature (1–2°). For each experiment fresh solutions of protein and alkyl sulfate were prepared and all determinations were done in duplicate. The concentration of free anion in equilibrium with bound anion was obtained by the determination of the concentration of alkyl sulfate anion outside the dialysis bag.

**Analytical Method.**—The investigation reported here required the quantitative measurement of long chain alkyl sulfate concentrations as low as $10^{-5}$ *M*. A search of the literature revealed that no adequate method was available. We therefore undertook the development of a suitable colorimetric method following along lines initiated by Brodie and Udenfriend.[11] The method is based upon the fact that octyl and higher alkyl sulfates form complexes with rosaniline hydrochloride which can be extracted into organic solvents. A detailed description of the method will be published elsewhere. It is sufficient to mention here that the procedure involves the addition of 4 ml. or less of alkyl sulfate solution to 1 ml. of $4 \times 10^{-4}$ M rosaniline hydrochloride in 0.025 *M* phosphate, *p*H 6.1, in a total volume of 5 ml., and the extraction of the colored complex with 5 ml. of a mixed solvent consisting of 50% chloroform and 50% ethyl acetate. The two-phase system is centrifuged and the light absorption of the lower phase, which contains the complex, is measured with a Klett colorimeter using a green filter. The method is suitable for concentrations as low as $10^{-5}$ *M* and has an accuracy of about 2%.

## Results

The protocol with attendant calculations for a typical dialysis experiment is shown in Table I. The values in the first column are simply one-half the initial outside concentrations of alkyl sulfate. The molar concentration of protein is based upon a value of 69,000[12] for the molecular weight of bovine serum albumin. The last two columns give the reciprocal of the average number of anions bound per molecule of protein ($1/r$) and the reciprocal of the free equilibrium anion concentration ($1/c$). These quantities are most convenient for graphical representation of the data. It may be noted that although the concentrations of protein and bound anion shown in columns 3 and 4 may be somewhat in error due to volume changes inside the dialysis bags, the values of $1/r$ and $1/c$ are independent of such variations.

It has been found by Klotz[13] that the value of $r$ depends on the protein concentration as well as on $c$, for the range 0.2 to 1%, in the binding of methyl orange by bovine serum albumin. A few observations with our systems on the effect of protein concentration in the range 0.5 to 0.05% have not revealed any significant dependence of $r$ on protein content, though we have not investigated this question in any great detail.

In Figs. 1 and 2 we present a summary of the

Because of the importance of a knowledge of the binding capacity of the protein, several experiments were done at room temperature using 2% protein and as high concentration of decyl and dodecyl sulfates as feasible. For the decyl sulfate salt the maximum equilibrium concentration of the free anion was $1.7 \times 10^{-3}$ *M* and that for the dodecyl sulfate was $3.25 \times 10^{-4}$. Under these conditions values of $r$ very close to 14 but not exceeding it were obtained. It must be emphasized, however, that this figure is not necessarily a maximum one since the data when plotted, for example, in the form of $r$ against log $c$ do not indicate 14 to be a limiting value. The significance of this fact will be explored in the following section.

## Discussion

**General Considerations.**—In order to justify a thermodynamic analysis of our data, it is necessary to show that the binding process is a reversible one. This can be done experimentally by immersing dialysis bags containing protein which have previously been equilibrated against an alkyl sulfate solution into 20 ml. of 0.025 *M* $PO_4$ buffer, *p*H 6.1 and determining the new equilibrium values of $r$ and $c$. The results of such an experiment with dodecyl sulfate at low temperature are shown by the two points in Fig. 2 indicated by arrows. This second equilibration, in contrast to the usual binding experiment, involves a net removal of anion from combination with the protein.

A complication which must be avoided with long-chain anions to permit a thermodynamic treatment is the formation of micelles. This has been achieved in the present study by working well below the critical concentrations[10] for micelle formation, taking into account the effect of salts on these values.[14]

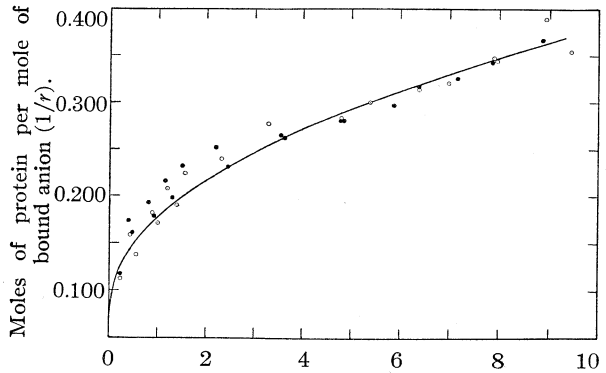

Fig. 1.—Binding data for octyl sulfate: O, low temp.; ●, room temp.

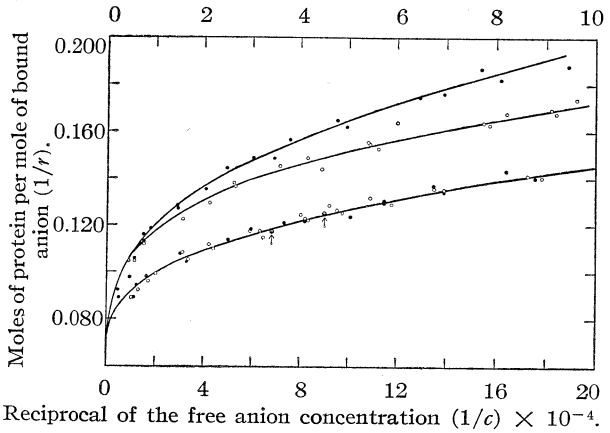

Fig. 2.—Binding data for decyl and dodecyl sulfates; upper two curves and top scale refer to decyl sulfate and lower curve and bottom scale to dodecyl sulfate; reversibility points (see text) indicated by arrows; O, low temp.; ●, room temp.

**Simple Theory.**—The application of the law of mass action to the case of multiple binding leads to the following simple relation between $r$ and $c$ under the conditions that all the binding sites have the same intrinsic association constant $K$ and that, aside from the statistical factor, the free energy of binding to any particular site is independent of binding to other sites.[15,16] The value

$$\frac{1}{r} = \frac{1}{Kn}\,\frac{1}{c} + \frac{1}{n} \qquad (1)$$

of $K$ depends, of course, on the particular system under consideration and $n$ represents the average maximum number of sites per molecule, *i. e.*, the binding capacity. According to equation (1) a plot of $1/r$ *vs.* $1/c$ will give a straight line. From the slope of this line and its intercept with the $1/r$ axis the values of $K$ and $n$ can be obtained. Such

(14) M. L. Corrin and W. D. Harkins, THIS JOURNAL, **69**, 683 (1947).

(15) A. L. von Muralt, *ibid.*, **52**, 3518 (1930).

(16) I. M. Klotz, *Arch. Biochem.*, **9**, 109 (1946).

a procedure has been used by Klotz, Walker and Pivan[5] in their study of the binding of anionic dyes by bovine serum albumin and by Teresi and Luck[7] in an investigation of the binding of other organic anions by the same protein.

As is evident from Figs. 1 and 2 the binding of alkyl sulfates by bovine albumin does not satisfy the conditions noted above since the experimental points deviate significantly from linearity and increasingly so with decrease of $1/c$. This deviation is more striking with decyl sulfate than with dodecyl sulfate because the data for the former cover a wider range of $1/r$. From the shape of the curves it appears that, ignoring the statistical contribution, the binding of each additional anion on an albumin molecule involves a smaller decrease in free energy than the binding of the previous one. There are a number of possible factors which would lead to such an effect and we now proceed to consider them.

**Electrostatic Interaction.**—Studies of the acid–base titration curves of soluble proteins and the effect of ionic strength on these curves have shown that it is necessary to introduce an electrostatic correction to account adequately for the shapes of these curves.[17,18] This correction is associated with the variation of charge on the protein during the titration and is based on the Debye–Huckel theory of interionic attraction.

The contribution of the electrostatic interaction to the free energy of binding has been calculated by Klotz, *et al.*,[5] for the binding to bovine serum albumin of the monovalent anion methyl orange, and the divalent anion azosulfathiazole. More recently Scatchard[19] has developed an explicit relation between $r$ and $c$ containing an electrostatic interaction term which is applicable with high accuracy for values of $n > 4$. This relation can be put in a form analogous to (1) as follows

$$\frac{1}{r} = \frac{1}{Kn}\frac{e^{2w'r}}{e^{w}}\frac{1}{c} + \frac{1}{n} \qquad (2)$$

where $w' = (1 + 1/n)w$ and $w$ is given by

$$w = \frac{\epsilon^2 Z^2}{2DkT}\left(\frac{1}{b} - \frac{\kappa}{1 + \kappa a}\right) \qquad (3)$$

in which $\epsilon$ is the electron charge, $Z$, the charge on the small anion, $D$, the dielectric constant of the medium, $k$, Boltzmann's constant, $T$ the absolute temperature, $b$, the radius of the protein molecule, $a$, the distance of closest approach, and

$$\kappa = \left(\frac{4\pi N\epsilon^2}{1000\ DkT}\right)^{1/2}\Gamma^{1/2} \qquad (4)$$

Here, $N$ is Avogadro's number and $\Gamma$ is twice the ionic strength of the medium. To calculate $w$ we have assumed, following Klotz, *et al.*,[5] a value of 30 Å. for $b$ and 31.5 Å. for $a$. Since $\Gamma$ for 0.025 $M$ $PO_4$ buffer at $p$H 6.1 is 0.0644, we have calculated a value of 0.0451 for $w$ at 27°. This represents an electrostatic free energy contribution of 54 cal./mole for the binding of each additional anion to the protein.

To test the adequacy of the electrostatic interpretation of our results by the application of equation (2), we have plotted our experimental data in the form of $1/r$ *vs.* $e^{2w'r}/c$. For this purpose a value of 10 was assigned to $n$ to obtain $w'$. An examination of such a plot reveals no reduction in the deviation of the data from a straight line. It appears that the electrostatic free energy correction is too small by almost an order of magnitude. Even if $w'$ is treated as a parameter it is impossible to adjust its value so that the experimental points fall on a linear curve. It is clear, therefore, that not only is the electrostatic effect unable to explain our results but that any interaction or correction which takes the mathematical form represented in equation (2) will be unsatisfactory.

There is some question whether any electrostatic correction should be made in our case since Klotz, *et al.*,[5] found, in the presence of phosphate buffer, that the binding of the monovalent anion methyl orange obeyed a linear relation between $1/r$ and $1/c$ without such a correction. We have therefore chosen in the following discussion and calculations to omit further consideration of the electrostatic effect.

**Heterogeneity Theory.**—On *a priori* grounds there is no reason to believe that the intrinsic association constants of all the binding sites are identical. We must therefore consider the possibility that a variation of these constants would account for the shape of our binding curves. Indeed, qualitatively, it is clear that if the binding constants are not the same, the slope of the curve of $1/r$ *vs.* $1/c$ should decrease with increasing $1/c$, as is experimentally the case. Before we attempt a quantitative formulation, we want to consider two other possible effects associated with the paraffin chain character of the anions.

It is well known that due to the large organic groups in these anions, they tend to interact with one another in aqueous systems as evidenced by the formation of micelles. One may ask therefore if the association of one anion on a particular site may not lead with increase in concentration of free anion to the adsorption of at least a second one in the same neighborhood of the protein due to interaction between the paraffin chains. This phenomenon would be similar to micelle formation but might be expected to occur at a somewhat lower concentration due to the immobilization of half of the dimer by the protein. However, it can be inferred from an inspection of our curves that if such were the case significant dimerization should have already occurred at concentrations of $5 \times 10^{-6}$ $M$ for dodecyl sulfate, $3 \times 10^{-5}$ $M$ for decyl sulfate and $1 \times 10^{-4}$ $M$ for octyl sulfate. These values are approximately 1000-fold less than the critical concentrations for micelle formation[9]

and for this reason it appears unlikely to us that such an effect is significant for the interpretation of our results.

Due to the relatively great length of the alkyl sulfate it is imaginable that steric interference may lead to a continuous reduction of binding energy with increase in $r$. That this is probably not important here is indicated by a comparison of the data for decyl and dodecyl sulfates. If one considers a specified range of $1/r$, say 0.100 to 0.140, and compares the curvature exhibited by the experimental points in this range for the two anions, there is no indication of a greater curvature for the dodecyl sulfate. Such a difference would be expected as a consequence of the greater length of the dodecyl anion resulting in more extensive steric interference. The probable absence of steric effects also is suggested by the fact that the value of $\sigma$ (see below) is not greater for dodecyl than for decyl sulfate. The quantity $\sigma$ is a measure of the spread of $K$ values which must be assumed to account for our data in accordance with the heterogeneity theory which we will now discuss.

We take as our model a protein molecule with a large number of binding sites which combine with small ions or molecules independently of each other. We then assume that the number and distribution of the intrinsic binding constants are such as to be adequately described in terms of the free energy of binding by a Gauss error function which when normalized is

$$(1/\sqrt{\pi}\sigma)e^{-[\ln(K/K_0)]^2/\sigma^2} \qquad (5)$$

where $K_0$ is an average binding constant and $\sigma$ measures the range of values of $K$. This formulation is similar to that used by Pauling, Pressman and Grossberg[20] to describe the heterogeneity of binding of hapten by antibody in competition with antigen. In their case the heterogeneity was associated with differences among the antibody molecules whereas we are concerned with differences among the sites on the same molecule. The shape of this distribution function for $\sigma = 1$ to 4 is shown in Fig. 1 of their paper. The fraction of the total number of sites on the molecule which have a particular value of $K$ in an infinitesimal region is given by

$$\frac{dn}{n} = \frac{1}{\sqrt{\pi}} e^{-[\ln(K/K_0)]^2/\sigma^2} d\,[\ln (K/K_0)] \qquad (6)$$

With the aid of this relation and the condition that the sites act independently it is easily shown that the average fraction of sites occupied as a function of $c$ is expressed by

$$\frac{r}{n} = 1 - \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} \frac{e^{-\alpha^2}}{1 + K_0 c e^{\alpha\sigma}}\, d\alpha \qquad (7)$$

in which $\alpha$ has been substituted for $\ln(K/K_0)/\sigma$. For purposes of calculation and plotting it is convenient to put equation (7) in the form

$$\frac{n}{r} = \frac{1}{1 - f(c)} \qquad (8)$$

where

$$f(c) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} \frac{e^{-\alpha^2}}{1 + K_0 c e^{\alpha\sigma}}\, d\alpha \qquad (9)$$

Unfortunately, the integral in (9) cannot be evaluated analytically and recourse must be had to numerical or graphical integration for the computation of $f(c)$. Prior to such integration the values of the parameters $K_0$ and $\sigma$ must be fixed. It turns out, however, that $f(c) = 1/2$ for all values of $\sigma$ when $K_0 c = 1$. This means that $K_0$ is equal to the reciprocal of the free anion concentration at which the protein is half-saturated and its value can be obtained directly from the experimental data if the value of $n$ has been previously ascertained. The value of $\sigma$ is taken to be that which gives the best agreement between experimental and calculated binding curves. It is of interest to note that for $\sigma = 0$, $f(c) = 1/(1+K_0c)$ and equation (8) reduces to (1). That is, the simple theory is a limiting case of the more general heterogeneity theory.

The application of equation (8) to experimental binding data is most readily and generally done by preparing theoretical curves of $n/r$ *vs.* $1/K_0c$ for various values of $\sigma$. For this purpose numerical integration was carried out using Weddle's rule[21] with integration limits $-2.4$ to 1.2 or $-2.4$ to 2.4 depending largely on the value of $\sigma$. The theoretical curves are shown in Figs. 3 and 4 for two different ranges of $1/K_0c$. It is important to note that beyond $1/K_0c = 1$, the curves do not deviate much from linearity. In fact, if binding data of not high accuracy were to fall on such a curve, the temptation would be to draw a straight line through the points and conclude that the binding obeys the simple theory. This situation has important implications for the interpretation of data in the literature which we shall discuss below.

On the basis of the curves in Figs. 3 and 4 we have calculated the theoretical curves shown as solid lines in Figs. 1 and 2 using $n = 14$. The values of $K_0$ and $\sigma$ employed are listed in Table II. It is clear that a satisfactory fit of the curves with the data is obtained except possibly for very

TABLE II

CONSTANTS AND THERMODYNAMIC DATA FOR BINDING OF ALKYL SULFATES BY BOVINE SERUM ALBUMIN. THE DATA REFER TO THE BINDING OF ONE MOLE OF ALKYL SULFATE

| Compound | Temperature | $\sigma$ | $K_0 \times 10^{-4}$ | $-\Delta F^0$, kcal. | $\Delta S^0$, E. U. |
|---|---|---|---|---|---|
| Octyl sulfate | Room and low | 4.5 | 0.4 | 5.01[a] | 16.7 |
| Decyl sulfate[c] | Room | 5 | 2.5 | 6.03[a] | 13.3 |
| Decyl sulfate[c] | Low | 6 | 3.4 | 5.70[b] | 13.3 |
| Dodecyl sulfate | Room and low | 5 | 18.2 | 7.22[a] | 24.0 |

[a] Calculated for 27°. [b] Calculated for 2°. [c] $\Delta H^\circ = -2.0$ kcal.

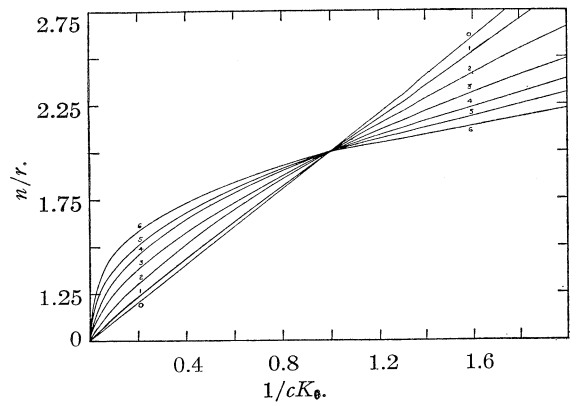

Fig. 3.—Theoretical binding curves for $\sigma = 0$ to 6 for range of high binding.

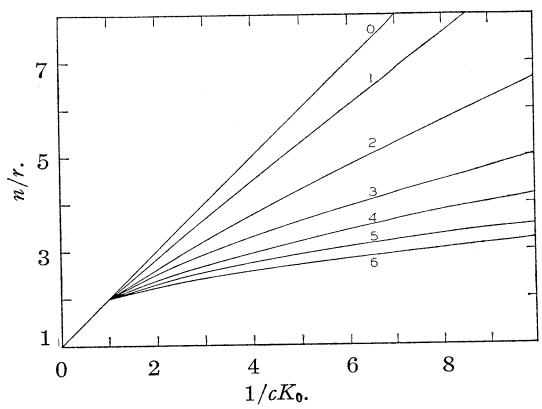

Fig. 4.—Theoretical binding curves for $\sigma = 0$ to 6 for range of low binding.

low values of $1/c$ where the curves tend to be slightly higher than the points. It may be noted that our procedure involves the approximation of substituting a continuous spectrum of $K$ values for what must be a discontinuous set for any particular molecular species of albumin. There is, however, the possibility that crystallized albumin is not molecularly homogeneous with respect to its binding properties. Our analysis would not reveal such a condition because it does not really distinguish between variation of binding energy among the sites on a single molecule as compared to differences among different molecules. However, because of the large range of values of $K$ indicated by values of $\sigma$ of 4 or 5, which in turn would imply considerable differences among the albumin molecules, we are inclined to attribute most of the effect to variation among the sites within the individual molecules. A rough calculation shows that for $\sigma = 5$ and a value of $K_0$ corresponding to $-\Delta F^\circ = 6$ kcal, the range of $K$ values would correspond to a range of $-\Delta F^\circ$ from approximately 2 kcal. to 10 kcal.

It will be noted in Table II that there is some variation in the values of $\sigma$. It would be premature to attempt at this point to assign any physical significance to this variation both because of the relatively small differences involved and because of the limited range of $r$ for which $\sigma$ is employed in the theoretical calculation.

The question may be raised as to whether our choice of distribution function is uniquely suitable to account for our data. It appears to us that it is very likely not so and that other distribution functions may be equally adequate. This view is based on the fact that our data cover a rather narrow range of $1/r$ so that the suitability of the distribution function is not put to a severe test. Further, this distribution does not fit in with the kind of physical picture of the interaction which we favor though, of course, no definite judgment on this point can be made at the present time.

**Thermodynamic Considerations.**—Although the values of $K_0$ listed in Table II are average values, their comparison with one another is nevertheless of significance. It is clear that the binding becomes greater with increase in the length of the paraffin chain. This is, of course, obvious from the data of Figs. 1 and 2. Its importance follows from the fact that it shows that probably the whole alkyl group is involved in the interaction with the protein in addition to the electrostatic interaction between charged groups.

The study of the temperature dependence of the binding of alkyl sulfates has also led to interesting conclusions. Although the data for octyl sulfate are not as good as that for the other homologs, it appears that the binding of the octyl anion is practically independent of temperature as with dodecyl sulfate. On the other hand, decyl sulfate binding is dependent on temperature and an average value for $\Delta H^\circ$ of $-2.0$ kcal. is obtained. This is a rather unexpected difference among the homologs and, though it may have important implications for the structure of albumin, confirmation and extension of this kind of data is required before theoretical interpretation is justified.

The binding of the alkyl sulfates is largely or wholly an entropy effect. The standard entropy changes for the process are listed in the last column of Table II. To what extent these changes are associated with the release of water molecules bound to protein and anion and/or structural changes of the protein, it is not possible to decide at this time. The predominance of the entropy contribution to the free energy of complex formation between copper (cupric) and bovine albumin has been demonstrated by Klotz and Curme.[22]

Another important point which emerges from the thermodynamic data is that there is danger in the tendency, which is found in the literature, to interpret an increased binding as due to larger van der Waals forces because of increase in size of the non-polar portion of the bound molecule.

(22) I. M. Klotz and H. G. Curme, THIS JOURNAL, **70**, 939 (1948).

The comparison of dodecyl with decyl sulfate shows that the binding of the smaller anion yields a larger reduction in the energy of the system and serves to emphasize the desirability of measuring the temperature dependence of binding whenever possible.

**Significance of $n$.**—Previous work[5,7] on the binding of organic anions by albumin has proceeded on the assumption that it is possible to define a value of $n$ for the anions studied by the extrapolation of the $1/r$ *vs.* $1/c$ plot, corrected where necessary for electrostatic effects. We have already indicated that though we have taken $n = 14$ for the alkyl sulfates, we do not regard this value as necessarily the binding capacity of albumin. In the binding of methyl orange Klotz, *et al.*,[5] obtained a value of 22 for $n$ by extrapolation. However, the maximum value of $r$ obtained experimentally was apparently about 15 and the curve of $r$ *vs.* log $c$ gave no indication of tending toward a limiting value. It is therefore quite possible that the correct value of $n$ is larger than 22 and that all the binding sites do not have the same value of $K$ as the apparent linearity of the $1/r$ *vs.* $1/c$ plot would suggest.

The interpretation of Teresi and Luck's data[7] according to the simple theory is even more questionable because the range of $1/r$ and especially $1/c$ is more restricted.[23] Furthermore the data are not of high accuracy due to the fact that the amount of bound anion was only about one tenth of free anion. According to their results *o*-nitrophenolate is bound more strongly than *p*-nitrophenolate though $n = 6$ for the former and 25 for the latter compound. This appears rather unlikely to us on physical grounds and is especially open to question because the calculation of the intrinsic constants depends on the prior determination of $n$. In fact, if $n$ is assumed to be the same for the two compounds the fact that the binding curve of *p*-nitrophenolate lies below that of *o*-nitrophenolate would indicate that contrary to the conclusion of Teresi and Luck, the former compound is bound more strongly.

Such a reversal could arise if the portions of the binding curves of the two anions being compared corresponded to different ranges of $1/K_0c$ as shown in Figs. 3 and 4. The possible danger of being misled because of such a situation is readily seen by a comparison of our octyl and decyl sulfate data. If one considers the octyl sulfate data for the range of $1/c = 2 \times 10^4$ to $10 \times 10^4$, one could draw the best straight line through the points and conclude that $n = 5$ and that the intrinsic association constant $K$ is $10 \times 10^4$. On the other hand, if the data for decyl sulfate were limited to the range $1/c = 1 \times 10^4$ to $3 \times 10^4$, the conclusion would be reached that $n = 10$ and $K = 5 \times 10^4$. Thus a comparison of the two limited sets of data would lead to the inference that the binding capacity of the protein for octyl sulfate is less than for decyl but that the former is more strongly bound, though both conclusions are contrary to fact.

It appears, therefore, that the interpretation of the extrapolated value of $1/r$ as measuring the binding capacity of the protein for a particular anion is of dubious validity. Such a value may be quite adventitious depending on the concentration range studied and the magnitude of $\sigma$ or any other parameter which reflects the variation of $K$ values. A possibility that deserves serious consideration is that the binding capacity is the same for all organic anions, within a certain size range, and is equal to the number of positively charged sites on the surface of the protein molecule. If this were actually the case it would mean that for any particular organic anion the values of $K$ for the various sites would cover a very wide range.

**Structural Implications.**—The binding of organic anions to serum albumin very probably involves the electrostatic interaction between a positively charged group on the protein and the negative group of the anion.[24,25] However, not all of the positive groups of the protein are equally available for binding. This is clear from the analytical data for bovine serum albumin[8] which shows that there are 84 such groups at *p*H 6.1 from the arginine and lysine residues alone. Yet according to our results only 14 groups are involved in binding.

It appears useful to make a division of the cationic groups into two sets, one which is practically completely excluded from the association reaction in the native protein possibly because of inaccessibility, and the second set the members of which can bind organic anions but may do so with varying affinity. Some justification for such a distinction is to be found in the results of a study of the interaction between sodium dodecyl sulfate and horse serum albumin by Neurath and Putnam.[26] They observed that this protein could form a stoichiometric complex with about 55 detergent anions per albumin molecule without detectable changes in molecular shape. At higher detergent–protein ratios a second complex was formed involving the combination of about 110 anions per protein molecule. As shown by diffusion and viscosity measurements the formation of the second complex was accompanied by an increase in the molecular asymmetry of the protein. It may be remarked that the study with horse serum albumin was carried out with much higher concentrations of detergent, above the critical concentration for micelle formation, than was the case in our experiments.

(23) The values of $K$ and $\Delta F$ listed in their paper require correction due to an oversight in calculation (see *J. Biol. Chem.*, **177**, 383 (1949)).

(24) I. M. Klotz and F. M. Walker, THIS JOURNAL, **69**, 1609 (1947).

(25) F. W. Putnam and H. Neurath, *J. Biol. Chem.*, **159**, 195 (1945).

(26) H. Neurath and F. W. Putnam, *ibid.*, **160**, 397 (1945).

Perhaps the most interesting question of structural significance raised by our results has to do with the variation of $K$ values among the 14 sites which bind alkyl sulfate. Though, obviously no detailed answer is possible now, it does appear that the configuration of the protein in the interacting area around each positive charge is not the same for all the sites. It would be of considerable interest to determine the degree of such heterogeneity for the binding of organic anions of different sizes and shapes.

**Acknowledgment.**—We are indebted to Professor R. Keith Cannan for the generous hospitality afforded us in his laboratory during the conduct of this investigation. We are also grateful to Dr. I. M. Klotz of Northwestern University for many enlightening discussions.

## Summary

The reversible binding of homologous alkyl sulfates by bovine serum albumin has been studied at two temperatures by the method of equilibrium dialysis. This has required the development of a colorimetric method for determining low concentrations ($10^{-5}$ $M$) of these compounds. Deviations of the binding curves from the simple theory based on the mass action law have been shown to be inexplicable on the basis of electrostatic effects. A new heterogeneity theory based on a particular distribution of the intrinsic binding constants has been proposed and has been found to account quantitatively for our results. The values of the thermodynamic functions $\Delta F°$, $\Delta H°$ and $\Delta S°$, for the binding process have been calculated and the importance of the entropy contribution emphasized. The validity of the determination of binding capacity ($n$) by linear extrapolation has been subject to question and interpretations of binding data in the literature reconsidered. Finally, some structural implications of our results have been noted.

# Biophysical Studies of Blood Plasma Proteins. IX. Separation and Properties of the Immune Globulins of the Sera of Hyperimmunized Cows[1]

BY E. L. HESS[2,3] AND H. F. DEUTSCH

## Introduction

The antibody fraction of normal bovine serum has been previously separated in high yield by means of ethanol fractionation.[4] Our attention has now been directed to the application of these procedures for the recovery of the antibody enriched fractions of the sera of cows immunized to *Brucella abortus* organisms and Newcastle virus. The various globulin fractions separated have been subjected to solubility, molecular kinetic and immunological study.

## Experimental

The hyperimmune sera were prepared by inoculating two Holstein cows with Newcastle virus in whole egg embryo and with the viable *Brucella abortus* organisms at four-day intervals over a three-month period. In addition, a low titer serum pool of two calves immunized to diphtheria and tetanus toxin was studied briefly. The increase of the serum $\gamma$-globulins was followed by electrophoretic analysis and the extent of antibody production was determined by immunological assays.

*Brucella abortus* antibodies of two types, agglutinins and bactericidins, were assayed according to the methods published by Huddleson[5] and Irwin and Beach,[6] respectively. Newcastle virus hemagglutination inhibiting and neutralizing antibodies were assayed according to the method of Brandly, Jungherr, Moses and Jones.[7] The titers reported are based upon the assay of fractions reconstituted in phosphate buffer to their original serum concentration.

Except in certain subfractionations as indicated below, the fractionation steps follow the procedure outlined in Fig. 5 of the prior article.[4] The course of the fractionation of the hyperimmune bovine serum is shown by the electrophoretic diagrams in Fig. 1. The designation of the fractions is consistent with that adopted in the earlier report. Precipitates A from various sera were pooled for subsequent subfractionation or rework operations.

Standard electrophoretic and sedimentation procedures were followed in the physical chemical characterizations of the fractions. Solubility studies utilized the customary phase rule solubility procedures as reviewed by Herriott[8] and the successive extraction of the solid phase with

aliquots of buffer. The usual precautions of equilibration and approach of equilibrium from both under and supersaturated solution were observed. Veronal, cacodylate and acetate buffers of $\mu = 0.01$ and 0.1 were used in the solubility and electrophoretic studies.

## Results

Analytical and antibody data for the serum and the various fractions are shown in Table I. The assays clearly show that the major portion of the antibodies is precipitated from the diluted serum at *p*H 7.6 and 18% ethanol. This precipitate (A) which amounted to 24 g./liter of serum in the case of normal cows and 34 g./liter of serum with the hyperimmune serum, represents more than 90% of the γ-globulins present in the original serum (electrophoretic analysis). Further fractionation of precipitate C gives products richer in the antibodies. It is apparent from Table I that the major portions of the antibodies separate with the $\gamma_1$-globulin fraction (Ppt. C-1).

In an effort further to concentrate the antibodies, certain subfractionations, exploratory in nature, were tried. For example, precipitate C-1 was separated into three fractions at $\mu = 0.003$ by varying *p*H and the ethanol concentrations. Brucella abortus agglutinins and Newcastle virus neutralizing antibody concentrations were doubled (as indicated by serial dilution assays) in the fraction that was soluble in the aqueous phase at $\mu = 0.003$, *p*H = 5.8, protein concentration = 0.5%, but which precipitated upon addition of ethanol to 25% concentration. In another instance, when the *p*H of an aqueous solution of precipitate C (protein = 0.5%, $\mu = 0.013$) was varied over the range 5.5 to 6.3 there occurred a precipitation of from 7.5 to 11.4% of the total protein in solution. The precipitate in each case gave negligible antibody titers.

Both the $\gamma_1$- and $\gamma_2$-globulins have sedimentation constants of $s_{20w} = 7.4S$ at a protein concentration of approximately 1% in 0.15 *M* NaCl. The sedimentation constants are substantially independent of concentration from 0.25 to 1% protein, and are in exact agreement with those previously reported[4] for the $\gamma_1$- and $\gamma_2$-globulins from normal bovine serum. The criterion of molecular mass homogeneity previously applied[4] revealed an essentially monodisperse system. Evidence of traces of a heavier component, $s_{20w} = 18S$, was found in the case of the $\gamma_1$-globulins, in contrast to its absence in the corresponding precipitate from normal bovine serum.

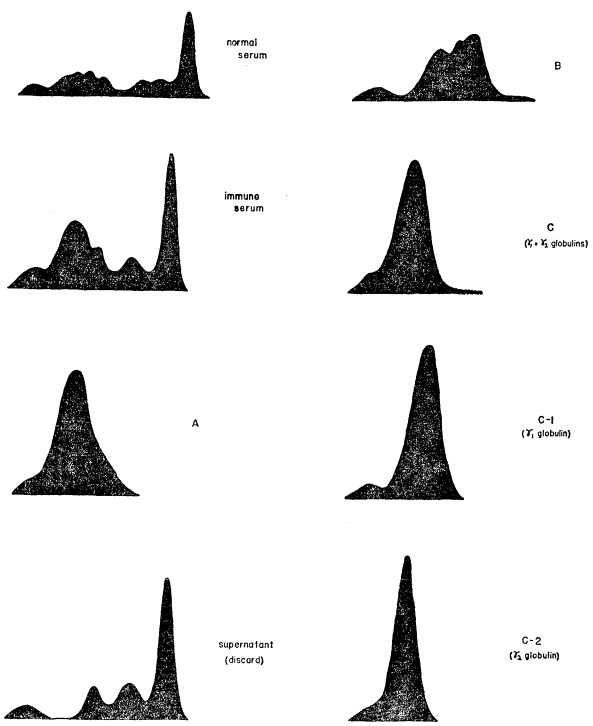

Fig. 1.—Electrophoretic patterns of hyperimmune bovine serum fractions in veronal buffer *p*H 8.6, $\mu = 0.10$ after 7200 seconds at 6.0 volts/cm. Concentration of protein is 3% in all cases; normal serum in barbiturate–citrate buffer at *p*H 8.60, $\mu = 0.088$, $E = 8.5$ volts/cm. Detailed statements of conditions for these separations appear in Fig. 5 of ref. (4).

Isoelectric points ($pI_e$) determined from the customary plot of mobilities ($U$) against *p*H are

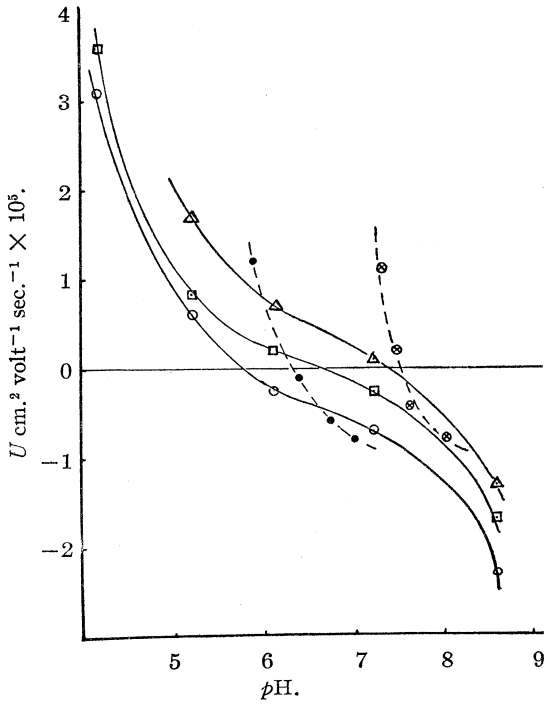

Fig. 2.—*p*H–mobility relationships:

| | | | | |
|---|---|---|---|---|
| □ | γ-globulins | $\mu$ = 0.10 | $pI_e$ 6.60 |
| ○ | $\gamma_1$-globulins | $\mu$ = .10 | $pI_e$ 5.85 |
| △ | $\gamma_2$-globulins | $\mu$ = .10 | $pI_e$ 7.35 |
| ● | $\gamma_1$-globulins | $\mu$ = .01 | $pI_e$ 6.35 |
| ⊗ | $\gamma_2$-globulins | $\mu$ = .01 | $pI_e$ 7.50 |

shown in Fig. 2. The $pI_e$ are sensitive to $\mu$ and increase with decreasing $\mu$. The isoionic points ($pI_i$) as determined by extrapolating the $pI_e$ obtained in $\mu$ = 0.1 and $\mu$ = 0.01 buffers to $\mu$ = 0 gives *p*H values of 6.4 for the $\gamma_1$-globulins and 7.5 for the $\gamma_2$-globulins. In Table II are assembled data obtained from electrophoretic studies at $\mu$ = 0.10. The heterogeneity constants ($H$) are calculated according to the method of Sharp, Taylor, Beard and Beard.[9]

The apparent diffusion constants are calculated from the relation $D^* = (Xi)^2/2t$.[10,11] The time ($t$) is in seconds, $X_i$ is the half width of the gradient curve of the electrophoretic pattern at the point of inflection ($h_i$), where $h_i$ is equal to $1/\sqrt{e}$ times the height of the maximum ordinate. The ascending and descending boundaries are virtually enantiographs at $\mu$ = 0.10. The values of the heterogeneity and the apparent diffusion constants listed in columns 3 and 4 of Table II are averages for the ascending and descending boundaries.

[a] Values are calculated from Schlieren patterns after 120 minutes at $E$ = 5.0 volts cm.$^{-1}$ $\mu$ = 0.10 in all cases at ≦ 1° C. [b] All acetate and cacodylate buffers, $\mu$ = 0.02 with the sodium salt of the acid and $\mu$ = 0.08 with NaCl.

Resolution of the schlieren pattern into more than a single peak was not observed at any of the *p*H values listed in Table II although the γ-globulins showed reversible electrical spreading to a marked degree. At $\mu$ = 0.01, the electrophoretic boundaries for both the $\gamma_1$- and $\gamma_2$-globulins are very asymmetric and actually resolve into several peaks. In Fig. 3 the resolution of these two globulin fractions at $\mu$ = 0.01 and 0.1 are compared, while Fig. 4 shows the reversible spreading phenomenon and the resolution at a *p*H close to the "average" $pI_e$ of the $\gamma_1$-globulins. The asymmetry and the separation of more or less distinct components precludes the calculation of heterogeneity constants at $\mu$ = 0.01 for either $\gamma_1$- or $\gamma_2$-globulins.

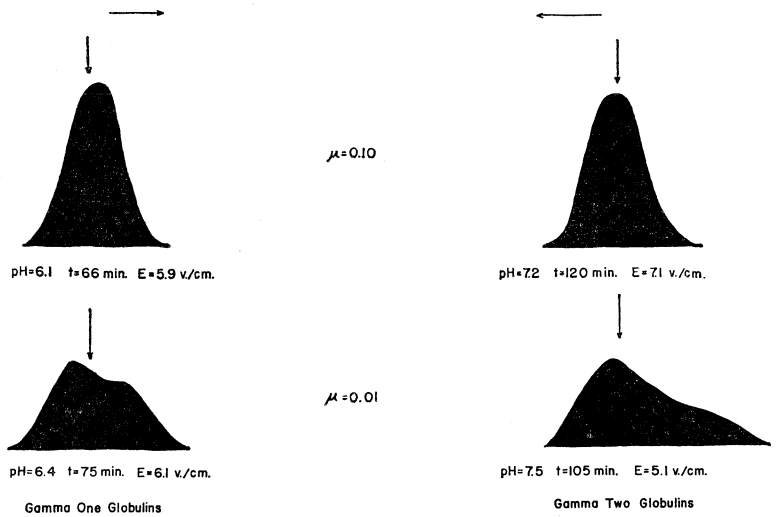

Fig. 3.—The effect of ionic strength on electrophoretic resolution.

The successive extraction of 6.7 g. of $\gamma_1$-

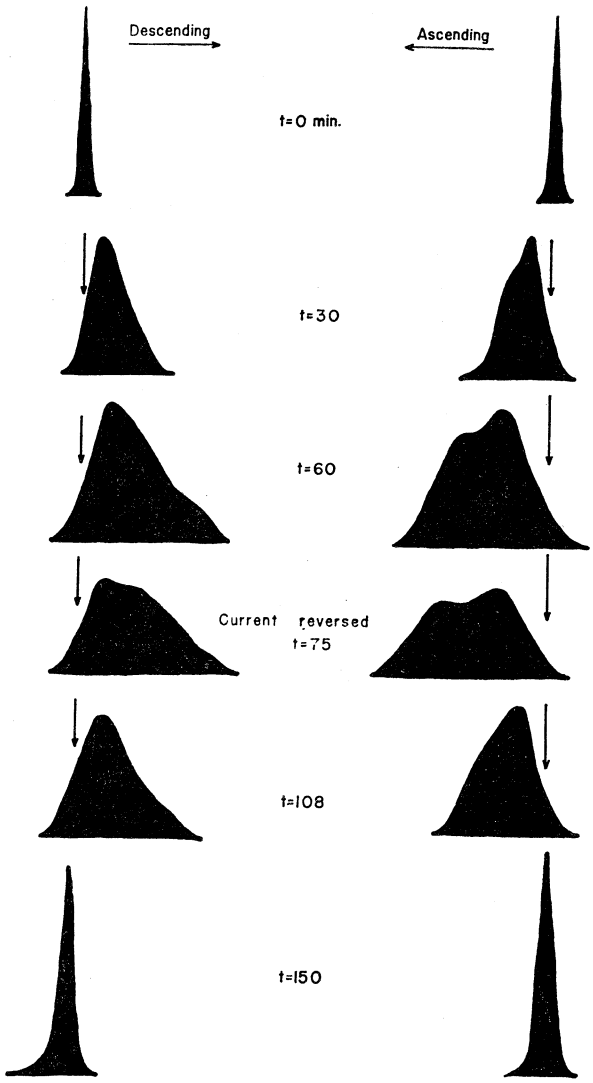

Fig. 4.—Electrophoretic reversible spreading of $\gamma_1$-globulins: $p$H, 5.95, $\mu$ = 0.01, $E$ = 6.1 v./cm.

globulins (Ppt. C-1) with 25-ml. portions of sodium cacodylate buffer at $p$H = 5.95±0.05, $\mu$ = 0.01, yielded the data plotted in Fig. 5. It is apparent that the solid phase remaining after ten extractions represents within the limit of error of the nitrogen determination a protein of constant solubility. Electrophoretic patterns of the supernatants from the first, fourth, seventh and tenth extractions are shown in Fig. 6. Progressive increase in symmetry is evident. However, even the residue possessing a relatively constant solubility clearly shows spreading far greater than can be attributed to normal diffusion. Phase rule solubility curves for the $\gamma_1$- and $\gamma_2$-globulins in $\mu$ = 0.01 buffers at their "average isoelectric points" give no evidence of a major component of relatively constant solubility and corroborated the heterogeneous nature of the fractions as revealed by electrophoretic spreading and solu-

bility extraction procedures. Under the above conditions the $\gamma_1$-globulin fraction is far less soluble than the $\gamma_2$-globulin fraction and even in the most dilute solutions it fails to dissolve completely. The phase rule solubility behavior of the $\gamma_2$-globulins is similar to that observed by Englehardt[12] with myosin solutions. In low ionic strength aqueous solutions at higher protein concentrations the $\gamma_2$-globulins do not separate into the customary solid and liquid phases but separate into a liquid phase and a gel.

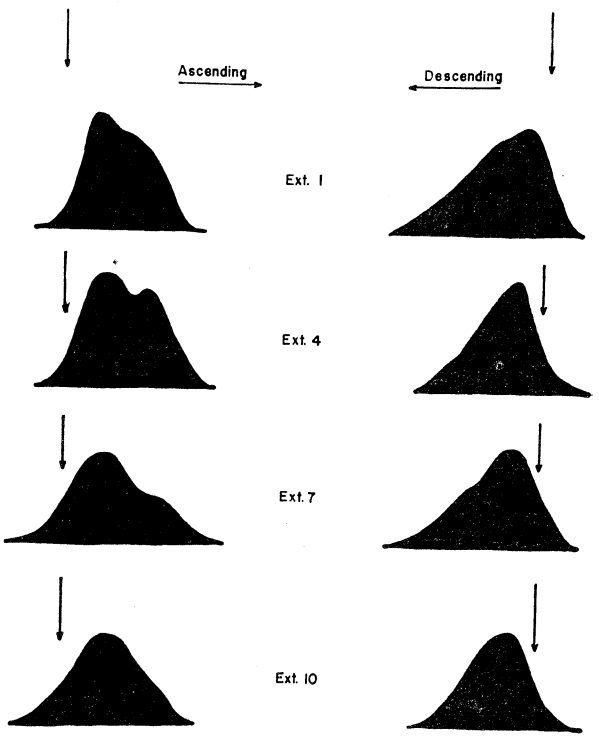

Fig. 6.—Electrophoretic patterns of $\gamma_1$-globulin extracts: $\mu$ = 0.01; $p$H 5.95; $t$ = 60 minutes; $E$ = 6.0 volts/cm.

(12) Englehardt, *Adv. in Enzymol.*, **VI**, 147 (1947).

That the procedures used on adult animals apply to calf serum is substantiated both by yield and antibody recovery data. Actual yields are somewhat low, however, due to the lower $\gamma$-globulin levels in the younger animals. Percentage yields of each fraction are essentially the same as reported in Table I.

## Discussion

The fractionation methods developed for removal of the $\gamma$-globulins from normal bovine sera[4] have been found to be applicable to immune bovine sera with the resultant separation of the major portion of the serum antibodies. Larger amounts of antibody fractions are obtained per unit of serum as a consequence of a higher concentration of $\gamma$-globulins in the starting serum.

Differences in solubility of the antibodies studied are shown by the greater solubility of the *Brucella abortus* bactericidins as compared with the agglutinins. Thus, a significant portion of the bactericidins remain in the supernatant from the first precipitate (Ppt. A, Fig. 1) although the agglutinating antibodies seem to be almost quantitatively removed. More quantitative antibody assay methods are needed to determine the exact solubility differences.

Subfractionation of the $\gamma$-globulins reveals that further separation of individual antibodies by chemical methods is feasible. Thus, while the neutralizing antibodies for Newcastle virus are found in both the $\gamma_1$- and $\gamma_2$-globulin fractions, the hemagglutination inhibiting antibody appears to reside largely in the $\gamma_1$-globulin fraction. However, the concentration of the former antibody as well as those to Brucella organisms are distinctly lower in the $\gamma_2$-globulin fraction. The result for the Brucella antibodies may be in contrast to the response of the horse to bacterial antigens where immunization to bacterial cells causes a marked increase in the normal $\gamma$-globulins ($\gamma_2$) levels[13] as compared to the $\gamma_1$-globulin (T-component) area. The actual distribution of the horse antibodies to bacterial antigens is however unknown.

Further aqueous subfractionations at $\mu = 0.013$, however, reveal that both of the Newcastle virus antibodies are concentrated largely in the pseudoglobulin fraction of precipitate C-1. Thus while as much as 15% of this portion may be removed as aqueous insoluble material no significant amounts of the Newcastle antibodies are removed. Such findings indicate that as regards the antibodies studied in this work a larger amount of protein ($\gamma_1$-englobulin) can be removed with Ppt. B, Fig. 1 without significant loss of the antibodies if this precipitation is carried out at *p*H 6.1 rather than at *p*H 4.9.

A rework of a $\gamma_1$-globulin fraction involving the variables *p*H, ionic strength and ethanol concentration to give three subfractions resulted in the Newcastle virus neutralizing antibody being concentrated entirely in the more soluble (pseudoglobulin) fraction of C-1. No hemagglutination inhibiting antibody was detectable in any of the above three subfractions although recombination of two of the fractions resulted in a low but significant titer. Further studies of this apparent antibody complex are being carried out.[14]

Electrophoretic spreading experiments in $\mu = 0.1$ and 0.01 buffers reveal that the $\gamma$-globulin fractions are electrically inhomogeneous. The inhomogeneity (spreading greater than can be attributed to diffusion and which is electrically reversible) is more evident at low ionic strengths ($\mu = 0.01$). Such data indicating the presence of electrokinetically inhomogeneous *molecular* species have been previously noted.[4,10,15,16,17,18,19]

Solubility studies corroborate the heterogeneous nature of antibody fractions that give a single electrophoretic peak at $\mu = 0.10$. Successive extraction procedures utilizing a buffer solution of relatively low ionic strength tend to leave a residue of more uniform electrophoretic composition than the starting fraction, but one that still shows marked reversible electrophoretic spreading. In this respect the reversible spreading type of experiment provides a delicate criterion of homogeneity.

The $\gamma_1$- and $\gamma_2$-globulins reveal the same degree of mass molecular homogeneity exhibited by the corresponding fractions from normal bovine serum. The sedimentation constants, however, are somewhat higher than one reported by Cohn and his associates[20] but are essentially in agreement with the values obtained by Pedersen[21] for salt fractionated material.

**Acknowledgments.**—We wish to thank the following individuals who aided us in this work: Dr. David Berman of the Department of Veterinary Science provided us with the *Brucella abortus* antigen, immunized and helped bleed the animals, and performed the agglutination and bactericidal assays. His coöperation, advice and assistance were invaluable. Mr. R. M. Hansen, also of the Department of Veterinary Science, performed the Newcastle virus hemagglutination inhibition and neutralizing assays. Mr. Edwin M. Hanson made the sedimentation velocity runs and designed and constructed much of the multiple stirring apparatus for the solubility studies. We are grateful to Professor J. W. Williams for his continued interest in this research.

## Summary

Two γ-globulin fractions, isoelectric at *p*H 5.85 and 7.35 in $\mu = 0.1$ buffers, were prepared by methods previously described, from sera of cows immunized to Brucella abortus and Newcastle virus. These fractions are inhomogeneous as indicated by electrophoretic spreading experiments and solubility studies, but are essentially monodisperse as regards sedimentation behavior. The antibodies studied are largely concentrated in the fraction of lower isoelectric point ($\gamma_1$-globulins). Concentration and separation of certain antibodies were obtained, indicating the feasibility of chemical separation of individual antibodies from polyvalent systems.

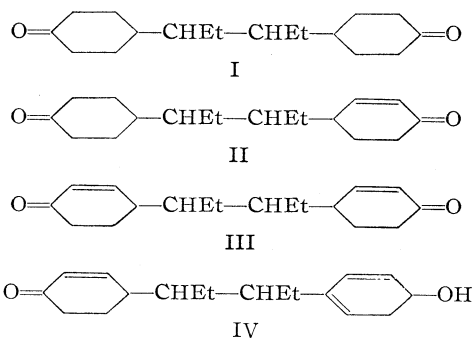
# Hydrodiethylstilbestrol Compounds. IV. The Unsaturated Ketones[1,2]



BY HERBERT E. UNGNADE AND PAUL W. TUCKER[3]

Unsaturated ketones derived from perhydrostilbestrol have been described by Schoeller and coworkers.[4] The di-unsaturated diketones are said to be colorless oils, the mono-unsaturated compounds have not been characterized nor is any criterion of purity disclosed in the pertinent examples. Since the compounds are claimed to possess androgenic activity up to one capon unit per mg., it appeared possible that purified preparations might possess considerable biological activity.

The substances have been prepared essentially as described by the previous investigators. The two known perhydrodiketones (I)[4,5] can be brominated rapidly in chloroform[4] or in glacial acetic acid[6] with the introduction of one or more atoms of bromine. In view of the possibility of replacing the tertiary hydrogens of the hexane chain in the diketones (I) the bromination has now been effected by means of N-bromosuccinimide which supposedly does not react with tertiary hydrogens in the absence of peroxides.[7]

Bromination of the diketones (I) with N-bromosuccinimide in carbon tetrachloride proceeds rapidly with the introduction of one atom of bromine. The second and third bromines are introduced more slowly, the second bromine entering preferentially the unbrominated nucleus. On the basis of recovered succinimide (98–100%) the reaction is nearly quantitative. The glassy bromodiketones are best dehydrobrominated by refluxing with collidine. Chromatographic adsorption of the crude glassy substances on alumina from benzene solution yields homogeneous products containing benzene of solvation which can be removed only by vacuum sublimation.

Ultraviolet absorption spectra of the analytically pure sublimates (II) and (III)[8] show relatively low extinction values at 225 mμ and only a weak secondary maximum at 280–285 mμ. Both phenolic ketones (IV) give the expected phenolic band of 280 mμ. Traces of a phenolic by-product (V) have been isolated from the dehydrobromination of the *meso*-tribromodiketone regardless whether it is prepared by direct bromination or with N-bromosuccinimide. This substance has a strong maximum at 300 mμ which may be taken as evidence for the presence of a double bond conjugated with the phenolic ring.[9] A red ketonic by-product is obtained in the same reaction which must possess a multiple conjugated system in view of its color. The formation of these by-products and the small extinction values for the compounds (II) and (III) lend support to the assumption that N-bromosuccinimide may also attack tertiary hydrogens even in the absence of peroxides and that the substances (II), (III) and (IV) probably consist of mixtures of conjugated and non-conjugated unsaturated ketones.

The *meso* compounds (II) and (III) have been tested biologically. Both show little or no androgenic activity in the seminal vesicle test with three daily doses of 1.0 and 0.75 mg. of substance, respectively.[10]

## Experimental[11]

**Bromination of the Diketones.**—The calculated amount of N-bromosuccinimide was added to a solution of the diketone dissolved in carbon tetrachloride. The mixtures were refluxed for four and one-half, five and one-half and nine hours, respectively, for introducing one, two or three atoms of bromine. Part of the solvent was removed by distillation and the reaction mixtures were allowed to cool. The succinimide was filtered off and washed with carbon tetrachloride. Evaporation of the solvents from the filtrates gave the crude bromo compounds which were used without further purification. The experimental values are listed in Table I.

TABLE I

BROMINATION OF THE DIKETONES

| Diketone, g. | $CCl_4$, cc. | N-Bromosuccinimide, g. | Yield of bromodiketone, % |
|---|---|---|---|
| *meso* 4.0000 | 50 | 2.5632 | 98.2 |
| *meso* 8.0000 | 100 | 10.2172 | 91.7 |
| *meso* 12.0000 | 150 | 23.0688 | 98.9 |
| *dl* 5.0000 | 50 | 3.2040 | 98.0 |
| *dl* 10.0000 | 100 | 12.8160 | 98.0 |
| *dl* 15.0000 | 150 | 19.2240 | 90.0 |

**Dehydrobromination of the Bromodiketones.**—The bromodiketones, dissolved in 4 to 6 parts by weight of collidine, were refluxed for one and one-half hours in an oil-bath. The collidine hydrobromide was filtered off and washed with benzene. The filtrates were extracted with benzene and the combined benzene solutions were washed with 10% aqueous hydrochloric acid and water, dried by distillation and evaporated. The dark colored glassy substances were dissolved in benzene and extracted with Claisen alkali. The remaining benzene solutions were washed, dried and adsorbed on alumina. The ketonic fractions were eluted with benzene and distilled to remove the solvent. The identity of the fractions was checked by means of their ultraviolet absorption spectra. Traces of starting material showed very low extinction values over the range of 215–335 mμ.

Phenolic substances were obtained only in minute quantities from mono- and dibromodiketones, but formed in fairly good yield from the tribromodiketones. They were regenerated by acidification of the Claisen alkali solutions with 1:1 aqueous hydrochloric acid, extracted with benzene, washed, dried and distilled. The residual material was adsorbed on alumina from benzene solution and eluted with the same solvent. The fraction with appropriate ultraviolet spectrum was sublimed under reduced pressure.

Vacuum sublimation of both phenolic and non-phenolic ketones was carried out in a molecular pot still with a path length of 1 cm. at 160–180° ($1 \times 10^{-4}$ mm.). Yields and constants of the unsaturated ketones are given in Table II.

**Ultraviolet Absorption Spectra.**—The unsaturated ketones were run in 95% alcohol in concentrations of 0.000185 mole per liter in a Beckman spectrophotometer.[8] The saturated *meso*-diketone (I) was run in a 0.005 molar solution. The extinction values are given in Table III.

## Summary

Analytically pure unsaturated diketones and unsaturated phenolic ketones derived from perhydrostilbestrol have been prepared by bromination and dehydrobromination of the saturated diketones.

On the basis of the absorption spectra of the products and the by-products in the reaction it is proposed that N-bromosuccinimide may attack tertiary hydrogens even in the absence of peroxides and that the products may consist of mixtures of conjugated and non-conjugated unsaturated ketones.

The mono- and di-unsaturated *meso*-diketones fail to show any appreciable androgenic activity.

# Derived Steroids. III. 5-Androsten-17-ol-3-carboxylic Acid[1]

BY ROBERT H. BAKER AND EDWARD N. SQUIRE[2]

Marker[3] prepared 17-androstanone-3-carboxylic acid and found that it had estrogenic properties. We now report the synthesis of a similar compound (IV) with the additional feature of a double bond in the 5,6-position.

Two methods were used to prepare IV. Since the steroid halides form Grignard reagents only in the presence of preformed Grignards, it appeared that *t*-butylmagnesium chloride would serve both this role and as reducing agent for the 17-keto group.[4] This route produced only an 8% yield of the acid and it proved better to reduce the ketone by standard procedures and proceed by the longer route.

The ketone (I) is reduced only slowly and crystallization of the product gives what appears to be a molecular compound of I and II. This substance, m. p. 134°, resists separation by chromatography on alumina, but after acetylation the ester and ketone may be separated by either crystallization or chromatography. So prepared, II and its acetate agree in m. p. with the products prepared by Kuwada[5] by the action of thionyl chloride on 17-acetoxy-5-androsten-3-ol.

Because of the low solubility of II in ether, and the still lower solubility of III, the treatment with methyl Grignard was best carried out on the more soluble acetate of II. This produced a fine suspension of III which even then required a prolonged contact with carbon dioxide. Maximum yields of the acid (IV) were not obtained with less than eighteen hours for Grignard formation and eight hours for carbonation.

## Experimental[6]

**3-Chloro-5-androsten-17-one** (I).—This was prepared essentially by the method of Wallis and Fernholz[7] except that the phosphorus pentachloride was added slowly and the product was purified by absorption from chloroform solution on alumina, m. p. 154–154.4°.

**3-Chloro-5-androsten-17-ol** (II).—A solution made from 60 ml. of isopropyl alcohol containing 0.037 mole of aluminum isopropoxide and 1.15 g. (0.0037 mole) of I was refluxed for fourteen hours, and then slowly distilled to a residue of 15 ml. This was hydrolyzed with hydrochloric acid, extracted with ether and crystallized from methanol, m. p. 128–138°. The solid was dissolved in 10 ml. of benzene, diluted with 40 ml. of petroleum ether (b. p. 60–70°) and passed through a column containing 15 g. of alumina. Elution with the same solvent, 50 ml., produced 390 mg., m. p. 120–135°. The next four fractions, eluted with benzene, gave 650 mg. of the chloro alcohol, m. p. 162.5–165.5°, lit.[5] 163°.

**3-Chloro-17-acetoxy-5-androstene.**—This could be prepared by heating (95°) the 120–135°-melting product with acetic anhydride and pyridine for two hours. Repeated crystallization from methanol gave m. p. 182–184°, lit.,[5] 183°. For preparative purposes the pure chloro alcohol was used.

**5-Androsten-17-ol-3-carboxylic Acid** (IV).—To a mixture of methylmagnesium iodide and magnesium, made from 2.28 g. ($1.6 \times 10^{-2}$ mole) of the iodide and 1.0 g. ($4.1 \times 10^{-2}$ mole) of metal, in 5 ml. of ether there was added a solution of 0.702 g. ($2 \times 10^{-3}$ mole) of 3-chloro-17-acetoxy-5-androstene in 35 ml. of ether. This mixture was refluxed under nitrogen and stirred for twenty-four hours. The mixture was then cooled by a dry ice-acetone bath and subjected to 790 mm. pressure of dry carbon dioxide during sixteen hours, then for two more hours at room temperature. The reaction mixture was decomposed with 10% hydrochloric acid and extracted with 50 ml. of ether. The carboxylic acid was extracted from the ether with four 25-ml. portions of 5% potassium hydroxide. The alkaline solution, after extraction with ether, was acidified to precipitate the acid which was then crystallized from ether to give four fractions, 0.540 g., m. p. 220–243° (top fraction 240–243°). Crystallization from benzene gave m. p. 239–242°. The analytical sample was dried four days at 100° *in vacuo* over phosphorus pentoxide.

*Anal.* Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.96, 75.45; H, 9.92, 9.74.

The ether washes contained suspended solid which was removed by filtration, 20 mg., m. p. *ca.* 300°. This is probably 3,3′-bis-5-androsten-17-ol formed similarly to the bicholesteryl.[1]

Evaporation of the neutral ether washes left a product which did not crystallize well from methanol, 0.2 g., m. p. 138–154°. In this was identified **5-androsten-17-ol** by conversion into the acetate, 0.1 g., m. p. 135–136°, lit.,[8] 133–135°.

The acid (IV) was also prepared directly from 3-chloro-5-androsten-17-one. To 1.0 g. ($3.2 \times 10^{-3}$ mole) of the

chloroketone in 50 ml. of ether there was added 0.243 g. ($1 \times 10^{-2}$ mole) of magnesium powder and 10 ml. of 2 *N* *t*-butylmagnesium chloride. The mixture was refluxed for four hours, and carbonated as previously described to give 83 mg. of the acid, m. p. 243°.

**3-Carbomethoxy-5-androsten-17-ol.**—A solution of 10 ml. of absolute methanol, 110 mg. ($3.4 \times 10^{-4}$ mole) of IV and 6 drops of concd. sulfuric acid was refluxed for twenty-four hours. The mixture was poured into water, extracted with ether and washed free of acid by alkali. Crystallization from methanol–petroleum ether followed by chromatography over alumina from benzene–petroleum ether gave 80 mg., m. p. 141–142°.

*Anal.* Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.73. Found: C, 75.20; H, 9.79.

**17-Acetoxy-5-androsten-3-carboxylic Acid.**—A crude sample, 250 mg., of the acid (IV) was heated at 100° for two hours with excess acetic anhydride in pyridine. The product obtained by pouring into water was dissolved in acetone and filtered to remove some insoluble material. Slow crystallization from acetone gave 110 mg., m. p. 211–213°, $[\alpha]^{23}D$ −40.6 (*C*, 4.90 in chloroform).[9]

*Anal.* Calcd. for $C_{22}H_{32}O_4$: C, 73.29; H, 8.95. Found: C, 73.00; H, 8.99.

**Acknowledgment.**—We wish to thank Dr. Wayne Cole of the Soya Products Division of the Glidden Co. for supplying the dehydroisoandrosterone.

## Summary

5-Androsten-17-ol-3-carboxylic acid has been prepared by carbonation of a Grignard reagent. Its acetate and methyl ester are described.

(9) The specific rotations of the intermediates and other compounds in this series will appear in a future publication by Dr. Squire.

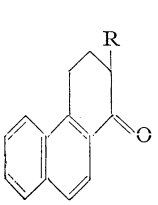
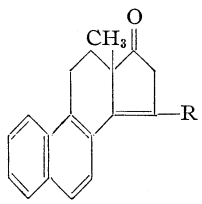
# The Stobbe Condensation with 1-Keto-2-methyl-1,2,3,4-tetrahydrophenanthrene. A New Approach to β-17-Equilenone[1]

BY WILLIAM S. JOHNSON, VERNER L. STROMBERG AND JACK W. PETERSEN[2]

A few years ago we described a convenient synthesis of the ketone I (R = H) by the cyclization of the half-ester II produced by a Stobbe condensation with III (R = H), followed by hydrolysis and decarboxylation of the resulting keto ester I (R = $COOC_2H_5$).[3] Since then this scheme has been applied successfully by Riegel, Siegel and Kritchevsky[4] to the synthesis of a number of derivatives of I (R = H) containing alkyl substituents at the 3-position of the phenanthrene nucleus.

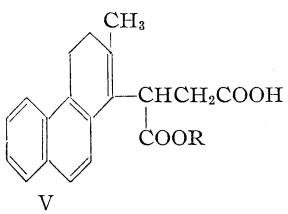


I

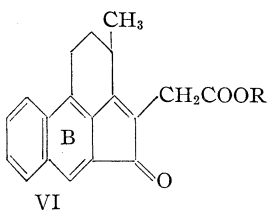


II

It seemed of particular interest to extend the synthesis to the homologous ketone III (R = $CH_3$) containing the methyl substituent at the 2-position, since if the cyclization proceeded into the alicyclic ring, a substance IV (R = $COOC_2H_5$) would be produced which is known to be convertible by hydrolysis, decarboxylation and hydrogenation into the 17-equilenones (3-desoxyequilenins).[5] The results of such an investigation are reported in this communication.



III



IV

The Stobbe condensation with III (R = $CH_3$) proceeded less readily than with the unsubstituted ketone III (R = H), but by altering conditions a non-homogeneous half-ester V (R = $CH_3$)[6] was obtained in excellent yield, from which a pure crystalline isomer was isolated in 61% yield.

V

VI

Cyclization of the crude half-ester V (R = $CH_3$ or $C_2H_5$) with a mixture of zinc chloride, acetic acid and acetic anhydride gave a neutral crystalline product of the expected composition. Because of its bright yellow color, however, it was presumed to be the indenone derivative VI produced by cyclization accompanied by ester exchange as observed in other studies.[7] That the ring had indeed closed into the aromatic nucleus was proved by oxidative degradation to benzenepentacarboxylic acid evidently arising from ring B (formula VI).

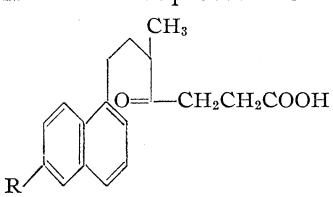
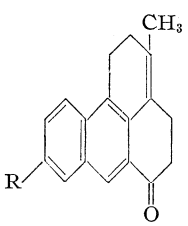
(7) Johnson and Goldman, THIS JOURNAL, **67**, 430 (1945).



VII



VIII

To circumvent ring closure to VI the carbomethoxy group was removed before cyclization as in previous studies with the lower homolog.[3] Saponification with barium hydroxide gave the crystalline dibasic acid V (R = H)[6] which lost carbon dioxide readily on warming in the presence of an acid catalyst. The product consisted of oily lactonic material and a mixture of unsaturated acids from which a pure isomer VII (R = H)[6] was isolated in 41% yield. This product and the crystalline lactone VIII (R = H) produced by treatment of VII (R = H)[6] with cold hydrogen fluoride[8] proved to be identical (by mixed melting point determinations) with samples prepared from IX (R = H) according to a scheme employed by Haberland[9] for the synthesis of VII (R = $OCH_3$) and VIII (R = $OCH_3$) by the cyclization of the keto acid IX (R = $OCH_3$). For the cyclization of IX (R = H) hydrogen fluoride proved to be much better than sulfuric acid, the lactone VIII (R = H) being obtained in 93% yield. In spite of this improvement the method involving the Stobbe condensation proved to be easier for preparing the unsaturated acid VII (R = H),[6] particularly since the conversion of the lactone into this acid did not proceed well.

IX

X

Even though Haberland's[9] attempts to cyclize the unsaturated acid VII (R = $OCH_3$) have been shown[5] to give what is most likely the ketone X (R = $OCH_3$) arising from cyclization into the aromatic nucleus, nevertheless it seemed worth investigating other methods of ring closure of VII (R = H), particularly since in the tetralone series[8] it was discovered that cyclization could take place into either the alicyclic or the aromatic nucleus depending on the conditions. Accordingly VII (R = H) was treated with zinc chloride, acetic acid and acetic anhydride as described for the cyclization of II,[3] but only dark intractable oils were produced. By reducing the amount of zinc chloride to trace quantity, however, a neutral nonsaponifiable oil was obtained from which a ketone crystallized in 21% yield (m. p. 152° after purification). Analysis was compatible with the formula $C_{18}H_{16}O$, and since both 14,15- and 15,16-dehydro-17-equilenone have considerably lower melting points,[5] this substance was presumed to be the product X (R = H) of cyclization into the aromatic nucleus. From the mother liquor a second ketone crystallized in 20% yield. This substance proved to be 14,15-dehydro-17-equilenone, IV (R = H) melting at 135° as shown by comparison of the ketone and semicarbazone with authentic samples. Since reduction of IV (R = H) is known to give β-17-equilenone,[5] the present scheme represents a new synthesis of desoxyequilenin. From previous experience it seems probable that some of the tautomeric 15,16-dehydro-17-equilenone remained in the oily residue.[5] An investigation in the methoxy series which is now in progress is expected to afford a new synthesis of 14,15-dehydroequilenin methyl ether, and hence of equilenin.[9a]

## Experimental[10]

**The Stobbe Condensation with 1-Keto-2-methyl-1,2,3,4-tetrahydrophenanthrene.**—A cold solution of 3.02 g. of potassium in 63 ml. of dry *t*-butyl alcohol was mixed with 12.9 g. of dimethyl succinate and 15 ml. of this mixture was added from a dropping funnel to 2.50 g. of the ketone (m. p. 72–73°) contained in the flask of a special apparatus,[11] the whole operation being conducted under an atmosphere of nitrogen. The flask was immersed in an oil-bath at 50° and the remainder of the solution added slowly with stirring over a period of four hours. After an additional hour at 50° the mixture was cooled, acidified with hydrochloric acid, and the alcohol removed under reduced pressure. The semi-solid residue was taken up in ether, washed with water, then extracted with 1 *N* ammonium hydroxide. Acidification of the alkaline solutions gave 3.57 g. (93% yield) of crude yellow oily half-ester which solidified on standing, m. p. 119–143°. Crystallization from benzene–petroleum ether (b. p. 60–68°) followed by recrystallization from dilute methanol gave 2.37 g. (61% yield) of colorless needles, m. p. 156–159°. Repeated recrystallization from this solvent raised the melting point of this substance, **β-carbomethoxy-β-(2-methyl-3,4-dihydro-1-phenanthryl)-propionic acid,**[6] to 159–160.5°.

*Anal.* Calcd. for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22. Found: C, 73.78; H, 6.42.

**β-Carboxy-β-(2-methyl-3,4-dihydro-1-phenanthryl)-propionic Acid.**[6]—To a solution of 10.0 g. of the half-ester, m. p. 156–159°, in 860 ml. of alcohol was added a solution of 126 g. of barium hydroxide octahydrate in 720 ml. of water. The mixture was boiled under reflux for one hour, and most of the alcohol was removed under reduced pressure. The cooled (ice–salt-bath) semi-solid residue was acidified with 1 to 1 hydrochloric acid, the temperature

(9a) This expectation has now been realized, the acid VII (R = $OCH_3$),[6] m. p. 184–185°, giving 14,15-dehydroequilenin methyl ether in low yield. (Added in proof, March 22, 1949.)

(10) Unless otherwise specified, all melting points are corrected.

(11) See the apparatus used in "Step 4" of the synthesis of equilenin, ref. 5.

always being kept below 10° to prevent decarboxylation. The precipitated dibasic acid amounted to 9.51 g. (99% yield), m. p. 190–194° dec. A single recrystallization from acetone-benzene gave colorless prisms melting at 209–211° dec. After repeated recrystallization the m. p. was 209.5–210° dec.

*Anal.* Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85. Found: C, 73.61, 73.52; H, 5.92, 5.77.

The **anhydride** was produced by the action of boiling acetyl chloride on the dibasic acid. Crystallization from benzene-petroleum ether (b. p. 60–68°) gave colorless prisms, m. p. 147.5–148°.

*Anal.* Calcd. for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52. Found: C, 77.97, 78.21; H, 5.38, 5.61.

**β-(2-Methyl-3,4-dihydro-1-phenanthryl)-propionic Acid, VII** (R = H).[6]—Decarboxylation of the dibasic acid (1.000 g.) (m. p. 209–210°) was effected by heating with 18 ml. of pyridine, 30 ml. of concentrated hydrochloric acid and 10 g. of oxalic acid. After twenty-five minutes under reflux the calculated volume of gas was evolved. The mixture was diluted with water and the organic material taken up in ether, washed with water and extracted with 1 *N* ammonium hydroxide. Acidification of the alkaline extracts gave 0.652 g. (76% yield) of colorless acid, m. p. 95–110°. Recrystallization from dilute methanol gave 0.352 g. (41% yield) of fairly pure material, m. p. 125–128°. Further recrystallization gave colorless plates, m. p. 131–132° undepressed on admixture with the sample of VII (R = H) prepared by the Haberland scheme (see below); calcd.: neut. equiv., 266.3. Found: neut. equiv., 265.0.

A sample of the unsaturated acid was lactonized by treatment with cold anhydrous hydrogen fluoride.[8] Recrystallization of the neutral fraction from methanol gave the lactone VIII (R = H), m. p. 155–157°, undepressed on admixture with the sample prepared by the Haberland synthesis (see below).

**Cyclization of the Unsaturated Acid VII** (R = H).[6]—A solution of 0.400 g. of the above unsaturated acid in 20 ml. of acetic anhydride to which 2 drops of a solution of zinc chloride in acetic acid (20 mg./ml.) had been added was boiled under reflux for eight hours in an atmosphere of nitrogen. The acetic anhydride was decomposed with methanol, and the volatile materials removed on the steam-bath. The red solution was diluted with water, and extracted with ether. The ether solution was washed with 5% sodium hydroxide to remove acidic material, concentrated, and the residue heated on the steam-bath with 20 ml. of 10% potassium hydroxide solution for ten minutes in an atmosphere of nitrogen. The unsaponified material was taken up in ether, washed with 5% sodium hydroxide, 5% hydrochloric acid, and saturated sodium chloride solution. The red glass remaining on evaporation of the ether was evaporatively distilled at 155° (0.1 mm.) giving 0.328 g. of yellow semi-solid distillate. Crystallization from ether gave 0.078 g. (21% yield) of pale yellow needles, m. p. 145.5–150°, probably X (R = H). Repeated recrystallization from alcohol gave yellow needles, m. p. 152.1–152.7°.

*Anal.* Calcd. for $C_{18}H_{16}O$: C, 87.06; H, 6.50. Found: C, 87.14; H, 6.15.

The **semicarbazone** crystallized from pyridine in the form of pale yellow needles, m. p. (in an evacuated tube) 245.2–246.2° dec. (introduced at 235°).

*Anal.* Calcd. for $C_{19}H_{19}ON_3$: C, 74.73; H, 6.27. Found: C, 74.82; H, 5.94.

The filtrate from which the 152° ketone separated was evaporated to dryness and crystallized from alcohol to give 0.074 g. (20% yield) of colorless needles, m. p. 118–123°. Recrystallization gave material melting at 134.5–135.5° alone or when mixed with an authentic specimen of 14,15-dehydro-17-equilenone, m. p. 135.5–136°.[5]

The **semicarbazone** crystallized from pyridine in the form of colorless needles, m. p. 248–250° dec., undepressed on admixture with a sample of the derivative (m. p. 248.5–250° dec.) prepared from authentic ketone.[5]

*Anal.* Calcd. for $C_{19}H_{19}ON_3$: C, 74.73; H, 6.27. Found: C, 74.64; H, 5.97.

**Cyclization of the Half-Ester V** (R = $CH_3$).[6]—A mixture of 1.2 g. of the crude half-ester, 6 ml. of acetic acid containing fused zinc chloride (20 mg./ml.), 6 ml. of acetic acid and 12 ml. of acetic anhydride was boiled under reflux for ninety minutes, cooled, treated with water to hydrolyze the acetic anhydride and evaporated under reduced pressure. The residual red oil was taken up in ether, washed with 5% potassium hydroxide solution and, after evaporation of the solvent, crystallized from benzene–ligroin. **Methyl 3-methyl-1,2,3,5-tetrahydroacephenanthryl-3a,4-ene-5-one-4-acetate, VI** (R = $CH_3$), was thus obtained as bright yellow prisms, m. p. 134–137°; yield 0.340 g. (30%). A sample prepared for analysis melted at 136.5–138°.

*Anal.* Calcd. for $C_{20}H_{18}O_3$: C, 78.41; H, 5.92. Found: C, 78.10; H, 5.98.

Ultraviolet absorption in ethanol: $\lambda_{max.}$ 235 mμ (log *E* 4.30), 279 (4.73), 412 (3.41).

A cyclization with 0.150 g. of pure half-ester, m. p. 156–158°, gave 0.070 g. (49% yield) of crude product, m. p. 124–128°.

The same substance was produced when the cyclization was conducted with phosphorus pentoxide in boiling benzene.

**Cyclization of the Half-Ester V** (R = $C_2H_5$)[6] was carried out with the crude acidic material produced by the condensation of 2.10 g. of the ketone III (R = $CH_3$) with 1.74 g. of diethyl succinate in the presence of potassium *t*-butoxide according to procedures already described.[3] The oily half-ester could not be crystallized and was cyclized directly with 13.5 ml. of acetic acid containing fused zinc chloride (20 mg./ml.), 18.5 ml. of acetic acid and 27 ml. of acetic anhydride as described above for the methyl ester. The crude product, 0.150 g., crystallized from benzene–ligroin in the form of yellow prisms, m. p. 113–118°. Recrystallization raised the m. p. to 115–116.5°.

*Anal.* Calcd. for $C_{21}H_{20}O_3$: C, 78.72; H, 6.29. Found: C, 78.48; H, 5.98.

Ultraviolet absorption in ethanol: $\lambda_{max.}$ 235 mμ (log *E* 4.30), 279 (4.72), 412 (3.40).

**Oxidation of Keto Ester VI** (R = $CH_3$) **to Benzenepentacarboxylic Acid.**—A mixture of 0.340 g. of the keto ester, 2 ml. of concentrated nitric acid and 1.5 ml. of water was heated in a sealed tube at 180–200° for eighteen hours. The residue obtained after evaporation was crystallized once from concentrated nitric acid; yield 0.058 g. of crude colorless acid, m. p. 222–227°, dec. (reported,[12] 232–233°, dec.). The pentamethyl ester prepared with diazomethane melted at 146.5–148.8° (reported,[13] 147–148°).

**1-Bromo-3-methyl-5-(1-naphthyl)-2-pentanone.**—A solution of 11.40 g. of α-methyl-γ-(1-naphthyl)-butyric acid in 25 ml. of chloroform was treated with 18 ml. of purified thionyl chloride. After refluxing for one hour the mixture was evaporated at 40° under reduced pressure, the thionyl chloride being completely removed by adding small portions of chloroform to the residue and repeating the evaporation. The acid chloride was dissolved in 25 ml. of dry ether and added slowly to a dry ether solution of diazomethane prepared from 20.8 g. of nitrosomethylurea. After one and one-half hours at room temperature 25 ml. of 48% hydrobromic acid was added with shaking. The organic layer was separated, washed with water, then with a saturated solution of sodium bicarbonate, and dried over anhydrous sodium sulfate. Crystallization of the oily residue obtained on evaporation from ether-petroleum ether gave 8.80 g. of brownish product, m. p. 57–60°. An additional 1.65 g. of material, m. p. 52–58° was crystallized from the mother liquor making the total yield 68%. This product was satisfactory for the next step of the synthesis which gave homogeneous material in 86% yield, thus establishing the nature of the bromo ketone which could not be purified satisfactorily for analysis.

(12) Fleischer and Retze, *Ber.*, **56**, 228 (1923).

(13) Ruzicka and Rudolph, *Helv. Chim. Acta*, **10**, 915 (1927).

**4-Keto-4-methyl-7-(1-naphthyl)-heptanoic Acid, IX** (R = H).—The bromo ketone (5.16 g.) in 20 ml. of dry toluene was added to a solution of sodiomalonic ester prepared from 4.08 g. of diethyl malonate and 0.38 g. of sodium shot in 20 ml. of toluene, whereupon a precipitate formed immediately. After refluxing for four hours, the mixture was evaporated under reduced pressure and the residue saponified by heating for four hours on the steam-bath with 11.5 g. of potassium hydroxide in 15 ml. of water and 5 ml. of alcohol. The substituted malonic acid which was separated by acidification, followed by ether extraction, was decarboxylated by heating at 150–160° for twenty minutes. The brown residue was dissolved in benzene, treated with Norit, and crystallized from benzene–petroleum ether; yield 4.14 g. of slightly brownish needles, m. p. 82–84°. A sample purified for analysis by repeated recrystallization from benzene–petroleum ether was colorless and melted at 89–90°.

*Anal.* Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 75.80; H, 7.20.

**Lactone, VIII** (R = H) **of β-(1-Hydroxy-2-methyl-1,2,-3,4-tetrahydro-1-phenanthryl)-propionic Acid.**—Anhydrous hydrogen fluoride (about 40 g.) was added to 1.15 g. of the keto acid contained in a platinum vessel chilled in an ice–salt mixture. After five minutes the reagent was evaporated in a current of air, and the solid residue taken up in ether and washed with sodium bicarbonate solution. The residue obtained on evaporation of the ether was triturated with 5 ml. of cold ether leaving 1.00 g. (93% yield) of tan crystals of the lactone, m. p. 152–155°. Recrystallization from methanol gave colorless prisms, m. p. 155–156°.

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.16; H, 6.81. Found: C, 81.38; H, 6.92.

The lactone was also produced in high yield when the methyl ester of IX (R = H) was treated with hydrogen fluoride.

**β-(1-Hydroxy-2-methyl-1,2,3,4-tetrahydro-1-phenanthryl)-propionic acid** was prepared from 0.150 g. of the above lactone by hydrolysis with 0.250 g. of sodium hydroxide in 10 ml. of water. After heating for three hours on the steam-bath the clear solution was chilled and acidified slowly with cold dilute acetic acid. The crystalline hydroxy acid which precipitated (0.145 g.) was recrystallized from methanol giving colorless needles, m. p. 187–188° with dec. (lactonization). Further recrystallization did not raise the melting point.

*Anal.* Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 75.97; H, 7.12.

In contrast to the 7-methoxy derivative[9] this hydroxy acid showed no tendency to undergo dehydration to the unsaturated acid, but reverted to the lactone. In order to prepare the unsaturated acid VII (R = H) the procedure of Bachmann, Cole and Wilds[14] for the dehydration of β-hydroxy esters was applied. Thus the hydroxy ester produced from 0.100 g. of the lactone and 2 ml. of methanolic hydrogen chloride, was treated with pyridine (2 drops) and thionyl chloride (3 drops) in 0.5 ml. of benzene for thirty minutes at room temperature, then for ten minutes at 40°. The product was worked up *via* saponification with 45% potassium hydroxide; yield 0.035 g. (35%) of colorless crystals, m. p. 122–126°, soft at 118°. Two recrystallizations from benzene–petroleum ether gave colorless plates, m. p. 131.5–132°.

*Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.16; H, 6.81. Found: C, 81.10; H, 7.16.

## Summary

A synthetic scheme involving the Stobbe condensation, previously developed for the production of steroid-like structures from 1-keto-1,2,3,4-tetrahydrophenanthrene, has now been applied with some modifications to the 2-methyl derivative to give a homolog containing the 13-angular methyl group. The product, 14,15-dehydro-17-equilenone, is the precursor of β-17-equilenone (3-desoxyequilenin).

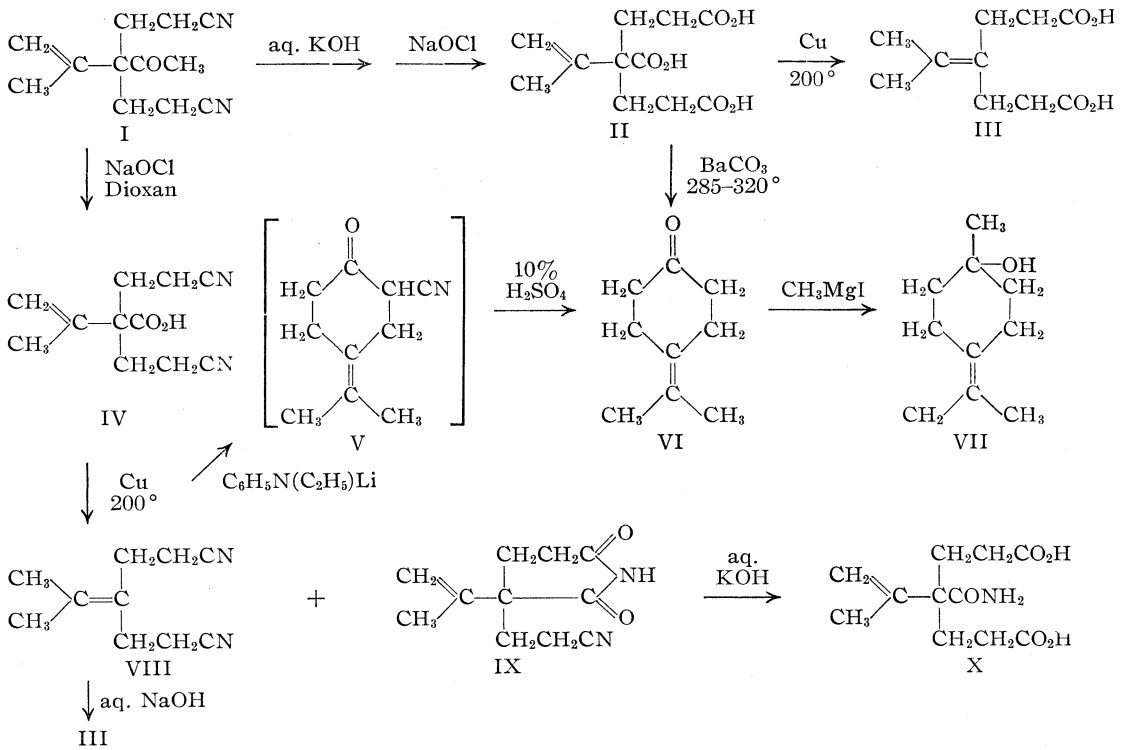
# Decarboxylation and Cyclization Reactions of Some Pimelic Acid Derivatives

BY ROBERT L. FRANK AND JAMES B. MCPHERSON, JR.



The cyanoethylation reaction described by Bruson and Riener[1] affords a convenient method for the preparation of pimelic acid derivatives, certain of which suggest themselves as possible intermediates in the syntheses of cyclohexanones related to some of the monocyclic terpenes. In this paper are reported the decarboxylations and ring closures of a group of compounds derived from γ-acetyl-γ-isopropenylpimelonitrile (I), the cyanoethylation product of mesityl oxide. We have been particularly interested in the lability of the unsaturation of the isopropenyl group during these reactions.

Pyrolysis of γ-carboxy-γ-isopropenylpimelic acid (II), a derivative reported by Bruson and Riener,[1] at 285–320° in the presence of barium carbonate resulted in simultaneous decarboxylation and ring closure to give a substituted cyclohexanone. Ozonolysis showed this material to be almost entirely 4-isopropylidenecyclohexanone (VI), since the products isolated were acetone and 1,4-cyclohexanedione. Derivatives of formaldehyde or formic acid were not obtained, although these were detected by faint color tests. Thus this pyrolysis was accompanied by nearly complete isomerization of the double bond of the isopropenyl group. Further evidence for the isopropylidene structure for the cyclohexanone was obtained by reaction with methylmagnesium iodide to give γ-terpineol (VII) rather than β-terpineol. Incidentally, this constitutes a total synthesis for this naturally-occurring terpene.[2]

During the heating of γ-carboxy-γ-isopropenylpimelic acid (II) it was noted that carbon dioxide was evolved at temperatures considerably below 300°. This indicated that simple decarboxylation might be occurring before the cyclization reaction,

(1) Bruson, THIS JOURNAL, **64**, 2457 (1942); Bruson and Riener, *ibid.*, **65**, 18 (1943).

(2) Simonsen, *Ind. For. Rec.*, **10**, 1 (1923).

a conclusion confirmed by heating the triacid (II) with copper-bronze at 200° to give 32% of a dicarboxylic acid. Further work as described below showed the latter to be γ-isopropylidenepimelic acid (III). Thus even under these milder conditions there was isomerization of the isopropenyl group.

Similar decarboxylation of γ-carboxy-γ-isopropenylpimelonitrile (IV), obtained in 81% yield by the haloform reaction on γ-acetyl-γ-isopropenylpimelonitrile (I), also resulted in shifting of the double bond. The product (VIII), obtained in 34% yield, gave acetone on ozonolysis; no formaldehyde was detected. Hydrolysis of the dinitrile gave the same dicarboxylic acid obtained from γ-carboxy-γ-isopropenylpimelic acid (II). We therefore believe the dibasic acid to have the isopropylidene structure represented by III.

As a by-product in the decarboxylation of the dinitrile (IV) there was also obtained an equal amount of a crystalline solid. This was shown by analysis and molecular weight determination to be isomeric with the starting material (IV), although not subject to similar decarboxylation. Further pyrolysis gave only tar. A neutral equivalent showed the presence of no free carboxyl group, although the compound was soluble in aqueous sodium hydroxide. It was insoluble in sodium bicarbonate solution. A saponification equivalent indicated two saponifiable groups; the product of this determination was isolated as a crystalline dicarboxylic acid having the composition $C_{11}H_{17}NO_5$. To this has been assigned the structure γ-formamido-γ-isopropenylpimelic acid (X) and to the by-product itself the structure α-cyanoethyl-α-isopropenylglutarimide (IX). Supporting evidence is the infrared absorption spectrum of the latter and its comparison with the spectrum of glutarimide in the CO (1705 cm.$^{-1}$) and NH (3000–3200 cm.$^{-1}$) regions (Fig. 1). The failure of complete saponification of α-cyanoethyl-α-isopropenylglutarimide (IX) to a tricarboxylic acid is to be expected because of the tertiary nature of the γ-formamido grouping (X).

The formation of an imide by interaction of a cyano and a carboxyl group has been known since 1869[3] and has recently been studied by Wiley and Guerrant.[4]

A further reaction of 4-isopropylidenepimelonitrile (VIII) has been its ring closure by the Thorpe reaction to 2-cyano-4-isopropylidenecyclohexanone (V). Hydrolysis of the latter with 10% aqueous sulfuric acid gave a low yield of a ketone, the 2,4-dinitrophenylhydrazone of which gave no depression in mixed m. p. with that of 4-isopropylidenecyclohexanone (VI). A semicarbazone was also obtained; this was different from but isomeric with that formed by the 4-isopropylidenecyclohexanone (VI) derived from γ-carboxy-γ-isopropenylpimelic acid (II). Its formation indicates the possible presence of the isopropenyl analog of the ketone (VI).

Infrared absorption spectra have also been studied because it was hoped they might provide a method for differentiating isopropenyl and isopropylidene groups in this series. As indicated by

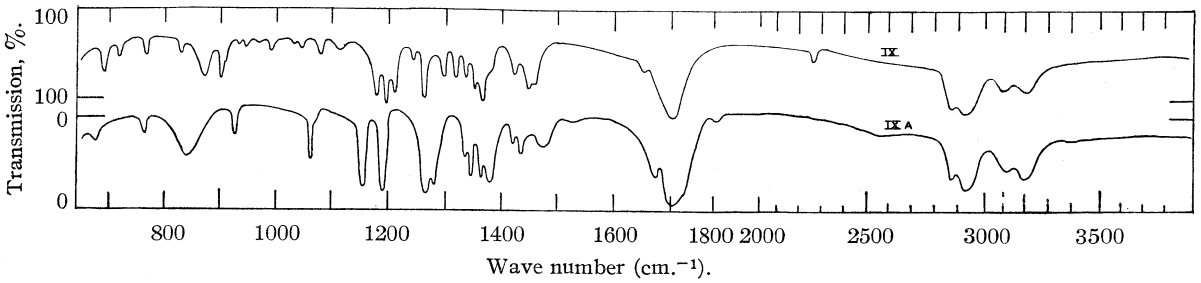

Fig. 1.—Infrared spectra of glutarimides: IX is α-cyanoethyl-α-isopropenylglutarimide; IXA is glutarimide.

Thompson and Torkington,[5] however, both terminal and non-terminal double bonds produce absorption maxima in the region 890–970 cm.$^{-1}$. In this region particularly the absorption depends not only on the position of the double bond, but also on the complete molecular structure. As shown in Fig. 2, all of our compounds, isopropenyl and isopropylidene, exhibit maxima between 890 and 918 cm.$^{-1}$.

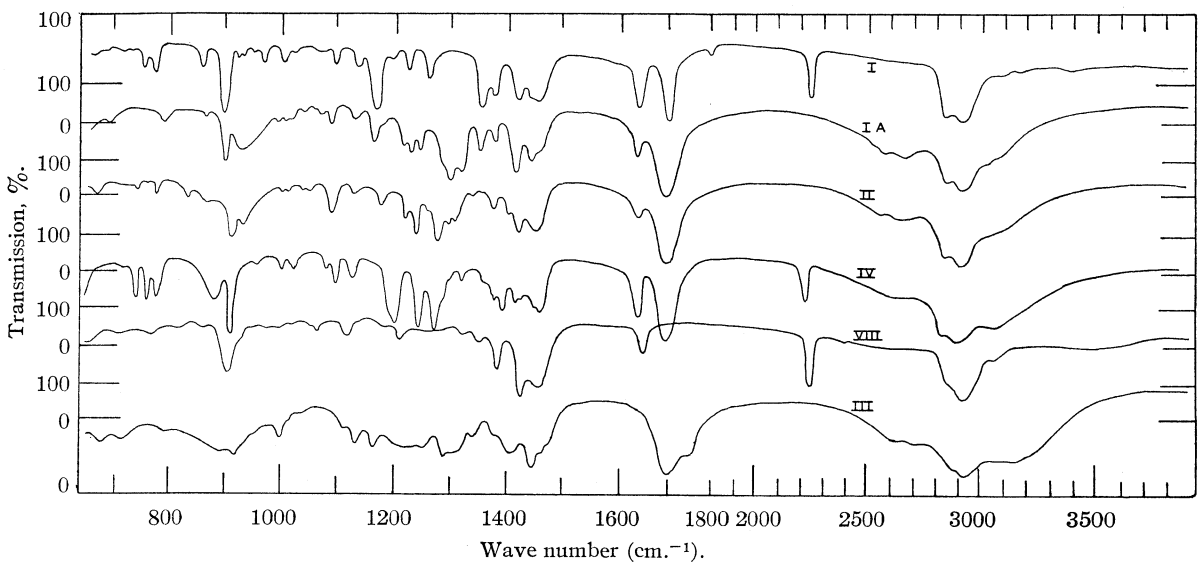

Fig. 2.—Infrared spectra: the Roman numerals correspond to those of the manuscript; IA is γ-acetyl-γ-isopropenylpimelic acid.

## Experimental

**γ-Acetyl-γ-isopropenylpimelonitrile (I).**—The method of Bruson and Riener[1] was employed using 98.0 g. (1.00 mole) of purified mesityl oxide, 106.0 g. (2.00 moles) of acrylonitrile, 100 ml. of *t*-butyl alcohol and 5 g. of Triton B (40% aqueous benzyltrimethylammonium hydroxide). The yield of product was 72 g. (35%), m. p. 115–117°; saponification equiv. calcd.: 102.1; found: 98.0. The purity of the mesityl oxide is critical, and the commercial product generally results in low yields. Purification is accomplished by washing with aqueous sodium carbonate and with water, drying over calcium chloride, and distilling.

**γ-Acetyl-γ-isopropenylpimelic Acid and γ-Carboxy-γ-isopropenylpimelic Acid (II).**—The procedures of Bruson and Riener[1] were used. Saponification of 28.6 g. (0.14 mole) of γ-acetyl-γ-isopropenylpimelonitrile by means of 20.8 g. (0.37 mole) of potassium hydroxide in 230 ml. of water gave 24.4 g. (72%) of γ-acetyl-γ-isopropenylpimelic acid, m. p. 137.5–138.5°; neutral equiv. calcd., 121.1; found, 120.1. The haloform reaction with 38.6 g. (0.159 mole) of this acid dissolved in 84 ml. of 20% aqueous sodium hydroxide and 512 ml. of 9.5% sodium hypochlorite solution, prepared by the method of Newman and Holmes,[6] yielded 26.0 g. (67%) of colorless crystalline tricarboxylic acid, m. p. 158–160°; neutral equiv. calcd., 81.4; found, 81.5.

**4-Isopropylidenecyclohexanone (VI).**[7]—An intimate mixture of 46.7 g. (0.191 mole) of γ-carboxy-γ-isopropenylpimelic acid and 1.51 g. (0.0076 mole) of barium carbonate was heated in three separate batches in a 50-ml. distilling flask fitted with a thermometer which extended to the bottom of the flask. Strong effervescence began at 285°, causing the temperature to drop to 275°. The temperature was ultimately increased to 320° as a mixture of water and yellow oil distilled. The distillates from the three batches were combined, the water separated, the oil dissolved in ether, washed with aqueous sodium bicarbonate and with water, and dried over calcium sulfate. Distillation gave 12.0 g. (45%) of colorless liquid product having a cedar-like odor, which on redistillation had the constants: b. p. 54° (1 mm.); $n^{20}$D 1.4817; sp. gr.$^{20}_{20}$ 0.959; *MR* calcd. 41.1; *MR* found 41.2.

(7) Preliminary work on this reaction was performed by Mrs. Blossom Katz.

*Anal.*[8] Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.21. Found: C, 77.07, 77.36; H, 10.10, 10.10.

The semicarbazone, prepared by the directions of Shriner and Fuson,[9a] melted at 196–198° after six crystallizations from ethanol.

*Anal.* Calcd. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78. Found: C, 61.63; H, 8.67.

The 2,4-dinitrophenylhydrazone, prepared by the method of Shriner and Fuson,[9b] recrystallized three times from ethanol and seven from methanol to form orange platelets, melted at 130.5–132°.

*Anal.* Calcd. for $C_{15}H_{18}N_4O_4$: C, 56.59; H, 5.70. Found: C, 56.78; H, 5.75.

**Ozonolysis of 4-Isopropylidenecyclohexanone (VI).**—A stream of 4% ozone was passed at a rate of 88 ml. per minute through a solution of 1.01 g. (0.0072 mole) of 4-isopropylidenecyclohexanone in 15 ml. of methylene chloride in a Dry Ice-bath for two and one-half hours. The ozonide solution was then added dropwise at room temperature with stirring to a mixture of 1.7 g. of 30% hydrogen peroxide, 0.1 ml. of concentrated sulfuric acid, and 35 ml. of water. The mixture was stirred at room temperature for forty-five minutes and then gradually heated to boiling and refluxed for one hour. The methylene chloride escaping through the condenser was collected in a Dry-Ice trap and tested for formaldehyde by means of methone.[10] No formaldehyde was detected. The condenser was set downward for distillation and 24 ml. of aqueous distillate collected. Testing of this distillate with methone[10] failed to detect formaldehyde, but aqueous resorcinol and concentrated sulfuric acid gave an orange-red ring, indicating a trace of formaldehyde.[11a] Heating with mercuric oxide gave a faint gray precipitate of mercury, a weak indication of formic acid.[11b] The haloform reaction[9c] gave a copious precipitate of iodoform, and acetone was further identified by the formation of its 2,4-dinitrophenylhydrazone,[9b] m. p. 120–123°, and mixed m. p., 121–125°, with an authentic sample.

The aqueous pot residue from the above distillation was neutralized with sodium carbonate, extracted with ether, acidified with sulfuric acid, and saturated with ammonium sulfate. A brown oil separated and was removed. The aqueous solution was extracted with chloroform, the chloroform solution washed with water, dried over magnesium sulfate, and evaporated to dryness. The residual oil was dissolved in 95% ethanol and the solution evaporated to yield white crystalline 1,4-cyclohexanedione, m. p. 68–73°. This was sublimed at 60° and 28 mm. pressure to give about 50 mg. of colorless needles, m. p. 77–78°. A mixed m. p. with an authentic sample, prepared by the method of Baeyer,[12] melted at 77–78°.

**γ-Terpineol (VII).**—The method was based on that of Perkin[13] for β-terpineol. A solution of 3.98 g. (0.029 mole) of 4-isopropylidenecyclohexanone in 10 ml. of anhydrous ether was added slowly with stirring to the Grignard reagent from 15.6 g. (6.84 ml., 0.118 mole) of methyl iodide, 2.64 g. (0.109 gram-atom) of magnesium, and 70 ml. of anhydrous ether. The reaction mixture, after standing overnight, was decomposed by pouring into a mixture of 8 g. of ammonium chloride in 125 g. of ice and water. The solution was barely acidified with hydrochloric acid, the ether layer removed, and the aqueous layer extracted with three 25-ml. portions of ether. The combined ether solutions were washed with dilute aqueous sodium bicarbonate and with water, dried over magnesium sulfate, evaporated, and the oily residue steam distilled. The crude yellow liquid product, separated from the distillate, weighed 1.76 g. Distillation (65° ( 1 mm.)) gave 0.77 g. of oil which crystallized on chilling, m. p. 57–66°. Sublimation at 45–50° (15 mm.) yielded 0.16 g. (3.6%) of white tabular crystals, m. p. 63–67° (lit.[14] 69–70°), having an odor reminiscent of lilacs.

*Anal.* Calcd. for $C_{10}H_{18}O$: C, 77.87; H, 11.76. Found: C, 76.85; H, 11.97.

**γ-Isopropylidenepimelic Acid (III).**—Five grams (0.0205 mole) of γ-carboxy-γ-isopropenylpimelic acid mixed with 0.5 g. of copper–bronze powder was heated under a stream of nitrogen to 195–205°. Formation of carbon dioxide was evidenced by a white precipitate when the evolved gases were passed through aqueous calcium hydroxide. The mixture was cooled, dissolved in acetone, filtered and the filtrate evaporated to a brown oil. This, after solution in 10% aqueous sodium hydroxide and acidification with concentrated hydrochloric acid, yielded 1.3 g. (32%) of crystalline product, m. p. 102–105°. An additional 0.3 g. (7%) was obtained by extraction of the acidified solution. Recrystallization of the combined product gave shiny white platelets, m. p. 104.5–106° (lit.[15] 97°); neutral equiv. calcd., 100.1; found, 101.1.

*Anal.* Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.06. Found: C, 60.05; H, 8.29.

**γ-Carboxy-γ-isopropenylpimelonitrile (IV).**—To a stirred solution of 2.68 moles of sodium hypochlorite in *ca.* 2300 ml. of water in a 5-l., three-necked flask was added 850 ml. of peroxide-free dioxane and the mixture was cooled to 0–10°. A solution of 121.6 g. (0.596 mole) of γ-acetyl-γ-isopropenylpimelonitrile in 810 ml. of dioxane was then added dropwise, and the cold reaction mixture stirred for four additional hours. The excess hypochlorite was decomposed by the addition of aqueous sodium bisulfite, the reaction mixture filtered, and the filtrate washed with two 200-ml. portions of ether. The aqueous filtrate was acidified with concentrated hydrochloric acid and allowed to stand for twelve hours at 0°. The white solid then present was collected on a filter, washed with cold water, and dried at 90°. It was digested in 900 ml. of hot water to dissolve inorganic salts, precipitated by chilling, collected on a filter, and dried at 100° to yield 99.9 g. (81%) of white powder, m. p. 164–166°. An analytical sample was prepared by recrystallization as shiny platelets from ethylene chloride, m. p. 166–167.5°; neutral equiv. calcd., 206.2; found, 210.3.

*Anal.* Calcd. for $C_{11}H_{14}N_2O_2$: N, 13.59. Found: N, 13.44.

**γ-Isopropylidenepimelonitrile (VIII) and α-Cyanoethyl-α-isopropenylglutarimide (IX).**—Forty-five grams (0.184 mole) of γ-carboxy-γ-isopropenylpimelonitrile was mixed with 4.5 g. of copper–bronze and 4.5 g. of powdered soft glass and heated in a small flask to 200–230° under a stream of nitrogen until evolution of carbon dioxide had ceased. The mixture was cooled and 50 ml. of benzene added, and the solid residue removed by filtration. The filtrate was washed with dilute sulfuric acid, aqueous sodium bicarbonate and water, dried over magnesium sulfate, and some of the benzene removed by distillation. At this point crystals formed in the solution; addition of ether increased this formation. These were removed by filtration and combined with the original solid residue. Fractional distillation of the benzene solution then gave 12.3 g. (41%) of colorless liquid γ-isopropylidenepimelonitrile, b. p. 135–137° (1 mm.); $n^{20}D$ 1.4733.

*Anal.* Calcd. for $C_{10}H_{14}N_2$: C, 74.03; H, 8.70. Found: C, 73.81; H, 8.59.

The combined solid residue, containing copper and glass, was warmed with 50 ml. of acetone and filtered. Evaporation of the filtrate gave a greenish-brown solid which after two recrystallizations, from dilute hydro-

chloric acid and from ethanol, yielded 9.8 g. (26%) of white tabular $\alpha$-cyanoethyl-$\alpha$-isopropenylglutarimide, m. p. 119–121°: mol. wt. calcd., 206; found (Rast), 221, 198; saponification equiv. calcd. for two saponifiable groups, 103.1; found, 100.2, 99.1. The product was soluble in 5% aqueous sodium hydroxide and insoluble in 5% aqueous sodium bicarbonate.

*Anal.* Calcd. for $C_{11}H_{14}N_2O_2$: C, 64.06; H, 6.84; N, 13.59. Found: C, 63.84; H, 6.93; N, 13.53.

When mixed with 0.7 g. of copper–bronze, 7.0 g. of product heated to 350° showed no apparent decarboxylation; only a black tar was formed.

**Hydrolysis of $\gamma$-Isopropylidenepimelonitrile (VIII).**—A mixture of 0.7 g. (0.0043 mole) of the dinitrile, 0.4 g. (0.01 mole) of sodium hydroxide and 5 ml. of water was refluxed for six hours. Acidification with concentrated hydrochloric acid and recrystallization of the precipitate from petroleum ether and from water gave 0.1 g. of shiny white platelets, m. p. 104.5–106°; mixed m. p. with $\gamma$-isopropylidenepimelic acid (III) 104.5–106°.

**Ozonolysis of $\gamma$-Isopropylidenepimelonitrile (VIII).**—Two grams (0.0123 mole) of the dinitrile dissolved in 25 ml. of purified carbon tetrachloride was cooled in an ice–salt-bath and a stream of *ca.* 200 ml. per minute of 2.6% ozone passed through it for one hour. The ozonide formed a separate layer during this time. The solvent was evaporated (30° at 30 mm.), and 70 ml. of water and 2.85 g. of zinc dust added to the liquid ozonide. The mixture was heated gradually to boiling and 50 ml. distilled into an ice-cooled receiver containing 10 ml. of water. Both the distillate and the residue, tested by means of methone,[10] showed no indication of formaldehyde; nor was formic acid detected.[11b] From the aliquot of the distillate was prepared a 17% yield (based on the dinitrile) of the 2,4-dinitrophenylhydrazone of acetone,[9b] m. p. 125–126°; mixed m. p. with an authentic sample 125–126°.

**$\gamma$-Formamido-$\gamma$-isopropenylpimelic Acid (X).**—One gram (0.0048 mole) of $\alpha$-cyanoethyl-$\alpha$-isopropenylglutarimide (IX) was heated just below the b. p. for one hour with 1.1 g. (0.019 mole) of potassium hydroxide in 20 ml. of water. The solution was cooled, acidified with concentrated hydrochloric acid, evaporated to dryness at room temperature; the solid was dissolved in acetone, the solution filtered, and the filtrate allowed to evaporate to give 0.9 g. (77%) of colorless tablets, m. p. 154–160°. Two crystallizations from water raised the m. p. to 164.5–166°; neutral equiv. calcd., 121.6; found, 121.1.

*Anal.* Calcd. for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.05; N, 5.76. Found: C, 54.53; H, 7.15; N, 5.88.

Boiling of $\gamma$-formamido-$\gamma$-isopropenylpimelic acid with 3% aqueous potassium hydroxide for sixteen hours and with sulfuric–nitrous acid mixture[16] for one hour failed to hydrolyze the amide to a tricarboxylic acid.

**Ring Closure of $\gamma$-Isopropylidenepimelonitrile (VIII).**—A solution of lithium N-ethylaniline was prepared by the procedure of Ziegler and co-workers[17] from 47.6 g. (0.392 mole) of N-ethylaniline in 200 ml. of ether and *n*-butyllithium solution made by the directions of Gilman, Zoellner and Selby[18] from 4.1 g. (0.59 gram-atom) of lithium and 25.3 g. (0.274 mole) of *n*-butyl chloride in 50 ml. of ether. This was stirred and heated to gentle refluxing in a 1-l., three-necked flask, and a solution of 16.3 g. (0.10 mole) of $\gamma$-isopropylidenepimelonitrile in 100 ml. of anhydrous ether was added dropwise over a period of five hours. A white precipitate formed as soon as the addition was begun. The reaction mixture was then poured quickly into 360 ml. of 2 *N* hydrochloric acid. The layers were separated; the aqueous layer extracted with three 100-ml. portions of ether, and all the ether solutions combined and washed twice with 20% hydrochloric acid and with water, then dried over magnesium sulfate. Evaporation of the solution gave 13.8 g. of a brown oil, crude 2-cyano-4-isopropylidenecyclohexanone. Attempts to hydrolyze this oil were unsuccessful using 10% aqueous sodium hydroxide and 37 and 50% sulfuric acid solutions. Hydrolysis was accomplished in low yield by means of 10% aqueous sulfuric acid. To 718 ml. of 10% acid was added 8.4 g. of the oil, and the mixture was refluxed for six hours, then steam-distilled. The residue was refluxed for an additional twelve hours and steam distilled. The combined distillates were extracted with ether, the extracts dried over magnesium sulfate, and evaporated to leave 1.0 g. of residual oil from which a 2,4-dinitrophenylhydrazone[9b] and a semicarbazone[9a] were prepared. The 2,4-dinitrophenylhydrazone, orange platelets from ethanol, m. p. 130–132°, showed no depression in mixed m. p. with that of 4-isopropylidenecyclohexanone (VI) prepared by pyrolysis of the triacid (II).

*Anal.* Calcd. for $C_{15}H_{18}N_4O_4$: C, 56.59; H, 5.70. Found: C, 56.39; H, 5.93.

The semicarbazone, colorless crystals from ethanol, m. p. 193–195°, when mixed with that of 4-isopropylidenecyclohexanone (VI), m. p. 196–198°, gave a depressed m. p. 176–185°.

*Anal.* Calcd. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78. Found: C, 61.60; H, 8.91.

**Infrared Absorption Spectra.**—Determinations were kindly carried out by Mrs. J. L. Johnson, using a Perkin–Elmer Model 12B infrared spectrometer with rock salt optics. The solids were suspended in Nujol for the measurements; the liquid was used pure in a 0.025-mm. cell.

## Summary

1. $\gamma$-Acetyl-$\gamma$-isopropenylpimelonitrile, the cyanoethylation product of mesityl oxide, has been studied as a starting material for substituted cyclohexanones related to monocyclic terpenes.

2. Decarboxylations of $\gamma$-carboxy-$\gamma$-isopropenylpimelonitrile and $\gamma$-carboxy-$\gamma$-isopropenylpimelic acid, with and without ring closure of the latter, result in rearrangement of the isopropenyl to isopropylidene groups.

# Directive Influence of the Acetylamino Group in the Friedel–Crafts Acylation of the Acetylaminonaphthalenes

BY NELSON J. LEONARD AND ARCHIBALD M. HYSON[1]

The structure of the main product of Friedel–Crafts acetylation of acet-2-naphthalide (I) was recently established[2] as 7-acetylamino-1-acetonaphthone (II). The structure of the secondary product obtained in the same reaction[3] has now been established as 6-acetylamino-2-acetonaphthone (III). The primary and secondary products of Friedel–Crafts acetylation of acet-1-naphthalide (IV) have been proved to be 4-acetylamino-1-acetonaphthone (V) and 5-acetylamino-1-acetonaphthone (VI).

The isolation of an isomeric acetylaminoacetonaphthone, along with the main product (II)[2] of the Friedel–Crafts acetylation of I, was previously realized by Brown, Jacobs, Winstein, Levy, Moss and Ott.[3] They suggested that the isomer was probably the 6-substituted product, and this assumption has now been proved correct. The minor product (III) was converted to 6-hydroxy-2-acetonaphthone, which was methylated to give 6-methoxy-2-acetonaphthone, and this was oxidized to 6-methoxy-2-naphthoic acid. All three compounds were known previously, and direct comparison with an authentic sample of the acid was also possible. The ratio of the products II and III of ring-acetylation was approximately 12:1 (on the basis of amounts isolated after hydrolysis). The reaction proceeded in an identical manner when 2-naphthylamine was used and acet-2-naphthalide was formed *in situ*.

Since the β-acetylamino group was found to direct substitution entirely in the unsubstituted ring, it was of interest to determine the directive influence of the acetylamino group in the α-position. The products of Friedel–Crafts acetylation of acet-1-naphthalide (IV) were V and VI, isolated as 4-amino-1-acetonaphthone and 5-amino-1-acetonaphthone in a ratio of approximately 4:1. The reaction proceeded in an identical manner when 1-naphthylamine was used and acet-1-naphthalide was formed *in situ*. The structure of 4-amino-1-acetonaphthone was proved by conversion to a hydroxyacetonaphthone and a methoxyacetonaphthone identical with compounds prepared by the Friedel–Crafts acetylation of 1-methoxynaphthalene,[4] the structures of which had been established unequivocally as 4-hydroxy-1-acetonaphthone and 4-methoxy-1-acetonaphthone. The structure of the 5-isomer was proved by replacement of the amino group by chlorine, followed by hypochlorite oxidation to the known 5-chloro-1-naphthoic acid.

When the results of the Friedel–Crafts acetylation of the acetylaminonaphthalenes are compared with those of other electrophilic substitution reactions (*e. g.*, nitration) of the acetylaminonaphthalenes, it is apparent that an additional factor must be considered in the reaction involving aluminum chloride—probably the steric effect of the amino group or its large complex with aluminum chloride. The β-acetylamino group usually directs electrophilic substitution at the 1-, 6- and 8-positions, with the 1-position favored, but in the Friedel–Crafts acetylation substitution occurs only at the unhindered 6- and 8-positions. The α-acetylamino group usually directs electrophilic substitution at the 2-, 4- and 5-positions, but in the Friedel–Crafts acetylation substitution occurs only at the unhindered 4- and 5-positions.

## Experimental[5]

**Friedel–Crafts Acetylation of Acet-2-naphthalide. 6-Amino-2-acetonaphthone.**—The Friedel–Crafts acetylation of acet-2-naphthalide was carried out according to the method of Brown and his co-workers.[3] After hydrolysis two aminoacetonaphthones were isolated: 7-amino-1-acetonaphthone, m. p. 108.5–110°,[2] and a position isomer. It was found necessary to purify the isomer through its hydrochloride. The contaminating hydrochloride of 7-amino-1-acetonaphthone was less soluble in water and the major portion was removed by fractional crystallization. Precipitation of the more soluble hydrochloride with ammonia gave the free base, which was recrystallized from ethanol as pale yellow prisms, m. p. 166.5–168° (reported, 163–164°).[3]

*Anal.* Calcd. for $C_{12}H_{11}NO$: C, 77.80; H, 5.99; N, 7.57. Found: C, 78.00; H, 6.15; N, 7.70.

### Proof of Structure of 6-Amino-2-acetonaphthone

**Conversion to 6-Hydroxy-2-acetonaphthone.**—Four-tenths of a gram of the amine was precipitated as the hydrochloride in finely divided form and was diazotized by the addition of sodium nitrite in the usual manner. The diazonium salt solution was allowed to stand overnight at room temperature, after which the diazonium reaction was completely destroyed by heating the solution for one hour on the steam-bath. Two volumes of ethanol were added, and the solution was decolorized, filtered, and cooled. The precipitate was recrystallized from aqueous ethanol, then from benzene; m. p. 170–171° (reported, 171°).[4]

**6-Methoxy-2-acetonaphthone.**—This compound was prepared from 6-hydroxy-2-acetonaphthone by alternate additions of 2.5 *N* sodium hydroxide solution and dimethyl sulfate at steam-bath temperature until the addition of base no longer produced any yellow color. When the reaction was complete, sufficient hot methanol was added to dissolve all oily material, and the solution was cooled. The colorless, flaky crystals which separated melted at 104.5–105.5° (reported, 105°).[6]

**6-Methoxy-2-naphthoic Acid.**—The 6-methoxy-2-acetonaphthone in methanol solution was oxidized in the usual manner with a solution of sodium hypochlorite (commercial Clorox). The acid was recrystallized from ethanol; m. p. 209–210.5°, after sintering (reported, 209°,[6] 205°).[7] It was identical with an authentic sample of 6-methoxy-2-naphthoic acid.

**Friedel–Crafts Acetylation of 2-Naphthylamine.**—To a cooled mixture of 14.3 g. (0.1 mole) of 2-naphthylamine, 67 g. (0.5 mole) of anhydrous aluminum chloride and 400 ml. of carbon disulfide under anhydrous conditions was added 15 g. (0.24 mole) of redistilled acetyl chloride over a period of thirty minutes. The reaction was allowed to proceed at room temperature for three hours and then at reflux temperature for three hours. The cooled solvent was decanted and the residue was decomposed by the addition of 500 g. of cracked ice followed by 200 ml. of 10 *N* hydrochloric acid. The mixture was heated on the steam-bath until all the solid dissolved. The hot solution was decolorized, filtered, and cooled. The precipitated hydrochloride was separated, suspended in water, and neutralized by the addition of ammonia to give 8.5 g. of crude aminoacetonaphthone. After one recrystallization from benzene, the compound melted at 109–110° and was identical with an authentic sample of **7-amino-1-acetonaphthone.** The acetyl derivative was also identical with authentic 7-acetylamino-1-acetonaphthone. The acidic filtrate from the precipitated hydrochloride was treated with excess aqueous potassium hydroxide, and the solid which separated was extracted with acetone. The acetone extract was evaporated, and the residue was treated with hot 2 *N* hydrochloric acid. The acid extract was decolorized and cooled, with deposition of 1.8 g. of hydrochloride, identified as **6-amino-2-acetonaphthone** hydrochloride by conversion to 6-methoxy-2-naphthoic acid as previously described.

**Friedel–Crafts Acetylation of Acet-1-naphthalide. 4-Amino-1-acetonaphthone and 5-Amino-1-acetonaphthone.**—The same molar proportions and the same conditions were used as in the Friedel–Crafts acetylation of 2-naphthylamine. The reaction mixture was cooled, the carbon disulfide was decanted, and the complex was decomposed by the addition of ice. The insoluble material was collected and 19 g. of this crude product was subjected to hydrolysis by refluxing forty-five minutes with 500 ml. of 1.5 *N* hydrochloric acid. The solution was refluxed an additional twenty minutes with 8 g. of decolorizing carbon and was filtered hot. The solid hydrochloride (A) which separated on cooling was removed by filtration, and the acidic filtrate (B) was retained. The solid (A) was suspended in water and the mixture was made basic with ammonia to precipitate the free amine. Recrystallization from benzene–ligroin gave 7 g. of **4-amino-1-acetonaphthone** (31% yield based on acet-1-naphthalide) as yellow prisms, m. p. 135.5–136.5°.

*Anal.* Calcd. for $C_{12}H_{11}NO$: C, 77.80; H, 5.99; N, 7.57. Found: C, 77.69; H, 5.81; N, 7.43.

The filtrate (B) from the separation of the 4-amino-1-acetonaphthone hydrochloride was rendered basic with ammonia and the yellow precipitate (3.5 g.) was removed by filtration. The ammoniacal filtrate was extracted with ether and the ethereal solution was evaporated to give a greenish oil. More such oil was obtained from the mother liquor remaining after the recrystallization of the yellow precipitate. The combined oil was dissolved in hot 1.5 *N* hydrochloric acid, from which 1.8 g. of colorless crystalline hydrochloride separated on cooling (9% yield based on acet-1-naphthalide). This **5-amino-1-acetonaphthone hydrochloride** was recrystallized from ethanol–ether; m. p. 248–251°, with decomposition.

*Anal.* Calcd. for $C_{12}H_{12}ClNO$: C, 65.00; H, 5.46; N, 6.32. Found: C, 64.92; H, 5.65; N, 6.59.

**5-Amino-1-acetonaphthone** was liberated from its hydrochloride by treatment with aqueous ammonia, followed by cooling. The yellowish plates which separated were recrystallized from benzene–ligroin; m. p. 96.5–97.5°.

*Anal.* Calcd. for $C_{12}H_{11}NO$: C, 77.80; H, 5.99; N, 7.57. Found: C, 77.68; H, 6.02; N, 7.62.

### Proof of Structure of 4-Amino-1-acetonaphthone

**Conversion to 4-Hydroxy-1-acetonaphthone.**—Two grams of 4-amino-1-acetonaphthone, m. p. 135.5–136.5°, was precipitated as the hydrochloride in finely divided form and was diazotized by the addition of sodium nitrite in the usual manner. The solution of the diazonium salt was added dropwise, with stirring, to 50 ml. of 4 *N* sulfuric acid heated to the boiling point. After the addition was complete, the mixture was heated for an additional five minutes and was then cooled. The solid which separated was dissolved in hot 2 *N* sodium hydroxide and was reprecipitated by acidification of the decolorized solution. Recrystallization from benzene–ligroin gave 1.0 g. of long, silky, colorless needles, m. p. 197.5–199°. The compound gave no melting point depression when mixed with an authentic sample of 4-hydroxy-1-acetonaphthone prepared by the method of Witt and Braun.[4]

**4-Methoxy-1-acetonaphthone.**—The compound was made from 4-hydroxy-1-acetonaphthone by the same method which was employed for the methylation of 6-hydroxy-2-acetonaphthone, and was purified by recrystallization from ligroin; m. p. 69–71°. The compound gave no melting point depression when mixed with an authentic sample of 4-methoxy-1-acetonaphthone prepared by the method of Witt and Braun.[4]

### Proof of Structure of 5-Amino-1-acetonaphthone

**Conversion to 5-Chloro-1-naphthoic Acid.**—One-half gram of the amine hydrochloride, m. p. 248–251°, was suspended in 10 *N* hydrochloric acid and solid sodium nitrite was added in small portions until diazotization was complete. The excess nitrous acid was destroyed by the addition of urea. One-half gram of copper bronze powder was added to the solution of the diazonium salt, and the mixture was warmed on the steam-bath until the evolution of nitrogen ceased. The cooled reaction mixture was extracted with two 25-ml. portions of carbon tetrachloride. The combined extracts were washed with 2 *N* sodium hydroxide and finally with water. The carbon tetrachloride solution was evaporated, leaving a small amount of reddish oil which was oxidized in methanol solution by sodium hypochlorite in the usual manner. When the reaction was complete, the excess hypochlorite was destroyed by the addition of bisulfite and the solution was acidified with mineral acid. The precipitated organic acid, after recrystallization from aqueous ethanol, then from benzene, melted at 251–252°. The melting point of the compound was not depressed on admixture with an authentic sample of 5-chloro-1-naphthoic acid. The authentic sample was prepared in an unequivocal manner starting with 1,5-dinitronaphthalene. 5-Nitro-1-naphthylamine was prepared from the dinitro compound by the

(6) Fries and Schimmelschmidt, *Ber.*, **58**, 2835 (1925).

(7) Short, Stromberg and Wiles, *J. Chem. Soc.*, 319 (1936).

method of Hodgson and Walker.[8] The preparation of 5-chloro-1-nitronaphthalene was carried out by replacing the amino group of 5-nitro-1-naphthylamine by chlorine,[9] followed by reduction of the nitro group to form 5-chloro-1-naphthylamine.[10] 5 - Chloro - 1 - naphthonitrile[11] was formed by replacement of the amino group by nitrile through the diazonium salt and was finally hydrolyzed to 5-chloro-1-naphthoic acid by the method of Gomberg and Blicke.[12]

**Friedel–Crafts Acetylation of 1-Naphthylamine.**—The same molar proportions of reactants, conditions of reaction, and methods of hydrolysis and isolation were employed as in the Friedel–Crafts acetylation of the acet-1-naphthalide. The products, in somewhat lower yields, were identified as 4-amino-1-acetonaphthone and 5-amino-1-acetonaphthone by comparison with the samples isolated previously.

**7-Bromo-1-nitronaphthalene.**—This compound was prepared from 8-nitro-2-naphthylamine[13] by the method which Hodgson and Walker[14] applied to the preparation of 2-bromo-1-nitronaphthalene.

**7-Bromoacet-1-naphthalide.**—A mixture of 1 g. of 7-bromo-1-nitronaphthalene 20 ml. of glacial acetic acid, 4 ml. of acetic anhydride and 2 g. of iron powder was heated at reflux temperature for one hour. Additional iron powder (3 g.) was added and refluxing was continued an additional hour. The mixture was poured into 150 ml. of water and the whole was cooled in an ice-bath. The precipitate (0.8 g.) was recrystallized from ethanol as colorless needles, m. p. 195.5–196.5°.

*Anal.* Calcd. for $C_{12}H_{10}BrNO$: C, 54.57; H, 3.82; N, 5.30. Found: C, 54.24; H, 3.60; N, 5.13.

**7-Bromo-1-naphthylamine.**—The acetyl derivative in aqueous ethanol was heated under reflux with 10 *N* hydrochloric acid for five hours. The clear solution, upon cooling, deposited the amine hydrochloride as glistening plates, m. p. 260°, with decomposition. The free base was precipitated by treatment of the hydrochloride in aqueous solution with aqueous sodium carbonate. Recrystallization from aqueous ethanol gave colorless needles, m. p. 65–66°.

*Anal.* Calcd. for $C_{10}H_8BrN$: C, 54.08; H, 3.63; N, 6.31. Found: C, 53.78; H, 3.33; N, 6.31.

The **benzoyl** derivative was obtained in the usual manner and was recrystallized from ethanol and benzene; m. p. 211–212°.[15]

*Anal.* Calcd. for $C_{17}H_{12}BrNO$: C, 62.59; H, 3.71; N, 4.29. Found: C, 62.85; H, 3.80; N, 4.56.

**Attempted Preparation of 2-Amino-1-acetonaphthone by a Bucherer Type Reaction.**—Two grams of 2-hydroxy-1-acetonaphthone[16,17] was placed in a mortar and was finely ground with 8 g. of calcium chloride ammonia complex which had been prepared by the addition of pulverized anhydrous calcium chloride to liquid ammonia.[18] The mixture was placed in a bomb of 37 ml. capacity and was heated at 200° for seven hours. After cooling, the solid was removed and was pulverized in a mortar. This powder was extracted with two 100-ml. portions of moist ether and the ether was removed. The residue after ether evaporation was extracted with 300 ml. of hot 3 *N* hydrochloric acid. The hot acid extract was filtered and the filtrate was cooled and neutralized with ammonia. The precipitate was recrystallized three times from benzene–ligroin to give 1.0 g. of colorless plates, m. p. 126–127.5°.

*Anal.* Calcd. for $C_{20}H_{17}NO$: C, 83.59; H, 5.96; N, 4.88. Found: C, 83.18; H, 6.17; N, 5.02.

The analysis indicated that the material could be an equimolar mixture of 2-naphthol and 2-naphthylamine. Equivalent quantities of pure 2-naphthol and pure 2-naphthylamine were mixed and the mixture was recrystallized from benzene–ligroin. The melting point of the colorless plates which separated was 126–128°, and the melting point of a mixture of this product with the material described above was identical.

The Bucherer reaction was repeated using seven and one-half times the previous quantities of reactants in a 250-ml. bomb. From this reaction there was isolated 6.4 g. of 2-naphthylamine, as determined by mixed melting point.[19]

## Summary

1. The structure of the product formed in lesser amount, along with 7-acetylamino-1-acetonaphthone, in the Friedel–Crafts acetylation of acet-2-naphthalide in carbon disulfide solution has been established as 6-acetylamino-2-acetonaphthone.

2. The products of the Friedel–Crafts acetylation of acet-1-naphthalide have been proved to be 4-acetylamino-1-acetonaphthone and 5-acetylamino-1-acetonaphthone, with the former in preponderance.

3. The results indicate that the acetyl group does not enter a position *ortho* to the acetylamino group.

(19) The intermediate in the modified Bucherer reaction is probably the 1,3-diketonic form of 2-hydroxy-1-acetonaphthone, which should be quite susceptible to cleavage by ammonia. The β-naphthol thus formed could undergo normal conversion (partial or total) to β-naphthylamine.

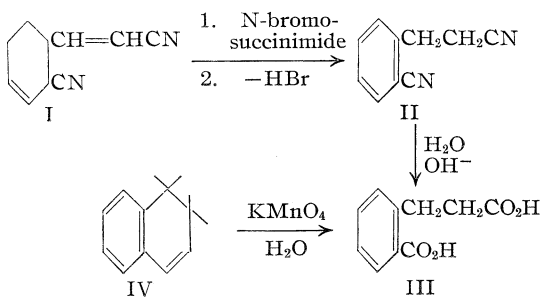
# 1-Cyano-1,3-butadiene. III. The Dimer of 1-Cyano-1,3-butadiene

BY H. R. SNYDER AND GEORGE I. POOS



In the course of further studies of the chemistry of 1-cyano-1,3-butadiene,[1,2] a dimer[2a] of the substance has been isolated and characterized. In common with many butadienes, 1-cyano-1,3-butadiene condenses with itself in the Diels–Alder fashion to yield a cyclic dimer,[3] which in this instance proved to be 1-(β-cyanovinyl)-2-cyano-3-cyclohexene (I).

Separation of the *cis* and *trans* forms of the diene by fractional distillation[2] was always accompanied by a considerable loss due to the formation of higher-boiling material in the still-pot. The dimeric compound was isolated by high vacuum distillation of the gummy still residues. After redistillation, the thick oil could be induced to crystallize to a low-melting solid. There was no indication of the presence of more than one dimer. Microanalysis and molecular weight determinations were correct for a dimeric structure.

Attempts to hydrolyze the dimer with alkaline hydrogen peroxide and with acid resulted in the production of intractable materials. Hydrolysis with base of varying strength, with and without a solvent, produced an acidic substance which appeared to be polymeric. It was not possible to effect dehydrogenation of the dimer by heating to 320° with 10% palladium on carbon.

Proof of the dimer structure was obtained by aromatization followed by hydrolysis to a known aromatic acid according to the following scheme (equation A). The dimer (I) was brominated with one equivalent of N-bromosuccinimide and the

Equation A

product was dehydrobrominated by heating with isoquinoline to yield *o*-cyanohydrocinnamonitrile (II). Basic hydrolysis of II yielded *o*-carboxyhydrocinnamic acid (III) which was identified by comparison with an authentic specimen. The preparation of III for comparison was accomplished by oxidizing 1,2-dihydronaphthalene (IV) with cold aqueous permanganate according to the method of Straus and Lemmel.[4]

It was of interest to investigate the relative contributions of the *cis* and *trans* isomers in the dimerization of 1-cyano-1,3-butadiene. When the higher-boiling isomer ($n^{20}$D 1.4960, presumably *trans*) was maintained at 100° for sixteen hours in the presence of a polymerization inhibitor (picric acid), 66% of the material was converted into the dimer, and the remainder could be accounted for as monomer and polymer. On the other hand, in two similar experiments with the lower-boiling isomer ($n^{20}$D 1.4852, presumably *cis*), heating nine and eighteen hours produced only 13% dimer, the major portion of the diene having been converted into polymer.

The dimer itself is a rather stable compound and shows little tendency to polymerize. Since it might be considered possible that polymerization of the monomer proceeds through the dimer under the conditions described in the experiments above, a sample of the dimer was maintained at 100° in the presence of picric acid for twenty-five hours. When the material was distilled, no polymeric residue remained.

These experiments indicate that I is formed chiefly by the dimerization of the higher-boiling 1-cyano-1,3-butadiene.

## Experimental[5,6]

**Isolation of the Dimer.**—In a short-path distillation apparatus 30 g. of the brown gummy residue from the fractionation of 1-cyano-1,3-butadiene was distilled, yielding 22 g. of a heavy yellow oil, b. p. 122–123° (0.2 mm.), $n^{20}$D 1.5170, and leaving a hard, polymeric residue in the pot. Redistillation of the oil did not alter its boiling point or index of refraction. However, after standing a portion of the redistilled material solidified.

A solution of several grams of the twice-distilled liquid dimer in hot 95% ethanol was treated with Darco, filtered and cooled to about 50°. Water was then added dropwise to cloudiness and the solution was cooled slowly with scratching of the walls of the flask until crystals formed. After drying *in vacuo* the colorless crystals melted at 53–54°. This product was recrystallized twice from absolute ether–petroleum ether (30–60°) and submitted for microanalysis; m. p. 53–54°.

*Anal.* Calcd. for $C_{10}H_{10}O_2$: C, 75.91; H, 6.37; mol. wt., 158.2. Found: C, 76.09; H, 6.59; mol. wt., 136, 142 (ebulloscopic in benzene).

**Aromatization of the Dimer. A. Bromination.**—To a mixture of 2.00 g. of the crystalline dimer (m. p. 53–54°) and 45 ml. of benzene was added 2.40 g. of N-bromosuccinimide. The mixture was heated with stirring until it became homogenous and then was refluxed until a negative test for active bromine was obtained with acidified potassium iodide solution (three hours). The hot solu-

(5) All melting points are uncorrected.

(6) Microanalyses by Miss Emily Davis.

tion was cooled to 0° and the precipitated succinimide was collected on a filter and washed with several portions of cold benzene (wt. 1.19 g., m. p. 123–124.5°).

B. **Dehydrobromination.**—The benzene solution from above was concentrated, transferred to a small flask, and the remainder of the benzene was removed. To the residual yellow oil 8 ml. of isoquinoline was added portionwise with agitation. The flask was then set in an oil-bath and the bath was heated to 180° for twenty-five minutes, then to 190° for five minutes, after which the flask was removed and allowed to cool.

An excess of dilute hydrochloric acid was added to the mixture and the acid solution was extracted thoroughly with benzene. The benzene extracts were combined; the dark solution was washed first with dilute hydrochloric acid and then with water and finally concentrated to a small volume. The resulting black oily solution was transferred to a short-path distilling bulb with benzene and the low-boiling material was distilled at atmospheric pressure. Distillation of the residue yielded 1.50 g. (76%) of a pale yellow oil; b. p. 110° (0.2 mm.), $n^{20}D$ 1.5468. After redistillation the oil was water-white ($n^{20}D$ 1.5468) and a sample of it solidified on standing to a low-melting solid. Another sample of this colorless redistilled oil was then taken up in absolute ether–petroleum ether (30–60°) and the solution was inoculated with the solid and cooled to yield fluffy white needles which were collected on a filter, washed with petroleum ether and air dried; m. p. 41–42.5°. Subsequent hydrolysis of this compound to III identified it as *o*-cyanohydrocinnamonitrile. The crystalline dinitrile was recrystallized two times from absolute ether–petroleum ether (30–60°) and submitted for microanalysis; m. p. 41–42.5°.

*Anal.* Calcd. for $C_{10}H_8N_2$: C, 76.90; H, 5.16. Found: C, 76.79; H, 5.29.

**Hydrolysis of *o*-Cyanohydrocinnamonitrile (II).**—A mixture of 0.50 g. of II, 5 ml. of 20% potassium hydroxide and 5 ml. of 95% ethanol was brought to boiling on a steam cone and was allowed to reflux until ammonia evolution had practically ceased (twenty-four hours). Most of the alcohol was distilled, the aqueous residue was cooled and then was neutralized dropwise with concentrated hydrochloric acid. Before the neutral point was reached, a brown solid separated which was collected on a filter, washed with several ml. of water (washings added to the filtrate) and dried; 0.12 g., m. p. 205–215° (dec.). This basic substance was not identified. Acidification of the basic filtrate from above yielded 0.07 g. of an infusible, neutral solid which was presumed to be the diamide of III. After standing overnight, the acidic filtrate had deposited crystals of acid which were collected, washed and dried; 0.14 g., m. p. (155°) 164–166°. Concentration of the mother liquors yielded an additional 0.14 g. of crude acid. One recrystallization from water (Darco) raised the melting point to 166.5–168°. After two more recrystallizations from water the product melted at 166.5–168° alone or when mixed with authentic III prepared as described below.

*Anal.* Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19. Found: C, 61.99; H, 5.29.

**Preparation of *o*-Carboxyhydrocinnamic Acid[4] (III).**—The oxidation of 2.00 g. of 1,2-dihydronaphthalene with aqueous potassium permanganate solution at 9–11° yielded 0.34 g. of III, m. p. 163–167° (lit.[4] 162–164°), along with unchanged hydrocarbon. After several recrystallizations from water (Darco) the pure acid melted at 166.5–168° (lit.[4] 166–167°).

**Dimerization Experiments with *cis*- and *trans*-1-Cyano-1,3-butadiene.**—Into a small distilling flask was placed 3.0 g. of higher-boiling 1-cyano-1,3-butadiene ($n^{20}D$ 1.4960) and *ca.* 0.1 g. of picric acid. The flask was stoppered and left on a steam cone until the material had thickened to a sirupy consistency (sixteen hours). When the contents of the flask was submitted to high vacuum distillation there was obtained as distillate 2.0 g. (66%) of oily dimer, $n^{20}D$ 1.5172. From the Dry Ice-trap there was recovered *ca.* 0.5 g. (16%) of monomeric cyanodiene. A small amount of polymeric residue remained in the flask.

In a like manner, 3.0 g. of the lower-boiling isomer ($n^{20}D$ 1.4852) was heated for eighteen hours to yield 0.4 g. (13%) of dimer ($n^{20}D$ 1.5112). Recovered monomer amounted to *ca.* 0.5 g. (16%) while the major portion of the material remained as polymer in the flask. From a second experiment with the same quantity of lower-boiling isomer, 0.4 g. (13%) of dimer ($n^{20}D$ 1.5155) and 0.9 g. (30%) of monomer were isolated after nine hours at 100°.

Several grams of once-crystallized dimer was heated with picric acid on the steam cone for twenty-five hours and then distilled. The material was unchanged, and left no polymeric residue upon distillation.

## Summary

The cyclic dimer of 1-cyano-1,3-butadiene has been isolated and characterized as 1-(β-cyanovinyl)-2-cyano-3-cyclohexene. The structure was proved by aromatization of the dimer to *o*-cyanohydrocinnamonitrile and hydrolysis of this dinitrile to the known *o*-carboxyhydrocinnamic acid. Experiments with the *cis* and *trans* isomers of 1-cyano-1,3-butadiene indicate that the higher-boiling isomer (presumably *trans*) is the chief source of the dimer.

URBANA, ILLINOIS RECEIVED OCTOBER 11, 1948

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF THE UNIVERSITY OF MARYLAND]

# 1,3,5,7-Octatetraene

BY G. FORREST WOODS AND LOUIS H. SCHWARTZMAN[1]

The reaction of 2,4-pentadienal[2] with methylmagnesium bromide was shown to yield 1,3-hexadien-5-ol. This latter substance was dehydrated very readily over activated alumina to yield 1,3,5-hexatriene.[3]

$$CH_2{=}CH{-}CH{=}CH{-}CHO + CH_3MgBr \longrightarrow$$
$$CH_2{=}CH{-}CH{=}CH{-}CHOH{-}CH_3 \longrightarrow$$
$$H{-}(CH{=}CH)_3{-}H$$

Pentadienal has now been utilized as a starting material for the synthesis of 1,3,5,7-octatetraene.

Allylmagnesium bromide (I) reacts very smoothly with 2,4-pentadienal (II) to yield 1,3,7-octatrien-5-ol (III). The possibility of a rearrangement in the reactions leading to (III) or rearrangement of (III) itself had to be considered.[3,4] Accordingly, 1,3,7-octatrien-5-ol was catalytically reduced to the saturated alcohol, 4-octanol (IV) and identified as the α-naphthylurethan, and the

(1) National Institute of Health Predoctorate Fellow.

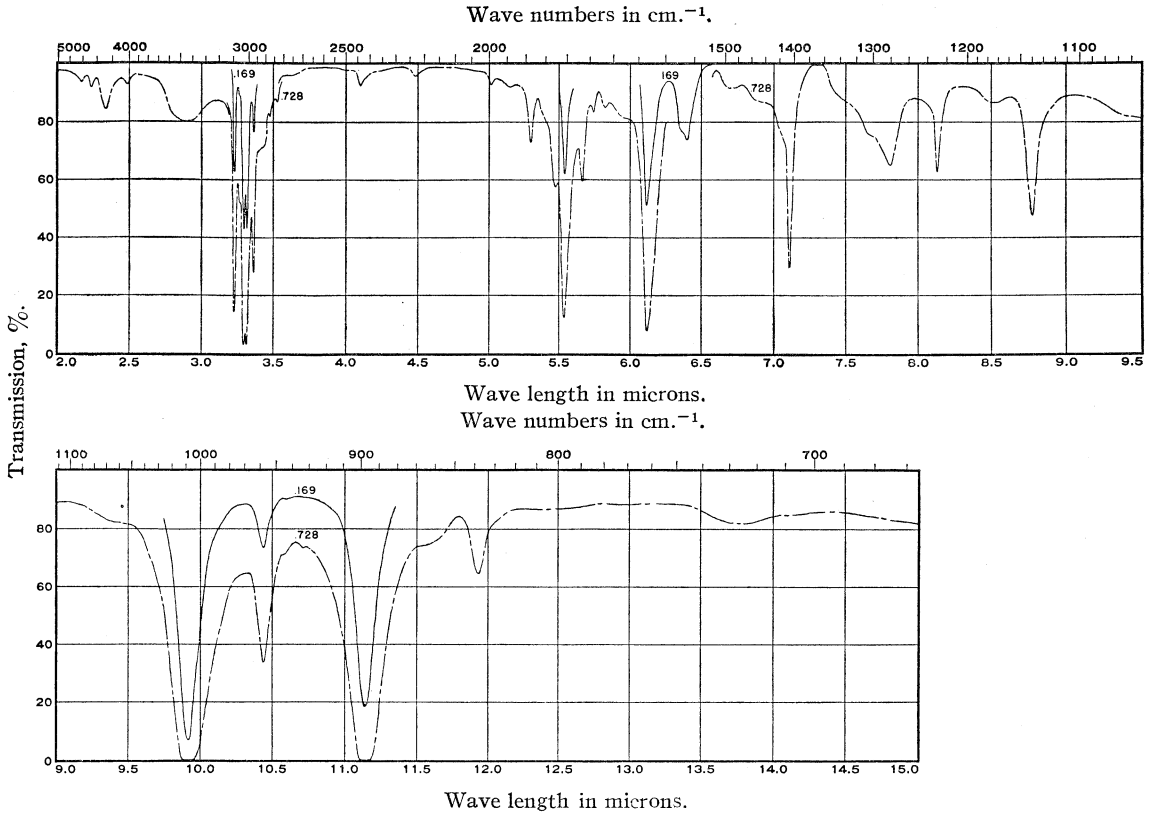
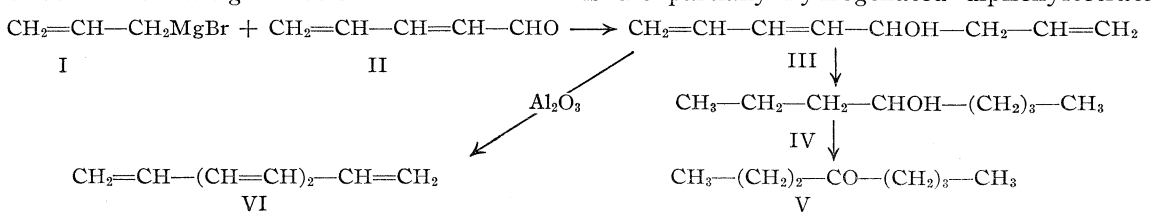
(4) Heilbron, Jones, McCombie and Weedon, *J. Chem. Soc.*, 84, (1945).





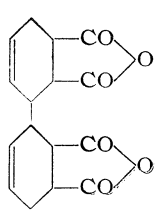


Fig. 1.—Infrared absorption spectrum of 1,3,5,7-octatetraene.

alcohol oxidized to the known 4-octanone (V) and identified as the semicarbazone. In this manner the absence of any rearrangement was established. The catalytic dehydration with activated alumina of the unsaturated alcohol, 1,3,7-octatrien-5-ol, led to the hydrocarbon 1,3,5,7-octatetraene (VI), a white crystalline solid melting at approximately 50° which was recrystallized from petroleum ether. The hydrocarbon sublimes on warming and rapidly polymerizes on standing. The equations for these reactions are given below.

The following facts were used to establish the structure of VI. The hydrocarbon, VI, upon catalytic reduction, absorbed almost four moles of hydrogen and the product of reduction was established as *n*-octane. The infrared spectrum,[5] Fig. 1, which is very similar to that of 1,3,5-hexatriene[4] indicates the absence of allenic, acetylenic, or benzenoid structures. Elemental analyses indicate the formula $C_8H_{10}$.

It is interesting to note that the ultraviolet absorption spectra, Fig. 2, of octatetraene is considerably different from that reported for cyclooctatetraene.[6] Treatment of octatetraene in petroleum ether with bromine leads to a relatively stable tetrabromide, $C_8H_{10}Br_4$, of unknown structure, while the Diels–Alder reaction yields a molecule into which two maleic anhydride structures have been incorporated. Several structures for this substance, $C_{16}H_{14}O_6$, are possible, one of which is the partially hydrogenated diphenyltetracarboxylic acid dianhydride, VII. It seemed that this substance should readily undergo dehydrogenation to the known 2,2′,3,3′-diphenyltetracarboxylic acid dianhydride. Since our attempts to dehydrogenate this substance were unsuccessful, we believe that the adduct is not VII. However, quantitative hydrogenation of this same adduct led to the absorption

VII

(5) The infrared spectrum was kindly determined for us by Dr. Don C. Smith of the Naval Research Laboratory.

(6) Cope and Bailey, THIS JOURNAL, **70**, 2305 (1948).

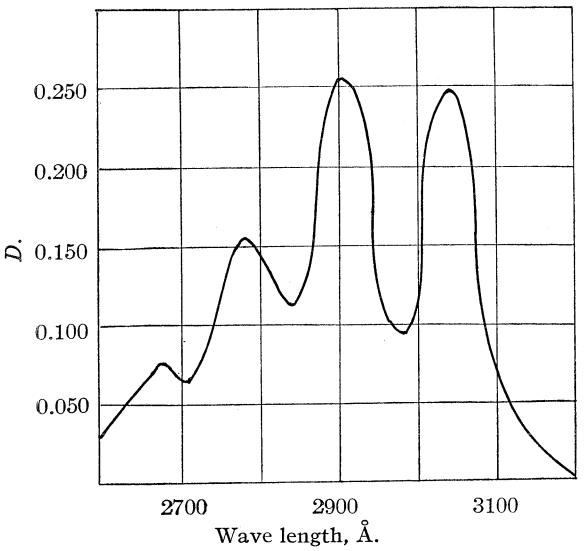

Fig. 2.—Ultraviolet absorption spectrum of 1,3,5,7-octatetraene.

of two moles of hydrogen showing that the molecule still had two ethylenic links, again substantiating the proof of four ethylenic links in the original hydrocarbon. Since 1,3,5,7-octatetraene can exist in either of three geometrical isomerides, we believe that we have one of these isomers pure in view of our method of purification. The difficulties of assigning configuration to this substance would be greater than for 1,3,5-hexatriene[4] in which instance we were unsuccessful.

To illustrate a property of octatetraene we report an incident which occurred in handling the material. A freshly recrystallized sample of octatetraene of about 1 g. was standing in a Büchner funnel covered with a beaker. This material underwent a decomposition somewhat less violent than an explosion. Marked white fumes were given off and a pungent aldehyde odor was present. We assume that a combustion takes place as a consequence of the heat liberated in the polymerization of octatetraene. It was because of the rate of polymerization that we are unable to report a melting point or give an evaluation to the extinction coefficients of the ultraviolet or infrared absorption curves of octatetraene.

## Experimental

**1,3,7-Octatrien-5-ol (III).**—An ethereal solution (600 ml.) of allylmagnesium bromide was prepared from 80 g. of allyl bromide and 45 g. of powdered magnesium using Gilman's procedure.[7] The ether solution of allylmagnesium bromide was then pumped with nitrogen away from the excess magnesium powder. To this chilled solution, was added 41 g. of pentadienal[2] dissolved in 100 ml. of anhydrous ether. The mixture was stirred for an additional fifteen minutes at room temperature. The Grignard addition complex was decomposed with a saturated aqueous solution of ammonium chloride and the ether layer separated, washed with water and sodium bicarbonate solution, and dried over magnesium sulfate. After removal of the ether under reduced pressure the octatrienol was distilled in a nitrogen atmosphere: b. p. 70–71° (6 mm.), $n^{22}D$ 1.4931; yield 55 g. (90%). *Anal.* Calcd. for $C_8H_{12}O$: C, 77.37; H, 9.74. Found: C, 77.35; H, 9.84.

**Reduction of 1,3,7-Octatrien-5-ol.**—This material (4 g.), dissolved in 70 ml. of ethyl alcohol, was hydrogenated with Raney nickel at room temperature and atmospheric pressure. The hydrogen uptake was 91% of the calculated value for three ethylenic links, and the time required for this uptake was approximately thirty minutes. The alcoholic solution was filtered and distilled under reduced pressure. The 4-octanol (3.8 g.) distilled at 79° (20 mm.), $n^{24}D$ 1.3890.[8]

The α-naphthylurethan of 4-octanol, prepared in the usual way and recrystallized from petroleum ether (30–60°), melted at 60–61° and gave no depression in a mixed melting point determination with an authentic sample of this compound. *Anal.* Calcd. for $C_9H_{25}NO_2$: C, 76.22; H, 8.42. Found: C, 76.21; H, 8.22.

4-Octanol (6.9 g.) was oxidized with potassium dichromate (31.4 g.) dissolved in 200 ml. of water containing 42 g. of sulfuric acid. The temperature of the oxidation medium was not allowed to rise above 50°. The product, 4-octanone, was isolated by steam-distillation and extraction with ether. The ether extract was dried over magnesium sulfate and the ether removed under reduced pressure. 4-Octanone (3 g.) boiled at 164–168°.

The semicarbazone of this material prepared in the usual way melted at 95–97° after several recrystallizations from methyl alcohol–water and gave no depression with an authentic sample of the semicarbazone of 4-octanone. *Anal.* Calcd. for $C_9H_9N_3O$: C, 58.35; H, 10.34. Found: C, 58.42; H, 10.09.

**1,3,5,7-Octatetraene (VI).**—1,3,7-Octatrien-5-ol was distilled under reduced pressure (25 mm.) in a nitrogen atmosphere through a column, 35 cm. long of 16-mm. Pyrex tubing, filled with activated alumina (8–12 mesh) and heated by means of two electrical heating elements to a temperature of 250–280°. Two connected receivers were used, one cooled with an ice–calcium chloride-bath, and the other with an acetone–Dry Ice-bath. The products solidified in the receiver but, upon warming, the material melted, and most of the water layer was withdrawn by means of a medicine dropper. The residual material was dried over calcium oxide and crystallized from petroleum ether (20–40°) in a nitrogen atmosphere. From such a run 22 g. of 1,3,7-octatrien-5-ol yielded 11 g. (58%) of octatetraene.

The analysis of this substance required a special procedure. A combustion tube was mounted so that two gas entry lines were present into one of which the sample was to be introduced. The two gas lines were connected by a stopcock. The sample of octatetraene was introduced into the system in one line through which a slow stream of nitrogen was passing. The other line was introducing the oxygen. Warming of the sample sublimed the material into the combustion chamber. Finally oxygen was introduced through the sample line and the region of the sample strongly heated to burn the residual polymeric material which had formed from the octatetraene. *Anal.* Calcd. for $C_8H_{10}$: C, 90.51; H, 9.49. Found: C, 89.75; H, 9.77.

**Octatetraene Tetrabromide.**—A dilute solution of bromine in petroleum ether was added dropwise to a solution of octatetraene dissolved in petroleum ether. The bromine color was quickly discharged and a white crystalline material precipitated which, after several recrystallizations from acetone–water, melted at 123–125°. This substance is not very stable and evolves hydrogen bromide and darkens on standing. *Anal.* Calcd. for $C_8H_{10}Br_4$: C, 22.56; H, 2.35. Found: C, 23.75; H, 2.78.

**Reduction of Octatetraene.**—Reduction of octatetraene (4.5 g.) dissolved in 60 ml. of glacial acetic acid with 5% palladinized charcoal catalyst required approximately an

(7) Gilman and McGlumphy, *Bull. soc. chim.*, **43**, 1322 (1928).

(8) Levene and Marker (*J. Biol. Chem.*, **91**, 405 (1931)) report a boiling point of 79° (16 mm.) and $n^{24}D$ 1.3898.

hour at the end of which time slightly less than the theoretical amount of hydrogen had been consumed. The solution was filtered, poured into water and the acetic acid neutralized with sodium hydroxide. The product was extracted with ether, and the ether solution dried with magnesium sulfate and finally with metallic sodium. After removal of the ether, the residue was distilled (from sodium). *n*-Octane distilled at 126–128°; $n^{30}D$ 1.4001; $d^{25}_4$ 0.714.

**Diels-Alder Reaction of Octatetraene.**—A solution of maleic anhydride (5 g.), octatetraene (2.5 g.), and benzene (50 ml.) was heated under reflux in a nitrogen atmosphere on a steam-bath for six hours. Almost immediately a white solid precipitated which became more copious as the reaction proceeded. Chilling and filtering the benzene solution yielded 4.5 g. of white solid which melted at 238–242° after several recrystallizations from glacial acetic acid. *Anal.* Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67; neut. equiv. (four carboxylic groups), 75. Found: C, 63.44; H, 4.78; neut. equiv., 73.

Refluxing of this material in moist xylene yielded another white crystalline solid which after recrystallization from acetone–xylene melted at 247–250°. This is the free tetracarboxylic acid. *Anal.* Calcd. for $C_{16}H_{18}O_8$: C, 56.80; H, 5.36. Found: C, 56.45; H, 5.41.

Reduction of the dianhydride $C_{16}H_{14}O_6$ (0.92 g.) dissolved in 25 ml. of glacial acetic acid with 5% palladinized charcoal at room temperature and atmospheric pressure required approximately one-half hour at the end of which time the reduction had stopped and the hydrogen absorption was the theoretical amount calculated for two ethylenic links. The solution, filtered, was poured into water and the solid isolated by filtration. After several recrystallizations from acetone–water a white solid melting at 260–261° was obtained. *Anal.* Calcd. for $C_{16}H_{22}O_8$: C, 56.13; H, 6.47. Found: C, 56.24; H, 6.58.

Attempts to dehydrogenate the dianhydride, $C_{16}H_{14}O_6$ were unsuccessful. However, when 2 g. of the anhydride was refluxed with 1 g. of palladinized charcoal and 10 ml. of *p*-cymene, a substance which precipitated on cooling was removed along with the catalyst upon filtration. The solid was leached out with hot acetone which upon cooling yielded a white solid. Recrystallization of this material from xylene gave a white solid melting at 267–268°, an isomer of the starting material. *Anal.* Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67. Found: C, 63.37; H, 4.76.

**Ultraviolet Absorption Spectrum.**—The ultraviolet absorption spectra of 1,3,5,7-octatetraene was determined in purified cyclohexane. The instrument was a Beckmann quartz ultraviolet spectrophotometer.

**Infrared Absorption Spectra.**—The infrared absorption spectra of a sample of octatetraene dissolved in carbon disulfide was determined for us by Dr. Don C. Smith of the Naval Research Laboratory.

## Summary

The preparation and properties of an isomer of 1,3,5,7-octatetraene are reported.

# Catalysis with (−)Aluminum 2-Methylbutoxide[1]

BY ROBERT H. BAKER AND LOREN E. LINN[2]

The versatility of aluminum alkoxides in synthetic work prompted the preparation and use of an optically active one with the hope of achieving asymmetric syntheses.

The aluminate of *fermentation* amyl alcohol has been previously described[3] but because of the difficulty of purifying the product we have preferred to prepare the *active* aluminate indirectly from previously purified materials. These indirect preparations have previously been carried out with esters,[4] but in this work the alcohol, (−)2-methylbutanol, was easily exchanged with either aluminum isoproxide, *t*-butoxide, or *d,l*-2-butoxide.[5] With the latter alkoxide there was no activity of the 2-butanol that distilled from the reaction mixture.

In consequence of the high ionic character of the carbonyl group in ketones, 47%,[6] and the electronegativity of aluminum it seems that the principal contributing structure of the activated complex in the Meerwein–Ponndorf reaction would involve a carbonium ion, I or II.[7] The acceptance of the hydride ion would then lead to either of two diastereomers with the thermodynamically most stable being produced in excess.

That this excess would not be expected to be large can be seen from the mass of experience in the reduction of optically active ketones with symmetrical aluminum alkoxides which generally give comparable amounts of the two alcohols.[8] Actually the system is considerably more complex than indicated by formulas I and II due to the fact that as the reaction progresses the nature of the alkoxyl groups changes. This factor would be expected to diminish the yield of asymmetric product.

Acetophenone is not well suited to this reaction

because of its oxidation potential relative to aldehydes[9] and its ease of condensation[10] but since it is reported to have been reduced to an active carbinol in a similar but non-reversible reaction,[11] attempts were made to reduce it. No phenylmethylcarbinol was obtained and it is of interest only to record that successive fractions of (−)2-methylbutanol which distilled from the mixture were progressively more racemized.[12]

*p*-Chlorobenzophenone was reduced only partially in order to favor the possible asymmetric synthesis but the carbinol was inactive.

The availability of the active alcoholate made it possible to study the Tischtschenko reaction with (+)2-methylbutanal. The kinetics of this reaction are first order in aldehyde and consistent with the possibility of a rapid formation of a complex of one molecule of aldehyde and catalyst.[13] No model for this complex has been proposed but Dr. B. Abramovitch in this Laboratory has been able to relate the role of the catalyst in the Meerwein–Ponndorf–Oppenauer reaction to that of the Tischtschenko[13] by showing a similar promoting effect of electronegative additives like zinc or aluminum halides in the Oppenauer[14] isomerization of dehydroisoandrosterone.

(+)2-Methylbutanal, 94% optically pure, and (−)aluminum 2-methylbutoxide, 96% optically pure, gave an ester which on hydrolysis was shown to be composed of an acid and an alcohol which were of comparable optical purity, 60%. The slightly higher value of the alcohol portion is accountable for on the basis of alkoxyl exchange with the catalyst.[4] The ester was shown not to be racemized by prolonged heating with the catalyst hence the molecules of aldehyde which suffer reduction and oxidation have probably a common intermediate with the racemization step as a side reaction following perhaps the mechanism of the usual acid catalyzed type of enolization.

The present information does not allow the assignment of a reasonable role of the complex in the final formation of ester.

## Experimental

**(−)Aluminum 2-Methylbutoxide.**—A solution of 6.5 g. (0.032 mole) of aluminum isopropoxide in 10 g. (0.11 mole) of 2-methylbutanol, $\alpha^{26}D$ −9.26°, 2 dm., homogeneous; $n^{20}D$ 1.4100,[15] was distilled under a 16-plate column until 5 g. of isopropyl alcohol had been collected. The residue was then heated *in vacuo* at 200° to give 8.8 g., 88%, of the solid alkoxide, $[\alpha]^{25}D$ −1.0° in toluene. Hydrolysis of the product with water produced the unracemized alcohol.

**Attempted Reduction of Acetophenone.**—A solution of 27 g. (0.094 mole) of (−)aluminum 2-methylbutoxide in 50 ml. of (−)2-methylbutanol was treated with 20 g. (0.16 mole) of acetophenone and the solution subjected to 16-plate distillation. The distillate, collected in four fractions, was 2-methylbutanol, $n^{20}D$ 1.4108–1.4100. The weights and $\alpha$, 2 dm., were as follows: 5 g., −5.6°; 11 g., −5.5°; 16 g., −3.1°; 13 g., −1.9°. An additional 50 g. of alcohol was put in and the fractionation continued to give 5 g., −7.3°; 30 g., −7.4°; 4 g., −6.8°. The residue was hydrolyzed and the organic layer distilled at 10 mm. into five fractions, 22 g., b. p. 90–150°. These fractions were impure and had homogeneous rotations of *ca.* +1°, 2-dm. No phenylmethylcarbinol was isolated.

**Reduction of 4-Chlorobenzophenone.**—A solution of 2 g. (0.009 mole) of the ketone and 6 g. (0.024 mole) of aluminum *t*-butoxide in 36 g. (0.41 mole) of (−)2-methylbutanol was distilled at 16-plates until the head temperature reached 114°, three hours. Hydrolysis of the residue, separation, distillation of the alcohol and crystallization from petroleum ether gave 1.07 g., 53% of 4-chlorobenzhydrol, m. p. 60–61°.[16] A 9.2% solution in benzene gave no rotation.

**(+)2-Methylbutyl 2-Methylbutanoate.**—(+)2-Methylbutanal, $\alpha^{25}D$ + 45.3°; 2-dm. homogeneous, was prepared by the method of Badin and Pacsu[17] and purified by 16-plate distillation from a batch protected with hydroquinone.

Following the method of Danilov,[18] a mixture of 25 g. (0.29 mole) of the aldehyde and 2 g. (0.007 mole) of (−)-aluminum 2-methylbutoxide was held at 0° for one hour, at room temperature for forty minutes, and at 80° for thirty minutes. Hydrolysis of the alkoxide with water and 16-plate distillation of the organic layer gave 15 g., 60%, of the ester, b. p. 61–61.6° (11 mm.); $n^{20}D$ 1.4135; $\alpha^{26}D$ + 17.7°, 2-dm. homogeneous.

This ester was also isolated as a by-product of the aldehyde preparation, the homogeneous rotation being +26.8°, 2-dm. If this is assumed to be of the same optical purity as the aldehyde, 94%, the pure ester should be $\alpha^{25}D$ + 28.3°, 2-dm. The Tischtschenko ester has 62% of this rotation.

**Hydrolysis of the Tischtschenko Ester.**—The ester, 5.5 g., was refluxed with 100 ml. of 6 *N* barium hydroxide for thirty-eight hours. The alcohol and acid were isolated by steam distillation and purified by distillation. The acid, $\alpha^{22}D$ + 10.6°, 1-dm. homogeneous; $n^{21}D$ 1.4054, was 59% and the alcohol, $\alpha^{21}D$ −3.01°, 1-dm. homogeneous; $n^{21}D$ 1.4102, was 62% pure.[19]

## Summary

1. The preparation of the aluminate of (−)2-methylbutanol is described.

2. This optically active catalyst failed to bring about asymmetric reduction of aceto-

# Resonance and Polarity in the Molecules of Three Colored Compounds[1]

BY LAWRENCE M. KUSHNER AND CHARLES P. SMYTH

Dipole moment measurements made in this Laboratory have been used[2,3,4,5] to throw light on the resonance conditions in the molecules of certain un-ionized dyes, the results being satisfactorily correlated with the light absorption of the compounds. Dr. L. G. S. Brooker of the Eastman Kodak Company recently suggested to us measurements on three further colored compounds and furnished samples.

The three compounds are 3-ethyl-5-[4-(1-ethyl-3,3 - dimethyl - 2(3) - indolylidene) - butenylidene]-rhodanine (I), 1,3-diethyl-5-[4-(1-ethyl-3,3 - dimethyl - 2(1) - indolylidene) - 2 - butenylidene]-2-thiobarbituric acid (II) and 1,3-diethyl-5 - [(1,3 - diethyl - 2(3) - benzimidazolylidene)-butenylidene]-barbituric acid (III), all three belonging to a new group of un-ionized dyes known as the merocyanines.[5a] These dyes contain the amide system, the essential grouping of which is

In such dyes one of the two extreme resonance structures is uncharged while the other is a dipole. Some discussion of these dyes from the resonance standpoint has already appeared.[5b] Proof was advanced that in I the polar structure Ib (see Discussion of Results) must be of higher energy and contribute less than the non-polar structure Ia, since replacement of the indolenine ring by one that was more basic (in the restricted sense used by Brooker) reduced the deviation in $\lambda_{max.}$, whereas replacement by a less basic nucleus increased the deviation. Nevertheless the dipole moment of the compound was expected to be considerable.

## Experimental Method

The dipole moments were measured in solution in benzene or dioxane. The benzene used as solvent for the more soluble compounds, I and II, was a thiophene-free product from the Barrett Company, which was purified by drying with sodium wire followed by distillation from the wire (boiling point, 80.55–80.90° at 772.8 mm.; dielectric constant at 30°, 2.2672). The dioxane used as solvent for the almost insoluble compound III was "practical" 1,4-dioxane from the Carbide and Carbon Chemicals Corporation, which was distilled from 101.1 to 101.5° at 762.9 mm., dried over sodium wire and redistilled from the sodium wire, the fraction used boiling at 101.0° at 757.7 mm. Its dielectric constant, measured directly at 30°, was 2.1984 ± 0.0002.

Because of the virtual insolubility in benzene and very low solubility in dioxane of compound III, the preparation of the solutions presented a problem. It was overcome by weighing out the compound in a small glass cup on a high sensitivity analytical balance and transferring both cup and compound to a 100-cc. weighing bottle, to which the dioxane was then added. In the case of the most concentrated solution, it was necessary to warm the mixture to achieve true solution. As there was obviously a risk of evaporating some dioxane, the final weighing to determine the weight of dioxane in the solution was not made until all the solid had been dissolved and the solution had cooled.

The dielectric constants of the dilute solutions were measured with a heterodyne beat apparatus developed from one which has been previously described.[6] The precision of the apparatus was increased by replacing the precision measuring condenser formerly used by a General Radio Company 722–D instrument, on which an 1100 micromicrofarad scale was employed. The dielectric cell was similar to that previously described.[7] The densities of the benzene solutions were measured at 30° with an Ostwald–Sprengel pycnometer, the technique employed being similar to that previously described.[8] The dipole moments were calculated from the experimental data by the method of Halverstadt and Kumler.[9] The dielectric constants, $\epsilon_{12}$, and specific volumes, $v_{12}$, of the solutions were found to be linear functions of the mole fractions, $c_2$, of the solutes according to the equations

$$\epsilon_{12} = \epsilon_1 + \alpha' c_2$$
$$v_{12} = v_1 + \beta' c_2$$

The dielectric constants, $\epsilon_1$, and specific volumes, $v_1$, for the pure solvents given by these equations when applied to the plots of the experimental data against $c_2$ agreed well with the directly measured values. The calculated values along with the values of $\alpha'$ and $\beta'$, the slopes of the lines, were used to calculate the polarization of the solute at infinite dilution

$$P_\infty = 3\alpha' v_1 M_1/(\epsilon_1 + 2)^2 + (M_2 v_1 + M_1\beta')(\epsilon_1 - 1)/(\epsilon_1 + 2)$$

in which $M_1$ is the molecular weight of the solvent and $M_2$ is that of the solute. The dipole moment was then obtained from the usual equation

$$\mu = 0.01281 \times 10^{-18} [(P_\infty - R_D)T]^{1/2}$$

The molar refractions for the D sodium line, $R_D$, which could not be measured directly because of the color of the compounds, were calculated from values of bond refractions in the literature.[10] A small correction of 2 cc. was added to the values as a rough estimate of the exaltation arising from the conjugated systems in the molecules. The effects of errors in the calculation of $R_D$ and of the approximation made in using $R_D$ instead of the true sum of the electronic and atomic polarizations are negligible in comparison with the experimental errors in the determination of $P_\infty$.

The low solubilities of these large and highly polar molecules in non-polar solvents cause the errors in the dipole moment values to be larger than is usual in solution measurements, particularly, in the case of compound III, which was too insoluble for measurement in benzene and soluble in dioxane only to the extent of mole fraction $3 \times 10^{-6}$ at 30°. Since it was unprofitable to attempt to measure the densities of the extremely dilute solutions of III, the value of $v_1$ was calculated in this case from the density of pure dioxane[11] and its temperature coefficient.[12] The value of $\beta'$ was roughly estimated by assuming that the volume of the most concentrated solution was that of the dioxane alone, dividing this volume by its weight, and using the value of $v_{12}$ thus obtained along with that for $v_1$ to calculate $\beta'$. Although this rough value of $\beta'$ is, presumably, too large, the effect of its error upon the moment value is small in comparison with that of the errors in the dielectric constant values, which vary over a range of only 0.001 from the value for the solvent, but show, nevertheless, a satisfactory linear dependence upon $c_2$.

## Experimental Results

The values of $\epsilon_{12}$ and $v_{12}$ for the solutions are given in Table I and the values of the constants calculated from them in Table II.

## Discussion of Results

The dipole moment found for the molecule of compound III is the largest yet observed for a molecule other than that of a salt or a zwitterion. The reason for the large moments of these compounds becomes apparent when one considers the polar structures, b, shown below, which can be readily formed by shift of an electron pair from a nitrogen in the non-polar structure, a, through the conjugated system to a carbonyl oxygen. The term "non-polar" is used to distinguish the structures of relatively low polarity from those in which an electron pair has shifted from one side of the molecule to the other.

If the polar structures, b, are not very different in energy from the non-polar, a, resonance between the a and b structures will give rise to dipole moments whose size depends largely on the amounts of the contributions of the polar structures. The moments of the non-polar structures should differ somewhat from one another and cannot be calculated with exactness. None of them should exceed $2.5 \times 10^{-18}$ and little error will arise in our considerations from the assignment of a rough value $m_a = 2.0 \times 10^{-18}$ to the non-polar structure

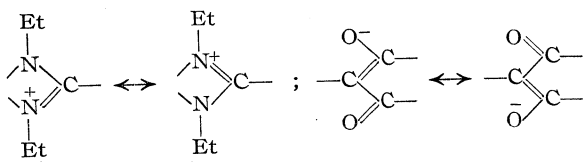
of each of the three compounds. Compound I can have only one contributing polar structure, b, compound II has two identical polar structures, while compound III has four polar structures indistinguishable from one another. The conceivable doubly charged structure for compound III cannot arise for, as soon as one nitrogen and one oxygen are charged, the other oxygen and nitrogen are no longer connected by a conjugated chain. The polar structures should have approximately equal energies and approximately equal dipole moments, $m_b$. The large values found for the dipole moments in Table II as compared to the relatively small values calculated for the non-polar structures, a, show the considerable stability of the polar structures, b. The increase in moment from compound I to II to III corresponds qualitatively to the increase in the number of contributing polar structures from 1 to 2 to 4. In most molecules, the possible polar structures are so much less stable than the non-polar that their contributions are relatively small and their amounts, as indicated by the dipole moment, are a fair measure of the amount of resonance. This is not far from being the case in compound I, but in compound III, the four polar structures make so large a contribution that, as shown by the absorption measurements of Dr. L. G. S. Brooker and his colleagues, increased stabilization of the polar structures by the use of a polar solvent decreases the amount of resonance.

One can write[13] three equations for the moments, $\mu$, of the molecules

$$\mu_I = (1 - x_I)m_a + x_I m_b$$
$$\mu_{II} = (1 - x_{II})m_a + x_{II} m_b$$
$$\mu_{III} = (1 - x_{III})m_a + x_{III} m_b$$

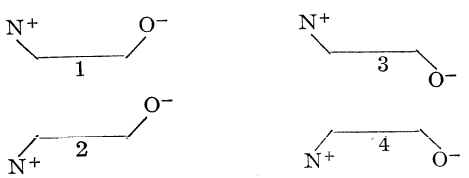
where $x$ is the fractional contribution of all the polar structures for each molecule, $m_a$ is the moment of the so-called non-polar structure, which, because of its relatively small size, can, without serious error, be taken as the same for all three molecules, and $m_b$ is the moment which should be virtually the same for all the polar structures. If $m_a$ is taken as $2.0 \times 10^{-18}$, the observed values can be put in for $\mu_I$, $\mu_{II}$ and $\mu_{III}$ and the equations solved simultaneously for the ratios of the fractional contributions of the polar structures, $m_b$ being eliminated by substitution. The ratios thus obtained are

$$x_{II}/x_I = 1.57 \text{ and } x_{III}/x_I = 3.21$$



The absorption measurements indicate that the amount of resonance in compound II is not greatly affected by increase in the polarity of the solvent. This suggests that, in the non-polar solvent, the contribution of the polar forms may be somewhat less than half, an amount which may be increased to somewhat more than half by a polar solvent without greatly altering the amount of resonance. If, in line with this suggestion, $x_{II}$ is set equal to 0.4, $x_I$ is given by the calculated ratios as 0.25 and $x_{III}$ as 0.81, values which are consistent with the fact that the absorption measurements show that a polar solvent increases the amount of resonance in compound I and decreases it in compound III. It might be argued qualitatively that since, in

(13) Smyth, THIS JOURNAL, **63**, 57 (1941).



compound II, the amount of resonance is not far from a maximum, the contributions of the non-polar structure and of each of the two polar structures should be nearly equal, that of the non-polar structure being slightly greater in a non-polar solvent than that of each of the two polar structures. In this case, $(1 - x_{II})$ would be about 0.4 and $x_{II}/2$ about 0.3. This would make $x_I = 0.38$ and $x_{III} = 1.22$, an impossibly large answer. It is evident that, since $x_{III}$ must be less than 1, $x_I$ must be less than 0.31, $x_{II}$ must be less than 0.49, and $m_b$ must be greater than $18 \times 10^{-18}$.

Substitution of the value $x_{II} = 0.4$ in the equation for $\mu_{II}$ or of the corresponding values of $x_I$ and $x_{III}$ in the other equations gives $m_b = 21.4 \times 10^{-18}$ for the moment of the polar structures. The maximum value which the polar structure could have is the moment of the structure with an extended, planar, zig-zag chain, in which the charges are separated by a maximum distance. The value calculated approximately for this structure from the bond lengths and angles is $42 \times 10^{-18}$, while the value calculated from the mean square moment for all the possible orientations around the bonds of the chain is $30 \times 10^{-18}$. Even the lower of these two values is much higher than the value 21.4, estimated on the basis of reasonable values for the amounts of the contributions of the polar structures. Conversely, the use of the moments calculated for the ionic structures without allowance for decrease of moment by an empirically introduced inductive distortion[14] would give lower values than those assumed for the amounts of the contributions from the polar structures, as previously observed.[13]

Consideration of the four polar structures, IIIb, for compound III shows that they can change from one to another by shifts of electrons at the ends of the butenylidene chain.

The four polar structures, represented schematically below, are hereafter referred to as 1, 2, 3 and 4.

The total wave function, $\psi_{III}$, for the system can be expressed as

$$\psi_{III} = a\phi + b(\chi_1 + \chi_2 + \chi_3 + \chi_4)$$

where $\phi$ is the wave function of the non-polar structure, $\chi_i$ is the wave function of the $i^{th}$ polar structure, and $a$ and $b$ are constants representing the contribution of each structure to that of the molecule as a whole. The total energy, $W_{III}$, of the system is given by the expression

$$W_{III} = \int \psi^*_{III} H \psi_{III}\, d\tau / \int \psi^*_{III} \psi_{III}\, d\tau$$

Substitution for $\psi_{III}$ in the above equation with the assumptions that $\phi$ and $\chi_i$ are normalized and orthogonal functions and that the integrals representing the resonance between structures 1 and 4, and 2 and 3 are small compared with the other exchange integrals, leads to the expression

$$W_{III} \cong [a^2C + 8abE_{CP} + 4b^2 (P + E_N + E_O)]/(a^2 + 4b^2)$$

where

$C = \int \phi^* H \phi d\tau$ = energy of non-polar structure

$P = \int \chi_i^* H \chi_i d\tau$ = energy of the $i^{th}$ polar structure (all polar forms are assumed to have the same energy)

$E_{CP} = \int \phi^* H \chi_i d\tau$ = exchange energy between the non-polar and any polar structure

$E_N = \int \chi_1^* H \chi_2 d\tau = \int \chi_3^* H \chi_4 d\tau$ = exchange energy between structures 1 and 2, 3 and 4

and $E_O = \int \chi_1^* H \chi_3 d\tau = \int \chi_2^* H \chi_4 d\tau$ = exchange energy between structures 1 and 3, and 2 and 4.

Minimizing the energy with respect to the quantities $a$ and $b$, gives the ratio

$$a/b = 4E_{CP}/(W_{III} - C)$$

and the expression

$$W_{III} = [(P + C + E_N + E_O) \pm ((P - C + E_N + E_O)^2 + 16E^2_{CP})^{1/2}]/2$$

Since the minimum energy is desired, it is obvious that the negative sign must be used. Substitution for $W_{III}$ in the expression for $a/b$, yields the equation

$$a/b = 2K/[1 - (1 + K^2)^{1/2}]$$

where

$$K = 4E_{CP}/(P - C + E_N + E_O)$$

Substitution for $\psi_{III}$ in the equation

$$\mu_{III} = \int \psi^*_{III} \mu \psi_{III}\, d\tau / \int \psi^*_{III} \psi_{III}\, d\tau$$

with the assumption that integrals of the type $\int \phi^* \mu \chi_i d\tau$, $\int \chi^*_i \mu \chi_j d\tau$ are negligible in comparison with those of the type $\int \phi^* \mu \phi d\tau$ and $\int \chi_i^* \mu \chi_i d\tau$, gives

$$\mu_{III} \cong (a^2\mu_c + 4b^2\mu_i)/(a^2 + 4b^2)$$

where $\mu_c = \int \phi^* \mu \phi d\tau$ = dipole moment of the non-polar form, and $\mu_i = \int \chi_i^* \mu \chi_i d\tau$ = dipole moment of the $i^{th}$ polar form (it is assumed that all the polar forms have the same moment).

Substitution for $a/b$ gives the final equation

$$\mu_{III} = [K^2\mu_c + \mu_i(2 - 2(1 + K^2)^{1/2} + K^2)]/2(1 - (1 + K^2)^{1/2} + K^2),$$

where $\mu_c$ is the moment of the non-polar structure. Substitution of the values $\mu_{III} = 17.7 \times 10^{-18}$, $\mu_c = 2.0 \times 10^{-18}$ and $\mu_i = 40.0 \times 10^{-18}$, an approximation slightly lower that the maximum possible value, gives $E_{CP}/(P - C + E_N + E_O) = -1.41$, and 0.766 and 0.321 for $a$ and $b$, respectively.

The similarities of the structures of compounds I, II and III are such that it is reasonable to as-

(14) Hugill, Coop and Sutton, *Trans. Faraday Soc.*, **34**, 1518 (1938).

sume that the non-polar and polar wave functions do not change significantly from one compound to another. Therefore, the wave functions for compounds I and II are obviously

$$\psi_I = a\phi + b\chi$$

and

$$\psi_{II} = a\phi + b(\chi_1 + \chi_3)$$

By procedures similar to these previously described, the following relations are obtained for compound I.

$$W_I = (a^2C + 2abE_{CP} + b^2P)/(a^2 + b^2)$$

where $a = 0.940$ and $b = 0.359$, and

$$E_{CP}/[P - C] = -0.455$$

For compound II

$$W_{II} = [a^2C + 4abE_{CP} + 2b^2(P + E_O)]/[a^2 + 2b^2]$$

where $a = 0.891$ and $b = 0.319$ and

$$E_{CP}/[(P - C) + E_O] = -0.478$$

From these equations, it is possible to arrive at the following energy relationships

$$W_{III} = 1.97E_{CP} + 0.41E_N + 0.41E_O + (0.59C + 0.41P)$$
$$W_I = 0.67E_{CP} + (0.87C + 0.13P)$$
$$W_{II} = 1.10E_{CP} + 0.20E_O + (0.80C + 0.20P)$$

where

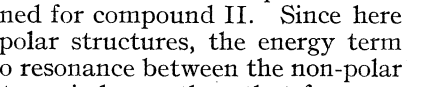
$$(P - C) = -2.20E_{CP},\ E_O = 0.10E_{CP},\ E_N = 1.39\ E_{CP}$$

In the case of compound I, there is resonance between the non-polar and polar structures which gives rise to a resonance energy term $0.67E_{CP}$, and a dipole moment of $6.9 \times 10^{-18}$. Compound II, in addition to having a somewhat larger contribution to the total energy of the system, $1.10E_{CP}$, arising from the existence of two polar structures, has an energy term $0.20E_O$ which is due to resonance between the two polar structures. The calculations show that this energy term is rather small, since $E_O = 0.10\ E_{CP}$, and, therefore, the polar structures are stabilized only to the extent of raising the dipole moment from $6.9 \times 10^{-18}$ to $9.7 \times 10^{-18}$. In compound III, the polar form is stabilized to a much greater extent by resonance between structures 1 and 2, and 3 and 4, the resonance energy here being $0.41E_N$, plus $0.41E_O$, arising from resonance between the polar structures as mentioned for compound II. Since here there are four polar structures, the energy term corresponding to resonance between the non-polar and polar structures is larger than that for compounds I or II. It is seen then that the dipole moment of compound III, $17.7 \times 10^{-18}$, is very large, not only because there are four possible polar structures, but because there is resonance between the polar structures which gives them added stability. Similarly, even though there are two polar structures for compound II, there is not much resonance between them, and the dipole moment is lower than would be expected.

The values of $x$ and $a$ and $b$ have been calculated for the other seemingly possible values of $m_b = \mu_i$, and all are summarized in Table III. Since $x$ represents the total fractional contribution of polar structures for each compound, while, for compounds I, II and III, $a^2_I + b^2_I = 1$, $a^2_{II} + 2b^2_{II} = 1$, and $a^2_{III} + 4b^2_{III} = 1$, for comparison with $x$, the values of $b$ are listed as $4b^2_{III}$, $2b^2_{II}$ and $b^2_I$.

TABLE III

CONTRIBUTIONS OF POLAR STRUCTURES CALCULATED FOR DIFFERENT MOMENT VALUES FOR THE POLAR STRUCTURES



| $m_b$ | $x_I$ | $x_{II}$ | $x_{III}$ | $b^2_I$ | $2b^2_{II}$ | $4b^2_{III}$ |
|---|---|---|---|---|---|---|
| >18 | <0.31 | <0.49 | <1.0 | .. | .. | .. |
| 21.4 | .25 | .40 | .81 | .. | .. | .. |
| 30 | .18 | .28 | .56 | 0.17 | 0.28 | 0.44 |
| 40 | | | | .13 | .20 | .41 |
| 42 | .12 | .19 | .39 | | | |

$x_{III} = 3.21\ x_I$; $x_{II} = 1.57\ x_I$

No solutions for $a$ and $b$ could be obtained for $\mu_i = 21.4$ or lower, which shows that the seemingly reasonable assumption, $x_{II} = 0.4$, based on the observed absorption is not justified. Since the dipole moment calculated for an undistorted polar structure has been found, in other cases, to indicate an unexpectedly small amount of resonance, it would seem that the fractional contributions based on the intermediate value 30 for the moment of the polar structures may be the most reasonable. Table III shows that, within the limits $m_b = \mu_i = 30 - 40$, the total contributions of the polar structures for each molecule do not change greatly. Therefore, although the exact contribution in the case of each molecule cannot be stated, their relative values are known, and suffice to explain the magnitudes of the measured moments.

**Acknowledgment.**—The writers wish to express their deep indebtedness to Dr. L. G. S. Brooker of the Kodak Research Laboratories for materials, information and advice and to Professor Walter Kauzmann for aid in the quantum mechanical calculations.

## Summary

The dipole moments of three dyes of the merocyanine series have been measured in very dilute solutions. The merocyanines are un-ionized dyes characterized by the amidic resonating system . One molecule receives a contribution from one polar structure, one from two polar structures and one from four polar structures. The large dipole moments increase as the number of contributing polar structures increases to such an extent that the moment of the molecule with four contributing polar structures is larger than that previously found for any molecule other than that of a salt or a zwitterion. The dipole moment values qualitatively confirm predictions of the relative polarities of the substances and make possible exact calculations of the relative contributions of the polar structures. The absolute amounts of these contributions are cal-

culated on the basis of reasonable values for the moments of the polar structures. A quantum mechanical calculation of the relative energies of the structures explains the quantitative deviations from the amounts of the contributions to be expected merely on the basis of the number of contributing polar structures.

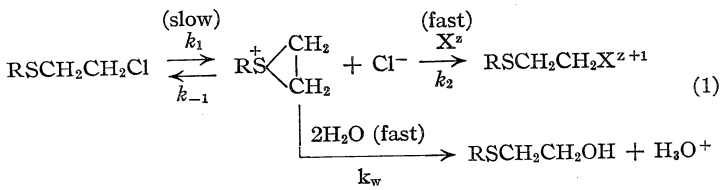
# Kinetics of Hydrolysis and Displacement Reactions of β,β′-Dichlorodiethyl Sulfide (Mustard Gas) and of β-Chloro-β′-hydroxydiethyl Sulfide (Mustard Chlorohydrin)[1]

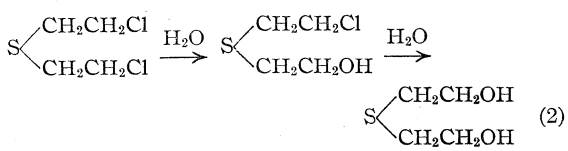
BY PAUL D. BARTLETT AND C. GARDNER SWAIN



## Introduction

The existence of the ethylenebromonium ion (I) and its participation in bromination reactions were first postulated in 1937 by Roberts and Kimball.[2] An elegant demonstration of the participation of such ions in displacement reactions of β-bromoalkyl compounds was provided by Winstein and Lucas[3] in 1939. During World War II it was recognized by American workers that the closely analogous ethylenesulfonium ion (II) offered an attractive explanation of the *first-order* displacement reactions[4] of β,β′-dichlorodiethyl sulfide (mustard gas, III) a type of displacement kinetics not shown by any primary alkyl chloride.[5] Ogston, whose extensive studies of this reaction were the basis of most of the ideas used in the mustard program, observed

I II III



certain facts which at the time appeared incompatible with the simple view of the mechanism expressed in eqn. 1

(1)

and indeed with any mechanism involving only this number of steps. The facts which presented the difficulty were: (1) that the "competition factor," defined as the ratio $k_2/k_w$ for any molecule or ion X capable of reacting with the ethylenesulfonium ion, varied widely with the concentration of X in the case of chloride ion, whereas it was expected to be constant; and (2) that although, to a first approximation, the rates of reaction of mustard with all substances depended only upon the concentrations of mustard and of chloride ion, which are concerned in the first step of the mechanism, yet the initial measured first-order rate constant for the reaction of mustard with certain strong competitors such as sodium monothiophosphate was 10% greater than with water or weaker competitors.

It was important to our work to obtain definite proof of the adequacy or inadequacy of Equation (1) to describe the displacement reactions of mustard gas. We therefore undertook some careful kinetic studies of the system and as a result were able to explain the above apparent anomalies satisfactorily within the scheme of Equation (1). The experimental approach had the following features. "Mustard chlorohydrin," β-chloro-β′-hydroxydiethyl sulfide, was prepared in a state of purity which permitted the two stages of mustard hydrolysis indicated in eqn. 2 to be studied separately. The progress of reaction was followed both by the convenient and accurate intermittent alkali titration of Peters and Walker[4] and by polarographic determination of the rate of liberation of chloride ion. The first of these methods was already adapted to following the kinetics of rapid reactions with half-periods of

(2)

only a few minutes; we have adapted the polarographic method to the same purpose, thus permitting a comparison between the rates of liberation of chloride and hydrogen ions, which affords a test of the occurrence of appreciable concentrations of sulfonium ions during the reaction.

(1) This work was performed during 1943–1944 under Contract NDCrc 136 between Harvard University and the National Defense Research Committee of the Office of Scientific Research and Development.

The ionic strength was controlled in all runs. The importance of these features will be brought out in the discussion which follows.

## Experimental

**Materials.**—β-Chloro-β′-hydroxydiethyl sulfide (mustard chlorohydrin) was prepared by the method of Grant and Kinsey.[6] After the replacement of half of the hydroxyl of thiodiglycol by chlorine the unconverted thiodiglycol and sulfonium salts were removed by water–ether extraction, followed by a slow and incomplete removal of mustard by cyclohexane or petroleum ether. Judged by the halogen analyses, the best samples after this procedure contained 3–4% of mustard. The excess chlorine content was reduced to 2% by sublimation under a pressure of $3 \times 10^{-5}$ mm. with efficient magnetic stirring of the liquid charge which was maintained at 0–5°. A middle fraction was melted off the Dry Ice–cooled condenser, weighed accurately, and immediately made into a 0.0187 *M* stock solution with undried Merck reagent acetone without allowing the undiluted chlorohydrin to be at room temperature for more than ten minutes. This solution showed no detectible hydrolysis when kept at 4° in a cold room over a period of two months. It was observed that undissolved mustard chlorohydrin developed about 5% of chloride ion in an hour, but that this chloride ion disappeared on solution of the material in acetone. The ionic material is presumably the dimer

$$HOCH_2CH_2SCH_2CH_2\overset{+}{S}\begin{matrix}CH_2CH_2OH\\CH_2CH_2Cl\end{matrix}\quad Cl^-$$

which is formed reversibly, and is present to an appreciable fraction at equilibrium in the chlorohydrin as solvent but not in acetone.

We investigated a sample of the chlorohydrin prepared by the photochemical reaction between monothioethylene glycol and vinyl chloride,[7] but could not get as pure material from it as by the method described.

β,β′-Dichlorodiethyl sulfide (mustard gas) was prepared from thiodiglycol.[8] A fraction melting at 14.35 ± 0.10° was redistilled and a small middle fraction saved for kinetic purposes. It was apparently quite free from disulfide since a hydrolyzed solution gave no trace of a polarographic wave anywhere between the large sharp chloride and hydrogen waves at +0.20 and −1.5 volts, respectively, *vs.* the saturated calomel electrode. Determinate stock solutions were made by weighing 0.74–0.91 g. of mustard accurately on an analytical balance and making up to 250 cc. with undried Merck reagent acetone. No chloride ion could be detected in these freshly made solutions by distributing 25 cc. between benzene and water in a separatory funnel and titrating the water layer with 0.00500 *M* silver nitrate potentiometrically. After standing at room temperature for ten months the amount of ionic chloride corresponded to only 0.15% reaction in a kinetic run.

The sodium benzenesulfonate used to control the ionic strength was Eastman product repeatedly crystallized from 95% ethanol until the percentage of sodium chloride dropped from about 1% to under 0.00040%, corresponding to less than 0.2% of the chloride ion liberated in a kinetic run.

The 0.05 *M* benzenesulfonic acid used for neutralizations was Eastman practical grade and contained less than 0.0004% of chloride ion by titration. The shape of a titration curve with sodium hydroxide showed it to be free from weak acids.

A 0.0518 *M* sodium hydroxide solution was prepared from a filtered 50% solution with freshly boiled distilled water and properly protected from atmospheric carbon dioxide. It was standardized with 0.0499 *M* hydrochloric acid, which had been indirectly standardized by titration against weighed potassium acid phthalate.

In the intermittent titrations, we used 0.50 cc. per 100 cc. of aqueous reaction medium, of one of the following indicators: 0.1% aqueous brom thymol blue neutralized to *p*H 7.0; 1:3 0.1% aqueous cresol purple with 0.1% aqueous thymol blue neutralized to *p*H 8.0; or 1:2 0.1% aqueous brom cresol green with 0.1% aqueous methyl red neutralized to *p*H 5.1. This last mixture was partly insoluble and had to be shaken before use. The mixed indicators were kept in brown bottles. They gave distinctly sharper endpoints than single indicators. In all cases a standard cell, identical in size and shape to the reaction cell and containing 100 cc. of a phosphate buffer for the *p*H chosen, 5 cc. of acetone and 0.50 cc. of indicator, was clamped in the thermostat beside the reaction cell to make an accurate color comparison possible. The molarity of indicator used in a reaction was about 0.5% of the initial molarity of chlorohydrin or mustard.

Sodium monothiophosphate was shown by Ogston to be a useful competitor in reactions of mustard because at *p*H 8.0 it liberates hydrogen ion quantitatively when it reacts.

$$HPSO_3^= + RCl \longrightarrow RPSO_3^= + Cl^- + H^+$$

This compound was easily prepared by hydrolysis of Eastman practical grade thiophosphoryl chloride with sodium hydroxide. Twenty cc. of thiophosphoryl chloride was added to a solution of 48 g. of sodium hydroxide and 5 cc. of dioxan in 200 cc. of water, shaken with periodic cooling in a water-bath to prevent too rapid a reaction, then kept at 100° on the steam-bath for an hour to dissolve all the thiophosphoryl chloride. After evaporating somewhat in an open evaporating dish at room temperature and cooling in ice, 61 g. of large white crystals precipitated. These were collected, washed with alcohol and ether to dry, recrystallized from 69 cc. of water at 100° and finally cooled in ice yielding 48 g., then recrystallized several times more. The competitive power of the product, measured by the total amount (56%) of acid liberated on reaction with mustard with an equal molarity of the non-acid-liberating thiosulfate present, did not change with further crystallizations.

An acid titration of sodium monothiophosphate with a glass electrode showed two well defined waves with *pK* values of roughly 10.2 and 5.6 at 25°. Therefore at *p*H 7.9–8.0 it is most completely in the form of $HPSO_3^=$. At *p*H 8.0 Ogston reports that its "competition factor" is $3.8 \times 10^4$ compared to $2.7 \times 10^4$ for thiosulfate and $8.0 \times 10^3$ for hydroxyl ion.

The dry salt crystallized with its full twelve molecules of water seems to be stable over long periods of time. The partially dehydrated salt develops a pronounced odor of hydrogen sulfide in a few days. A 0.05 *M* solution decreases in iodine titer about 5% in a week at room temperature, faster after that. This is probably a chemical decomposition to phosphite and sulfur. In contrast to thiosulfate, one mole of thiophosphate equals two equivalents of iodine since the reaction product with iodine is colloidal sulfur.

$$PSO_3^= + I_2 + H_2O \longrightarrow H_2PO_4^- + 2I^- + S$$

The titration is sharper with no buffering or added acid.

Aqueous solutions of sodium monothiophosphate are strongly alkaline. There should be no delay in degassing and using a solution which has been neutralized to *p*H 8.0 by an equivalent of acid preparatory to a run. The $HPSO_3^=$ ion is unstable and decomposes over a period of a day.

**Apparatus.**—The cell used for the intermittent titrations is shown in Fig. 1. It consisted of a 4.6 × 21 cm. test-tube with a capillary side tube entering near the bottom for a gas inlet. The shaft of a small glass propeller stirrer passed down through a glass sleeve in the rubber stopper in the top of the cell and rested in a small depression blown in the bottom of the cell which served as a bearing. The propeller was driven at high speed by an air blast directed on a small notched disc on the shaft outside the cell, and caused the gas bubbles entering below to break and com-

pletely fill the solution. By turning of a stopcock the gas stream could be introduced into the cell over the surface through a tube in the rubber stopper instead of under the surface.

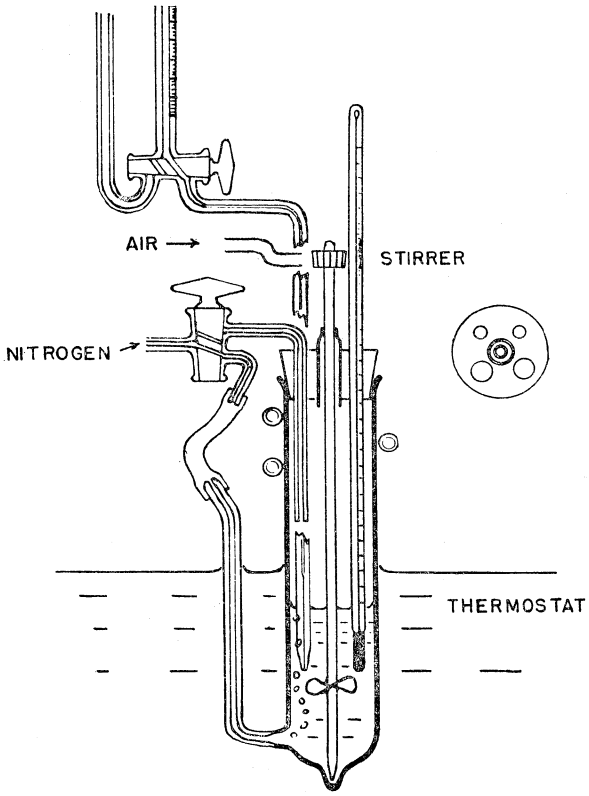

Fig. 1.—Apparatus for rapid intermittent titration of hydrogen ion liberated in hydrolysis of mustard and mustard chlorohydrin. Inset—top view of rubber stopper. Center hole, air-driven stirrer; upper holes, nitrogen inlet and thermometer; lower holes, microburet and nitrogen outlet.

Reagents were added from a 5-cc. microburet with its long capillary tip below the surface of the solution in the cell. The microburet and all other burets, pipets and volumetric flasks used in this work were standardized.

The reaction cell for following chloride liberation with the dropping mercury electrode was identical with the cell used for the intermittent titrations except that it was modified into an H-cell by blowing a side tube and auxiliary cell into the side of the reaction cell. The side tube had a 2.5-cm. medium-coarse fritted disc on the reaction side. This was covered with a plug of 3% agar gel containing 0.15 *M* sodium benzenesulfonate. A saturated mercurous sulfate electrode was made so that it could be readily removed and stored in a bottle containing saturated potassium sulfate when not in use. When placed in this cell it was covered with 0.15 *M* sodium benzenesulfonate to the same height as the solution in the reaction half.

**Intermittent Titration for Hydrogen Ion.**—Appropriate amounts of reagents and stock solutions were made up to 100 cc. with water in a volumetric flask. This solution was introduced into the titration cell. Purified nitrogen was then passed for forty-five minutes through this solution and through the acetone stock solution of mustard or chlorohydrin, the gas being first saturated with water in the one case and acetone in the other. The temperature in the cell was brought to exactly 23.70°; then 4.96 cc. of the acetone stock solution was added rapidly from a syringe pipet, the stopwatch being started when the addition was half complete. There was an immediate temperature rise to 25.00° and the total volume was 104.2 cc. The cell, air blast for the stirrer, buret, etc., were all on the same vertically sliding mount so that the cell could be dropped into position in the thermostat at 25.00° without delay.

The Peters–Walker intermittent titration might well be called the kineticist's dream. The rate of reaction of mustard or of its chlorohydrin is independent of the *p*H over a wide range; it is therefore possible to read the buret, add a small increment of alkali to the reaction, and watch for the color-change of the indicator, which marks the point at which an amount of acid has been produced exactly equivalent to the first increment of alkali. When this color change occurs the time is noted, the buret is read again and another increment of standard base is added to the reacting solution. It has been amply verified that it makes no difference whether the reaction is conducted on the acid or alkaline side of the change-point, or, as in our experiments, on the two sides alternately. The time of color change of the indicator could be noted within one second. The first such point was usually obtained about forty seconds after the beginning of the reaction. In these experiments, the standard 0.0518 *M* base was added in increments of 0.200 cc.

As an infinite time or 100% point, 13.3 times the half life was used. This corresponds to 99.99% completion for a first order reaction. This figure always checked the figure calculated from the weighing data within 3%. Corrections were made in the data when the temperature at one minute was more than 0.05° removed from 25.00°, by adding to all times 1.2% of their value multiplied by the average deviation in tenths of a degree up to 70% reaction. This is the calculated correction based on a 3.3-fold change of rate between 25 and 35°. Runs deviating by more than 0.2° were discarded.

**Polarographic Determination of Chloride.**—A preliminary polarogram on a hydrolyzed solution of 0.00097 *M* mustard gas showed sharp chloride and hydrogen ion waves with half-wave potentials of +0.20 and −1.5 volts *vs.* the saturated calomel electrode. The hydrogen wave had a pronounced maximum, but the chloride did not appear to have one. There was no sign of a wave between the two. The plateau region of the chloride wave began at about +0.25 volt. Since the half-wave potential of chloride increases 59 millivolts for each tenfold decrease in concentration we selected 0.35 volt to be sure of being on the plateau at 2% reaction. This corresponds to −0.05 volt *vs.* our saturated sulfate electrode.

The ordinary polarographic technique of averaging the current by use of a ten- to twenty-second period galvanometer would result in too much lag to follow accurately a reaction with a half-life of three minutes. Therefore a Moll microgalvanometer with a full period of one-fifth of a second was used with a scale at 1.2 meters distance to follow the entire current swing during the life of each drop. The maximum of the swing was recorded. The circuit was connected as shown in Fig. 2. Since the cell resistance was of the order of 100 ohms and the maximum current was about 10 microamperes, the internal voltage drop and hence the applied voltage varied during the course of a run by about 1 millivolt. Also the voltage, which was set at 0.05 volt, was that applied to the cell in series with the galvanometer and its series and shunt resistances, and differed by several millivolts from that applied to the cell itself. However this arrangement of the circuit caused no error because of the way in which chloride was measured.

The galvanometer was first standardized with a 0.0499 *M* solution of hydrochloric acid as follows. One hundred cc. of 0.15 *M* sodium benzenesulfonate and 4.96 cc. of acetone were placed in the reaction cell, the dropping electrode inserted, known amounts of hydrochloric acid from zero to 4 cc. added from the 5-cc. microburet, and the maximum of the fifth or any following swing recorded after each increment. The first two or three swings were abnormally large until the region near the tip of the electrode had been partially depleted of chloride and a steady state had established itself. This variation in local con-

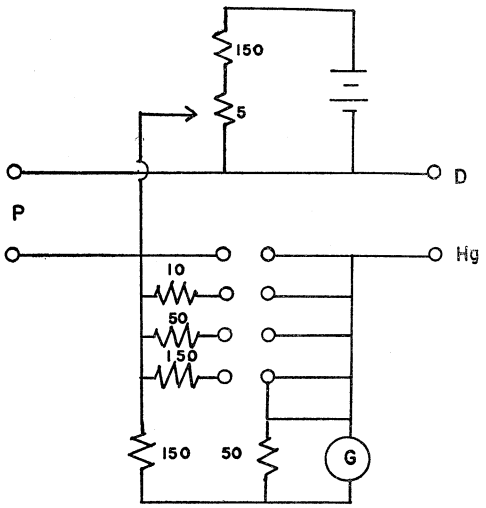

Fig. 2.—Circuit used in polarographic determination of chloride ion: P, to potentiometer; D, dropping electrode; Hg, mercurous sulfate electrode; G, galvanometer. The numbers are resistances in ohms.

centration because of electrolysis by the drop is the principal source of error in this analysis. Since the initial galvanometer reading is the same in a kinetic run as in the standardization, the resulting plot of galvanometer reading *vs.* cc. of hydrochloric acid enables kinetic data to be translated into per cent. reaction directly.

It was found that thiodiglycol did have a small effect on the current. For example, 0.0036 *M* added thiodiglycol gave a current four times the normal residual current, or one equal to that obtained at 35% reaction with the chlorohydrin. It might seem, therefore, that there are two serious errors in this procedure other than difference in local depletion of chloride between the standardization and the run: first, the volume is increased 4% in the standardization, not at all in the run; second, thiodiglycol accumulates as a reaction product, but is not present in the standardization. However these "errors" are proportional to the measured percentage reaction, which in turn is based on the final *observed* current, and so are not errors at all.

The procedure followed was the same as that in the runs with intermittent titration for hydrogen ion up to a point fifteen seconds after the start of the run. Then the stirrer and the thermostat motor and heater were turned off (to eliminate vibrations) and the nitrogen stream diverted to pass over the surface. The first galvanometer reading was usually obtained at about thirty seconds. Since the hydrogen ion liberated is not neutralized, the *p*H falls steadily to nearly 3.0 by the end of the reaction.

The shunts on the galvanometer made it possible to decrease the sensitivity several times as the reaction proceeded. Thus large, easily measured deflections were obtained on the meter scale at all percentage reactions. A standardization curve was prepared for each sensitivity.

Table I gives data on the machine-made capillaries which we used. The drop time given is that observed during the runs, *i.e.*, in the salt solutions with the voltage applied. Since the two runs on mustard, 100 and 105, gave the same results, the drop time does not seem to be an important factor affecting the accuracy by this method.

TABLE I

| Run no. | Capillary | Length, cm. | Height of Hg above tip, cm. | Drop time, sec. |
|---|---|---|---|---|
| 74 | A | 4.5 | 65 | 1.02 |
| 101 | A | 4.5 | 57.5 | 1.20 |
| 100 | A | 4.5 | 57.5 | 1.22 |
| 105 | B | 11 | 65 | 2.22 |

**Results with Mustard Chlorohydrin.**—Data for seventeen typical kinetic runs on the hydrolysis and displacement reactions of mustard chlorohydrin at 25° in water containing 5% acetone are plotted in Fig. 3. To avoid confusion in the figure, not all the experimental points are plotted, but a selection to avoid superposition of points as far as possible. All the plots are seen to be linear when the logarithm of mustard chlorohydrin concentration, as inferred from the production of hydrogen or chloride ion, is plotted against time, up to 90% reaction and beyond. There were no points which were not on the lines.

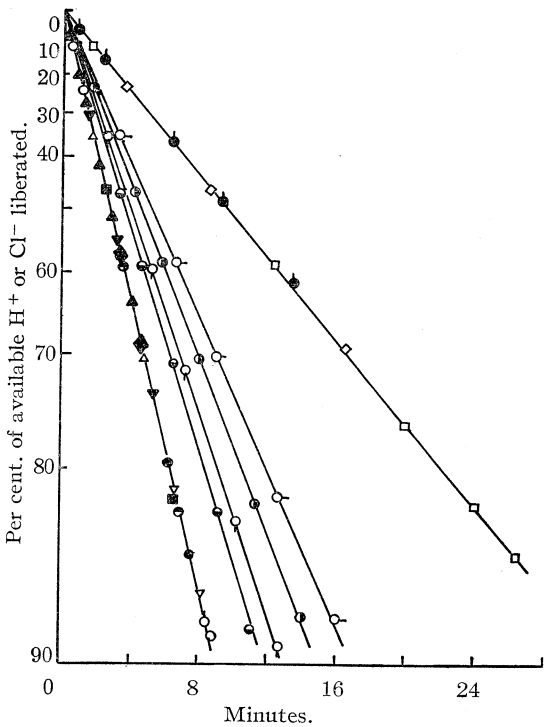

Fig. 3.—Logarithmic plots of seventeen experiments on hydrolysis and displacement reactions of mustard chlorohydrin (β-chloroethyl-β′-hydroxyethyl sulfide). Points plotted are selected to avoid overlapping. The ordinate scale is a logarithmic one, the ordinates being proportional to log $C_0/C$ as inferred from chloride ion determinations in runs 74 and 101, and from hydrogen ion titrations in the other fifteen runs. All runs are at ionic strength 0.144 except those designated "no inert salt." The significance of the points is as follows: ▲, Run 74 (chloride ion determined); ▼, Run 101 (chloride ion determined); △, Run 63; ▽, Run 76; ○, Run 116, 0.00096 *M* $NaH_2PO_4$; ◔, Run 123, no inert salt; ◓, Run 122, 0.00192 *M* NaCl; ◕, Run 111, 0.142 *M* NaCl; □, Run 125, 0.142 *M* NaCl, 0.00096 *M* $NaH_2PO_4$; ◇, Run 126, 0.142 *M* NaCl, immediate additions of NaOH; ◒, Run 117, 0.192 *M* NaCl; ⚲, Run 121, 0.0192 *M* NaCl, no inert salt; ◑, Run 118, 0.0385 *M* NaCl; ○-, Run 119, 0.0385 *M* NaCl, no inert salt; ●, Run 127, 0.127 *M*, NaCl, 0.0043 *M* sodium monothiophosphate (P); ■, Run 64, 0.0043 *M* P; ◆, Run 77, 0.0043 *M* P.

In all the runs not otherwise described the ionic strength was 0.144, being brought to this value by adding the necessary amount of sodium benzenesulfonate. The initial molarity of mustard chlorohydrin in each case was 0.00089 *M*.

Ten of the runs have the same first order rate constant within the experimental error, 0.260 ± 0.016 min.$^{-1}$ These ten include two runs in which the percentage reaction figures represent chloride ion liberated as a percentage of total chloride liberated up to a time equal to 13.3 times the half-life (99.99% reaction). They also include eight runs in which the percentage figures represent hydrogen ion liberated as a percentage of total hydrogen ion at 13.3 times the half-life. Of the eight hydrogen-ion runs having the same rate constant, two were like the chloride-ion runs in having no added competitors (only the usual inert salt addition to bring the ionic strength up to 0.144 *M*); one had 0.00096 *M* monosodium phosphate added to keep the *p*H below 6.0, and was followed with a *p*H 5.1 indicator; one had the inert salt omitted; one had 0.00192 *M* chloride added; three had 0.0043 *M* sodium monothiophosphate added; and one of these also had 0.127 *M* chloride added.

The other seven runs all had considerable amounts of added chloride, and the data represent hydrogen ion liberated. In three of these runs the chloride ion concentration was 0.142 *M*, and accordingly the usual addition of inert salt to make the total ionic strength up to 0.144 ± 0.003 *M* was omitted. One of the three runs was done in the usual way with the brom thymol blue indicator yellow and blue about equal amounts of time; one had 0.00096 *M* monosodium phosphate added to keep the *p*H below 6.0, and was followed with a *p*H 5.1 indicator; and in the other, which had brom thymol blue and no buffer, additions of sodium hydroxide equivalent to 25% reaction were made as soon as each end-point was reached to keep the *p*H above 10.0 half of the time. The three runs have the same rate constant within experimental error, showing the unimportant part played by *p*H in this reaction. The other four runs represent intermediate amounts of chloride added, with and without inert salt added to make the ionic strength up to 0.144 *M*.

It is qualitatively predicted from eqn. 1 that a sufficiently high concentration of chloride ion should be able to reconvert an appreciable fraction of the ethylenesulfonium ion into starting material in competition with water and the other reagents present. Such an effect would appear as a simple lowering of the first-order rate constant for the over-all reaction, as can be shown by a simple derivation based on eqn. 1.

The fact that the logarithmic plots are linear shows that concentrations of chloride ion up to 0.00089 *M* produce no observable effect of this kind. Nor does any effect appear at a chloride ion concentration of 0.00192 *M* (Run 122). At ten times this concentration of chloride ion there is a marked retardation of hydrolysis (Runs 117 and 121) but no effect upon the rate of reaction in the presence of monothiophosphate (Run 127) even by 0.127 *M* sodium chloride. These results provide a basis for calculating the competition factor of chloride ion, as will be done in a later section, and they emphasize the fact that the competition factor of thiophosphate is enormously greater than that of chloride ion.

The identity of the rates in Runs 116 and 123, with and without inert salt, shows that the initial cyclization is insensitive to ionic strength, while the distinct difference in rate between Nos. 117 and 121 shows that the *reverse* reaction between sulfonium ion and chloride ion must be retarded by an increase in ionic strength. This, too, will be treated quantitatively below. It is immediately obvious, however, that in kinetic experiments with sodium chloride as the only added salt, the determined competition factor of chloride ion will be lower, the higher the sodium chloride concentration, as a result of this property.

Since there is no evidence of any difference between the rates of appearance of hydrogen ion and of chloride ion (runs 63, 74, 76, 101), there is no accumulation during the hydrolysis of either an ethylenesulfonium ion or a dimeric sulfonium ion, to any extent observable by our technique.

Finally, the total absence of any effect of sodium monothiophosphate on the rate of hydrolysis of, or displacement in, mustard chlorohydrin strongly suggests that the difunctional character of mustard itself is somehow responsible for the accelerating effect noted by Ogston in the presence of thiophosphate and other competitors.

**Results with Mustard.**—Figure 4 shows data for eleven typical kinetic runs on mustard, temperature, solvent and ionic strength being the same as in the case of the chlorohydrin. In contrast to the case of the chlorohydrin, none of the first-order plots is linear, all being convex upward. Since the hydrolysis and displacement reactions of mustard involve the replacement of both chlorine atoms, the nature of the reacting molecule changes from the early to the late part of the reaction, and the reaction in the case of mustard is a succession of two reactions, one of mustard and one of the chlorohydrin. Unless both species undergo cyclization at identical rates, it is evident that a logarithmic plot based upon the evolution of chloride ion or of hydrogen ion must show curvature, and the type of curvature observed indicates that $k_1$ for mustard is lower than for the chlorohydrin. This would be expected on the basis of the reasoning developed in connection with the so-called nitrogen mustards.[9]

Five of the runs fit the same curve on this plot and therefore are described by the same pair of first order rate constants within the experimental error. These are runs without effective competitors added. Two of the five represent liberation of chloride ion, and the other three liberation of hydrogen ion. One of the hydrogen ion runs was done by the ordinary technique with the *p*H varying from 4 to 10; one had 0.00096 *M* sodium dihydrogenphosphate buffer to keep the *p*H below 6.0 and was followed with a *p*H 5.1 indicator, and the other had 0.00192 *M* chloride added.

Four of the curves give data for the liberation of hydrogen ion in runs with considerable amounts of added chloride. Except for their curvature they are similar to the curves obtained with the chlorohydrin. However, the remaining curve in Fig. 2 gives data for liberation of hydrogen ion in two runs with 0.0043 *M* added sodium monothiophosphate. In contrast to the case with chlorohydrin this curve differs from the normal curve without competitors, the rate of reaction here being considerably greater than the normal rate.

When a concentration of chloride (0.00192 *M*) twice that formed by 100% reaction was added at the start (run 8), the initial rate was the same as without additions within experimental error. Therefore this increase in rate with thiophosphate added is too large to be explained as an elimination of reversal by chloride ion. It is easy to see why the later stages of the reaction with thiophosphate should be faster than the later stages of the simple hydrolysis, for the substance undergoing reaction is a sulfide containing in the one case the group $-CH_2CH_2SPO_3^=$ and in the other case the group $-CH_2CH_2OH$, of which the former, with its double negative charge, should be more base-strengthening than the latter and should therefore contribute more to the reactivity of the sulfide sulfur in the cyclization step.

## Quantitative Treatment of Results

**Notation.**—For the equations to follow, it will be convenient to establish the following notation. The symbols for molecular species will denote molecules in chemical equations, and their concentrations in moles per liter when in mathematical equations.

M = mustard, $(ClCH_2CH_2)_2S$

C = mustard chlorohydrin, $ClCH_2CH_2SCH_2CH_2OH$

V = $ClCH_2CH_2SCH_2CH_2SPO_3^=$

P = $PSO_3^=$

M* = mustard ethylenesulfonium ion, $ClCH_2CH_2\overset{+}{S}\begin{matrix}CH_2\\|\\CH_2\end{matrix}$

C* = chlorohydrin ethylenesulfonium ion, $HOCH_2CH_2\overset{+}{S}\begin{matrix}CH_2\\|\\CH_2\end{matrix}$

Subscript zero refers to concentration at zero time

$k_1$, $k_{-1}$, $k_2$, $k_w$ as defined in eqn. 1.

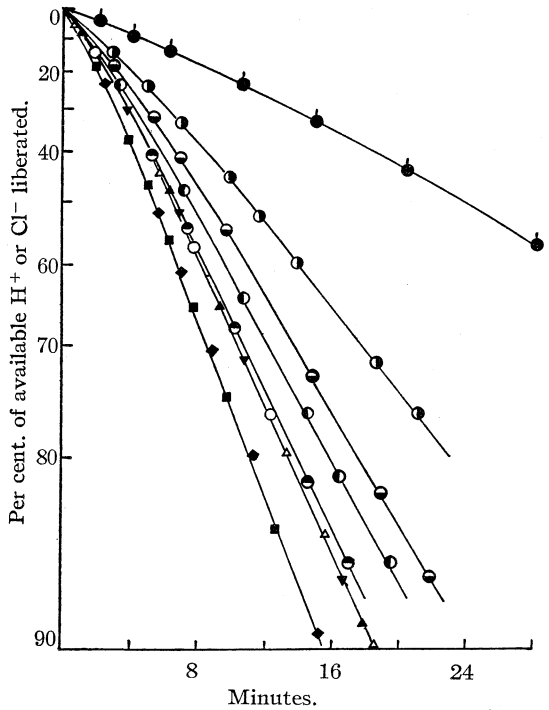

Fig. 4.—Logarithmic plots of eleven experiments on hydrolysis and displacement reactions of mustard ($\beta,\beta'$-dichlorodiethyl sulfide). Points plotted are selected to avoid overlapping. The ordinates are proportional to $\log (Cl^-)_\infty/((Cl^-)_\infty - (Cl^-))$ in runs 100 and 105, and to $\log (H^+)_\infty/((H^+)_\infty - (H^+))$ in the other nine runs, the subscript $_\infty$ referring to the concentration at the end of the reaction. All runs are at ionic strength 0.144. The significance of the points is as follows: ▲, run 100 (chloride ion determined); ▼, run 105 (chloride ion determined); △, run 28; ○, run 114, 0.00096 *M* $NaH_2PO_4$; ◒, run 8, 0.00192 *M* NaCl; ◐, run 19, 0.0096 *M* NaCl; ◒, run 9, 0.0192 *M* NaCl; ◑, run 20, 0.0385 *M* NaCl; ●, run 21, 0.142 *M* NaCl; ■, run 16, 0.0045 *M* sodium monothiophosphate (P); ◆, run 18, 0.0045 *M* P.

$k_{1M}$, $k_{1C}$, $k_{1V}$, etc., are the $k_1$'s for the reactions of M, C and V, respectively

$F^{\mu}_{Cl-} = (k_{-1}/k_w)$ at the ionic strength $\mu$.

$F^{\mu}_{X} = (k_2/k_w)$ at the ionic strength $\mu$

These are the competition factors of Ogston, except that the ionic strength was not specified in Ogston's work.

$b = (Cl^-)_0$

$$k_{bC} = \frac{\left[\frac{d(H^+)}{dt}\right]_{[Cl^-]_0 = b}}{C}$$ for chlorohydrin

$$k_{bM} = \frac{\left[\frac{d(H^+)}{dt}\right]_{[Cl^-]_0 = b}}{M}$$ for mustard

**Ionic Strength Effects.**—We shall now consider quantitatively the dependence of the competition factor upon the concentration of the competitor. The kinetic results with the chlorohydrin show that, within the accuracy of the

experiments, the rate of hydrolysis or displacement is determined entirely by $k_{1C}$ when there is no added chloride ion, and $k_{WC}$ may be considered to be infinitely great compared to $k_{1C}$.[10] This is an extreme not reached in any of the nitrogen mustards, but approached with increasing chlorination in the series: $ClCH_2CH_2N(C_2H_5)_2$, $(ClCH_2CH_2)_2NC_2H_5$, $(ClCH_2CH_2)_3N$.[9] It is reasonable that decreasing basicity of the basic center should increase the values of the ratios $k_w/k_1$, $k_2/k_1$ and $k_{-1}/k_1$ thus decreasing the extent to which the ethylene-onium intermediate accumulates during reaction.

Since $k_{WC}$ is large relative to $k_{1C}$, the following simplified treatment is valid: In the absence of added chloride ion

$$\frac{\left[\frac{d(H^+)}{dt}\right]_{[Cl^-]_0=0}}{C} = k_{1C} = k_0$$

In the presence of an added excess of chloride ion such that its concentration $b$ remains approximately constant during reaction, and in the absence of other competitors

$$\frac{\left[\frac{d(H^+)}{dt}\right]_{[Cl^-]_0=b}}{C} = k_{1C}\frac{k_{WC}}{k_{WC} + k_{-1C}\,b} = k_{bC}$$

The ratio of rates in presence and absence of added chloride ion is thus equal to $k_{WC}/(k_{WC} + k_{1C}b)$ or to $1/(1 + F_{Cl}b)$, the special form for chloride ion of a general expression derived by Ogston and applied by him and by Clark, Cohen and Harris[11] to the estimation of competition factors for the bifunctional reagent, mustard. The explicit form for $F_{Cl}$ is

$$F_{Cl} = \frac{1}{b}\left[\frac{k_0}{k_{bC}} - 1\right] \qquad (3)$$

The nature of this equation is such as to magnify errors in the kinetic runs when two runs with rates differing only slightly are used to determine competition factors. For example, if $F_{Cl}$ is determined from Runs 76 and 117, and the rate of each reaction is subject to a maximum uncertainty of 6%, the maximum uncertainty in $F_{Cl}$ becomes 52%. Nevertheless, if we use the four runs, 76, 111, 117 and 118, at ionic strength 0.144, to calculate $F_{Cl}^{0.144}$, we obtain values of 18.1, 15.6 and 16.6, which are all within less than 8% of the weighted mean of 16.9. From this value for the competition factor we can calculate back the relative rates in the three runs with chloride added with a mean deviation of 2.7%. However, this procedure applied to Runs 119 and 121 with sodium chloride but without inert salt, at lower ionic strengths, yields calculated values of relative rate deviating from the observed by 7.8 and 12%, outside the experimental error in both cases. It appears from these results that the competition factor of chloride ion is a function of ionic strength, but not of chloride ion concentration at constant ionic strength.

From the Bronsted rate equation[12] and the limiting Debye–Hückel equation,[13] one can predict semi-quantitatively for a dilute solution how the rate constant for a reaction between oppositely charged ions should respond to changes in ionic strength. The constant $k_{-1}$ is of this type, while $k_1$ and $k_w$ are not and should show a zero salt effect by the Bronsted theory. Then using the Debye–Hückel relation for the activity coefficient of ions

$$-\log \gamma = 0.5Z^2\sqrt{\mu} - \beta\mu \qquad (4)$$

and the Brönsted law applied to $k_{-1}$

$$k_{-1} = k_{-1}^0\frac{\gamma_{C^+}\gamma_{C^-}}{\gamma^*} \qquad (5)$$

we obtain

$$\log_{10} k_{-1} = \log_{10} k_{-1}^0 - \sqrt{b} + (\beta_{C^+} + \beta_{Cl} - \beta^*)b \qquad (6)$$

or

$$\log_{10} F_{Cl^-} = \log_{10}\left(\frac{k_{-1}^0}{k_w}\right) - \sqrt{b} + (\beta_{C^+} + \beta_{Cl^-} - \beta^*)b \qquad (7)$$

if the total ionic strength is due to added chloride. Here the $\gamma$'s are activity coefficients, $\mu$ is the ionic strength, $Z = 1$ = the valence of each reacting ion, $k_{-1}^0$ and the $\beta$'s are constants independent of the conditions. If the cyclic intermediate, $C^*Cl^-$, has a minimum in its mean activity coefficient curve at $1.0 \pm 0.5$ $M$ ionic strength as do most uni-univalent electrolytes, then $\beta_{C^+} + \beta_{Cl^-} = 0.50 \pm 0.20$. Since the transition state is a neutral molecule, $\beta^*$ is negative,[14] and $-\beta^*$ probably adds about 0.20 more to the sum. We shall use 0.70 as the estimated value of $\beta_{C^+} + \beta_{Cl^-} - \beta^*$. (The results of the calculation are not much affected by a variation of $\pm$ 0.20 in its assumed value.) We shall use the experimental data to determine $(k^0 - 1/k_w)_{\mu=0}$, which should be a *true constant*. This might be called the "competition factor at zero ionic strength," and will be denoted by $F_{Cl}^0$. Its value is calculated from the competition factors in Table II. The

TABLE II

$F_{Cl}$ AS A FUNCTION OF IONIC STRENGTH; APPLICATION OF THE DEBYE–HÜCKEL LIMITING LAW TO RUNS WITHOUT INERT SALT

(10) Calculations based on eqn. 1 without this simplification show that the assumption $k_w/k_1 = \infty$ introduces about a 3% error into the calculated competition factor of chloride ion if $k_w$ is actually as small as 30 $k_1$, and a negligible error, for these experiments, if $k_w \gg 100\ k_1$.

weighted mean value for $F^0_{Cl}$ is 32.2; using this value and calculating back, we obtain the calculated values of $F^\mu_{Cl}$ and of $k_b/k_0$ shown in the fifth and sixth columns of Table II. It will be noted that the value of $F^{0.142}_{Cl}$ calculated is 17.0, compared with the mean value of 16.9 obtained from the four runs made at ionic strength 0.144. The mean deviation of the calculated relative rates from the observed is 2.8%, satisfactorily within the experimental uncertainty.

Although these experiments do not cover a range sufficient to establish the validity of this treatment in any unique way, it is clear that the variation of competition factor with concentration of the competitor, previously thought to be an obstacle to the acceptance of the simple ethylenesulfonium ion mechanism, is an entirely normal effect of ionic strength which would be predicted on the basis of accepted theories. Such variation should, of course, be exhibited by other competitors bearing an ionic charge, though not by neutral competitors. Linstead and Doering[15] found that the competition factors of acetate ion for mustard in 0.05 *M*, 0.19 *M* and 0.4 *M* acetate solutions were 8.2, 5.4 and 4.7, respectively, this variation being of the general sort called for by the present theory.

**The Determination of $k_{1M}$.**—The value of $k_1$ for mustard itself should be the same with all competitors, and the question remains: is the initial slope of a line such as those in Fig. 4 an adequate measure of the initial $k_1$? This question can be answered quantitatively by using the first-order rate constant evaluated for mustard chlorohydrin and the equation for successive first-order reactions. It is seen from Fig. 4 that the logarithmic curves of fraction of total available hydrogen ion remaining unliberated are smooth curves showing no resolution into initial and final linear portions. In past work[4] $k_{1M}$ has been estimated as the slope of the earliest portion of such a curve for which experimental points were available, the hope being that the small amount of C or V formed during such interval would not appreciably affect the rate of production of hydrogen ions. Whether this is true or not obviously depends upon the relative magnitudes of $k_{1M}$ and $k_{1C}$ or, in the case at hand of the use of a strong competitor, the relative magnitudes of $k_{1M}$ and $k_{1V}$. Our direct measurement of $k_{1C}$ offers a means of determining $k_{1M}$ from the kinetic data on mustard without making any approximation about limiting slopes. We need only assume that with mustard, as with the chlorohydrin, $k_w >> k_{-1}$, so that the entire process may be treated as a pair of consecutive irreversible first-order reactions.

In such a system the liberation of hydrogen ion should closely follow the law[16]

$$[H^+] = M_0\left[2 - \left(\frac{k_{1M} - 2k_{1C}}{k_{1M} - k_{1C}}\right)e^{-k_{1M}t} - \frac{k_{1M}}{k_{1M} - k_{1C}}\, e^{-k_{1C}t}\right] \quad (8)$$

From the work with mustard chlorohydrin we know that in runs with no added chloride ion and with no added competitor, $k_{1C} = 0.260 \pm 0.016$ min.$^{-1}$. For this value of $k_{1C}$, a value of $k_{1M} = 0.155 \pm 0.010$ gives the closest agreement between the curve calculated from eqn. 8 and the experimental curves for mustard under these same experimental conditions. With this value of $k_{1M}$ the calculated curve lies slightly above the experimental up to 70%, slightly below beyond 70%, but the deviations in time at 50% and 90% are within 1 and 3%, respectively, or well within the experimental error.

Similarly we can determine the $k_{bM}$ corresponding to various amounts of added chloride. From the values of $k_{bM}$ we can then calculate the competition factor of chloride at 0.144 *M* ionic strength for M*, *i.e.*, in the first of the two processes making up the reaction. We can then compare the competition factor of chloride for M* with the corresponding factor of chloride for C*, which determines the reactivity of chloride in the second half of the reaction.

Table III gives the data for the runs with chloride added, all done at an ionic strength of 0.144 *M*, and the calculated values of $k_{bM}$ and $k_{bC}/k_{bM}$. It is reasonable to assume that the

TABLE III

DETERMINATION OF $k_{bM}$ AT DIFFERENT CHLORIDE ION CONCENTRATIONS AT 25° IN WATER CONTAINING 5% ACETONE

| Run | $b$ | $t_{70\%}$ | $k_{bC}$ | $k_{bM}$ | $k_{bM}/k_{bC}$ |
|---|---|---|---|---|---|
| 28 | 0.0000 | 10.30 | 0.260 | 0.155 | 0.595 |
| 8 | .0019 | 10.55 | .260 | .152 | .585 |
| 9 | .0192 | 13.65 | .194 | .118 | .610 |
| 20 | .0385 | 17.65 | .153 | .090 | .590 |
| 21 | .142 | 38.70 | .072 | .041 | .570 |
| | | | | Av. | .59 |

competition factors at zero ionic strength would also be the same for mustard as for the chlorohydrin, *viz.*, 32. Thus the discriminating ability of an intermediate between competitors is not affected to a detectable extent by differences in structure of the sort existing between mustard and mustard chlorohydrin.

With the values at hand for $k_{1M}$, $k_{1C}$ and $F^\mu_{Cl}$, the entire curves for mustard with various amounts of chloride added can be calculated within experimental error.

The course of the displacement experiments with sodium monothiophosphate differs from that of the hydrolytic experiments in that the ethylenesulfonium ions, when formed, react exclusively with thiophosphate ion. The kinetic equation for the two successive reactions is accordingly identical with Equation (8) except

(15) R. P. Linstead and W. E. Doering, NDRC Report, April 15, 1942.

(16) C. G. Swain, THIS JOURNAL, **66**, 1696 (1944); A. Rakowski, *Z. physik. Chem.*, **57**, 321 (1907).

for the replacement of $k_{1C}$, wherever it occurs, by the hitherto unknown constant $k_{1V}$. Since the other constant of this equation $k_{1M}$, is now known, it becomes possible to determine the value of $k_{1V}$ in the same manner as was just done using eq. 8.[16] A calculated curve using $k_{1V} = 0.70$ approximates the experimental curve most closely, and the sensitivity of the calculated curve to the assumed value suggests the limits ± 0.05 for this constant. The calculated curve has the same general shape as the experimental, lying above it throughout but always within 2% of it on the time coördinate.

Thus both hydrogen ion and chloride ion are liberated by mustard in dilute solution according to the equation

$$[H^+] = [Cl^-] = a\left[2 - \left(\frac{k_{1M} - 2k_1'}{k_{1M} - k_1'}\right)e^{-k_{1M}t} - \left(\frac{k_{1M}}{k_{1M} - k_1'}\right)e^{-k_1't}\right]$$

where $k_{1M} = 0.155$, and $k_1' = 0.260$ ( $= k_{1C}$) or 0.70 ( $= k_{1V}$) according to whether or not thiophosphate is added. From this equation it would seem that it should have been possible to estimate $k_{1M}$ from the initial slope of a simple logarithmic plot [ln $(2a - H^+)$ *vs.* $t$], instead of by the curve-fitting method which we actually employed. The limiting initial slope on such a plot is $k_{1M}/2$. Ogston, Linstead and others used early points, with the origin, to measure the initial rate in this way. However, the value obtained is far from correct if any realizable fraction of the curve is used to define the slope. Even if points be used as early as 5.0% of total reaction, which are the earliest points that we have been able to obtain by the intermittent titration technique, the estimates of the initial rate so reached are still in error by 6% in the runs without thiophosphate added, and by 16% in the runs with thiophosphate added (see Table IV). This difference in errors is the cause of Ogston's observation that the initial rate with thiophosphate added was about 10% faster than without the addition. The present study accounts for this observation on the basis that the first rate constant (and initial rate) is the same under both conditions, and that only the second rate constant differs, according to whether the second step is ionization of chlorohydrin or of thiophosphate displacement product.

TABLE IV

ERRORS INVOLVED IN CALCULATING $k_{1M}$ FROM INITIAL SLOPE OF OVER-ALL CURVE FOR REACTION OF MUSTARD GAS

| Rate constants $k_1$ | Rate constants $k_2$ | Point $t$ | Used %$H^+$ | $k_1$ Calcd. from point and origin | Error, % |
|---|---|---|---|---|---|
| 0.155 | 0.260 | 1/2 | 4.0 | 0.162 | 4.5 |
| .155 | .260 | 1 | 8.2 | .171 | 10 |
| .155 | .700 | 1/2 | 4.3 | .177 | 14 |
| .155 | .700 | 1 | 9.3 | .196 | 26 |

**Experimental Errors.**—Our best estimate of the maximum error in the runs with intermittent titration for hydrogen ion is ± 6% in the rate constant or time value for 50% reaction. This corresponds to a 2.0% analytical error in the 50% point if the zero point is correct, or a 1.0% error in opposite directions in each. In the polarographic chloride runs a reasonable estimate of the maximum uncertainty is about ± 10% in rate constant. The largest uncertainty in the runs with intermittent titration was in the matching of color against the standard color at the zero point and endpoints. This was greatest with the *p*H 5.1 indicator and the *p*H 8.0 indicator in runs with sodium monothiophosphate added where it amounted to ± 0.015 cc. (± 1.5 divisions on the microburet) or 0.9% of the total reaction. The "time of mixing" error was under five seconds (3% in rate constant at 50% reaction). Standardization of glassware and factors of solutions were accurate to 0.5% (< 2% in rate constant), temperature control to 0.05°, *p*H of end-points to 0.2 *p*H unit, solution volume to 2%, ionic strength to 2%. In the polarographic runs the larger 3% error in individual chloride values was due to electrolysis at the dropping electrode and local depletion of the chloride concentration near the drop during the run.

**Effect of Dimerization.**—Since the absolute chloride and hydrogen ion values are the same within experimental error during the first 70% of reaction, it is clear that the C–C dimer, $HOCH_2CH_2SCH_2CH_2S^+(CH_2CH_2Cl)CH_2CH_2OH\text{-}Cl^-$, does not accumulate as an intermediate during the early stages of the reaction. Such an accumulation would be kinetically equivalent to accumulation of $C^+$.

The average final end-point in 15 runs without added thiophosphate was 1.700 cc., with an average deviation of 0.017 cc. The average endpoint in three runs with added thiophosphate was 1.737 cc., with an average deviation of 0.018 cc. This 0.037 cc. difference in endpoint is outside the experimental error and corresponds to the production of 2.2% of the hydrolyzed dimer, $HOCH_2CH_2SCH_2CH_2S^+(CH_2CH_2OH)_2Cl^-$, in the runs without thiophosphate added. However, there is an uncertainty in this value of at least ± 50%. Two sets of paired runs, with and without thiophosphate added, indicated only 1.2% dimer. In the preceding analysis of the experimental data we have neglected the effect of this dimer formation and based percentage reaction on the final endpoints actually observed in each individual run. If 2.2% of the carbon were sidetracked by dimer formation, and half of this dimer were formed by the time of 50% reaction there would be no error resulting from this procedure. Even if we assume that as little as one quarter of the total dimer is formed up to 50% reaction, the time and rate constant at 50% reaction would still be in error by less than 3.5%. This is less than the experimental error. If we had done kinetic runs with the initial molarity of C greater

than 0.001 $M$, it would have been necessary to take this dimerization into account in the quantitative treatment.

## Summary

The rate of hydrolysis of $\beta,\beta'$-dichlorodiethyl sulfide (mustard gas) and of $\beta$-chloro-$\beta'$-hydroxydiethyl sulfide (mustard chlorohydrin) in aqueous solution containing 5% of acetone at 25° has been measured at different concentrations of chloride and monothiophosphate ions and at controlled ionic strength. The rate of liberation of hydrogen ions, measured by the intermittent titration method of Peters and Walker, is identical within the experimental uncertainty with the rate of liberation of chloride ions, followed polarographically with a short-period galvanometer, a fact which shows that neither ethylenesulfonium ions nor any dimeric sulfonium ions accumulate appreciably during reaction.

The results of 17 runs on mustard chlorohydrin and 11 runs on mustard have been interpreted in some detail by means of the mechanistic scheme of eq. 1, involving a rate-determining formation of an ethylenesulfonium ion followed by competition for this ion by water, chloride ion and other competitors such as thiophosphate ion, all at rates much greater than that of the initial cyclization. The "competition factor" of chloride ion, defined as the ratio of the rate constants for reaction of the ethylenesulfonium intermediate with chloride ion and with water, is shown to be independent of the chloride ion concentration at constant ionic strength, but to depend upon ionic strength in a manner predictable from the Brønsted rate equation and the limiting Debye–Hückel law for the activity coefficient of an ion.

By first determining the strictly unimolecular rate constant (0.260 ± 0.016 min.$^{-1}$) for hydrolysis or displacement of mustard chlorohydrin and then introducing this into the equation for two successive unimolecular reactions, the first rate constant for mustard has been calculated as 0.155 ± 0.010 from the data covering the two steps in its hydrolysis to thiodiglycol, which are not resolvable by any simpler method. From this constant and the data for displacement of the two chlorines successively by monothiophosphate, the constant for cyclization of the S-2-(2-chloroethylthio)-ethyl monothiophosphate ion is determined to be 0.70 ± 0.05. The fact that this ion cyclizes more than twice as fast as mustard chlorohydrin produced, in earlier experiments, the false appearance of mustard having a faster initial reaction in the presence of thiophosphate than in its absence.

# Kinetics and Mechanism of the Reactions of Tertiary $\beta$-Chloroethylamines in Solution. III. $\beta$-Chloroethyldiethylamine and tris-$\beta$-Chloroethylamine[1]

BY PAUL D. BARTLETT, SIDNEY D. ROSS AND C. GARDNER SWAIN

In the first[2] and second[3] papers of this series the existence of a general mechanism was established whereby a tertiary $\beta$-chloroethylamine undergoes internal cyclization to an ethylene-immonium ion as a first step common to hydrolysis, dimerization and displacement reactions. By quite different methods in the cases of methyl-bis-$\beta$-chloroethylamine and ethyl-bis-$\beta$-chloroethylamine it was possible to determine the separate rate constants for the steps in this mechanism, and to show how the observed difference between predominating hydrolysis and predominating dimerization rested upon moderate differences between the relative values of the constants for these two homologs.

Two other tertiary $\beta$-chloroethylamines have been examined more briefly and such quantitative information about them as was obtained is here presented. In the case of $\beta$-chloroethyldiethylamine the ethylene-immonium ion is comparatively stable and its formation can be observed uncomplicated by other reactions. We have not determined the rates of reaction of this ion with displacing reagents, although such measurements should present no difficulties. In the case of tris-$\beta$-chloroethylamine hydrolysis occurs to bis-$\beta$-chloroethylethanolamine hydrochloride with much less accumulation of the intermediate ethyleneimmonium ion than in the previous cases; in this respect this amine is intermediate between the other "nitrogen mustards" and $\beta,\beta$-dichlorodiethyl sulfide ("mustard gas").[4] In the presence of alkali to neutralize the liberated hydrochloric acid, the hydrolysis proceeds through successive stages to triethanolamine.[5]

## Experimental

**Preparation of β-Chloroethyldiethylamine.**—Thionyl chloride (166.6 g., 1.4 moles) in 75 cc. of chloroform was added dropwise with external cooling to diethylethanolamine (117 g., 1 mole) in 75 cc. of chloroform. The reaction was extremely vigorous and was moderated by the addition of a further 75 cc. of chloroform. After the addition was complete the reaction flask was removed from the ice-bath and heated for six hours in an oil-bath at 65°. The solvent was removed *in vacuo;* the solid was filtered off, washed with ligroin and acetone, and finally recrystallized from acetone containing a little alcohol after decolorization with Norit. The hydrochloride thus obtained melted with decomposition at 205°. After recrystallization the hydrochloride was used for the preparation of the free amine just before each run in the same manner described for methyl-bis-β-chloroethylamine.[2]

**Isomerization of β-Chloroethyldiethylamine.**—The kinetic procedure was essentially that of Part I.[2] This amine is a strong enough base so that hydrochloric acid can be titrated in the presence of the amine hydrochloride using methyl orange as an indicator. In the run shown in Table I the appearance of chloride ion in 1:1 acetone–water at 25° was followed by Volhard titrations of the aqueous

extract, and the disappearance of basic nitrogen was followed by extracting the benzene extract with standard hydrochloric acid and back-titrating to the methyl orange end-point. The two sets of figures for the degree of reaction agree within 2.5%. The unimolecular rate constant is 0.198 min.$^{-1}$. Tables II and III show two similar runs with and without the addition of sodium chloride. The

unimolecular plots, shown in Fig. 1, yield rate constants of 0.203 and 0.204 min.$^{-1}$, respectively. The lack of inhibition by chloride ion is accompanied by normal unimolecular kinetics, but with a slowing beyond 90% reaction which suggests reversibility.

A reaction of β-chloroethyldiethylamine proceeding with first-order kinetics and liberating all of the chlorine of the compound in ionic form might be (a) cyclization to the ethylene-immonium salt, (b) dimerization to a bisquaternary piperazinium salt, or (c) hydrolysis. Only in case (a) would the addition of hydrochloric acid to the solution, followed by evaporation to dryness *in vacuo*, be expected to reverse the reaction and yield β-chloroethyldiethylamine hydrochloride. This experiment was carried out and yielded 93.5% of a solid melting with decomposition at 203–204° (m. p. of β-chloroethyldiethylamine hydrochloride, 205°) and yielding on analysis 21.39% ionic and 39.09% total chlorine (calcd. for β-chloroethyldiethylamine hydrochloride, 20.60% and 41.20%). These results correspond to a mixture of 86% β-chloroethyldiethylamine hydrochloride and 14% diethylethanolamine hydrochloride or the bisquaternary piperazinium dimer, indicating that the solution on which the kinetic study was made contained at the end at least 86% of the unhydrolyzed ethylene-immonium ion.

Comparison of the glass-electrode potentials of half neutralized hydrochlorides by the method described in Part II,[2] indicated the following ratios of base strengths

$$\frac{K_B \text{triethylamine}}{K_B \text{ diethylethanolamine}} = 7.3$$

$$\frac{K_B \text{ triethylamine}}{K_B \text{ diethyl-β-chloroethylamine}} = 460$$

An attempt to follow the rate of formation of the cyclic intermediate by the thiosulfate titration[6] failed, since this

(6) C. Golumbic, J. S. Fruton and M. Bergmann, *J. Org. Chem.*, **11**, 518, 536 (1946).

reagent did not react rapidly enough with the intermediate. The rate of this slow reaction with thiosulfate was later measured by Cohen.[7]

TABLE IV

HYDROLYSIS AND DIMERIZATION OF TRIS-β-CHLOROETHYLAMINE IN 2:1 ACETONE–WATER AT 25° (0.0363 *M* AMINE)

**tris-β-Chloroethylamine.**—Table IV gives the results of a run on this amine in which the appearance of chloride ion was followed by Volhard titration while the appearance of hydrogen ion was followed by titration with sodium hydroxide using thymolphthalein as indicator. The figures obtained by the two methods are close together early in the reaction, indicating that the reaction is chiefly hydrolysis. A divergence later between the alkali and silver titers suggests that with low hydroxyl ion concentrations as much as 20% of the total reaction may be dimerization.

Beside the divergence between the curves of chloride ion and hydrogen ion production, and the upward concavity of the latter curve, the plot of these results (Fig. 2) shows two other peculiarities. The reproducibility does not seem

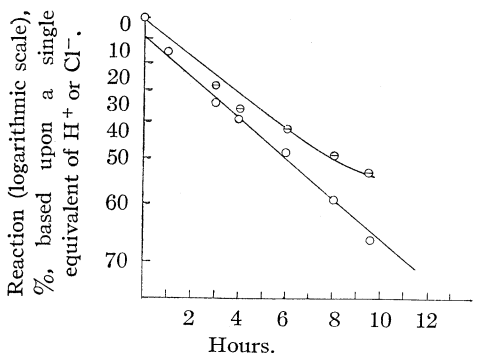

Fig. 2.—Reaction of tris-β-chloroethylamine in 2:1 acetone–water at 25°, followed by titration with sodium hydroxide (⊖) and with silver nitrate (O).

to be as good as that in the slower runs with sodium chloride added and the faster runs with sodium hydroxide, described below. Also in contrast to these other runs, the lines of per cent. reaction against time on a logarithmic plot do not pass through zero at zero time, but rather through about 10% reaction. The probable interpretation of this is as follows. The actual cyclization step (see Fig. 3) is about three times as fast as the liberation of chloride ion in this run, and the reaction proceeds initially at the rapid rate until enough chloride ion is accumulated to make the reversal of the initial cyclization step an important competitor with the hydrolysis. The 10% discrepancy corresponds to the approximate amount of ethylene-immonium ion which accumulates in this earliest stage of the reaction. This immonium ion reacts rapidly with hydroxyl ion in the titration and hence registers as hydrogen ion. The roughness of the "acid" line in this plot suggests that the completeness of the reaction between hydroxyl ion and the immonium ion is a function of the time elapsed during the titration.

In predominance of hydrolysis and in relatively slight

(7) Barnet Cohen, N. D. R. C. reports, 1943.

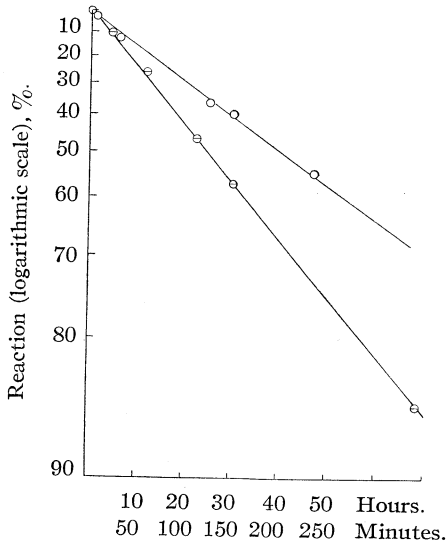

Fig. 3.—Upper curve, hydrolysis of tris-β-chloroethylamine in 2:1 acetone–water containing sodium chloride (upper time scale); lower curve, hydrolysis of tris-β-chloroethylamine in 2:1 acetone–water containing sodium hydroxide (lower time scale).

accumulation of the cyclic intermediate, tris-β-chloroethylamine is more like β,β′-dichlorodiethyl sulfide (mustard gas) than are the other amines, and forms a connecting link between the comparatively simple kinetics of hydrolysis of mustard and the complex situation with methyl-bis-β-chloroethylamine. The lower basic strength (and perhaps also the greater branching in space) of the trichlorinated amine causes a decrease in $k_2$ (and also $k_1$) relative to $k_w$.[8]

The basic dissociation constants measured in this medium in the same way as in the case of diethyl-β-chloroethylamine, are

$$\frac{K_B \text{ triethylamine}}{K_B \text{ triethanolamine}} = 210$$

$$\frac{K_B \text{ triethylamine}}{K_B \text{ tris-β-chloroethylamine}} = 1.5 \times 10^7$$

These results indicate a ratio of basic strengths in 2:1 acetone–water of $3.3 \times 10^4$ for diethyl-β-chloroethylamine and tris-β-chloroethylamine, as compared with the ratio of $2.7 \times 10^4$ in water.[9]

With sodium chloride added to the solution the reaction became very much slower and truly unimolecular with no initial rapid reaction. There was certainly less than 3% cyclic intermediate concentration at any time in the run at an initial amine concentration of 0.0384 with 0.0955 *M* sodium chloride added. The rate in this run was 5.2% of that in the likewise unimolecular run with 0.208 *M* hydroxyl ion added, which practically eliminated reversal of the first step (Fig. 3). The latter run gives $k_1$ as $5.5 \times 10^{-3}$ min.$^{-1}$.

In pure unbuffered water as a solvent, bis-β-chloroethylethanolamine hydrochloride is the principal final reaction product. However, the ethyleneimmonium ion (called "B" in Part I[2] and below) accumulates to a substantial extent in water. This is shown by the fact that hydrogen ion production did not become appreciable until the chloride ion concentration had reached 0.006 *M* in a solution kept saturated with amine. The difference between chloride and hydrogen ion concentration at this point cannot be due to cyclic dimer, for this would not

(8) See the mechanism presented in Part I (ref. 2).

(9) B. Cohen, E. R. VanArtsdalen and J. Harris, THIS JOURNAL, **70**, 282 (1948).

give rise to hydrogen ion later; therefore this difference between titers is largely a measure of cyclic intermediate.

The reaction in water was studied by the technique which was successfully applied by Wilson[10] and more recently by Northrop[11] to the kinetic study of mustard. This technique consists in simplifying the kinetics by keeping the solution essentially saturated with starting material at all times by means of vigorous stirring of the solution with pure amine. In the presence of sufficient amounts of added chloride or hydroxyl ion the reaction shows zero-order kinetics; without any added electrolyte the rate of production of chloride ion decreases during reaction on account of the reversibility of the initial step and the diminution of the steady-state concentration of the cyclic intermediate B. Figure 4 shows the data for a typical run.

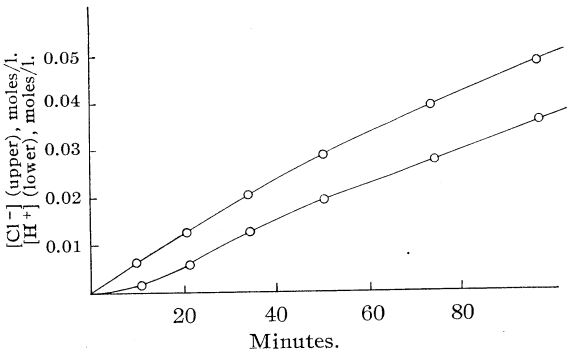

Fig. 4.—Reaction of tris-β-chloroethylamine in saturated aqueous solution at 25°, followed by titration with sodium hydroxide (lower) and with silver nitrate (upper curve).

After hydrogen ion production has begun and approximately reached the rate of further chloride production we can set the rate of change of (B) equal to zero and derive the approximate relation

$$(B) = \frac{k_1 c}{k_{-1}(Cl^-) + k_w}$$

where $c$ is the solubility of the amine in water. The rate of appearance of chloride ion is

$$\frac{d(Cl^-)}{dt} = k_1 c - k_1(B)(Cl^-) = k_1 c \frac{k_w}{k_{-1}(Cl^-) + k_w}$$

This derivative is equal to the slope of the curve of $(Cl^-)$ as a function of time. If we denote this slope by $S$, and its value at zero time by $S_0$, then by substitution in this equation we get

$$\frac{S_0 - S}{S} = \frac{k_{-1}}{k_w}(Cl^-)$$

from which the ratio $k_{-1}/k_w$ can be estimated graphically. The average of a number of such determinations in a run without added chloride was 17, the maximum deviation from the mean being about 10%. From a run with 0.1433 $M$ sodium chloride added, the ratio was estimated to be 18.

From the extent to which hydrogen ion production lags behind chloride ion, the concentration of intermediate at the steady state can be estimated as of the order of 0.012 molar.

Because of the reactivity of tris-β-chloroethylamine toward water, its solubility cannot be determined by the usual methods. The solubility was determined by combining the value $k_1 c$ = 0.00062 mole/liter min., which is the initial slope of a plot of chloride ion concentration *vs.* time, with the value of $k_1$ = 0.310 min.$^{-1}$ at 25° determined by Cohen.[7] The solubility in water at 25° is thus found to be 0.0020 mole per liter.

(10) R. E. Wilson, E. W. Fuller and M. O. Schur, THIS JOURNAL, **44**, 2762 (1922).

(11) J. H. Northrop, N. D. R. C. Reports, 1943.

In all these runs, there being no buffer present, the reaction comes to a virtual stop when one equivalent of chloride has been produced per mole of reacting amine. Because a hydroxyethylamine is a somewhat stronger base than a chloroethylamine and will hence combine preferentially with the acid present, the bulk of the product would be expected to be the bis-β-chloroethylethanolamine hydrochloride. This product has been isolated as the picrylsulfonate in yields of 93%.[12]

## Discussion

In Table V are summarized the rate constants in 2:1 acetone–water solution which have been determined for the four *t*-β-chloroethylamines studied in this series of researches. Among the three successively chlorinated triethylamines the rate of initial cyclization falls, and the reactivity of the ethylene-immonium ion rises, with decreasing basicity of the original amine. (This fact is apparent qualitatively from the stability, partial accumulation, and non-accumulation of the ethylene-immonium ion, respectively, in the successively chlorinated triethylamines.) From this regularity it might be guessed that β,β′-dichlorodiethyl sulfide, which is still less basic than tris-β-chloroethylamine and otherwise chemically analogous to it, would show still less accumulation of cyclic intermediate during its reaction in aqueous media, as is the case. The steady decrease in rate of cyclization ($k_1$) is in accord with the picture of an intramolecular displacement of the $S_N2$ type,[13] since successively weaker bases are being used as nucleophilic reagents. The steady increase in reactivity of the ethylene-immonium ions with chloride ion ($k_{-1}$) may be due to the increased electron deficiency on the ring carbon atom being attacked, caused by increasing chlorination of the molecule.

The differences shown in the table between methyl- and ethyl-bis-β-chloroethylamine are substantial, and one might be inclined to question their reality in view of the entirely different ways in which the constants were determined in the two cases. However, differences of this magnitude must necessarily exist between two compounds which show the qualitative differences in behavior in solution noted with these two homologs. The differences can be summarized by saying that the ethylene-immonium ion of the ethyl compound is formed faster than that of the methyl compound and reacts faster toward every reagent except the parent amine ($k_2$). The latter reaction is an alkylation of a methylamine in the one case and of an ethylamine in the other, and rate differences attributable to steric hindrance have been observed in such cases. On the other hand, steric hindrance of this type does not appear to be so important a factor in ring closure,[14] and would not be expected to dominate the opening of a three-membered ring by water or by a small ion at an

[a] $\Delta pK_A$ is defined in Part II, THIS JOURNAL, **69**, 2977 (1947). [b] I = internal cyclization. [c] At the ionic strength prevailing when initial amine concentration = 0.1501. [d] H = hydrolysis. [e] D = dimerization. [f] At the ionic strength prevailing when initial amine concentration = 0.118.

unbranched carbon atom, in the reactions to which $k_{-1}$ and $k_w$ refer. The greater rate of cyclization of the ethyl over the methyl compound in water is largely a matter of entropy of activation;[9] there may even be some release of steric interference with the ethyl group associated with the conversion of one of its neighbor groups into a ring.

## Summary

In connection with the mechanism of hydrolysis, dimerization and displacement reactions of methyl-bis-β-chloroethylamine and ethyl-bis-β-chloroethylamine, studied in Parts I and II of this series, respectively, two related compounds have been examined kinetically. β-Chloroethyldiethylamine in 2:1 acetone–water solution undergoes cyclization to diethylethylene-immonium chloride without complicating reactions, and more rapidly than its analogs previously studied. tris-β-Chloroethylamine is hydrolyzed slowly, with 10% or less accumulation of bis-β-chloroethylethylene-immonium chloride as an intermediate in the reaction in 2:1 acetone–water solution. The kinetics of its hydrolysis has also been studied in water kept saturated with the amine by vigorous stirring. A table is given comparing the individual rate constants in the reactions of the several amines studied in 2:1 acetone–water solution, and the variation of these rate constants with structure is interpreted in part.

# The Kinetics of the Decomposition of Potassium Persulfate in Aqueous Solutions of Methanol

BY PAUL D. BARTLETT AND JOHN D. COTMAN, JR.

## Introduction

It has been known for some time that the decomposition of a diacyl peroxide in an organic solvent may be, in its over-all course, a reaction between the peroxide and the solvent.[1–6] Recently three lines of evidence have pointed to the fact that often this participation of the solvent has the character of a chain reaction, free radicals arising in the process being able to induce the decomposition of further peroxide.[4–6] Such chain-induced decomposition is revealed (1) by great differences in the rates of decomposition of the same peroxide in different solvents, (2) by characteristic order of reaction, (3) by inhibition of the chain reaction by typical inhibitors, and (4) by the nature of the products.

The decomposition of potassium persulfate, an analog of the diacyl peroxides, has been much studied in water.[7–10] In solutions buffered against the accumulation of hydrogen ion, the decomposition follows the over-all course

$$2^-OSO_2O—OSO_2O^- + 2H_2O \longrightarrow 4HSO_4^- + O_2$$

and is thus, as with diacyl peroxides, a reaction between the peroxidic substance and the solvent. However, in contrast to the decomposition of diacyl peroxides in organic solvents, the reaction is strictly of the first order,[7–9,11] and it has not been observed to be retarded by any inhibitor. Although two of the three marks of chain decomposition are thus lacking, the effect of organic substances on the rate of persulfate decomposition is striking. Saturation of the buffered aqueous solution of potassium persulfate with ethyl acetate[11] caused an eightfold increase in the rate of its decomposition. Methanol was observed by Marie and Bunel[12] to have a similar accelerating

effect upon the decomposition of persulfate. Instances of the oxidation of organic compounds by persulfate suggest rather general attack of persulfate or radicals from persulfate[13] upon the C–H link. Because of these facts it was of interest to us to investigate the mechanism of the accelerating effect of an organic compound in aqueous solution upon the decomposition of persulfate. We chose methanol because of its unlimited solubility in water, its availability in high purity, and the hope of an easy quantitative determination of its fate in the reaction.

## Experimental Procedure

The potassium persulfate and methanol used were reagent grade.

Persulfate was titrated by a modification of the method recommended by Rosin.[14] The solution to be analyzed was made 1 *M* in potassium iodide and one gram of sodium bicarbonate was dissolved in it. To this sample was added 20–25 cc. of 10% sulfuric acid. During and after the liberation of the carbon dioxide, which provided a convenient means of sweeping out the oxygen, the solution stood in a glass-stoppered flask. After standing for thirty minutes in the dark at room temperature, the liberated iodine was titrated with standard thiosulfate. Five test samples titrated by this method showed persulfate amounting to 99.4, 100.2, 99.0, 100.2 and 99.6% of the theoretical. In the absence of methanol satisfactory results were had by the titration method of Müller,[15] which consists of boiling an aliquot for three minutes with potassium iodide and 2 *M* sodium hydroxide. The resulting mixture of iodide and iodate is acidified and the iodine titrated. Methanol interferes with this method.

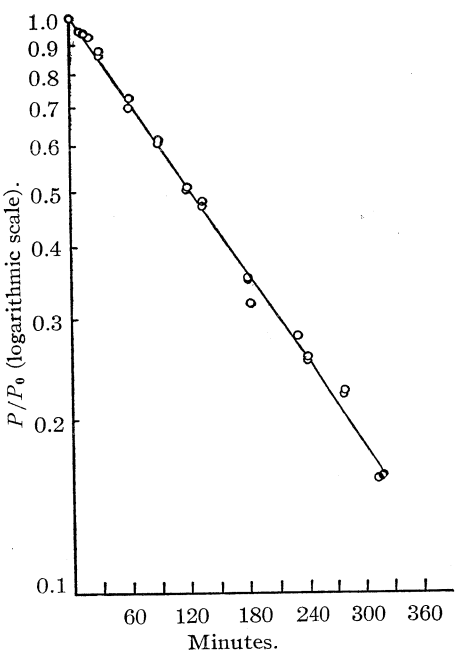

Fig. 1.—Decomposition of potassium persulfate at concentration from 0.00240 to 0.0134 *M* in water at *p*H 8 at 79.8 ± 0.05° (four runs).

A stock buffer solution was prepared which was 0.003 *M* in monopotassium phosphate, 0.097 *M* in the ion $HPO_4^{=}$ (by adding sodium hydroxide), and 0.1 *M* in potassium sulfate. The *p*H and ionic strength were thus maintained at the same value in all the runs.

To minimize the decomposition of persulfate during heating before the addition of the methanol, about 200 cc. of the buffered solvent was first brought to 80° in the thermostat. This hot solvent was then added to the freshly prepared solution of weighed solid potassium persulfate dissolved at room temperature in about 50 cc. of the solvent the system made up to volume in a volumetric flask and reimmersed in the thermostat for about twenty minutes, when it had reached the temperature of the bath. Then 20 cc. of methanol, preheated in a bulb to 80°, was forced through a tube under its own vapor pressure into the reaction vessel. This rapid addition resulted in efficient mixing. There was some 15% decomposition of the persulfate prior to the admission of the methanol. Aliquot portions of the reacting solution were taken with a pipet at successive times and titrated by the procedure described.

The presence of formaldehyde in a solution in which the persulfate had decomposed in the presence of methanol was demonstrated by the formation of a silver mirror with Tollens reagent and by the isolation of the 2,4-dinitrophenylhydrazone of formaldehyde, fluffy yellow needles, m. p. 161–163°. Thereafter formaldehyde was titrated in the product solutions by the method of Romijn,[16] with which methanol and formic acid are said not to interfere.[17]

## Results

Figure 1 shows a logarithmic plot of four runs on the decomposition of persulfate at 79.8° without added methanol. The initial persulfate concentrations in these runs were 0.00240, 0.00241, 0.0131 and 0.0134. The agreement of all these runs, as well as the linearity of the plots over 85% decomposition of the persulfate, confirms the first-order character of the decomposition in the absence of added organic compounds.

The qualitative effect of the addition of 0.976 *M* methanol can be observed by making a similar logarithmic plot of the data in this case. The initial apparent first-order rate constant is 0.140 in the presence of methanol. This substance when present in a concentration of about 1 *M* thus accelerates the decomposition of persulfate by a factor of 25.

In addition to its accelerating effect upon the decomposition of persulfate, the presence of methanol changes the order of the reaction so that the logarithmic plots are no longer linear. Straight lines are obtained, however, for all the runs involving methanol if the reciprocal of the square root of persulfate concentration is plotted against time (plot of a 3/2 order reaction) as is done in Fig. 2 for a typical run. Table I summarizes the values of the 3/2 order rate constants so determined, for three different concentrations of methanol. The rate constants are not proportional to the methanol concentration, but appear to vary with its square root. That this change in rate is also as-

(13) See, for example, C. Moritz and R. Wolfenstein, *Ber.*, **32**, 432, 2531 (1889), on the oxidation of toluene and ethylbenzene, and E. Bekier and S. W. Kijowski, *Rocznicki Chem.*, **15**, 136 (1935) (*Chem. Abst.*, **30**, 3306 (1936)), on the oxidation of acetone catalyzed by silver ion.

sociated with a change in the over-all course of the reaction is shown by a series of titrations for formaldehyde, conducted on the solutions after reaction was complete, and included in Table I.

Of the values of $k_{3/2}$ listed in Table I, the value for 1.464 *M* methanol is the result of a single run; that for 0.976 *M* methanol is the average of five runs yielding constants of 0.807, 0.785, 0.781, 0.813 and 0.780; the constant for 0.488 *M* methanol is the average of three runs yielding constants of 0.610, 0.640 and 0.647.

In a study of the polymerization of allyl alcohol in aqueous solution made in this Laboratory in 1944,[18] the decomposition of the initiating persulfate was observed to deviate from first-order kinetics. Because of the polymerization occurring, the nature, functionality, and concentration of the alcohol was changing during these experiments; however, we have now found that in the one experiment with a high concentration of allyl alcohol (6.30–5.02 *M* during the run) the decomposition of persulfate was clearly of the 3/2 order, while in the other experiments the kinetics more closely approximates this order than it does first order. In the presence of the high concentration of allyl alcohol at 55° the 3/2 order rate constant was 0.33 liters$^{1/2}$ moles$^{-1/2}$ min.$^{-1}$.

RATE CONSTANTS AND FORMALDEHYDE FORMATION IN THE DECOMPOSITION OF 0.015 *M* POTASSIUM PERSULFATE AT 79.8° ± 0.05° AT *p*H 8

| Initial methanol concn., moles/l. | $k_{3/2}$ liters$^{1/2}$ moles min.$^{-1}$ | $k_{3/2}/\sqrt{[CH_3OH]}$ | Per cent. formaldehyde, based on peroxide decomposed |
|---|---|---|---|
| 1.952 | .. | .. | 100.5 |
| 1.464 | 1.04 | 0.86 | 99.1 |
| 0.976 | 0.79 | .80 | 92.9 |
| 0.488 | 0.63 | .90 | 82.8 |
| 0.195 | .. | .. | 72.9 |

## Discussion

At no point in the investigation has any evidence appeared that the decomposition of persulfate ion can be induced by any radicals normally involved in its aqueous decomposition. Therefore the simplest interpretation of the mechanism is by some such scheme as the following

$$S_2O_8^{=} \xrightarrow{k_1} 2SO_4^{-\cdot} \qquad (1a)$$

$$SO_4^{-\cdot} + H_2O \xrightarrow{k_2} HSO_4^{-} + OH\cdot \qquad (2)$$

$$2OH\cdot \xrightarrow{k_3} H_2O + {}^1/_2O_2 \qquad (3)$$

Although there are two kinds of free radicals involved in this chain, admitting of three possible chain-terminating steps, yet the order of the reaction tells us that the sulfate ion radicals $SO_4^{-\cdot}$ do not recombine with one another appreciably, for if they did so the reaction would be of half order with respect to persulfate ion, and even a small contribution from such a recombination would make the observed first-order rates vary with initial concentration of persulfate. Furthermore, if sulfate ion radicals and hydroxyl radicals combined they would form Caro's acid, which Palme[10] found to be absent under these experimental conditions. The inclusion of Equation 3 in the above scheme does not imply the exclusion of a similar disproportionation between a hydroxyl radical and a sulfate ion radical. It seems, however, that with water as the solvent Equation 2 represents the most probable fate for the sulfate ion radical. It will be noted that although the sequence Equations 1–3 involves free radicals, initiation, termination and transfer, there is no chain propagation reaction in the sense of attack on the starting material by radicals.

(18) M. E. Fleischer, unpublished experiments.

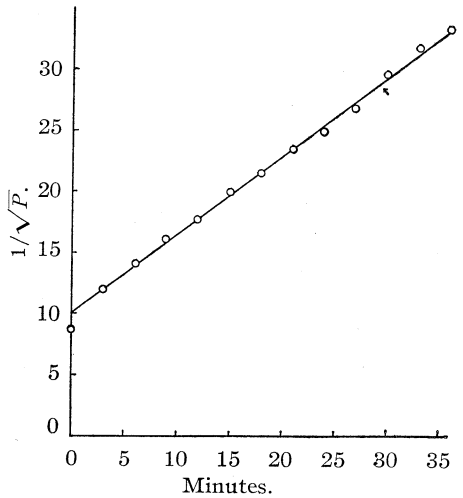

Fig. 2.—Decomposition of persulfate (0.01375 *M*) at 79.8° and *p*H 8 in presence of 0.488 *M* methanol, plotted as a 3/2 order reaction. The arrow marks 90% reaction.

By comparison of the over-all rates of decomposition of persulfate with and without methanol present we may conclude that in 1 *M* methanol 96% of the persulfate ions disappear by being attacked by a free radical other than those present in the water reaction. This new free radical must also be one which is present at a steady-state concentration proportional to the square root of the concentration of persulfate ions. These requirements are met by the following scheme.

$$S_2O_8^{=} \xrightarrow{k_{1a}} 2SO_4^{-\cdot} \qquad (1a)$$

$$S_2O_8^{=} + CH_3OH \xrightarrow{k_{1b}} HSO_4^{-} + SO_4^{-\cdot} + CH_2OH\cdot \qquad (1b)$$

$$SO_4^{-\cdot} + CH_3OH \xrightarrow{k_4} HSO_4^{-} + CH_2OH\cdot \qquad (4)$$

$$CH_2OH\cdot + S_2O_8^{=} \xrightarrow{k_5} HSO_4^{-} + SO_4^{-\cdot} + CH_2O \qquad (5)$$

$$2CH_2OH\cdot \xrightarrow{k_6} CH_3OH + CH_2O \qquad (6)$$

It would of course be possible that Reaction 2 should occur here as well as in the absence of methanol, and the methanol be attacked by the result-

ant hydroxyl radicals instead of directly by sulfate ion radicals. In the related problem of the emulsion polymerization of allyl acetate,[11] although the concentration of the organic compound in the aqueous phase was considerably less than here, it was definitely shown that at least 75% of the polyallyl acetate chains were initiated by sulfate ion radicals rather than by hydroxyl radicals.[19] Allyl acetate, therefore, competes very successfully with water for the sulfate ion radicals, and it seems probable that methanol does likewise.

The sequence of steps 1a–4–5–6 leads to the kinetic equation

$$\frac{-\mathrm{d}(S_2O_8^{=})}{\mathrm{d}t} = k_{1a}(S_2O_8^{=}) + k_5\sqrt{\frac{k_{1a}}{k_6}}(S_2O_8^{=})^{3/2} \quad (7)$$

It is reasonable in view of the strong acceleration by methanol that the second term of this expression should be more important than the first, and such a mechanism would therefore predict the observed 3/2 order kinetics. The sequence of steps 1b–4–5–6 leads to the slightly different equation

$$\frac{-\mathrm{d}(S_2O_8^{=})}{\mathrm{d}t} = k_{1b}(S_2O_8^{=})(CH_3OH) + k_5\sqrt{\frac{k_{1b}}{k_6}}(S_2O_8^{=})^{3/2}(CH_3OH)^{1/2} \quad (8)$$

This equation, again with neglect of the first term on the right, predicts not only the 3/2 order of the reaction but also the linear dependence of the rate constant on the square root of methanol concentration (Table I). Equations (7) and (8) are derived on the assumption that every sulfate ion radical reacts with methanol to produce a hydroxymethylene radical. As the concentration of methanol is reduced to the point where this is no longer true, Equations 1–6 predict that an increasing fraction of the sulfate ion radicals will react with water (or possibly with the accumulating formaldehyde), leading to shorter chains and smaller total amounts of formaldehyde, as observed.

It is assumed that the removal of hydrogen from methanol occurs from carbon, leading to a hydroxymethylene radical rather than from oxygen to yield a methoxyl radical, since the relative normal energies of the C–H and O–H bonds (87.3 and 110.2 kcal. mole, respectively)[20] make the former process seem much the more probable.

Reaction 5, as depicted, may well be an over-all process which actually occurs in two steps

$$CH_2OH\cdot + S_2O_8^{=} \longrightarrow SO_4\dot{-} + HOCH_2OSO_3^{-} \quad (5a)$$

$$HOCH_2OSO_3^{-} \longrightarrow CH_2O + HSO_4^{-} \quad (5b)$$

Very little is known as yet concerning the mode of attack of free radicals upon peroxides in the induced decomposition.

Finally, there is no definite evidence for Equation 6 in preference to a direct union of the two hydroxymethylene radicals to yield ethylene glycol. The high yield of formaldehyde is scarcely conclusive on this point, since the chains are obviously long enough to limit the occurrence of chain-termination products to a few per cent. of the total. Any of these indicated variations could be introduced into the proposed reaction scheme without vitiating its kinetic consequences.

It should be noted that the evidence for the absence of chain decomposition of persulfate in water in the absence of organic compounds is of a negative character and is not altogether complete. In the decomposition of benzoyl peroxide in ether solutions the kinetics, as here, is that of a first order reaction, yet induced decomposition is readily suspected because the reaction is so much faster than in other solvents, and the presence of free radicals other than those of oxygen is shown by the uptake of oxygen during the reaction with the formation of new peroxides. In the case of persulfate decomposing in water solution there can be no free radicals other than those of oxygen, and oxygen-sensitivity is therefore not to be expected even if a long chain reaction were taking place. There is a possible mechanism for this reaction which includes induced decomposition of persulfate ions by hydroxyl radicals, and which still predicts decomposition of the first order. Such a mechanism includes adding to Equations 1a and 2 the following

$$OH\cdot + S_2O_8^{=} \xrightarrow{k_9} HSO_4^{-} + SO_4\dot{-} + {}^1/_2O_2 \quad (9)$$

$$OH\cdot + SO_4\dot{-} \xrightarrow{k_{10}} HSO_4^{-} + {}^1/_2O_2 \quad (10)$$

The induced decomposition of persulfate by hydroxyl radicals will be of the first order now only if Equation 10 represents the mode of chain termination rather than Equation 3. This possibility is mentioned only for completeness; as far as our evidence goes, persulfate decomposition in water may well be an example of the case, unusual to date, in which the spontaneous, unimolecular decomposition is uncomplicated by any induced process involving the free radicals of the chain.

## Summary

The decomposition of potassium persulfate at 79.8° in aqueous solution at *p*H 8 is strictly of the first order, with no evidence of induced decomposition by free radicals analogous to that observed in the decomposition of diacyl peroxides in organic solvents. The presence of methanol or allyl alcohol accelerates the reaction (as much as 25-fold in the case of methanol) and the alcohols change the reaction to one of 3/2 order. In the reaction with methanol formaldehyde is produced, its amount being equivalent to the persulfate decomposed when the initial methanol is 1.5 *M*, and becoming less at lower methanol concentrations. Mechanisms are presented to account for these observations.

CAMBRIDGE, MASSACHUSETTS RECEIVED OCTOBER 11, 1948

(19) Of the polymer molecules, 75% contained sulfate end-groups. The fraction of the kinetic chains initiated by sulfate ion radicals must be at least as high as this and may be higher because of chain transfer leading to some polymer molecules without any end-group from the initiator (ref. 11).

# The Critical Point of Nitromethane

BY D. N. GRIFFIN

## Introduction

Up to the present time only calculated values have been available for the critical temperature of nitromethane. The critical point of nitromethane has now been determined experimentally.

Methods for obtaining calculated values for the critical constants are based on other physical constants such as boiling points, surface tensions, and molecular weights. Guldberg[1] and Guye[2] proposed the following rule for obtaining the approximate critical temperature from the boiling point of a substance

$$T_b = 2/3(T_c) \quad (1)$$

where $T_b$ is the absolute boiling point and $T_c$ the absolute critical temperature. Ramsay and Shields[3] proposed the equation

$$\gamma(Mv)^{2/3} = K(t_c - t\ 6) \quad (2)$$

where $\gamma$ is the surface tension, $M$ the molecular weight, $v$ the specific volume, $K$ a universal constant, $t_c$ (°C.) the critical temperature, and $t$ (°C.) the ambient temperature. Boyd and Copeland[4] used the Ramsay–Shields equation in conjunction with their own data on the surface tension of nitromethane and obtained a critical temperature of 623°K. (350°C). Other empirical methods for determining the critical constants have been proposed to give greater accuracy than the Guldberg–Guye rule. Taft and Stareck[5] considered

$$T_f + T_b = T_c \quad (3)$$

where $T_f$ is the absolute freezing point, to be more useful than the Guldberg–Guye rule whereas Lautié[6] proposed

$$4(T_c/T_b) + 10(T_b/T_c) = 12.69 \quad (4)$$

Mei-Chio Chen and Dji-Bin Hu[7] related the critical temperature to the molecular weight as well as to the boiling point in their equation

$$T_c = 10^{1.59/\sqrt{M}}T_b \quad (5)$$

where $M$ is the molecular weight.

The values of the critical temperature of nitromethane as given in Table I were obtained by applying equations (1) through (5).

TABLE I

COMPARISON OF VARIOUS CALCULATED VALUES OF THE CRITICAL POINT OF NITROMETHANE

| Taft and Stareck | (3) | 619 | 346 |
| Lautié | (4) | 640 | 367 |
| Mei-Chio Chen and Dji-Bin Hu | (5) | 597 | 324 |

## Experimental Methods

Experimental methods of determining the critical point are based on the physical transition that takes place at the critical point. If a glass tube is partially filled with a liquid and sealed, the meniscus formed between the liquid and gas phases may be seen to disappear when the system is heated above the critical region, and will reappear when cooled back down through the critical region. The disappearance of the meniscus marks the transition of the liquid to a single gas phase at or near the critical point. Although usually sharply defined, this phenomenon does not necessarily mark the true critical point; instead, it might be considered to occur in the critical region. If the quantity of liquid placed in the tube is either too great or too small, the meniscus will disappear at a temperature below the true critical temperature. This effect is described later in this section. It has also been observed that even after the transition to a single gas phase at the apparent critical point, the density of the gas is not uniform throughout the tube but remains greater in the lower portions. Winkler and Maass[8] reported that the density difference for a fixed available space decreases with a rise in temperature, but is measurable up to at least 10° above the critical point.

When a pure liquid and its vapor co-exist in a closed system, the pressure exerted at a given temperature, that is, the vapor pressure of the liquid at that temperature, is independent of the total quantity of the substance present. Above the critical point, only one phase can exist; hence the pressure, at constant volume, will vary according to the quantity of the substance present. These facts may be applied to the determination of critical constants.

If a plot is made of pressure *vs.* temperature for a sample heated in a constant-volume system, a point of discontinuity in the curve will mark the transition from a liquid–vapor system to a single-phase system. However, this point of discontinuity will correspond to the critical point only if the proper size of sample is used, for if a sample of insufficient size is chosen, it will pass entirely into the vapor phase at some temperature below the critical temperature. Similarly, if a sample is too large, it will expand and entirely fill the tube with liquid before the critical point is reached. If the proper size of sample is chosen, the densities of the liquid and vapor phases become equal at the critical point, and they become a single phase without any discontinuity appearing in the pressure–temperature curve. This density is known as the critical density. Because of the indefiniteness of the point of discontinuity near the critical point, it is necessary to interpolate to the critical density by choosing samples having mean bulk densities both greater and less than the critical density.

Ipatieff and Monroe[9] used the bomb technique to determine the critical points for several substances. To obtain the critical point, they plotted pressure *vs.* temperature. The resultant curve gave a region of discontinuity in the critical region. They stated that they observed no effect

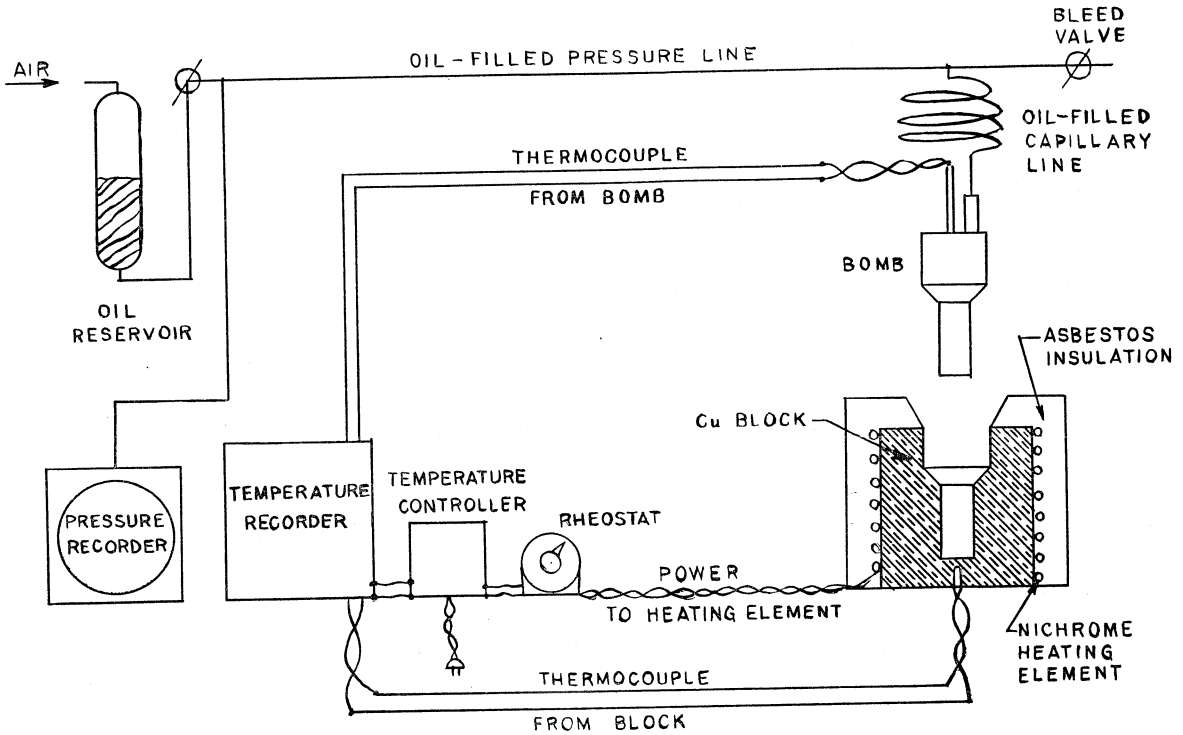

Fig. 1.—Diagram of thermal decomposition apparatus.

when the size of sample was varied, but their method of representing the data graphically failed to show the actual point of discontinuity in each case.

The bomb technique was also used to obtain the critical point of nitromethane. A plot was made of log $p$ *vs.* $1/T$ for each test and compared with a similar plot of the vapor pressure of nitromethane. In each case, a straight line was produced, corresponding to the vapor pressure up to a point at which a sharp break occurred indicating a transition to a single-phase system. The temperature at which the break occurred, and the nature of the curve above that temperature, depended upon the size of the sample used. A plot was then made of these transition points *vs.* sample size. A maximum in the curve occurred at 315°, which was considered to be the true critical temperature $t_c$. The critical density $d_c$ was obtained from the weight of the sample at this point, and the volume of the bomb, whereas the vapor pressure corresponding to the critical temperature was the critical pressure $p_c$.

## Description of Data and Results

Samples of purified nitromethane, varying from 1.5 to 3.5 ml. in volume (1.71 to 3.98 g.), were placed in a stainless-steel bomb having an internal volume of 8.2 ml., and were heated by means of an electrically heated copper block into which the bomb fitted (Fig. 1). The temperature was recorded by a thermocouple located within the bomb and attached to a Leeds and Northrup Micromax recording potentiometer. The pressure was recorded by a Brown Bourdon-type recording gage connected to the bomb by an oil-filled capillary line.

The data used for the vapor pressure of nitromethane were experimental values obtained in work done in the Department of Chemical Engineering of the California Institute of Technology.[10] Experimental values were obtained to above 500 p.s.i.a.; hence extrapolated values up to the critical point were considered valid (Fig. 2).

When log $p$ was plotted against $1/T$ for samples

(10) Unpublished data.

between 1.5 and 2.3 ml. in volume (1.17 and 2.62 g.), the curve at the temperatures above the transition point fell below the vapor pressure line, indicating that all the sample in each case passed into the vapor phase before the critical temperature was reached (Fig. 3). Thus the samples were too small; *i.e.*, the mean bulk densities were less than the critical density for nitromethane. In the case of samples between 2.6 and 3.5 ml. in volume (2.96 and 3.98 g.), the pressures developed above the transition point were in excess of the extrapolated vapor pressure, indicating that the internal volume of the apparatus was entirely filled with expanded liquid (Fig. 4). These samples were therefore too large; *i.e.*, the mean bulk densities were greater than the critical density. A 2.5 ml. (2.84-g.) sample was used, and the resultant log $p$ *vs.* $1/T$ curve showed only a slight deflection in the critical region and had the maximum observed temperature of the transition point (Fig. 5). The mean bulk density of this sample was therefore nearly equal to the critical density.

At temperatures above the critical temperature, slow decomposition of the nitromethane caused an upward trend in the log $p$ *vs.* $1/T$ curves irrespective of the size of the samples used. This effect is evident in Figs. 3, 4 and 5.

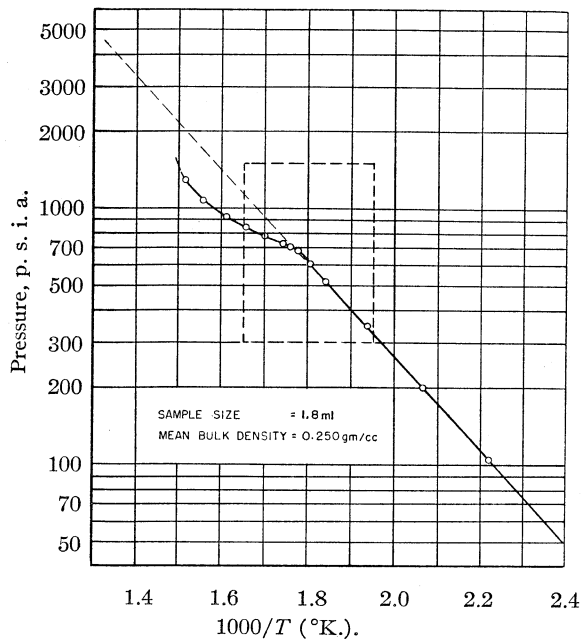

Fig. 3.—Pressure effect in critical region of sample of nitromethane having mean bulk density less than critical density.

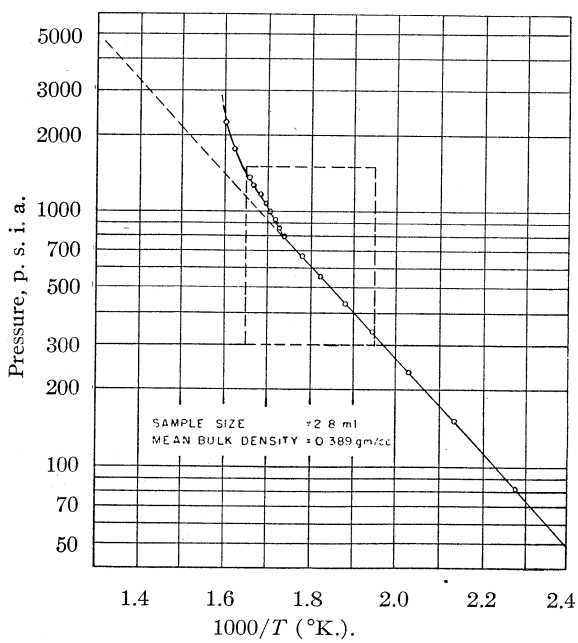

Fig. 4.—Pressure effect in critical region of sample of nitromethane having mean bulk density greater than critical density.

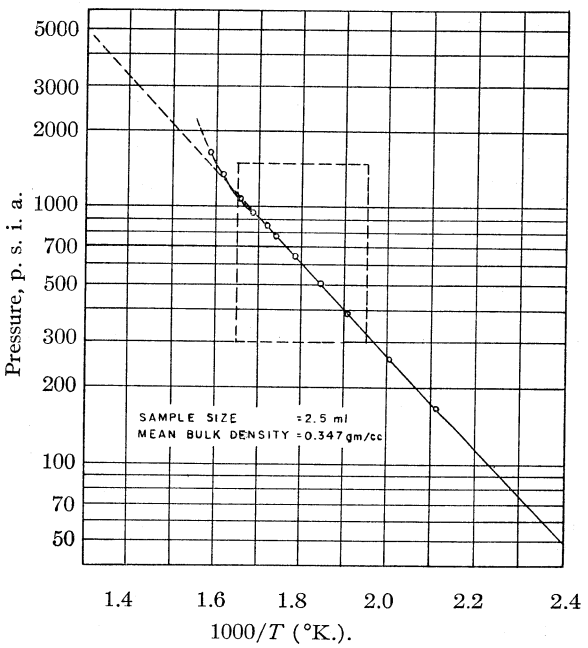

Fig. 5.—Pressure effect in critical region of sample of nitromethane having mean bulk density nearly equal to critical density.

To obtain the true critical point, a plot was made of the temperature of the transition points *vs.* sample size (Fig. 6). The maximum in the curve occurred at 315° (588°K.) and at a sample size of 2.535 ml. (2.885 g.). This point gives a critical temperature of 315° and a critical density of 0.352 g./cc. The critical pressure, which corresponds to the vapor pressure at the critical temperature, is 915 p.s.i.a.

## Summary

This method offers a means of determining graphically the values for $t_c$, $p_c$ and $d_c$ for liquids

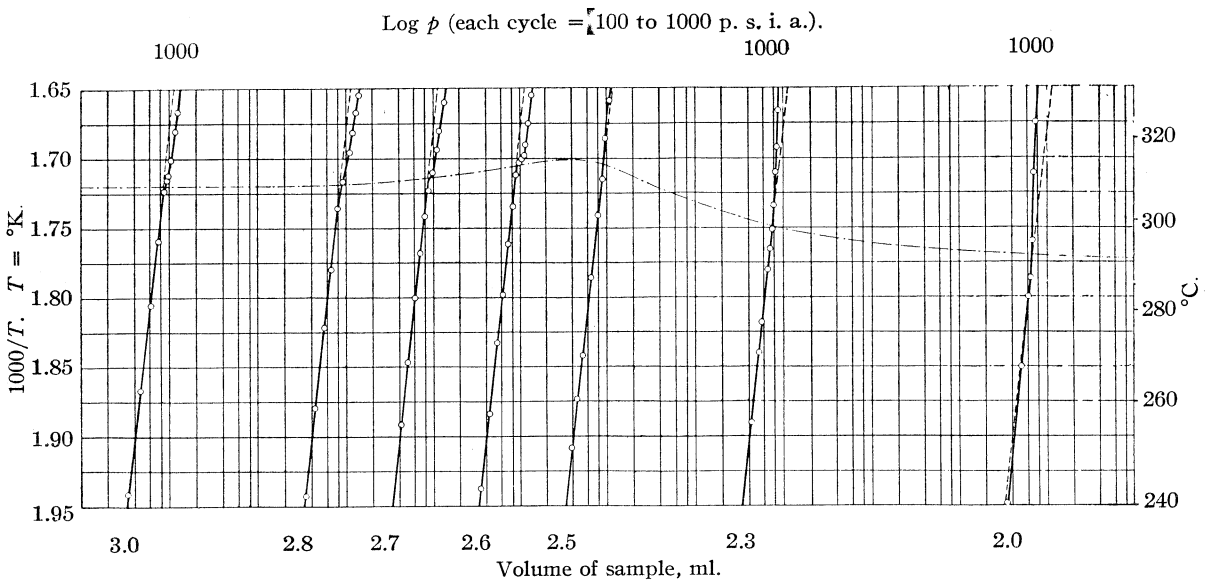

Fig. 6.—Critical point of nitromethane, obtained by interpolating to maximum of critical region: – – – –, vapor pressure of NM (extrapolated); ——, experimental data; —·—·—·—, linear plot of points of deviation.

having high critical temperatures. It is apparently limited in accuracy only by the accuracy of the instruments used in measuring temperature and pressure.

The following critical constants were obtained for nitromethane: $t_c = 315 \pm 1°$, $p_c = 915 = \pm 15$ p.s.i.a., and $d_c = 0.352 \pm 0.004$ g./cc.

# The Structure of Neoprene. II.[1] Determination of End-Groups by Means of Radiosulfur

BY W. E. MOCHEL AND J. H. PETERSON

It is now generally agreed that in the free radical polymerization of vinyl compounds and dienes, fragments of the initiator become combined as end-groups in the polymer molecules.[2] The polymerization catalysts, so-called, are compounds that decompose under polymerization conditions to form free radicals, which in turn become the true, primary initiators. In some cases it has been postulated, on the basis of kinetics studies, that the catalyst first combines with the monomer to produce a complex which subsequently rearranges to an activated molecule,[3] but the structure of the resulting polymer would also involve the catalyst or some fragment as a terminal group. However, not all polymer molecules need have the primary initiator as an end-group. For example, it has recently been demonstrated[4] that the mercaptans used as regulators, or modifiers, particularly in diene polymerizations, are chain transfer agents[5] which likewise become attached as end-groups on the polymer molecules. Other possibilities must also be considered, such as chain transfer with monomer and termination of two chains by mutual interaction without combination[6] to yield additional types of end-groups.

Determination of the end-groups in neoprene (polychloroprene) was therefore undertaken to obtain further knowledge about the structure and formation of this synthetic elastomer. The general purpose chloroprene polymer, Neoprene

Type GN, is prepared in aqueous emulsion by a free radical mechanism initiated with potassium persulfate; the polymerization is carried out in the presence of elemental sulfur, and the final latex is treated with tetraethyl thiuram disulfide. Thus the product may contain sulfur from any of three different sources. For a study of this type,[7] radiosulfur, $S^{35}$, was particularly convenient because it could be used to label the different sulfur-containing materials added.[8]

## Results and Discussion

**Sulfur Modification.**—In the polymerization of Neoprene Type GN, elemental sulfur dissolved in the monomer appears to act as a polymerization modifier. Without the sulfur, an insoluble, non-plastic polymer is formed even at low conversion, but polymerization of chloroprene containing 0.5–1.5% of sulfur to approximately 90% conversion followed by treatment with 2.5% of tetraethyl thiuram disulfide yields a soluble, plastic polychloroprene. To investigate the mechanism of this sulfur modification, radiosulfur was used to tag the modifier in a typical Neoprene Type GN emulsion polymerization system[9] and polymer samples, after extraction with acetone to remove free sulfur, were analyzed for combined modifier sulfur by radioactivity assay.

As indicated in Table I the sulfur modifier content, after extraction of the uncombined sulfur, generally increased with conversion both in the original samples, *i. e.*, before treatment with tetraethyl thiuram disulfide, and after the thiuram treatment. This gradual increase in sulfur modifier content was probably due to the increasing sulfur/monomer ratio as the polymerization progressed, rather than to any significant change in mechanism. About 30–60% of the 0.7% of tagged sulfur added to the monomer became combined, but part of that originally combined appeared to be lost during the thiuram disulfide treatment. Statistical analysis of the data for combined modifier sulfur indicated a probability of less than 1% that the differences between untreated and thiuram-treated samples were due to experimental error. Reëxtraction of the samples with acetone for three days failed to change the sulfur contents significantly and this procedure appeared satisfactory for removal of free sulfur.[10]

The thiuram disulfide treatment appeared to remove some radiosulfur, but this was shown to be due to an exchange reaction which as yet has not been completely elucidated. The ratio of tagged sulfur, by radioassay, to total sulfur, as determined by chemical analysis, was lower for untreated polymers (average 1.4) than for those treated with tetraethyl thiuram disulfide (average 1.8). Also, the total sulfur content remained relatively constant while the radiosulfur content decreased as the amount of tetraethyl thiuram disulfide added was increased (see Table II).

TABLE I

RADIOSULFUR-TAGGED MODIFIER IN NEOPRENE TYPE GN

|---|---|---|---|
| Phenyl-α-naphthylamine | 0.37 | 0.51 | 1.4 |
| 1% Thiuram disulfide | .27 | .47 | 1.8 |
| 2.5% Thiuram disulfide | .24 | .47 | 2.0 |
| 5% Thiuram disulfide | .21[a] | .48 | 2.3 |

[a] Standard deviation was only 0.004%.

Sulfur extracted from a thiuram-treated polymer was recrystallized from acetone (m.p. determined was 119.5–120°; original sulfur, m.p. 119–120° and mixed m.p. 118–119°) and found to have a specific activity of 2490 counts per milligram per sixty-four seconds compared to the specific activity of 5025 for the original sulfur. Although sulfur and tetraethyl thiuram disulfide refluxed in boiling acetone or benzene did not appear to exchange appreciably in two hours, a radio exchange did occur when sulfur and the thiuram were heated together in a melt at 95–100° as shown in Table III.

TABLE III

SULFUR-TETRAETHYL THIURAM DISULFIDE EXCHANGE

(Initial S:S* ratio was 2:1)[a]

| Sulfur | Specific activity counts/64 sec./mg. |
|---|---|

disulfide react under these conditions to form a thiuram polysulfide in which sulfur exchange occurs and that this polysulfide decomposes again to the disulfide and free sulfur. The recovery of sulfur or thiuram disulfide was never quantitative; there was always a non-crystallizable oil left.

Although it was demonstrated that sulfur exchange with tetraethyl thiuram disulfide can occur in a melt at 95–100°, the conditions used for the neoprene treatment were considerably different and the same mechanism may not hold. The polychloroprene latex (*p*H 11.5–12.0) was treated with a dispersion of the thiuram at 40° for a few minutes, the latex coagulated and, after drying two or three days at room temperature under vacuum, the polymer was extracted with boiling acetone for three days. Furthermore, the indicated exchange in neoprene must involve combined sulfur, not elemental sulfur alone (see Table I), although the sulfur involved may be bound only by coördinate linkages to other sulfur atoms.

Further evidence that there is a reaction between the combined sulfur modifier and the tetraethyl thiuram disulfide was obtained from changes in properties of the polymer. The sulfur-modified polymers prepared in 10 to 90% conversion were insoluble in benzene or chloroform and nonplastic if isolated from the latex without treatment with tetraethyl thiuram disulfide but, after treatment in alkaline emulsion, corresponding polymers were completely soluble and plastic. This solubilization of gel polychloroprene did not occur appreciably unless the sulfur modifier was used. At monomer conversions below 10%, sol polymer of very high intrinsic viscosity was isolated without thiuram treatment but the intrinsic viscosity was decreased by treatment with the thiuram disulfide.

A polychloroprene made in 80% conversion with 0.7% of radioactive tagged sulfur and treated with 2.5% of tetraethyl thiuram disulfide was extracted with acetone to remove uncombined sulfur and fractionated from benzene solution using methanol as precipitant.[1] The results of analyses of the fractions, shown in Table IV, indicate an approximate constancy of combined sulfur from the modifier over a range of molecular weights from 92,000 to 321,000.

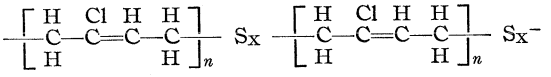

TABLE IV

FRACTIONATED NEOPRENE TYPE GN CONTAINING RADIOSULFUR

[a] Fraction gelled during preparation for molecular weight measurements. [b] Number average molecular weight by osmotic pressure measurement.

Obviously the sulfur was not acting as an "end-grouper" like the typical chain transfer agents, since some thirty-one sulfur atoms were combined in each polymer molecule, on the average, in fraction B. On the basis of this evidence the sulfur is believed to be combined essentially as a co-monomer, as has been demonstrated in the case of oxygen.[12] This hypothesis is also in accordance with the observation by Schulz[13] that sulfur is a polymerization inhibitor for styrene, *i. e.*, sulfur reacts with the free radicals to form new, inactive, resonance-stabilized radicals. However, in the case of chloroprene the free radicals ending in sulfur can continue growth. Contrary to the situation in the reaction of oxygen with styrene, the addition of sulfur to the chloroprene free radical appears to be much slower than the growth reaction; consequently, only a small amount of sulfur becomes combined and high molecular weight copolymers are obtained. The number of sulfur atoms combined successively has not been determined but it is probably of the order of 2–6.[14,15] From the chloroprene to sulfur ratio it may be postulated that the structure of Neoprene Type GN before treatment with tetraethyl thiuram disulfide is, in part, the following, where x may be 2 to 6 and $n$ is, on the average, 80 to 110 times x (the observed values are higher because of the sulfur exchange)

(Non-linear linkages of an unknown nature are undoubtedly also present in minor amounts.) The sulfur linkage is believed to be cleaved by a reaction with tetraethyl thiuram disulfide, or its alkaline degradation products, by a mechanism still under investigation. This cleavage yields a soluble, plastic polymer by reducing the average molecular weight below the critical value for gelation.[16] Thus sulfur, unlike mercaptan modifiers, does not directly control molecular weight but yields a product whose molecular weight can subsequently be reduced by the necessary amount to render the gel soluble.

**Persulfate Initiation.**—To investigate the mechanism of polymerization initiation by persulfates, polychloroprene was prepared using as catalyst, or initiator, potassium persulfate tagged with radiosulfur. The removal of all uncombined persulfate fragments from the polymers was the greatest difficulty in this work. For

example, a typical polymer (prepared in 70% conversion with 0.6% of potassium persulfate), differed in its persulfate sulfur content when treated in various ways as shown in Table V.

TABLE V

POLYCHLOROPRENE MADE WITH RADIOPERSULFATE

| Successive treatments | Time | Tagged sulfur, % |
|---|---|---|
| None (original polymer) | ..... | 0.102 |
| Mill-washed with 60° water | 20 min. | 0.056 |
| Mill-wash repeated | 30 min. | .054 |
| Extracted with acetone | 3 days | .049 |
| Extracted with methanol | 3 days | .036 |
| Original extracted with boiling water | 3 days | .040 |
| Dissolved in benzene and precipitated with methanol | ..... | .0091 |

After examination of several possibilities, three successive precipitations of the polymers from dilute benzene solution with acetone appeared to be the best procedure for removal of uncombined residues; the tagged sulfur content could thus be reduced to about 0.004–0.005%, with a standard deviation of 0.0006%. The possibility must always be considered that the samples assayed contained residual uncombined inorganic residues from the persulfate. Since rather lengthy treatment of the samples was necessary to obtain constant, reproducible analytical values it may be possible that some persulfate sulfur originally combined was lost by hydrolysis or ester interchange, but this is unlikely at the temperatures involved.[17]

Within experimental error there appeared to be no significant differences in amount of combined persulfate sulfur at different monomer conversion levels.

Fractionation of differently modified polychloroprenes initiated with tagged persulfate, by precipitation from benzene solution with methanol, yielded high molecular weight fractions having relatively high tagged sulfur contents and low molecular weight fractions having little or no combined persulfate sulfur. Results obtained for an unmodified polymer, one modified with 0.7% of elementary sulfur and one modified with 0.30% of dodecyl mercaptan, indicated a difference in the mechanism of initiation (see Table VI). Since these fractionations were carried out in identical manner, it is believed that comparison of the results gives a valid indication of a difference in mechanisms.

The unmodified and sulfur-modified polychloroprenes contained combined sulfur from the persulfate, indicating actual chain initiation by a persulfate fragment, probably $SO_4^-$.[17b] In the case of the sulfur-modified, thiuram-treated polymer, Neoprene Type GN, the radiosulfur assay indicated that from 8 to 17 polymer molecules were formed per combined sulfur atom from

[a] Molecular weights were determined viscometrically and checked osmotically. [b] Calculated number of polymer molecules per tagged-sulfur atom. [c] Reprecipitation three times from benzene reduced tagged sulfur content to 0.005%. [d] Analysis of a large sample at a long counting period indicated the presence of 0.00006% of tagged sulfur.

the primary initiator and reaction kinetic chain lengths ranged from approximately 1,000,000 to 5,000,000. The formation of 8 to 17 polymer molecules for each primary initiator, presumably by chain transfer with monomer, is not at all unlikely and is of the same order of magnitude as has been reported for other systems.[18]

The unmodified polymer, isolated at very low monomer conversion to obtain a soluble product, contained less persulfate sulfur than the Neoprene Type GN but the amount combined was significantly more than in the case of the mercaptan-modified polymer. Reaction kinetic chain lengths for the unmodified polymer ranged from 5,000,000 to 8,000,000, running through 10 to 52 polymer molecules, for each persulfate sulfur atom combined. Of course, the kinetic chain lengths would be lower if monomer initiation occurred with other free radicals such as hydroxyl, formed by reaction of persulfate with water.

(18) *Cf.* Schulz and Harboth, *Die makro. Chemie*, **1**, 106 (1947), Melville and Tuckett, *J. Chem. Soc.*, 1211 (1947).

Hydroxyl free radical combination is a possibility which has not been excluded.[17a]

In the case of the mercaptan-modified polymer the final fractions of the polymer contained practically no persulfate sulfur. The amount of persulfate sulfur remaining in fraction F would correspond to a kinetic chain length of approximately 53,000,000, running through 377 molecules, which is considered too high. Chain transfer should not change the reaction kinetic chain length[19] but only the average degree of polymerization. On the basis of available evidence it is proposed that a different initiation mechanism is operating in the presence of the dodecyl mercaptan. It is believed that the potassium persulfate reacts with the dodecyl mercaptan to form free radicals which in turn initiate the polymerization. A possible reaction is

$$K_2S_2O_8 + 2RSH \longrightarrow 2RS\cdot + 2KHSO_4$$

It may be this type of reaction which is responsible for the promoter action of mercaptans, particularly in butadiene polymerization.[20]

Since the high molecular weight fractions always contained large amounts of radiosulfur the possibility must be considered that molecules initiated by persulfate fragments precipitated with the high molecular weight polymer because of reduced solubility. (It is highly improbable that the persulfate-initiated polymer molecules would, on the average, grow to longer polymer chain lengths than others.) It is believed that residual uncombined persulfate fragments, *i. e.*, inorganic sulfates having low solubility in benzene, are carried down by the high molecular weight fractions as they precipitate. The potassium acid sulfate expected would have low solubility in benzene and might need only the nucleus of precipitating polymer to be carried down.

**Mercaptan Modification.**—To complete this investigation it was considered desirable to examine the action of dodecyl mercaptan, a typical chain transfer agent,[4] in the polymerization of chloroprene. Accordingly, radiosulfur-tagged dodecyl mercaptan was substituted for the sulfur modifier in a typical polymerization system for Neoprene Type GN and the polymer obtained was analyzed, after extraction with acetone.

Typical results, illustrated in Table VII, indicated that the polymers isolated at 10–86% conversions contained on the average more than one mercaptan sulfur atom per polymer molecule. Complete precipitation of these polymers from benzene solutions failed to change the sulfur contents appreciably and a duplicate experiment gave similar values for sulfur content; therefore it is believed that the sulfur remaining was actually combined in the polymer molecules. Note also that there was no significant change in sulfur content as the conversion changed, indicating uniform mercaptan consumption. About 50% of the added mercaptan was combined.

[a] $\overline{M}_n$ by osmotic pressure.

A polymer was prepared using 1% of the dodecyl mercaptan tagged with radioactive sulfur and was fractionated after three complete precipitations to remove uncombined mercaptan residues. This polymer, of lower molecular weight, and presumably containing fewer side branches per molecule, contained an even greater excess of combined mercaptan sulfur over the theoretical one atom per molecule than the fractions of corresponding molecular weight from the low mercaptan polymer (see Table IX). Similar results were obtained with a product isolated at 25% conversion to reduce the branching still further.

From these results it was apparent that the dodecyl mercaptan was not combined in a simple 1:1 ratio of mercaptan to polymer molecule, as

would be expected for linear polymer if only chain transfer were involved.[21] There are three obvious ways in which the mercaptan content could be increased: (1) cross-linking reactions involving growth through double bonds in the polymer chains[22]; (2) mutual combination of two growing chains initiated by RS· to give a maximum of two sulfur atoms per molecule; (3) addition of mercaptan molecules to the double bonds in the polymer chains by the usual free radical mechanism.[23] These reactions would give rise to the structures

Mechanism 1 undoubtedly is operative and probably accounts at least in part for the higher-than-average sulfur content of fractions A and B. However, since 1.0% mercaptan yielded polymers containing more sulfur than those made with only 0.30% of the mercaptan it appears that crechanisms 2 and/or 3 are important. Inmeased amounts of mercaptan might well lead to a larger number of growing chains at any given moment and hence a higher probability of termination by mutual combination (mechanism 2); but this mechanism alone cannot lead to the values 3.58 and 3.05 found for fractions A and B of Table VIII. In view of the mild conditions employed for free-radical addition of mercaptans to double bonds of butadiene polymers and rubber,[24] mechanism 3 appears to be the most probable as an explanation of the results observed. The last columns of Tables VIII and IX express the amount of combined sulfur in excess of the theoretical one atom per polymer molecule, reduced to a common molecular weight. The values indicate that, on the average, the second atom of sulfur becomes combined after reaction kinetic chain lengths of 600,000 and 200,000, respectively, for polymerization in the presence of 0.30 and 1.0% of dodecyl mercaptan. The average value for the reduced excess sulfur content for the 1% mercaptan polymers is approximately three times the value obtained when roughly a third as much mercaptan was used. This is strong evidence for a simple mass effect which would be more likely in mechanism 3 than in the others.

## Experimental Details

**Materials.**—The radiosulfur used in this investigation was supplied as irradiated potassium chloride by Clinton Laboratories (now Oak Ridge National Laboratory) and was obtained on allocation from the U. S. Atomic Energy Commission. Carrier sulfur was added and the labeled sulfur isolated by a series of operations involving oxidation to sulfate, precipitation as barium sulfate, reduction to barium sulfide, conversion to hydrogen sulfide and oxidation to free sulfur.[25] It was recrystallized from carbon disulfide before use. This sulfur had an original activity of $1.3 \times 10^6$ counts per mg. per 64 seconds.

To prepare potassium persulfate the stock solution of tracer as potassium sulfate plus potassium chloride was converted to potassium hydrogen sulfate and oxidized electrolytically to potassium persulfate,[26] containing radiosulfur.

For the preparation of dodecyl mercaptan containing radiosulfur, the radioactive barium sulfide described above was acidified and the hydrogen sulfide was passed into a methanol solution of sodium methoxide to form sodium hydrosulfide. This was then treated with dodecyl bromide at 120° in a pressure tube for three hours and the radiosulfur-labeled dodecyl mercaptan was isolated and distilled (104–110° (3 mm.)) to yield a product of 96% purity by iodometric titration.

**Polymerization.**—The polymerizations were carried out in the usual manner[27] at 40°. The sulfur-modified poly-

(21) Smets and Reiske [*Bull. Soc. Chim. Belg.*, **56**, 159 (1947)] found that the chlorine content of polymethyl methacrylate polymerized in carbon tetrachloride was always slightly less than calculated on the basis of simple transfer.

(27) Walker and Mochel, "Proc. International Rubber Tech. Conf.," London, 1948, Preprint No. 11.

mers were made with 0.7% sulfur. The mercaptan-modified polymers were prepared in the same way, substituting 0.30–1.0% of dodecyl mercaptan for the sulfur. Likewise, for the unmodified polymer no change in the system was made except omission of the modifier. Samples of the latex were removed, treated with 2.5% of tetraethyl thiuram disulfide in emulsion or with 0.5% of phenothiazine and 1.0% of phenyl-α-naphthylamine in emulsion. They were then coagulated with ethanol and dried at room temperature *in vacuo*. Analysis indicated that polymers prepared in this way contained only small amounts of residual soap and other adjuvants.

**Preparation of Samples.**—As indicated in the Discussion, the polymer samples were extracted or precipitated to remove uncombined sulfur and sulfur compounds. For elemental sulfur and some mercaptan samples the polymers were extracted continuously with acetone or methanol for three to four days in ASTM rubber extractors or Soxhlet apparatus. In other experiments the samples were dissolved in benzene to make 1–5% solutions and the polymer precipitated completely by addition of about 2 volumes of methanol or acetone. Further addition of methanol produced no cloudiness in the clear supernatant liquid.

**Radioactivity Assay.**—The dry polymer samples were oxidized by the Carius method to obtain a clear solution of sodium sulfate. The sulfate was precipitated as the benzidine salt on special funnels, dried and counted directly with Geiger counters.[28] A control from the labeled sulfur compound under study was always counted at the same time as the unknowns to eliminate the necessity of reliance on decay calculations and to check counter operation with theory based on decay. Sufficient sodium sulfate carrier was added to both control and unknowns to make the sample sizes comparable so that errors due to absorption were eliminated. Furthermore, the control samples were adjusted to roughly the same order of magnitude of counts as the unknowns.

**Acknowledgments.**—The authors gratefully acknowledge the assistance of Miss Doris Peterson in the radioactivity determinations and of Dr. J. B. Nichols and Miss Beverly Price for the osmotic pressure measurements. We also extend our sincere thanks to Drs. D. M. McQueen, B. C. Pratt and G. D. Patterson for their aid and encouragement, and to Professors F. T. Wall and C. S. Marvel for many helpful discussions during the course of this research.

## Summary

By use of radioactive sulfur it has been shown that sulfur-modified neoprene, *i. e.*, Neoprene Type GN, is essentially a copolymer of chloroprene and sulfur in the approximate ratio of 100 chloroprene units per sulfur atom. The sulfur units, possibly disulfides, are cleaved by an alkaline emulsion of tetraethyl thiuram disulfide, so that a gel polymer containing combined sulfur can thus be converted to a soluble, plastic product. The mechanism of this cleavage reaction has not been completely elucidated as yet.

Potassium persulfate, used as initiator for the polymerization of neoprene, appears to be combined with the polymer in Neoprene Type GN in amounts equivalent to 8–17 polymer molecules formed for each sulfur-containing initiator fragment. However, when dodecyl mercaptan is used as modifier, a large proportion of the polymer molecules contain essentially no combined sulfur from the persulfate and it appears that the true initiator is the RS· free radical formed by reaction of the mercaptan with potassium persulfate.

Dodecyl mercaptan used as a polymerization modifier or chain transfer agent, is combined in a greater amount than the one mercaptan per polymer molecule expected on the basis of simple chain transfer. High molecular weight fractions contained 3–4 mercaptan sulfur atoms per polymer molecule and the results suggest that mercaptan addition to the double bonds of the polymer had occurred.

# Some *t*-Butyl Hydroperoxide Derivatives of Aldehydes and Ketones

BY FRANK H. DICKEY, FREDERICK F. RUST AND WILLIAM E. VAUGHAN

*t*-Butyl hydroperoxide combines with aldehydes and ketones to form a series of new compounds which contain either one or two peroxide groups for each carbonyl group. The synthesis is in accord with the equations

$$(CH_3)_3COOH + RR'CO \rightleftharpoons (CH_3)_3COOCOH \quad (1)$$
(R above, R′ below)

$$(CH_3)_3COOCOH + (CH_3)_3COOH \rightleftharpoons ((CH_3)_3COO)_2CRR' + H_2O \quad (2)$$
(R above, R′ below)

where R and R′ may be organic radicals or hydrogen.

Reaction 1 is exemplified by formaldehyde and chloral in which cases reaction 2 apparently is of little or no consequence. Rieche[1] mentions the reaction of alkyl hydroperoxides with aldehydes to form hydroxydialkyl peroxides (monoperoxides). However, the ketones investigated in the present work all form liquid bis-(*t*-butylperoxy)-alkanes, as does benzaldehyde.

## Experimental

**Reactants.**—The *t*-butyl hydroperoxide was a commercial product which was purified by steam distillation. After the low boiling fractions had been removed and the distilling temperature had reached 92–93°, the kettle contents were cooled and the phases separated. The upper, hydroperoxide phase, after drying with sodium sulfate, analyzed 78–82%. The ketones and aldehydes were all

[a] M. p., °C. [b] %Cl. [c] Acetyl value, eq./100 g. [d] See text "Analytical-Total Peroxide." I = *t*-butyl hydroxymethyl peroxide. II = *t*-butyl $\alpha$-hydroxy-$\beta,\beta,\beta$-trichloroethyl peroxide.

commercial products which were purified when necessary by careful fractionation.

**bis-(*t*-Butylperoxy)-alkanes.**[2]—The bis-(*t*-butylperoxy)-alkanes were prepared by treating 0.67 mole of the carbonyl compound with 0.133 mole of *t*-butyl hydroperoxide (78–82%) at room temperature in the presence of concentrated hydrochloric aid (0.1 ml.) as the catalyst. In each case 15 g. of boric anhydride was used to dry the mixture and take up the water of reaction. Each mixture was allowed to stand for about one month after which it was analyzed in accordance with the procedure described in the following section. High yields of the acetone and methyl ethyl ketone derivatives have been obtained in periods of time as short as a few hours.

Isolation of the pure compounds from reaction mixtures in the cases of acetone and methyl ethyl ketone can be easily accomplished by simply extracting the unreacted starting materials with water. In these instances the yields of the isolated products approach the conversions indicated by the analytical method, 80% in the case of acetone and 75% in the case of methyl ethyl ketone (see Table I). However, with the higher carbonylic compounds, water extraction is not satisfactory because of their limited solubility. In the present work, these derivatives were isolated for determination of physical constants and analysis by repeated extraction of the reaction mixture with aqueous 50% ethyl alcohol; this procedure obviously removes a major portion of the desired compound because of solubility in the extractant and the yields ranged from *ca.* 15% on input hydroperoxide in the case of benzaldehyde to *ca.* 65% for methyl propyl ketone. A more efficient procedure would be removal of the remaining starting materials by low pressure distillation; the yields would then approach the conversions indicated by the titration analyses. It is emphasized that great care should be exercised in such operation as it is known[3] that heat will cause these compounds to decompose, in some cases with explosive violence.

***t*-Butyl Hydroxymethyl Peroxide.**[4]—Two hundred eighty grams (2.4 moles) of 78% *t*-butyl hydroperoxide was gradually stirred into 200 g. of 36–38% formalin solution (2.4 moles) at room temperature and the product then vacuum distilled. The peroxide came over at 52–53° at 8–9 mm. A yield of 65.5%, 188 g., was obtained.

***t*-Butyl $\alpha$-Hydroxy-$\beta,\beta,\beta$-trichloroethyl Peroxide.**—Chloral (0.1 mole, 15 g.) was introduced a few drops at a time into a cooled (0°) solution of *t*-butyl hydroperoxide (0.2 mole) in 75 ml. of hexane. A small amount of calcium chloride was included in the mixture to remove the water. Reaction time was one hour, after which the calcium chloride was filtered off. The peroxide crystallized out when the hexane solution was cooled to −40°. The yield was 8.2 g., 27%.

### Analytical

**Total Peroxide.**—A 1.0-ml. sample of the reaction mixture was added to 10 ml. of acetic acid and *ca.* 2 g. of solid potassium iodide. The solution was heated on the steam-bath under reflux for twenty minutes, cooled and the free iodine titrated with thiosulfate.

***t*-Butyl Hydroperoxide.**—A 1.0-ml. sample of the product was added to a solution containing 50 ml. of isopropyl alcohol, 2 ml. of acetic acid and 2 ml. of saturated potassium iodide solution. The mixture was heated to boiling for two minutes, cooled and the liberated iodine titrated.

**bis-(*t*-Butylperoxy)-alkanes.**—The difference between the total peroxide value and the hydroperoxide value is taken as the bis-(*t*-butylperoxy)-alkane. Control experiments have shown that 97–99% of the hydroperoxide present is determinable by the above procedure. There is also some participation by the carbonyl derivatives in the analysis for copresent hydroperoxide, which may vary from as high as 6–7% in the case of the acetone derivative to 1% or less for the cyclohexanone derivative. The conversions of *t*-butyl hydroperoxide to the bis-(*t*-butylperoxy)-alkanes given in Table I are, therefore, subject to these limitations of accuracy.

## Results and Discussion

Some new diperoxy compounds derived from *t*-butyl hydroperoxide and ketones are listed in Table I, together with analytical data obtained on the purified products. Also included are data on the diperoxy derivative of benzaldehyde and on the monoperoxy compounds obtained from formaldehyde and chloral. All except the solid chloral derivative are clear, colorless liquids with mild, pleasant odors. They show excellent potentialities as polymerization catalysts and the methyl ethyl ketone derivative in particular is highly effective in the polymerization of allyl esters.[3]

When 2,2-bis-(*t*-butylperoxy)-butane was decomposed[5] in cumene at 110°, 92% of the *t*-butoxy radicals was accounted for as *t*-butyl alcohol and at least 82% of the reacted cumene was found as dicumyl. This is related to the corre-

# Aromatic Cyclodehydration. XXII.[1] The Mechanism of the Cyclization of *o*-Benzylphenones. III

BY CHARLES K. BRADSHER AND FRANK A. VINGIELLO[2]

In acid media, *o*-benzylphenones (I) may be cyclized to yield anthracene hydrocarbons[3,4,5] (IV). Berliner[5] has found (where R′ = $CH_3$) that the

rate of cyclization decreases with increasing length of group R until *n*-butyl is reached, and remains approximately the same for *n*-pentyl and *n*-hexyl.

This was explained in terms of an increasing order of electron release with increase in size of the alkyl group[6] up to butyl, resulting in an increase in electron density on the positive central carbon atom, thus making the substitution reaction more difficult.

The present investigation was undertaken to determine (1) whether a similar difference in cyclization rates exists in the series in which R′ = H, (2) the effect on the cyclization rate when the inductive effect is varied, while steric factors are kept essentially constant and (3) the effect of varying R′ while R remains constant.

The procedure used in our rate studies differs from that employed by Berliner in that the reaction mixture was not refluxed, but heated in a thermostat in glass-stoppered tubes, and the weight of product isolated was corrected to allow for solubility in the cyclizing medium.[7]

TABLE I

RATES OF CYCLIZATION OF SOME *o*-BENZYLPHENONES (I)[a]

| R | $K$, (hr.$^{-1}$) × $10^{-2}$ |
|---|---|
| H | 540 |
| $CH_3$ | 70 |
| $C_2H_5$ | 30 |
| $C_6H_5CH_2$ | 23 |
| *p*-$CH_3C_6H_4$ | 4.2 |
| *p*-$BrC_6H_4$ | 4.2 |
| *p*-$ClC_6H_4$ | 4.1 |
| *p*-$FC_6H_4$ | 2.8 |
| $C_6H_5$ | 4.4 |
| $C_6H_5$ (R′ = $CH_3$) | 13 |
| $C_6H_5$ (R′ = $C_6H_5$) | 13 |

[a] R′ = H unless otherwise noted.

Like Berliner,[5] we have found the rate of cyclization to be of first order with respect to ketone concentration, and, as he has pointed out, the earlier statement by one of us and Smith that "the rate of cyclization of *o*-benzylphenones is roughly independent of the nature of the R group" is erroneous.[8]

In addition to the ketones mentioned, we have measured the rate of cyclization of *o*-benzylbenzaldehyde[9] (I, R = H; R′ = H). Under the conditions we have used, the rate of formation of anthracene was so great as to make accurate timing difficult.

The comparison of the rates shown by the *para*-substituted phenyl ketones (R′ = H; R = *p*-$XC_6H_4$) affords a test of the relative importance

(4) Bradsher and Smith, *ibid.*, **65**, 451 (1943).

(5) Berliner, *ibid.*, **66**, 533 (1944).

(6) Berliner has been careful to emphasize that equally plausible explanations might be obtained from purely stereochemical considerations.

(7) While the solubility of the aryl anthracenes was small, that of the methyl- and ethylanthracenes was large enough to make errors in the solubility determination a significant source of error in the final rate.

(8) This statement, for which the senior author accepts full responsibility, was based upon only a few yields obtained under conditions which were not comparable.

(9) The cyclization of this compound was first observed by Bergmann, *J. Org. Chem.*, **4**, 1 (1939).

[a] All solids were crystallized from ethanol except the fluoro ketone which was crystallized from petroleum ether. [b] Fluorine analyses by Mrs. A. R. Gilbert. [c] Analyses by Oakwold Laboratories. [d] Analysis by Micro-Tech. Laboratories.

of steric factors and of the electron-release of substituent groups, in that here the size of the groups may be considered as closely comparable. It is interesting to note that with the exception of the *p*-fluorophenyl ketone the *para*-substituted phenyl ketones, within the limits of probable experimental error, give the same rate as the parent phenyl ketone.

The significance of the lower rate shown by the fluorophenyl ketone is not clear, for the decreasing order of the electron release of the various substituent groups, as indicated by the ionization of the *para*-substituted benzoic acids[10] appears to be $CH_3>H>F>Cl>Br$.

The similarity in cyclization rates shown by the other four phenyl ketones (I, R′ = H; R = *p*-$XC_6H_4$) should not lead to the conclusion that inductive effects are absent. It is probable that a decrease in the effective positive character of the central carbon atom of the conjugate acid (II) would lead to a lower rate of cyclization of that acid (II → IV).

The dependence of the rate of the over-all reaction (I → IV) upon hydrogen ion concentration[5] makes it clear that this rate depends upon the position of the equilibrium I ⇄ II. It seems probable that an increase in the electron density at the carbonyl group of the ketone (I) must increase the proportion of conjugate acid present at equilibrium,[11] and in this way act to *hasten* the over-all reaction. Since the relative magnitude of these two opposing effects cannot be determined, it is not possible to predict even the direction of the change in rate which would be expected for a given substitution.

The introduction of either a methyl[5] or phenyl group at R′ (R = $C_6H_5$) was found to lead to an increase in rate. In both cases this may be due to an increase in electron density at the *ortho* position at which cylization takes place, although it should be noted that where R′ = $C_6H_5$ there are four such positions with a corresponding increase in the probability of reaction.

(10) Watson, "Modern Theories of Organic Chemistry," Oxford, 1941, pp. 98–103.

(11) F. O. Rice, "The Mechanism of Homogeneous Organic Reactions," The Chemical Catalog Company, Reinhold Publ. Corp., New York, N. Y., 1928, p. 52.

In conclusion, it might be said that, for similar experimental conditions, the rate of cyclization of *o*-benzylphenones depends upon several factors, the most important of which appear to be: (1) the steric nature of R and perhaps also of R′, (2) the position of the equilibrium between ketone and conjugated acid (I ⇄ II), (3) the effective positive character of the central carbon atom of the conjugate acid, (4) the electron density at the *ortho* position of the benzene ring into which cyclization takes place and (5) the number of such positions available.

## Experimental

**Apparatus.**—The constant temperature unit consisted of a large upright metal cylinder insulated with asbestos and provided with a reflux condenser. Attached to the upper plate of the cylinder, and extending downward within it were several heating wells made of metal pipe, about 21 mm. in internal diameter and 29 cm. in length, sealed at the lower end. When *n*-butyl alcohol was refluxed in the cylinder, a constant temperature of 117.5° was maintained in the wells.

The reaction tubes consisted of Pyrex test-tubes of about 18 mm. internal diameter and about 40 ml. capacity. Each had at the upper end, a 24/40 joint provided with two glass hooks and was closed with a glass stopper similarly equipped. The reaction tubes fitted closely in the heating wells which contained mineral oil for more effective transfer of heat.

**Materials.**—The liquid ketones used in the rate studies were carefully fractionated and showed a boiling range of one degree or less. The solid ketones were carefully recrystallized to constant melting point and dried under reduced pressure.

The acid cyclizing medium was prepared as a stock solution by adding 166.4 ml. of 48% hydrobromic acid to 43.6 ml. of distilled water and 700 ml. of glacial acetic acid.

**Cyclization Procedure.**—Into a reaction tube were placed 200–500 mg. of the ketone and 20 or 30 ml.[12] of the stock cyclizing reagent. The time was recorded and the tube heated over a free flame with shaking for about forty-five seconds, during which time the ketone dissolved, and the solution came to a slow boil. The tube was quickly stoppered (secured by means of rubber bands) and inserted into one of the wells of the constant temperature cylinder kept at 117.5°. At the end of an appropriate period,[13] the mixture was cooled, crystallization induced, and the mixture allowed to stand for five hours at approximately 15°. At the end of this period, the crystals were transferred quantitatively to a weighed sintered glass funnel,

(12) The larger volume was used when the more insoluble ketones were being cyclized.

(13) At least four and frequently five or six different time intervals were used for each compound.

washed with 10 ml. of cold water, and dried to constant weight in a vacuum desiccator. The product was weighed and, in each instance, the melting point was determined.

The solubility of each of the anthracene derivatives was determined by putting a weighed quantity through the same procedure used in the cyclization, and determining the dissolved portion by difference. The solubilities varied from 195 mg. (20 ml.) for 9-ethylanthracene to 2 mg. (30 ml.) for 9,10-diphenylanthracene.

**Preparation of Ketones.**—All but three of the ketones employed in this study have been described previously. These three were prepared from *o*-benzylbenzonitrile[9,3] by the action of the following Grignard reagents in the following yields: *p*-fluorophenylmagnesium bromide (77%); *p*-tolylmagnesium bromide (38%); benzylmagnesium chloride (72%). Further details concerning these ketones and the new anthracene derivatives can be found in Table II.

## Summary

The rates of cyclization of ten ketones and one aldehyde have been measured at 117.5°. The data suggest that steric factors as well as electronic effects may play an important part in determining the rate of cyclization.

DURHAM, N. C. RECEIVED NOVEMBER 1, 1948

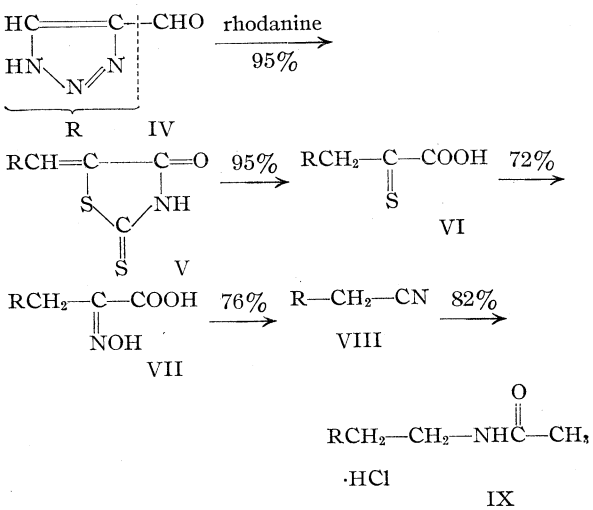
# The Synthesis of Triazole Analogs of Histamine and Related Compounds

BY JOHN C. SHEEHAN AND CHARLES A. ROBINSON[1]

The concept of metabolite antagonism[2] has proved to be an especially profitable starting point for the synthesis of biologically active compounds. It is generally believed that close structural similarity is desirable in fashioning molecules as possible metabolite antagonists. Many of the powerful known antagonists differ only slightly in structure; for example, riboflavin and chloroflavin, thiamine and pyrithiamine, and adenine and benzimidazole. For this reason it seemed strange that in the case of antagonists to histamine, compounds with close structural similarity have been generally neglected in the wide search for antihistaminics. Since the triazole ring has been shown to be antagonistic to the imidazole ring in the cases of the triazole analogs of adenine and guanine,[3] the triazole analogs of histamine and histidine were synthesized.

I Histamine



II 1,2,3-Triazole-4-ethylamine

III

α-Amino-1,2,3-triazole-4-propionic acid

The starting compound for the syntheses was 1,2,3-triazole-4-carboxaldehyde (IV), previously prepared by Hüttel[4] from propiolaldehyde and hydrazoic acid. Although the preparation of propiolaldehyde diethyl acetal from acrolein has been reported previously,[5] considerable difficulty was encountered until the modified procedure described in the Experimental Section was used. Extraction of the propiolaldehyde diethyl acetal with chloroform avoids the difficult separation of the azeotrope of this product and ethanol since chloroform does not extract ethanol from the aqueous solution. With this and other improvements a markedly higher over-all yield (50%) was obtained. The diethyl acetal was hydrolyzed and converted into 1,2,3-triazole-4-carboxaldehyde in 50% yield without isolation of the propiolaldehyde.

The synthesis of the nitrile (VIII) was accomplished by the rhodanine method,[6] analogous to the excellent procedure of Julian and Sturgis.[7]

(7) P. L. Julian and B. M. Sturgis, THIS JOURNAL, **57**, 1126 (1935).

The rhodanine compound (V), prepared in 95% yield, was hydrolyzed to VI in 95% yield. On treatment with hydroxylamine this crude thioketo acid was converted into the oximino acid (VII) in 72% yield. Only one isomer of the oxime was isolated.

Recrystallization of the oxime gave an 88% recovery of analytically pure product. Decarboxylation and dehydration of VII by heating in acetic anhydride led to the recrystallized nitrile (VIII) in 76% yield regardless of whether crude or recrystallized oxime was used. In this reaction of acetic anhydride on VII, a by-product was detected by its brilliant blue ferric chloride test and was isolated in 1.5% yield by virtue of its water insolubility. Analysis indicates that this by-product is an acetyl derivative of the nitrile (VIII).

The nitrile (VIII) was hydrogenated by the general method of Carothers and Jones,[8] using acetic anhydride as a solvent with platinum oxide catalyst to yield the acetylated amine. The absorption of hydrogen stopped at the theoretical amount, indicating no tendency to hydrogenate the triazole ring under these conditions. The difficult purification of the acetylated amine as the base can be avoided by isolation of the pure hydrochloride (IX) in 82% yield. Hydrolysis of either the base or its hydrochloride (IX) to pure, crystalline 1,2,3-triazole-4-ethylamine dihydrochloride was quantitative. The free base (II) was obtained from the dihydrochloride by treatment with sodium ethoxide in ethanol. The amine dihydrochloride was reconverted into the acetylated amine by the Schotten–Baumann procedure using acetic anhydride, and the product was isolated as the pure hydrochloride (IX) in 76% yield.

N-Isopropyl-1,2,3-triazole-4-ethylamine was prepared in 82% yield from the amine (II) and acetone by a reductive alkylation procedure based on that of Hancock and Cope.[9]

N-Isopropylhistamine was prepared from histamine by the same reductive alkylation procedure. Since the base did not crystallize, it was converted into the pure dihydrochloride in 84% over-all yield. Due to the necessity for complete absence of histamine, the pharmacological sample was tested for primary amine using the sensitive nickel chloride and 5-nitrosalicylaldehyde test.[10] A negative test was obtained, whereas histamine produced a strong test.

A brief, slight blocking action against the arterial blood pressure response (dog) to histamine was observed with 1,2,3-triazole-4-ethylamine; the N-isopropyl derivative had no activity. N-Isopropylhistamine gave a typical histamine response, but it was only about $^1/_{30}$ as active as the parent compound.[11]

(10) F. R. Duke, *Ind. Eng. Chem., Anal. Ed.*, **17**, 196 (1945).

(11) The pharmacological testing was done by Dr. Leo Dickinson and Mr. Justin Hoekstra of Bristol Laboratories, Syracuse, N. Y.

DL-α-Amino-1,2,3-triazole-4-propionic acid (III) was prepared by two independent routes. The catalytic hydrogenation of the oximino acid (VII) was extremely slow and the yield of the amino acid was small (17%). As an unambiguous method, the synthesis was also accomplished through the azlactone.

From 1,2,3-triazole-4-carboxaldehyde (IV), the crude azlactone was obtained (52%) as a mixture of a ring-acetylated azlactone and a small amount of the non-acetylated form which was separated through its insolubility in chloroform. The latter compound was readily converted into the former by acetylation. Purified samples of both forms gave α-benzamido-1,2,3-triazole-4-acrylic acid dihydrate on hydrolysis (86–88%). The yield of the acrylic acid dihydrate from the crude mixture of azlactones was 85%. α-Benzamido-1,2,3-triazole-4-propionic acid was obtained in 61% yield by hydrogenation of the acrylic acid in glacial acetic acid using platinum oxide. Hydrolysis of this benzamido acid gave analytically pure DL-α-amino-1,2,3-triazole-4-propionic acid (III) in 51% yield; this compound had the same decomposition point and the same properties as the product from the hydrogenation of VII.

## Experimental[12]

**Propiolaldehyde Diethyl Acetal.**—α,β-Dibromopropionaldehyde diethyl acetal was prepared in 79% yield from acrolein following essentially the procedure of Grard[5] except that the crude α,β-dibromopropionaldehyde was used without distillation while the diethyl acetal was distilled at 108–110° (10 mm.) before the next step.

To a solution of 35 g. (0.625 mole) of potassium hydroxide pellets in 240 ml. of absolute ethanol was added in a thin stream with good stirring 72.5 g. (0.250 mole) of α,β-dibromopropionaldehyde diethyl acetal, allowing the temperature to rise to 50–55°. After cooling to 10°, the potassium bromide was removed by filtration and washed well with 40 ml. of absolute ethanol. The dried potassium bromide amounted to 30 g. (100% of theory for one molecular equivalent). The combined filtrate and washes was refluxed for two and one-half hours. After cooling to 20°, the pale yellow solution containing crystallized potassium bromide was poured into 2 l. of water and extracted three times with 235 ml. of chloroform. The extracts were washed twice with 20 ml. of water and dried over anhydrous magnesium sulfate.

After removal of chloroform by distillation through a short Vigreux column at atmospheric pressure, the residue was fractionated using an eighteen-inch Fenske column. The fraction distilling at 138–139.5° amounted to 20.3 g. (63%) and remained colorless on storing at 5°. Grard[5] reported a boiling point of 137–141°.

**1,2,3-Triazole-4-carboxaldehyde (IV).**[13]—A mixture of 32.7 g. (0.255 mole) of propiolaldehyde diethyl acetal and 50 ml. of 0.2 *N* sulfuric acid containing 100 mg. of hydroquinone was heated on a steam-bath under a reflux condenser with frequent shaking. The two-phase mixture gradually became homogeneous. Reflux was continued until the solution remained homogeneous on cooling to 15°; a total of forty-five minutes heating was required. After cooling, 16 g. of ammonium sulfate was added and the red oil was separated. The aqueous layer was extracted with 40 ml. of ether and the combined oil

(12) All melting points are corrected.

(13) Due to a marked tendency for polymerization of the propiolaldehyde, sufficient time must be available to complete this step without interruption.

and extracts was dried over anhydrous sodium sulfate for thirty minutes.

After removing the desiccant the propiolaldehyde–ether–ethanol mixture was distilled until the vapor reached 75°. Additional product remaining in the high-boiling residue was removed by twice adding anhydrous ether and again distilling to 80°. The total distillate was immediately added to 0.19 mole of a titrated hydrazoic acid–ether solution prepared by method B of Audrieth and Gibbs.[14] Heat of reaction caused gentle reflux, after which the solution was allowed to stand at room temperature overnight. The solvent and excess hydrazoic acid were removed by cautious distillation, leaving a colorless crystalline product which amounted to 12.5 g. (50%) after thorough drying; m. p. 141–142°. Hüttel[4] reported a melting point of 141–142° for this compound.

**5-(1,2,3-Triazolyl-4-methylene)-rhodanine (V).**—To a hot solution of 23.3 g. (0.240 mole) of 1,2,3-triazole-4-carboxaldehyde and 32.0 g. (0.240 mole) of rhodanine in 210 ml. of glacial acetic acid, 59.8 g. of freshly fused sodium acetate was added. With frequent shaking, the mixture was refluxed for twenty minutes during which time a bright yellow product separated. After cooling and slurrying with 700 ml. of water, the product was removed by filtration and washed well with water, then with acetone until the filtrate was clear, and finally with ether. The dried product weighed 48.5 g. (95%) and did not melt below 300°. This compound is insoluble in all common organic solvents. An analytical sample was prepared by solution in 0.2 *N* ammonium hydroxide followed by acidification to give yellow needles.

*Anal.* Calcd. for $C_6H_4N_4OS_2$: C, 33.95; H, 1.90; N, 26.40. Found: C, 33.69; H, 2.09; N, 26.48.

**1,2,3-Triazole-4-thiopyruvic Acid (VI).**—A solution of 48.5 g. (0.228 mole) of the crude triazole–rhodanine compound (V) in 238 ml. of 15% sodium hydroxide solution was heated on a steam-bath at 88–92° for twenty minutes with occasional shaking. The chilled solution was added in a thin stream with rapid stirring to an excess of 2.5 *N* hydrochloric acid (368 ml.), maintaining the temperature below 10°. After being stirred for one-half hour in an ice-bath, the cream-colored product was collected, washed with ice-water, and carefully dried at slightly above room temperature. The yield of material decomposing at 157° with gas evolution was 37.1 g. (95%). This product was non-crystalline and has not been further purified. With ferric chloride it gave a brilliant green coloration.

**1,2,3-Triazole-4-pyruvic Acid Oxime (VII).**—Hydroxylamine was prepared by dissolving 20.8 g. (0.30 mole) of hydroxylamine hydrochloride in 18.4 ml. of warm water and adding sodium ethoxide solution prepared from 6.88 g. (0.30 mole) of sodium in 200 ml. of ethanol. The sodium chloride was removed by filtration and washed with 22 ml. of ethanol. To this solution 17.1 g. (0.10 mole) of the crude thioketo acid (VI) was added and the solution was refluxed gently for twenty minutes; at the end of this time the evolution of hydrogen sulfide had ceased. After removing the solvent under reduced pressure, the residual thick sirup was dissolved in 86 ml. of 5% sodium hydroxide solution, filtered and acidified to *p*H 1 with 2.5 *N* hydrochloric acid; on scratching an immediate crystallization began. After allowing several hours for crystallization, the pale yellow crystals were removed by filtration, washed with ice-water, and dried at 55°. The product decomposing at 168° with gas evolution amounted to 12.2 g. (72%).

Recrystallization of a sample of this material from twelve volumes of hot water gave glistening pale yellow flakes in 88% recovery, m. p. 169° with decomposition.

*Anal.* Calcd. for $C_5H_6N_4O_3$: C, 35.30; H, 3.56; N, 32.93. Found: C, 35.41; H, 3.76; N, 32.82.

This compound is slightly soluble in ethanol and nearly insoluble in acetone, ether, benzene or cold water.

(14) L. F. Audrieth and C. F. Gibbs, "Inorganic Syntheses," Vol. I, edited by H. S. Booth, McGraw-Hill Book Co., Inc., New York, N. Y., 1939, p. 77.

**1,2,3-Triazole-4-acetonitrile (VIII).**—A suspension of 5.1 g. (0.030 mole) of the crude oximino acid (VII) (finely powdered) in 30 ml. of acetic anhydride was heated to 80–85° in an oil-bath; a vigorous evolution of gas ensued and the heat of reaction occasionally necessitated removing the flask from the bath. After thirty minutes at 80–85°, the material had completely dissolved and gas evolution ceased. The pale orange solution was concentrated under reduced pressure in a 60° bath until no more acetic anhydride distilled. With stirring and cooling to 20°, 2.5 *N* sodium hydroxide solution was added until all the residual acetic anhydride had decomposed; the *p*H was adjusted to 6.

The nitrile was extracted to completion with ether, adjusting the *p*H to 6 as necessary between extractions. The nitrile is incompletely extracted from more basic or more acidic solutions. Removal of ether from the dried extracts left a colorless crystalline mass which was dried to constant weight under reduced pressure, giving a crude yield of 3.1 g. (96%); m. p. 78–85°. The crude product, recrystallized from absolute ethanol–chloroform, gave a recovery of colorless crystals of 2.47 g. (80%) or a yield of 76% including second crops; all crops melted between 89 and 91°. An analytical sample recrystallized from hot benzene was obtained as beautiful colorless needles melting at 91–91.5°.

*Anal.* Calcd. for $C_4H_4N_4$: C, 44.44; H, 3.73; N, 51.83. Found: C, 44.79; H, 3.85; N, 52.09.

1,2,3-Triazole-4-acetonitrile is readily soluble in water, ethanol, acetone or ether.

A by-product was isolated from the aqueous mother liquors by adjusting the *p*H to 5 and extracting with ether. The product obtained by evaporating the ether was washed well with cold water to remove traces of the nitrile (VIII) and then dried at 65°. The pale yellow product weighed 0.065 g.; m. p. 212° with evolution of gas. Two recrystallizations from hot water gave a good recovery of tiny, nearly colorless crystals decomposing at 214°.

*Anal.* Calcd. for $C_6H_6N_4O$: C, 48.00; H, 4.03; N, 37.32; mol. wt., 150.14. Found: C, 48.00; H, 4.28; N, 37.67; mol. wt., 144 (Rast).

This acetylated by-product produces a brilliant blue coloration with ferric chloride solution.

**N-Acetyl-1,2,3-triazole-4-ethylamine Hydrochloride (IX).**—A solution of 1.95 g. (0.0180 mole) of the recrystallized nitrile (VIII) in 25 ml. of acetic anhydride was shaken under hydrogen with 0.30 g. of platinum oxide. After nine hours the theoretical amount of hydrogen had been taken up and no more was absorbed on further shaking. After removing the catalyst by filtration, the solution was treated with just sufficient water to decompose the excess acetic anhydride. The pale yellow solution was concentrated to an oil under reduced pressure, and the residue was twice dissolved in absolute ethanol and reconcentrated to dryness.

The hydrochloride was formed by dissolving the oil in 10 ml. of absolute ethanol and adding 6 *N* ethanolic hydrogen chloride in slight excess. On the addition of 40 ml. of absolute ether to the clear solution a colorless product crystallized. The yield of dried material melting with decomposition at 166–166.5° was 2.80 g. (82%). An analytical sample recrystallized from ethanol–acetone was obtained as tiny colorless crystals; m. p. 166–166.5° with decomposition.

*Anal.* Calcd. for $C_6H_{11}N_4OCl$: C, 37.79; H, 5.82; N, 29.39. Found: C, 37.90; H, 5.87; N, 29.58.

**N-Acetyl-1,2,3-triazole-4-ethylamine.**—The nitrile (VIII) (0.54 g., 0.0050 mole) was hydrogenated as described above in the preparation of the hydrochloride (IX). The oil obtained after concentration of the acetic anhydride was dissolved in 5 ml. of water and extracted with 15 ml. of *n*-butanol. The extracts were treated with charcoal and concentrated to a colorless oil under reduced pressure. After dissolving in ethyl acetate and again concentrating, the oil crystallized giving a slightly sticky product. This was dissolved in 35 ml. of hot ethyl ace-

tate and filtered to remove an oily residue; on concentration, 0.63 g. (82%) of crystalline product melting at 65–76° was obtained.

A sample of this crude material was purified by sublimation at 0.002 mm. and 125° (m. p. 76–82°) followed by two recrystallizations from ethyl acetate–ether to give a pure crystalline product melting at 81–82°.

*Anal.* Calcd. for $C_6H_{10}N_4O$: C, 46.74; H, 6.54; N, 36.34. Found: C, 46.48; H, 6.53; N, 36.34.

This compound is soluble in water, absolute ethanol, acetone and in hot ethyl acetate; it is nearly insoluble in ether or benzene.

**1,2,3-Triazole-4-ethylamine Dihydrochloride.**—Hydrolysis of 2.29 g. (0.0120 mole) of the recrystallized N-acetylamine hydrochloride (IX) was accomplished by reflux with 119 ml. of 2.5 *N* hydrochloric acid for three hours. The colorless solution was concentrated under reduced pressure giving a mass of rosettes. After drying to constant weight, the yield was quantitative (2.22 g.); m. p. 181–182° with decomposition. Recrystallization from absolute methanol–ether gave a 92% recovery (2.03 g.); m. p. 185–186° with decomposition. A second recrystallization failed to alter the melting point.

Hydrolysis of the N-acetylamine base (m. p. 65–76°), in a similar manner, gave a quantitative yield of the dihydrochloride. In this case the product was twice recrystallized from 97% ethanol–acetone giving colorless rosettes, m. p. 179–180° with decomposition.

*Anal.* Calcd. for $C_4H_{10}N_4Cl_2$: C, 25.95; H, 5.45; N, 30.27. Found: C, 25.81; H, 5.47; N, 30.50.

It appears that the melting point of this compound depends on the solvent from which it crystallizes; the higher melting product (185–186°) from methanol–ether on crystallizing again from water gave the lower melting point (181–182°).

**1,2,3-Triazole-4-ethylamine (II).**—A solution of 1.50 g. (0.00810 mole) of 1,2,3-triazole-4-ethylamine dihydrochloride (m. p. 181–182° dec.) in 36 ml. of warm 97% aqueous ethanol was added to a solution of sodium ethoxide prepared from 0.373 g. (0.0162 mole) of sodium in 12 ml. of absolute ethanol. After fifteen minutes at 20°, the crystallized sodium chloride was removed by filtration and washed with absolute ethanol. The colorless filtrate was concentrated under reduced pressure to a crystalline solid weighing 0.96 g. (105%). This crude material was freed from sodium chloride by dissolving in 25 ml. of hot absolute ethanol, removing the inorganic salts by filtration, and evaporating the solvent under reduced pressure. The yield of crystalline, halogen-free product was quantitative (0.91 g.); m. p. 154–155.5°. This product can be further purified by recrystallization from hot absolute ethanol.

An analytical sample was prepared by sublimation of a portion at 0.05 mm. and 100°; m. p. 157.5–159°.

*Anal.* Calcd. for $C_4H_8N_4$: C, 42.84; H, 7.19; N, 49.97. Found: C, 42.50; H, 7.07; N, 50.40.

1,2,3-Triazole-4-ethylamine is soluble in water and in hot absolute ethanol; it is nearly insoluble in ether, acetone, ethyl acetate or chloroform.

**N-Isopropyl-1,2,3-triazole-4-ethylamine.**—In a micro-hydrogenator, 100 mg. of platinum oxide in 5 ml. of absolute ethanol was pre-reduced. Then, 0.628 g. (0.0056 mole) of the crude amine (II) (m.p. 154–155.5°) in 7 ml. of absolute ethanol, 0.52 ml. (0.0071 mole) of acetone, and one drop of water to effect complete solution were added, and the solution was stirred under hydrogen at atmospheric pressure. The rate of hydrogenation dropped sharply when the theoretical amount of hydrogen had been absorbed (3.8 hours). After removal of the catalyst, the filtrate was concentrated to a colorless crystalline solid weighing 0.84 g. (97%); m. p. 136–138°.

Recrystallization from seven volumes of hot absolute ethanol gave a 72% recovery of crystals melting at 142.5–144°. A second recrystallization from methyl ethyl ketone gave beautiful, colorless crystals; m. p. 143–144°.

*Anal.* Calcd. for $C_7H_{14}N_4$: C, 54.52; H, 9.15; N, 36.33. Found: C, 54.58; H, 9.28; N 35.81.

Second crops from the recrystallizations increased the recovery of pure product to 0.707 g. (82%).

This compound is soluble in water, slightly soluble in cold absolute ethanol and soluble in hot acetone; it is nearly insoluble in ether or benzene.

**N-Isopropyl-4-imidazoleëthylamine Dihydrochloride.**—In a micro-hydrogenator, 50 mg. of platinum oxide in 5 ml. of absolute ethanol was pre-reduced. To this, 0.222 g. (0.0020 mole) of histamine (Eastman Kodak Co., Synthetic) in 5 ml. of absolute ethanol and 0.25 ml. (0.0034 mole) of acetone were added, and the solution was stirred under hydrogen at atmospheric pressure. The rate of hydrogenation dropped sharply when the theoretical amount of hydrogen had been absorbed (four hours). After removing the catalyst, the colorless filtrate was concentrated to an oil weighing 0.33 g. (108%).

This free base did not crystallize even after evaporative distillation of a sample at 0.001 mm. and 70° and refrigeration for several weeks. The remainder of the crude base (0.20 g. containing 0.00121 mole) was converted into the dihydrochloride by dissolving in 5 ml. of acetone and adding 6 *N* ethanolic hydrogen chloride in slight excess. After collecting the crystals and drying in a desiccator, the colorless product weighed 0.26 g. (95%); m. p. 185–193°. Recrystallization of 0.25 g. of the crude dihydrochloride from absolute ethanol–ethyl acetate gave a 62% recovery of product melting at 197–198°. From the mother liquors a second crop melting at 195–196° gave a total recovery of 0.220 g. (83% over-all yield).

An analytical sample was prepared by a second recrystallization of the first crop; m. p. 197.5–199°.

*Anal.* Calcd. for $C_8H_{17}N_5Cl_2$: C, 42.48; H, 7.58; N, 18.58. Found: C, 42.58; H, 7.74; N, 18.81.

**Condensation of 1,2,3-Triazole-4-carboxaldehyde with Hippuric Acid.**—A mixture of 4.30 g. (0.024 mole) of hippuric acid, 8.6 ml. of acetic anhydride and one drop of triethylamine was heated rapidly with stirring in a vessel protected from moisture until there was complete solution (110°). To the orange-colored solution cooled to 60°, 1.94 g. (0.020 mole) of 1,2,3-triazole-4-carboxaldehyde and 3.0 ml. of glacial acetic acid were added, and the solution was heated at 60 ± 3° in an oil-bath for two hours. Lemon-yellow needles began to crystallize after thirty-five minutes of heating. After allowing fifteen hours at room temperature for crystallization, the needles were collected, washed with 5 ml. of glacial acetic acid, and dried at 70°. The product amounted to 2.93 g. (52%); m. p. 161–164°.

This crude mixture was washed with boiling water to remove excess hippuric acid and the dried product (2.40 g.) was slurried with 20 ml. of chloroform and the insoluble, non-acetylated azlactone was removed by filtration. The addition of ether to the filtrate gave lemon-yellow crystals (1.63 g.); m. p. 181–182.5°. Further recrystallizations from chloroform–ether gave an analytical sample of the ring-acetylated azlactone of α-benzamido-1,2,3-triazole-4-acrylic acid; m. p. 181.5–182.5°.

*Anal.* Calcd. for $C_{14}H_{10}N_4O_3$: C, 59.57; H, 3.57; N, 19.85. Found: C, 59.42; H, 3.65; N, 20.16.

The chloroform-insoluble fraction from the purification of the ring-acetylated azlactone amounted to 0.250 g. and decomposed at 219°. After three recrystallizations from methanol–water, an analytical sample of the azlactone of α-benzamido-1,2,3-triazole-4-acrylic acid was obtained as pale yellow needles decomposing at 223°.

*Anal.* Calcd. for $C_{12}H_8N_4O_2$: C, 60.00; H, 3.36; N, 23.33. Found: C, 59.95; H, 3.59; N, 23.34.

**α-Benzamido-1,2,3-triazole-4-acrylic Acid.**—A suspension of 3.0 g. of the crude mixture of azlactones in 250 ml. of 0.25 *N* sodium hydroxide solution was rapidly heated to boiling. After boiling for a few seconds, the clear solution, cooled in ice, was made strongly acid with 50 ml. of 2.5 *N* hydrochloric acid. Crystallization as tiny cubes began on scratching. After one hour at 0–5° the cream-colored product was removed by filtration, washed with cold water, and dried in a desiccator over Drierite. The product, obtained as the dihydrate, weighed 2.66 g. (85%);

m. p. 187° with decomposition (capillary inserted at 110°). Two recrystallizations from hot water gave colorless crystals which were dried in a desiccator over Drierite; m. p. 189° with decomposition (capillary inserted at 110°).

*Anal.* Calcd. for $C_{12}H_{10}N_4O_3 \cdot 2H_2O$: C, 48.98; H, 4.80; N, 19.04. Found: C, 49.01; H, 5.00; N, 19.39.

On drying at 75–85° the dihydrate loses two molecules of water. The dihydrate is soluble in acetone, ethanol or hot water.

DL-α-Benzamido-1,2,3-triazole-4-propionic Acid.—In a micro-hydrogenator, 200 mg. of platinum oxide in 7 ml. of glacial acetic acid was pre-reduced. Then, 0.553 g. (0.00188 mole) of crude α-benzamido-1,2,3-triazole-4-acrylic acid dihydrate and 5 ml. of glacial acetic acid were added, and the solution was stirred under hydrogen at atmospheric pressure. During the hydrogenation an addition of 100 mg. of platinum oxide was made to maintain the rate. When the theoretical amount of hydrogen had been absorbed, the reaction was stopped and the catalyst removed. Concentration of the filtrate under reduced pressure gave an oil which crystallized on adding water. The gray product which was removed by filtration and dried at 65° weighed 0.390 g. (79%); m. p. 206–208° with decomposition.

The crude product (0.39 g.) was recrystallized from 18 ml. of hot water, yielding 0.30 g. (61%) of colorless crystals; m. p. 217.5–218.5° with decomposition. An analytical sample was prepared by a second recrystallization from hot water; m. p. 219–220° with decomposition.

*Anal.* Calcd. for $C_{12}H_{12}N_4O_3$: C, 55.38; H, 4.65; N, 21.53. Found: C, 55.12; H, 4.88; N, 21.24.

This compound is soluble in absolute ethanol and insoluble in ether or acetone.

DL-α-Amino-1,2,3-triazole-4-propionic Acid (III). A. Hydrolysis of the Benzoyl Compound.—Hydrolysis of 0.78 g. (0.0030 mole) of α-benzamido-1,2,3-triazole-4-propionic acid was accomplished by reflux for six hours with 20 ml. of 2.5 *N* hydrochloric acid. After ether extraction and charcoal treatment, the aqueous solution was concentrated under reduced pressure to a colorless oil which was twice dissolved in water and reconcentrated to dryness (wt. 0.56 g., 97%). Aniline was added to a warm solution of the oil in 10 ml. of absolute ethanol until the *p*H was 4–5. After twelve hours at room temperature, the crystalline amino acid was collected, washed with absolute ethanol and ether, giving 0.29 g. (62%) of product decomposing with gas evolution at 260°.

The crude product on recrystallization from water–ethanol gave 0.24 g. (51%) of tiny, colorless crystals decomposing at 266°. A second recrystallization failed to alter the decomposition point.

*Anal.* Calcd. for $C_5H_8N_4O_2$: C, 38.46; H, 5.16; N, 35.88. Found: C, 38.36; H, 5.38; N, 35.71.

This compound is moderately soluble in cold water and soluble in hot; it is insoluble in absolute ethanol or ether.

B. Hydrogenation of VII.—After pre-treatment of 0.460 g. (0.0027 mole) of recrystallized oximino acid (VII) in absolute ethanol with Raney nickel catalyst, 0.0028 mole of ethanolic hydrogen chloride was added and the solution was stirred with 200 mg. of platinum oxide in a micro-hydrogenator under hydrogen at atmospheric pressure. After seven days the theoretical amount of hydrogen had been absorbed. The solution, from which the catalyst had been removed, was concentrated to dryness under reduced pressure, dissolved in water, filtered, and again concentrated to a brittle, tan solid weighing 0.55 g. After recrystallization from ethanol–ethyl acetate and water–acetone, the crystalline hydrochloride amounted to 0.14 g. and decomposed at 219°.

Without further purification, 0.040 g. of the hydrochloride was treated with the calculated amount of dilute ammonium hydroxide and the solution concentrated to dryness under reduced pressure. Solution of the residue in hot water and the addition of two volumes of ethanol produced colorless crystals. After washing with aqueous ethanol (1:1) and drying at 65°, the amino acid decomposed at 266° and weighed 0.020 g. (17% from VII).

## Summary

1,2,3-Triazole-4-ethylamine and DL-α-amino-1,2,3-triazole-4-propionic acid, the triazole analogs of histamine and histidine, as well as N-isopropyl-1,2,3-triazole-4-ethylamine and N-isopropylhistamine have been synthesized for pharmacological study.

# Quinazolines. VIII. The Synthesis of an Amino Alcohol Derived from 2,4-Quinazolinedione-5-carboxylic Acid[1]

BY C. H. WANG AND BERT E. CHRISTENSEN

Methods for the synthesis of 2,4-dimethylquinazoline derivatives with an acetyl-substituent in the 7- and 8-positions have recently been described.[2,3] The 5-isomer, however, could not be synthesized by these procedures due to the difficulties encountered in the attempted preparation of the necessary intermediate 3-acetamino-1,2-diacetylbenzene or 3-acetamino-2-acetylbenzoic acid required for the cyclization.[4]

Since it would be useful to this Laboratory to have a quinazoline compound with an amino alcohol substituent in the 5-position, the possibility of utilizing the easily prepared 2,4-quinazolinedione-5-carboxylic acid (I) as the starting material (see Fig. 1) was studied. This intermediate was converted to the acyl chloride (II), which upon treatment with diazomethane formed the diazoketone and at the same time was simultaneously methylated in the 1,3-positions to yield 5 - diazoacetyl - 1,3 - dimethyl - 2,4 - quinazolinedione (III). This diazoketone upon treatment with dry hydrogen bromide gas was converted to the bromomethyl ketone (IV); however, one of the methyl substituents (either 1 or 3) was lost in the process.

The bromoacetyl derivative (IV) readily combined with morpholine to yield an aminoketone

(V) which was in turn catalytically reduced to the desired amino alcohol (VI).

In order to confirm the simultaneous methylation of the 1,3-positions of (II) during the diazomethane reaction, the starting material (I) was methylated with excess diazomethane. This gave an ester (methyl 1,3-dimethyl-2,4-quinazolinedione-5-carboxylate (VII)), which was identical with that reported both by Scott and Cohen[5] as well as by Lange, Chisholm and Szabo.[6] These investigators had employed dimethyl sulfate as the methylating agent. The ester (VII) was hydrolyzed to the acid (VIII) which upon chlorination with thionyl chloride gave a good yield of 1,3-dimethyl-2,4-quinazolinedione-5-carbonyl chloride (IX). When the acyl chloride (IX) was treated with diazomethane, a diazoketone identical with (III) was produced. These data confirm the earlier observations of the methylation of the 1,3-positions of 2,4-quinazolinedione-5-carbonyl chloride with diazomethane.

Although VII on the basis of mixed melting point tests was identical with the ester prepared by Scott and Cohen, the acid (VIII) obtained by the hydrolysis of VII, was not the same as the 1,3-dimethyl-2,4-quinazolinedione-5-carboxylic acid reported by these workers.[5,6] Scott and Cohen originally prepared the acid by the direct methylation of I using a limited amount of dimethyl sulfate. In order to confirm the earlier work, the methyl ester (VII) prepared in this Laboratory by the method of Scott and Cohen was hydrolyzed to the free acid. This acid was found to be identical with VIII which was obtained as the hydrolysis product of the ester (VII) (prepared by the diazomethane reaction) and different from the dimethyl acid originally reported by these workers. In order to clarify these results the free acid (X) was again prepared in this Laboratory by the direct methylation procedure of Scott and Cohen; the methylation product was found to be a high melting compound as described by these workers. However, carbon and hydrogen data indicate an incomplete methylation yielding the 1(or 3)-methyl-2,4-quinazolinedione-5-carboxylic acid in place of the 1,3-homolog. Since the earlier deduction had been based on nitrogen analysis only, it is possible that the acid in question was the 1(or 3)-methyl-2,4-quinazolinedione-5-carboxylic acid (X) and not the 1,3-dimethyl homolog as originally reported.

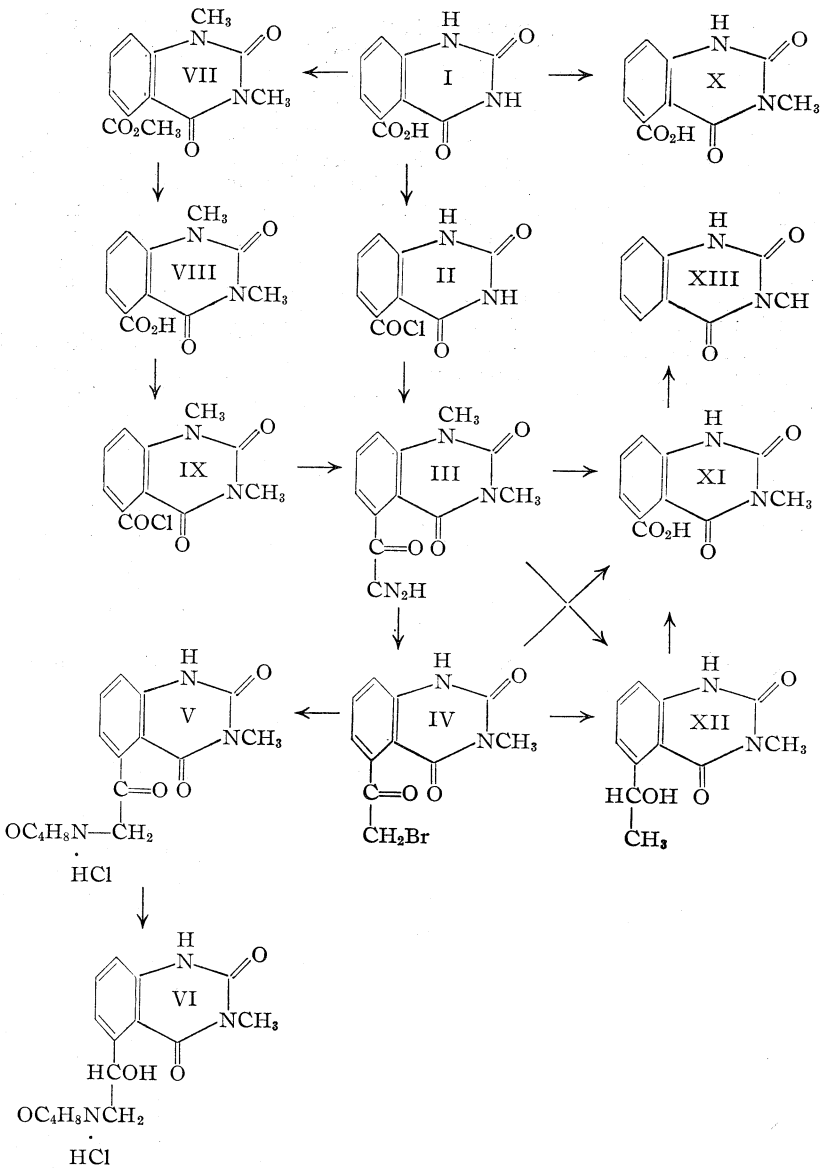

Fig. 1.

Because of the unpredictable ease with which the methyl substituent had been removed during the mild acid treatment of the diazoketone (III), further experiments with III were undertaken. The compound (III) upon oxidation with neutral permanganate again lost a methyl substituent to yield 1(or 3)-methyl-2,4-quinazolinedione-5-carboxylic acid (XI). The loss of a methyl substituent was again observed during reduction

(5) Scott and Cohen, *J. Chem. Soc.*, **119**, 664 (1921).

(6) Lange, Chisholm and Szabo, THIS JOURNAL, **61**, 2170 (1939).

which yields 5-(1-hydroxyethyl-1(or 3)-methyl)-2,4-quinazolinedione (XII). Both the bromomethyl ketone (IV) and the reduction product (XII) after a permanganate oxidation gave acids which on the basis of mixed melting point tests were judged to be identical with XI. From these results, as well as from the analytical data, it was concluded that the same methyl substituent was quantitatively removed during each of the described operations.

The problem of determining the position of the remaining methyl group was approached through decarboxylation experiments. The acid (XI) after removal of the carboxyl group, gave a methyl-2,4-quinazolinedione (XIII) which melted sharply at 198°. This melting point did not agree with 234[7]–237[8]–242°[9] (XIV) reported for the 3-methyl-2,4-quinazolinedione or 147°[8] (XV) or 265°[10] (XVIII) which had been reported for the 1-isomer.

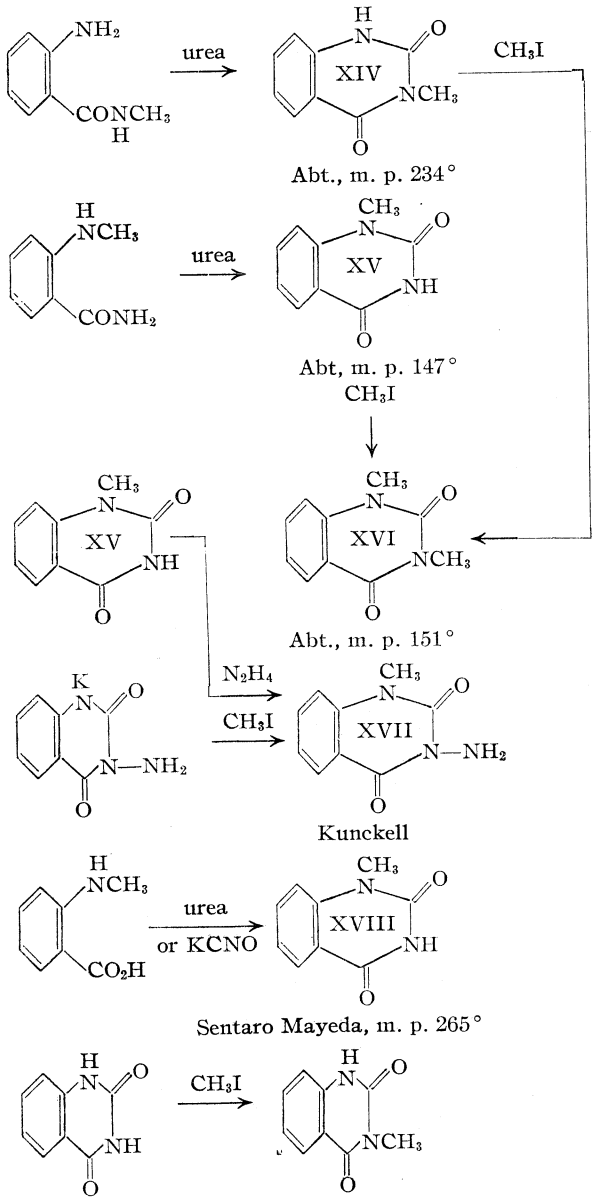

Fig. 2.

A review of the literature reveals that Abt had prepared both the 3- and 1-methyl-2,4-quinazolinediones (XIV) (XV) (m.p.'s 234, 147°) by the cyclization of 2-aminomethylbenzamide and 2-methylaminobenzamide, respectively, with urea (see Fig. 2). Both the 1- and 3-methyl-2,4-quinazolinediones prepared by Abt, after further methylation with methyl iodide, gave an identical known product 1,3-dimethyl-2,4-quinazolinedione (XVI), m.p. 151°.[8] Furthermore, Abt prepared by direct methylation using alkaline methyl iodide, a compound m.p. 147° which he concluded was 1-methyl-2,4-quinazolinedione[8] (XV).

The proof of structure of the 1-methyl isomer m.p. 147° was later confirmed indirectly by the experiments of Kunckell[11] who isolated 3-amino-1-methyl-2,4-quinazolinedione (XVII) as the product of the reaction of the 1-methyl isomer (XV) with hydrazine. The identical compound had previously been obtained by the methylation of the potassium salt of 3-amino-2,4-quinazolinedione, with methyl iodide[11] (see Fig. 2).

On the other hand, Sentaro Mayeda cyclized 2-methylaminobenzoic acid with both urea and potassium cyanate and obtained the same product 1-methyl-2,4-quinazolinedione (XVIII) m.p. 265–266° (see Fig. 2).[10] Confirmation of the existence of (XVIII) m.p. 265–266° was later reported by Seide[12] who prepared this compound by an entirely different series of reactions. Furthermore the experiments of Sentaro Mayeda pertaining to the 1-isomer were confirmed in this Laboratory.

Bogert[7] later reported that the product of the direct methylation of 2,4-quinazolinedione with alkaline methyl iodide was the 3-methyl isomer which he concluded was identical with the 3-methyl-2,4-quinazolinedione (XIV) m.p. 234°, prepared by the cyclization procedures of Abt. Bogert's work has likewise been confirmed in this Laboratory. It is possible that the different results obtained by Bogert and Abt (products m.p. 234° and 147°, respectively) upon direct methylation of 2,4-quinazolinedione may be due to different thermal conditions of the experiments.

In view of the anomalous melting point data, mixed melting point tests were run between each of the following: (1) 3-methyl-2,4-quinazolinedione (XIV), m.p. 242°, prepared by the method of Bogert with a small amount of 1-methyl-2,4-quinazolinedione (XVIII), m.p. 265° prepared by the method of Sentaro Mayeda (also *vice*

*versa*); (2) compound (XIV) with the decarboxylation product (XIII), m.p. 198°; (3) compounds (XVIII) and (XIII). In each test there was an appreciable lowering of the melting point which proves that XIII could hardly be a mixture of XIV and XVIII.

One must conclude that there is reasonable support for the structures proposed by Abt and Sentaro Mayeda for both the 1- and 3-methyl-2,4-quinazolinediones. The only data which appear questionable are the melting points, which can best be explained on the basis of, (1) multiple melting points; (2) possibility of isomeric mixtures of 1- and 3-methyl-; or (3) the possibility of stereoisomerism. However, the mixed melting point behavior precludes the first two possibilities, leaving only the alternate explanation, namely, the existence of two stereoisomers of both 1- and 3-methyl-2,4-quinazolinediones. A similar type of isomerism has been reported in the alkaloid literature.[13] If such is the case, then the decarboxylation product (XIII) m.p. 198° appears to be the other stereoisomer of 3-methyl-2,4-quinazolinedione, m.p. 242°.

If XIII is not a stereoisomer of 1(or 3)-methyl-2,4-quinazolinedione then the methyl substituent must be in some other position or attached in some other manner. This would change many of the accepted ideas regarding the methylation products of the quinazolones. For this reason, further detailed studies of this interesting phenomenon are being undertaken by this Laboratory.

## Experimental[14]

**5-Diazoacetyl-1,3-dimethyl-2,4-quinazolinedione (III).**—2,4-Quinazolinedione-5-carboxylic acid (I) was prepared and converted to the corresponding acid chloride by the method of Lange and co-workers. The addition of a few drops of quinoline to the thionyl chloride, besides materially shortening the time of chlorination, gave a purer product.

Twelve and four-tenths grams (0.0553 mole) of 2,4-quinazolinedione-5-carbonyl chloride (II) was pulverized into a fine powder and added gradually with stirring to 600 ml. of an ice-cold benzene solution of diazomethane prepared from 60 g. of N-nitroso-methylurea (0.40 mole of diazomethane). The reaction took place rather slowly as indicated by the rate of evolution of nitrogen gas. After stirring for six hours, the solution was allowed to warm to room temperature and then left standing overnight. The insoluble residue (0.5 g.) was removed by filtration and the solvent concentrated under reduced pressure to 100 ml. After standing in a refrigerator for two days the crystalline diazoketone was removed. The mother liquor was then evaporated to dryness under reduced pressure and the gummy residue redissolved in warm acetone. An additional amount of the diazoketone was obtained by the addition of ether to the acetone solution. The combined fractions weighed 10.1 g. (80%).

For analysis, a portion of the crude diazoketone was recrystallized twice from acetone yielding hard, colorless cubes which on standing decompose, m. p. 157–159°.

*Anal.* Calcd. for $C_{12}H_{10}O_3N_4$: C, 55.80; H, 3.91; N, 21.70. Found: C, 55.7; H, 3.88; N, 21.7.

The diazoketone was also prepared from 1,3-dimethyl-2,4-quinazolinedione-5-carboxylic acid (VIII) *via* the acyl chloride in a similar manner. The yield in this instance was only 40%.

**5-Bromoacetyl-1(or 3)-methyl-2,4-quinazolinedione (IV).**—Six grams (0.023 mole) of 5-diazoacetyl-1,3-dimethyl-2,4-quinazolinedione (III) was dissolved in 60 ml. of dry chloroform. The solution was cooled with an ice-bath and then treated with a stream of dry hydrogen bromide until the evolution of nitrogen ceased. The precipitated bromomethyl ketone was filtered, washed with ether and dried in a vacuum. Some additional product was obtained by concentration of the mother liquor. The combined yield weighed 6.6 g. (91%). A portion of this product was recrystallized twice from an alcohol–ether mixture to yield white crystals, m. p. 200–201°.

*Anal.* Calcd. for $C_{11}H_9O_3N_2Br$: C, 44.44; H, 3.05; N, 9.43; Br, 26.9. Found: C, 44.8; H, 3.15; N, 9.49; Br, 27.3.

**5-(2-Morpholine-1-oxoethyl)-1(or 3)-methyl-2,4-quinazolinedione Hydrochloride (V).**—Four and five-tenths grams (0.015 mole) of 5-bromoacetyl-1(or 3)-methyl-2,4-quinazolinedione (IV) was suspended in 50 ml. of acetone. To this was added dropwise with shaking 2.6 g. (0.030 mole) of redistilled morpholine. The bromomethyl ketone dissolved gradually accompanied by the precipitation of crystalline morpholine hydrobromide. After standing overnight, the morpholine hydrobromide was removed by filtration and the solvent concentrated under reduced pressure to 10 ml. Fifty milliliters of water was added to the concentrate; the precipitated crude amino ketone was filtered, washed thoroughly with water and vacuum dried. The crude product (m. p. 180° dec.) was then dissolved in 20 ml. of absolute ethanol, cooled with an ice-bath and dry hydrogen chloride gas was bubbled into the solution. The hydrochloride of the amino ketone precipitated upon the addition of dry ether in the form of a voluminous precipitate, which was separated from the mother liquor by means of centrifugation. The product (2 g.) after washing twice with dry ether was a hygroscopic white solid decomposing at about 150°.

*Anal.* Calcd. for $C_{15}H_{18}O_4N_3Cl$: N, 12.38; ionizable Cl, 10.44. Found: N, 12.5; ionizable Cl, 10.20.

The monopicrate of the amino ketone was prepared by dissolving a sample of the hydrochloride in water and adding saturated aqueous sodium picrate solution. The precipitate obtained after recrystallization from ethanol–ether mixture was a yellow mass. On heating, it turned brownish in color at about 120° and decomposed at 140°.

*Anal.* Calcd. for $C_{21}H_{20}O_{11}N_6$: C, 47.35; H, 3.80; N, 15.78. Found: C, 47.7; H, 4.03; N, 15.6.

**5-(2-Morpholine-1-hydroxyethyl)-1(or 3)-methyl-2,4-quinazolinedione Hydrochloride (VI).**—A solution containing 0.56 g. (0.0016 mole) of the amino ketone hydrochloride (V) and 50 ml. of dry methanol was reduced in a low-pressure hydrogenation apparatus at 30 p. s. i. pressure in the presence of 200 mg. of 10% palladium-on-carbon catalyst. After shaking for two hours, the catalyst was removed by filtration and the solution concentrated to 10 ml. The amino alcohol hydrochloride precipitated by the addition of dry ether was separated by centrifuging and yielded 0.30 g. (53%) of a slightly colored, very hygroscopic solid. For analysis, a portion of this product was reprecipitated twice from ethanol with dry ether, yielding a very hygroscopic white mass which decomposed without melting at about 200°.

*Anal.* Calcd. for $C_{15}H_{20}O_4N_3Cl$: N, 12.30; ionizable Cl, 10.38. Found: N, 12.52; Cl, 10.50.

The monopicrate was prepared by adding a saturated aqueous sodium picrate solution to an aqueous solution of the amino alcohol hydrochloride. The product after recrystallization from an alcohol–ether mixture was a yellow solid decomposing at about 150°.

*Anal.* Calcd. for $C_{21}H_{22}O_{11}N_6$: C, 47.17; H, 4.16; N, 15.72. Found: C, 47.6; H, 4.16; N, 15.6.

**1,3-Dimethyl-2,4-quinazolinedione-5-carboxylic Acid (VIII).**—Five grams (0.023 mole) of 2,4-quinazolinedione-

(13) Willstätter, *Ber.*, **29**, 936 (1896); Willstätter and Muller, *ibid.*, **31**, 1202 (1898); Hess, *ibid.*, **52**, 1622 (1919).

(14) All melting points are corrected.

5-carboxylic acid (I) was added in portions with stirring to 200 ml. of an ice-cold ethereal solution of diazomethane prepared from 20 g. of N-nitrosomethylurea (0.13 mole of diazomethane). The reaction appeared to take place rapidly as evidenced by the vigorous evolution of nitrogen gas. After standing at room temperature for six hours, the filtered ethereal solution was evaporated to dryness to yield 4.0 g. (66%) of slightly colored crystals. The crystals were purified by two recrystallizations from ethanol yielding 3.1 g. of colorless product, m. p. 142–143°. This product (VII) was found to be identical with the ester obtained by Lange, Chisholm and Szabo from the complete methylation of 2,4-quinazolinedione-5-carboxylic acid with dimethyl sulfate and sodium hydroxide.

Three grams (0.012 mole) of the ester was hydrolyzed by refluxing with 20 ml. of 20% hydrochloric acid for three hours; toward the end of the hydrolysis, colorless crystals separated out. After standing in the refrigerator overnight, the mixture was separated by filtration giving 2.0 g. (70%) of needles. A portion of this product was recrystallized from ethanol for analysis, m. p. 250–253°.

*Anal.* Calcd. for $C_{11}H_{10}O_4N_2$: C, 56.39; H, 4.31; neut. equiv., 234. Found: C, 56.8; H, 4.50; neut. equiv., 238.

**1,3-Dimethyl-2,4-quinazolinedione-5-carbonyl Chloride (IX).**—One and six-tenths grams (0.072 mole) of 1,3-dimethyl-2,4-quinazolinedione-5-carboxylic acid (VIII) was refluxed for half an hour with 20 ml. of thionyl chloride containing three drops of quinoline. The resultant clear solution was concentrated to a few ml. and the crystalline acid chloride was removed by filtration, washed with a small amount of dry ether; yield 1.6 g., (95%), m. p. 178–180° with decomposition.

*Anal.* Calcd. for $C_{11}H_9O_3N_2Cl$: Cl, 14.68. Found: Cl, 14.3.

The acyl chloride (IX) upon treatment with diazomethane gave a diazoketone which was judged to be identical with (III) on the basis of mixed melting point tests.

**1-(or 3)-Methyl-2,4-quinazolinedione-5-carboxylic Acid (X).**—Scott and Cohen reported that limited methylation of 2,4-quinazolinedione-5-carboxylic acid with dimethyl sulfate in the presence of sodium hydroxide yields 2,4-dimethoxyquinazoline-5-carboxylic acid. However, Lange, Chisholm and Szabo later claimed that the product was actually 1,3-dimethyl-2,4-quinazolinedione-5-carboxylic acid. The acid obtained after repeating the work in this Laboratory (after two recrystallizations from ethanol) was a monomethyl acid as shown by the analysis, m. p. 332–333° (uncor.).

*Anal.* Calcd. for $C_{10}H_8O_4N_2$: C, 54.54; H, 3.66; neut. equiv., 220. Found: C, 54.5; H, 3.85; neut. equiv., 221, 222.

**5-(1-Hydroxyethyl)-1(or 3)-methyl-2,4-quinazolinedione (XII).**—A suspension containing 1 g. (0.0034 mole) of 5-bromoacetyl-1(or 3)-methyl-2,4-quinazolinedione (IV) or 0.9 g. (0.0036 mole) of 5-diazoacetyl-1,3-dimethyl-2,4-quinazolinedione (III) and 10 ml. of a 10% stannous chloride solution in concentrated hydrochloric acid was heated on a water-bath with stirring for two hours. The resultant clear solution was diluted with 20 ml. of water and, after standing overnight, yielded 0.7 g. (95%), and 0.35 g. (45%) of colorless crystals melting at 212–213°.

*Anal.* Calcd. for $C_{11}H_{12}O_3N_2$: C, 59.97; H, 5.50; N, 12.72. Found: C, 59.8; H, 5.21; N, 12.9.

**1-(or 3)-Methyl-2,4-quinazolinedione-5-carboxylic Acid (XI).**—One gram (0.0039 mole) of 5-diazoacetyl-1,3-dimethyl-2,4-quinazolinedione (III) or 1.0 g. (0.0034 mole) of 5-bromoacetyl-1(or 3)-methyl-2,4-quinazolinedione (IV) or 0.51 g. (0.0023 mole) of 5-(1-hydroxyethyl)-1(or 3)-methyl-2,4-quinazolinedione (XII) was suspended in 50 ml. of a water solution containing 1.25 g. (0.008 mole) of potassium permanganate. The mixture was maintained at 80° with stirring for one hour. After removing the precipitated manganese dioxide, the clear, slightly colored solution was carefully acidified with dilute hydrochloric acid. The crystals which formed on cooling were separated, yielding 0.60 g. (66%), 0.40 g. (62%) and 0.14 g. (27%) of product, respectively. A portion of each was purified by decolorizing with carbon and recrystallizing twice from aqueous alcohol, m. p. 230–237° with evolution of gas.

*Anal.* Calcd. for $C_{10}H_8O_4N_2$: C, 54.53; H, 3.66; neut. equiv., 220. Found: C, 54.9; H, 3.83; neut. equiv., 218.

**1(or 3)-Methyl-2,4-quinazolinedione (XIII).**—Two and a half grams (0.011 mole) of 1(or 3)-methyl-2,4-quinazolinedione-5-carboxylic acid (XI) was heated to 250° in a sublimation apparatus. After the evolution of carbon dioxide ceased, the residue was sublimed at 200° under reduced pressure. The sublimate (0.70 g., 35%) was triturated with a small amount of 1% sodium carbonate solution and the insoluble residue recrystallized from ethanol; hard needles, m. p. 198–199°.

*Anal.* Calcd. for $C_9H_8O_2N_2$: C, 61.34; H, 4.58. Found: C, 61.2; H, 4.80.

## Summary

Methods for the preparation of an amino alcohol derived from 2,4-quinazolinedione-5-carboxylic acid are given in detail. Several unusual reactions of 5-diazoacetyl-1,3-dimethyl-2,4-quinazolinedione are described. Evidence supporting the existence of two isomeric 1-methyl-2,4-quinazolinediones and two isomeric 3-methyl-2,4-quinazolinediones is presented.

# Streptomyces Antibiotics. XXII. Configuration of Streptose and Streptobiosamine

BY FREDERICK A. KUEHL, JR., ROBERT L. CLARK, MARY NEALE BISHOP, EDWIN H. FLYNN AND KARL FOLKERS

The degradative preparation of dihydrostreptosonic acid lactone and the configuration of streptose and streptobiosamine have been communicated[1]; the details of these studies and a new improved preparation of the lactone are described herein. The improvement also made available crystalline tetraacetyldihydrostreptobiosamine.

Although the structural formula[2] of streptobiosamine was determined, certain stereochemical aspects of the structure remained to be elucidated. The configuration of the glycosidic linkage between streptose and N-methyl-L-glucosamine has been calculated[3] to be $\alpha$-L on the basis of the rotations of tetraacetylbisdesoxystreptobiosamine[4] and its components.[5,6,7] The stereochemical features of streptobiosamine remaining unknown concerned the streptose moiety, and for the elucidation of this aspect of the molecule, the lactone and the hydrazide of dihydrostreptosonic acid have been prepared to determine the sign of their optical rotations.

Methyl pentaacetyldihydrostreptobiosaminide[8] (I), which is prepared from dihydrostreptomycin, was converted into ethyl pentaacetylthiodihydrostreptobiosaminide by reaction with ethyl mercaptan and hydrogen chloride. The crude thioglycoside was reacetylated, and the product was treated with mercuric chloride and

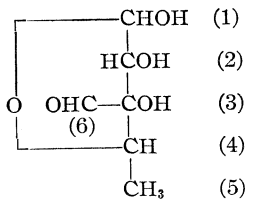
strontium carbonate for the preparation of pentaacetyldihydrostreptobiosamine[9] (II). The hy-

(9) Stavely, Wintersteiner, Fried, White and Moore, *ibid.*, **69**, 2742 (1947).

drolysis of this thioglycoside by mercuric chloride is similar to that used in the preparation of tetraacetylstreptobiosamine.[2] The amorphous pentaacetyldihydrostreptobiosamine (II) was acetylated to give the crystalline hexaacetyldihydrostreptobiosamine (III). This derivative is identical with hexaacetyl-$\alpha$-dihydrostreptobiosamine which has been described by others.[9]

Oxidation of pentaacetyldihydrostreptobiosamine (II) with bromine in the presence of strontium carbonate followed by reacetylation gave amorphous hexaacetyldihydrostreptobiosamic acid lactone, which was not further characterized. Hydrolysis of this oxidation product with 5% hydrochloric acid gave N-methyl-L-glucosamine and a new crystalline compound, $C_6H_{10}O_5$, which was designated dihydrostreptosonic acid lactone. Although dihydrostreptosonic acid lactone may be obtained by this series of reactions, the process is laborious and another degradative series was sought.



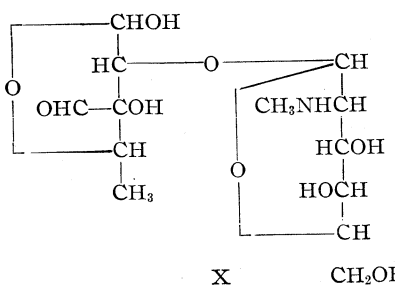
Streptomycin has been converted stepwise in good yields to ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal (IV) and to tetraacetylstreptobiosamine (V).[2] It has now been found that crystalline tetraacetylstreptobiosamine (V) may be hydrogenated with Raney nickel catalyst to tetraacetyldihydrostreptobiosamine (VI). In this hydrogenation, the preferential reduction of the formyl group takes place to an extent of at least 65%. Proof of this preferential reaction was secured by acetylation of the tetraacetyldihydrostreptobiosamine (VI) to give the known hexaacetyldihydrostreptobiosamine (III).

Tetraacetylstreptobiosamine (V) reacted with acetic anhydride in pyridine solution to give a crystalline product of the composition $C_{27}H_{39}NO_{17}$, which has been formulated as heptaacetylstreptobiosamine (VIII).

Tetraacetyldihydrostreptobiosamine (VI) was oxidized also with bromine, and then after hydrolysis the dihydrostreptosonic acid lactone (VII) was obtained. The preparation of the lactone by the latter series of reactions was more satisfactory.

Dihydrostreptosonic acid lactone was easily separated from N-methyl-L-glucosamine, because of its solubility in acetone. The compound behaved as a lactone upon potentiometric titration, and showed an absorption band at 5.65$\mu$ in the infrared corresponding to the lactone carbonyl group. Titration of dihydrostreptosonic acid lactone with sodium periodate showed that oxidation ceased in fifteen minutes after the consumption of two moles of oxidant. The oxidation liberated formaldehyde which was isolated as the dimedone derivative. These data, in conjunction with the known structure of streptobiosamine,[2] permit structure VII to be written for dihydrostreptosonic acid lactone.

Carbon atom 4 of streptose (VIII) was shown to be L, since streptobiosamine was degraded to



VIII

4-desoxy-L-erythrose[10]; by convention then, streptose is an L-sugar. The hydroxyl groups at carbon atoms 2 and 3 of streptose are known to have *cis* configuration, because bisdesoxystreptose formed an acidic complex with boric acid.[11] The knowledge of the configuration about either $C_2$ or $C_3$ would complete the elucidation of the total configuration of streptose.

The application of Hudson's rule[12] of optical rotation to streptosonic acid diamide,[2] which is dextrorotatory, indicates that the hydroxyl group at $C_2$ lies on the right. The application of the rule to this compound may be questioned, since the substance is a diamide. However, the application of the rule to dihydrostreptosonic acid amide would be more satisfactory, but the lactone was recovered after attempts to prepare the amide. The application of the hydrazide rule of Levene and Hudson to the hydrazide of dihydrostreptosonic acid (IX) was possible, since the lactone reacted readily with hydrazine in alcoholic solution to give the hydrazide (IX) in almost quantitative yield. Since the hydrazide was dextrorotatory, the hydroxyl group at $C_2$ may be assumed to be on the right; this confirms the configuration deduced from the rotation of the diamide of streptosonic acid. Credence in the applicability of these rules to those branched chain compounds is strengthened by the observation that both streptosonic acid lactone[2] and dihydrostreptosonic acid lactone are levorotatory. These lactones must be levorotatory if Hudson's lactone rule is applicable, since it is established conclusively that the configuration about $C_4$ of this lactone is L. The nature of the $\gamma$-lactone group of dihydrostreptosonic acid lactone is established by the above-mentioned periodate oxidation results.

The configuration of streptobiosamine may now be represented by structure X.

## Experimental

**Pentaacetyldihydrostreptobiosamine (II) from Dihydrostreptomycin.**—A 5.43-g. sample of methyl pentaacetyldihydrostreptobiosaminide[2] (prepared from dihydrostreptomycin) was suspended in 50 ml. of ethyl mercaptan and the solution was saturated with dry hydrogen chloride. The crystals dissolved after several hours and the product deposited from the solution as an oil after standing overnight at room temperature. The ethyl mercaptan was removed *in vacuo* and the product was reacetylated by reaction with acetic anhydride in the presence of sodium acetate for one-half hour on the steam-bath. The acetylated product, after removal of excess acetic anhydride *in vacuo*, was separated from inorganic matter by extraction with chloroform. The chloroform extractives were dissolved in 200 ml. of 50% acetone and the solution was refluxed with 20 g. of strontium carbonate and 8 g. of mercuric chloride for one-half hour. After cooling, the reaction mixture was filtered and concentrated *in vacuo* to remove the acetone. The resulting aqueous solution was extracted continuously with chloroform to give 5.641 g. of amorphous pentaacetyldihydrostreptobiosamine.

**Hexaacetyldihydrostreptobiosamine (III) from Dihydrostreptomycin.**—A 621-mg. portion of pentaacetyldihydrostreptobiosamine was reacetylated in 8 ml. of acetic anhydride and 15 ml. of pyridine by allowing the mixture to stand for two days at 5°. The acetylation product was obtained as an amorphous powder, 532 mg. A solution of this material in 10 ml. of 3:7 chloroform–ether was passed over 25 g. of acid-washed alumina. The column was developed with 25 ml. of 3:7 chloroform–ether, 25 ml. of 1:1 chloroform–ether, 25 ml. of chloroform, and finally with 25 ml. of 1:9 methanol–chloroform. The product was removed from the column by elution with 25 ml. of 1:5 methanol–chloroform. It weighed 323 mg. and when it was dissolved in chloroform–ether, the solution deposited 102 mg. of crystalline hexaacetyldihydrostreptobiosamine, m. p. 141–143°. After a second recrystallization, the product melted at 146–147°.

*Anal.* Calcd. for $C_{25}H_{35}O_{15}N$: O-acetyl, 36.5. Found: O-acetyl, 36.6.

**Dihydrostreptosonic Acid Lactone (VII) from Pentaacetyldihydrostreptobiosamine.**—A solution of 2.5 g. of pentaacetyldihydrostreptobiosamine in 100 ml. of water containing 3 g. of bromine and 12 g. of strontium carbonate was maintained at 25° overnight in the dark. The reaction mixture was then filtered and concentrated *in vacuo* until all the bromine was removed. The resulting colorless solution was shaken with excess silver carbonate, filtered, then treated with hydrogen sulfide and filtered once more. The aqueous solution was concentrated *in vacuo* to a residue which was acetylated in pyridine–acetic anhydride. The crude acetylation product, 1.984 g., failed to crystallize. A 1.6-g. portion of this product was hydrolyzed by dissolving in 30 ml. of 5% hydrochloric acid and refluxing the solution for two hours. The hydrolysate was clarified by treatment with Darco and concentrated *in vacuo* to a residue. This dried residue was dissolved in 4 ml. of methanol and 75 ml. of acetone was gradually added. The precipitated N-methyl-L-glucosamine hydrochloride was removed by filtration and the filtrate was concentrated *in vacuo* to a residue. This product was further purified by dissolving it in 1 ml. of methanol and again adding 60 ml. of acetone. A final purification was accomplished by dissolving the acetone soluble material in dioxane and filtering the traces of the methylamino sugar. The product, 402 mg., was dissolved in 2 ml. of dioxane and treated with 20 ml. of chloroform. The dihydrostreptosonic acid lactone crystallized; yield, 190 mg., m. p. 135–138°. After recrystallization from chloroform-methyl ethyl ketone, the lactone melted at 143–144°, $[\alpha]_D$ −32° (*c*, 0.40 in water).

*Anal.* Calcd. for $C_6H_{10}O_5$: C, 44.45; H, 6.22; mol. wt., 162. Found: C, 44.02; H, 5.87; eq. wt., 167 (potentiometric titration).

**Tetraacetylstreptobiosamine[2] (V).**—A solution of 45.9 g. of crude ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal which was obtained by the acetylation of 35.9 g. of crystalline ethyl thiostreptobiosaminide diethyl mercaptal hydrochloride, 75.4 g. of mercuric chloride, and 92 g. of cadmium carbonate in 920 ml. of 50% acetone was heated under reflux for forty minutes. Vigorous mechanical stirring was required to prevent bumping. The resulting slurry was cooled, filtered and concentrated *in vacuo* to *ca.* 250 cc. The product was removed from the aqueous concentrate by continuous chloroform extraction. The chloroform extract, dried and adjusted to a volume of 100 ml., was poured onto a column of 100 g. of acid washed alumina. Elution of the column with 350 ml. of chloroform gave, after evaporation of the solvent, 27.7 g. of amorphous material. Crystallization of this material from acetone–absolute ether yielded 11.765 g. of product, m. p. 184–187°. After several recrystallizations from the same solvent, the tetraacetylstreptobiosamine melted at 188–189°, $[\alpha]_D$ −78.4° (*c*, 1.00 in chloroform).

*Anal.* Calcd. for $C_{21}H_{31}O_{13}N$: C, 49.89; H, 6.19; N, 2.77; acetyl, 34.0; O-acetyl, 25.5. Found: C, 49.90; H, 6.48; N, 2.73; acetyl, 34.3; O-acetyl, 25.3.

**Tetraacetyldihydrostreptobiosamine (VI).**—Twenty-four grams of tetraacetylstreptobiosamine was dissolved in 150 ml. of methanol and 400 ml. of water and shaken with 18 g. of Raney nickel catalyst. The mixture was then centrifuged and the filtrate was hydrogenated in the presence of another 18-g. portion of Raney nickel catalyst at 40 lb. pressure of hydrogen. Hydrogen ceased to be absorbed after three and one-half hours. The nickel was removed by filtration, and the solvent was removed *in vacuo*. A solution of the residue in 200 ml. of chloroform was dried, filtered, and concentrated *in vacuo* leaving 24 g. of a gum. To a solution of the gum in 100 ml. of methanol, was added 200 ml. of ether and 150 ml. of petroleum ether. After standing overnight, 10.4 g. of product was removed by filtration, m. p. 188–190° (cor.). The mother liquor was concentrated to 25 ml., and 25 ml. of ether and 25 ml. of petroleum ether were added. After cooling the solution overnight, 5.0 g. of additional product was obtained, m. p. 188–189°. After recrystallization from methanol–ether, the tetraacetyldihydrostreptobiosamine melted at 190–191°, $[\alpha]^{25}_D$ −86.5° (*c*, 1.0 in chloroform).

**Hexaacetyldihydrostreptobiosamine (III).**—Ten grams of tetraacetyldihydrostreptobiosamine was dissolved in 60 ml. of pyridine, and 60 ml. of acetic anhydride was added. After standing overnight, the solvents were removed *in vacuo*. The residue was dissolved in 50 ml. of methanol and the solution was filtered. To the filtrate was added 100 ml. of ether and then petroleum ether to the point of incipient cloudiness. After crystallization began, 300 ml. of petroleum ether was added, and the mixture was cooled overnight. The hexaacetyldihydrostreptobiosamine was removed by filtration; 7.7 g., m. p. 141–143°. After several recrystallizations from methanol–ether, it melted at 146–147°, $[\alpha]^{25}_D$ −113° (*c*, 0.5 in chloroform).

*Anal.* Calcd. for $C_{25}H_{37}O_{15}N$: C, 50.76; H, 6.30; N, 2.37. Found: C, 50.68; H, 6.23; N, 2.54.

**Heptaacetylstreptobiosamine (VIII).**—A solution of 413 mg. of tetraacetylstreptobiosamine in 4 ml. of pyridine and 2 ml. of acetic anhydride was allowed to stand for eighteen hours at 0°. The solvent was removed *in vacuo* and the residue was dissolved in ice water. Extraction with chloroform removed 460 mg. of an oily product. This material was dissolved in 4 ml. of 1:3 acetone–absolute ether and poured onto a column of 10 g. of acid-washed alumina. The column was then developed with 15 ml. of the same solvent mixture and then eluted with 20 ml. of 1:1 acetone–ether to give 236 mg. of an oil. A solution of this oil in a mixture of acetone, ether, and petroleum ether deposited 28 mg. of heptaacetylstreptobiosamine; m. p. 151–152°, $[\alpha]_D$ −106° (*c*, 0.70 in chloroform). Further recrystallizations did not alter the melting point.

*Anal.* Calcd. for $C_{27}H_{39}O_{17}N$: C, 49.94; H, 6.06; O-acetyl, 39.7. Found: C, 49.98; H, 6.40; O-acetyl, 39.5.

**Dihydrostreptosonic Acid Lactone (VII) from Tetraacetyldihydrostreptobiosamine.**[1]—Oxidation of 5.7 g. of crystalline tetraacetyldihydrostreptobiosamine yielded

after hydrolysis 433 mg. of dihydrostreptosonic acid lactone.

**Determination of Periodate Consumption by Dihydrostreptosonic Acid Lactone.**—A 5-ml. aqueous solution of 12.0 mg. of the lactone and 78.0 mg. of sodium metaperiodate was allowed to stand at room temperature. The periodate consumption was determined by the standard arsenite method.[13] A 1-ml. aliquot required 7.975 ml. of sodium arsenite solution (1 ml. ≅ 1.09 mg. of sodium meta periodate) corresponding to 2.1 moles after fifteen minutes. No further consumption was observed after one hour.

**Oxidation of Dihydrostreptosonic Acid Lactone (VII).**—A 36.6-mg. quantity of dihydrostreptosonic acid lactone was dissolved in 11.7 ml. of water containing 98 mg. of paraperiodic acid (determined by titration with standard sodium arsenite solution). After two hours, a 1-ml. aliquot was removed and treated with strontium carbonate. The excess strontium carbonate and strontium iodide was removed by filtration. The aqueous filtrate was adjusted to a volume of 1.5 ml. and then treated with 1.5 ml. of an alcoholic solution containing 50 mg. of dimedone. After two hours at 5°, the crystalline product was removed by filtration; yield, 5.5 mg. (97% theory), m. p. 193–194°. After recrystallization of the product from alcohol–water, the melting point did not change. When this derivative was mixed with the dimedone derivative of formaldehyde, no depression of melting point was observed; m. p. 193–194°.

**Hydrazide of Dihydrostreptosonic Acid (IX).**—A solution of 183 mg. of dihydrostreptosonic acid lactone in 10 ml. of ethanol and 0.5 ml. of hydrazine hydrate was allowed to stand for two hours at room temperature. Fifteen milliliters of chloroform was then added and the solution was allowed to stand for one and one-half hours at 5°. The crystalline hydrazide was removed by filtration; yield, 204 mg., m. p. 135–136°. After several recrystallizations from methanol–water, it melted at 137–139°, $[\alpha]^{25}D$ + 23° (*c*, 0.9 in water).

*Anal.* Calcd. for $C_6H_{14}N_2O_5$: C, 37.09; H, 7.26; N, 14.4. Found: C, 36.91; H, 6.96; N, 14.8.

**Acknowledgment.**—The authors are indebted to Dr. Nelson Trenner and his associates for potentiometric titrations and infrared absorption data, and to Mr. Richard Boos and his associates for microanalytical data.

## Summary

Methyl pentaacetyldihydrostreptobiosaminide was converted into amorphous pentaacetyldihydrostreptobiosamine, through the intermediate ethyl thioglycoside, which gave a crystalline hexaacetyldihydrostreptobiosamine. Oxidation of pentaacetyldihydrostreptobiosamine with bromine gave amorphous hexaacetyldihydrostreptobiosamic acid lactone which was hydrolyzed to N-methyl-L-glucosamine and the new dihydrosteptosonic acid lactone.

Tetraacetylstreptobiosamine was hydrogenated selectively with Raney nickel catalyst to the new crystalline tetraacetyldihydrostreptobiosamine. Oxidation and hydrolysis of the tetraacetyldihydro derivative gave also dihydrostreptosonic acid lactone. The lactone gave a hydrazide.

Application of rules of rotation to streptosonic acid diamide and dihydrostreptosonic acid hydrazide indicates that the configuration at $C_2$ is D. The configuration of streptose and streptobiosamine are now known.

RAHWAY, NEW JERSEY RECEIVED SEPTEMBER 27, 1948

# Reactions of Free Hydroxyl Radicals with Organic Compounds

BY NICHOLAS A. MILAS, LOUIS E. STAHL[1] AND BENJAMIN B. DAYTON[2]

In previous publications on hydroxylation of organic compounds in solution with hydrogen peroxide in the presence of catalysts[3] or ultraviolet light[4] we postulated the formation and subsequent reaction of free hydroxyl radicals with organic compounds.[5,6] Hydroxylations of this type have not been attempted previously in the gaseous phase in spite of the fact that numerous reactions have been studied with free hydroxyl radicals usually obtained by the dissociation of water or mixtures of water and oxygen in glow discharges.[7–10]

The present investigation describes some experiments in which free hydroxyl radicals were allowed to react in the gaseous phase with saturated and unsaturated hydrocarbons. It has been found that free hydroxyl radicals are much more reactive in the gaseous phase than in solution. For example, in solution hydroxyl radicals are not known to react with saturated aliphatic hydrocarbons, while in the gaseous phase they react readily with methane to form chiefly carbon dioxide and formic acid, small amounts of methanol, and traces of ethanol. With ethylene and a large excess of hydroxyl radicals, formaldehyde, formic acid and carbon dioxide were the chief products with possible traces of ethylene glycol. When ethylene was used in large excess so that it entered the discharge tube, besides formaldehyde, acetylene and ethane were found among the condensa-

tion products, while a considerable amount of a white solid polymer of aromatic odor was formed in the inner surface of the discharge tube. With isobutylene, acetone and formaldehyde were the chief products isolated. In all cases hydrogen peroxide and organic peroxides were also detected among the condensation products when liquid nitrogen was used as the cooling bath while no hydrogen peroxide or organic peroxides were detected when solid carbon dioxide–acetone mixture was the cooling bath.

## Discussion

Perhaps the high reactivity of hydroxyl radicals in the gaseous phase is due to the fact that as they emerge from the discharge tube they are associated with considerably more energy than those which are formed in solution. Furthermore, the hydroxyl radicals in solution may be associated with other groups while those in the gaseous phase are free. Besides, it is quite possible that under the conditions of our experiments other reactive groups, such as atomic hydrogen, may be present in the gaseous phase which, together with the hydroxyl radicals, may initiate reaction outside the glow discharge to produce other radicals. Although a number of possibilities have occurred to us regarding the interpretation of these reactions, we do not wish to propose them at present, since we have not carried out detailed kinetic studies.

## Experimental

**Arrangement of Apparatus.**—A high frequency oscillator[11] similar to that used[12] for the conversion of ergosterol to vitamin D was used in these experiments. It had a frequency range of 4,000 to 22,000 kilocycles. When the oscillator was operating at 19,000 kilocycles with a tank current of 21 amperes, plate current of 340 milliamperes, plate voltage of 1800 volts and filament voltage of 10 volts and maintaining the water vapor at a pressure of 0.1 to 0.2 mm., ample hydroxyl radicals were obtained as judged by the light red or pink color of the glow.[13] The apparatus and traps were arranged as shown in Fig. 1. A Cenco Hyvac oil pump was connected to tube A which was loosely packed with anhydrous calcium chloride. The two-way stopcock B served to draw air into the oil pump when the latter was stopped for purposes of withdrawing samples for analysis. The dibutyl phthalate manometer C was connected to a dibutyl phthalate pump[14] and calibrated to read directly in millimeters of mercury. This was used with the precautions recommended by von Brandenstein and Klumb.[15] The large trap D was immersed in liquid nitrogen during runs to condense all gases with the exception of hydrogen. The organic gases were slowly fed in at E passing through the capillary F and into the reaction or mixing chamber G (4 × 4 cm.). The visible glow in the discharge chamber H (6 × 25 cm.) extended only to the mouth of the reaction chamber.

The water was fed in from I through the capillary J. To prevent condensation of moisture which turned into ice and clogged the mouth of the capillary, the long arm between I and J was wrapped with asbestos tape. The rate of flow of water vapor was controlled by the temperature of I.

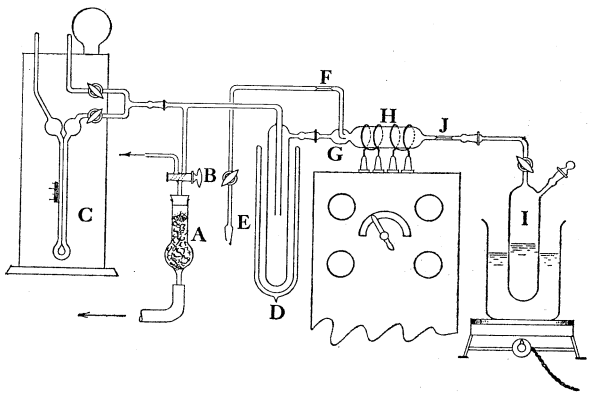

Fig. 1.—Diagram of apparatus for hydroxylation of organic compounds in the gaseous phase.

The pure organic gases were stored over brine and were introduced at E by means of an auxiliary apparatus consisting of a calibrated buret and the usual leveling bottles. The rate of flow was so adjusted as to prevent the organic gases from entering the discharge chamber thereby causing a discoloration of the glow and a deposit of a white solid in the inner surface of the discharge tube.

Before any run was made, the glass apparatus was treated with hot chromic–sulfuric acid solution and thoroughly washed with tap water followed by distilled water and baked in an oven. Since the recombination and destruction of free radicals is known to be a surface reaction, water vapor was passed through the system before the discharge was turned on to poison the glass surface thereby inhibiting this reaction.

**Reaction of Free Hydroxyl Radicals with Ethylene.**—When 1090 cc. (N. T. P.) of ethylene was allowed to react with excess hydroxyl radicals (from water vapor at 0.1–0.2 mm.) in the course of twelve hours, 500 cc. of gaseous and 9 cc. of liquid products were obtained. An analysis of the gaseous products showed the presence of 70% carbon dioxide, 4% ethylene and 26% ethane. The liquid was strongly peroxidic, the peroxide being mainly hydrogen peroxide, since it was largely destroyed by a clean platinum gauze. A weak test for the presence of organic peroxides was noted after the hydrogen peroxide was thoroughly destroyed. When the liquid was distilled, all but about 0.2 cc. of a yellowish oil distilled at 99°, indicating that most of it was water. However, the distillate gave a strong fuchsin–aldehyde reaction and a positive reaction for formic acid. The formaldimethone was prepared,[16] m. p. 188° (cor.), showing that the aldehyde was chiefly formaldehyde. The residual oil boiled above 110° and was suspected of being ethylene glycol. Attempts to prepare a dibenzoate or a di-*p*-nitrobenzoate yielded fine colloidal suspensions which were difficult to purify. In view of small quantities obtained in each experiment it was not found possible to establish definitely the presence of ethylene glycol.

When the experiment was run in such a manner that excess ethylene was allowed to enter the discharge tube, the glow of the discharge changed from pink to purple. After a run of nine hours, the gas analysis showed no carbon dioxide but considerable acetylene and much ethylene. A white deposit which was probably a polymer of ethylene covered the inner surface of the discharge tube. About 1 cc. of a yellow oil condensed in the liquid air trap which gave the usual tests of peroxides, aldehydes and formic acid. In addition, the liquid gave a positive iodoform reaction indicating the presence of small amounts of either ethyl alcohol or acetaldehyde. The formaldimethone prepared from this liquid melted at 185–188° (cor.).

**Reaction of Free Hydroxyl Radicals with Methane.**—In the first experiment 860 cc. (N. T. P.) of methane was

(16) Huntress and Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1941, p. 155.

introduced into the reaction chamber very slowly in the course of twelve hours. At the end of the run the gases were analyzed and found to contain 80% carbon dioxide, no unsaturated hydrocarbons, small amounts of oxygen and saturated hydrocarbons (assumed to be methane). About 10 cc. of water-like liquid having an ethereal odor was collected in the liquid air trap. A test for hydrogen peroxide was negative, although a positive test for organic peroxides was obtained. A clean platinum gauze failed to destroy the peroxides. Both the fuchsin–aldehyde test and the "dimedon" reaction were negative. Both the resoninol–sulfuric acid and the U. S. P. tests[17] for methyl alcohol were strongly positive. Formic acid was also found to be present.

In a second run an excess of methane was used and it was allowed to enter the discharge chamber giving a blue-white glow at one end with the pink (water) glow limited to the end of the tube at which the water vapor entered. A volume of 3 liters of methane was used in this run. The gases were not analyzed. About 16 cc. of a liquid was obtained in the liquid air trap, and was found to give the same positive tests as that of the previous run, but in addition it gave a positive iodoform reaction indicating the presence of small amounts of ethanol.

**Reaction of Free Hydroxyl Radicals with Isobutylene.**—Isobutylene was prepared by the dehydration of *t*-butyl alcohol (80 g.) with oxalic acid (27 g.) and the vapors collected in a trap immersed in acetone–carbon dioxide ice. It was then distilled from the trap by allowing the vapors to pass through a 2-foot vertical column packed with calcium chloride and condensed in another trap to which was attached a stopcock and a ground glass female joint. The isobutylene (10 g.) was introduced into the reaction chamber through the connection E (Fig. 1) by allowing it to evaporate slowly. During the run some isobutylene entered the discharge tube thereby forming purple rings nearer to the reaction chamber while the pink glow (water) persisted in the left half of the discharge tube. At the end of four hours the reaction was stopped and the products condensed in the liquid air trap examined. A liquid (4 cc.) was obtained having a strong odor of formaldehyde. It gave a positive fuchsin–aldehyde test and the formaldimethone prepared from it melted at 188° (cor.). After the removal of formaldehyde the remaining solution gave a strong test for acetone using the sodium nitroprusside reaction.[18] The original liquid also gave a positive test for organic peroxides showing that hydrogen peroxide was probably bound either to formaldehyde or to acetone. The gases were not analyzed.

(17) Reference 16, p. 427.

## Summary

1. The reaction between free hydroxyl radicals formed in a glow discharge and methane, ethylene and isobutylene was studied in the gaseous phase.

2. It has been found that free hydroxyl radicals are much more reactive in the gaseous phase than in solution.

3. Methane was mainly converted to carbon dioxide. Other products found were small amounts of peroxides, methanol, ethanol and formic acid.

4. Ethylene was converted mainly to carbon dioxide, small amounts of peroxides, formaldehyde, formic acid and possibly ethylene glycol. With a large excess of ethylene no carbon dioxide was formed, but formaldehyde, formic acid, traces of ethanol and possibly ethylene glycol, acetylene and a solid polymer were noted.

5. With isobutylene, peroxides, formaldehyde and acetone were the chief products detected.

# The Addition of Benzene to an Acetylenic Ketone

BY CHARLES L. BICKEL AND AUGUSTUS J. FABENS[1]

The literature contains several reports on the reaction of benzene and some of its simple substitution products with $\alpha,\beta$-unsaturated ketones. Vorländer and Friedberg,[2] as well as Fuson and co-workers,[3] used a mixture of aluminum chloride and hydrogen halide as the condensing agent, Fuson reporting that these reactions are reversible. Kohler[4] found that benzene adds to chalcone in the presence of sulfuric acid, giving $\beta,\beta$-diphenylpropiophenone as the only identified product. This reaction is also assumed to be reversible,[5] although the nature of the aromatic residues does not permit a study of reversibility in this case.

The reaction of aromatic compounds with the more highly unsaturated acetylenic ketones has not been reported. The present investigation is a study of the reaction of *o*-chlorophenylbenzoyl acetylene with benzene in the presence of sulfuric acid. Two products have been isolated from this reaction, *o*-chlorodibenzoylmethane and $\beta$-(*o*-chlorophenyl)-chalcone. The diketone is the sole product when a sulfuric acid solution of the acetylenic ketone is treated with water[6]; thus, the isolation of the diketone in this instance indicates either incomplete reaction with benzene or a reversible reaction. $\beta$-(*o*-Chlorophenyl)-chalcone is the product of the net addition of benzene to the acetylenic ketone. A mechanism which is consistent with the known facts is formulated as follows

(1) A senior in the Phillips Exeter Academy during the school year, 1948–1949.

(2) Vorländer and Friedberg, *Ber.*, **56**, 1144 (1923).

(6) Bickel, THIS JOURNAL, **69**, 74 (1947).

Certain observations indicate that the reaction with benzene is not reversible. Reversibility would lead to the formation of dibenzoylmethane and β-phenylchalcone, assuming that the *o*-chlorophenyl group is as easily loosed as the phenyl group.[7] Neither of these compounds was detected in the reaction products. The most conclusive evidence of irreversibility was obtained by treating β-(*o*-chlorophenyl)-chalcone with benzene and sulfuric acid. None of the β-diketone was produced.

The substituted chalcone, like other ethylenic compounds, is soluble in sulfuric acid. The extended period of exposure to the acid appears to convert the chalcone into other products. Thus, as the reaction time is increased in order to decrease the yield of the diketone, the yield of chalcone is decreased. The product or products of this reaction are being investigated and may be reported at a later date.

Attempts to decrease the side-reactions have so far met with no success. The acetylenic ketone was recovered when seventy-five per cent. sulfuric acid was substituted for concentrated sulfuric acid; the use of fuming sulfuric acid decreased the yield of diketone but also materially decreased the yield of chalcone.

This investigation was assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

## Experimental[8]

Since there were no significant variations in the procedure used in all of the runs, the general procedure is described in detail and the results for all runs are summarized in tabular form.

Concentrated sulfuric acid was added to a solution of *o*-chlorophenylbenzoylacetylene[9] in benzene contained in a 250 ml. glass-stoppered Erlenmeyer flask equipped with a Pyrex-enclosed bar magnet, the magnet being rotated at a rate which assured efficient mixing of the two layers. At the end of the stirring operation, the mixture was poured onto ice, the benzene layer washed with water and the benzene evaporated by a current of air. The residue was taken up in ether, the ether solution washed with water and then shaken with saturated cupric acetate solution. The copper salt of the β-diketone was filtered off, washed, dried, weighed and finally converted to the diketone which was isolated and identified.[10] The filtrate from the cupric acetate treatment was shaken with dilute hydrochloric acid, the ether layer washed with water, dried and concentrated, giving β-(*o*-chlorophenyl)-chalcone or unchanged acetylenic ketone.

TABLE I

SUMMARY OF RESULTS[a]

| Time, days | $H_2SO_4$ | Cu salt | Chalcone | Acetylene |
|---|---|---|---|---|
| 2 | 46 | 6.30 | 4.0 | None |
| 7 | 46 | 5.70 | 3.55 | None |
| 14 | 46 | 2.00 | 0.5 | None |
| 4 | 5 | Trace[b] | <0.1 | None |
| 3 | 0.8 | None | None | >9.5 |
| 3 | 46[c] | 5.56 | 2.35 | None |
| 9 | 37[d] | None | None | 10 |

[a] Ten grams of acetylenic ketone and 125 ml. of benzene were used in each run. The times are in days; all other figures are weights in grams. [b] Dark green color in the ether layer but no solid copper salt. [c] Twenty-four grams of concentrated sulfuric acid and 22 g. of 30% fuming sulfuric acid. [d] Twenty-eight grams of concentrated sulfuric acid and 9 g. of water.

**β-(*o*-Chlorophenyl)-chalcone.**—The chalcone is quite soluble in ether, very sparingly soluble in petroleum ether, and crystallizes in sulfur-yellow stout needles melting at 106–107°.

*Anal.* Calcd. for $C_{21}H_{15}OCl$: C, 79.0; H, 4.74. Found: C, 78.4, 78.8; H, 4.78, 4.80.

Chromic acid oxidation of the chalcone in glacial acetic acid solution gave the calculated quantities of benzoic acid and *o*-chlorobenzophenone. The *o*-chlorobenzophenone, melting at 47°, was identified by comparison with a known sample synthesized by the reaction of phenylmagnesium bromide with *o*-chlorobenzaldehyde and by the subsequent oxidation of the *o*-chlorobenzhydrol to *o*-chlorobenzophenone.

**The Reaction of the Chalcone with Benzene and Sulfuric Acid.**—A mixture of 10 g. of the chalcone, 125 ml. of benzene and 46 g. of concentrated sulfuric acid was stirred (magnetic stirrer) for one week and then worked up as described above. Cupric acetate gave no evidence of a β-diketone. Three grams of the chalcone was recovered and the residual oil has as yet yielded no solid products.

## Summary

*o*-Chlorophenylbenzoylacetylene reacts with a mixture of benzene and sulfuric acid to give *o*-chlorodibenzoylmethane and β-(*o*-chlorophenyl)-chalcone. The evidence indicates that the benzene reaction is irreversible.

EXETER, NEW HAMPSHIRE RECEIVED DECEMBER 28, 1948

(7) Fuson (ref. 3) obtained β,β-diphenylpropiophenone by the action of benzene on 2-chlorochalcone.

(8) A magnetic stirrer was used in all of the experiments in which a long period of stirring was required. This made possible the use of a glass-stoppered Erlenmeyer flask and the elimination of the ordinary sleeve type stirrer and the vibration inherent in most stirrers of this type.

# Dimensions of Coiling Polymer Molecules from Viscosity and Light Scattering[1]

BY A. M. BUECHE

In a recent treatment[2] of the intrinsic viscosity of polymer solutions it was pointed out that viscosity data can be used to find the dimensions of polymer molecules in solution. It was shown that data relating the intrinsic viscosity to the molecular weight could be interpreted in terms of the radius of the molecular sphere and the permeability to solvent flow of the polymeric material inside this sphere.

The concept of the molecular sphere was introduced as an approximation in the viscosity theory so that the results could be expressed in closed form. The polymeric molecule was represented by a sphere of radius, $R_s$, having a constant average permeability and polymer density inside. Outside of the sphere the polymer density was taken as zero. The permeability of the molecule to solvent flow was characterized by a shielding length, $L$. $R_s$ and $L$ both depend on molecular weight for linear coiling molecules and are the two parameters evaluated when the suggested treatment of intrinsic viscosity data is followed.

When light is scattered by a molecule larger than about one-twentieth of the wave length it is not scattered symmetrically around the molecule. Due to interference of the light scattered from different parts of the molecule the scattered intensity is greater in the directions close to the direction of the primary beam. This dissymmetry of the scattered light has been shown to be a measure of the dimensions of the molecule.[3] In the case of linear coiling molecules the dissymmetry can be expressed in terms of $R$, the root mean square of the distance from the beginning to the end of the molecule and the wave length, $\lambda$, of the light in solution. The expression for the angular dependence of the relative intensity, $I$, after correction for the polarization of the light is

$$I \sim \frac{2}{x^2}[e^{-x} - (1 - x)] \qquad (1)$$

where

$$x = \frac{2\pi^2 s^2}{3}\left(\frac{R^2}{\lambda^2}\right)$$

and $s = 2\sin(\theta/2)$. Here $\theta$ is the angle between the directions of the primary and scattered beams. If for measuring the scattering dissymmetry only the two angles, 45° and 135°, are used the expression for the quotient, $I_{45}/I_{135}$, of the intensities of these angles can be closely approximated by

$$I_{45}/I_{135} = 1 + 6.556(R/\lambda)^2 \qquad (2)$$

for values of the quotient of the intensities up to 2. If $R^2$ is proportional[4] to the number of units in the molecular chain the quantity $(I_{45}/I_{135} - 1)$ will be proportional to the length of the extended molecule or, for a given polymer, to the molecular weight.

The relationship expressing proportionality between $R^2$ and the molecular weight was derived by Taylor and others on the assumption that parts of the coiling molecule do not interfere with one another in the course of its Brownian motion. This can never be strictly true for a coiling molecule. It seems to be a good approximation, however, for polymers dissolved in good solvents, as in the present case, where the molecules are rather highly extended. In poor solvents where the molecules are more compact the deviations from proportionality between $R^2$ and the molecular weight may be rather large.

In the limit of very permeable linear coiling molecules or low molecular weights it was shown theoretically that the diameter $2R_s$ of the molecular sphere is approximately equal to $R$. They are related by the equation

$$2R_s = 1.056R \qquad (3)$$

The viscosity and light scattering experiments reported here were undertaken to determine the validity of equation (3) for polymer molecules of higher molecular weights and usual permeabilities. The experimental results obtained in the study of solutions of polystyrene in benzene also give information about the stiffness of the polystyrene molecule and indicate that the polystyrene fractions used are not branched or cross-linked as has been reported in some cases.[5]

## Experimental

Six polystyrene fractions[6] were dried under vacuum and weighed amounts were dissolved in reagent grade benzene. Dust was removed from the solutions by filtration through a fine glass filter.

The polystyrene was prepared by thermal polymerization of styrene at an average temperature of 100°. It was fractionated by the method described by Badgely.[7] The essential feature of this method is that a precipitant is used which boils higher than the solvent, and the precipitant–solvent ratio is changed by distillation under reduced pressure. The fractionation procedure was carried out only once.

The light scattering measurements were made using an

instrument designed by P. P. Debye.[8] The phototube below the stage was used in conjunction with the travelling mirror dipping into the solutions. The solutions were held in a rectangular glass cell having a volume of about 300 cc. All measurements were made using the mercury blue line ($\lambda$ = 4358 Å.) as isolated by Corning filters. The scattered light was measured at the three angles, 45, 90 and 135°. The meter readings were converted to absolute scattering values by comparing them with readings obtained from a benzene solution of polystyrene whose turbidity had been determined by the "absolute camera" method.[3]

The refractive index differences between solutions and solvent were measured in a differential refractometer similar to that described by P. P. Debye.[8] This refractive index difference, $\mu - \mu_0$, was a linear function of the concentration in the range 0 to 0.01 g./cc. and independent of the molecular weight. For polystyrene in benzene and $\lambda$ = 4358 Å. the difference can be expressed by

$$\mu - \mu_0 = 0.1151C$$

where $C$ is the concentration in g./cc.

The molecular weights of the fractions were obtained from the 90° scattering values by the usual extrapolation of the concentration divided by the turbidity to infinite dilution. Since some dissymmetry of scattering was observed for each fraction the molecular weights obtained by 90° scattering alone were too low. They were multiplied by the necessary correction factors[3] obtained from equation (1). The corrected molecular weights were found to range from 135,000 to 895,000.

To avoid a direct extrapolation of the dissymmetries to infinite dilution the quantities $C/I_{45}$ and $C/I_{135}$ were plotted as functions of the concentration. These plots were linear at low concentrations. The dissymmetries were obtained by forming the quotients of the intercepts at $C = 0$. The instrument itself was responsible for a dissymmetry, $I_{45}/I_{135} = 1.10$ because the primary beam was not symmetrical around the center of the scattering cell. The dissymmetries as calculated from the intercepts were corrected by dividing by this number.

Flow times, $t$ and $t_0$, of solutions and solvent were measured in an Ostwald viscometer at 38°. The kinetic energy correction was found to be negligible. The intrinsic viscosities were obtained from the intercepts at $C = 0$ of the ln $(t/t_0)$ *vs.* $C$ plots. Account was taken of the difference in concentration of the solutions at room temperature and 38°.

The experimental data are given in Table I and the extrapolated quantities obtained from it are given in Table II.

## Results and Discussion

The dissymmetries are plotted as a function of the molecular weights, $M$, in Fig. 1. The equation of the least squares straight line through the points is

$$I_{45}/I_{135} = 1 + 9.66M\cdot10^{-7} \qquad (4)$$

This linear dependence of dissymmetry on $M$ is what would be expected from a linear coiling molecule in a good solvent as previously discussed. If the molecules were highly branched or cross-linked this linear dependence would not exist. This can be seen in an approximate way by the following considerations.

Suppose the molecule were so highly cross-linked that for light scattering measurements it acted as a sphere of constant density. The diameter of the molecule would then be proportional to the cube root instead of the square root of the molecular weight. It is to be expected that for lesser degrees of cross-linking the diameter would be proportional to an intermediate power. Although there are a number of difficulties to be overcome such data may be useful in making an estimation of the degree of cross-linking.

The dependence of $R$ on the molecular weight can be found from equations (2) and (4) to be

$$R = 1.11M^{1/2} \qquad (5)$$

For a molecular weight of 1,000,000 this leads to $R = 1110$ Å. R. H. Ewart[9] and P. Doty[10] have obtained values of $R$ for polystyrene in other solvents. Ewart investigated a range of molecular weights in carbon tetrachloride and found $R = 1050$ Å. for $M = 1{,}000{,}000$. Doty investigated a polystyrene sample having $M = 4.8 \cdot 10^6$ in toluene. Making use of the proportionality between $R$ and $M^{1/2}$ his value leads to $R = 1080$ Å. The agreement among the three values is better than was expected when the experimental errors are considered.

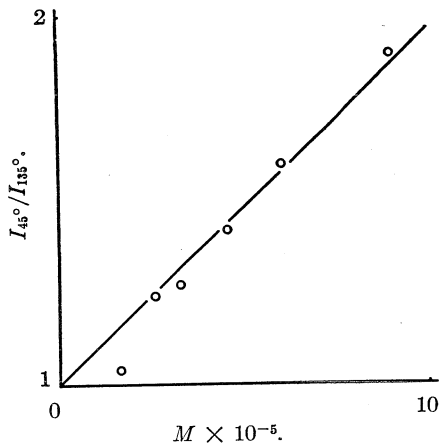

Fig. 1.—Dissymmetries of polystyrene fractions *vs.* molecular weight.

The intrinsic viscosity, $[\eta]$, of a polymer in solution can be expressed as

$$[\eta] = (\Omega/m)\ \phi\ (R_s/L) \qquad (6)$$

where $\Omega$ is the volume of the molecular sphere, $m$ is the mass of one molecule and $\phi(R_s/L)$, a function of the shielding ratio, $R_s/L$, ranges from 0 to 2.5. In utilizing this equation to obtain the size of the molecular sphere a scheme proposed in the original paper[2] was followed.

Figure 2 is a plot of log $[\eta]$ *vs.* log $M$. The slope, $\epsilon$, of the best straight line through the points is 0.850. Values of $R_s/L = 2.85$ and $\phi = 0.560$ corresponding to this slope are found from the table in reference (2). The average molecular weight of the range studied is 384,000 and the corresponding value of the intrinsic viscosity is 116 cc./g. Substitution of these values into equation (6) leads to a value $2R_s = 606$ Å. This is equivalent to the value $2R_s = 1030$ Å. for $M = 1{,}000{,}000$. Fig. 3 is a plot of $[\eta]$ *vs.* $M$. The solid line is that predicted by equation (6) using the quantities determined above. The data agree with the theoretical curve within experimental error.

The value of $2R_s = 1030$ Å. from viscosity is to be compared with $1.056R = 1170$ Å. as determined by light scattering. The two differ by 13%. Since this is about the precision expected from the experiments the diameter of the molecular sphere and the root mean square of the distance between the ends of the molecule can be said to be equal within experimental error.

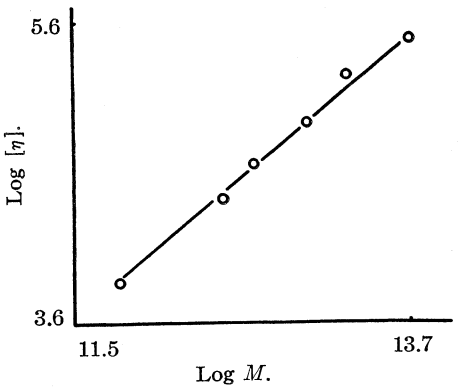

Fig. 2.—Natural logarithmic plot of the intrinsic viscosities of polystyrene fractions *vs.* molecular weight.

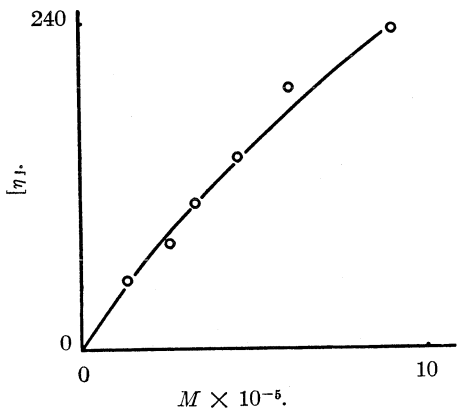

Fig. 3.—Intrinsic viscosities of polystyrene fractions *vs.* molecular weight.

The diameter of the molecular sphere as calculated from these measurements is in some disagreement with that obtained by R. H. Ewart[9] by the same method for polystyrene in benzene. Ewart's measurements lead to $2R_s = 880$ Å. for $M = 1{,}000{,}000$. We are unable to account for the discrepancy between his value and ours of 1030 Å. except for the fact that the samples are not the same. Both values are less than the value of $R$ found by light scattering. This might indicate that the average distance between the ends of the molecule is slightly larger than the diameter of the molecular sphere.

Taking the average of all the measurements the distance between the ends of the polystyrene molecule is about 3.4 times larger than the distance calculated supposing free rotation in the molecular chain. The polystyrene molecule, therefore, shows a considerable degree of stiffening[4] which would correspond to an oscillation

(9) R. H. Ewart, U. S. Rubber Company, Passaic, N. J., private communication.

(10) P. Doty, W. Affens and B. Zimm, *Trans. Faraday Soc.*, *XLIIB*, **66** (1946).

around each bond of 200°, calculated from Debye's modification of the Kuhn equation, instead of the 360° for free rotation. Since the intrinsic viscosity is proportional to $R_s^3$ it is about 39 times larger than would be expected for a polystyrene molecule having free rotation.

## Summary

Molecular dimensions for polystyrene fractions in benzene have been obtained from viscosity and light scattering data. It was found that the root mean square of the distance between the ends of the molecule is approximately equal to the diameter of the molecular sphere needed for the explanation of viscosity. Evidence for the absence of appreciable branching or cross-linking in the polystyrene fractions was obtained. Polystyrene molecules in benzene were found to be much stiffer than would be expected from a free rotation model. This stiffness is responsible for the relatively high viscosities of polystyrene solutions.

# Properties of Electrolytic Solutions. XXXVIII. The Distribution of Hexadecylpyridonium Chloride between Water and Nitrobenzene at 25°

BY PHILIP F. GRIEGER[1] AND CHARLES A. KRAUS

## I. Introduction

The purpose of the present investigation was to determine the distribution of a long chain electrolyte between water and a slightly soluble organic liquid of relatively high dielectric constant, and thereby to test (by a method apparently hitherto untried) the validity of certain ideas which are currently held to be true, concerning aqueous long chain electrolyte solutions. Hexadecylpyridonium chloride was chosen as the salt because its critical concentration in water is convenient for the purpose of this work. Nitrobenzene was chosen as the reference liquid because its solubility in water is low (about 0.2% by weight), its dielectric constant is relatively high (34.5) and especially because considerable information was available on the conductance of long chain salts in this solvent.

Previous measurements made in this Laboratory on long chain electrolytes in nitrobenzene indicate that the activity product of simple ions can be evaluated from a knowledge of the conductance of these solutions.[2] Then, from distribution and conductance measurements, the activity product of simple ions in water saturated with nitrobenzene can be established and, in turn, the concentration product of simple ions in the aqueous solvent can be approximated. In the light of this information, another test can be made of the two leading hypotheses on long chain electrolyte solutions: (I) complete dissociation of the electrolyte at concentrations less than critical; (II) association of the electrolyte (to form one or more polyionic species) at concentrations greater than critical. The experimental results presented here are consistent with these two hypotheses.

In the distribution experiments concentrations were determined conductometrically; it was found that significantly precise measurements could be made at concentrations approaching $10^{-4}$ $N$, or well below the critical concentration, $5.8 \times 10^{-4}$ $N$.

Although the solubility of nitrobenzene in water is low, the conductance of hexadecylpyridonium chloride in water saturated with nitrobenzene differs significantly in the neighborhood of the critical concentration (and below) from the conductance of this salt in pure water. Hence, the distribution results reported here must be regarded as appertaining specifically to the solvent: water saturated with nitrobenzene.

**Conventions.**—Salt concentrations are given in moles per liter of solution, exclusively. Quantities that refer to the water phase are designated by primes, while quantities that refer to the nitrobenzene phase are not specially marked. In some instances where only the water phase is under consideration (and no ambiguity can result), the water phase quantities have not been primed.

## II. Experimental

**Apparatus and Procedure.**—The methods used in determining the conductance of the solutions have been adequately described in earlier papers of this series.[3]

The distribution measurements were made in a cell similar to those used in previous conductance work in this Laboratory, except that a side chamber (large enough to hold all the nitrobenzene in the system) was sealed to the cell near its base. By manipulating the cell, it was possible to place either the water or nitrobenzene layer in contact with the electrodes. It was found that equilibrium could be established (as judged by the constancy of the resistances of the separate phases) within a reasonable time, usually one or two days, by moving the cell in such a way that the liquids were caused to pass slowly through each other. By careful mixing, foam and emulsion formation were practically eliminated. The electrodes of the cell were lightly platinized.

The distribution experiments were carried out simply, as follows: after weighing the cell dry, nitrobenzene and then

(3) Evers and Kraus, THIS JOURNAL, **70**, 3049 (1948); Pickering, Thesis, Brown University, 1947.

water were added, the cell being weighed after each addition. The liquids were mixed and the conductance of each phase was determined. In general, the solvent conductances were: aqueous phase, $10^{-6}$; nitrobenzene phase, 1 to 2 $\times$ $10^{-8}$. A known quantity of salt was added (either as concentrated nitrobenzene or water solution) and the liquids were mixed and allowed to stand, alternately, until the resistances became constant (to less than a part per thousand). The experimental observables were, then: the specific resistance of each phase, the weight of nitrobenzene, water and salt in the system. All measurements reported here were made at 25 $\pm$ 0.01°.

**Solvents.**—Water[3] of specific conductance 1 $\times$ $10^{-6}$ was used. The nitrobenzene was purified by Dr. H. L. Pickering.[2] Its specific conductance was less than $10^{-9}$.

**Salt.**—Hexadecyl alcohol (m. p., 47.3°) was fractionally distilled at reduced pressure (about 1 mm.), (m. p., 49.1°). This was converted into the iodide as described by Evers.[3] It was fractionally distilled at reduced pressure (m. p., 22.8°). Hexadecylpyridonium iodide was prepared from this as described by Evers.[3] It was recrystallized from isopropyl alcohol plus ether and then from acetone. Hexadecylpyridonium chloride was prepared by metathesis of the iodide with silver chloride in absolute ethanol. The chloride was recrystallized twice from acetone to which a little ethanol was added. This preparation was carried out by Dr. G. L. Brown.[4] The conductance of this salt was determined in water; its conductance was unchanged by one more crystallization from acetone plus ethanol.

## III. Experimental Results

In Table I (and Fig. 1) are presented values of the equivalent conductance, $\Lambda$, as a function of the square root of concentration, $\sqrt{C}$, for hexadecylpyridonium chloride in water and water saturated with nitrobenzene. In the latter case, the measurements were made in the presence of a small amount (about 0.1% by weight) of excess nitrobenzene. The method of computing $\Lambda$ in this case is described below.

TABLE I

CONDUCTANCE OF HEXADECYLPYRIDONIUM CHLORIDE IN WATER AND WATER SATURATED WITH NITROBENZENE AT 25°

| $100\sqrt{C}$ | $\Lambda$ | $100\sqrt{C}$ | $\Lambda$ |
|---|---|---|---|
| A. Water | | | |
| 1.186 | 92.7 | 2.999 | 89.84 |
| 1.377 | 91.8 | 3.126 | 89.01 |
| 1.924 | 90.48 | 3.339 | 85.07 |
| 2.274 | 89.92 | 3.466 | 82.56 |
| 2.424 | 89.69 | 3.785 | 75.88 |
| 2.572 | 89.39 | 4.196 | 68.92 |
| 2.693 | 89.86 | 4.674 | 62.89 |
| 2.709 | 90.01 | 5.316 | 56.75 |
| 2.861 | 89.96 | | |
| B. Water Saturated with Nitrobenzene | | | |
| 1.225 | 90.8 | 2.372 | 89.50 |
| 1.746 | 90.36 | 2.567 | 86.36 |

| 2.284 | 89.82 | 3.962 | 64.95 |

In Table II (and Fig. 2), $\Lambda$ is given as a function of $\sqrt{C}$ for hexadecylpyridonium chloride in nitrobenzene and nitrobenzene saturated with water. In the latter case, the measurements were also made in the presence of a small amount (about 0.1% by weight) of excess water. The method of computing $\Lambda$ in this case is described below.

TABLE II

CONDUCTANCE OF HEXADECYLPYRIDONIUM CHLORIDE IN NITROBENZENE AND NITROBENZENE SATURATED WITH WATER AT 25°

| $100\sqrt{C}$ | $\Lambda$ | $100\sqrt{C}$ | $\Lambda$ |
|---|---|---|---|
| A. Nitrobenzene | | | |
| 0.9168 | 29.73 | | |
| 1.355 | 28.95 | | |
| 1.767 | 28.03 | | |
| 2.385 | 26.62 | | |
| B. Nitrobenzene Saturated with Water | | | |
| 1.565 | 30.27 | 3.821 | 27.02 |
| 1.986 | 29.72 | 4.046 | 26.65 |

| 3.254 | 27.88 | 5.474 | 24.46 |
| 3.568 | 27.39 | | |

The conductances and distribution ratios were computed by successive approximation in the following way. The conductance in nitrobenzene saturated with water and in the presence of a small excess of water was determined: $\kappa$ was plotted against concentration, where concentration was computed on the assumption that the water phase contained no salt. A similar plot was made for water saturated with nitrobenzene. The first approximation to the distribution ratio was computed from the specific conductances of the two phases, using the plots described above to establish concentration as a function of conductance. The concentrations in the conductivity experiments were then corrected by taking into account the amount of salt that was present in the small excess water phase in the nitrobenzene saturated with water experiments, and in the small excess nitrobenzene phase in the water saturated with nitrobenzene experiments, using the first approximation distribution ratios. The $\Lambda$ values in Tables I and II were computed using these corrected concentrations.

The densities of the solutions were assumed to be equal to those of the pure solvents. The densities of water and water saturated with nitrobenzene were assumed to be the same (0.9971). The density of nitrobenzene was taken as 1.999.[5] The density of nitrobenzene saturated with water was found to be 1.1979.

The solubilities of water in nitrobenzene solutions of hexadecylpyridonium chloride and of nitrobenzene in water solutions of this salt were not precisely determined but solubilities were approxi-

(4) G. L. Brown, Thesis, Brown University, 1947.

(5) Walden and Birr, *Z. physik. Chem.*, **163A**, 281 (1932).

mated which were good enough to permit of accurate calculation of the distribution ratio.[6]

In Table III (and Fig. 4, curve 1), the ratio: (salt concentration, water phase)/(salt concentration, nitrobenzene phase) is given as a function of salt concentration water phase. The ratios were obtained as follows: the concentration of the nitrobenzene phase was determined from its conductance, the concentration of the water phase was determined by difference from a knowledge of the weights of salt, of nitrobenzene and of water in the system. In making this calculation, it was assumed that the solubility of water in nitrobenzene is 0.2% by weight and that the solubility of nitrobenzene in water is 0.2% by weight.

The concentration in the water phase was also determined directly by measuring its conductance. The distribution ratios so obtained are not presented here, but they are in satisfactory agreement with the ones listed in Table III, considering that the solvent correction for the water phase is about one hundred times the corresponding correction in the nitrobenzene phase. The ratios determined directly are higher in every case (corresponding to an undercorrection for solvent conductance). In the dilute end, they differ from those given in Table III by about 3%; in the concentrated end, by about 1%.

The uncertainty introduced by lack of precise measurements on the solubilities of nitrobenzene in water and *vice versa* is slight. Thus, in the experiment at $C' = 3.590 \times 10^{-4}$, if it is assumed that the liquids have zero solubility in each other, a value of $C'/C$ is computed that is only 0.3% lower than the value listed in Table III.

For the nitrobenzene saturated with water phase, salt concentration was determined as a function of specific conductance using the empirical equation

$$C = 3.210 \times 10\kappa + 1.349 \times 10^{5}\kappa^{2} - 2.12 \times 10^{8}\kappa^{3} \quad (1)$$

For twenty concentrations between $2 \times 10^{-4}$ and $3 \times 10^{-3}$, the mean deviation between observed and calculated values of $C$ is 0.093%, the largest deviation being 0.2%. In determining the ratios directly, a large scale plot of $C'$ as a function of $\kappa$ for water saturated with nitrobenzene was used.

In column 3 of Table III are also given values of the ratio of activity products $C'f'/C\alpha f$ in water and nitrobenzene. These values will be discussed below.

(6) To a large quantity of nitrobenzene solution, for example, small weighed amounts of water were added. The mixtures were agitated and allowed to stand until the conductance after each addition of water was constant. Saturation was judged visually and by the form of the conductance *vs.* water content plot. Thus, at a salt concentration of $1.3 \times 10^{-3}$ *N*, the solubility of water was judged to be 2.5 mg./g. soln., and at a salt concentration of $5.7 \times 10^{-3}$, 2.3 mg./g. soln. Similarly, in water at a salt concentration of $1.1 \times 10^{-4}$, the solubility of nitrobenzene was judged to be 2 mg./g. soln., and at a salt concentration of $1.2 \times 10^{-3}$, 1.9 mg./g. soln. The solubility of nitrobenzene in pure water is about 2 mg./g. water. Gross and Saylor, THIS JOURNAL, **53**, 1744 (1931), give 1.78 mg./g. water at 15° and 2.05 mg./g. water at 30°. While the solubility of nitrobenzene doubtless increases with increasing salt concentration, this effect is so small that it may be neglected.

## IV. Discussion

**1. Conductance in Aqueous Solution.**—As shown in Fig. 1, the equivalent conductance, $\Lambda$, for hexadecylpyridonium chloride in water and water saturated with nitrobenzene, is nearly the same at concentrations less than critical (with nitrobenzene present), namely, $5.8 \times 10^{-4}$. At concentrations greater than this in pure water, $\Lambda$ passes through a slight maximum before falling off rapidly. In pure water, the critical (rise) point lies at $6.7 \times 10^{-4}$ slightly higher than the break in the presence of nitrobenzene. In water saturated with nitrobenzene, $\Lambda$ decreases sharply at $5.8 \times 10^{-4}$. In Fig. 1, the water saturated with nitrobenzene curve has been drawn with $5.8 \times 10^{-4}$ as the critical concentration; actually, a somewhat lower value, as low as $5.7 \times 10^{-4}$, might have been chosen.

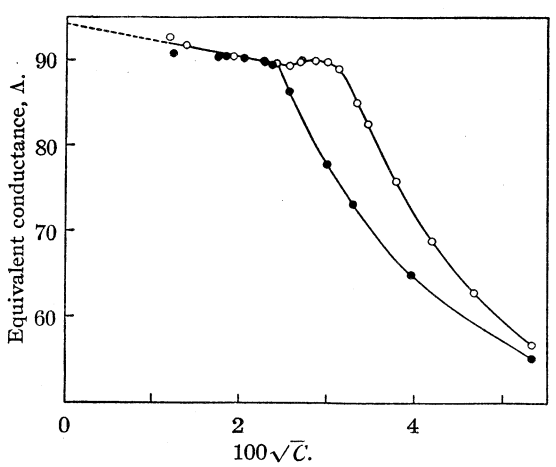

Fig. 1.—Conductance at 25° of hexadecylpyridonium chloride in: open circles, water; solid circles, water saturated with nitrobenzene.

The value of $\Lambda_0$, as determined by extrapolation, lies between 93 and 94, which corresponds to 17 or 18 for the limiting conductance for hexadecylpyridonium ion. This value is about the same as

that approximated for the octadecyltrimethylammonium ion.[7]

**2. Dissociation Constant in Nitrobenzene.**—The properties of hexadecylpyridonium chloride are greatly modified on addition of water up to saturation. This will be evident on inspection of Fig. 2 in which values of $\Lambda$ are plotted against $\sqrt{C}$ for solutions in nitrobenzene in the absence and presence of water to saturation.

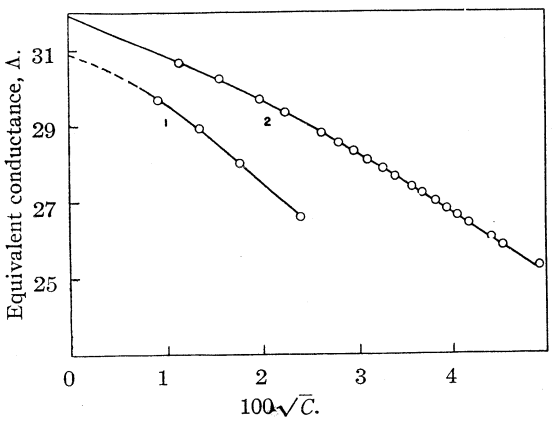

Fig. 2.—Conductance at 25° of hexadecylpyridonium chloride in: (1) nitrobenzene; (2) nitrobenzene saturated with water.

Fuoss plots[8] for the results of Table II are shown in Fig. 3. For hexadecylpyridonium chloride in nitrobenzene, $\Lambda_0 = 30.9$, $K = 4.26 \times 10^{-3}$; in nitrobenzene saturated with water, $\Lambda_0 = 31.9$, $K = 1.19 \times 10^{-2}$. In the latter case, the deviation from the straight line at $C = 3 \times 10^{-3}$ $N$ (the highest nitrobenzene phase concentration in the distribution experiments) is positive and amounts to about 1%. The observed value of $\Lambda$, then, is about 1% lower[9] than that calculated using $K = 1.19 \times 10^{-2}$. Thus, $\alpha$ computed from $\alpha = \Lambda/\Lambda_0 f(Z)$ is about 1% lower than $\alpha$ calculated from $K = 1.19 \times 10^{-2}$.

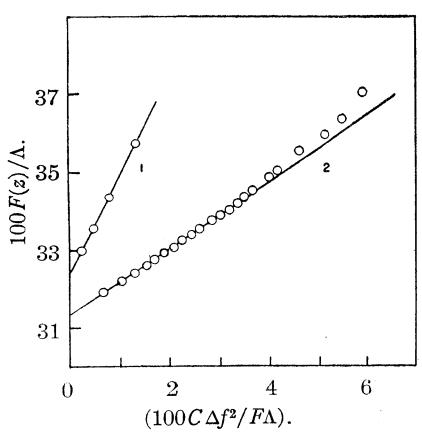

Fig. 3.—Fuoss plots for hexadecylpyridonium chloride in: (1) nitrobenzene; (2) nitrobenzene saturated with water.

**3. Calculated Activity Product.**—In what follows, let $C$ be total salt concentration; $C_+$, $C_-$, $a_+$, $a_-$, the corresponding ion concentrations and activities; $f$, the mean activity coefficient; $\alpha$, the degree of dissociation. Assume that simple positive and negative ions exist in both aqueous and nitrobenzene phases. For equilibrium in the system, it is necessary that

$$a'_+ a'_- / a_+ a_- = k \qquad (2)$$

where $k$ is the distribution constant. If the electrolyte is completely dissociated in the water phase, then

$$C'f'/Cf\alpha = \sqrt{k} \qquad (3)$$

In Table III, columns 3 and 6, values of $C'f'/Cf\alpha$ are given as a function of $C'$.[10] This ratio is shown graphically in Fig. 4, curve 2; it is constant at concentrations less than $5.80 \times 10^{-4}$ and increases (nearly linearly) with $C'$ at higher concentrations. The critical concentration determined by this method is in good agreement with that derived from the $\Lambda$–$\sqrt{C'}$ plot. For the eleven (not all listed in Table III) determinations between $C' = 1.64 \times 10^{-4}$ and $5.80 \times 10^{-4}$, the activity ratio is 0.300 ± 0.001; for the seventeen (all) at concentrations less than $5.80 \times 10^{-4}$, the activity ratio is 0.302 ± 0.003. The constancy of the calculated activity ratio is consistent with hypothesis (I). In what follows, $k$ is taken as $9.00 \times 10^{-2}$.

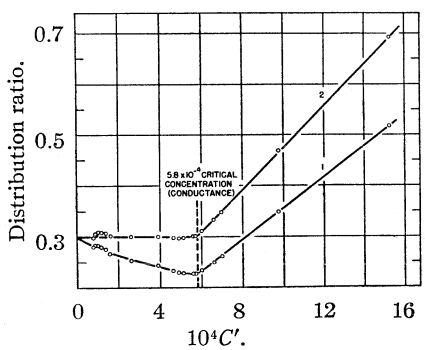

Fig. 4.—Distribution of hexadecylpyridonium chloride between water and nitrobenzene at 25°: (1) concentration ratio; (2) activity ratio.

**4. Simple Ion Product at Concentrations Greater than Critical.**[11]—In Table IV are listed, for water saturated with nitrobenzene, the simple ion activity product (Eq. (2)) and an estimate of the simple ion concentration product. The latter quantity has been computed using $\log_{10} f =$

(7) Grieger and Kraus, THIS JOURNAL, **70**, 3803 (1948), estimated 18 for the limiting conductance of octadecyltrimethylammonium ion.

(8) Using $Z = (0.7838\ \Lambda_0 + 44.64)\Lambda_0^{-3/2}\sqrt{\Lambda C}$; $\log_{10} f = -1.736\sqrt{C\alpha}$

(9) The slope is 0.0820. The % deviation in $\Lambda$ is approximately equal in magnitude (but slightly less) to the % deviation in the Fuoss plot.

(10) Values of $C'f'/Cf\alpha$ have been computed using $\log_{10} f' = -0.5065\sqrt{C'}$ (for $f$, see note 8) and $k = 1.19 \times 10^{-2}$.

(11) The primes have been omitted in Sections 4 and 5.

$-0.5065(C_+C_-)^{1/4}$. The values so obtained are uncertain, because the ionic strength of the solution is unknown, but they are probably not greatly in error. For example, if $\log_{10} f = -0.5065\sqrt{C}$ is used to estimate the activity coefficient, values of the simple ion concentration product are obtained that differ from those listed in Table IV by a few per cent. at most.

Also listed in Table IV, for convenience, are the quantities $C_+C_-/C^2$ and $C_+C_-/C$.

TABLE IV

SIMPLE ION ACTIVITY AND CONCENTRATION PRODUCT IN WATER SATURATED WITH NITROBENZENE AT CONCENTRATIONS GREATER THAN CRITICAL

| $C \times 10^4$ | $a_+a_- \times 10^7$ | $C_+C_- \times 10^7$ | $C_+C_-/C^2$ | $C_+C_-/C \times 10^2$ |
|---|---|---|---|---|
| 5.968 | 3.13 | 3.31 | 0.929 | 5.55 |
| 6.606 | 3.33 | 3.52 | .808 | 5.34 |
| 6.958 | 3.38 | 3.57 | .737 | 5.13 |
| 9.773 | 3.66 | 3.89 | .407 | 3.98 |
| 15.228 | 3.98 | 4.21 | .182 | 2.77 |

The fact that $C_+C_-/C^2$ is less than unity, is consistent with the assumption of ion association at concentrations greater than critical (hypothesis II).

Since neither the simple long chain nor the gegenion concentrations can be larger than $C$, the quantity $C_+C_-/C$ represents a lower limit on either simple ion concentration. This ratio falls off with increase in $C$, but at $C = 1.5 \times 10^{-3}$, the simple ion concentrations cannot be less than about one-fifth the total salt concentration.

**5. Calculation for One Complex Species.**[11]— If it is assumed that in the water phase there exist only simple ions and only complex species made up of $i$, long chain ions, and $j$, gegenions, then the three concentrations and $i$ and $j$ can be found from conductivity, distribution and transference data.[12] Let $C$ be the salt concentration; $C_+$, $C_-$, and $C_{ij}$ be the concentration of the simple long chain ion, the gegenion and the $ij$ complex ion; $u_+$, $u_-$, and $u_{ij}$, the corresponding mobilities (cm./sec. per volt/cm.); $\kappa$, the specific conductance (ohm$^{-1}$cm.$^{-1}$); $p = C_+C_-$; and $t_+$, the cation transference number. Then, if $i > j$

$$10^3\kappa/N\kappa = \bar{\kappa} = C_+u_+ + c_-u_- + (i - j)(C_{ij}u_{ij})$$
$$t_+\bar{\kappa} = C_+u_+ + iC_{ij}u_{ij}$$

$$p = C_+C_- \qquad (4)$$
$$C = C_+ + iC_{ij}$$
$$C = C_- + jC_{ij}$$

These equations can be combined (without any assumption about $u_{ij}$) to give

$$\Lambda/\Lambda_+ = y + q\,\Lambda_-/y\Lambda_+ + ((q/y) - y)(-y + t_+\Lambda/\Lambda_+)/(1 - y) \qquad (5)$$

where $y = C_+/C$, $q = p/C^2$, $\Lambda_+ = N\epsilon u_+$, $\Lambda_- = N\epsilon u_-$. Further, $C_{ij}$, $i$ and $j$ can be established if some rule is adopted for $u_{ij}$. Corresponding to $u_{ij} = u_+(i - j)/i^{1/3}$

$$i^{2/3} = (-y + t_+\Lambda/\Lambda_+)^2/(\Lambda(1/\Lambda_+) - y - q\Lambda_-/y\Lambda_+)(1 - y) \qquad (6)$$

Once $C_+$ is found from Eq. (5), $C_-$ comes immediately from $p = C_+C_-$; $i$ can be obtained from Eq. (6) and then $C_{ij}$ and $j$ from the material balance equations in (4).

In Table V, the experimental quantities, $\Lambda$, $p$ and $t_+$, are given for several round values of $C$, together with the five calculated quantities. $\Lambda$ and $p$ were taken from graphs of the data given here. The values of $t_+$ listed in Table V are estimates. Their basis is as follows. Hartley, Collie and Samis[13] found for hexadecylpyridonium bromide in water at 35°: $t_+ = 0.22$ at $7 \times 10^{-4}$ $N$ (critical concentration); $t_+ = 1.34$ at $3.2 \times 10^{-3}$ $N$. It has been assumed, here, that $t_+$ is a linear function of concentration for hexadecylpyridonium bromide at 35° over the range $7 \times 10^{-4}$ to $3.2 \times 10^{-3}$ $N$. The same relation has been assumed for hexadecylpyridonium chloride in water saturated with nitrobenzene at 25° over the range $5.8 \times 10^{-4}$ to $1.4 \times 10^{-3}$ $N$ and, further, that $dt_+/dc$ is the same for both systems. In short, $t_+$ as given in Table V corresponds to

$$t_+ = 0.19 + 4.5 \times 10^2(C - 5.80 \times 10^{-4})$$

For the calculations listed in Table V, no attempt has been made to estimate the variation of $\Lambda_+$ and $\Lambda_-$ with $C$. These calculations were made using $\Lambda_+ = 17$, $\Lambda_-/\Lambda_+ = 4.2$.

TABLE V

CALCULATED QUANTITIES ASSUMING ONE COMPLEX SPECIES

| $C \times 10^4$ | $\Lambda$ | $p \times 10^7$ | $t_+$ | $C_+ \times 10^4$ | $C_- \times 10^4$ | $C_{ij} \times 10^4$ | No. of ions in complex species: Long chain $i$ | No. of ions in complex species: Gegenions $j$ | Charge of complex species $i - j$ |
|---|---|---|---|---|---|---|---|---|---|
| 6.00 | 89.1 | 3.42 | 0.20 | 5.73 | 5.97 | 0.068 | 3.97 | 0.44 | 3.53 |
| 8.00 | 81.0 | 3.72 | .27 | 5.36 | 6.94 | .574 | 4.60 | 1.85 | 2.75 |
| 10.00 | 75.3 | 3.91 | .34 | 4.90 | 7.98 | .713 | 7.15 | 2.83 | 4.32 |
| 12.00 | 71.0 | 4.05 | .40 | 4.68 | 8.65 | .913 | 8.02 | 3.67 | 4.35 |
| 14.00 | 67.4 | 4.16 | .48 | 4.48 | 9.29 | 1.026 | 9.28 | 4.59 | 4.69 |

As may be seen from Table V, the calculated long chain ion concentration decreases over the range in $C$ tested while the gegenion concentration shows a sharper increase. The complex species concentration builds up as $C$ increases; both $i$ and $j$ increase, but their difference over the range $C = 10^{-3}$ to $1.4 + 10^{-3}$ is roughly constant.

(12) This calculation is similar to that given by van Rysselberghe, *J. Phys. Chem.*, **43**, 1049 (1939).

(13) Hartley, Collie and Samis, *Trans. Faraday Soc.*, **32**, 795 (1936).

## V. Summary

1. The distribution of hexadecylpyridonium chloride between water and nitrobenzene at 25° has been determined. The simple ion activity product in water divided by the simple ion activity product in nitrobenzene is $9.00 \times 10^{-4}$.

2. The conductance of hexadecylpyridonium chloride in water, water saturated with nitrobenzene, nitrobenzene and nitrobenzene saturated with water, has been determined at 25°.

3. In water saturated with nitrobenzene, the breakpoint in $\Lambda$ comes at 5.7 to 5.8 $\times 10^{-4}$. In pure water, $\Lambda$ passes through a slight maximum starting approximately at $6.7 \times 10^{-4}$.

4. The ion pair dissociation constant in nitrobenzene has been evaluated by the Fuoss method. $k = 1.19 \times 10^{-2}$ in nitrobenzene saturated with water, while in pure nitrobenzene, $k$ is only about one-half that, namely, $4.26 \times 10^{-3}$.

5. The calculated sample ion activity ratio is constant at concentrations less than $5.8 \times 10^{-4}$, but increases at higher concentrations. This indicates that at concentrations less than critical, the salt is completely dissociated in the water phase. The value of the critical concentration determined in this way is in good agreement with that determined from the $\Lambda - \sqrt{C}$ plot.

6. An estimate has been made of the simple ion concentration product at concentrations greater than critical. An attempt has been made to calculate the state of the system on the assumption that only one complex species exists at concentrations greater than critical.

# The Differential Diffusion Coefficient of Potassium Chloride in Aqueous Solutions

BY HERBERT S. HARNED AND RALPH L. NUTTALL

In a recent article,[1] we described in detail an apparatus and technique for the determination of the diffusion coefficients of electrolytes by means of conductance measurements. Values of the diffusion coefficient of potassium chloride at concentrations from 0.001 to 0.01 $N$ at 25° were reported. The results at 25° have been extended to higher concentrations[2] and determinations in the dilute concentration range have also been made at 20 and 30°. The present communication contains the new results and a summary of all the results with emphasis on their theoretical computation.

TABLE I

THE DIFFUSION COEFFICIENTS OF POTASSIUM CHLORIDE IN AQUEOUS SOLUTION AT 20, 25 AND 30°

$c$ is concn. in moles per liter, $\mathbf{D} \times 10^5$

(2) Harned and Nuttall, *Ann. N. Y. Acad. Sci.*, in press.

## Experimental

All the determinations are included in Table I. The manipulation and technique was the same as previously described. However, five kinds of cells which differed in containing electrodes of different areas were employed. Four of them had rectangular electrodes of areas indicated in the table and the fifth circular electrodes of millimeter diameter.

## Theoretical Calculations[3]

Onsager and Fuoss[4] have developed a theory for the variation of the diffusion coefficient of electrolyte with its concentration. For 1:1 electrolytes, their final equation is

$$\mathbf{D} = 16.629 \times 10^{10} T \left(\frac{\overline{M}}{c}\right)\left(1 + c\,\frac{\partial \ln y_{\pm}}{\partial c}\right) \quad (1)$$

where

$$\left(\frac{\overline{M}}{c}\right) \times 10^{20} = 1.0748 \left(\frac{\lambda_1^0 \lambda_2^0}{\lambda_1^0 + \lambda_2^0}\right) - \frac{22.148}{\eta_0 (DT)^{1/2}} \left(\lambda_1^0 - \lambda_2^0\right) \frac{\sqrt{c}}{1 + A'\sqrt{c}} + \frac{9.304 \times 10^7}{\eta_0 (DT)^2}\, c\phi \quad (2)$$

$\mathbf{D}$ is the diffusion coefficient (cm.² sec$^{-1}$), $D$ the dielectric constant, $T$ the absolute temperature, $c$ the electrolyte concentration in moles per liter, $\eta_0$ the viscosity of the medium and $\lambda_1^0$, $\lambda_2^0$ are the equivalent conductances at infinite dilution.

(3) In this part, we have employed the symbols of Harned and Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corp., New York, N. Y., 1943, p. 178–180. See also Harned, *Chem. Rev.*, **40**, 461 (1947).

(4) Onsager and Fuoss, *J. Phys. Chem.*, **37**, 2689 (1932).

TABLE II

DATA EMPLOYED IN THEORETICAL CALCULATIONS

| $T$ | $D$ [7] | $\eta_0$ [8] | $\lambda_1^0$ [9] | $\lambda_2^0$ [9] | $a$ [10] | $2B$ [10] | $S_{(f)}$ [10] |
|---|---|---|---|---|---|---|---|
| 293.16 | 80.36 | $10.087 \times 10^{-3}$ | 66.24 | 68.56 | 3.8 | 0.0182 | 0.5046 |
| 298.16 | 78.54 | $8.949 \times 10^{-3}$ | 73.52 | 76.34 | 3.8 | .0213 | .5092 |
| 303.16 | 76.75 | $8.004 \times 10^{-3}$ | 80.766 | 84.176 | 3.8 | .0260 | .5141 |

These expressions reduce to the Nernst limiting equation

$$\mathbf{D}_0 = 17.873 \times 10^{-10} T \left(\frac{\lambda_1^0 \lambda_2^0}{\lambda_1^0 + \lambda_2^0}\right) \qquad (3)$$

when $c$ equals zero. To evaluate the term containing the activity coefficient, $y_\pm$, on the mole per liter scale, which expresses the effect produced by the gradient of the chemical potential, we have employed the equation

$$\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) = 1 - \frac{1.1514\, S_{(f)}\sqrt{c}}{(1 + A'\sqrt{c})^2} + 4.605\, Bc - c\psi(d) \qquad (4)$$

where

$$\psi(d) = \frac{\frac{\partial d}{\partial c} + 0.001\,(2M_1 - M_2)}{d + 0.001\,(2M_1 - M_2)c} \qquad (5)$$

In these equations $A'\sqrt{c} = \kappa a = \kappa \mathring{a} \times 10^{-8}$, where $a$ and $\mathring{a}$ represent the mean distances of approach of the ions in centimeters and Ångström units, respectively, and $\kappa$ is the Debye and Hückel reciprocal distance. $S_{(f)}$ is the limiting function of the Debye and Hückel theory and $B$ an empirical constant. $M_1$ and $M_2$ are the molecular weights of the solvent and solute respectively.[4]

The second and third terms on the right of equation (2) represent the effect of electrophoresis. Values of the function $\phi(\kappa a)$ or $\phi(A'\sqrt{c})$ are given in tabular form by Harned and Owen.[5,6] The values of the quantities employed in the computations are compiled in Table II. Upon introduction of these values in equations (1), (2) and (4), we obtain the numerical equations

$$20°\text{C.:}\ \mathbf{D} = 4.875 \times 10^{13}\left(\frac{\overline{M}}{c}\right)\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) \qquad (6)$$

$$\frac{\overline{M}}{c} \times 10^{20} = 36.210 - \frac{0.00423\sqrt{c}}{1 + 1.245\sqrt{c}} + 16.62\, c\, \phi(1.245\sqrt{c}) \qquad (7)$$

$$\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) = 1 - \frac{0.5810\sqrt{c}}{(1 + 1.245\sqrt{c})^2} + 0.0430\, c - c\psi(d) \qquad (8)$$

$$c\psi(d) = \frac{0.00990c - 0.00336c^{3/2}}{0.99823 + 0.00990c - 0.0024c^{3/2}} \qquad (9)$$

$$25°\text{C.:}\ \mathbf{D} = 4.958 \times 10^{13}\left(\frac{\overline{M}}{c}\right)\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) \qquad (10)$$

$$\frac{\overline{M}}{c} \times 10^{20} = 40.253 - \frac{0.00573\sqrt{c}}{1 + 1.249\sqrt{c}} + 18.96c\, \phi(1.249\sqrt{c}) \qquad (11)$$

(5) Ref. 4, p. 130.

(6) Harned, *Chem. Rev.*, **46**, 461 (1947).

$$\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) = 1 - \frac{0.5873\sqrt{c}}{(1 + 1.249\sqrt{c})^2} + 0.0490c - c\psi(d) \qquad (12)$$

$$c\psi(d) = \frac{0.00959c - 0.00348c^{3/2}}{0.99707 + 0.00959c - 0.00232c^{3/2}} \qquad (13)$$

$$30°\text{C.:}\ \mathbf{D} = 5.0412 \times 10^{13}\left(\frac{\overline{M}}{c}\right)\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) \qquad (14)$$

$$\frac{\overline{M}}{c} \times 10^{20} = 44.3011 - \frac{0.00775\sqrt{c}}{1 + 1.253\sqrt{c}} + 21.47c\, \phi(1.253\sqrt{c}) \qquad (15)$$

$$\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) = 1 - \frac{0.5919\sqrt{c}}{(1 + 1.253\sqrt{c})^2} + 0.0599c - c\psi(d) \qquad (16)$$

$$c\psi(d) = \frac{0.0094c - 0.0034c^{3/2}}{0.9957 + 0.0094c - 0.0023c^{3/2}} \qquad (17)$$

The values of $c\psi(d)$ were evaluated from the density computations of Scott[11] by means of the equations

$$d(20°) = 0.99823 + 0.04843c - 0.00224c^{3/2} \qquad (18)$$

$$d(25°) = 0.99707 + 0.04811c - 0.00232c^{3/2} \qquad (19)$$

$$d(30°) = 0.9957 + 0.0479c - 0.0023c^{3/2} \qquad (20)$$

## Theoretical Considerations

A glance at Table I in which the results computed by the theoretical equations are tabulated reveals a remarkable agreement of experiment with theory at all three temperatures. This is illustrated by Fig. 1 where our results are represented by circles and the theoretical values by the curves B. At concentrations below 0.05 $N$, there is little doubt of the validity of the theoretical result. The agreement at the higher concentrations at 25° is unexpected. This may be partly due to a fortunate choice of salt and temperature since at 25° the relative viscosity of potassium chloride in water changes less than 0.3% over a concentration range from zero to 0.5 normal. Further, one would expect a deviation from theory due to the change in dielectric of the medium with increase in salt concentration.

The curves in Fig. 1 illustrate the nature of the theoretical calculation. Curve A is calculated from the limiting equation

$$\mathbf{D} = \mathbf{D}_0 - S_{(D)}\sqrt{c} \qquad (21)$$

(7) Ref. 4, p. 112; (8) ref. 4, p. 128; (9) 25°: ref. 12, p. 172; Shedlovsky, THIS JOURNAL, **54**, 1423 (1932); Longsworth and MacInnes, *ibid.*, **60**, 3073 (1938); 20° and 30°: Zeldes, Dissertation, Yale University (1947); (10) ref. 4, p. 381; $S(f)$ and $B$ adjusted to universal constants given by Birge, *Rev. Mod. Phys.*, **13**, 233 (1941).

(11) Scott, *J. Phys. Chem.*, **35**, 2315 (1931).

where

$$S_{(D)} = \frac{3.754 \times 10^{-3}}{D^{3/2}T^{1/2}}\left(\frac{\lambda_1^0 - \lambda_2^0}{\lambda_1^0 + \lambda_2^0}\right) + \frac{3.683 \times 10^{-8}}{\eta_0 D^{1/2}T^{1/2}}\left(\frac{\lambda_1^0 - \lambda_2^0}{\lambda_1^0 + \lambda_2^0}\right)^2 \quad (22)$$

At 25°, equation (21) becomes

$$D \times 10^5 = 1.9958 - 1.170\sqrt{c} \quad (23)$$

Only at very great dilution does the experimental curve approach coincidence with the limiting law.

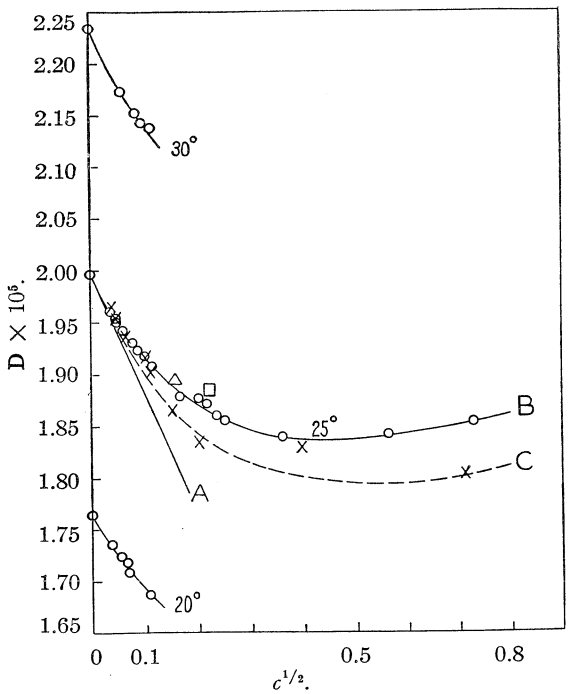

Fig. 1.—Diffusion coefficient of potassium chloride in water at 20, 25 and 30°: (1) circles represent observed results; (2) crosses represent diaphragm cell measurements; (3) triangle, Cohen and Bruins; (4) square, Lamm; A, limiting law by equations (21) and (22); B and solid curves at 20 and 30° represent the complete theoretical calculation according to equations (1), (2), (4) and (5); C, calculated by equation (24) which omits electrophoresis.

The dashed curve C was obtained from equation (1) by introducing the limiting value of $(\overline{M}/c)$ to give at 25°

$$D = 4.958 \times 10^{13} \times 40.253 \times 10^{-20}\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right) \quad (24)$$

$$= 1.9958 \times 10^{-5}\left(1 + c\frac{\partial \ln y_\pm}{\partial c}\right)$$

Consequently, it represents the result obtained by neglecting the effect of electrophoresis. The deviation of this curve from the complete theoretical result represented by curve B is always greater than the deviations of the experimental points. Consequently, for this salt, our results appear to confirm the theory of the electrophoretic effect. It is interesting to note that since the mobilities of the potassium and chloride ions are so nearly equal the electrophoretic correction is due only to the third term in equation (2) involving $\phi(A'\sqrt{c})$.

## Comparison with Results by Other Methods

The only other measurements at concentrations below 0.01 $N$ which can be compared with ours, were obtained by the diaphragm cell method. Gordon[12] has calculated differential diffusion coefficients of potassium chloride from the data of McBain and Dawson,[13] Hartley and Runnicles[14] and his own experiments. These measurements[15] have been revised by Gordon by using a cell calibration which is based on our results below 0.01 $N$ and are designated by crosses in Fig. 1. At low concentrations the agreement is very good but as the concentration increases their results are somewhat lower than ours.

At higher concentrations, our results can be compared to those of Cohen and Bruins,[16] Lamm,[17] and Clack.[18] Cohen and Bruins used a layer analysis method by employing a four compartment cell and allowing a 0.1 $N$ potassium chloride solution in the bottom compartment to diffuse into the other three compartments. The compartments were then separated and the solutions in each analyzed with the greatest care by the use of a liquid interferometer. The average concentration in the four compartments was 0.025 $N$ and the mean diffusion coefficient was $1.674 \times 10^{-5}$ cm.²/sec. at 20°, or $1.893 \times 10^{-5}$ cm.²/sec. at 25°, if our estimate of the influence of temperature is employed. This value is shown by the triangle in Fig. 1. It is somewhat ambiguous since it is neither a true differential nor an integral diffusion coefficient. Hartley and Runnicles contended that it corresponds approximately to an integral diffusion coefficient for 0.06 $N$ potassium chloride diffusing into water and it must correspond to a differential diffusion coefficient at a concentration close to the average concentration of 0.025 $N$. Lamm, using his optical scale method obtained a diffusion coefficient of $1.667 \times 10^{-5}$ cm.²/sec. at 20° for 0.1 $N$ potassium chloride diffusing into water which corresponds to a value of $1.885 \times 10^{-5}$ cm.²/sec. at 25°. This is represented by the square in Fig. 1 at the mean concentration of 0.05 $N$. Both Cohen and Bruins' and Lamm's values compare favorably with ours. The results of Clack who employed a steady state optical method at 18.5° and at concentrations from 0.08 $N$ to higher concentrations are about 4% lower than ours.

(12) Gordon, *J. Phys. Chem.*, **5**, 522 (1937); *Ann. N. Y. Acad. Sci.*, **46**, 285 (1945).

(13) McBain and Dawson, *Proc. Roy. Soc.* (*London*), **A118**, 32 (1935).

(14) Hartley and Runnicles, *ibid.*, **A168**, 401 (1938).

(15) Harned, *Chem. Rev.*, **40**, 461 (1947).

(16) Cohen and Bruins, *Z. physik. Chem.*, **103**, 337 (1923).

(17) Lamm, *Nova Acta Reg. Sci. Upsala*, **IV**, 10(6) 1937.

(18) Clack, *Proc. Phys. Soc.* (*London*), **36**, 313 (1924).

This estimate was made by using the temperature coefficient obtained by us at low concentrations.

The effect of temperature is very marked. However, the relative change with concentration in dilute solution is almost independent of temperature. For a concentration of 0.01 $N$ the ratio $D/D_0$ is 0.9593, 0.9591, and 0.9589 at 20, 25 and 30°, respectively.

## Summary

1. Determinations of the diffusion coefficient of potassium chloride in water at 20°, 25° and 30° have been obtained by a conductance method previously described by us.[19]

2. In the region of concentration from 0.001 to 0.01 $N$, excellent agreement with the theory of Onsager and Fuoss is obtained, and the Nernst limiting law for electrolytic diffusion is confirmed.

3. Comparison of our results with those obtained by the diaphragm cell method, by layer analysis and by the optical scale method indicates good agreement considering the wide variety of mechanisms and theories of these methods.

# The Heats of Dilution of Aqueous Solutions of Four Amino Acids at 25°[1]

BY L. S. MASON, W. F. OFFUTT[2,3] AND A. L. ROBINSON

Previous communications from this Laboratory have reported on the heats of dilution of aqueous solutions of glycine,[4] α- and β-alanine,[5] and four aminobutyric acids.[6] Examination of the results for these seven amino acids indicated that the structure of the organic radical was more important than the location of the amino group in determining the thermochemical properties studied.[6] The same conclusion was reached when the differential entropies of dilution of these same aqueous solutions were calculated.[7] Study of the heats of dilution of aqueous solutions of amino acids was continued to obtain further evidence affecting this conclusion. This paper reports results for α-amino-*n*-valeric acid, valine, norleucine and ε-aminocaproic acid.

## Experimental

**Apparatus and Method.**—Except for minor changes, the calorimeter is the same as that used in previous investigations.[6] The thermopile had been sealed into the Dewar vessel, which comprises the calorimeter vessel, with wax, thus dividing the vessel into two watertight compartments. The junctions of the thermopile had been separated from the solutions in the calorimeter by a plastic coating, so that dilutions in organic solvents might be made if desired, two copper vessels were constructed, one for each half of the calorimeter, which conformed to the inner surface of the Dewar vessel and whose flat surfaces fitted snugly against the junctions of the thermopile. The interiors of these vessels could not be satisfactorily gold plated; instead, a plastic coating was baked on. This coating provided an electrical resistance greater than 10 megohms. Electrical resistance of 1000 megohms between the thermopile junctions and the copper vessels was furnished by sheets of mica of 0.04 mm. thickness.

The two electrical heaters were made by winding no. 40 Advance wire spirally around a glass tube. The wire was soldered to platinum nibs which lead through the wall of the tube to heavy copper leads. Several coats of a silicone resin were baked on over the wire for insulation from the solutions in the calorimeter.

The volumes of the monel metal dilution pipets were 10.36 (left) and 10.32 (right) ml. To maintain a constant dilution ratio of one to 100 in the two halves of the calorimeter, the twin calorimeters held 1036 and 1032 ml. of water, respectively.

The amino acid solutions were prepared immediately before each day's series of measurements to minimize bacterial action. Following each day's measurements, the calorimeter was rinsed with distilled water. The calorimeter was disinfected periodically with 10% formaldehyde solution.

Solutions were made up by volume. Concentrations were converted to molalities using the density data of Dalton and Schmidt[8] for valine and the data of Daniel and Cohn[9] for ε-aminocaproic acid. The densities of α-amino-*n*-valeric acid and norleucine solutions were determined by standard methods using specific gravity bottles. The results may be expressed by the following equations for 25°

| | |
|---|---|
| α-Amino-*n*-valeric acid ($m$ <0.6) | $d = 0.9971 + 0.0240\,m$ |
| Norleucine ($m$ <0.05) | $d = 0.9971 + 0.0188\,m$ |

It has been suggested[10] that atmospheric carbon dioxide dissolved in the dilution water may affect the heats of dilution of amino acids at low concentrations by disturbing their dissociation equilibria. This effect was not observed in the previous studies[4,5,6] of this series. A further test was made by performing dilutions with norleucine solutions using water in equilibrium with atmospheric carbon dioxide and with free access of the atmosphere to the interior of the calorimeter. Results were compared with runs made with carbon dioxide-free water (specific conductance $0.4 \times 10^{-6}$ ohm$^{-1}$ cm.$^{-1}$) and with the calorimeter sealed from the atmosphere. The results agreed within the limits of the experimental error.

Dilutions were made to the limits of solubility of the

TABLE II

DERIVED VALUES FOR $S$, $\phi L_2$, $\bar{L}_1$, AND $\bar{L}_2$

| | α-Amino-*n*-valeric acid[a] | Valine | Norleucine | ε-Aminocaproic acid |
|---|---|---|---|---|
| $S$ | (1) 280 | (6) −476 | (11) −2030 | (16) $-514 - 293 \times 10^3m + 54.2 \times 10^6m^2$ |
| $\phi L_2$ ($m$ <0.015) | (2) 280 $m$ | (7) −476 $m$ | (12) −2030 $m$ | (17) $-514m - 147 \times 10^3m^2 + 18.1 \times 10^6m^3$ |
| $\phi L_2$ | (3) 218 $m$ | (8) 189 $m$ | (13) 306 $m$ | (18) $-3.23 + 3.23\ e^{-474m} + 294m + 437m^2 - 689m^3$ |
| $\bar{L}_1$ | (4) $-3.93\ m^2$ | (9) $-3.40\ m^2$ | (14) $-5.51\ m^2$ | (19) $(27.58e^{-474m} - 5.30)m^2 - 15.75m^3 + 37.24m^4$ |
| $\bar{L}_2$ | (5) 436 $m$ | (10) 378 $m$ | (15) 612 $m$ | (20) $-3.23 + 3.23\ (1 - 474m)e^{-474m} + 588m + 1311m^2 - 2756m^3$ |

[a] Numbers in parentheses identify the equations.

amino acids except for ε-aminocaproic acid. In this case the highest concentration diluted was about 0.4 $m$ since the heat effects produced were near the upper limit of the useful capacity of the calorimeter.

**Materials.**—Distilled water from the stock supply was distilled again from a Yoe still and stored in Pyrex flasks. The specific conductance of this water in equilibrium with the carbon dioxide of the atmosphere was about $10^{-6}$ ohm$^{-1}$ cm.$^{-1}$.

α-Amino-*n*-valeric acid and valine were purchased from the Eastman Kodak Company. They were recrystallized once from water and three times from alcohol-water mixtures. The most soluble and least soluble fractions from water were discarded, as were the most soluble fractions from the alcohol-water solutions.

ε-Aminocaproic acid was obtained from Dr. H. R. Snyder of the University of Illinois. It was dissolved in water and sufficient alcohol was added to form a 90% alcoholic solution from which most of the amino acid precipitated. Three such precipitations were carried out.

Norleucine of Analytical Purity was supplied by Amino Acid Manufacturers of the University of California. Specified impurities were so low that this acid was not purified further.

Ash content determinations and elementary analysis for nitrogen gave the results:

| | Ash, % | Nitrogen, % Found | Theoretical |
|---|---|---|---|
| α-Amino-*n*-valeric acid | 0.01 | 12.13 | 11.96 |
| Valine | .02 | 12.27 | 11.96 |
| Norleucine | .04 | 10.88 | 10.68 |
| ε-Aminocaproic acid | .21 | 10.73 | 10.68 |

The analyses for nitrogen agree with the theoretical values within the limits of error of the determination.

The purified acids were dried to constant weight at 80° in a vacuum oven and stored in a desiccator until used.

## Experimental Results and Treatment of Data

**Relative Apparent Molal Heat Contents.**—The experimentally determined intermediate heats of dilution are given in Table I. The average values of the measured heat effects for the long chord dilutions ($m_1$ to $m_2$) are listed in column 5, the number of experiments in column 4, the av-

erage deviation from the mean value in column 6, and the molal heats of dilution with their probable errors in column 13. The corresponding quantities for the short chord dilutions ($m_3$ to $m_2$) are listed in columns 9, 4, 10, and 14. Calculated heat effects are given in columns 7 and 11; the equations referred to are listed in Table II. The differences between measured and calculated heat effects are shown in columns 8 and 12.

Established methods[11,12,13] were used for the treatment of the heats of dilution data.

Figures 1, 2, 3 and 4 are plots of the short chords, $\overline{P} = \Delta H_{3\to 2}/\Delta m_{3\to 2}$, derived from the heats of dilution in the very dilute region. Each chord represents the average value of the derivative of the apparent molal heat content with respect to the molality in the range covered by the length of the chord. The intercept of a curve drawn through the chords gives the limiting slope of the apparent molal heat content and the area under a curve to a concentration $m$ gives the relative apparent molal heat content ($\phi L_2$), or the negative of the integral heat of dilution at that concentration.

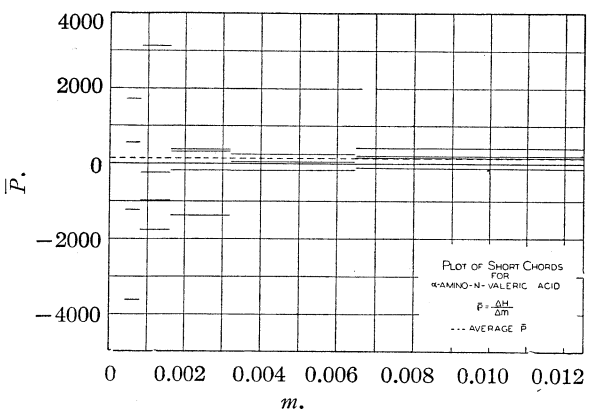

Fig. 1.—Plot of short chords for $\alpha$-amino-$n$-valeric acid: $\overline{P} = \Delta H/\Delta m$; – – –, average $\overline{P}$.

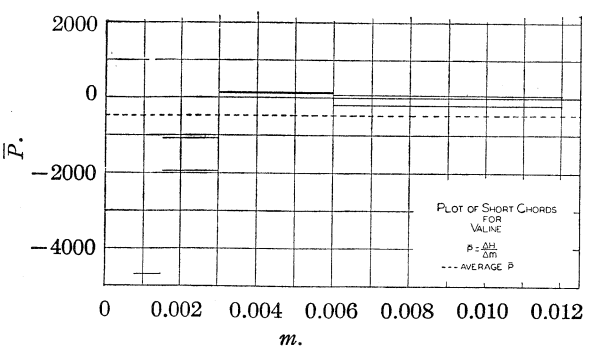

Fig. 2.—Plot of short chords for valine: $\overline{P} = \Delta H/\Delta m$; – – –, average $\overline{P}$.

(12) A. L. Robinson and W. E. Wallace, *ibid.*, **63**, 1582 (1941).

(13) A. L. Robinson and W. E. Wallace, *Chem. Revs.*, **30**, 195 (1942).

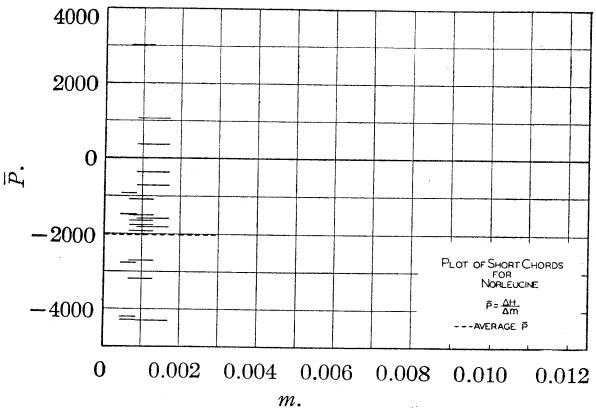

Fig. 3.—Plot of short chords for norleucine: $\overline{P} = \Delta H/\Delta m$; – – –, average $\overline{P}$.

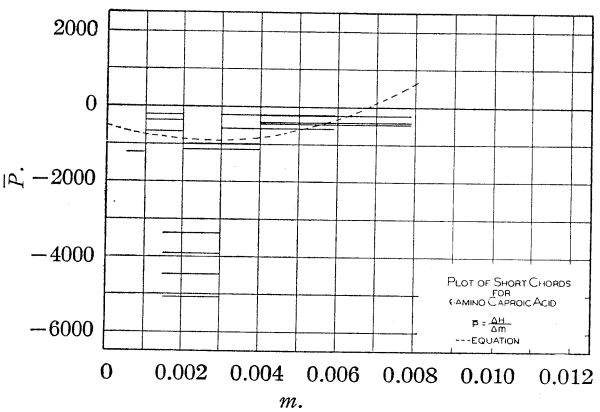

Fig. 4.—Plot of short chords for $\epsilon$-aminocaproic acid: $\overline{P} = \Delta H/\Delta m$; – – –, equation.

For $\alpha$-amino-$n$-valeric acid, valine, and norleucine, an inspection of the plots of $\overline{P}$ vs. $m$, shown in Figs. 1, 2, and 3, respectively, indicated that an analytical derivation for the slope, $S = \partial(\phi L_2)/\partial m$, was unwarranted. Instead, average $\overline{P}$ values for the entire concentration range of the short chords were obtained by averaging the mean values of the chords for each concentration interval, weighting each mean value according to its probable error. The dotted lines represent these average $\overline{P}$ values.

For $\epsilon$-aminocaproic acid, Fig. 4, there seemed to be a trend in the $\overline{P}$ values sufficiently pronounced to justify an analytical treatment. A three-constant least-squares equation was derived which is shown in the figure by a dotted line.

Equations for the slopes for the four acids are given in Table II (eq. 1, 6, 11, and 16). Integration of these equations gives expressions for $\phi L_2 (m < 0.015)$, equations 2, 7, 12, and 17 of Table II.

$\phi L_2$ values calculated from equations 2, 7, 12, and 17, for $m_2$ were combined with the experimental $\Delta H_{1\to 2}$'s for the long chord dilutions to give $\phi L_2$ values for the concentrations $m_1$. Least

squares equations for $\phi L_2$ for the entire concentration range studied were then derived, the data being weighted according to the reciprocal of the squares of the probable errors. These are equations 3, 8, 13 and 18 of Table II. For α-amino-*n*-valeric acid, valine and norleucine, linear equations adequately represent the data, but for ε-aminocaproic acid a cubic equation seemed necessary with an added exponential term to show the reversal of slope of $\phi L_2$ at the lowest concentrations. Although the $\overline{P}$ *vs.* *m* plots indicate a reversal of slope for valine and norleucine at their lowest concentrations, the data in the most dilute region were not considered sufficiently precise to justify showing this reversal in the $\phi L_2$ equations which cover the entire concentration range of this study.

Plots of equations 3, 8, 13 and 18 and the experimental points from which they were derived are shown in Fig. 5. $\phi L_2$ values from these equations at rounded concentrations are listed in Table III. *q*-Values for the long chord dilutions, calculated from equations 3, 8, 13 and 18, are listed in column 7 of Table I. The differences between measured and calculated values are given in column 8 of Table I. *q*-Values for the short chord dilutions, calculated from equations 2, 7, 12 and 17, and the differences between measured and calculated values are given in columns 11 and 12 of Table I.

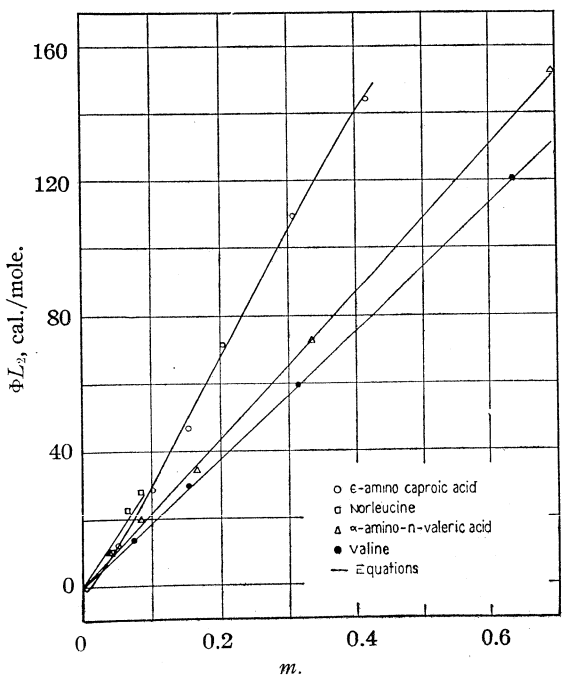

Fig. 5.—Plot of $\Phi L_2$ *vs.* *m*: O, ε-amino caproic acid; □, norleucine; △, α-amino-*n*-valeric acid; ●, valine; —, equations.

Valine is the only acid studied in this investigation for which heats of dilution have been measured previously. Values calculated from equation 8 are compared with the data of Zittle and Schmidt:[14]

| m | $\phi L_2$ cal. mole$^{-1}$ Zittle and Schmidt | This work |
|---|---|---|
| 0.1 | 15 | 19 |
| .2 | 60 | 38 |
| .5 | 125 | 96 |
| .63 | 150 ± 25 | 119 |

The probable errors of the $\phi L_2$ values of this study are less than 2 calories per mole. The apparatus used by Zittle and Schmidt gave values with probable errors of 25 calories per mole.

**Relative Partial Molal Heat Contents.**—Equations for the relative partial molal heat contents of solvent ($\bar{L}_1$) and solute ($\bar{L}_2$) for each of the four amino acids are listed in Table II. These equations were derived from the equations for $\phi L_2$ by the procedure due to Rossini.[15]

**Relative Partial Molal Entropy of Water.**—($\bar{S}_1 - \bar{S}_1^0$) values (differential entropies of dilution) for three of these systems were calculated by the procedure used[7] for glycine, the alanines, and four aminobutyric acids. The activity values for water used in the calculations were taken from the vapor pressure studies of Smith and Smith.[16] No activity measurements for norleucine solutions are available. The ($\bar{S}_1 - \bar{S}_1^0$) values calculated for α-amino-*n*-valeric acid, valine, and ε-aminocap-

## Discussion of Results

Plots of $\phi L_2$ *vs.* $m$ for the eleven amino acids studied in this laboratory are shown in Fig. 6. To a first approximation the variation of $\phi L_2$ is linear in $m$ in all cases, neglecting minor uncertain features of several of the plots at very low concentrations. To a grosser first approximation the $\phi L_2$ values increase regularly with the number of carbon atoms in the aliphatic radical. This observation has been made before.[6,7] Excluding glycine, the $\phi L_2$ values for the ten amino acids with $n$ = 2, 3, 4, and 5 carbon atoms in the aliphatic radical are coarsely represented by $\phi L_2 \cong (45 + (n - 2)85)m$. The data for all acids studied are much better than this coarse approximation, but it serves to emphasize the relative unimportance of the location of the $NH_3^+$ group in the molecule for determining the thermochemical properties studied in these investigations. In contrast, the dielectric increments for these same solutions[17] show a strong dependence on the location of the $NH_3^+$ groups.

A possible explanation for the rough regularity of $\phi L_2$ with $n$ for these solutions lies in the configurations of the amino acid molecules in solution. If this is a coiled configuration, with close approach of the $NH_3^+$ and $COO^-$ groups, the dipole moments of all these amino acids would be approximately equal. Changing dipole–dipole interactions with dilution would make a fairly constant contribution to $\phi L_2$ (the $\phi L_2$ of glycine), and the varying interactions of the hydrophobic aliphatic radicals with water would be responsible for the dependence of $\phi L_2$ on $n$. A coiled configuration for an amino acid molecule in solution seems plausible because of electrostatic interaction between $NH_3^+$ and $COO^-$. Differences among isomers could be attributed to slight differences of dipole moments and to differences in water-radical interactions due to radical configurations imposed by the electrostatic interaction.

The differential entropies of dilution plotted in Figure 7 likewise show a strong dependence on $n$, regardless of the location of the $NH_3^+$ group, because of the minor importance of the free energy term in the expression[7]

$$\bar{S}_1 - \bar{S}_1^0 = (\bar{L}_1 - RT \ln (a_1/N_1))/T$$

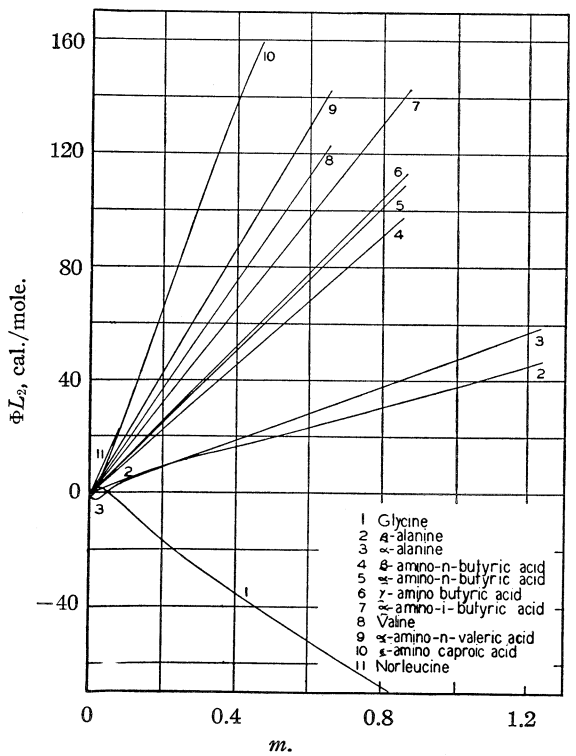

Fig. 6.—Plot of $\Phi L_2$ *vs.* $m$ for 11 amino acids: 1, glycine; 2, β-alanine; 3, α-alanine; 4, β-amino-*n*-butyric acid; 5, α-amino-*n*-butyric acid; 6, γ-aminobutyric acid; 7, α-amino-*i*-butyric acid; 8, valine; 9, α-amino-*n*-valeric acid; 10, ε-amino caproic acid; 11, norleucine.

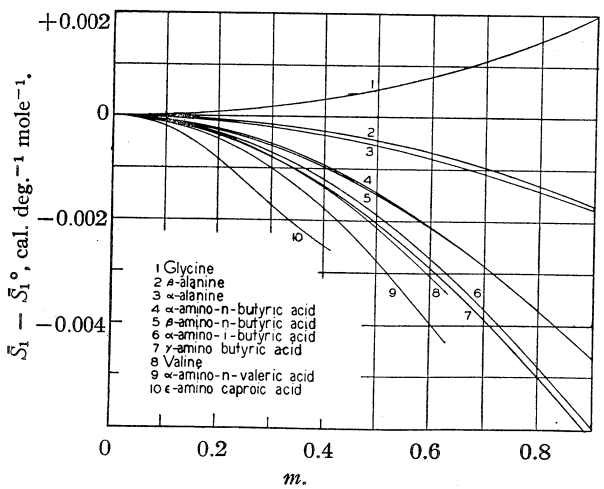

Fig. 7.—Plot of $\bar{S}_1 - \bar{S}_1^\circ$ *vs.* $m$ for ten amino acids: 1, glycine; 2, β-alanine; 3, α-alanine; 4, α-amino-*n*-butyric acid; 5, β-amino-*n*-butyric acid; 6, α-amino-*i*-butyric acid; 7, γ-aminobutyric acid; 8, valine; 9, α-amino-*n*-valeric acid; 10, ε-aminocaproic acid.

(17) E. J. Cohn and J. T. Edsall, "Proteins, Amino Acids, and Peptides," Reinhold Publishing Corporation, New York, N. Y., 1943, p. 146.

from which they were calculated. For the ten amino acids the relation $(\bar{S}_1 - \bar{S}_1^0) = km^2$ holds fairly well; the dependence on $m^2$ is a further reflection of the relative importance of the heat content term in the equation for $(\bar{S}_1 - \bar{S}_1^0)$. The $k$ values are listed.

| | $k$ |
|---|---|
| Glycine | 0.0023 |
| α-Alanine | −.0023 |
| β-Alanine | −.0020 |
| α-Amino-*n*-butyric | −.0058 |
| α-Amino-*i*-butyric | −.0076 |
| β-Amino-*n*-butyric | −.0056 |
| γ-Aminobutyric | −.0076 |
| α-Amino-*n*-valeric | −.0109 |
| Valine | −.0084 |
| ε-Aminocaproic | −.0185 |

These negative $(\bar{S}_1 - \bar{S}_1^0)$ values (for all cases except glycine) have been interpreted[7] as structure strengthening effects on the water, the effect increasing with the size of the hydrocarbon residue.

Regardless of the value of these suggestions, it seems clear that purely electrostatic interactions, calculated[18,19,20] for various simplified models, do not suffice to explain the thermochemical behavior of these solutions. The aliphatic radicals seem responsible for the large differences of properties measured.

## Summary

Heats of dilution of aqueous solutions of α-amino-*n*-butyric acid, valine, norleucine and ε-aminocaproic acid at 25° have been measured to below 0.001 *m*. From these measurements relative apparent molal heat contents, relative partial molal heat contents, and differential entropies of dilution have been calculated.

Results for eleven amino acids are compared and discussed.

# The Liquidus Curve for Aluminum in Mercury

BY HERMAN A. LIEBHAFSKY

The liquidus curve for the aluminum–mercury system is well established above 400° by the concordant results of two investigations.[1,2] Data which complete this curve were obtained in 1934 as part of an investigation into the chemical problems of the mercury boiler and are given below.

## Experimental

The "solubility" of commercial (99+%) aluminum in pure mercury was measured by rotating an aluminum-glass stirrer (see Fig. 1) in the solubility vessel, which was inside a cylindrical furnace whose temperature was taken as the temperature of the experiment. Because aluminum amalgam is very easily oxidized, the experiments were carried out in a hydrogen atmosphere. (The hydrogen, passed over copper at 400° and then through a liquid air trap, was pure enough not to cause appreciable oxidation of the amalgam. Since the analytical method measured dissolved metal only, a slight oxidation would not have vitiated the results.) The stirrer fitted into a metal chuck and was driven at approximately 300 r. p. m. with an electric motor. From time to time, samples of amalgam were withdrawn by means of previously evacuated sampling tubes, whose lower tips could easily be broken by forcing them against the bottom of the solubility vessel. The mercury withdrawn was usually replaced.

These samples were immediately analyzed by breaking the bulbs beneath approximately 2 *N* hydrochloric acid in the reaction vessel (Fig. 1) and measuring the evolved hydrogen in a gas buret containing mercury. The vessel was flushed out with hydrogen, stoppered tightly, and connected to the gas buret before each bulb was broken. Gentle warming ensured complete liberation of hydrogen. When the analytical system had returned to room temperature, the volume of hydrogen (assumed to be saturated with water vapor) was read on the buret. The volume of mercury was measured in the graduated side tube attached to the reaction vessel. With room temperature and pressure known, the aluminum content of the sample of amalgam could then be calculated.

As in all investigations of the interaction of mercury with metals, wetting—which does not occur until the natural oxide (or oxygen) film on the metal has been penetrated or removed—had first to be established. In this investigation, wetting was accomplished by simply heating the stationary stirrer in the assembled apparatus in the presence of hydrogen, the rod having been previously sandpapered and rubbed with a clean towel. Usually the wetting was uniform; for example, when such a rod was immersed in mercury and rapidly heated to 360°, wetting began within ten minutes and was complete on the immersed portion of the rod in approximately ten minutes more. Wetting above the liquid line did not occur, which shows that mercury vapor is not so effective in penetrating the natural oxide film. Occasionally, wetting occurred preferentially on the immersed area; aluminum would then disappear most rapidly from the wetted areas, where the rod would be eaten away. The experiments were scheduled so that the amount of aluminum passing into the mercury from the stationary rod did not exceed the solubility at the temperature of the first experiment after a new rod was wetted. Since the hydrogen atmosphere was usually maintained even between experiments, it was possible to use a wetted rod more than once.

The time required to saturate the relatively small volume (*ca.* 35 cc.) of mercury used in the experiments could not be readily determined. With an unwetted rod, this time would depend largely upon the rate at which the mercury penetrated the natural oxide (or oxygen) film, and this unreproducible rate increases markedly with the temperature. For a wetted rod, the usual case, detailed experimental data indicated that the time in question was probably less than an hour. When only one value of the

## Discussion

The data of interest in connection with the present results are summarized in Fig. 2, which contains two previously unpublished values by Messrs. F. J. Norton and R. H. Harrington of this Laboratory, whose experimental method closely resembled that of Klemm and Weiss.[2]

In contrast with the results obtained at higher temperatures, the data of the present investigation agree fairly well with the straight line in Fig. 2. (Obviously, this agreement does not mean that the linear relationship is rigorously valid.) In drawing this straight line, the equation for which is given below Table I, the results obtained above 300° have been given some weight. The extrapolated value of the solubility for 20° is 0.0023%, in satisfactory accord with Fogh's[3] statement that all but 0.002 g. of aluminum separates from 100 g. of a saturated solution of aluminum in boiling mercury subsequently cooled to room temperature. Though it is conventional to speak of

(3) Fogh, *Kgl. Danske Videnskab. Selskab. Math.-phys. med.*, **3**, No. 15, 6 pp. (1921), abstracted in *Chem. Zentr.*, **94**, III, 993 (1923).

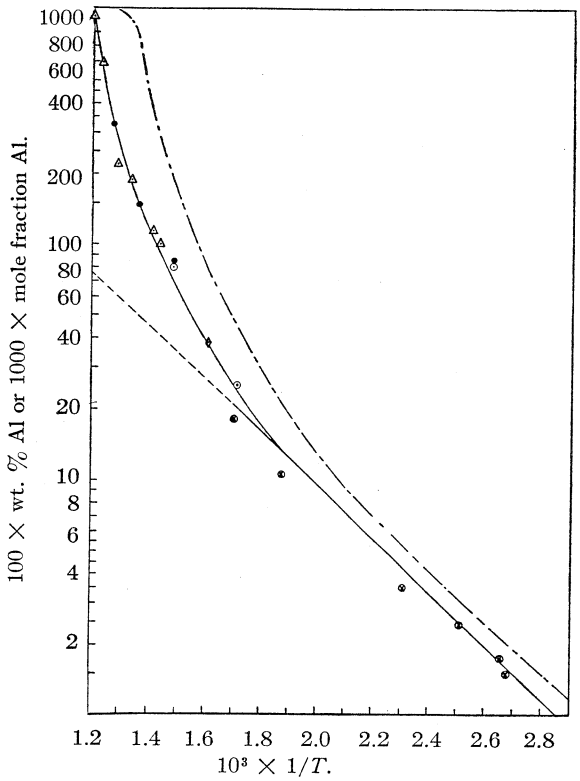

Fig. 2.—Liquidus curve of aluminum in mercury: △, reference 2; ●, ref. 1; ⊙, Norton and Harrington; ⊗, this investigation; ◇, ref. 3; —·—, mole fraction Al (points not shown, abscissa transposed so that 1.2 = 1.0); —, wt. % Al.

solubility in cases such as these, it is important to realize that the actual equilibria are established between a liquid solution of aluminum in mercury and a solid phase containing mercury and aluminum, about whose composition the information is incomplete and conflicting.[4]

As is well known, it is possible in principle to calculate the heat of fusion of aluminum from data like those in Fig. 2.[5] Though a definitive treatment of these data must await the establishment of the solidus curve, it is useful to calculate values of the *apparent* heat of fusion defined by

$$\Delta H_A^a = -4.575(\Delta \log N_A / \Delta 1/T)_P \qquad (1)$$

where $N_A$ is the mole fraction of aluminum in the liquid phase at temperature $T$ and constant pressure $P$, and the increments are taken between successive temperatures conveniently spaced. The variation of $\Delta H_A^a$ with composition is clear from Fig. 3, the ordinates for which were obtained as indicated. In the most concentrated region, $N_A$ was calculated by use of the equation % aluminum by weight = $100 - (660 - t°)$, where $t$ is the centigrade temperature, which adequately

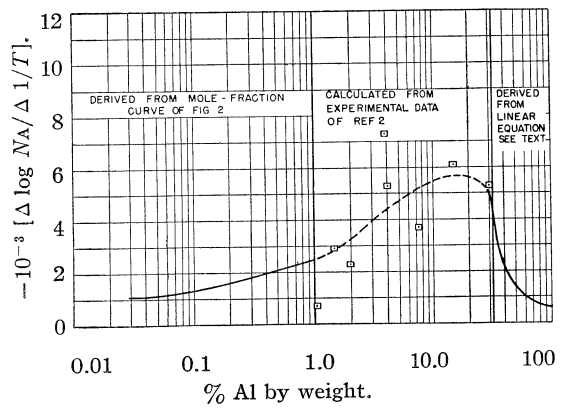

Fig. 3.—Variation of apparent heat of fusion with composition.

expresses the results of Smits and de Gruijter[1a] (*cf.* ref. 4, Fig. 59). In the intermediate region, where the mole-fraction curve has an inflection point, it seemed best to calculate ordinates directly from the experimental results of Klemm and Weiss.[2]

In the aluminum-rich region, the ordinate of Fig. 3 corresponds very closely to +2550 cal., the heat of fusion recommended for aluminum by Kelley.[5] (+2547 cal. was calculated for the interval 90–100% Al.) The pronounced variability over the rest of Fig. 3 may be due to variations in the activity coefficients, to changes in the composition of the solid in equilibrium, or to both.

I wish to thank my colleagues, Messrs. F. J. Norton and R. H. Harrington for permission to publish their two experimental results, and Mr. K. Berman for helping with the calculations.

## Summary

1. The aluminum–mercury liquidus curve has been completed by the making of measurements designed to give good results with dilute aluminum amalgams.

2. Within the temperature range 76–312°, the per cent. by weight of aluminum "soluble" in mercury is given by the equation $\log_{10} s = 1.240 - (1132/T)$ to within about 10%.

3. The apparent heat of fusion in this system passes through a maximum as the aluminum content is increased. In nearly pure aluminum, the value of this heat agrees remarkably well with the heat of fusion recommended by Kelley for this element.

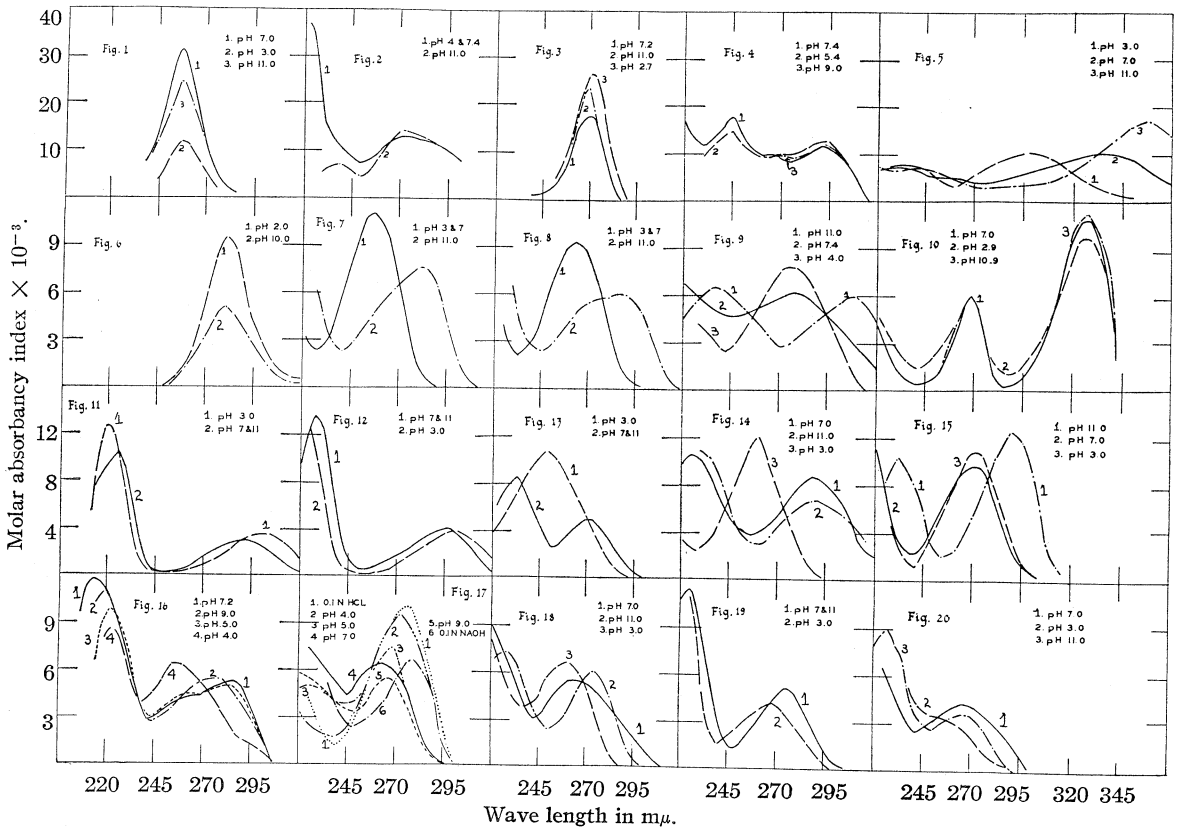
# The Ultraviolet Absorption Spectra of Some Pyrimidines. Chemical Structure and the Effect of *p*H on the Position of $\lambda_{max.}$[1]

BY MIRIAM MICHAEL STIMSON[2]

It has been suggested by Brooker[3] that symmetrical ions should be more stable than unsymmetrical ones. So far this has not been demonstrated experimentally although symmetrical dyes are more stable to *p*H changes than are unsymmetrical ones. In the following discussion an attempt will be made to correlate symmetry and *p*H response in a group of pyrimidines.

One of the most striking of the absorption characteristics of the pyrimidines is the effect of *p*H on the intensity and, frequently, on the position of the absorption maximum ($\lambda_{max}$). This change in the position of the absorption maximum with *p*H-($\Delta\lambda_{max}$) seems not to be solely dependent on the nature of the substituent on the pyrimidine ring, since barbituric acid[4] although having a pronounced change in the molar absorbancy index, shows no appreciable change in the position of $\lambda_{max}$, while uracil has $\Delta\lambda_{max}$ of 24 m$\mu$. Again it may be noted that in the case of 2-hydroxy-4,6-diaminopyrimidine there is no appreciable change in the position of the absorption maximum with change in *p*H; such a change is observed with both cytosine and isocytosine. From these various types of response to change in *p*H it is suggested that the effect of *p*H might be empirically related to the symmetry of the molecule. Thus both barbituric acid and 2-hydroxy-4,6-diaminopyrimidine may be considered as symmetrical, if the plane of symmetry be imagined to pass through the 2,5-positions. On this basis the pyrimidines under consideration may be classified as symmetrical or unsymmetrical.



In Table I are listed seven pyrimidines, all of which are considered symmetrical with respect to the above mentioned plane. From the data presented the following empirical conclusions may be drawn: (1) The long wave absorption maximum of these compounds seems to be either unaffected or only slightly shifted by the *p*H values employed. (2) In either the 4,6-dihydroxy- or the 4,6-diaminopyrimidines, in which there is also a hydroxy

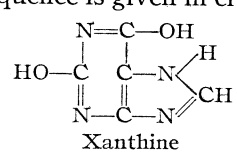


Figs. 1 to 20.—1, Barbituric acid; 2, 2-mercapto-4,6-dihydroxy-5-ethylpyrimidine; 3, 2-hydroxy-4,6-diaminopyrimidine; 4, 2-mercapto-4,6-diaminopyrimidine; 5, 5-nitrouracil; 6, 2-hydroxy-4,5,6-triaminopyrimidine; 7, uracil; 8, thymine; 9, isobarbituric acid; 10, 4,6-dihydroxypyrimidine; 11, 2-aminopyrimidine; 12, 2-amino-6-chloropyrimidine; 13, 2-chloro-6-aminopyrimidine; 14, 5-aminouracil; 15, 5-carboxyuracil; 16, isocytosine; 17, cytosine; 18, isocytosine-4-acetic acid; 19, 2-ethoxy-4-aminopyrimidine; 20, 2-methyl-4-hydroxy-6-ethoxypyrimidine.

group on the 2-position, the replacement of this hydroxy group by an –SH group is accompanied by the appearance of two maxima.[5] (3) The molar absorbancy index of an absorption band at any given *p*H apparently depends, within either a symmetrical or unsymmetrical structure, on the nature and number of the substituents, but auxochromes do not display their usual character when their introduction causes change from an unsymmetrical to a symmetrical structure. This can be seen by a comparison of both $\lambda_{max}$ and $\Delta\lambda_{max}$ for cytosine, 2-hydroxy-4,6-diaminopyrimidine, 2-hydroxy-4,5,6-triaminopyrimidine.

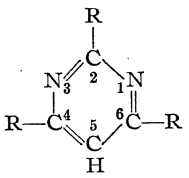
Those compounds not symmetrical with respect to the 2–5 plane show sufficient uniformity to permit sub-classification. In Table II are listed the data for various uracil derivatives, all of which have the substituent on the 5-position. In these compounds the data may be considered under two aspects, namely, the modification of the absorption pattern of the parent compound, uracil, and the effect of *p*H on $\lambda_{max}$. The following conclusions may be drawn: (1) The introduction of the additional auxochrome on the 5-position causes an increased bathochromic shift when the *p*H is changed from 3 to 11. (2) There is a formal relationship in the spectral response of carboxyuracil and of xanthine.[6] Both show a single band in acid solution and both have two pronounced bands in basic solution. That this is not unreasonable may be inferred from the formal structural relationship which also exists between the two compounds. (3) The same sequence is given in either

5-Carboxyuracil

Xanthine

acid or basic solution by the various uracil derivatives if they are arranged in order of increasing wave length of the long wave maximum

(acid) $H{=}NH_3^+ < CH_3 < COOH < OH < NO_2$



(basic) $H < NH_2{=}CH_3{=}COO^- < O^- < NO_2$.

The modification of the absorption spectrum shown by uracil may be, perhaps, more evident if $\Delta\lambda_{max}$ of uracil for the change from *p*H 3 to 11 be

(5) Fehnel and Carmack, at the Spring Meeting 1948, Chicago, reported a peak in the spectra of the alkylmercaptals at 235–240 mμ which corresponds to the short wave band in Figs. 2 and 4.

subtracted from the corresponding shift for each of the listed 5-uracil derivatives. If the log of the difference in the data between each of the uracils and uracil, respectively, be plotted against the dipole moment of the substituent, then practically a straight line relationship is obtained. The dipole moment data used are those listed in Landolt–Börnstein[7] for benzene derivatives. While these data do not accurately represent the values of the particular substituents in the uracil series, they may be considered as giving a relative evaluation. Of the six compounds tested only 5-carboxyuracil fails to show a difference in the shift of the absorption maximum as a regular function of the dipole moment. This failure of 5-carboxyuracil to respond as do the other uracil derivatives is not unreasonable in view of the formal structural and spectral similarities with xanthine.

In Table III are arranged the data of four 2-aminopyrimidines. In these compounds the upper half of the molecule is a substituted guanidine structure. The following observations may be made: (1) Each compound has two absorption bands. (2) The unsubstituted 2-aminopyrimidine and the derivative with a chlorine atom on the 6-position both show an increased separation of the absorption bands in acid solution as compared

with basic solution. (3) The derivative with the hydroxy group on the 6-position shows the least separation of the two absorption maxima in solution at *p*H 4.0, and the greatest separation at *p*H 7.2, of the *p*H values tested.

4. Consideration of the long-wave band only, shows that the *p*H effect permits the following sequence for substituents on the 6-position

| H | Cl | OH (4-acetic acid) | OH |
|---|---|---|---|
| −10 mμ | −4 mμ | 16 mμ | 26 mμ |

5. In the case of isocytosine (2-amino-6-hydroxypyrimidine) the greatest shift of the long-wave maximum occurs between *p*H 4 and the *p*H range 5–8; while at *p*H 9.0 there is a sudden shift of this band to an intermediate position. Furthermore, this new position is midway between the two subsidiary peaks as shown at *p*H 5.0.

6. A consideration of the lower of the two subsidiary peaks (264 mμ) together with the peaks at *p*H 4 and 9 shows that the shift from *p*H 4 to *p*H 5 is 6 mμ and from *p*H 5 to *p*H 9, 12 mμ. These same values are obtained from the data of isocytosine-4-acetic acid.

TABLE IV

| | 280 | 3600 | 247 | 11000 | 0.1 *N* NaOH |

Table IV includes the data for some unsymmetrical pyrimidines, none of which contains the 2 amino group. Examination shows that:

1. The spectrum of each compound shows two maxima for at least one *p*H value investigated.

2. The two peaks of the 2-hydroxy-6-aminopyrimidine (*p*H 5) are separated by the same amount as those of 2-chloro-6-aminopyrimidine (*p*H 7), although the latter are displaced 4 mμ toward longer wave lengths.

3. The position of $\lambda_{max}$ shifts progressively toward shorter wave lengths in 2-hydroxy-6-amino pyrimidine (cytosine) when the *p*H is changed from 2 to 9, but at *p*H 11, $\lambda_{max}$ occurs at a wave length longer than at *p*H 2.0. Thus in this particular compound the auxochromic character of the amino group appears only if *p*H 2 and 11 are considered.

4. In the case of the 2-chloro-6-aminopyrimidine the generally recognized characteristics of the amino group are evident (*cf.* 2-amino-6-chloropyrimidine).

5. The ratio of the positions of the short- and the long-wave maxima for 2-methyl-4-hydroxy-6 ethoxypyrimidine and the corresponding ratio for isocytosine shows that the relative separations and also $\Delta\lambda_{max}$ are similar, thus indicating a possible equality in the positional effect of the 4- and the 6-positions when occupied by the hydroxy group.

An over-all examination of the data reveals that, of the common auxochromes, the hydroxy group and the amino group both fail to produce the usual bathochromic effect when their introduction into the molecule results in a change from an unsymmetrical to a symmetrical molecule. This is illustrated by the following: (a) the introduction of the hydroxy group in uracil to give barbituric acid; (b) the introduction of the amino group into cytosine to give 4,6-diamino-2-hydroxypyrimidine.

The resulting symmetrical compounds do not show a shift of $\lambda_{max}$ with *p*H and, further, show their principal absorption maximum at slightly shorter, rather than at longer, wave lengths than do the theoretical parent compounds.

## Experimental

**Materials.**—Barbituric acid (Eastman Kodak Co.) was thrice precipitated from aqueous alcohol and was used as a 0.0000528 *M* solution, at *p*H 3, 7, 11. The molar absorbancy index agrees substantially with that given by Heyroth and Loofbourow[8] and Loofbourow and Stimson.[4] The 2-thio-4,6-dihydroxy-5-ethylpyrimidine and 2-methyl-4-hydroxy-6-ethoxypyrimidine were obtained through the courtesy of Merck & Co., and the first of these was used in 0.0000465 *M* solution at *p*H 4, 7.4, 11. The latter was employed in 0.000246 *M* solution at *p*H 3, 7, 11.

4,6-Dihydroxypyrimidine was prepared according to Kenner, *et al.*[9] It was employed in a 0.0000156 *M* solution at *p*H 2.9, 7, 10.9.

2-Hydroxy-4,6-diaminopyrimidine was prepared according to Todd[10] and employed in a 0.0000317 *M* solution at *p*H 2.7, 7.2, 10.9.

The 2-hydroxy-4,5,6-triaminopyrimidine was prepared according to Wieland and Liebig[11] and was measured in a 0.000124 *M* solution at *p*H 2, 2.5, 3.3, 6.4, 7.4, 10, 11.

2-Thio-4,6-diaminopyrimidine, prepared according to Traube,[12] was employed as a 0.0000704 *M* solution in 0.1 *N* hydrochloric acid, and at *p*H 2.2, 3.6, 4.4, 5.2, 5.4, 7.4, 9, 11. All the di- and triamino derivatives were kept in subdued light between the time the solution was prepared and the spectra determined to prevent formation of any colored oxidation compound.[13]

Uracil was employed in a 0.0000142 *M* solution at *p*H

3, 7, 11. Thymine was prepared by Dr. Marian Van Ess of the Golden State Co., and was measured in a 0.000193 *M* solution at *p*H 3, 7, 11. 5-Amino- and 5-nitrouracil (Eastman) were purified by repeated precipitation from aqueous solution and were measured in 0.000238 *M* and 0.000112 *M* solutions, respectively, at *p*H 3, 7, 11.

Isobarbituric acid was obtained from Dr. F. F. Heyroth of the University of Cincinnati and was measured in a 0.0002 *M* solution at *p*H 4, 7.4, 11. 5-Carboxyuracil was prepared by Dr. Elizabeth Ballard and is the material reported by her.[14]

2-Aminopyrimidine was obtained through the courtesy of Dr. R. O. Roblin of the American Cyanamid Co., and was measured in a 0.000165 *M* solution at *p*H 3, 7, 11. 2-Amino-6-chloropyrimidine (m. p. 178–179°) and its isomer (m. p. 209–210°) were employed in 0.000325 and 0.000232 *M* solutions, respectively, at *p*H 3, 7, 11.

Isocytosine monohydrate[15] (m. p. 275°) was used in a 0.0001185 *M* solution at *p*H 4, 5, 5.4, 6.4, 7.2, 7.4, 8, 9. Isocytosine-4-acetic acid was prepared by the late Dr. David E. Worrall and was described by him.[16] It was measured at *p*H 3, 7, 11 in a 0.000115 *M* solution.

Cytosine monohydrate was prepared by the method of Hilbert and Johnson[17] and was measured in a 0.000031 *M* solution at 0.1 *N* hydrochloric acid, *p*H 4, 5, 7.4, 9, 11.

(15) Caldwell and Kline, *ibid.*, **62**, 2365 (1940).
(16) Worrall, *ibid.*, **65**, 2053 (1943).
(17) Hilbert and Johnson, *ibid.*, **52**, 1152 (1930).

The 2-ethoxy-6-aminopyrimidine was obtained from the American Cyanamid Co., and was used in a 0.000103 *M* solution at *p*H 3, 7, 11. 2-Methyl-5-cyano-6-aminopyrimidine (m. p. 243–244°) was employed in a 0.000223 *M* solution with 0.1 *N* hydrochloric acid, 0.1 *N* sodium hydroxide and *p*H 7.4.

Except for the listed cases where either hydrochloric acid or sodium hydroxide were used all *p*H values were obtained with Kolthoff buffer tablets. In every case the comparison cells were filled with corresponding buffer, acid or base.

## Summary

1. In the pyrimidines investigated, which have a plane of symmetry through the 2–5 positions, there is essentially no change in the position of $\lambda_{max}$ with change in *p*H.

2. 5-Uracil derivatives show an increase in $\lambda_{max}$ which may be related to the dipole moment of the substituent.

3. When the introduction of an auxochrome produces a symmetrical structure the introduction is not accompanied by the bathochromic shift usually met.

# Acetoxymethyl and Hydroxymethyldisiloxanes

BY JOHN L. SPEIER, B. F. DAUBERT AND R. R. MCGREGOR

As a continuation of the study of hydroxymethylsilicon compounds first reported by Speier, *et al.*,[1] who prepared trimethylsilylmethanol and studied its reactivity, acetoxymethyl and hydroxymethyldisiloxanes have been synthesized. The esters, acetoxymethylpentamethyldisiloxane and *sym.* bis-acetoxymethyltetramethyldisiloxane were prepared and from the latter *sym*-bis-hydroxymethyltetramethyldisiloxane was made by alcoholysis. The di-alcohol was found to be unstable, even at room temperature, but it could be handled, and a derivative was made with no noteworthy difficulty.

## Experimental

**Preparation of Acetoxymethyldisiloxanes.**—Chloromethylpentamethyldisiloxane[2,3] was heated to reflux gently for twenty-four hours with a slight excess of anhydrous potassium acetate in a volume of glacial acetic acid equal to that of the disiloxane. The chloromethyl compound was not noticeably soluble in the mixture, but dissolved after several hours as a large amount of potassium chloride precipitated. The mixture was finally washed thoroughly with distilled water, and the water insoluble material was distilled. Very nearly the following molar proportions of products resulted: hexamethyldisiloxane[4] 25 mole %, b. p. 98–99° at 735 mm., $n^{25}D$ 1.3748; acetoxymethylpentamethyldisiloxane, 50 mole %, b. p. 180 at 735 mm., $n^{25}D$ 1.4040, $d^{25}_4$ 0.902. *Anal.* Calcd. for $AcOCH_2SiMe_2OSiMe_3$: Si, 25.5; sapn. equiv., 220; molar refr.,[5] 59.82. Found: Si, 25.4; sapn. equiv., 219, 221; molar refr., 59.84; and *sym*-bis-acetoxymethyltetramethyldisiloxane, 25 mole %, b. p. 250° at 760 mm., $n^{25}D$ 1.4215, $d^{25}_4$ 0.993. *Anal.* Calcd. for $(AcOCH_2Me_2Si)_2O$: Si, 21.2; sapn. quiv., 139.2; molar refr., 71.42. Found: Si, 21.1; sapn. equiv., 142, 141; molar refr., 71.2.

When *sym*-bis-chloromethyltetramethyldisiloxane was similarly treated, a practically quantitative yield of this product resulted.

**Cleavage of Acetoxymethyldisiloxanes.**—Both acetoxymethylpentamethyldisiloxane and *sym*-bis-acetoxymethyltetramethyldisiloxane were found to be resistant to acid hydrolysis. Neither ester was hydrolyzed to any appreciable extent after refluxing as long as 56 hours with 6 *N* sulfuric acid.

Both esters undergo rapid decomposition when treated with aqueous alkali. Cleavage of the Si–C bond occurred with the formation of methyl acetate and polysiloxanes. In one typical experiment, the diacetate ester was added quickly to boiling 2 *N* sodium hydroxide solution in 50% ethanol under a one-foot Vigreux column. Methyl acetate was distilled from the mixture as quickly as possible to minimize its saponification by the alkali. Two low boiling fractions were obtained: I, b. p. 53–58, $n^{25}D$ 1.3551 had the odor of methyl acetate; sapn. equiv., calcd. 74; found, 78. This was the chief product. II, b. p. 58–67°, $n^{25}D$ 1.3361, yielded a 3,5-dinitrobenzoate, m. p. 106–107° and is thus identified as being largely methanol, b. p. 66°, $n^{25}D$ 1.3276, 3,5-dinitrobenzoate, m. p. 107°. This fraction also contained methyl acetate, judging by its odor and by the fact that it contained saponifiable material. When the distillate rose to a b. p. of 100°, the residue was cooled, acidified and extracted with benzene. The extract was distilled through the Vigreux column. Most of the silicon-containing product was obtained at 135–142°,

(5) Warrick, *ibid.*, **68**, 2455 (1946).

leaving a small residue of high boiling oil which was apparently a dimethylpolysiloxane polymer. The distillate crystallized on standing and, after drying in a clay plate, melted at 58–61°. When mixed with an equal amount of authentic hexamethylcyclotrisiloxane a m. p. of 60–63° was obtained. Hexamethylcyclotrisiloxane has the properties,[6] b. p. 133° at 760 mm., m. p. 64.5°.

*Anal.* Calcd. for $[(CH_3)_2SiO]_x$: Si, 37.8. Found: Si, 37.7, 37.8.

**Preparation of *sym*-bis-Hydroxymethyltetramethyldisiloxane.**—*sym*-bis-Acetoxymethyltetramethyldisiloxane was dissolved in about a fifteen-fold excess of absolute methanol and acidified with hydrogen chloride. After twenty-four hours at room temperature, about 90% of the theoretically possible amount of methanol–methyl acetate azeotrope, b. p. 53° at 740 mm., was removed by distillation through a still of about 50 theoretical plates. The mixture was cooled and made up to its original volume with absolute methanol. After an additional twenty-four hours, all volatile material was removed at 25° and 20 mm. pressure with a stream of dried air bubbling through the liquid. The non-volatile residue was *sym*-bis-hydroxymethyltetramethyldisiloxane, $n^{25}D$ 1.4358, $d^{25}_4$ 0.979; m. p. −7.5 to −5°; viscosity: 9.1 cs. at 56°; 32.6 cs. at 21°; *Anal.* Calcd. for $C_6H_{18}O_3Si$: Si, 28.87; OH, 17.5; mol. wt., 194; molar refr., 52.0. Found: Si, 28.55; 28.83; OH, 17.1, 17.1; mol. wt. (ebullioscopically in ethanol), 187; molar refr., 51.7.

The compound formed a di-3,5-dinitrobenzoate readily, m. p. after recrystallization from ethanol, 118.5–119°.

*Anal.* Calcd. for $C_{20}H_{22}N_4O_{13}Si_2$: Si, 9.63. Found: Si, 9.72.

As the material aged, its constants changed and the viscosity at 56° increased appreciably during one-half hour at this temperature. When heated for distillation at about 5 mm. pressure, water was eliminated and a complex resinous mass resulted which became quite fluid on exposure to water. This resinous material was not further characterized.

## Discussion

The chloromethyldisiloxanes react with potassium acetate in glacial acetate acid at a far more rapid rate than does chloromethyltrimethylsilane. A similar difference was found in reactivity by Sommer, *et al.*,[7] to apply to α-chloroethyldiethylsilanol, α-chloroethyltrialkylsilanes, and α-chloroethyldiethylphenylsilane, the first being about 12-fold more reactive than the last and about 170-fold more reactive than the α-chloroethyltrialkylsilanes. This may be analogous to the enhanced activity displayed by beta oxygenated organic halides under similar circumstances

The formation of two acetate esters from the mono chlorinated disiloxane resulted through the rearrangement of the siloxane structures in the acetic acid solution. Similar rearrangements have been described in previous publications.[8,9,10] The products were statistically distributed, indicating that the acetoxy group on the methyl substituent had no detectable effect upon the silicon oxygen bonds as an influence upon their ability to rearrange.

The acetoxymethyl group was cleaved very readily with the formation of methyl acetate and a siloxane bond. This cleavage is thus the same as that found by Krieble and Elliott[2] for the chloromethyl group. The formation of methyl acetate rather than methanol in the alkaline medium indicates that the cleavage reaction occurs at a rate faster than that of the saponification of the ester.

The instability of the hydroxymethylsiloxane structure is in complete contrast with the great stability displayed by trimethylsilylmethanol.[1] The reason for this instability cannot be confidently stated until the structure of the polymer formed has been established.

## Summary

Chloromethylpentamethyldisiloxane was found to react readily with potassium acetate in acetic acid to form a statistical distribution of hexamethyldisiloxane, acetoxymethylpentamethyldisiloxane, and *sym*-bis-acetoxymethyltetramethyldisiloxane. The acetoxymethyl group was cleaved by aqueous alkali to form methyl acetate and hexamethylcyclotrisiloxane as the chief products. *sym*-bis-Hydroxymethyltetramethyldisiloxane was prepared by methanolysis of the corresponding diacetate.

# *aldehydo*-D-Galactose Heptaacetate and *aldehydo*-D-Xylose Hexaacetate from Acetolysis of Guaran and Xylan[1]

BY ROY L. WHISTLER, EILEEN HEYNE AND JOSEPH BACHRACH

Acetolysis offers a means for the structural analysis of polysaccharides. This process often yields, in addition to acetates of the constituent monosaccharides, various oligosaccharide acetates and particularly disaccharide acetates, in which glycosidic linkages characteristic of the parent polysaccharide molecule are preserved unchanged and therefore available for further and more convenient study. An examination of the acetolysis products from guaran and xylan is in progress in this Laboratory. Separation of the various sugar acetates has been made by the excellent chromatographic technique of Wolfrom and co-workers.[2] Among the acetolysis products there is always present a considerable quantity of usual monosaccharide acetates. However, in addition there has been found among the acetolysis products of guaran and xylan, acetates of the monosaccharide aldehydrols. Thus, crystalline *aldehydo*-D-galactose heptaacetate and *aldehydo*-D-xylose hexaacetate have been isolated from guaran and xylan, respectively.

Guaran is the principal polysaccharide[3] of the endosperm of guar seed. It consists of galactose and mannose units in the ratio of 1:2, respectively. Present evidence suggests that its structure may be represented as a chain of mannose units with attached galactosidic side chains.[4,5] Acetolysis of guaran triacetate produces a mixture of products which can be separated by chromatography. The carbohydrate acetate occurring in the second zone from the bottom crystallizes and is identified as *aldehydo*-D-galactose heptaacetate. This compound has been synthesized previously from *aldehydo*-D-galactose pentaacetate and acetic anhydride,[6,7] and the DL-compound has been obtained by acetolysis of agar.[8] So far the corresponding acetylated aldehydrol of mannose has not been isolated from guaran acetolysate.

Corn cob xylan or its diacetate readily undergoes acetolysis and the products are easily separated by chromatography. From the bottom zone *aldehydo*-D-xylose hexaacetate may be obtained readily in crystalline condition. This compound was synthesized previously by Pirie[7] who isolated it as a sirup but was unable to obtain it in crystalline form. By employing chromatographic purification, however, the present authors have been able to obtain in crystalline condition the synthetic compound prepared by acetylation of *aldehydo*-D-xylose tetraacetate. The synthetic compound is identical with the crystalline specimen derived from acetolysis of xylan.

The possibility of obtaining acetates of the aldehydrol form of sugars from acetolysis of glycosides has been demonstrated by Freudenberg and Soff[9] who obtained *aldehydo*-D-glucose heptaacetate by acetolysis of the methyl tetraacetyl-D-glucosides. The inference is, therefore, that sugar aldehydrol acetates may be expected as normal products of acetolysis of polysaccharides. The present work tends to substantiate this view.

## Experimental

**Acetolysis of Guaran Acetate.**—Guaran triacetate was prepared as described previously.[3] Acetolysis was performed in a manner similar to that described by Nishida and Hashima for Konjak glucomannan.[10] A mixture of acetic anhydride (330 g.), glacial acetic acid (330 g.) and concentrated sulfuric acid (64 g.) in a 2 liter round-bottom flask was cooled to 0° in an ice-bath. Powdered guaran triacetate (32 g.) was slowly added with stirring. When all of the acetate had been added, the temperature was allowed to rise slowly to 25°. Any undissolved acetate went into solution during this period. The mixture was then allowed to stand at room temperature for thirty-one days. The acetolysis mixture was slowly poured into 3–5 liters of ice water and the solution neutralized with sodium bicarbonate. The acetates were extracted from the water solution with 5 portions of chloroform (total volume 1 liter). The chloroform extracts were evaporated to dryness, weighed, and extracted with 320 ml. of benzene to make a solution containing approximately 1 g. of solid per 10 ml.

**Chromatographic Separation of the Dissolved Acetates.**—The technique of McNeely, Binkley and Wolfrom[2] was followed. To the top of a 330 × 55 mm. (diam.) column of a mixture of 5 parts (by wt.) of "Magnesol" and 1 part of "Celite" was added 20 ml. of the benzene solution described above. The chromatogram was developed with 3500 ml. of benzene–ethanol (150:1 volume ratio). The column was extruded and streaked with a solution of 1% potassium permanganate in 2.5 *N* sodium hydroxide. The permanganate solution was applied in a thin stream to the column by ejection from a hypodermic syringe. Five zones quickly developed. The zone measurements from the top of the column were as follows: I, 0–15 mm.; II, 25–35 mm.; III, 100–120 mm.; IV, 230–255 mm.; and V, 285–315 mm. The zones were eluted with acetone, evaporated to dryness, and dissolved in 95% ethanol. Rectangular prism-like crystals developed in the solution from zone IV, m. p. 103°. The yield was approximately 3% of the original guaran triacetates. After several recrystallizations from ethanol, the crystals showed a melting point of 105–106° unchanged by further recrystalliza-

tion, $[\alpha]^{2}D$ 4.0 (*c*, 3 in $CHCl_3$). These values agree with those obtained by Pirie.[8] Oxidation of the crystals in 25% nitric acid gave mucic acid, m. p. and mixed m. p. 213–214°.

*Anal.* Calculated for $C_6H_7O_7(CH_3CO)_7$: C, 48.80; H, 5.73; $CH_3CO$, 61.2; mol. wt., 492.4. Found: C, 48.85; H, 5.87; $CH_3CO$ (Kunz and Hudson method[11]), 60.9; mol. wt. (Rast), 487.

**Preparation of xylan.**—Xylan was obtained by purification of hemicellulose-A (crude xylan) extracted from corn cob holocellulose with 10% potassium hydroxide as described previously.[12] The hemicellulose-A was redissolved in 4% potassium hydroxide and reprecipitated by addition of acetic acid to *p*H 4.5. The precipitate, after collection in a supercentrifuge, was freed from water by four passages through ethanol in a Waring Blendor and dried to a low moisture content (2–3%) over calcium chloride in a vacuum desiccator. On a dry basis it contained 3% uronic anhydride[13] and 94% xylan (from furfural determination[14]), $[\alpha]^{20}D$ −106° (*c*, 0.5 in 1 *N* sodium hydroxide).

**Xylan Acetate.**—Xylan acetate used in these acetolysis studies was prepared by an adaptation of the method of Hurd and Currie.[15] Approximately 10 g. of xylan which had not been dried previously was repeatedly washed with acetic acid in a Waring Blendor until free of water. It was then washed with acetic anhydride to remove most of the acetic acid, placed in a 500-ml. flask and treated with 200 ml. of acetic anhydride containing 0.5 ml. of nitric acid, thus giving a concentration of nitric acid of 0.25%. The mixture was kept at 70° for seven hours, filtered, if necessary, and poured into ice and water. A white fibrous precipitate was obtained which was washed free of acid in a Waring Blendor. The last traces of acid were removed by boiling in water for several minutes. The *p*H was maintained at about seven during this process. The yield was 10 to 14 g. *Anal.* Acetyl, 38.6%; nitrogen, 0.2 to 0.3%. The nitrogen content indicates that a small amount of nitration accompanies the acetylation.

Xylan acetate prepared by the above method was soluble in pyridine and strong films could be cast from such solutions.[16] Xylan acetate prepared by the method of Carson and Maclay[17] undergoes acetolysis in a similar manner but was found to be incompletely soluble in pyridine or other organic solvents and consequently was not cast into films.

**Acetolysis of Xylan Acetate.**—Dry xylan acetate (20 g.), ground in a Wiley mill to pass a 40-mesh sieve, was swelled in 250 ml. of acetic anhydride at 60° for twelve hours. The suspension was cooled to 0° and 20 ml. of a 1:1 mixture of acetic anhydride and sulfuric acid was gradually added with rapid stirring. The temperature was maintained at 0° for several hours and then permitted to come to room temperature. At this point an almost clear, slightly yellow solution was obtained which gradually darkened. Acetolysis was permitted to proceed for thirty to forty days. The dark brown solution was then poured into 3 liters of ice and water and placed in a refrigerator overnight, during which time most of the acetates settled out. The supernatant liquid was decanted ahd reserved. The precipitate was suspended in water, the suspension was neutralized with sodium bicarbonate and extracted several times with chloroform. The reserved supernatant liquid was neutralized and extracted similarly and the extracts combined. The chloroform was evaporated under reduced pressure and a dark sirup resulted. The yield was approximately 20 g. The sirup was dissolved in 500 ml. of benzene and 30 ml. of this solution was chromatographed at a time.

**Acetolysis of Xylan.**—Acetolysis of xylan was carried out in an identical manner except that it was unnecessary to grind the material in a Wiley mill.

**Chromatography of Acetates.**—The above method was used. Thirty ml. of the benzene solution was added to the top of a 48 × 350 mm. sorption column. The chromatogram was developed with 1 liter of benzene–ethanol (100:1 volume ratio). The column was extruded and streaked with potassium permanganate. Three zones developed. Positions of the zones, measured from the top of the column were as follows: I, 1–5 cm.; II, 6–10 cm.; III, 14–18 cm. Almost all of the dark colored material was held within the top 1 cm. of the column and was thus easily separated. The zones were cut apart, eluted with acetone, and evaporated to dryness. The sirup obtained from zone III was rechromatographed. On elution it crystallized from alcohol on standing at 0°. Yield of crude material was approximately 10% of the original acetate. After four recrystallizations, m. p. 54–55°, $[\alpha]^{25}D$ 4.1° (*c*, 10 in $CHCl_3$). *Anal.* Calcd. for $C_5H_6O_6(CH_3CO)_6$: acetyl, 61.44; C, 48.57; H, 5.75. Found: acetyl, 61.4; C, 48.69; H, 5.78.

**Synthesis of aldehydo-D-Xylose Hexaacetate.**—Crystalline aldehydo-D-xylosetetraacetate (2.3 g.), prepared according to the instructions of Wolfrom, *et al.*,[18] was added to a solution of 2.3 g. of zinc chloride in 100 ml. of acetic anhydride and the solution was allowed to stand overnight. The solution was poured into cracked ice and water, neutralized with sodium bicarbonate, and extracted with chloroform. The sirup obtained after evaporation of the chloroform was chromatographed as described above. Two zones were obtained, the lower one corresponding precisely in location to the third zone from the acetolysis experiment. This zone was eluted with acetone as before. The sirup obtained on evaporation of the solvent was crystallized from alcohol. The yield was 1 g. After three recrystallizations, the melting point and optical rotation were identical with the acetolysis product. A mixture of the material and acetolysis product showed no depression of the melting point.

## Summary

By chromatographic methods *aldehydo*-D-galactose heptaacetate and *aldehydo*-D-xylose hexaacetate have been isolated in crystalline form from the acetolysis degradation products of guaran triacetate and xylan diacetate, respectively. This is the first reported occurrence of crystalline *aldehydo*-D-xylose hexaacetate. Isolation of acetates of these sugar aldehydrols lends further support to the view that aldehydrol acetates are to be expected as normal constituents in the acetolysis products from polysaccharide degradation.

# Some Substituted β-Hydroxyethyl Sulfides

BY HENRY GILMAN AND LAWRENCE FULLHART

In connection with a study on the preparation of physiologically active sulfides and sulfones, some sulfur analogs of the pharmacologically important alkaloid, ephedrine, have been prepared. There have also been prepared related compounds in which the phenyl radical has been replaced by the vinyl group. This paper is being presented now in view of the publication of Prelog[1] and co-workers on similar compounds.

The compounds were prepared by the reaction of the mercaptan with the appropriate epoxy compound in a basic medium or by the reaction of the sodium mercaptide with the epoxide. It is obvious in a reaction of this type that two isomeric products are possible.

The reaction of mercaptans with unsymmetrical epoxides has not been extensively studied. Nenitzescu and Scarlatescu[2] have reported the addition of various alkyl mercaptans to epichlorohydrin. They report the following reactions between ethyl mercaptan and epichlorohydrin.

$$C_2H_5SH + CH_2CHCH_2Cl \longrightarrow C_2H_5SCH_2CHCH_2Cl \quad (OH;\ V)$$

$$C_2H_5SK + CH_2CHCH_2Cl \longrightarrow C_2H_5SCH_2CHCH_2 \quad (VI)$$

The proof of the structure of compound (V) was based on the fact that treatment of (V) with aqueous potassium hydroxide gave compound (VI), their identity being established by boiling point, refractive index and density.

$$C_2H_5SCH_2CHCH_2Cl \xrightarrow{\text{Aq. KOH}} C_2H_5SCH_2CHCH_2$$

(OH; V) (VI)

Compound (VI) was then converted into 2-hydroxy-3-diethylaminopropyl ethyl sulfide (VII) by treating it with diethylamine.

$$C_2H_5SCH_2CHCH_2 + (C_2H_5)_2NH \longrightarrow C_2H_5SCH_2CHCH_2N(C_2H_5)_2$$

(O; OH) (VII)

However, it is also possible that isomeric compounds could be formed from the same reaction as shown below.

$$C_2H_5SH + CH_2CHCH_2Cl \longrightarrow C_2H_5SCHCH_2Cl \xrightarrow{\text{Aq. KOH}} C_2H_5SCHCH_2$$

(O; $CH_2OH$; VIII) (O)

$$C_2H_5SK + CH_2—CHCH_2Cl \longrightarrow C_2H_5SCHCH_2Cl \longrightarrow C_2H_5SCHCH_2$$

(O; $CH_2OK$; IX) (O)

$$C_2H_5SCHCH_2 + (C_2H_5)_2NH \longrightarrow C_2H_5SCHCH_2N(C_2H_5)_2$$

(O; $CH_2OH$; X)

A reaction similar to the reaction of potassium ethyl mercaptide and epichlorohydrin has already been reported.[3] It was found that when epichlorohydrin is treated with sodium β-diethylaminoethyl mercaptide (II), β-diethylaminoethyl-2,3,-epoxypropyl sulfide (XI) is obtained. The structure of (XI), however, was not definitely established.

$$\text{C}_6\text{H}_5\text{—CH—CH}_2 + \text{NaSCH}_2\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2 \longrightarrow$$

(O; I) (II)

$$\text{C}_6\text{H}_5\text{—CH(OH)—CH}_2\text{—S—CH}_2\text{—CH}_2\text{N}(\text{C}_2\text{H}_5)_2 \quad \text{(III)}$$

In another case Fromm, Kapeller and Taubmann[4] treated epichlorohydrin with sodium benzyl mercaptide and obtained a product which they assumed was the symmetrical compound, 1,3-dibenzylmercapto-2-propanol (XII). However, the position of the hydroxyl group was not proved.

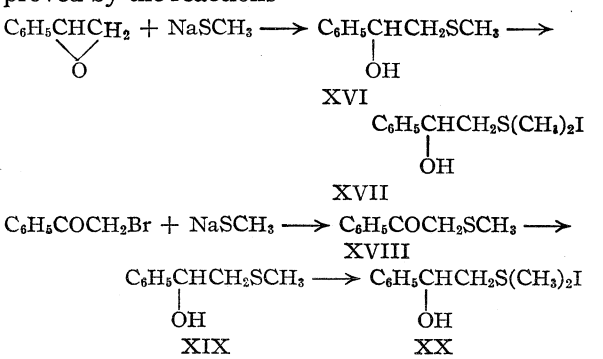
XII



It has been proposed for a number of years that unsymmetrical epoxides cleave in basic media to give secondary alcohols.[5,6,7,8] Recently Castro and Noller[9] have proved this hypothesis in the case of an unsymmetrical epoxide and ammonia. Kadesch[10] has made an extensive examination of the cleavage of 3,4-epoxybutene-1 (XIII). He has given proof for the structure of the compounds obtained and has also advanced a mechanism for the reaction. He found that the reaction of methanol with 3,4-epoxybutene-1 in an acid medium gave 2-methoxy-3-buten-1-ol (XIV) and that when the reaction was carried out in a basic medium 1-methoxy-3-buten-2-ol (XV) was obtained. The cleavage of propylene oxide with alcohols has been studied by Chitwood and

XIII XIV XV

Freure.[11] Their results were similar to those of Kadesch.

The above evidence would indicate that in the reactions which we have performed the secondary alcohols would be obtained. This has been proved by the reactions

XVI XVII XVIII XIX XX

The phenacyl methyl sulfide (XVIII) was reduced to β-phenyl-β-hydroxyethyl methyl sulfide by the Meerwein–Ponndorf[12] method using aluminum isopropoxide. Compounds (XVI) and (XIX) were converted to the corresponding methiodide by the method of Bost and Everett.[13]

The fact that the compounds (XVII) and (XX) were identical was shown by the method of mixed melting points.

A similar structure proof was tried earlier using γ-diethylaminopropyl mercaptan instead of methyl mercaptan. The constants of the γ-diethylaminopropyl β′-phenyl-β′-hydroxyethyl sulfide are in fairly close agreement but suitable solid derivatives could not be obtained.

In this connection β-diethylaminoethyl β′-phenyl-β′-hydroxyethyl sulfide was also prepared in two different ways. β-Diethylaminoethyl mercaptan was condensed with styrene oxide in the usual manner to give the proposed β-diethylaminoethyl β′-phenyl-β′-hydroxyethyl sulfide. In the second method phenacyl chloride was reduced to styrene chlorohydrin by the Meerwein–Ponndorf[12] reduction and condensed with sodium β-diethylaminoethyl mercaptide. The constants of these two products are almost identical but the method could not be considered a valid structure proof, as it is possible for the styrene chlorohydrin to be converted to styrene oxide in the basic medium. This could then react with the mercaptan and give rise to possible isomers. An example of this type of reaction has recently been reported by Whitmore[14] and co-workers. From the reaction of 2,3-dibromopropanol with piperidine there was obtained not only the expected 2,3-di-1-piperidyl-1-propanol but also the symmetrical 1,3-di-1-piperidyl-2-propanol. The symmetrical compound can be explained on the basis of the formation of an intermediate epoxide.

Incidental to the preparation of some of these compounds we prepared some of the thiols by treating sulfur with organolithium compounds. The reactions were smooth, giving yields averaging 60%. There was evidence of some disulfide formation. The reaction of Grignard reagents with sulfur has been reported several times in the literature,[15] but the reaction with organolithium compounds apparently had not been tried. The complementary nature of the Grignard reagent and the organometallic compounds of lithium should make this reaction a useful tool in obtaining heretofore unobtainable thiols.

## Experimental

**β-Diethylaminoethyl β′-Phenyl-β′-acetoxyethyl Ether.**—β-Diethylaminoethyl β′-phenyl-β′-hydroxyethyl ether (10 g., 0.042 mole) was acetylated at 100° with acetic anhydride (40 ml.) and sodium acetate (3 g.). The solution was treated with ammonium hydroxide and extracted with benzene, and the benzene solution was dried over sodium sulfate. The benzene was removed and the residue distilled at 138–141° (0.5 mm.) to give 9.2 g. (78%) of

[a] The potassium salt was prepared from equivalent quantities of solid potassium hydroxide and the mercaptan. The epoxide was added to this salt. [b] The reaction proceeded spontaneously when the ice-bath was removed. The product was cooled and diluted with water. [c] The reaction mixture was heated for twenty minutes. [d] This preparation was made from 0.18 mole of styrene oxide and 0.2 mole of the mercaptide. The reaction mixture was heated for fifteen minutes. [e] The sodium salt was prepared in toluene from equivalent quantities of the metal and the thiol.

product; $n^{20}D$ 1.4910; $d^{20}_{20}$ 1.0096; *MR* 79.61 (calcd.); 80.21 (obs.).

*Anal.* Calcd. for $C_{16}H_{25}O_3N$: N, 5.02. Found: N, 4.74, 4.88.

**β-Phenyl-β-hydroxyethyl Methyl Sulfide Methiodide.**—Prelog and co-workers[1] reported the methiodide as melting with decomposition at 132.5–133.5°, but we found the melting point to be 138–139° (dec.). A mixed m. p. with the similarly prepared methiodide of the compound prepared from styrene oxide and potassium methyl mercaptide was not depressed.

*Anal.* Calcd. for $C_{10}H_{15}OIS$: I, 40.92; S, 10.30. Found: I, 41.15; S, 10.47.

**Phenacyl Methyl Sulfide 2,4-Dinitrophenylhydrazone.**—This derivative was prepared by the method of Shriner and Fuson[16] incidental to the synthesis of β-phenyl-β-hydroxyethyl methyl sulfide from phenacyl methyl sulfide,[1] and melted at 164–165.5°.

*Anal.* Calcd. for $C_{15}H_{14}O_4N_4S$: N, 16.17. Found: N, 16.40.

**γ-Diethylaminopropyl Phenacyl Sulfide.**—To 0.1 mole of sodium ethoxide in absolute ethanol was added 14.7 g. (0.1 mole) of γ-diethylaminopropyl mercaptan in absolute ethanol. To this solution was added 19.9 g. (0.1 mole) of phenacyl bromide in absolute ethanol. The reaction mixture was refluxed under nitrogen for two hours and cooled. The suspended salt was filtered and the filtrate was concentrated under reduced pressure and extracted with ether. The ether extract was dried and distilled to give 16 g. (62%) of product distilling at 158–160° (0.8 mm.); $n^{20}D$ 1.5240; $d^{20}_{20}$ 1.0027; *MR* 79.79 (calcd.); 81.02 (obs.). In another preparation the following constants were obtained: b. p. 157–161° (1 mm.); $n^{20}D$ 1.5226.

*Anal.* Calcd. for $C_{15}H_{23}ONS$: N, 5.28. Found: N, 5.62.

The 2,4-dinitrophenylhydrazone was prepared by the usual method; its melting point was 183–184° after recrystallization from absolute ethanol.

*Anal.* Calcd. for $C_{21}H_{30}O_8N_5S$: N, 14.90. Found: N, 14.80.

**β-Diethylaminoethyl β′-Phenyl-β′-hydroxyethyl Sulfide.**—To sodium ethoxide (0.1 mole) in absolute ethanol was added 13.3 g. (0.1 mole) of β-diethylaminoethyl mercaptan in 25 ml. of absolute ethanol. To this solution was then added 15.6 g. (0.1 mole) of styrene chlorohydrin (prepared in 86% yield from phenacyl chloride and aluminum isopropoxide) in 25 ml. of absolute ethanol. The solution was cooled and the precipitated salt filtered. The filtrate was distilled to give 19.5 g. (78%) of product distilling at 152–155° (1.5 mm.); $n^{20}D$ 1.5425.

**γ-(β-Diethylaminoethylmercapto)propyl β′-Phenyl-β′-hydroxyethyl Ether.**—To a solution of 43 g. (0.225 mole) of β-diethylaminoethyl γ-hydroxypropyl sulfide and 11.2 g. (0.2 mole) of potassium hydroxide was added 21.6 g. (0.18 mole) of styrene oxide. The solution was refluxed for one hour and poured into water. The solution was acidified with 12 g. (0.2 mole) of glacial acetic acid and extracted with benzene. The benzene was dried and distilled to give 10 g. (15%) of product distilling at 160–174° (0.6 mm.). Redistillation gave the pure compound distilling at 180–182° (1.5 mm.); $n^{20}D$ 1.5448. The compound has a tendency to superheat.

*Anal.* Calcd. for $C_{17}H_{29}O_2NS$: N, 4.50. Found: N, 4.35.

**3-Diethylamino-1,2-epoxypropane.**[17]—In a 3-liter, 3-necked flask were placed 556 g. (6.0 moles) of epichlorohydrin, 432 g. (5.9 moles) of diethylamine and 18 g. (1.0 mole) of water. The solution was stirred for six hours at a temperature of 28–30°. The temperature was then lowered to 22° and 280 g. (7.0 moles) of sodium hydroxide in 456 ml. of water was added while the temperature was kept below 25°. The solution was stirred for forty minutes; a yellow layer separated out during this time. The yellow layer was removed and the water layer extracted with ether. The ether extracts and the original layer were combined and dried over potassium hydroxide. The ether solution was decanted and distilled to give 430 g. (56.5%) of product distilling at 69° (32 mm.); $n^{20}D$ 1.4362.

**Thiophenol.**—To 0.195 mole of phenyllithium in ether[18] was added cautiously 6.25 g. (0.195 g. atom) of sulfur. The reaction was exothermic. When all the sulfur had been added, color test (I)[19] for the presence of an organometallic compound was negative. The solution was then hydrolyzed with dilute hydrochloric acid and worked up. On distillation there was obtained 13 g. (62%) of thiophenol distilling at 68° (20 mm.); $n^{20}D$ 1.5885. Approximately 3 g. of material distilled at 115–121° (0.5 mm.); this material, which later solidified, may have been diphenyl disulfide.

***p*-Dimethylaminothiophenol.**—To a solution of *p*-dimethylaminophenyllithium prepared from 40 g. (0.2 mole) *p*-bromodimethylaniline[18] was added portion-wise 6.4 g. (0.2 g. atom) of sulfur. The reaction was exothermic and a precipitate formed. The mixture was hydrolyzed with the theoretical amount of hydrochloric acid. The ether layer was separated and dried. On distillation there was obtained 15 g. (50%) of product distilling at 122° (2 mm.). The reported[20] boiling point is 259–260°.

[a] The sodium salt, prepared from the metal and the mercaptan in toluene, was used. [b] The reaction mixture was refluxed for sixteen hours. It was then extracted with dilute base before working up. $d^{20}_{20}$ for the compound was 0.9431; *MR:* calcd., 84.57; obs., 83.85. [c] The reaction mixture was refluxed for eight hours, cooled and extracted with dilute base. [d] The epoxide (0.2 mole) was added to an ethereal solution of lithium thiophenolate (0.2 mole) prepared from phenyllithium and sulfur (see text). After refluxing overnight, the reaction mixture was decomposed with water. [e] The reaction mixture was refluxed for five hours, cooled and extracted with dilute base. [f] The reaction mixture was refluxed for twelve hours, cooled and diluted with water. [g] 0.05 molar quantities used. The mixture was refluxed for six hours, cooled and diluted with water.

TABLE III

COMPOUNDS PREPARED FROM 3,4-EPOXYBUTENE-1 AND SODIUM MERCAPTIDE

| Mercaptan | Product, sulfide | B. p., °C. | Mm. | $d^{20}_{20}$ | $n^{20}D$ | *MR* Calcd. | Obs. | Yield, % | N, % Calcd. | Found |
|---|---|---|---|---|---|---|---|---|---|---|
| p-Aminothiophenol[a] | β-Hydroxy-Δ³-butenyl p-aminophenyl | 165–168 | 0.8 | .... | .... | ... | ... | 51 | 7.18 | 7.20 |

[a] The mixture was refluxed for three hours, then diluted with water. [b] Refluxed twelve hours and diluted. [c] Refluxed eight hours and diluted.

**γ-Diethylamino-β-hydroxypropyl p-Tolyl Sulfone.**—A suspension of 17.9 g. (0.1 mole) of sodium p-toluenesulfinate and 12.9 g. (0.1 mole) of 3-diethylamino-1,2-epoxypropane in toluene was refluxed under a nitrogen atmosphere for twelve hours. The solution was diluted with water and worked up to give 5 g. (17.5%) of product distilling at 217° (1 mm.); m. p. 65–67°.

*Anal.* Calcd. for $C_{14}H_{23}O_3NS$: N, 4.92. Found: N, 5.12.

**Preparation of Substituted Sulfides.**—In general, 0.1 mole of the mercaptan was converted to the alkali metal salt either by solid potassium hydroxide or by sodium in benzene or toluene. This salt was then brought into reaction with an equivalent amount of the appropriate epoxide. (For individual times of heating, see footnotes to the Tables.) The reaction mixtures from preparations which used the potassium salt were diluted with water, acidified with glacial acetic acid, extracted with benzene, dried and distilled. The other reaction mixtures were diluted with water (and extracted with dilute base where noted), dried and distilled.

**Acknowledgment.**—The authors are grateful to the Pittsburgh Plate Glass Company for furnishing the 3,4-epoxybutene-1; to the Dow Chemical Company for furnishing the styrene oxide used in these experiments; and, particularly, to Parke, Davis and Company for arranging for the pharmacological tests, which will be reported elsewhere. They also wish to thank William Meikle and John Morton for assistance.

## Summary

A series of substituted β-hydroxyethyl sulfides has been prepared and described. Evidence has been given to indicate that the cleavage of unsymmetrical epoxides by mercaptans in the presence of base results in secondary alcohols.

A method for the preparation of thiols using organolithium compounds has been described.

AMES, IOWA RECEIVED JULY 20, 1948

# Condensation of α-Carbethoxy-γ-butyrolactones with Amidines and Guanidine

BY GLENN S. SKINNER, ETHEL ANDERSON AND ROBERT F. BOGART

It has been previously reported[1] that an α-alkyl-α-carbethoxy-γ-butyrolactone does not condense with an amidine to yield a tetrahydropyrimidine derivative but a product whose formation could be explained by the hydrolysis of an intermediate in which the lactone ring had remained intact.

By rapid and intimate mixing of the alkaline reaction product with a freezing mixture of ice and hydrochloric acid there is obtained the intermediate lactone amidine containing a small amount of the inner salt that is formed through the initial splitting of the lactone ring by aqueous alkali. A better procedure for the isolation of the pure lactone amidine involves the prior removal of the sodium as sodium chloride under anhydrous conditions.

The unalkylated lactone ester, however, readily condenses with amidines to yield the tetrahydropyrimidine derivatives. The greater reactivity of the unalkylated lactone ester is probably due to the residual active hydrogen atom. The formation of the sodium derivative of the intermediate that is made possible by the tautomerism of the amidine residue in the intermediate can then lead by the $1 \rightarrow 3$ shift mechanism to a more stable sodium derivative involving ring closure.

Due to the fact that an α-carbethoxy-γ-butyrolactone may be decarboxethylated[1] and that amidines may lose ammonia to form nitriles, some study was made to find the optimum conditions for the formation of the tetrahydropyrimidine derivative. In general, the best yields were obtained by heating the mixture of reactants at 45° (Table I). In the case of the 2-ethyl- and 2-phenyl- derivatives it was also shown that the yield was raised from 55.4 and 53.6 per cent. to 66.3 and 65.5 per cent., respectively, by the very slow addition of an alcohol solution of the lactone ester to the mixture as it was stirred at 45°. This is confirmation that one of the difficulties lies in the decarboxethylation of the ester.

## Experimental

**Lactone Amidine.**—A solution of sodium ethoxide was prepared from 0.243 mole of sodium and 100 cc. of alcohol. To the cooled (22°) and mechanically stirred solution were added 0.0866 mole of benzamidine hydrochloride and 0.0693 mole of α-isoamyl-α-carbethoxy-γ-butyrolactone. The bath was then heated rapidly to 45°. Heating was continued at this temperature for twenty-four hours and it was then heated three hours at 70°. The mixture was cooled in an ice-bath, and with good mixing, made just acid with 15.7 cc. of hydrochloric acid. The sodium chloride (13.3 g.) was filtered and washed with absolute alcohol. After concentration of the filtrate by distillation of the alcohol *in vacuo* from a bath, not heated above 50°, 5.4 g. of the lactone–amidine separated in the form of white crystals, m. p. 117–118°.

A mixture of the lactone–amidine and the inner salt resulting from the hydrolysis was prepared by the following procedure. To a stirred solution of sodium ethoxide prepared from 7.6 g. of sodium and 100 cc. of absolute alcohol there was added at 0° 18.8 g. of benzamidine hydrochloride and then 22.8 g. of α-isoamyl-α-carbethoxy-γ-butyrolactone. The temperature was allowed to rise to 23° in one hour. The mixture was heated two hours at 40° and

then two hours at 47°. Stirring was stopped and the mixture was heated twelve hours longer at 47°. Most of the alcohol (82 cc.) was removed by distillation under diminished pressure at this bath temperature. The residue was quickly and vigorously shaken with a mixture of 19 cc. of hydrochloric acid (1.19) and 80 g. of finely crushed ice. The cold mixture was filtered with suction and washed with ice-cold water and petroleum ether. The mixture weighed 22.24 g., m. p. 112–122° (dec.). Upon standing an additional 1.33 g. of impure inner salt separated from the filtrate, m. p. 132–134° (dec.).

Lowering the initial and final reaction temperatures to −10 and 23°, respectively, for a total reaction period of thirty-four hours decreased the yield to 6.85 g. Increasing the heating period to twenty-four hours at 45–48° followed by heating three hours at 70° decreased the yield to 7.34 g. When the temperature of the reaction mixture was allowed to rise to 89° in two hours and the mixture was then heated six hours longer at 89° the yield was decreased to 7.12 g.

To separate the lactone–amidine from the inner salt, 1 g. of the product was placed in a beaker cooled in a salt–ice mixture. To this was added with good stirring a precooled mixture of 2 cc. of hydrochloric acid (1.19) and 10 cc. of water. To the cold filtrate from a very small amount of undissolved material concentrated aqua ammonia was added from a buret until the maximum precipitation was obtained. Constant mixing and a temperature below 0° should be maintained. It is preferable to operate at −5°. The crystals were filtered with suction and washed with ice-cold water and a mixture of ether and ligroin, m. p. 114–115°. By dissolving this product in alcohol at 35° and crystallizing by cooling in a freezing mixture the melting point rose to 117°.

*Anal.* Calcd. for $C_{17}H_{22}O_3N_2$: N, 9.27. Found: N, 9.16.

The inner salt was best obtained by crystallizing from alcohol the product from those preparations in which no precautions were taken against hydrolysis of the lactone–amidine, m. p. 140–141 (dec.). The salt previously prepared under more vigorous conditions decomposed at 147°.

*Anal.* Calcd. for $C_{17}H_{24}N_2O_4$: C, 63.73; H, 7.55; N, 8.75. Found: C, 63.46; H, 7.49; N, 8.73.

The inner salt, by heating at its decomposition point, gave one equivalent of ammonia, benzonitrile and nonvolatilized material which behaved as a lactone but was not further identified.

**2-Alkyl-5-β-hydroxyethyl-4,6-diketo-3,4,5,6-tetrahydropyrimidines.**—In a typical experiment valeramidine hydrochloride (0.1250 mole) and α-carbethoxy-γ-butyrolactone (0.100 mole) were rapidly and thoroughly mixed at room temperature with a solution of sodium ethoxide prepared from 6.9 g. of sodium and 100 cc. of absolute alcohol. The mixture was brought rapidly to 45° and maintained at that temperature for twenty-five hours. After standing at room temperature for twelve hours the mixture was treated with 20 cc. of acetic acid mixed with 125 g. of ice and water. The yield was 16.1 g. (75.9%). Recrystallization from hot 50% alcohol gave nearly white crystals, m. p. 259–260° (dec.).

To isolate all of the compounds containing smaller radicals it was found necessary to concentrate the mother liquor. The pure products possess a faint yellow color.

**5-Alkyl-β-hydroxyethyl-2-iminobarbituric Acids.**—In a typical preparation, 18.0 g. of guanidine carbonate was added to a solution of sodium ethoxide prepared from 8.0 g. of sodium and 125 cc. of absolute alcohol. After stirring for ten minutes the mixture was cooled to 5° and 11.4 g. of α-*n*-amyl-α-carbethoxy-γ-butyrolactone was added dropwise with stirring. At the end of three hours at this temperature the mixture was allowed to stand twenty-four hours at room temperature. One liter of cold water was added and the filtered solution was made neutral to litmus with acetic acid. The crude acid was recrystallized by dissolving in a boiling mixture of 800 cc. of ethyl alcohol and 650 cc. of water; yield 9.86 g., m. p. 242° (dec.).

In attempts to isolate the intermediate complex salt the alcohol solution of guanidine and sodium ethoxide, after removal of the sodium carbonate, was mixed with 11.4 g. of α-isoamyl-α-carbethoxy-γ-butyrolactone at 19°. The temperature rose to 28° in two minutes and a precipitate began to form in twelve minutes. After twenty-four hours at room temperature the salt was filtered and washed with alcohol. The yield was 5.66 g. The filtrate gave 5.58 g. of crude 5-isoamyl-5-β-hydroxyethyl-2-iminobarbituric acid, m. p. 240–244°. After recrystallization from a mixture of 550 cc. of ethanol and 350 cc. of water the yield was 5.3 g., m. p. 248–249°. The salt continued to decompose under various conditions in attempts to get a constant weight for the sample. A sample after heating intermittently at 76° for fifty-six hours gave the following analysis: Calcd. for $C_{13}H_{23}O_4N_3Na_2$: Na, 13.89; N, 12.69. Found: Na, 16.29; N, 7.45. The substance had therefore suffered extensive decomposition.

**Acknowledgment** is made to the Research Fund of the University of Delaware for financial aid to Ethel Anderson.

## Summary

1. A comparison is made between the action of alkylated and unalkylated α-carbethoxy-γ-butyrolacetones on amidines. The intermediate lactone–amidine has been isolated.

2. The alkylated lactone esters have been condensed with guanidine.

# The Reduction of Substituted Nitrobenzenes at the Dropping Mercury Cathode

BY SALLY FREE DENNIS,[1,2] ALLEN S. POWELL AND MELVIN J. ASTLE

Substituted nitrobenzenes were among the first organic compounds to be investigated using the polarographic technique. The early work was performed by the Japanese, Shikata and his co-workers, and from this work Shikata and Tachi[3] formulated the "electronegativity rule of reduction potentials," *i. e.*, that organic compounds are more easily reduced as more electronegative groups are substituted in the same molecule.

These investigators measured the reduction potentials by the tangent method *vs.* the normal calomel electrode. This method of measurement deviates from present practice. It was felt desirable to extend their investigations of substituted nitrobenzenes and to determine the relative effect of the position of the substituent upon the reduction process.

The ortho-, meta- and para-isomers of nitrobenzoic acid, dinitrobenzene, nitrochlorobenzene, and nitrotoluene were selected for study. The reduction of these compounds at the dropping mercury cathode from carefully buffered solutions over the *p*H range 2 to 14 was investigated to determine the nature of the reduction process and the effect of the position of the substituent groups upon the half-wave reduction potential.

## Experimental

All of the compounds investigated were obtained from Eastman Kodak Company and were further purified before use. Water solutions of 0.002 *M* concentration of *o*- and *m*-nitrobenzoic acids and of 0.001 *M* concentration of *p*-nitrobenzoic acid were made up for use as master solutions. The dinitro-, chloronitro- and nitrotoluenes were made up as 0.002 *M* solutions in alcohol. Gelatin was incorporated into each of the master solutions as a water solution of such concentration that the sample for electrolysis (diluted 1:1 with buffer) would contain 0.0075% gelatin.

For *p*H values up to 8 McIlvaine's citric acid–disodium phosphate buffers were used as supporting electrolyte and for *p*H values greater than 8, Sörensen's glycine–sodium hydroxide buffers were used. The *p*H of each solution was checked with a Beckman *p*H meter.

The sample to be electrolyzed was prepared by mixing equal parts of the master solution of nitro-compound and the desired buffer solution. This solution was degassed in the electrolysis cell by passing nitrogen through the solution for seven to eight minutes. The electrolysis was carried out in a constant temperature bath at 25°.

An H-type cell containing a saturated calomel working electrode was used in conjunction with a Sargent Model XX Polarograph. The drop time of the capillary was found to be 3.2 seconds per drop and the value of $m^{2/3}t^{1/6}$ was 2.13 mg.$^{2/3}$sec.$^{-1/2}$ measured in water with no applied potential.

## Discussion of Results

The wave heights and half-wave potentials determined for the nitrobenzoic acids are tabulated in Table I. Inspection of the table reveals that all of the wave heights are approximately 15 microamperes for a 0.001 molar concentration of the acid. Using the value $8.28 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ for the diffusion coefficient of nitrobenzoic acid the value of $n$ in the Ilkovic equation is found to be 4.05 which indicates that the reduction of the nitro group proceeds only to the hydroxylamine. The diffusion coefficient was determined from the equivalent conductance of the nitrobenzoate ion at infinite dilution. Representative polarograms obtained with *o*-nitrobenzoic acid are shown in Fig. 1. The other two isomers gave similar curves.

first are not sufficiently well defined to make their interpretation possible with any degree of accuracy (Fig. 2), however, if correction is made for the effect on wave height of the alcohol required to increase solubility, the first wave is found to be approximately the height of that observed for the nitrobenzoic acid and therefore must represent reduction to the corresponding hydroxylamine. The alcohol effect was measured by reducing nitrobenzoic acid both from water and from 50% alcohol solutions. The ratio between wave heights for the same compound in the two solutions was about 5:4 which corresponds fairly well to the ratio of the nitrobenzoic acid to dinitrobenzene (first wave) heights.

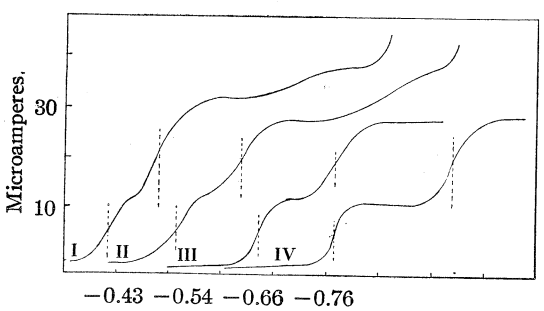

Fig. 2.—Polarograms for *o*-dinitrobenzene: I, *p*H 2.7; II, *p*H 4.6; III, *p*H 7.4; IV, *p*H 11.7. The divisions represent 0.25-volt intervals.

The half-wave potentials for the first and second waves plotted against *p*H are shown in Fig. 3. There is some doubt as to the exact potential of the second wave for the meta-isomer because of difficulty in measurement. It is noted that the order of ease of reduction is para > ortho > meta for the first wave and exactly the reverse for the second wave. This seems reasonable when one considers that the second reduction step takes place under the influence of the hydroxylamine group which is less electronegative than the nitro group. Also the hydroxylamine group is capable of hydrogen bonding with the ortho-nitro group and this would lead to increased ease of reduction of the ortho-compound as has been previously observed in the case of the nitrophenols.[4]

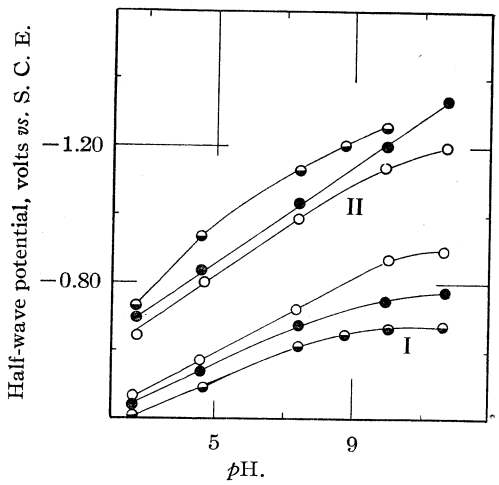

Fig. 3.—Effect of *p*H on the half-wave reduction potentials of the dinitrobenzenes: first wave I, and second wave II: ◒, para; ●, ortho; ○, meta.

As with the nitrobenzoic acids, the data indicate that the nitrotoluenes are reduced to the hydroxylamines at all *p*H values (Table III). In the acid solutions the ortho isomer is considerably more difficultly reduced than the meta- and para-isomers, and the order of ease of reduction changes in alkaline solution to meta > ortho > para. The current–voltage curves were similar to those shown for *o*-nitrobenzoic acid.

TABLE III

HALF-WAVE REDUCTION POTENTIALS (VOLTS *versus* THE S. C. E. CORRECTED FOR *IR* DROP) AND THE DIFFUSION CURRENTS (MICROAMPERES) FOR 0.001 *M* 50/50 ETHYL ALCOHOL–WATER SOLUTIONS OF NITROTOLUENES

| | Ortho | | Meta | | Para | |
|---|---|---|---|---|---|---|
| *p*H | *E* | *I* | *E* | *I* | *E* | *I* |

| 11.7 | −1.07 | 11.7 | −1.05 | 11.7 | −1.15 | 13.0 |

Figure 4 shows the effect of *p*H on the reduction potential for the four compounds in which the nitro group is ortho to the second substituent.

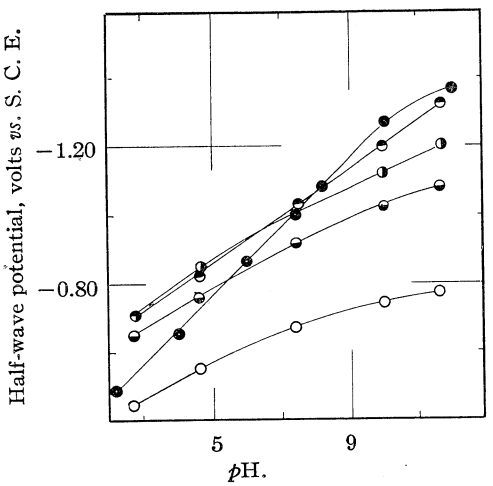

Fig. 4.—Effect of *p*H on the half-wave reduction potentials of the ortho-substituted nitrobenzenes: O, first wave, dinitrobenzene; ●, nitrobenzoic acid; ◒, nitrochlorobenzene; ◑, nitrotoluene; ◓, second wave, dinitrobenzene.

The same relationship is shown for the meta- and para-isomers in Figs. 5 and 6, respectively. Disregarding for a moment *o*-nitrobenzoic acid (which behaves anomalously), one can observe that in all cases, reduction becomes more difficult with the substituent in the order nitro >, carboxyl >, chloro >, methyl and that this order conforms with Shikata's rule of electronegativity. It would seem, therefore, that the effect of the substituent group is to attract the electrons away from the nitrogen leaving it relatively more positive than a nitrogen in a normal nitro group. This tendency toward placing a positive charge on the nitrogen causes the electrons around the nitrogen to be placed under greater constraint, and as a result the resonance within the nitro group is decreased and the nitro group more readily reduced.

The nitro group and carboxyl group show a $-I$ and a $-M$ effect. Both of these effects would decrease the electron density around the nitrogen thus facilitating the reduction of the nitro group. The $-M$ effect would have a greater effect in the ortho- and para-isomers. Consequently, the

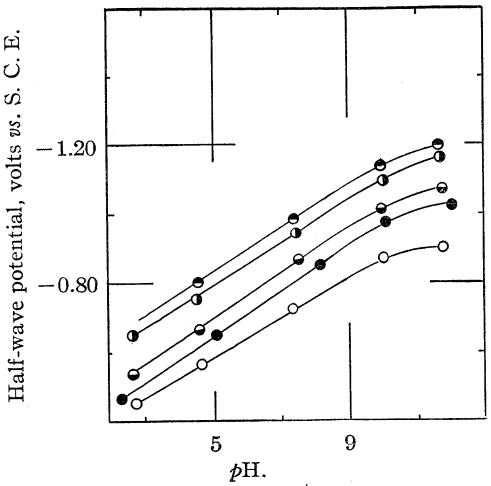

Fig. 5.—Effect of *p*H on half-wave reduction potential of meta-substituted nitrobenzenes: O, dinitrobenzene, first wave; ●, nitrobenzoic acid; ◒, chloronitrobenzene; ◑, nitrotoluene; ◓ dinitrobenzene, second wave.

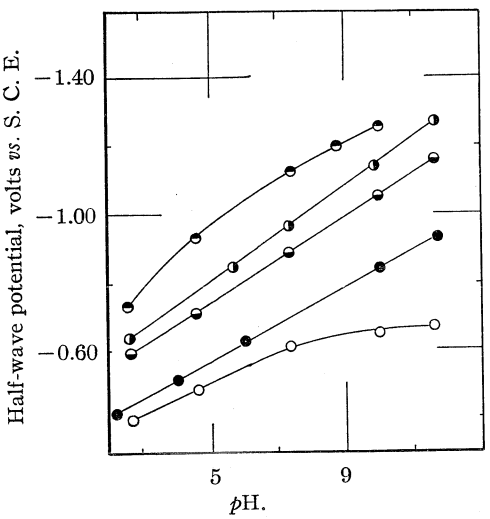

Fig. 6.—Effect of *p*H on the half-wave reduction potentials of para-substituted nitrobenzenes: O, dinitrobenzene, first wave; ●, nitrobenzoic acid; ◒, nitrochlorobenzene; ◑, nitrotoluene; ◓, dinitrobenzene, second wave.

meta-isomer should be the most difficultly reduced and this is what was observed except for *o*-nitrobenzoic acid which behaves anomalously in other respects.

Chlorine exhibits a $-I$ and a $+M$ effect while $-CH_3$ exhibits a $+I$ effect. Both of these groups therefore, should increase the electron density around the ortho- and para-positions relative to the meta-positions and therefore the meta-isomers should be more readily reduced. This is what has been observed.

When hydrogen bonding is possible, the ortho substituted nitro compounds are more readily reduced than either the corresponding meta- or para-isomers. This has been observed previously

in the investigations of nitro phenolic compounds[5] and was observed in the present work for the second stage reduction of dinitrobenzenes which represents the reduction of nitrophenylhydroxyl amines. The *o*-isomer which may form H-bonds between the nitro and the hydroxylamine group was more readily reduced than the corresponding meta- or para-isomers.

After the completion of the present work, Pearson[6] published the results of his investigations of the polarography of the nitrotoluenes and the dinitrobenzenes. Pearson using a potassium hydrogen phthalate–hydrochloric acid buffer over the *p*H range 2.5–3.8 and a potassium hydrogen phthalate–sodium hydroxide buffer over the *p*H range 4.1–7.4 reported half-wave potentials which were from about 0.25 to 0.35 volt more positive than those found in this Laboratory using different systems. Some of Pearson's work has been repeated and verified in this Laboratory. It seems improbable that the differences in reduction potentials could be accounted for on the basis of large differences in concentrations of the nitrobenzene derivatives used in the two investigations. It seems more probable that the reduction of the nitro group is a function not only of the *p*H but also of the nature of the buffer. This effect is being further investigated.

Pearson obtained a second wave at low *p*H values which corresponded approximately to a two electron process which, when added to the height of the first wave involving a four electron process, represented the complete reduction to the corresponding aniline. This second small wave has also been observed in this Laboratory at a *p*H of 2.7 for all the substituted nitrobenzenes but it was very poorly defined and so was not included in the tabulated data.

## Summary

The reduction of the ortho-, meta- and para-isomers of nitrobenzoic acid, dinitrobenzene, chloronitrobenzenes and nitrotoluene from buffered solutions at the dropping mercury cathode have been studied.

Within each group of isomers, the ortho-compound was more difficultly reduced than the para-compound. It is possible to correlate the electronegativity of the second substituent with the reduction potential of the nitro group and to qualitatively determine the effect of position on the degree of the electronegativity of that group.

*o*-Nitrobenzoic acid does not behave like the other ortho-compounds in that the reduction potential is much more sensitive to differences in *p*H of the solution.

In every case reduction stops with the formation of the corresponding hydroxylamines, with the exception of the dinitrobenzenes and in these cases the complexity of the curves make difficult the determination of the intermediate steps of reduction.

# Sulfate Esters as Intermediates in the Formation of 7-Dehydrocholesterol and Dicholesteryl Ether[1]

BY ALBERT E. SOBEL, PHYLLIS S. OWADES[2] AND JOSEPH L. OWADES[3]

A certain amount of evidence has accumulated pertaining to the importance of sulfate esters in the chemistry of steroids in the living organism. At least six different steroid sulfates have been isolated from urine,[4–9] as well as a dehydrosteroid which was postulated as having been formed from a sulfate ester during the course of isolation.[10] A sulfate containing lipid was found in brain.[11] Recently it has been shown that the human kidneys maintain a definite level of sulfate in the blood. The existence of this threshold suggests that the sulfate in the blood, heretofore considered to be simply excretory, plays some metabolic role.[12,13]

Naturally occurring 7-dehydrocholesterol and dicholesteryl ether are found associated with the relatively abundant cholesterol, from which they would seem to be derived. 7$\beta$-Hydroxycholesterol, the probable intermediate in the formation of 7-dehydrocholesterol, has also been isolated.

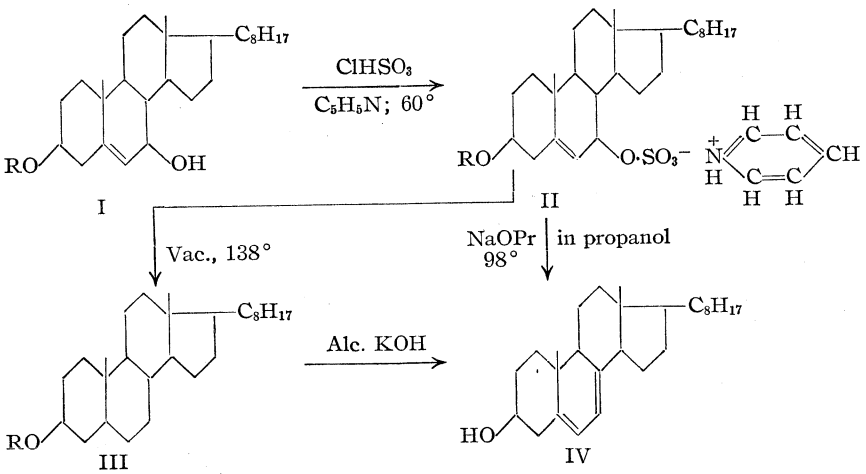

Fig. 1.

In view of this evidence, it seemed possible that sulfate esters might be the metabolic intermediates in the conversion of cholesterol to 7-dehydrocholesterol and dicholesteryl ether. We have shown in this investigation that the formation of these two steroids from their corresponding sulfates is possible *in vitro*.

It had previously been demonstrated that monovalent metal salts of cholesteryl sulfate decompose on heating to give 3,5-cholestadiene.[14,15] It was thus of added interest to determine whether the 7-position in the sterol nucleus underwent a similar reaction.

The method employed in the formation of 7-dehydrocholesterol from cholesterol is shown in Fig. 1. 7β-Hydroxycholesteryl phthalate (I) was made by permanganate oxidation of cholesteryl phthalate using a modification of the method of Heilbron, *et al.*[16] The 7-sulfate (II) was then prepared by treating the alcohol with a mixture of chlorosulfonic acid and pyridine. Decomposition of the sulfate, either in the dry state or in a solvent, resulted in 7-dehydrocholesterol (IV).

This investigation was facilitated by the use of two color reactions which distinguished between 7β-hydroxycholesterol and 7-dehydrocholesterol. The known steroid color tests for 7-dehydro and 7-hydroxy steroids, namely, the Rosenheim,[17] Callow,[18] Lifschutz,[19] and antimony trichloride reactions, give positive tests with both compounds. It was found that the Callow reaction could be modified so as to differentiate between these two steroids. The 7-dehydro compound gave a positive test with this reagent, whereas the 7-hydroxy compound remained colorless. The course of decompositions, as well as purification procedures, were readily followed with this test.

(18) Rosenheim and Callow, *ibid.*, **25**, 74 (1931).
(19) Bergstrom and Wintersteiner, *J. Biol. Chem.*, **145**, 309 (1942).

The activated glycerol dichlorohydrin reagent, which is used in the determination of Vitamin A,[20] was also helpful in distinguishing between these steroids. With this reagent the 7-dehydrocholesterol gave a negative reaction, but 7-hydroxycholesterol gave a dark blue color. This is the only substance which is known to give a blue color with activated glycerol dichlorohydrin.

Dicholesteryl ether was also prepared from sulfate esters. The pyridine radical in pyridinium cholesteryl sulfate was replaced by divalent or trivalent cations, namely, ferrous, ferric and aluminum. These cholesteryl sulfate salts, as well as the calcium salt,[21] decompose at varying temperatures to yield dicholesteryl ether (Fig. 2). The decomposition of the aluminum cholesteryl sulfate occurs spontaneously at room temperature. This low temperature reaction lends support to our hypothesis that sulfate esters are significant in the *in vivo* chemistry of the steroids.

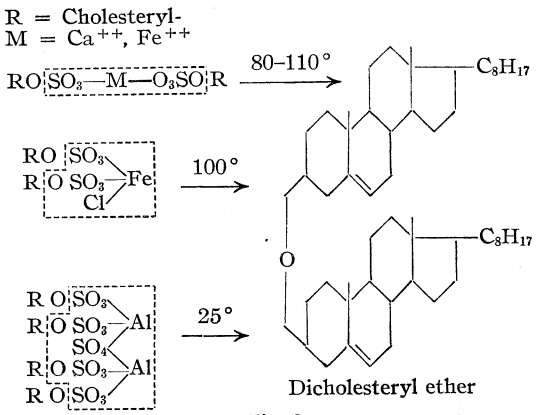

Fig. 2.

It is hoped that future investigations will isolate cholesteryl sulfates and an enzyme system that accomplishes these transformations *in vivo*.

## Experimental

**7β-Hydroxycholesteryl Phthalate.**—A modification of the method of Heilbron, *et al.*,[16] was employed. During a two to three hour period, 1 liter of 0.25 *N* potassium permanganate was added dropwise to a suspension of 10 g. of cholesteryl phthalate in 200 ml. of 1 *N* sodium carbonate. The mixture was vigorously stirred during the addition and for twenty-four hours afterward. Sulfur dioxide was then bubbled in slowly with strong agitation. When completely clarified, the mixture was cooled, filtered, washed with water and dried. The dry solid was extracted with cold

(20) Sobel and Werbin, *Ind. Eng. Chem., Anal. Ed.*, **18**, 570 (1946).
(21) Sobel and Spoerri, THIS JOURNAL, **64**, 482 (1942).

chloroform and ether (1:1). The residue was recrystallized twice from hot pyridine to which water was added until the solution turned cloudy and crystallization began. The yield was 1 g., m. p. 199–201°.

Saponification and recrystallization from methanol gave 7β-hydroxycholesterol, m. p. 178°, $\alpha^{20}D$ −87.3 (in chloroform).

**Pyridinium 7-Sulfate Cholesteryl Phthalate.**—Chlorsulfonic acid (1.2 g.) was added to a cooled solution of 8 ml. of dry pyridine and 27 ml. of dry chloroform. A suspension of 5.5 g. of 7β-hydroxycholesteryl phthalate in 80 ml. of dry chloroform was introduced. The cold mixture was stirred for twenty minutes, 30 ml. of dry pyridine was added and the solution heated in a water-bath at 60° for two hours. It was vacuum distilled under nitrogen to dryness and washed with cold water until chloride-free. It was then dried in vacuum and recrystallized by dissolving in cold chloroform and adding 8–10 volumes of cold petroleum ether. The yield was quantitative, m. p. 142–144° dec. The Rosenheim, Callow, Lifschutz and antimony trichloride color reactions, which are positive for 7β-hydroxycholesteryl phthalate, are negative for pyridinium 7-sulfate cholesteryl phthalate.

*Anal.* Calcd. for $C_{40}H_{55}O_8NS$: C, 67.66; H, 7.81; N, 1.97; S, 4.52. Found: C, 68.0; H, 7.62; N, 1.89; S, 4.46.

**Decomposition of Pyridinium 7-Sulfate Cholesteryl Phthalate.**—A. One-half gram of dry pyridinium 7-sulfate cholesteryl phthalate was placed in an Abderhalden pistol, the pistol evacuated, and xylene (b. p. 138°) refluxed over it for fifteen minutes. Decomposition took place immediately. The product was saponified with 10 ml. of 10% methanolic potassium hydroxide and taken up in peroxide-free ether and water. The ether extract was washed with water, dried over sodium sulfate, and filtered. The ether was blown off with nitrogen and the residue dried in a vacuum desiccator.

B. One-tenth gram of sodium was dissolved in 20 ml. of *n*-propyl alcohol (or ethyl alcohol) contained in a small round bottomed flask with an entering side arm. Pyridinium 7-sulfate cholesteryl phthalate (0.5 g.) was introduced and the solution refluxed for forty minutes. Nitrogen was bubbled through the side arm during the reaction. A brown oil and a white solid separated. The solution was cooled and extracted with ether and water. The water layer gave positive tests for sulfate, phthalate and pyridine. The ether layer, in which the brown oil had dissolved, was dried over sodium sulfate, filtered, and vacuum distilled under nitrogen to dryness.

The residues were shown to be 7-dehydrocholesterol by the absorption spectra, digitonide formation, antirachitic activity, color reactions and the 3,5-dinitrobenzoate derivative.

The yields, as calculated from the molecular extinction coefficient and the weight of the digitonides, were 69% for method A and 30% for method B.

The 3,5-dinitrobenzoate derivative,[22] m. p. 207°, showed no depression with a known sample of the 3,5-dinitrobenzoate of 7-dehydrocholesterol.

*Anal.* Calcd. for $C_{34}H_{46}O_6N_2$: C, 70.55; H, 8.01; N, 4.84. Found: C, 70.41; H, 7.97; N, 4.96.

**Modification of Callow Test.**—The reagent[18] (1 ml.) was added to a solution of the steroid (*ca.* 1 mg.) in 4 ml. of alcohol, instead of chloroform as originally proposed. The use of different solvents was first discussed by Sobel.[23] A yellow color was obtained with 7-dehydrocholesterol and no color with 7β-hydroxycholesterol.

**Activated Glycerol Dichlorohydrin Test.**—Four ml. of reagent[20] was added to a solution of the steroid (*ca.* 1 mg.) in 1 ml. of chloroform. 7β-Hydroxycholesterol gave a deep blue color, the dehydro compound gave no color.

**Ferrous Cholesteryl Sulfate.**—A solution of 10 g. of pyridinium cholesteryl sulfate[24] in 200 ml. of water was treated with a filtered solution of 10 g. of ferrous sulfate heptahydrate in 100 ml. of water. A white, gelatinous precipitate formed immediately. The suspension was stirred for one-half hour, then filtered and washed with water until the filtrate was free of sulfate and ferrous ions. It was then washed with acetone and dried in a vacuum desiccator. It was insoluble in water, ether or acetone; soluble in pyridine and *n*-amyl alcohol; m. p. 122–125° (dec.).

*Anal.* Calcd. for $C_{54}H_{90}O_8S_2Fe$: S, 6.50; Fe, 5.66. Found: S, 6.43; Fe, 5.60.

**Ferric Cholesteryl Sulfate.**—A solution of 13 g. of ferric chloride hexahydrate in 100 ml. of water was filtered and added to 100 ml. of a 5% pyridinium cholesteryl sulfate solution. The mixture was agitated for one-half hour and then centrifuged. The residue was washed with water until free of chloride ion, followed by an acetone and several benzene washes. It was dried in vacuum. The residue was tan colored; insoluble in water, benzene or chloroform; soluble in alcohol; m. p. 115–118° (dec.).

*Anal.* Calcd. for $C_{54}H_{90}O_8S_2ClFe$: S, 6.27; Fe, 5.46. Found: S, 6.34; Fe, 5.55.

**Aluminum Cholesteryl Sulfate.**—A solution of 12 g. of pyridinium cholesteryl sulfate in 120 ml. of water was treated with a filtered solution of 30 g. of aluminum sulfate octadecahydrate in 120 ml. of water and stirred for ten minutes. The suspension was filtered and washed with water until the washings were sulfate-free, and then washed with alcohol and dried in a vacuum desiccator. The residue was soluble in pyridine and *n*-butyl alcohol; insoluble in water, alcohol and dioxane; m. p. 115–120° (dec.).

*Anal.* Calcd. for $C_{108}H_{180}O_{20}S_5Al_2$: S, 7.97; Al, 2.68. Found: S, 7.84; Al, 2.52.

**Dicholesteryl Ether.**—Pyrolysis of the ferrous, ferric and aluminum cholesteryl sulfates in evacuated glass tubes resulted in the formation of dicholesteryl ether. The temperatures required for rapid decomposition were 138° for the ferric salt, and 115° for the ferrous and aluminum salts. The aluminum salt, in addition, was found to undergo this change in several weeks at room temperature. The decomposed material was extracted with warm benzene and filtered from the inorganic residue. The benzene was evaporated and the resinous mass that remained was leached with a mixture of ether and alcohol (1:1). The residue was dissolved in benzene and precipitated with alcohol or acetone. This was repeated several times and the final residue was washed with alcohol and dried; m. p. 205–207°. It gave no depression with a known sample of dicholesteryl ether. The tetrabromide derivative[25] melted at 166°.

## Summary

A sulfate ester of a 7-hydroxy steroid, the pyridinium sulfate of 7β-hydroxycholesteryl phthalate, was prepared. It decomposed to 7-dehydrocholesterol, analogously to a known reaction of 3-sulfate esters.

Two color reactions to distinguish between 7-hydroxy and 7-dehydro steroids were given, which, to the authors' knowledge, are the first reactions to accomplish this differentiation.

Dicholesteryl ether was obtained from ferrous, ferric and aluminum cholesteryl sulfates; at room temperature from the latter compound.

Based on the above findings and a survey of the literature, it is suggested that sulfate esters might be the metabolic intermediates in the conversion of cholesterol to 7-dehydrocholesterol and dicholesteryl ether.

# Chlorination of bis- and Chloro-bis-(perfluoroalkyl)-benzenes[1]

BY EARL T. MCBEE AND MARVIN R. FREDERICK[1a]

Chloro derivatives of trifluoromethylbenzene have been prepared[2] by chlorinating the latter in liquid phase at atmospheric pressure in the presence of iron(III) chloride. However, this procedure is not applicable to the chlorination of 1,3- and 1,4-bis-(trifluoromethyl)-benzenes[3] and similar compounds of longer side-chains since these compounds are more difficultly substituted. Chloro-bis-(trifluoromethyl)-benzenes have been prepared by fluorination of the chloro-bis-(trichloromethyl)-benzenes.[4,5] Since this paper was first submitted for publication, the chlorination of bis-(trifluoromethyl)-benzenes in an iron reactor at 150–170° under a chlorine pressure of 300 pounds per square inch has been described.[6]

A procedure generally applicable to the preparation of chloro-bis-(perfluoroalkyl)-benzenes has been devised which comprises vapor-phase chlorination at atmospheric pressure of a bis (perfluoroalkyl)-benzene in contact with activated carbon impregnated with an inorganic chloride. Iron(III) chloride was found to be the most satisfactory of the inorganic chlorides studied. No appreciable amount of the iron(III) chloride sublimed from the reactor and the catalyst showed little decrease in activity with use. Antimony(V) chloride was less effective than iron(III) chloride for chlorinations at temperatures below 250°. However, higher percentages of polychlorinated compounds were found in the product when the antimony catalyst was used. Antimony(V) chloride distilled from the reactor and, as a consequence, there was a rapid decline in catalyst activity. Nickel chloride on activated carbon was of about the same activity as iron(III) chloride. Iron, iron(III) chloride, or activated carbon used alone were much less active than activated carbon impregnated with an inorganic chloride.

Hydrolysis of the chloro derivatives of bis-(perfluoroalkyl)-benzenes by 60–80% sulfuric acid to the corresponding terephthalic and isophthalic acids[7] was used to establish structures.

## Experimental

### Preparation of Starting Materials

**bis-(Perfluoroalkyl)-benzenes.**—The bis-(trifluoromethyl)-benzenes were made from the corresponding bis-(trichloromethyl)-benzene by fluorination with anhydrous hydrogen fluoride in the presence of antimony(V) chloride at room temperature.[5] The bis-(pentafluoroethyl)-benzenes[8] and 1-(pentafluoroethyl)-4-(trifluoromethyl)-benzene[9] were prepared as described previously.

**Catalysts.**—The activated carbon-iron(III) chloride catalyst was prepared by soaking 200 g. of Columbia grade 8G, 8/14 mesh activated carbon in a solution of 60 g. of iron(III) chloride in 200 ml. of water made slightly acidic with hydrochloric acid. After soaking for one hour, the carbon was heated, first to 200°, and finally for twelve hours at 300°. The activated carbon–antimony(V) chloride catalyst was prepared by pouring antimony(V) chloride over activated carbon and then heating to 300°.

### Chlorinations

**Apparatus and Technique.**—A 3-liter, 3-necked flask equipped with a chlorine inlet, a thermometer, a reactor constructed either of glass or nickel 20 mm. by 500 mm., and a liquid return was used for the chlorinations. Chlorine was introduced through a flowmeter above the surface of the liquid in the flask. The reaction temperature was measured by a thermocouple or thermometer placed in the center of the reactor. Vapors issuing from the reactor passed through a water-cooled condenser welded directly to the reactor. Liquids were returned to the flask through a liquid trap and the gases were vented to an appropriate scrubber.

The technique used is illustrated by the following example. bis-(Trifluoromethyl)-benzenes (1263 g., 5.9 moles) prepared from technical xylene were poured into the flask. The reactor, packed with a catalyst of active carbon and iron(III) chloride, was heated to 250°, the material in the flask was heated to reflux (114°), and chlorine was added at about 0.8 mole per hour. Chlorination was continued for thirty-one hours, at the end of which time the boiling point of the contents of the flask was 127°. The product was removed from the flask, washed with a sodium bicarbonate solution, and then with water, dried, and rectified. There was obtained 438 g. (2.10 mole) of unreacted bis-(trifluoromethyl)-benzenes, 476 g. (1.91 moles) of chloro-bis-(trifluoromethyl)-benzenes composed of 5-chloro-1,3-bis-(trifluoromethyl)-benzene (b. p. 137–137.5°) and 2-chloro-1,4-bis-(trifluoromethyl)-benzene (b. p. 147–148°), and 486 g. (1.72 moles) of dichloro-bis-(trifluoromethyl)-benzenes. Conversions to chloro- and dichloro-bis-(trifluoromethyl)-benzenes were 32% and 29%, respectively. The yield of chloro-bis-(trifluoromethyl)-benzenes was 97%.

1,4-bis-(Trifluoromethyl)-benzene, 2-chloro-1,4-bis-(trifluoromethyl)-benzene, 1,3-bis-(trifluoromethyl)-benzene, 1-(pentafluoroethyl)-4-(trifluoromethyl)-benzene and bis-(pentafluoroethyl)-benzenes were chlorinated in a similar manner at temperatures in the range 200–250°. Properties of the chloro-bis-(perfluoroalkyl)-benzenes obtained are summarized in Table I.

**Acknowledgment.**—The authors wish to express their appreciation to the Army Air Forces Materiel Command for their financial support of this work which was carried out as part of the war research program.

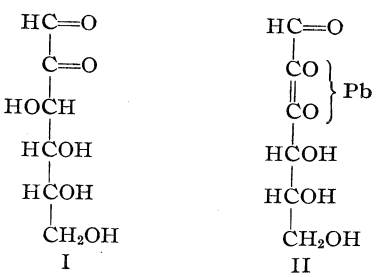
# NOTES

## Concerning the Structure of D-Glucosone

BY CHARLES E. BECKER[1] AND CLARENCE E. MAY



The structure of D-glucosone has not been definitely established.

Since it reacted in the cold with various hydrazines, particularly methyl phenylhydrazine, Fischer[2] believed that D-glucosone existed as the keto-aldehyde, I.

Since it reacted with Schiff reagent in the cold and was bound by sodium sulfite, Dixon and Harrison[3] concluded that D-glucosone contained a free carbonyl group.

Because of the selective absorption shown by its aqueous solutions in ultraviolet light, Bednarczyk and Marchlewski[4] felt that D-glucosone, like D-fructose and D-sorbose, possessed a free carbonyl group.

Evans, *et al.*,[5] have speculated that Fischer's lead–glucosone complex might be the salt of a 2,3-enediol

Hynd[6] retained Fischer's formula for D-glucosone but considered it possible that the compound might later be proved to contain one, or perhaps two, oxidic rings.

Since, in his opinion, the osones showed none of the characteristic reactions of the aldehydes

(bisulfite addition, hydroxamic acid reaction, Doebner's reaction) but did show a complete analogy with the reductones, Brüll[7] felt that D-glucosone must not have a structure corresponding to the formula assigned by Fischer but would exist rather as the hemiacetal form in equilibrium with the tautomeric enediol form

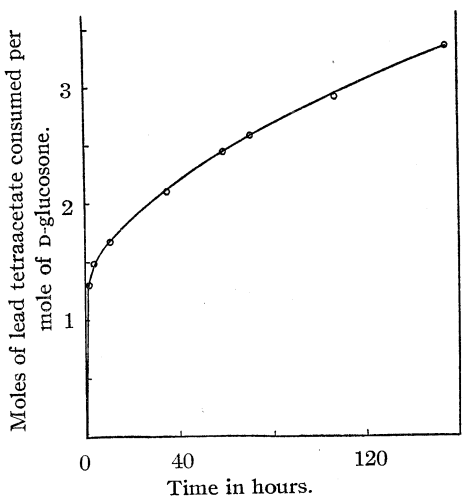
III

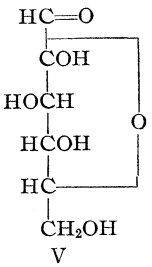
IV

Angeli and Marchetti[8] have reported that D-glucosone gives a positive hydroxamic acid reaction.

In view of Criegee's[9] observation that, in contrast to periodic acid, lead tetraacetate does not break ring structure if that structure is present, we felt that oxidation of D-glucosone with lead tetraacetate under the conditions set up by Hockett, *et al.*,[10] for such oxidations would furnish evidence as to the structure of D-glucosone.

It was found that oxidation of D-glucosone with lead tetraacetate produced no significant amount of formaldehyde. Figure 1 shows the kinetics of this oxidation. It was noted that D-glucosone does not consume iodine in acetic acid solution and that aqueous solutions of D-glucosone show slight mutarotation.





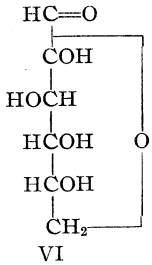


Fig. 1.—Oxidation of D-glucosone by lead tetraacetate.

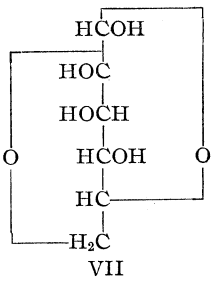

Structure III and the following structures for D-glucosone are not eliminated by these observations but, as yet, no selection can be made from amongst them.

V

VI

VII

## Experimental

**Materials.**—D-Glucosone was prepared by splitting D-glucose phenylosazone[11] with pyruvic acid according to Brüll,[12] purified from absolute alcohol, and had a specific rotation of $-1.40°$[13] at equilibrium ($c$, 0.550; $l$, 4; $H_2O$). It was hygroscopic, rapidly reduced Fehling solution, and gave an immediate precipitate with 2,4-dinitrophenylhydrazine at room temperature. This precipitate melted at 252° (capillary tube, rapid heating).

Lead tetraacetate[14] and aldehyde-free, specially dried acetic acid[10a] were prepared according to McClenahan, Hockett, *et al.*

Resublimed iodine, approximately 437 mg. (0.00172 mole), was dissolved in 25 ml. of special acetic acid containing 564 mg. (0.00376 mole) of sodium iodide; 5.5 ml. of 0.1 *N* sodium thiosulfate was equivalent to 4.0 ml. of this iodine solution.

**Methods.**—D-Glucosone, 52.7 mg. (0.000296 mole) in 50 ml. of acetic acid, was oxidized with 2.4 g. (0.00540 mole) of lead tetraacetate under the conditions set forth by Hockett, *et al.*,[10b] except that the reaction set-up was swept out with tank nitrogen instead of air. No significant amount of formaldehyde was formed.

D-Glucosone, 44.5 mg. (0.000250 mole) in 42 ml. of acetic acid, was oxidized with 57.45 ml. of 0.1323 *N* (0.00380 mole) of lead tetraacetate under the conditions set forth by Hockett, *et al.*[10a] (Fig. 1).

D-Glucosone, 24.8 mg. (0.000139 mole), was dissolved in 60 ml. of acetic acid. Four ml. of the iodine solution was added. After standing in the dark at room temperature for sixty minutes, the solution was diluted with 150 ml. of water, and titrated with 0.1 *N* sodium thiosulfate. It was found that no iodine had been consumed. This experiment was repeated, except that the D-glucosone was dissolved in water instead of acetic acid, with the same results.

**Mutarotation of D-Glucosone.**—An ice-cold aqueous D-glucosone solution containing lead acetate was treated with cold saturated barium hydroxide added dropwise with good stirring. The precipitated lead–glucosone complex was filtered off, washed well with ice-water, sucked as dry as possible, and resuspended in ice-water. Just enough cold 20% sulfuric acid was added dropwise with good stirring to break up the complex. The mixture was neutralized with a paste of barium carbonate, filtered rapidly, and the filtrate examined immediately in the polarimeter. After, 20, 26, 31, 35, 41 and 50 minutes the observed specific rotations were $-2.55$, $-2.18$, $-1.95$, $-1.73$, $-1.40$ and $-1.40°$, respectively.

## Chlorination of 2-Thiophenecarboxylic Acid

BY J. F. BUNNETT, D. M. BACHMAN, L. P. SNIPPER AND J. H. MALONEY

Steinkopf and Kohler[1] reported that direct chlorination of 2-thiophenecarboxylic acid (I) in boiling water or cold glacial acetic acid gave traces of 4,5-dichloro-2-thiophenecarboxylic acid (II), the predominant products being chlorinated tetrahydrothiophenes resulting from a combination of chlorination, decarboxylation and addition of chlorine to double bonds. In a pamphlet published by the Socony-Vacuum Oil Co.,[2] substantially the same statement was made. A more recent publication[3] from the Socony-Vacuum Laboratories mentioned the use of direct chlorination for the preparation of II, but no experimental details were given on the preparation which apparently was on a rather small scale. The preparation of a monochloro-2-thiophenecarboxylic acid by direct chlorination has not been reported.

We have found that by addition of excess hydrochloric acid to an alkaline solution of I and hypochlorite, 5-chloro-2-thiophenecarboxylic acid (III) can be obtained in yield about 45% (using a hypochlorite to I ratio of 1.7:1), while when the ratio is 2.5:1, rather small yields (14%) of II result. Other procedures such as passing chlorine through a buffered solution of I or allowing a buffered solution of I and hypochlorite to react also gave III or II, but not in as good yield or quality.

In most chlorinations by various techniques oily by-products were observed. These by-products from a number of runs were combined and distilled. A considerable fraction of b. p. 160–165° and $n^{16}$D 1.5624 was obtained. Nitration of this fraction gave a solid of m. p. 85–85.5°. This fraction was 2,5-dichlorothiophene (IV), since IV[3] has b. p. 162° and $n^{20}$D 1.5626, and gives on nitration[4] 3,4-dinitro-2,5-dichlorothiophene of m. p. 88–91°. The by-product oil from another run in which hydrochloric acid was added to an alkaline solution of hypochlorite and I in 3:1 ratio appeared to be a mixture of chlorinated thiophenes, with IV the principal constituent.

We first encountered the chlorination method reported here when III was obtained by the hypochlorite oxidation of 2-acetylthiophene, using the household bleach "Clorox" as a source of hypochlorite. When the hypochlorite solution used was strongly alkaline, only normal oxidation to I occurred.

It is possible that modification of the procedures we report here might result in better yields. We report the work at this time because we do not intend to investigate the matter further.

### Experimental[5]

**5-Chloro-2-thiophenecarboxylic Acid** (III).—A solution of 3 g. (0.023 mole) of 2-thiophenecarboxylic acid, 0.042 mole of sodium hypochlorite and excess sodium hydroxide in a total volume of 400 ml. was prepared. To this solution (*p*H 11.0) at 48° were added with stirring 25 ml. of 6 *M* hydrochloric acid during six minutes. The temperature rose to 53°, the *p*H dropped to 1.3, and a white precipitate appeared. With continued stirring, an additional 5 ml. of acid and then 107 g. of sodium chloride were added. The solid obtained by filtration of the chilled solution weighed 1.75 g. (46%), m. p. 134–137°. After recrystallization and sublimation the m. p. was 149–150°. The mixed m. p. with a sample of III prepared by permanganate oxidation of 5-chloro-2-acetylthiophene was not depressed.

**4,5-Dichloro-2-thiophenecarboxylic Acid** (II).—The above procedure was followed, with 1.9 g. (0.015 mole) of I and 0.037 mole of sodium hypochlorite being employed. Four-tenths of a gram (14%) of II, m. p. 182–187° was obtained. After recrystallization from water, the m. p. was 194–194.5°. Steinkopf and Kohler[1] reported m. p. 196–197°.

(5) Melting points are uncorrected.

## N-Substituted 2,4:3,5-Dimethylene-D-gluconamides

BY I. A. COLÓN, R. FERNÁNDEZ-GARCÍA, LUIS AMORÓS AND HILDA BLAY

The structure of 2,4:3,5-dimethylene-D-gluconic acid has been the subject of two recent publications.[1,2] We take this opportunity of recording a modification of Zief and Scattergood's preparation of 2,4:3,5-dimethylene-D-gluconic acid and also the preparation of some N-substituted dimethylene gluconamides which appear to be new. Their properties are listed in Table I.

### Experimental

**2,4:3,5-Dimethylene-D-gluconic acid.**—Dimethylene-D-gluconic acid was prepared by the method of Zief and Scattergood[2] which was modified by substituting calcium D-gluconate for D-glucono-δ-lactone. The calcium D-gluconate and the trioxane were dissolved completely by stirring. The yield of the acid was 64–66% of the theoretical. Using paraformaldehyde in essentially the same procedure, slightly higher yields were obtained (70%). The recrystallized acid had a m. p. of 219.4–220.8°; $[\alpha]^{27.5}$D + 38.1° (*c*, 0.136; water).

**Methyl 2,4:3,5-Dimethylene-D-gluconate.**—The ester was prepared by the method of Mehltretter, *et al.*[1]

**N-Substituted 2,4:3,5-Dimethylene-D-gluconamides.**—The dimethylene gluconamides were prepared by treating the ester with the corresponding amine in either water or alcohol as solvent. The butyl, isobutyl and ethyl amide were obtained by treating in water at room temperature for several days. The cyclohexyl amide was prepared by refluxing in water while the allyl and the hydroxyethyl amides were prepared by refluxing in methanol. The methyl amide was obtained from methanol at 0°. The

## The System Ammonium Sulfate–Ammonia

BY CHARLES M. DREW, HOWARD W. KRUSE, SOL SKOLNIK AND G. B. L. SMITH

Solvation of ammonium sulfate in liquid ammonia was first observed by Browne and Welsh.[1] Brief mention of this behavior also was made by Friedrichs[2] who stated that $(NH_4)_2SO_4 \cdot 3NH_3$, insoluble in liquid ammonia, was formed, and claimed that in a sealed tube this compound was stable up to 145°. The solubility was found to increase slightly with temperature.

Investigations in this Laboratory have verified the existence of ammonium sulfate 3-ammoniate. A pressure–concentration isotherm at −32.5° and vapor pressure data for this compound were determined. No other ammoniates were formed over the temperature range −33 to +8°.

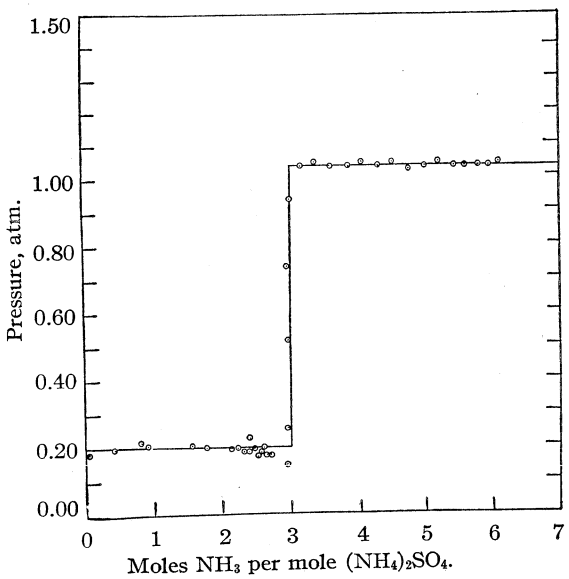

Fig. 1.—Pressure–concentration isotherm (−32.5°) of the system ammonium sulfate–ammonia.

### Experimental

The apparatus employed in this investigation was similar to the equipment described by Howard, Friedrichs and Browne[3] for the study of binary systems having one volatile component. Commercial anhydrous ammonia was dried by passing the gas through a tube containing potassium hydroxide and then through a tube containing fine sodium wire. Ammonium sulfate (J. T. Baker C.P.) was purified further by recrystallization.

The pressure–concentration isotherm shown in Fig. 1 was obtained by adding a measured excess of ammonia to a weighed sample of ammonium sulfate and then withdrawing small increments of the gas. Pressure readings were taken when the system reached equilibrium, usually after twenty-four hours. Vapor pressure data for ammonium sulfate 3-ammoniate which are shown graphically in Fig. 2, were determined in the same apparatus. These data may be summarized by the equation log $p$ (mm. Hg) = $10.2737 - 1934.4/T$°K.

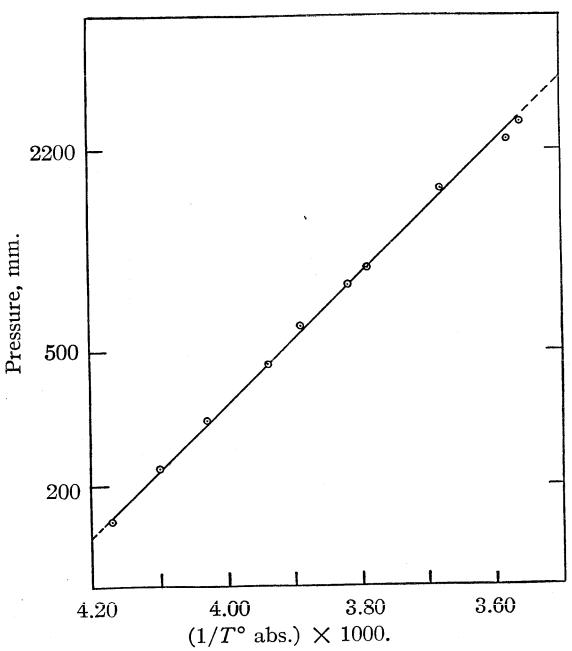

Fig. 2.—Vapor pressure of ammonium sulfate 3-ammoniate.

## Benzamidine Derivatives

BY ELLIS K. FIELDS

In conjunction with the Survey of Antimalarial Drugs this Laboratory synthesized a number of benzamidines containing pyridine, quinoline or phenanthridine rings in the molecules. In general these were prepared by the reaction of *p*-cyanobenzaldehyde with a nitrogen ring compound containing an active methyl group. The resulting cyano compound was converted to the imido-ether hydrochloride and then to the amidine, according to the scheme for α-picoline.

The compounds prepared in this work are listed in Table I. They have not been previously reported in the literature.

large excess of alcoholic ammonia reacted with the imido-ether hydrochloride and the resulting clear solution, after 2–3 days at room temperature, was evaporated on a steam-bath. The lower melting isomer resulted when a slight excess of alcoholic ammonia was used and the amidine filtered from solution without heating. There were no separations involved; the pure *trans* or *cis* form was obtained.

α-Propylquinoline was heated with *p*-cyanopropiophenone and zinc chloride in an attempt to prepare 3-(2-quinolyl)-4-(*p*-cyanophenyl)-hexene-3. At a temperature sufficient to cause the expected reaction, the mixture resinified.

### Procedures

**Cyano Compounds.**—*p*-Cyanobenzaldehyde[1] was condensed with the various methyl heterocyclic compound, according to Wallach and Wusten.[2] Quinaldine, lepidines 9-methylphenanthridine and 6-ethoxy-4-chloroquinaldine condensed readily at 100–130° in two to four hours. α-Picoline and γ-picoline required six to eight hours in sealed tubes at 180°, even in the presence of larger quantities of zinc chloride.

**Amidines.**—The preparation of the amidine from the condensation product of *p*-cyanobenzaldehyde and quinaldine is described as typical. When dry hydrogen chloride was passed into a solution of 1-(2-quinolyl)-2-(*p*-cyanophenyl)-ethene in dry benzene or ether containing the calculated amount of methanol, the hydrochloride of the unchanged cyano compound precipitated. No reaction occurred after hours of vigorous stirring or shaking. The cyano compound (4.7 g.) was dissolved in 350 cc. of dry chloroform containing a 10% excess of methanol. The solution was cooled in ice–salt and a vigorous stream of dry hydrogen chloride introduced. A white precipitate formed after twenty-five minutes. The mixture was kept at room temperature for twenty-four hours under a slight pressure of hydrogen chloride. The white solid was filtered, washed with chloroform, and shaken with 50 cc. of dry methanol containing 2 g. of ammonia. Most of the solid dissolved. The mixture was kept twenty-four hours at room temperature, filtered from a little ammonium chloride, evaporated to a small volume and chilled. The amidine hydrochloride crystallized in white plates, melting at 154° dec., soluble in methanol, hot water and acetone and slightly soluble in cold water.

**α-Propylquinoline.**—This compound was prepared by the method of Tschitchibabin[3] for γ-propylquinoline. By this synthesis was obtained a 60% yield of α-propylquinoline boiling at 274–275°.

α-Propylquinoline (5.13 g.), 4.77 g. of *p*-cyanopropiophenone,[4] and 0.5 g. of anhydrous zinc chloride were

Passing dry hydrogen chloride into solutions of the cyano compounds caused immediate precipitation of the corresponding hydrochlorides. The insolubility of the cyano hydrochlorides in benzene, ether, benzene plus methanol and other combinations of solvents was a stumbling block in the preparation of the amidines. The problem was solved by the discovery that dry chloroform was an excellent solvent for the cyano hydrochlorides, but dissolved practically none of the imido-ether dihydrochlorides.

1-(2-Quinolyl)-2-(*p*-amidinophenyl)-ethene hydrochloride and 1-(9-phenanthridyl)-2-(*p*-amidinophenyl)-ethene hydrochloride were obtained in two forms that had different melting points and presumably were *cis–trans* isomers. The higher melting isomer was obtained in each case when a

heated ten hours at 210–230°. There was no perceptible reaction. The mixture was refluxed twenty minutes at 280°, at which temperature it completely resinified.

These amidines were tested on ducks and proved to be extremely toxic.

DEVELOPMENT LABORATORY OF CHICAGO
CHICAGO, ILLINOIS RECEIVED NOVEMBER 5, 1948

## The Oxidation of Certain Ketones to Acids by Alkaline Hypochlorite Solution

BY MARTIN W. FARRAR AND ROBERT LEVINE

The advantages of hypohalite oxidation of methyl ketones[1,2] are well recognized, yet apparently little is known of the behavior of higher alkyl ketones under similar conditions.[3] We have found that higher alkylaryl and alkylheterocyclic ketones may likewise be cleaved in good yields to carboxylic acids by hypohalite oxidation. A detailed study on the stoichiometry and mechanism of this reaction is now in progress in this Laboratory.

**Procedure.**—A solution of sodium hypochlorite is prepared from 50 g. of "HTH" following the directions in the literature.[1] The solution is heated to 55°, and 0.1 mole of the ketone to be oxidized is added dropwise to the rapidly stirred solution, keeping the temperature at 60–70°. After the addition of the ketone is completed (about fifteen minutes), the reaction mixture is stirred at 70° for thirty minutes. Any unreacted sodium hypochlorite is then destroyed with sodium bisulfite solution. The contents of the flask s then heated to 100°, stirred and heated for fifteen minutes longer and then cooled to room temperature. The reaction mixture is then extracted with ether to remove any unreacted ketone, and the phases separated. The aqueous phase is acidified with concentrated hydrochloric acid. The crude acid is filtered on a Büchner funnel and recrystallized from hot water. In this way the following acids were obtained: benzoic, m. p. 121–122°[4] (64%) from propiophenone, 2-thiophenic, m. p. 129–130°[5] from *n*-propyl 2-thienyl ketone, and 5-methyl-2-thiophenic, m. p. 137–138°[6] (67%) from 5-methyl-2-propionylthiophene.

In the preparation of 2-furoic acid (59%) from ethyl 2-furyl ketone the procedure followed is similar to that described above except that the temperature of the reaction mixture is never allowed to rise above 65° during the addition of the ketone and the reaction is then completed by stirring the contents of the flask at 65° for fifteen minutes after the addition of the ketone is completed. The reaction mixture is then acidified, extracted with ether, and the solvent distilled. The residue solidified. Recrystallization of this solid gave 2-furoic acid, m. p. 131–132°[6] (59%).

## Extrapolation of Conductance Data for Weak Electrolytes

BY RAYMOND M. FUOSS AND THEODORE SHEDLOVSKY

Unambiguous extrapolations of conductance data, in order to determine $\Lambda_0$, the limiting conductance, and $K$, the dissociation constant for weak electrolytes, are possible in aqueous systems by synthesizing a hypothetical conductance curve for the completely dissociated portion of the weak electrolyte from conductance data on the corresponding strong electrolytes,[1] *e.g.*

$$\Lambda^*_{(HAc)} = \Lambda_{(HCl)} - \Lambda_{(NaCl)} + \Lambda_{(NaAc)} \qquad (1)$$

in which the $\Lambda$ values refer, of course, to the same ion concentration. The degree of dissociation is then given by $\Lambda/\Lambda^*$, since $\Lambda = 1000\kappa/c$ and $\Lambda^* = 1000\kappa/c_i$, $\kappa$ being the specific conductance, $c$ the equivalent electrolyte concentration, and $c_i$ the corresponding free ion concentration.

In non-aqueous systems, where the dielectric constant of the solvent is about 40 or less, this procedure cannot be employed since no strong electrolytes exist in such solvents. It therefore becomes necessary to evaluate $\Lambda_0$ and $K$ from the conductance data for the electrolyte itself. Two extrapolation methods have been proposed.

Fuoss and Kraus[2] wrote for 1–1 electrolytes

$$\Lambda = \gamma\,(\Lambda_0 - \alpha\sqrt{c\gamma}) \qquad (2)$$

where $\gamma$ is the degree of dissociation defined as the ratio of the concentration of free ions to the stoichiometric concentration $c$ and $\alpha$ is the Onsager coefficient

$$\alpha = 8.2 \times 10^5\Lambda_0/(DT)^{3/2} + 82/\eta(DT)^{1/2} \qquad (3)$$

where $D$ is the dielectric constant, $\eta$ the viscosity of the solvent, and $T$ the absolute temperature. Equation (2) was solved for $\gamma$ in terms of a function[3] $F(z)$ where

$$z = \alpha\sqrt{c\Lambda}/\Lambda_0^{3/2} \qquad (4)$$

and

$$\gamma = \Lambda/\Lambda_0\,F(z) \qquad (5)$$

Substituting Eq. (5) in the mass action equation and rearranging, one obtains

$$F/\Lambda = 1/\Lambda_0 + c\Lambda f^2/FK_F\Lambda_0^2 \qquad (6)$$

where $f$ is the activity coefficient which is computed from $(-\log f) = \beta\sqrt{c_i}$. A plot of $F/\Lambda$ against $c\Lambda f^2/F$ is linear at low concentrations and extrapolates to the reciprocal of the limiting equivalent conductance, with slope $1/K_F\Lambda_0^2$.

Shedlovsky[4] later proposed the equation

$$\Lambda = \Theta\Lambda_0 - \alpha(\Lambda/\Lambda_0)\sqrt{c\Theta} \qquad (7)$$

where $\Theta$ is the degree of dissociation. Equation (7) is a quadratic in $\Theta^{1/2}$ and is therefore much simpler to solve than Eq. (2), which is a cubic in

(1) D. A. MacInnes, THIS JOURNAL, **48**, 2068 (1926); M. S. Sherrill and A. A. Noyes, *ibid.*, **48**, 1861 (1926); D. A. MacInnes and T. Shedlovsky, *ibid.*, **54**, 1430 (1932).

(2) R. M. Fuoss and C. A. Kraus, *ibid.*, **55**, 476 (1933).

(3) R. M. Fuoss, *ibid.*, **57**, 488 (1935).

(4) T. Shedlovsky, *Jour. Franklin Inst.*, **225**, 739 (1938).

$\gamma^{1/2}$. The solution of (7) may then be written as

$$\Theta = S(z)\Lambda/\Lambda_0 \qquad (8)$$

where $S(z) \equiv (z/2 + \sqrt{1 + (z/2)^2})^2$, and $z$ is defined by Eq. (4). Substituting in the mass action equation and rearranging, we obtain

$$1/\Lambda S = 1/\Lambda_0 + c\Lambda Sf^2/K_S\Lambda_0^2 \qquad (9)$$

Here, at low concentrations, $1/\Lambda S$ is linear in $c\Lambda Sf^2$, with intercept $1/\Lambda_0$ and slope $1/K_S\Lambda_0^2$. The intercepts of Eqs. (6) and (9) are found to be identical, but the slopes, and therefore the dissociation constants[5] are sometimes different. The question naturally arises as to which of the two values to choose for the dissociation constant in such cases.

The derivation[2] of Eq. (2) is based on the Onsager limiting law

$$\Lambda = \Lambda_0 - \alpha\sqrt{c} \qquad (10)$$

If Onsager had computed resistance instead of conductance, the limiting law would have read

$$1/\Lambda = 1/\Lambda_0 + (\alpha/\Lambda_0^2)\sqrt{c} \qquad (11)$$

which rearranges to

$$\Lambda = \Lambda_0 - \alpha(\Lambda/\Lambda_0)\sqrt{c} \qquad (12)$$

Shedlovsky[4] has shown that Eq. (12) reproduces conductance data to significantly higher concentrations than does Eq. (10). The derivation[4] of Eq. (7) was based on the Onsager limiting law in the form (12), and results based on Eq. (9) are therefore to be preferred.

The difference between the various functions is illustrated in Fig. 1. Curve 2 represents actual data for potassium chloride[6] where $\Lambda_0 = 149.9$ and $\alpha = 93.9$. Curve 4 is for the familiar Onsager linear limiting Eq. (10). Curve 3 is for Eq. (12), using the same constants; it will be noted that it gives a closer approximation of the experimental results than Curve 4, *i.e.*, Eq. (10). Data for iodic acid,[7] a somewhat weak electrolyte, for which $K = 0.16$, $\Lambda_0 = 391.2$, $\alpha = 150$ are plotted in Curve 5. Although, strictly speaking, the abscissa, $\sqrt{c_i}$, depends on how $c_i$ is computed, *e.g.*, by the Fuoss or by the Shedlovsky function, these differences are too small to appear in Curve 5 on the scale of the figure. Due to ion association[8] (weak electrolytes) there are found strong negative deviations from the Onsager conductance equation, such as in Curve 5. The curves 2, 3 and 4 for potassium chloride are for $\Lambda/\Lambda_0 = (1000\kappa/c)(1/\Lambda_0)$ *vs.* $\sqrt{c_i}$, but since this salt is a strong electrolyte $c_i = c$. The slope of the linear Curve 4, $(\alpha/\Lambda_0)_{KCl}$ is 0.63, whereas the corresponding value for the ionized portion of iodic acid, $(\alpha/\Lambda_0)_{HIO_3}$ is 0.38. Let us change the ordinate scale for these three curves so that the slope for Curve 4 is 0.38 instead of 0.63. We may then suppose that

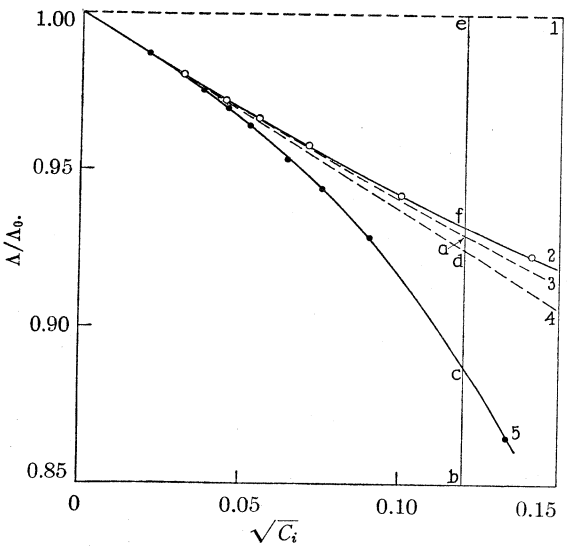

Fig. 1.—Comparsion of Conductance Functions.

the curves 2, 3 and 4 refer to $(1000\kappa/c_i)(1/\Lambda_0)$ *vs.* $\sqrt{c_i}$ for iodic acid instead of potassium chloride, and recall that for a weak electrolyte $c_i$ is the product of the stoichiometric concentration and of the degree of dissociation. The latter is therefore obtained as the ratio of $\Lambda/\Lambda_0 = (1000\kappa/c)(1/\Lambda_0)$ to $(1000\kappa/c_i)1\Lambda_0$ at the same value of $\sqrt{c_i}$. Thus, the Fuoss function assumes that $cb/db$ is a measure of the degree of dissociation, while the Shedlovsky function uses the ratio $cb/ab$, which is a better approximation, and incidentally the one which would naturally have been used if the limiting Onsager equation had been originally presented in the form of Eq. (11). The synthetic method (Eq. (1)) uses the ratio $cb/fb$ but as we have already pointed out, it is not available in solvents with dielectric constants below 40.

Extrapolation by Eqs. (6) or (9) is essentially use of the Ostwald dilution law, corrected for the effect of long range interionic forces on mobility and thermodynamic potential; the degree of dissociation in the classical theory, $\Lambda/\Lambda_0$, is measured by the ratio $cb/eb$ of Fig. 1.

The difference between $K_S$ and $K_F$ can be found as follows. By equating the two expressions, Eqs. (2) and (7) for $\Lambda$, substituting Eqs. (5) and (8) and solving, we obtain

$$\gamma = \Theta[1 + z(F^{-3/2}S^{-1} - S^{-1/2})] \qquad (13)$$
$$\equiv \Theta(1 + x) \qquad (13')$$

If we now substitute (13) in the mass action Eq. (6) and rearrange, we obtain

$$1/\Lambda S = 1/\Lambda_0 + c\Lambda Sf^2(1 + x)^2/K_F\Lambda_0^2 + x/\Lambda_0 \qquad (14)$$

Expansion of $S(z)$ and $F(z)$ in their power series gives

$$x = z^2 + O(c^{3/2}) \qquad (15)$$

and at low concentrations Eq. (14) thus reduces to

$$1/\Lambda S = 1/\Lambda_0 + c\Lambda Sf^2/K_F\Lambda_0^2 + \alpha^2 c\Lambda/\Lambda_0^4 \qquad (16)$$

(5) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corp., New York, N. Y., 1943; p. 190.

(6) T. Shedlovsky, THIS JOURNAL, **54**, 1411 (1932).

(7) C. A. Kraus and H. C. Parker, *ibid.*, **54**, 2429 (1932).

(8) R. M. Fuoss, *Chem. Revs.*, **17**, 27 (1935).

The limiting slope of Eq. (16) is

$$\frac{d(1/\Lambda S)}{d(c\Lambda Sf^2)_{c=0}} = \frac{1}{K_F\Lambda_0^2} + \frac{\alpha^2}{\Lambda_0^4} = \frac{1}{K_S\Lambda_0^2} \qquad (17)$$

whence

$$1/K_S = 1/K_F + \alpha^2/\Lambda_0^2 \qquad (18)$$

The difference shown in Eq. (18) is a consequence of the *difference* between $\Theta$ and $\gamma$; in the limit of zero concentration, both $\Theta$ and $\gamma$ approach unity, but as is readily seen from Eqs. (13′) and (15), their difference is linear in concentration, and the mass action extrapolation is essentially one on a linear concentration scale. According to Eq. (3), the ratio $\alpha/\Lambda_0$ has the following upper bounds if we set the Walden product $\Lambda_0\eta = 0.5$: $D = 40$, $\alpha/\Lambda_0 \leqslant 2$; $D = 20$, $\alpha/\Lambda_0 \leqslant 4$; $D = 10$, $\alpha/\Lambda_0 \leqslant 8$. Since $K$ decreases[9] rapidly as $D$ decreases, the two methods of extrapolation will not differ significantly when $K$ is less than about $10^{-3}$. In the approximate range $10^{-3} \leqslant K \leqslant 1$, however, we recommend extrapolation by means of Eq. (9).

## The Structure of Khellin

BY T. A. GEISSMAN

Khellin has been resynthesized by Späth and Gruber from its cleavage product, khellinone, by the application of the Kostanecki–Robinson method.[1] Since this synthesis is not entirely unamibiguous, often giving rise to mixtures of the desired chromone and the isomeric 4-methylcoumarin; and since khellin-like model compounds are not unequivocally distinguishable from the corresponding 4-methylcoumarins by absorption spectra, as recent work in this Laboratory has shown, some doubt has remained that khellin actually possesses the 2-methylchromone structure.

Khellin has now been resynthesized from khellinone by two methods which are known to lead unambiguously to 2-methylchromones, and with yields which surpass those usually recorded for the Kostanecki–Robinson reaction. Using a method analogous to that of Wittig,[2] khellinone, treated with sodium hydride in ethyl acetate, yielded a compound (A, see experimental below) which when treated with cold, concentrated hydrochloric acid was converted nearly quantitatively into khellin. The identity of the product was shown by its melting point and mixed melting point with authentic khellin (152–153°), and by analysis.

(1) Späth and Gruber, *Ber.*, **71B**, 106 (1938).
(2) Wittig, *Ann.*, **446**, 155 (1925).

In a second experiment, khellinone acetate, treated with sodium hydride in ethyl acetate, gave the compound A. This is C-acetylkhellinone, and is converted into khellin by cold, concentrated hydrochloric acid in substantially quantitative yield.

The acylation of substituted *o*-hydroxyacetophenones to yield diketones and, ultimately, chromones is a well-known reaction. 4-Methylcoumarins have not been observed as products of these reactions.

One prior example of the conversion of an *o*-acetoxyacetophenone into the corresponding *o*-hydroxyacetylacetophenone under conditions similar to those used in this work has been recorded.[3] The analogous reaction with *o*-benzoyloxyacetophenones, leading eventually to flavone derivatives, has been used extensively. Model experiments on a number of substituted *o*-acetoxyacetophenones have shown that this procedure is general as a method for the synthesis of 2-methylchromones in good yields.

Details of these reactions and products will be reported in a later publication.

### Experimental

**Khellinone** was prepared in 90% yield by the hydrolysis of khellin in 1% aqueous potassium hydroxide, according to the method of Späth and Gruber.[1]

**C-Acetylkhellinone.**—(A) To 0.5 g. of khellinone acetate in 5 ml. of dry ethyl acetate was added 0.5 g. of sodium hydride. The solution was warmed gently from time to time for an hour and allowed to stand overnight at room temperature. Crushed ice was added, followed by dilute hydrochloric acid, and the yellow solid collected by filtration. It weighed 400 mg. After recrystallization from aqueous methanol it formed pale yellow needles, which melted at about 90° when plunged into a preheated bath, but at temperatures up to about 122° when heated slowly. It is probable that this behavior is due to a slow dehydration under the influence of heat with the formation of khellin.

*Anal.* Calcd. for $C_{14}H_{14}O_6$: C, 60.48; H, 5.08. Found: C, 60.34; H, 5.11.

(B) To 0.5 g. of khellinone in 5 ml. of ethyl acetate was added 0.5 g. of sodium hydride. The mixture was allowed to stand overnight and worked up as in (A). The product weighed 413 mg. after recrystallization from dilute methanol.

C-Acetylkhellinone, in dilute aqueous methanol, gives with ferric chloride a momentary flash of green, the color then changing through green-brown to reddish-brown. Khellinone, under identical conditions, gives an intense, pure green.

**Khellin.**—To 200 mg. of C-acetylkhellinone was added 2 ml. of concentrated hydrochloric acid. The compound dissolved to give a deep orange solution. After solution was complete (about one minute) 20 ml. of water was added. Pure white needles of khellin separated (175 mg.; 94%). After recrystallization from dilute methanol it melted at 152–153° (unchanged by admixture with authentic khellin).

*Anal.* Calcd. for $C_{14}H_{12}O_5$: C, 64.59; H, 4.65. Found: C, 64.48; H, 4.89.

## The Reaction of Diazomethane with Phenols in the Presence of Propanol

BY SAMUEL M. GERBER AND DAVID Y. CURTIN

Schönberg and Mustafa[1] have reported that the reaction of stilbesterol with diazomethane and *n*-propanol in ether at 0° gave stilbesterol di-*n*-propyl ether as the only product isolated. The compound was obtained in unspecified yield and was identified by its satisfactory analysis, melting point and mixed melting point with an authentic sample of the dipropyl ether prepared by the method of Reid and Wilson.[2] Schönberg and Mustafa have used their results as evidence for a mechanism in which either I or II is the propylating agent. It has been widely accepted that related reactions of diazo compounds with the general formula III involve the initial addition of a proton to give IV which then undergoes a displacement or solvolysis reaction with a base.[3] It was of interest, therefore, to attempt to confirm and extend their work.

$CH_2{=}NNHOC_3H_7$ (I) $CH_2N{=}NOC_3H_7$ (II) $RCHN_2$ (III) $RCH_2N_2^+$ (IV)

We have repeated the reaction of stilbesterol with diazomethane in the presence of propanol under the conditions used by Schönberg and Mustafa and have obtained only the dimethyl ether (45% yield), monomethyl ether (33% yield of slightly impure product) and recovered stilbesterol (12%). Methylation at room temperature gave comparable results. In no case was there any evidence for the presence of the dipropyl ether.

The reactions of *p*-nitrophenol and 2,4,6-tribromophenol with diazomethane in the presence of propanol were also carried out and yielded in each case only the methyl ether and recovered starting material.

We are unable to explain the discrepancy between our results and those of Schönberg and Mustafa.

### Experimental[4]

**Reaction of Stilbesterol with Diazomethane.**—A solution of 1.00 g. of stilbesterol[5] in propanol and ether was treated with diazomethane[6] under the conditions used by Schönberg and Mustafa. Their method of isolation of the product (recrystallization from petroleum ether) was found to be unsatisfactory, however, and therefore that of Reid and Wilson[2] was used. Stilbesterol (11%) was recovered and nearly pure stilbesterol dimethyl ether (0.50 g., 45% yield) was obtained. It was identified by its melting point (122–124°) and mixed melting point with an authentic sample prepared from stilbesterol and methyl iodide.[2] Crude stilbesterol monomethyl ether (0.24 g., 22% yield, m. p. 110–112°) was also obtained. The reported melting point is 117°.[2] Its identity was confirmed by methylation by methyl iodide in a yield of 87% to stilbesterol dimethyl ether, m. p. 123.5–124.5°.

**Methylation of 2,4,6-Tribromophenol.**—Three grams of tribromophenol was treated with excess diazomethane in a propanol–ether mixture for thirty-six hours at room temperature. Tribromophenol (1.5 g., m. p. 92–93.5°) was recovered and a 42% yield of tribromoanisole, m. p. 86.5–87°, was obtained. The recorded melting point is 87°.[7]

**Methylation of *p*-Nitrophenol.**—*p*-Nitrophenol (3.4 g.) was methylated similarly (in propanol–ether for twenty-four hours at room temperature) to give *p*-nitroanisole, m. p. 53–54°, in a yield of 89%. The reported melting point is 54°.[8]

## The Preparation of *n*-Butyllithium

BY H. GILMAN, J. A. BEEL, C. G. BRANNEN, M. W. BULLOCK, G. E. DUNN AND L. S. MILLER

The method of preparation of *n*-butyllithium used until recently in these Laboratories gave from 50–65% yields in ninety minutes in diethyl ether as determined by the double-titration method.[1] A study of the reaction at lower temperatures has revealed that yields of 75–90% can be consistently obtained at about −10° using *n*-butyl bromide with diethyl ether as the solvent. Only conventional apparatus is needed and the reaction is substantially complete in ninety minutes. Table I gives data on several preparations made under varying conditions. *n*-Propyl, *n*-amyl and *n*-hexyl bromides gave by this procedure 78, 81 and 77% yields, respectively, of the corresponding lithium compounds.

### Experimental

***n*-Butyllithium.**—The following is a description of a typical preparation. Into a 500-ml. three-necked flask equipped with a stirrer, low temperature thermometer, and a dropping funnel, was placed 200 ml. of anhydrous ether (dried over sodium). After sweeping the apparatus with dry, oxygen-free nitrogen, 8.6 g. (1.23 g. atoms) of lithium wire[2] (weighing 4.2 to 4.3 g. per meter) was wound in a loose coil, rinsed with ether, and the flattened coil was cut into pieces about 7 mm. in length which fell directly into the reaction flask in a stream of nitrogen. With the stirrer started, about 30 drops of a solution of 68.5 g. (0.5 mole) of *n*-butyl bromide[3] in 100 ml. of ether was added from a dropping funnel and the reaction mixture was then cooled to −10° with a Dry Ice–acetone bath kept at approximately −30° to −40°. (The solution becomes slightly cloudy and bright spots appear on the lithium when the reaction has started.) The remainder of the *n*-butyl bromide was then added at an even rate over a thirty-minute period while maintaining the internal temperature at −10°. After addition was complete, the reaction mixture was allowed to warm up to 0 to 10° while stirring for one to two hours. The reaction mixture was then filtered by decantation through a narrow tube plugged with glass wool into a graduated dropping funnel previously flushed with nitrogen. The yield, as deter-

## Fluorene Analog of Amidone

BY DAVID GINSBURG[1] AND MANUEL M. BAIZER

Present interest in amidone analogs and derivatives[2,3] prompts us to report on the synthesis of a fluorene analog of amidone. This work was completed about a year ago but we have had no opportunity to establish the structure[4] of the isomer which was characterized.

Blicke and Zambito[5] state that the related "1,1-biphenylene-1-(β-dimethylaminoethyl)-butanone-2" is in the process of preparation. No details have appeared to date.

### Experimental[6]

**9-Formylfluorene.**—This compound was prepared in 74% yield by the procedure of Von and Wagner.[7]

**9-Formylfluorene Oxime.**—A 78% yield was obtained by the procedure of Vorländer.[8]

**9-Cyanofluorene.**—A 90% yield was obtained in the dehydration of 9-formylfluorene oxime by thionyl chloride in absolute ether.[8]

**Condensation of 9-Cyanofluorene with 1-Dimethylamino-2-chloropropane.**—The procedure followed was similar to the one used in the condensation of diphenylacetonitrile with the chloroamine to yield the precursors of the amidones.[9]

In a 250-ml., three-necked flask, equipped with thermometer, mercury-sealed stirrer and reflux condenser, 19.1 g. (0.1 mole) of 9-cyanofluorene and 12.2 g. (0.1 mole) of 1-dimethylamino-2-chloropropane were dissolved in 100 ml. of dry benzene at 25°. Sodium amide (4.3 g., 0.11 mole) was added, portionwise, with continuous stirring in the course of thirty minutes. The temperature rose spontaneously to 40° in one hour; ammonia was evolved. The mixture was refluxed for thirty minutes, cooled and 50 ml. of water added. The benzene layer was separated and shaken with 50 ml. of 20% hydrochloric acid. The benzene layer on evaporation left 2.5 g. of unchanged 9-cyanofluorene. The acid extract was made alkaline by the addition of 33% sodium hydroxide, and the oil which separated was extracted with 200 ml. of ether. The ethereal solution was dried and the solvent removed by distillation. The residual oil, presumed by analogy to be mixture (I) of 9-cyano-9-(β-dimethylaminopropyl)-fluorene and 9-cyano-9-(α-methyl-β-dimethylaminoethyl)-fluorene, weighed 25.5 g. Upon distillation a yellow oil was obtained; b. p. 195–199° (8 mm.).

**Reaction of I with Ethylmagnesium Bromide.**—A Grignard reagent was prepared from 9.7 g. (0.40 mole) of magnesium turnings and 44 g. (0.38 mole) of ethyl bromide in 100 ml. of dry ether. To the ethereal solution was added, in one portion, a solution of 29 g. (0.11 mole) of I in 35 ml. of dry xylene. A greenish precipitate formed after a few minutes of heating under reflux in an oil-bath at 95–100°. The heating was continued for three and one-half hours; the mixture was then decomposed, while still hot, by the careful addition of 40 ml. of concentrated hydrochloric acid dissolved in 100 ml. of water. After the addition of benzene three layers were formed. The two upper layers were removed together and heated on a steam-bath until the solvents had been vaporized. The residual oily hydrobromide was moistened with alcohol and chilled briefly in an acetone–solid carbon dioxide-bath, whereupon crystallization occurred. The solid was filtered and recrystallized from ethanol. The yield of II,[10] m. p. 232–234°, was about 75% based upon one-half the input of I.

*Anal.* Calcd. for $C_{21}H_{26}BrNO$: C, 64.94; H, 6.75; N, 3.61. Found: C, 64.43; H, 7.02; N, 3.77.[11]

The melting point of the base, liberated from II, is 57–60° and of the hydrochloride 262–263°.

## The Configuration at the 20-Position in Certain Steroids

BY W. KLYNE AND D. H. R. BARTON

Isomeric $C_{21}$ steroids bearing a secondary hydroxyl group at $C_{20}$ are commonly distinguished

by the indices $\alpha$ and $\beta$, without parentheses. Recently Fieser and Fieser[1] have discussed the relationships between the known configurations at $C_{17}$ and these hitherto arbitrarily designated configurations at $C_{20}$. They have elucidated with a high degree of probability the stereochemistry at $C_{20}$ of certain adrenal cortex steroids and related compounds having the side-chain in the 17($\beta$) position and a hydroxyl in the 17($\alpha$) position. The convention used by Fieser and Fieser to designate $C_{20}$ isomers, which has a definite stereochemical meaning, is so chosen as to agree with the arbitrary nomenclature of Reichstein.[2] Previously the latter author had pointed out that his use of the symbols 20$\alpha$ and 20$\beta$ did not imply any agreement between his convention and that adopted by Marker[3] for $C_{21}$ steroids having a hydrogen atom at $C_{17}$. Marker used the designation 20$\alpha$ for substances having the same configuration at $C_{20}$ as the common pregnanediol of human pregnancy urine,[4] and 20$\beta$ for the epimeric configuration.

The compounds whose $C_{20}$ configurations were allotted by Fieser and Fieser on purely chemical grounds were 17($\alpha$),20 diols and 17($\alpha$),20,21-triols, and the arguments were supported by reference to molecular rotation data.[5] Fieser and Fieser showed that the $\Delta_1$ values (changes in molecular rotation on acetylation)[6] of 20-hydroxyl compounds were characteristic, being in the 17-*n* series—strongly positive for their 20($\beta$) compounds and negative for their 20($\alpha$) compounds. These authors then allotted configurations to certain 20,21 diols having a hydrogen atom in the 17($\alpha$)-position on the basis of rotation evidence. They made no reference to compounds previously covered by Marker's convention, since the literature contains no adequate data on the rotations of these substances.

We have recently determined the rotations of some simple 17($\alpha$)-H, 20–OH compounds and their acetates. The $\Delta_1$ values of these compounds agree so well with the $\Delta_1$ values of the corresponding 17($\alpha$)–OH, 20–OH compounds (Table I) that we feel certain that the molecular rotation difference method is valid in this case. The data show that the convention of Fieser and Fieser and that of Marker are in agreement. Marker's 20$\alpha$ and 20$\beta$ compounds are, respectively, 20($\alpha$) and 20($\beta$) on the Fieser convention.

(4) Marrian, *Biochem. J.*, **23**, 1090 (1929).

(5) Previous work both among sugars and among steroids [*cf.* Barton and Cox, *J. Chem. Soc.*, 783 (1948)] has shown that molecular rotation differences are not always strictly additive when hydroxyl groups attached to neighboring carbon atoms are considered. However, qualitative agreement between data is sometimes sufficient to permit the use of the molecular rotation difference method in the assignment of configurations.

(6) These authors neglected the contributions of other positions ($C_3$ and/or $C_{21}$) to the $\Delta_1$ values of their compounds. Since $\Delta_1$ values for the 20($\beta$) position are large, while those for the 3($\beta$) and 21 positions are small, this procedure was justified.

small negative values for 20(α) compounds (*e. g.*, pregnanediol-20(α), 21-dione-3,11, $\Delta_1 = -29$) and large positive values for 20(β) compounds (*e. g.*, Reichstein's compounds K, E and U, which are all (17(α),20(β),21 triols, $\Delta_1 = +306, +428, +308$, respectively). The $\Delta_1$ value (at $C_{20}$) of the pregnanediol-3(α),20-one-11 3-acetate of Sarett[7] (+91) shows that it is a 20(β) compound, as might be expected from its method of preparation.

Table II shows the $\Delta_1$ values (at $C_{20}$) for 17(β), 20 diols of the 17-*iso* series. It will be seen that there is no really convincing agreement with the standard $\Delta_1$ values in the 17-*n* series. Since, also, in the comparable case of hydroxyl groups at $C_{11}$ and $C_{12}$ the molecular rotation data are in disagreement with the accepted configurations,[8,9] we feel that the conclusions of Fieser and Fieser regarding the 17-*iso* compounds, although possibly correct, should at present be treated with some reserve.

We are indebted to N. V. Organon, Oss, Holland, for a generous gift of pregnenolone acetate.

### Experimental[10]

**Allopregnanediol-3(β),20(α) Diacetate.**—Allopregnanol-3(β)-one-20 acetate was reduced with sodium and boiling ethanol.[11] The product was acetylated and the acetates chromatographed on alumina. Allopregnanediol-3(β),20(α)-diacetate after repeated crystallization from light petroleum had m.p. 163–165° (reported,[11] 165–168°); $[\alpha]_D$ −0.3° (*c*, 3.3), $[M]_D$ −1°.

**Allopregnanediol-3(β),20(α).**—The diacetate was hydrolyzed by boiling for two hours with aqueous alcoholic potassium hydroxide. The diol, recrystallized once from ether and once from acetone, had m.p. 218–219° (reported[11] 220–222°) $[\alpha]_D$ +23° (*c*, 0.9), $[M]_D$ + 72°.

**Allopregnanediol-3(β),20(β) 3-Acetate.**—$\Delta^5$-Pregnenol-3(β)-one-20 acetate was hydrogenated in ether-acetic acid solution using a platinum catalyst until the uptake of hydrogen was complete. The product was recrystallized repeatedly from methanol to give allopregnanediol-3(β),20(β) 3-acetate, m. p. 168–169°, $[\alpha]_D$ −6° (*c*, 3.6), $[M]_D$ −22° (1-dm. macro-tube).

*Anal.* Calcd. for $C_{23}H_{38}O_3$: C, 76.2; H, 10.6. Found: C, 76.5; H, 10.5.

**Allopregnanediol-3(β),20(β)-diacetate.**—The monoacetate was refluxed with acetic anhydride for one hour. The product was chromatographed on alumina and recrystallized from methanol to give the diacetate, m. p. 141–142° (reported[12] 142–143°), $[\alpha]_D$ +22° (c, 5.2), $[M]_D$ +89°.

## Studies in *p*-Cymene. II.[1] The Isomeric Aldehydes Derived from *p*-Cymene

BY CHARLES T. LESTER, RAYMOND E. DONALDSON AND JAMES C. OSWALD[2]

We have prepared the isomeric aldehydes, 2-methyl-5-isopropylbenzaldehyde[3] and 3-methyl-6-isopropylbenzaldehyde,[4] and studied their behavior when subjected to a variety of aldehyde reactions. Our objective was not to realize maximum yields, but to observe what differences, if any, were shown in the reactivities of the isomeric compounds.

Without exception all the experiments reported below indicate that the aldehyde group of 2-methyl-5-isopropylbenzaldehyde is more reactive than the aldehyde group of 3-methyl-6-isopropylbenzaldehyde. This difference is most noticeable in the self-condensation Cannizzaro reaction. The difference in reactivity of the isomeric aldehydes is in agreement with our previous report[1] concerning the saponification rate of the isomeric esters derived from *p*-cymene.

### Experimental[4a]

**Preparation of 2-Methyl-5-isopropylbenzaldehyde.**—*p*-Cymene was converted into 2-methyl-5-isopropylbenzyl chloride[5] in 49% yield. The aldehyde was prepared from the substituted benzyl chloride by the method of Sommelet.[6] This reaction was carried out with 37.5 g. of the chloride and 42 g. of hexamethylenetetramine. The aldehyde was isolated as the bisulfite addition compound; average yield, based on six preparations, 25 g., 65%. Hydrolysis of the bisulfite compound gave the aldehyde, b. p. 125° (20 mm.), in 65% yield. The aldehyde was converted, without modification of standard procedures, into a 2,4-dinitrophenylhydrazone,[7] m. p. 190–191°, and a semicarbazone,[8] m. p. 170–171°.

**Preparation of 3-Methyl-6-isopropylbenzaldehyde.**—The aldehyde was prepared from 3-bromo-*p*-cymene[9] according to the procedure of Smith and Nichols.[10] From the Grignard reagent prepared from 63.9 g. of 3-bromo-*p*-cymene was obtained (average of eight preparations) 21.6 g., 27% yield, of the aldehyde bisulfite compound. Hydrolysis of the bisulfite compound gave a 60% yield of the aldehyde, b. p. 123° (20 mm.). Attempts to prepare a 2,4-dinitrophenylhydrazone[7] and a semicarbazone[8] by the usual procedures were unsuccessful. However, when the aldehyde and proper reagents were heated in a boiling water-bath for one hour, a 2,4-dinitrophenylhydrazone, m. p. 192–193°, and a semicarbazone, m. p. 177–178° were obtained.

**Reaction of the Aldehydes with Acetone.**—The aldehydes were treated with the same molar quantities of reagents as described by Porter and Stewart[11] for benzaldehyde. Each reaction mixture was refluxed for five min-

utes and then allowed to sit at room temperature until the reaction was complete. For the reaction of 2-methyl-5-isopropylbenzaldehyde this entailed two days; for the 3-methyl-6-isopropylbenzaldehyde this entailed two weeks. We judged the reaction complete when the contents of the reaction vessels, stoppered after heating, appeared as a solid mass of crystals, with no visible liquid phase. From 7 g. of 2-methyl-5-isopropylbenzaldehyde and 1.3 g. of acetone was obtained 4.6 g., 61%, of bis-(2-methyl-5-isopropylbenzal)-acetone, m. p. 93.5–94.5°.

*Anal.* Calcd. for $C_{25}H_{30}O$: C, 86.6; H, 8.72. Found: C, 86.4; H, 8.69.

From the same quantities of 3-methyl-6-isopropylbenzaldehyde and acetone was obtained 4.5 g., 60%, of bis-(3-methyl-6-isopropylbenzal)-acetone, m. p. 95–96°.

*Anal.* Calcd. for $C_{25}H_{30}O$: C, 86.6; H, 8.72. Found: C, 86.3; H, 8.70.

**Preparation of Substituted Mandelic Acids.**—Using the same molar quantities of material and following in detail the procedure described by Fieser for the preparation of mandelic acid,[12] from 10 g. of the bisulfite compound of 2-methyl-5-isopropylbenzaldehyde was obtained 2.44 g., 36%, of (2-methyl-5-isopropylphenyl)-glycolic acid, m. p. 124–125°.

*Anal.* Calcd. for $C_{12}H_{16}O_3$: C, 69.2; H, 7.69; neut. equiv., 208. Found: C, 69.1; H, 7.68; neut. equiv., 206.8.

In like manner from 10 g. of the bisulfite compound of 3-methyl-6-isopropylbenzaldehyde was obtained 0.8 g., 12%, of (3-methyl-6-isopropylphenyl)-glycolic acid, m. p. 139–140°.

*Anal.* Calcd. for $C_{12}H_{16}O_3$: C, 69.2; H, 7.69; neut. equiv., 208. Found: C, 69.4; H, 7.83; neut. equiv., 208.9.

**Reaction of the Aldehydes with Sodium Bisulfite.**—A solution of 2.16 g., 0.0133 mole, of each aldehyde in 50 ml. of ether was placed in a glass bottle and 100 ml. of saturated aqueous sodium bisulfite was added to each bottle. The bisulfite solution was from the same stock solution. The bottles were stoppered and strapped together on the same shaking machine. At the end of four hours shaking 2.036 g., 57.4%, of the addition compound of 2-methyl-5-isopropylbenzaldehyde had precipitated. Further shaking for a total of twenty-four hours produced no additional precipitate. At the end of four hours 1.635, 46.1%, of the addition compound of 3-methyl-6-isopropylbenzaldehyde had precipitated. At the end of seven hours a total of 1.794 g., 51.1%, and at the end of twenty-two hours, a total of 1.976 g., 55%, had precipitated. No further precipitation occurred on an additional two hours shaking. At each time interval mentioned above, shaking was interrupted and the precipitate was filtered at the water pump. The precipitate was washed with ether and the ether solution of the aldehyde restored to its original volume by adding the washings and any additional ether necessary. Shaking was then resumed. The precipitate collected was dried and weighed.

**Cannizzaro Reaction.**—From 10 g. of 2-methyl-5-isopropylbenzaldehyde treated according to a standard procedure (the reaction mixture was allowed to sit for forty-eight hours[13]) was obtained 3 g., 57%, of 2-methyl-5-isopropylbenzoic acid, m. p. and mixed m. p. with authentic sample[1] 70–71°, and 5.1 g. of material, b. p. 137–138° (20 mm.). This proved to be a mixture of alcohol and unreacted aldehyde, since it gave positive fuchsin aldehyde test and reacted with 3,5-dinitrobenzoyl chloride to give an ester,[14] m. p. 74–75°.

*Anal.* Calcd. for $C_{18}H_{18}O_6N_2$: N, 7.81. Found: N, 7.66.

When 10 g. of the 3-methyl-6-isopropylbenzaldehyde was treated as above, less than 0.1 g. of acid was obtained and 8.9 g. of unreacted aldehyde was recovered. The reaction was repeated and the reaction mixture heated at 100° with mechanical stirring for one week. From this reaction was obtained 0.8 g., 12%, of 3-methyl-6-isopropylbenzoic acid, m. p. and mixed m. p. with authentic sample[1] 84–85°. In addition to the acid, 2.5 g. of material, b. p. 131–134° (20 mm.), was isolated. When treated with 3,5-dinitrobenzoyl chloride[14] and steam distilled to remove unreacted aldehyde, the ester of the 3-methyl-6-isopropylbenzyl alcohol, m. p. 76.5–78°, was obtained.

*Anal.* Calcd. for $C_{18}H_{18}O_6N_2$: N, 7.81. Found: N, 7.63.

**Acknowledgment.**—We wish to express our appreciation to B. F. Landrum, J. R. Proffitt and E. C. Surratt for their help in the analysis of our compounds.

## Alkylation of Thiophene by Propylene and Isobutylene

BY WALTER M. KUTZ AND B. B. CORSON

In view of the publication of Appleby, Sartor, Lee and Kapranos,[1] the compound reported by us[2] as probably being 2-*t*-butylthiophene was further examined. Comparison of its infrared spectrum with the spectrograms of the 2- and 3-isomers reported by Appleby and co-workers definitely showed the presence of the 3-isomer. The spectrum of our sample was also examined by those investigators. Their estimate of the content of the 3-isomer was about 30%; but owing to uncertainty as to the film thickness used in their characterization of the pure isomers (the original equipment having been replaced), it was not possible to make a quantitative infrared analysis. The estimate of the 3-isomer content from refractive index and density values was about 22%.

Inspection of our reported data on isopropylthiophene disclosed a typographical error. The density ($d^{20}_4$) of this product, prepared from propylene and isopropyl alcohol, was 0.9684 and 0.9687, respectively, instead of the reported values of 0.9884 and 0.9887. Our refractive index and density values fall between the values reported by Appleby and associates for the 2- and 3-isopropylthiophene isomers. Assuming linear blending relationship in these values, our product contained 78.5% of the 2-isomer and 21.5% of the 3-isomer according to refractive index, and 73.5% of the 2-isomer and 26.5% of the 3-isomer according to density, or an average of 76% of the 2-isomer and 24% of the 3-isomer as compared with 59% of the 2-isomer and 41% of the 3-isomer reported by Appleby and co-workers. This difference in product composition could well be due to the difference in the alkylation catalysts employed—"solid phosphoric acid" by Appleby, *et al.*, and "Filtrol" by us.

## The Apparent Ionization Constants of Acethydrazide and Glycylhydrazide

BY CARL R. LINDEGREN[1] AND CARL NIEMANN

In considering the reactions of glycylhydrazide with nitrous acid[2] the apparent ionization constants of acethydrazide and glycylhydrazide have been determined at 24 ± 1° and 25 ± 2°, respectively. With the former compound potentiometric titration of approximately 0.1 formal solutions, which were also 0.05, 0.10 or 0.20 formal in sodium chloride, with standard hydrochloric acid indicated that $pK'_A$ was independent of the ionic strength over the range studied and had a value of 3.24 for the reaction

$$[CH_3CONHNH_3]^+ \rightleftharpoons CH_3CONHNH_2 + [H]^+$$

The titration data for glycylhydrazide, obtained as described below, were evaluated by the method of Britten[3] because preliminary calculations indicated that the two constants were not sufficiently separated to permit evaluation on the basis of assumed non-interaction. $pK'_{A_1}$ was found to have a value of 2.38 and $pK'_{A_2}$ a value of 7.69. From these data and those available for other derivatives of glycine[4] it is not unreasonable to assume that $pK_{A_1} = 2.38$ for the reaction

$$[H_3NCH_2CONHNH_3]^{++} \rightleftharpoons [H_3NCH_2CONHNH_2]^+ + [H]^+$$

and $pK'_{A_2} = 7.69$ for the reaction

$$[H_3NCH_2CONHNH_2]^+ \rightleftharpoons H_2NCH_2CONHNH_2 + [H]^+$$

since the ionization constants of all the simpler α-amino acid esters and amides are in the neighborhood of $pK'_A = 7.7$.[4] The greater acidity of the hydrazinium group in the doubly protonated glycylhydrazide relative to the singly protonated acethydrazide appears to be a logical consequence of the presence of the positively charged ammonium group in the former compound though the difference ($\Delta pK = 0.86$) is only approximately one-half of that obtaining in the case of $[CH_3CH_2CH_2NH_3]^+ - [NH_3CH_2CH_2CH_2NH_3]^{++}$ ($\Delta pK = 10.6 - (8.6 + 0.3) = 1.7$) if 0.3 is added to the observed $pK'_{A_1}$ of the latter species to correct for a statistical factor of two.[5]

### Experimental

**Reagents.**—Acethydrazide, prepared from redistilled ethyl acetate and 85% hydrazine[6] was recrystallized twice from an ether–chloroform mixture and dried over potassium hydroxide. Glycylhydrazide was prepared essentially as described by Curtius and Levy,[2] the product recrystallized as described above and dried over phosphorus pentoxide.

**Procedure.**—Solutions were prepared which were approximately 0.10 formal in acethydrazide or 0.05 formal in glycylhydrazide and 0.05, 0.10 or 0.20 formal in sodium chloride. Five-ml. aliquots of these solutions were titrated with standard 0.10 normal hydrochloric acid using a Beckman Model G *p*H meter equipped with a Beckman type E glass electrode. In every case the *p*H meter was calibrated against a standard buffer solution before a titration.

**Results.**—With acethydrazide five determinations using solutions 0.20 formal in sodium chloride gave a value for $pK'_A$ for the first half of the titration curve of 3.21 ± 0.10; five determinations using solutions 0.10 formal in sodium chloride a value of 3.25 ± 0.10; and three determinations with solutions 0.05 formal in sodium chloride a value 3.23 ± 0.05. The average of all determinations was 3.24. With glycylhydrazide the following values were obtained for $pK'_{A_1}$ and $pK'_{A_2}$ in the order named: with 0.2 formal sodium chloride 2.38 and 7.68, 2.36 and 7.68; with 0.1 formal sodium chloride 2.42 and 7.68, 2.40 and 7.73; and with 0.05 formal sodium chloride 2.36 and 7.69; 2.38 and 7.67. The average of all of the above was $pK'_{A_1}$ 2.38 and $pK'_{A_2} = 7.69$.

## The Preparation of 2-Nitro-3,4-xylenol

BY GEORGE P. MUELLER AND WALTER S. PELTON[1]

A need for 2-nitro-3,4-xylenol, for which no preparation has been described, prompted its synthesis in this Laboratory. The method selected was the sulfonation of 3,4-xylenol in the 6-position and nitration in the 2-position, followed by desulfonation. The well-known exchange of nitro- for sulfo-group during nitration of phenolsulfonic acids occurred here, and some 2,6-dinitro-3,4-xylenol was always formed. However, by varying the temperature and the amounts of nitric and sulfuric acids used, conditions were found which permitted yields of 40% to be obtained.

It was observed that the 2,6-dinitro-3,4-xylenol, m.p. 125–126°[2] separating during nitration carried 2-nitro-3,4-xylenol with it to form a molecular compound, m.p. 67–68°. The presence of 2-nitro-3,4-xylenol here indicates that the reaction conditions bring about nitration and some desulfonation without introducing a second

(1) This note was taken from the thesis submitted by Walter S. Pelton to the Committee on Graduate Study of the University of Tennessee in partial fulfillment of the requirements for the M.S. degree.

(2) Datta and Varma, THIS JOURNAL, **41**, 2039 (1919).

nitro-group, and represents a certain loss of the desired product.

Proof of the structure was obtained by reduction to 2-amino-3,4-xylenol, m.p. 138–139°. The previously reported value for this aminophenol, prepared by reducing 6-hydroxy-2,3-dimethylazobenzene, was 126°.[3] Repetition of this earlier work gave a compound, m.p. 138–139°, identical with that obtained from the nitrophenol.

### Experimental

**2-Nitro-3,4-xylenol.**—Purified 3,4-xylenol, 122 g. (1.0 mole) was dissolved in 122 ml. of concentrated sulfuric acid and the solution warmed on the steam-bath until reaction was under way and the temperature had risen to 60–70°. Heating was then discontinued and the mixture stirred until crystallization occurred, and to the cooled mixture 600 ml. of water and 240 ml. of concentrated sulfuric acid were added. Nitration was accomplished by adding 70 ml. of nitric acid, sp. gr. 1.42 (1.1 moles), diluted with 100 ml. of water, dropwise, with stirring at 0–5° and allowing the temperature to remain thus for an hour after addition was complete. The mixture was poured into 1200 ml. of ice-water and filtered from the precipitated nitroxylenols. Sodium chloride added to the clear filtrate salted out 2-nitro-3,4-xylenol-6-sulfonic acid as a thick, orange precipitate. The latter was collected, the filtrate saturated with salt and a second crop of sulfonic acid collected after cooling for several hours. The crude nitrosulfonic acid was steam distilled at 130–140° from an initial volume of 1050 ml. of 70% sulfuric acid. After the initial distillate, mainly 3,4-xylenol, 2-nitro-3,4-xylenol, crystallizing in the condenser as an orange solid, was collected. After separating and drying this, it was recrystallized once from petroleum ether (b. p. 60–90°) yielding 68 g. (41%) of a slightly impure product, m. p. 67–70°. After recrystallizing six times from the same solvent it melted at 71.5–72.0°.

*Anal.* Calcd. for $C_8H_9O_3N$: C, 57.48; H, 5.43; N, 8.38. Found: C, 57.46, 57.58; H, 5.21, 5.25; N, 8.51, 8.61.

Nitration in glacial acetic acid and at lower and higher temperatures proved less satisfactory. Also, the amount of nitric acid proved to be critical. For example, 0.25-mole quantities of the xylenol in corresponding amounts of water and sulfuric acid were sulfonated and then nitrated at 0–5° with 40-ml. quantities of nitric acid in varying concentrations:

| Moles of $HNO_3$ in 50 ml. of solution | Yield of crystallized 2-nitro-3,4-xylenol Grams | % | Crude precipitated nitroxylenols, g. |
|---|---|---|---|
| 0.22 | 10.6 | 25 | 2.6 |
| .28 | 16.7 | 40 | 4.0 |
| .34 | 13.9 | 33 | 7.1 |
| .40 | 6.0 | 14 | 9.0 |

The crude nitroxylenols, precipitating on dilution of the nitrated mixture, when dried and treated with petroleum ether separated into a soluble portion, crystallizing on cooling, m. p. 67–68°, and an insoluble fraction which was recrystallized from alcohol. The latter was 2,6-dinitro-3,4-xylenol, m. p. 122.5–124.0°. The low-melting material was not identical with 2-nitro-3,4-xylenol and could be made to yield the 2,6-dinitro-compound on crystallization from alcohol. An equimolecular mixture of the 2-nitro- and 2,6-dinitroxylenols melted at 67–68° and did not depress the m. p. of the above material.

**2,4-Dinitrophenyl 2-Nitro-3,4-Xylyl Ether.**—This derivative was prepared by the procedure of Bost and Nicholson,[4] and recrystallized three times from ethyl alcohol; m. p. 157.0–157.5°.

*Anal.* Calcd. for $C_{14}H_{11}O_7N_3$: C, 50.45; H, 3.33; N, 12.61. Found: C, 50.41, 50.35; H, 3.15, 3.25; N, 12.38, 12.14.

**2-Amino-3,4-xylenol.**—Reduction of 2 g. of the nitrophenol with 10 g. of sodium hydrosulfite, 5 g. of sodium bicarbonate and 33 ml. of water[5] gave a solid which darkened readily. This was decolorized in alcoholic solution, the solvent removed *in vacuo* and the buff-colored residue recrystallized from benzene. The m. p. was 138–139°.

Catalytic reduction in absolute alcohol at 50 p. s. i. over palladium-on-charcoal catalyst[6] gave the identical compound in 98% yield.

*Anal.* Calcd. for $C_8H_{11}ON$: C, 70.05; H, 8.06; N, 10.21. Found: C, 70.15, 70.12; H, 7.82, 7.89; N, 10.10, 10.16.

6-Hydroxy-2,3-dimethylazobenzene was prepared and purified as described by King.[7] It was reduced to 2-amino-3,4-xylenol in accordance with the previously published procedure[3] and the product purified. The m. p. and mixed m. p.'s with samples prepared by the above methods were all 138–139°.

**2-Acetamino-3,4-xylenol.**—The aminophenol, 0.5 g., was treated with 2 ml. of acetic anhydride, the resulting solid dissolved in 10% potassium hydroxide and the desired derivative precipitated with dilute acid; yield 0.35 g., m. p. 159–160° after four recrystallizations from benzene.

*Anal.* Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.81. Found: C, 67.05, 66.94; H, 7.11, 7.09; N, 7.77.

## A Simple Device for Regulating Pressure or Vacuum

BY J. HOWARD MUELLER

In certain experimental procedures it is often necessary to apply moderate air pressure to a piece of apparatus over a considerable period of time. The increasing use of chromatographic columns for various purposes is a case in point. A simple device which may readily be constructed at little expense has proved extraordinarily useful for this purpose and possibly merits brief description. A compressed air supply is essential to its use, but this is almost universally available.

The principle employed is to form a valve between a stainless steel ball and a narrow "seat" turned in the end of a hole drilled through a lucite or metal rod. By applying more or less pressure on top of the ball, a slow stream of air passing upward through the hole is impeded, and variable pressures are obtained in a closed system of which this valve forms the outlet. The drawing illustrates the manner in which this may be accomplished. The stem of the regulator passes through a stopper inserted into a small filter flask, which is connected to the system. A very slow stream of air is admitted by slight opening of an ordinary valve on the supply line, and the pressure is set where desired by regulating the tension on the spring by means of the knurled headed screw. The air escapes through a small vent drilled in the wall of the cylinder just above the ball. In this way,

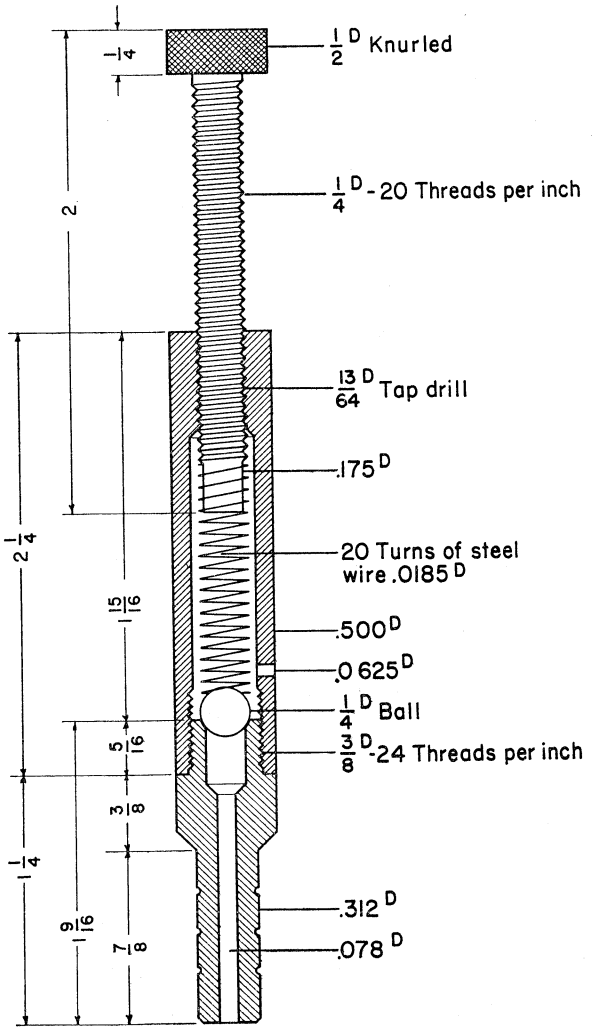

Fig. 1.

pressures varying from 2–3 mm. up to 150–200 mm. can be obtained quickly and maintained indefinitely without perceptible variation.

The same device may be used for regulation of a partial vacuum by adding a side-arm at the site of the air vent, connecting this to the apparatus, and leaving the opening below the ball free for the entrance of air.

## An Improved Method for the Preparation of Aromatic Diazoketones

BY MELVIN S. NEWMAN AND PHILIP BEAL, III

Common practice in the preparation of diazoketones involves the treatment of an acid chloride with two moles of diazomethane, one being destroyed by the hydrogen chloride produced.[1] Since this is wasteful of diazomethane, we have investigated the use of tertiary amines to remove the hydrogen chloride.

When benzoyl chloride was added to an ether solution containing one equivalent each of diazomethane and triethylamine, the diazoketone was produced in excellent yield. The reaction worked as well with anisoyl chloride. In the case of *n*-caproyl chloride, nitrogen was evolved during the addition and a mixture of products was formed. Indirect evidence for the presence of a considerable proportion of diazoketone in this mixture was obtained but it was not isolated. With the thought that the evolution of nitrogen during addition of caproyl chloride to the mixture of diazomethane and triethylamine might have been due to the $\alpha$-hydrogen, we repeated the experiment with trimethylacetyl chloride. The evolution of nitrogen during addition was less but still appreciable. The results when pyridine was used in place of triethylamine were not encouraging.

It thus appears that, at least with aromatic acid chlorides, diazomethyl ketones can be produced in excellent yield with the consumption of only one equivalent of diazomethane.

### Experimental

Ethereal solutions of diazomethane were prepared from N-nitrosomethylurea and were standardized.[2] The triethylamine was dried over barium oxide.

**Diazoacetophenone.**—A solution of 14.1 g. (0.1 mole) of benzoyl chloride in 25 cc. of ether was added during twenty minutes to a well-stirred cooled (ice–salt-bath) solution of 4.2 g. (0.1 mole) of diazomethane and 10.1 g. (0.1 mole) of triethylamine in 235 cc. of dry ether. A crystalline precipitate of triethylamine hydrochloride separated. After stirring in the cold for twelve hours, the hydrochloride, 11.8 g. (86%), was collected and washed with dry ether. The solvent was removed under reduced pressure from the combined filtrate and washings to yield 15.2 g. (104%) of crude crystalline diazoketone. An assay of this crude diazoketone by acid decomposition resulted in the collection of 93.6% of the theoretical amount of nitrogen. Recrystallization from low boiling petroleum ether (Skellysolve F) yielded the pure diazoketone, m. p. 47.8–48.4°,[3] with little loss. Experiments using pyridine in place of triethylamine were unpromising.

***p*-Methoxy-$\alpha$-diazoacetophenone.**—In a similar way, anisoyl chloride was converted into crude diazoketone in high yield. Recrystallization from benzene and petroleum ether, b. p. 60–70°, yielded pure diazoketone, m. p. 86–89° dec., in 73% yield.

**Reaction of Caproyl Chloride with Diazomethane.**—When a solution of 9.9 g. (0.064 mole) of caproyl chloride in 30 cc. of ether was added as above described during forty-five minutes to an ethereal solution containing equivalents of triethylamine and diazomethane 0.0224 mole (35%) of nitrogen was evolved. No further nitrogen was obtained after the mixture stood for twelve hours in the cold. Triethylamine hydrochloride was isolated in 91% yield, and from the filtrate and washings 9.7 g. (69%) of a crude diazoketone fraction which yielded only 58% of the theoretical amount of nitrogen on acid decomposition.

It was shown that triethylamine hydrochloride does not react with diazomethane under the conditions of this experiment. Hence we are unable to offer an explanation

for the gas observed with caproyl chloride but not with benzoyl or anisoyl chlorides.

**Reaction of Trimethylacetyl Chloride with Diazomethane.**—A solution of 24.1 g. (0.2 mole) of this acid chloride in 50 cc. of ether was added during eighty-five minutes to a cold solution of 20.4 g. (0.2 mole) of triethylamine and 8.5 g. of diazomethane in 275 cc. of ether. During the addition 0.022 mole (11%) of nitrogen was evolved, but on standing for twelve hours in the cold, no more nitrogen was liberated. The amine hydrochloride (96%) and crude diazoketone (98%) were isolated as described above. On treatment with acid, the crude diazoketone yielded 90% of nitrogen.

## Reduction of Anthracene and Phenanthrene with Lithium Aluminum Hydride

BY JOHN R. SAMPEY AND JESSIE M. COX

Nystrom and Brown[1] have found lithium aluminum hydride a useful reagent for a number of organic reductions. No work has been reported on the reduction of aromatic or condensed ring nuclei with this reagent. Preliminary attempts to reduce naphthalene and anthracene in ether and dioxane solutions were unsuccessful, but when the solid lithium aluminum hydride was shaken with molten anthracene and phenanthrene, reduction did take place, the former giving as high as 60% yields of tetrahydroanthracene, and the latter 22% of dihydrophenanthrene. These reductions take place even though the decomposition point of lithium aluminum hydride has been reported at 125–150°.[2] In all our reductions at high temperatures we mixed the powdered reagent thoroughly with the organic substances, and then employed vigorous shaking of the molten materials to ensure intimate mixing.

**Method of Reduction.**—A series of experiments is reported in which the temperature, the time and the ratio of reducing agent to anthracene and phenanthrene are varied. The experiments were run in a 200-ml. round-bottom flask, fitted with a calcium chloride tube, Bunsen valve and thermometer. The flask is heated with a Gyco heating jacket placed on a shaking machine. In each experiment 0.05 mole of the organic molecule was used. The molten material was shaken for the first two hours of each run, and then for fifteen minutes out of every thirty minutes; at the end of the time specified the hydride is decomposed by the slow addition of water. The reaction is vigorous and often flashes of fire were seen in the flask, but none of the reactions has gotten out of hand to date. After filtering and drying, the anthracene and its reduced form were extracted from the lithium and aluminum compounds with 200 ml. of hot chloroform and the phenanthrene with 200 ml. of ether or 95% alcohol. The unreduced hydrocarbons are less soluble than the hydrogenated products in the solvents used for the extractions, thus providing an effective method of separation. The tetrahydroanthracene was identified by a mixed melting point with a sample prepared by reduction of anthracene with Raney nickel (m. p. 103–104°). The dihydrophenanthrene and its picrate were identical with those prepared by Schmidt.[3]

**Results of Reduction.**—A 60% yield of tetrahydroanthracene was obtained by heating 0.05 mole of anthracene at 220–230° for six hours with 8 g. of lithium aluminum hydride; a 45% yield was obtained by cutting the hydride to one-half. Increasing the temperature to 240–270° or lengthening the time of heating also reduced the yield. A 22% yield of dihydrophenanthrene was obtained by heating 0.05 mole of phenanthrene at 220–230° for six hours with 8 g. of lithium aluminum hydroxide. Reducing the temperature to 180–200° and the quantity of hydride, reduced the yield to 10–17%.

**Acknowledgment.**—The authors acknowledge the interest of Dr. E. Emmet Reid in this research and the assistance of a grant from the Office of Naval Research.

## Electroseparation of Technetium from Rhenium and Molybdenum

BY L. B. ROGERS[1]

Heretofore, technetium has been plated from acidic solutions[2,3,4] under nearly the same conditions used for the deposition of rhenium. It seems quite likely, therefore, that the separation from rhenium would be poor. During the course of a polarographic study of technetium with G. E. Boyd[5] it was found that distinct reduction waves were found for pertechnitate in 2 *M* sodium hydroxide whereas perrhenate and molybdate did not reduce, at the platinum electrode, up to the potential at which hydrogen was evolved rapidly.

The brown-black precipitate which appeared on the electrode was soluble in a mixture of ammonia and hydrogen peroxide indicating that a lower oxide of technetium was formed since technetium metal is insoluble.[6] The height of the diffusion current confirmed the idea that the reduction step involved several electrons. Since the polarographic diffusion current reached a constant value at about −0.9 v. *vs.* the saturated calomel electrode (S.C.E.) and since the rapid evolution of hydrogen did not begin until about −1.2 v., the intermediate region of potential represented a promising one for the separation of technetium.

### Experimental Results

A 100-μl. sample of 2 *M* sodium hydroxide containing 0.2 mg. of technetium ($Tc^{99}$ − 9 × $10^5$ years) as $TcO_4^-$ plus a somewhat larger amount of molybdenum and a smaller amount of rhenium was placed upon a flat platinum foil used for the cathode. The anode was a large

Purification of technetium by electrodeposition: selected portions of Leeds and Northrup densitometer traces of spectra obtained with a Dietert 1.5 Meter Grating Spectrograph.

saturated calomel electrode, and it was connected to the sample by means of a sodium perchlorate salt bridge. After two hours of electrolysis at −1.1 v. *vs.* the S. C. E., a count of the supernatant showed that more than 95% of the technetium had been precipitated. This yield was confirmed by counting the cathode after it had been washed with distilled water.

The precipitate was dissolved in a mixture of ammonia and hydrogen peroxide, the solution evaporated to dryness on a steam-bath, and the residue dissolved in 100 $\mu$l. of 2 *M* sodium hydroxide. A comparison of the spectrographic analyses of the solution before and after electrolysis is shown in Fig. 1. After electrolysis, the presence of the molybdenum line was questionable thereby showing that a good separation had been obtained. The technetium line was only slightly weaker after electrolysis.

The rhenium lines were so weak in the original solution (not shown in Fig. 1) that their absence from the second solution was not considered to be adequate proof of a satisfactory separation. Therefore, 0.1 mg. of rhenium, as perrhenate, was added to the solution and a second electrolysis carried out. Figure 2 shows that a good separation was obtained.

A third electrolysis was performed under somewhat different conditions: 0.2 mg. Tc, 0.1 mg. Mo, and 0.1 mg. Re—all in the same valence states as before but dissolved in 1.5 ml. of 2 *M* sodium hydroxide. The electrolysis was done in a small platinum dish at −1.2 v., and it lasted fifteen hours. Figure 3 shows that the separation from molybdenum was again excellent while that from rhenium was only fair. It seems likely the combination of a more negative cathode potential with a greater decrease in the concentration of hydroxide ion, as a result of picking up carbon dioxide from the air, favored the reduction of rhenium. The yield of technetium was only 85%, a decrease which may have been due to the lack of stirring or to the lower concentration of both technetium and hydroxyl ions.

The method appears to be limited to the purification of fairly concentrated solutions, *i. e.*, $10^{-4}$ *M* or greater, because in two experiments involving concentrations of the order of $10^{-6}$ *M*, essentially no technetium was found in the ammoniacal solution of peroxide after it had been in contact with the cathode. Raising the concentration of sodium hydroxide in the solution undergoing electrolysis to 4 *M* did not improve the recovery. One must conclude from these experiments with dilute solutions that the oxide has an appreciable solubility.

**Acknowledgments.**—The author is indebted to G. E. Boyd for supplying the technetium, to C. Feldman and M. Murray for the spectrographic analyses, and to F. H. Sweeton for preparation of the figures.

## Polar Effects of Organosilicon Substituents in Carboxylic Acids[1]

BY L. H. SOMMER, J. R. GOLD, G. M. GOLDBERG AND N. S. MARANS

The acid strengths of carboxylic acids containing organosilicon substituents close to the carboxyl are of interest in connection with an elucidation of the polar effects of such substituents in organic molecules. We wish to report the synthesis and acid strengths of four silicon-containing carboxylic acids.

TABLE I

| Acid | Formula | M. p., °C. | Silicon, % Calcd. | Silicon, % Found | Neut. equiv. Calcd. | Neut. equiv. Found |
|---|---|---|---|---|---|---|
| I | $(CH_3)_3SiCH_2CO_2H$ | 40 | 21.2 | 21.3 | 132 | 133 |
| II[a] | $(CH_3)_3SiOSi(CH_3)_2$-$CH_2CO_2H$ | 17 | 27.2 | 26.7 | 206 | 207 |
| III | $(C_6H_5)(CH_3)_2SiCH_2$-$CO_2H$ | 90 | 14.4 | 14.3 | 194 | 193 |
| IV[b] | $(CH_3)_3SiCH_2CH_2CO_2H$ | 22 | 19.1 | 19.1 | 146 | 145 |

[a] Acid II has $n^{20}D$ 1.4149. [b] Acid IV has b. p. 147° (65 mm.), $n^{20}D$ 1.4279.

Acids I, II and III were synthesized in yields of 88, 85, and 69%, respectively, by carbonation of the Grignard reagents derived from the appropriate chlorides.[2] The Grignard reagents were added to an excess of Dry Ice in the form of chips and the reaction mixture allowed to stand for twelve hours. Subsequent to treatment with 5% hydrochloric acid, ether was removed from the acids by vacuum distillation at temperatures below 25°. These acids were not distilled. They were purified by two recrystallizations from heptane.[3] Acid IV was synthesized from chloromethyltrimethylsilane by the malonic ester synthesis (66% yield) and from iodomethyltrimethylsilane by the acetoacetic ester synthesis (63% yield). This acid was purified by distillation (65 mm.).

Determination of the acid strengths was made by a potentiometric method using a Leeds and Northrup 7662-A1 *p*H Indicator Assembly.[4] Stability of acids I–IV under the conditions used in this procedure was demonstrated by preparation of the sodium salts and regeneration of the acids.

The dissociation constant of *t*-butylacetic acid was determined for comparison with acid I. Propionic acid was run as a check on the accuracy of the method at the concentrations used.

| $(CH_3)_3SiOSi(CH_3)_2$ | .60 | .34 |
| $(C_6H_5)(CH_3)_2Si$ | .54 | .31 |
| $(CH_3)_3SiCH_2$ | 1.24 | .71 |
| $(CH_3)_3C$ | 1.00 | .57 |
| $CH_3$ | 1.34[a] | .77 |
| H | 1.75 | |

[a] Value found in this work, $1.32 \times 10^{-5}$.

According to current theory,[5] the acid-weakening effects of organosilicon substituents in acids I, II, and III show that *these substituents exert an inductive effect of electron-release relative to alkyl and hydrogen.*

The data for acid IV demonstrates that this effect diminishes rapidly in a saturated carbon chain. Additional theoretical aspects will be discussed in a later publication.

We thank Dr. A. W. Hutchison for valuable advice and Dr. N. C. Cook for the *t*-butylacetic acid.

## Grignard Reactions. XIX.[1] Preparation of 2,-4,4-Trimethyl-3-pentanone

BY CARLYLE J. STEHMAN,[2] NEWELL C. COOK AND FRANK C. WHITMORE[3]

The limitations of the Grignard reaction in the synthesis of highly branched compounds are well known. Such a synthesis, the reaction of *t*-amylmagnesium chloride with isobutyryl chloride, has previously given little or no ketone.[4,5]

Copper vessels for Grignard reactions have been in use in this Laboratory and others for many years. Crane, Boord and Henne[6] noted slightly better yields in copper than in glass. It has now been found that *t*-amylmagnesium chloride reacts with isobutyryl chloride in copper reactors to give 2,4,4-trimethyl-3-pentanone in yields up to 87%.

Further studies on the copper-catalyzed reaction of acid chlorides with Grignard reagents are in progress.

### Experimental

For preparation of the *t*-amylmagnesium chloride, and coupling of the Grignard reagent with isobutyryl chloride,

a jacketed copper Grignard reactor (20 liters capacity) developed at Penn State was used. To 608 g. (25 moles) of magnesium and 12,500 ml. of ether was added 2662 g. (25 moles) *t*-amyl chloride; from the product mixture was decanted 20 moles (12,200 ml.) of a clear ether solution of *t*-amylmagnesium chloride. This solution was then added dropwise at the rate of 450 cc. per hour to a mixture of 2150 g. (20 moles) of freshly prepared isobutyryl chloride in 4000 ml. of dry ether, at 16–18° and stirring continued for five days, also at 16–18°. After decomposing the product by pouring onto 10 kg. of ice, the ether layer and water layer were separately distilled. The combined ether layer distillates upon fractionation gave cuts 1–5, 88 g., b. p. 50–76° at 80 mm., $n^{20}D$ 1.3840–1.4092, containing isobutyraldehyde and isobutyl alcohol; cut 6, 22 g., b. p. 76–82° at 80 mm., $n^{20}D$ 1.4111; cuts 7–10, 89 g., b. p. 84–87.5° at 90 mm., $n^{20}D$ 1.4070–1.4081, containing isobutyl isobutyrate; cuts 11–14, 108 g., b. p. 88–94° at 100 mm., $n^{20}D$ 1.4091–1.4136, containing isobutyl isobutyrate and 2,4,4-trimethyl-3-pentanone; cuts 15–18, 2021 g., b. p. 94° at 100 mm. to 87° at 35 mm., $n^{20}D$ 1.4214, 2,4,4-trimethyl-3-pentanone; and cut 20, 41 g., residue. Based on isobutyryl chloride, yields were estimated as 73% 2,4,4-trimethyl-3-pentanone, 10% isobutyl isobutyrate, 2% isobutyraldehyde and 1% isobutyl alcohol.

In a second preparation, also on 20-mole scale, in which the rate of addition of Grignard solution (625 cc. per mole) was constant at about 600 cc. per hour, and the temperature was 14–17°, there were obtained yields of 87% 2,4,4-trimethyl-3-pentanone, 5% isobutyl isobutyrate, 0.1% isobutyraldehyde, and 2% isobutyl alcohol.

## Methylation of Guar Polysaccharide[1]

BY JOHN W. SWANSON

Purified guar polysaccharide, a mannogalactan consisting of 60% mannan and 37% galactan units, has been methylated, subjected to methanolysis, and the resulting glycosides separated into three principal fractions by means of high vacuum fractional distillation. Fraction 1 has been hydrolyzed to the corresponding sugar and identified as 2,3,4,6-tetramethylgalactose, through its crystalline anilide. This derivative was obtained in a yield sufficient to account for 90% of the galactose present in the original polysaccharide. A sample of the unfractionated glycoside mixture was also hydrolyzed and converted to the anilides; only one crystalline anilide has been recovered. This anilide, which was identical with the above, was obtained in sufficient yield to account for 87% of the galactose present. The other two principal fractions (3 and 4 in Table I) correspond to trimethyl and dimethyl sugar units, respectively. These fractions have not been conclusively identified, but they appear to be largely methylated mannose derivatives.

Although insufficient data have been obtained to make any conclusive statements, it is interesting to note that at least 90% of the galactose units appear to be present in the polymer chain as side units and, therefore, possess four free hydroxyl groups. If the other two main fractions are principally trimethyl and dimethyl mannose, respectively, then the following types of units may be present in guar polysaccharide

a b

G = anhydrogalactose unit
M = anhydromannose unit

Moe, Iwen and Miller[2] have reported that guar mannogalactan in buffered medium consumes one mole of periodic acid per hexose unit. Structures (a) and (b) might also consume an *average* of one mole of periodic acid per hexose unit because each of the side galactose units would presumably consume two moles of periodate and the units located at the branching points would consume no periodic acid, whereas the units from which branching does not occur would consume one mole of periodic acid. Such a reaction with the galactose units would be expected to lead to the formation of a considerable quantity of formic acid. Whistler and co-workers[3] have recently published formic acid data which support the proposed structure as indicated by methylation.

### Experimental

**Methylation of Guar.**—Ten grams of purified guar polysaccharide was dissolved in 500 ml. of water and methylated under nitrogen by the simultaneous dropwise addition during five hours of 100 ml. of dimethyl sulfate and 280 ml. of 30% sodium hydroxide. After complete reaction of the dimethyl sulfate, the excess alkali was carefully neutralized with dilute sulfuric acid and the partially methylated product was salted out with sodium sulfate. The supernatant salt solution was dialyzed, evaporated under vacuum, and the residue combined with the precipitated gum product. The polysaccharide content of this residue was so small after two methylations that this procedure was not deemed necessary for later methylations. The product from the first methylation was then redispersed in water and the methylation repeated. The final product (or part thereof for methoxyl determination) was dissolved in chloroform, dried over anhydrous sodium sulfate, and precipitated with an excess of light petroleum ether. After five to six methylations and reprecipitation to remove ash, the methoxyl content was 45.4% and the ash content 0.8%; yield 11.5 g., 91.2%; $[\alpha]^{23}D$ + 46.4 ($CHCl_3$, *c* 0.67.)

**Methanolysis of Methylated Guar.**—Five and one-half grams of the methylated guar was dissolved in 80.5 ml. of anhydrous methanol and 46.5 ml. of methanol–hydrogen chloride was added (final concentration of hydrogen chloride, 3.0%). The high viscosity decreased very rapidly. The mixture was centrifuged to remove 0.02 g. of a dark solid, giving a clear light yellow solution. The optical rotation was followed to a constant value ($[\alpha]^{23}D$ + 66.5°) at room temperature and then to a constant value of $[\alpha]^{23}D$ + 74.8° after refluxing on a steam-bath for six and one-fourth hours. The hydrochloric acid was neutralized with silver carbonate and, after filtration, the solution was evaporated under vacuum to a sirup. The

small amount of ash was removed by addition of ethyl ether and filtration. The remainder of the glycosidic sirup (5.7 g.) was distilled at 0.04 mm. and 120–142° (bath temperature). The product, a water-white viscous sirup, weighed 5.6 g.; the methoxyl content was 51.9%.

**Fractionation of the Distilled Glycosides.**—The distilled mixture of glycosides (4.44 g.) was placed in a 25-ml. pear-shaped flask containing glass wool and attached to a high-vacuum fractionating apparatus similar to that described by Hibbert.[4] The mixture was slowly fractionated during twelve hours under a vacuum of 0.006 mm. and a bath temperature range of 110–160°. The last fraction was not distilled through the column because of its high boiling point and extremely viscous nature. The data for the various fractions are presented in Table I.

[a] Refractive index of mixed glycosides 1.4597.

**Preparation of the Anilide of Fraction One.**—Fraction one (0.28 g.) was hydrolyzed under reflux at 85° in 10 ml. of *N* sulfuric acid for fifteen hours and then converted to the anilide by the method described by White.[5] The product, after five recrystallizations from absolute ethanol, melted at 193–194°. Calcd. for 2,3,4,6-tetramethylgalactose anilide, m. p. 193.5°, $C_{16}H_{25}O_5N$: C, 61.7; H, 8.1; N, 4.5; $OCH_3$, 39.8. Found: C, 61.7; H, 8.2; N, 4.4; $OCH_3$, 39.8. A 90% yield of the galactose was obtained in the form of this crystalline anilide.

A sample of the mixed glycosides was also hydrolyzed and similarly converted to the anilides. Only one crystalline anilide was recovered in 85% yield; this was identical with that obtained from fraction one.

## Mechanism of the Copper and Halogen-Ion Catalysis of Dissolution of Copper

BY ZOLTÁN SZABÓ

The rate of solution of Cu in acid, in the presence of oxygen at saturation, is known to increase with the concentration of $H^+$ and $Cl^-$ ions, and to increase linearly with the concentration of the $Cu^{++}$ ions produced, except at high $[Cu^{++}]$ where it lags behind the first-order rate with respect to $[Cu^{++}]$. The observed independence of the rate of stirring indicates that the rate of dissolution is not controlled by diffusion to and from the metal surface. These facts can be accounted for by the three-step mechanism

$$(1)\quad Cu = Cu^{++} + \ominus$$
$$(2)\quad Cu^{++} + Cu = 2Cu^{+}$$
$$(3)\quad Cu^{+} + \oplus = Cu^{++}$$

where (1) includes reactions between Cu and $O_2$ or OH, and (3) is representative, in particular, of the reaction (3′) $2Cu^+ + 2H^+ + 1/2O_2 = 2Cu^{++} + H_2O$.

Since the activity of $Cu^+$ in the solution is low at all times, and these ions are steadily removed through (3′), the oxidation–reduction potential $Cu^+/Cu^{++}$ is very much higher than $Cu/Cu^+$, and reaction (2) proceeds from left to right. Absence of an effect of the rate of stirring indicates that (2) is a fast reaction. Consequently, the rate determining step is (3), specifically (3′). The activity of $Cu^+$ is still further lowered, and (2) still further shifted to the right, by formation of complex ions $[CuCl_n^{(n-1)-}]$. This accounts for the accelerating effect of $Cl^-$ ions.

From (3′), the rate of solution of the metal is

$$-d[Cu^+]/dt = k'[Cu^+]^2[O][H^+]^2$$

or, if $Cu^+$ is mainly present as complex ion

$$-\frac{d[CuCl_n^{(n-1)-}]}{dt} = k''[CuCl_n^{(n-1)-}]^2[O][H^+]^2$$

With the equilibrium constants $[Cu^+]^2/[Cu^{++}] = K_1$

$$\frac{[Cu^+][Cl^-]^n}{[CuCl_n^{(n-1)-}]} = K_2, \text{ and}$$

$$\frac{\zeta_1[Cu^{++}][Cl^-]^{2n}}{[CuCl_n^{(n-1)-}]^2} = K_2^2$$

and noting $k'K_1 = k_1$, and $k''K_1 = k_2$, these equations become, respectively

$$-d[Cu^+]/dt = k_1[Cu^{++}][H^+]^2[O] \qquad (A)$$

and

$$-\frac{d[Cu^+]}{dt} = k_2[Cu^{++}][H^+]^2[O]\frac{[Cl^-]^{2n}}{K_2^2} \qquad (B)$$

Either *A* or *B* accounts for the first-order rate law in $[Cu^{++}]$. With regard to the effect of $Cl^-$ ions, if one assumes $n = 3$ and $[Cl^-] = 10^{-2}$, the ratio $[Cl^-]^6/K_2^2$ becomes $\sim 1$.[1] The concentration $[Cl^-] \approx 10^{-2}$ actually divides the ranges of applicability of equations *A* and *B*, the former being valid at $[Cl^-] < 10^{-2}$, the latter at $[Cl^-] > 10^{-2}$. There are not enough data to test the second order with respect to $[H^+]$; in an experiment of Glauner,[2] the ratio of the amounts of Cu dissolved in 0.27 *N* and in 0.135 *N* acid was 32:5, that is higher than proportional to $[H^+]$.[2]

The corrosion is predominantly brought about by (2), the role of (1) being primarily to initiate the autocatalytic process, whereas the rate is determined by (3′).

By analogous considerations, autocatalysis can be expected in the dissolution of iron but not in the case of lead. This is in agreement with observations.

# NEW COMPOUNDS

## Phenylpropionyl-*dl*-alanine and Phenylbutyryl-*dl*-alanine

Two new derivatives of alanine have been prepared from the amino acid and the corresponding acid chlorides in the presence of alkali.[1] After isolation, each compound was thrice recrystallized from water, dried, washed with benzene, dried and analyzed. The recrystallizations served to raise the melting points one to three degrees to constant values.

**β-Phenylpropionyl-*dl*-alanine.**—M. p. 139.5–140° (uncor.).

*Anal.* Calcd. for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33; neut. eq., 221. Found: C, 65.06; H, 6.76; N, 6.36; neut. eq., 223.[2]

**γ-Phenylbutyryl-*dl*-alanine.**—M. p. 120–121° (uncor.).

*Anal.* Calcd. for $C_{13}H_{17}O_3N$: C, 66.35; H, 7.28; N, 5.96; neut. eq., 235. Found: C, 66.21; H, 7.27; N, 6.07; neut. eq., 233.

Phenylacetyl-*dl*-alanine was also prepared by the above procedure and was found to melt at 150.5–151°. Shiple and Sherwin report 150–152°.[1]

### Preparation of *m*-Aminophenyl β-Piperidinoethyl Ketone Mono-hydrochloride

In connection with a problem in this Laboratory, we had occasion to prepare *m*-aminophenyl β-piperidinoethyl ketone mono-hydrochloride. Mannich[1] was not able to obtain this compound by chemical reduction of the nitro base because of the unstable nature of the amine in acid solution and the nitro base was not reduced by catalytic hydrogenation. However, we have obtained the *m*-aminophenyl β-piperidinoethyl ketone mono-hydrochloride by catalytic reduction of *m*-nitrophenyl β-piperidinoethyl ketone mono-hydrochloride in aqueous solution with palladium on charcoal.

Following a procedure of Mannich,[2] the *m*-nitrophenyl β-piperidinoethyl ketone hydrochloride was prepared. The melting point of the crude material was 178–179°, softens at 175°. When recrystallized from alcohol–acetone and from 12A absolute alcohol the m. p. was 180–181°[3] (literature[1] m. p. 171–172°). *Anal.* Calcd. for $C_{14}H_{19}ClN_2O_3$: N, 9.35. Found: N, 9.43.

*m*-Aminophenyl β-Piperidinoethyl Ketone Mono-hydrochloride.—Twelve grams (0.04 mole) of *m*-nitrophenyl β-piperidinoethyl ketone hydrochloride was dissolved in 100 ml. of water and hydrogenated in a Parr shaker in the presence of 1.2 g. of 5% palladium on activated charcoal (American Platinum Works, Newark, New Jersey) under 20 lb. pressure of hydrogen. The reduction was complete in thirty minutes. The solution was filtered from the catalyst and concentrated under reduced pressure to a sirup. About 50 ml. of absolute alcohol was added and the mass triturated. After a short period the soft mass crystallized. Eight grams of material, m. p. 175–178° (dec.), was obtained on filtering. (A mixed m. p. with starting material showed a depression of 18°.) An additional two grams of lower m. p. was obtained on addition of several volumes of dry ether. The total yield of crude material was 10 g. (92.5%). After treating with Darco and crystallizing three times from absolute alcohol, an analytical sample had m. p. 176–177° (dec.). *Anal.* Calcd. $C_{14}H_{21}ClN_2O$: C, 62.55; H, 7.50; N, 10.42. Found: C, 62.34; H, 7.74; N, 10.42.

We wish to thank E. F. Shelberg, Chief Microanalyst, for the microanalyses here reported.

# COMMUNICATIONS TO THE EDITOR

## THE NUCLEOTIDE COMPOSITION OF RIBONUCLEIC ACIDS[1]

*Sir:*

In continuation of our nucleic acid studies, procedures have been developed[2] that permit the separation on filter paper and estimation by spectrophotometry of all ribonucleotides encountered in ribonucleic acids. The separations were performed in an ammonia atmosphere with isobutyric acid as solvent. The components were demonstrated on the chromatograms by the previously described indirect method[2] or directly by inspection under the "Mineralight."[3] Although uridylic acid shared its position on the chromatogram with guanylic acid, the complete nucleotide analysis of ribonucleic acids could be effected by either of the following procedures. *Procedure 1:* 6–20 mg. of ribonucleic acid was kept at *p*H 13.5 for twelve to fifteen hours at 30°. The solution was brought to *p*H 3 to 4 (final volume 1 cc.) and submitted to separation in 0.01-cc. portions. Guanylic acid was eluted together with uridylic acid and the extinction at 265 and 245 mμ determined. The concentrations of the two components were calculated by simultaneous equations based on the absorption of the pure nucleotides. *Procedure 2:* 6–14 mg. of ribonucleic acid was suspended in absolute methanol and the purines liberated by gaseous hydrogen chloride.[4] The evaporation residue of the total hydrolysate was brought to *p*H 13.5. The rest of the operations followed Procedure 1. In this manner uridylic and cytidylic acids, guanine, and adenine could be separated and quantitatively determined on one chromatogram without supplementary calculations.

The results are summarized in Table I and compared with the quantities of free purines and pyrimidines found in acid hydrolysates of nucleic acids (*Procedure 3*).[4] It will be seen that the nucleotide analyses presented here contribute to a more complete understanding of ribonucleic acid composition, mainly with respect to uridylic acid which has proved relatively resistant to formic acid hydrolysis.[4] They also reveal remarkable differences between ribonucleic acids from different sources.

## REARRANGEMENT OF 2-BROMOBICYCLO[2,2,2]OCTANE WITH SILVER BROMIDE

*Sir:*

We have found that the brominative decarboxylation[1] of a suspension of the silver salt of bicyclo[2,2,2]octane-2-carboxylic acid[2] (I) affords 2-bromobicyclo[1,2,3]octane (II), m. p. 39–41°. The structure of II is tentatively assigned on the grounds (a) that reduction with sodium and alcohol gives bicyclo[1,2,3]octane (III) [*Anal.* Calcd. for $C_8H_{14}$: C, 87.19; H, 12.81. Found: C, 86.88; H, 13.14], m. p. 139.5–141°, reported 133°[3,4] and 141°[5] and (b) that aqueous alcoholic alkali gives an alcohol, m. p. 183–184°, which is apparently identical with the bicyclo[1,2,3]octane-2-ol, m. p. 183°, of Alder and Windemuth[5] by virtue of the similarity of the phenylurethan [*Anal.* Calcd. for $C_{15}H_{19}O_2N$: C, 73.44; H, 7.81; N, 5.71. Found: C, 73.62; H, 7.74; N, 5.64], m. p. 128–129.5°, reported[5] 130° and the hydrogen phthalate [*Anal.* Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61. Found: C, 70.11; H, 6.74], m. p. 118–119°, reported[5] 116–117°.

This rearrangement, the first example of the conversion of the bicyclo[2,2,2]octane system to the bicyclo[1,2,3]octane system,[6] has prompted examination of the effect of silver bromide on the potentially initial product, 2-bromobicyclo[2,2,2]-octane (IV). Unrearranged IV [*Anal.* Calcd. for $C_8H_{13}Br$: C, 50.81; H, 6.93; Br, 42.26. Found: C, 50.90; H, 6.89; Br, 42.13], m. p. 64–65.5°, is prepared from bicyclo[2,2,2]octene[2] by the addition of hydrogen bromide in ether,[7] and can be reduced to bicyclo[2,2,2]octane (V), m. p. 169.5–170.5°. On treatment in carbon tetrachloride either with silver bromide or with silver acetate and bromine but not with bromine alone, IV is converted in good yield to II (identified by reduction to III).

The silver bromide-catalyzed rearrangement affords strong experimental support to the hypothesis that silver bromide is a Lewis acid of sufficient strength to weaken *observably* the carbon–bromine bond of an alkyl bromide. Limiting the establishment of a mechanism for the brominative decarboxylation is the corollary hypothesis that the alkyl bromide actually *isolated*, having been subject to alteration by silver bromide, is not necessarily identical with the bromide produced initially in the decarboxylation. Consequently, the rearrangement observed in the decarboxylation of I may not, in the absence of further experimentation, form the basis for a mechanistic hypothesis. Similarly no mechanistic significance is attributable to the optical inactivity of the 3-bromoheptane isolated from the brominative decarboxylation of optically active silver heptane-3-carboxylate,[8] in the absence of observations on the optical stability of 3-bromoheptane in the presence of silver bromide.

## VITAMIN $B_{12}$. V. IDENTIFICATION OF CRYSTALLINE VITAMIN $B_{12a}$

*Sir:*

Catalytic reaction of vitamin $B_{12}$ with hydrogen has yielded a crystalline product which shows high hematopoietic activity in pernicious anemia, although it is somewhat less active than vitamin $B_{12}$.

To a solution of 26.3 mg. of vitamin $B_{12}$ in 15 ml. of water, 78 mg. of platinum oxide catalyst was added and the mixture was shaken with hydrogen at atmospheric pressure for twenty hours. During reaction, the red color changed to dark brown, but on contact with air the red color returned indicating changes in the cobalt ion. The filtrate from the catalyst was evaporated *in vacuo* at 25°. The residue was dissolved in 1 ml. of water and 6 ml. of acetone was added. After several hours, 1–2 mg. of precipitate formed and was removed. Acetone (2 ml.) was added again and, after standing, 4–5 mg. of precipitate was removed. Acetone (2 ml.) was added, and dark-red crystals formed during twenty-four hours; yield, 12 mg. Further addition of acetone yielded more crystalline material.

After two recrystallizations from water by the addition of acetone, the red crystals showed refractive indices[1a] of $\alpha$, 1.580; $\beta$, 1.640; and $\gamma$, 1.654. The cobalt (4.58%) and phosphorus (2.43%) content reveal that the $B_{12}$ molecule is not grossly altered.

(1) Courtesy of (a) Dr. Charles Rosenblum; (b) Mr. David Hendlin; (c) Dr. Gladys Emerson; (d) Dr. Walther Ott.

The spectrum of an aqueous solution of this compound showed: broad band at 2700–2770 Å. ($E^{1\%}_{1\,cm.}$ 137); 3150 Å. ($E^{1\%}_{1\,cm.}$ 80); 3525 Å. ($E^{1\%}_{1\,cm.}$ 150); 4150 Å. ($E^{1\%}_{1\,cm.}$ 29); 5300 Å. ($E^{1\%}_{1\,cm.}$ 58). This spectrum is similar to but different from that of vitamin $B_{12}$.[2] In artificial mixtures, the presence of about 10% $B_{12}$ in $B_{12a}$ is recognizable in the spectrum; about 30% $B_{12a}$ in $B_{12}$ is not easily discernible.

This new and biologically active crystalline compound is designated vitamin $B_{12a}$.

Vitamin $B_{12a}$ shows an activity[1b] of about $5.2 \times 10$ u./mg. for the growth of *L. lactis* and $1–3 \times 10^6$ u./mg. for *L. leichmanii*, and about one-half the "animal protein factor" activity[1c] of $B_{12}$ in rats[3] and 30 ± 15% of $B_{12}$ activity[1d] in chicks.[4]

Dr. Randolph West[5] tested 25 μg. of vitamin $B_{12a}$ parenterally in a single pernicious anemia patient and observed about 30% of a maximal hematological response.

## THE PROMOTER EFFECT OF PLATINIC CHLORIDE ON RANEY NICKEL

*Sir:*

In 1936, Lieber and Smith[1] found that small amounts of platinic chloride, added to Raney nickel catalyst just prior to the start of the reduction, produced a marked enhancing effect on the activity of the catalyst. Since this early investigation there has been a marked enhancement in the activity of Raney nickel catalyst itself due to improvements in the procedure for the preparation of the catalyst from the Raney nickel–aluminum alloy[2a] over that of the method[2b] used in (1). Accordingly, it was considered important to investigate the promoter effect on the improved types of Raney nickel, particularly that designated as "W-6".[2a]

Following the procedure of Adkins and Billica,[2a] we have been unable to duplicate the activity reported by them for W-6, but are in agreement that it is the "most active nickel catalyst known".[2a] Comparative hydrogenations were carried out at room temperature under a pressure of 45 p. s. i. in a 250-ml. glass bottle shaken at about 190 oscillations per minute. The reaction mixture (containing 0.05 mole hydrogen acceptor, except where noted) was made up to a volume of 100 ml. with dry ethanol and contained 3 g. of wet W-6 Raney nickel.

(1) E. Lieber and G. B. L. Smith, THIS JOURNAL, **58**, 1417 (1936).
(2) (a) H. Adkins and H. R. Billica, *ibid.*, **70**, 695 (1948); (b) H. Adkins and L. W. Covert, *ibid.*, **54**, 4116 (1932).

Using 0.220 millimole of platinic chloride we have found *very marked* promoting actions for the hydrogenation of the nitro-, aldehyde and the nitrile groups, the ketone group being completely poisoned. The promoting action of triethylamine on W-6 alone, for the carbonyl function, as noted by Adkins[2a] was confirmed, but more significantly the combination of triethylamine and platinic chloride *produced promotions far exceeding any activity previously known*, and manifesting itself at *incredibly low concentrations of platinic chloride.* This is illustrated by the following data for the hydrogenation of benzaldehyde to benzyl alcohol

| | Time, minutes |
|---|---|
| W-6 alone | 170 |
| W-6 plus 0.220 m.mol $PtCl_4$ | 17 |
| W-6 plus $Et_3N$[a] | 60 |
| W-6 plus $Et_3N$ plus 0.220 m.mol $PtCl_4$ | 6[b] |
| W-6 plus $Et_3N$ plus 0.026 m.mol $PtCl_4$ | 7 |
| W-6 plus $Et_3N$ plus 0.004 m.mol $PtCl_4$ | 13 |
| W-6 plus $Et_3N$ plus 0.002 m.mol $PtCl_4$[c] | 29 |

[a] 2 ml. triethylamine added. [b] Check runs have given low as three to four minutes. [c] Corresponds to 0.4 mg. Pt.

Moreover the combination of triethylamine plus platinic chloride enables the hydrogenation of acetone to proceed rapidly. We have also noted the formation of triethylamine chloroplatinate prior to the start of the reduction and we will investigate the promoter action of aminochloroplatinates as promoters. Further, the combination of triethylamine plus platinic chloride was found to *markedly* promote the hydrogenation of other functional groups as well as the carbonyl group.

Further studies are under way and will be the subject of more complete reports.

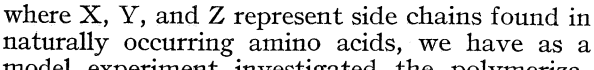
## THE APPLICATION OF THE CURTIUS REACTION TO THE POLYMERIZATION OF TRIGLYCINE



*Sir:*

In attempts to develop procedures for the preparation of complex peptides of the general structure (I)

(I)

where X, Y, and Z represent side chains found in naturally occurring amino acids, we have as a model experiment investigated the polymerization of a triglycine unit derived from triglycine hydrazide dihydrochloride (II)

(II)

R = (—$CH_2$—CO—NH—$CH_2$—CO—NH—$CH_2$—)

(*Anal.* Calcd. for $C_6H_{15}O_3N_5Cl_2$: N, 25.37; Cl, 25.68. Found: N, 25.66; Cl, 25.41) and have obtained a product having properties similar to those reported for polyglycines.[1,2,3,4]

Treatment of an aqueous solution of 2 g. of (II) with sodium nitrite followed by the addition of dilute sodium hydroxide resulted in the formation of a precipitate which was washed with water and dried; yield, 0.83 g. (*Anal.* Found: C, 38.89; H, 5.47; N, 23.14). This white powder was insoluble in water and most organic solvents, but dissolved in concentrated hydrochloric acid and in strong alkali. The peptide nature of the compound was demonstrated by hydrolysis of 203 mg. of the substance with concentrated hydrochloric acid followed by benzoylation, yielding 500 mg. of recrystallized hippuric acid, m. p. 186–188° (*Anal.* Calcd. for $C_9H_9O_3N$: N, 7.82. Found: N, 8.18). The infrared absorption spectrum[5] further substantiated this conclusion. The formation of polymers by the interaction of (II) with nitrous acid may be considered to occur according to the following scheme, with triglycine azide hydrochloride (III) as an intermediate.

$$\mathrm{HCl\cdot H_2N{-}(R){-}CONHNH_2\cdot HCl}$$
$$\downarrow \mathrm{NaONO}$$
$$\underset{\text{(III)}}{\mathrm{HCl\cdot H_2N{-}(R){-}CON_3}} + \mathrm{NaCl} + \mathrm{H_2O}$$
$$\downarrow \mathrm{NaOH}$$
$$\mathrm{H_2N{-}(R){-}CON_3} + \mathrm{NaCl} + \mathrm{H_2O}$$
$$\downarrow \mathrm{H_2N{-}(R){-}CON_3}$$
$$\mathrm{H_2N{-}(R){-}CO{-}NH{-}(R){-}CON_3} + \mathrm{N_3H}$$
$$\downarrow \mathrm{H_2N{-}(R){-}CON_3}$$
$$\mathrm{H_2N{-}(R){-}CO{-}NH{-}(R){-}CO{-}NH{-}(R){-}CON_3} + \mathrm{N_3H}$$
$$\text{etc.}$$

This indicates that under our experimental conditions the rate of reaction of the hydrazide group in (II) with nitrous acid greatly exceeds the rate of deamination of the amino group, leading to the formation of (III) which undergoes polymerization as soon as the amino group is liberated by the addition of alkali.

Although the high insolubility of the product has precluded the determination of its molecular weight, the available evidence indicates strongly that the product represents a polyglycine (or a mixture of polyglycines). The application of this scheme to the polymerization of more complex tripeptides is under investigation.

## MASS SPECTROMETRIC EXAMINATION OF THE ISOMERIZATION OF *n*-PROPYL CHLORIDE

*Sir:*

The products of the isomerization of *n*-propyl chloride on aluminum chloride in the presence of deuterium chloride have been examined with a mass spectrometer to obtain further information about the mechanism of the rearrangement. If, as frequently postulated,[1] the isomerization occurs by elimination of hydrogen chloride and recombination according to Markownikoff's rule, a reasonable concentration of deuterium would be expected in the isopropyl chloride. Since no deuterium was found in the product, the experiments described here seem to establish the fact that the rearrangement at low temperatures (0°) does not proceed to any appreciable extent by the elimination of hydrogen chloride: $CH_3CH_2CH_2Cl \rightleftarrows CH_3CH{=}CH_2 + HCl \rightleftarrows CH_3CHCl{-}CH_3$.

The experiments were carried out in 150-cc. reaction vessels into which about 0.1 g. of aluminum chloride had been sublimed. Mixtures containing 5 cm. each of deuterium chloride or hydrogen chloride and *n*-propyl chloride were allowed to react at 0°. Samples were withdrawn at suitable time intervals for analysis with a Nier type mass spectrometer. Similar experiments were carried out in which propene was allowed to react with hydrogen chloride or deuterium chloride under the same conditions.

The mass spectral data summarized in Table I show that, after one hour at 0° when isomerization was practically complete, no deuterium was found in the isopropyl chloride. Under these same conditions and on the same catalyst deuterium chloride added to propene to give isopropyl chloride containing deuterium (compare masses 64, 66, 79 and 81).

The extent of the isomerization in a given length of time (60 to 70% in five minutes at 0°) was not appreciably changed by the presence of an equal pressure of either hydrogen chloride or deuterium chloride. This is further indication that hydrogen chloride is probably not involved in the rate-controlling process of the isomerization. The hydrochlorination of propene occurred under the same conditions but at an appreciably slower rate (10 to 20% in five minutes at 0°) with some polymerization. With an equal molar mixture of hydrogen chloride and deuterium chloride, the hydrogen chloride added to propene 2.2 times faster than did deuterium chloride.

In view of the result of the above experiments some other mechanism must be involved, possibly the formation of a carbonium ion,[2] or its equivalent, followed by an intramolecular hydride ion shift and recombination with a chloride ion of the catalyst. Additional exchange reactions are being

## THE SYNTHESIS OF CYCLOPENTENOLONES OF THE TYPE OF CINEROLONE

*Sir:*

Henze[1] has studied 3-hydroxy-2,5-hexanedione and 2-hydroxy-1-phenyl-1,4-pentanedione. Hunsdiecker[2] has shown that aliphatic 1,4-diketones cyclize to cyclopentenones only if a $-CH_2-$ group is present in position 5.

We have prepared six hydroxy diketones of formula I by the reaction of pyruvaldehyde with aqueous solutions of alkali salts of beta-keto acids[3] at room temperature and about $p$H 8, under what may be considered "biological" conditions. On completion of the reaction, the products are extracted and distilled (60–75% yields). We have found that these hydroxydiketones could be cyclized to the cyclopentenolones of formula II by agitation with aqueous alkali (usually 2%) at room temperature, the products being then extracted and distilled (50–65% yields).

$CH_3COCHO$ +
$RCH_2COCH_2COONa$ ⟶

(a) R = $-n$-$C_4H_9$; (b) R = $-CH_2CH{=}CHCH_3$; (c) R = $-CH_2CH{=}CH_2$; (d) R = $-CH_2C(CH_3){=}CH_2$; (e) R = $-CH_2CH_2CH{=}CH_2$; (f) R = $-CH_2CH{=}C(CH_3)_2$.

Hydroxydiketones[4]: Ia, $C_{10}H_{18}O_3$ 1.4514, 64.48, 9.74, 64.10, 9.56; Ib, $C_{10}H_{16}O_3$, 1.4679, 65.19, 8.76, 64.75, 8.79; Ic, $C_9H_{14}O_3$, 1.4657, 63.51, 8.29, 62.82, 8.05; Id, $C_{10}H_{16}O_3$, 1.4687, 65.19, 8.76, 65.28, 8.38; Ie, $C_{10}H_{16}O_3$, 1.4675, 65.19, 8.76, 65.01, 8.52; if, $C_{11}H_{18}O_3$, 1.4715, 66.64, 9.15, 66.80 8.75.

Cyclopentenolones[4]: IIa, $C_{10}H_{16}O_2$, 1.4945, 71.39, 9.59, 71.10, 9.64; IIb, $C_{10}H_{14}O_2$, 1.5143, 72.26, 8.49, 71.75, 8.40; IIc, $C_9H_{12}O_2$, 1.5141, 71.02, 7.95, 70.23, 8.07; IId, $C_{10}H_{14}O_2$, 1.5120, 72.26, 8.49, 72.48, 8.18; IIe, $C_{10}H_{14}O_2$, 1.5089, 72.26, 8.49, 71.88, 8.35, IIf, $C_{11}H_{16}O_2$, 1.5100, 73.29, 8.95, 73.44, 8.71.

Compound IIb, although having the same structure, is not identical with natural *dl*-cinerolone. However, its dihydro derivative is identical with compound IIa, and with *dl*-dihydrocinerolone. A similar lack of identity of synthetic 2-(2-butenyl)-3-methyl-2-cyclopenten-1-one with *dl*-cinerone has been reported[5] and attributed to geometric isomerism in the side chain.

The cyclopentenolones of formula II have been acylated with natural *d*-chrysanthemum monocarboxylic acid, and IIc with the *dl-cis-trans* synthetic acid, to furnish esters analogous to cinerin I.

All of these, except the ester of IIa, exhibit high toxicity and knockdown to flies, those of IIc and IId exceeding the "pyrethrins" in toxicity. These synthetic esters are more stable than the pyrethrins and cause no irritation when applied as sprays or aerosols.

The above synthesis of cyclopentenolones opens the way to the technical production of esters of the pyrethrin type since the synthesis of chrysanthemum monocarboxylic acid has been improved[6] and a more suitable substitute for this acid may yet be discovered.

Details of this research will be published later.

## THE INHOMOGENEITY OF HEPARIN

*Sir:*

It has been generally conceded that even highly purified heparin is non-homogeneous.[1] By

(1) R. Jensen, O. Snellman and B. Sylvén, *J. Biol. Chem.*, **174**, 265 (1948); J. E. Jorpes and S. Gardell, *ibid.*, **176**, 267 (1948); M. L. Wolfrom and R. A. H. Rice, THIS JOURNAL, **69**, 2918 (1947).

the application of the Craig[2] counter-current distribution technique several samples of sodium heparinate were distributed between amyl alcohol and an aqueous buffer at *p*H 6.5, using 2.5% laurylamine as a "carrier."[3] After the distribution was completed, the material in the several solvent phases was recovered by shaking each with 0.5 *M* dipotassium hydrogen phosphate.

Initially, peaks representing three fractions were located by means of anthrone[4] (Curve A). Only the two larger fractions appear to have anticoagulant activity (Curve B). The approximate homogeneity of the two outer fractions is indicated by the relative constancy of the distribution coefficients as calculated[2] over several adjacent tubes. These coefficients are shown by the numbers superimposed on the graph of Fig. 1.

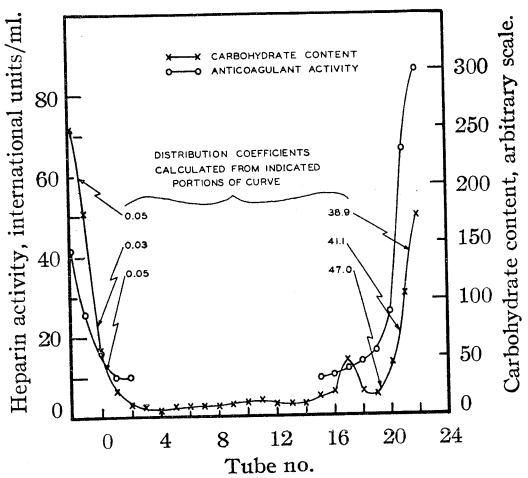

Fig. 1.

Separation of a 1-g. sample of sodium heparinate yielded, after removal of salts by dialysis, two major fractions. Preliminary data on these fractions are as follows (dry basis):

| | Low coeff. fraction | High coeff. fraction |
|---|---|---|
| Ash, % | 23.39 | 33.88 |
| Potassium (calcd. from ash), % | 10.46 | 15.19 |
| Nitrogen, % | 3.33 | 2.93 |
| Sulfur, % | 8.42 | 13.33 |
| S/N ratio | 1.10 | 1.98 |
| K/S ratio | 1.02 | 0.93 |
| Activity (intl. u./mg.) | 59 ± 6 | 215 ± 22 |

We wish to express our indebtedness to Dr. John Burke for the physiological assays and to Mr. Joseph Alicino for the microchemical analyses.

## SYNTHESIS OF ISOPROPYLCYCLOPROPANE

*Sir:*

The preparation of ethylcyclopropane and isopropylcyclopropane from methylcyclopropyl ketone has been reported recently by Van Volkenburgh, Greenlee, Derfer and Boord.[1] Because of the publication of their paper, it is desirable to report that we have been investigating the syntheses of several alkylcyclopropanes from methylcyclopropyl ketone, the results of which are being withheld until a series of hydrocarbons is completed. Our method of hydrogenation of isopropenylcyclopropane to yield essentially pure isopropylcyclopropane may be of immediate interest, however, since Van Volkenburgh, *et al.*, were able to obtain a product of only 85 mole per cent. purity by their procedure.

Dimethylcyclopropylcarbinol and isopropenylcyclopropane were prepared in essentially the same manner as previously described.[1] Hydrogenation of isopropenylcyclopropane ($n^{20}$D 1.4256) at 1500 to 2000 p.s.i. of hydrogen in the presence of a commercial barium-promoted copper chromite catalyst[2] at 100 to 130° was found to yield an extremely pure product with little or no ring cleavage. Fractionation of the hydrogenation product at 50-plate efficiency through a glass helix-packed column yielded distillate 80% of which had a refractive index of 1.3863–1.3864 (index range including forerun and residues was 1.3856 to 1.3864). Freezing curves were determined for consecutive cuts of this material and were found to vary from −113.30 to −113.17°. Physical constants of the purest cut, based on the freezing points, are given in the table with our constants for isopropenylcyclopropane:

TABLE I

| | | Isopropenylcyclopropane | Isopropylcyclopropane |
|---|---|---|---|
| F. p., °C. | | −102.34 m. p. | −113.17 |
| B. p., °C. at 760 mm. | | 70.33 | 58.37 |
| $n^{20}$D | | 1.42550 | 1.38639 |
| $d^{20}$, g./ml. | | 0.75153 | 0.69829 |
| Carbon, % | Calcd. | 87.7 | 85.6 |
| | Found | 87.6 | 85.6 |
| Hydrogen, % | Calcd. | 12.3 | 14.4 |
| | Found | 12.2 | 14.4 |

From the freezing point of our material it appears that the calculation of purity and the "100 per cent. pure" freezing point of reference 1 for isopropylcyclopropane are in error. This is not surprising since the accuracy of such calculations decreases rapidly as purity decreases. The "100 per cent. pure" freezing point, calculated from our data by the geometrical method of Taylor and Rossini,[3] is estimated to be −113.07 ± 0.05°. As-

suming that this is the true freezing point and that the $\Delta t$/mole per cent. impurity is 0.20° as given in reference 1, the purity of their sample is estimated to be 74% and ours is 99.5 mole per cent.

The infrared spectrum of the sample of isopropylcyclopropane used to determine the physical constants gave the absorption maxima in Table II.

## POLAROGRAPHIC DETERMINATION OF THE MOLECULAR WEIGHT OF SERUM ALBUMIN BY ITS EFFECT ON THE DIFFUSION CURRENT OF METHYL ORANGE

*Sir:*

The purpose of this note is to describe the great difference in the effect of gelatin and serum albumin on the diffusion current of $10^{-4}$ $M$ methyl orange in a 0.01 $N$ phosphate buffer of $p$H of 7.2, or in very dilute potassium chloride solutions and to show that the complex formation between serum albumin and methyl orange can be studied quantitatively by the polarographic method.

The polarographic behavior of methyl orange in water in the presence of various supporting electrolytes without proteins shows several complicated features which are the subject of further work. Under the conditions described below in the presence of proteins these complications were eliminated.

A small amount of gelatin (0.01%) reduces $i_d$ by 10%, but larger amounts (up to 1%) exert hardly any further effect. The addition of serum albumin causes a continuous reduction of $i_d$ until the protein concentration is about 0.5%. These observations can be interpreted in agreement with the results of Klotz,[1] *et al.*, who found that serum albumin combines, but that gelatin does not combine with methyl orange. Polarographically we found that at a concentration of about 0.5% serum albumin practically all the methyl orange ($10^{-4}$ $M$) has combined with the protein. Application of the Ilkovič equation gave a value of the diffusion coefficient of the complex of $9.05 \times 10^{-7}$ cm.$^2$ sec.$^{-1}$ at 25°. Using this value in the Stokes–Einstein equation yields a value of 66,000 for the molecular weight, which is in good agreement with reported values of molecular weight (68,000 to 70,000) of serum albumin. The decrease of $i_d$ of methyl orange by serum albumin at various concentrations can be made use of in the calculation of the binding constant.

The effect of serum albumin on the diffusion current of $10^{-4}$ $M$ methyl orange in 0.01 to 0.05 $N$ potassium hydroxide solutions is negligibly small. This again is in agreement with the results of Klotz,[1] who found that serum albumin does not combine with the dye at these high $p$H values.

More extensive polarographic studies on the effect of proteins in the native and denatured state on various dyes and other compounds are planned.

The authors acknowledge a grant from the Public Health Service, which enabled them to carry out this work.

## INHIBITING EFFECT OF NITRIC OXIDE ON THE THERMAL DECOMPOSITION OF DIETHYL KETONE

*Sir:*

Previous studies on the thermal decomposition of acetone[1] and methyl ethyl ketone[2] established the fact that the rates are uninhibited by the addition of nitric oxide. Instead, small amounts of nitric oxide, probably due to its reaction with the ketene intermediate, cause marked catalysis and this effect increases with the amount of inhibitor added. Propylene, on the other hand, reduces the rates of both reactions to a limiting value, indicating that free radicals are indeed present.

In our present investigations we find that small amounts of nitric oxide reduce the rate of decomposition of diethyl ketone to a definite, limiting value which is readily reproducible. The figure, where $\rho$ is the rate with a given amount of inhibitor, $\rho_0$, that with none, and $\rho_\infty$, the limiting rate, shows that the amount of inhibition is essentially independent of ketone pressure, indicating that the radical producing reaction must be of the first order. No catalytic effect was observed up to 20 mm. partial pressure of nitric oxide. The mean chain length is 2.0, the same value as determined for the thermal decomposition of methyl ethyl ketone with propylene. Preliminary experiments reveal that the decomposition of methyl propyl and methyl isopropyl ketones are uninhibited by nitric oxide.

The inhibiting effect of nitric oxide on diethyl ketone is in striking contrast to its effect on other ketones investigated so far. One would logically expect the primary decomposition reactions to be basically similar, and certainly methyl ethyl and diethyl ketones should initially produce the same kind of chain propagating radicals. This surpris-

ing effect of nitric oxide on diethyl ketone may be explained by postulating that (1) the decomposition of diethyl ketone initially produces a free radical different from that of other ketones; or, (2) the mechanism of this decomposition is radically different from that of the other ketones, perhaps no ketene intermediate being formed. While both possibilities are feasible, the former appears more likely, since a comparison of the inhibiting effects of nitric oxide and propylene on ketone decompositions strongly suggests that the efficiency of these inhibitors is dependent upon the type of free radical present.
