# Edward Curtis Franklin

## 1862–1937

Edward Curtis Franklin, President of the American Chemical Society in 1923, was born on March 1, 1862 in Geary City, Kansas, and died at Stanford University on February 13, 1937, after becoming in the intervening seventy-five years one of America's most honored and best loved scientists.

As a boy, Franklin was definitely not a scholar, though it is easily understandable why the primitive educational facilities of the schools in a frontier society should have had but little appeal when contrasted with the attractions to be found outdoors.

Kansas was in the hands of the Indians until 1854, and Franklin thus grew up in a country which had not yet been spoiled by the ruthless hands of civilization. The eagerness with which he availed himself of his surroundings has been recounted in a brief autobiographical sketch which describes his boyhood pleasures of hunting, of fishing, of swimming in the Missouri (even then it was noted as being muddy), and of collecting fossils from its limestone banks. Seemingly, there was an infinite variety of nuts, fruits and berries to be picked for use and of wild flowers to be admired. His delight in the beauties of the outdoor world, and particularly of the mountains, stayed with Franklin throughout his life.

As a youth, he roamed the hills along the Missouri; as a young man, he climbed the mountains of Colorado and crossed the Alps on foot during a year as a student in Germany. In his Stanford days, he was active in the Sierra Club until his fifties, having by then climbed five peaks over fourteen thousand feet high and many only slightly lower. At sixty-seven, as a guest to the South African meeting of the British Association for the Advancement of Science, his only regret was the inability to climb Kilimanjaro, seen on the return trip at a distance of thirty or forty miles, towering some nineteen thousand feet above the clouds. In later years, his mountain climbing was done with an automobile, and in 1933, he drove to the fourteen thousand foot summit of Mount Evans.

In the last few years of his life, he managed to see again most of the scenic wonders of our land as in 1936 when he drove to Kansas "by way of the Hoover Dam, Zion Canyon, Bryce Canyon, the North Rim of the Grand Canyon, Albuquerque, Santa Fe, and Boulder, Colorado," and thence on a "wild tour of thirteen thousand miles lecturing before groups of defenseless chemists through the Middle West to Philadelphia and Washington, and thence south to Florida and home by way of the southern route." To Franklin, the longest road was always the best if it offered the slightest promise of more interesting views, whether these be new or old.

In the period of 1914 to 1918 when I had the privilege of working with him, it was always Franklin who first succumbed to spring or fall fever and proposed that we play hookey on a Saturday afternoon and run away on our bicycles into the hills back of Stanford. The game which was sought might be dove, quail, or squirrels, or ducks that could be hunted from a "sneak-boat" on nearby San Francisco Bay. The return was

usually empty handed, but the treasured hours spent on these brief, back-to-nature jaunts were always followed by a vigorous and enthusiastic attack on the laboratory problem which had been so rudely abandoned.

At the age of fifteen, Franklin was sent away to a small sectarian college. There he found himself both physically and spiritually starved, and after two months, he ran away. Fifty years later, it still was possible to find schools in that region where the rations in the dining hall might keep a canary alive but certainly not happily singing. It is quite easy to understand that a man, who throughout his life was characterized by the blunt and honest frankness of his language, could hardly be content in a rigid, fundamentalist environment when, even as a youth, he was inclined to be a "free-thinker" and agnostic.

From 1880 to 1884, Franklin was a pharmacist's assistant in Severance, Kansas, where he also ran a small job-printing shop and played a cornet in the village band. It was with no thought of making a new start on an education that he visited his younger brother, then a student in the University of Kansas in the fall of 1884; but once on the campus, the congenial surroundings aroused his interest, and he decided to enroll as a special student in chemistry at the age of twenty-two. During the first three undergraduate years, he did odd jobs around the chemical laboratory and as a senior, acted as an assistant in qualitative and quantitative analysis.

Apparently, he showed promise as a teacher for he was retained on the faculty as an assistant in chemistry from 1888 to 1893, as an associate professor from 1893 to 1899, and became professor of physical chemistry in 1899 which position he held until 1903. However, he was still restless and footloose and felt uncertain about his future. Thus, we find him from 1890 to 1891 as a student in Germany and from 1893 to 1895 at Johns Hopkins where he gained his doctorate. These excursions might be regarded as part of an orderly preparation for a university career if one did not know that much of the year abroad was spent in sight-seeing rather than given over to serious study and had he not again taken leave in 1896 for a one year visit to Costa Rica as chemist and co-manager of a gold mine and mill. The fact is—and he has recorded his doubts—Franklin was still uncertain as to his fitness for the teaching profession. But, there was no such doubt in the minds of his students. As E. E. Slosson, a Kansas alumnus who was one of them, has so succinctly put it, "all of his former students are his friends, and that is more than can be said of most teachers."

Others have described him as relying but very little on books as a means of gaining knowledge but this conclusion is not warranted by the evidence. It is true that in the 1890's, the entire Kansas University chemical library was held in two small cases which were located in the department office and that the number of scientific journals received by the university as a whole was very small indeed. But each journal was impatiently watched for and eagerly read upon its arrival.

The story of the discovery of argon was hardly read when plans to check the separation were made. It is probable that the first samples of both argon and helium to be prepared in America were separated by Franklin. This was certainly true of Dewar vessels and one of the earliest, if not the first X-ray tube which was American made, was prepared for the use of Professor Blake of the Physics Department. He did rely on the written word for information, but the printed description of new and interesting discoveries was not sufficiently satisfying to him. He had to do them with his own hands and see them with his own eyes. (A considerable number of argon- and helium-containing Plücker tubes were prepared at this time and sent to friends and acquaintances in various universities. Franklin was proud of his glass blowing skill, as well he might be; one of his most satisfying experiences was to find on his arrival at Stanford that his gifts to that school had been stored in an exhibit case among other valued items.)

The diligence with which he trained himself in the laboratory arts, the eagerness with which he followed the chemical literature and the pleasure he enjoyed in repeating the more outstanding discoveries of the day offer additional evidence as to the diversity of Franklin's interest in the material world. The things which might be seen and experienced within the walls of a laboratory were now fully as appealing as the outdoor attractions had been to the youth. Like Kipling's Elephant Child of the "Just So Stories," Franklin was filled with the most insatiable curiosity about all things around him throughout his entire life.

However, while this repetition of the work of others was very interesting and satisfying, it did not reveal in him those characteristics which are the essentials of a creative worker. The spark which was to kindle the fire of Franklin's imagination came from one of his students, H. P. Cady. In the autumn of 1896 Cady, as an undergraduate, was working in the regulation course of quantitative analysis. "Observing after a time that the young man was becoming bored with his task, the writer (Franklin), at the time giving instruction in analytical chemistry, proposed to him that he prepare several of the cobalt-ammine salts and confirm the composition of one or two of them by analysis. Some days later with a beautifully crystallized specimen of one of these interesting salts in his hand Cady stated that the ammonia in these and other salts containing ammonia must function in a manner very similar to that of water in salts with water of crystallization. He suggested furthermore that liquid ammonia would probably be found to resemble water in its physical and chemical properties. As a direct conse-

quence of Cady's suggestion has followed all the work done in this country on liquid ammonia."

Franklin promptly ordered a cylinder of liquid ammonia and prepared the Dewar vessels and other apparatus needed in Cady's proposed study of ammonia as an electrolytic solvent. But the ammonia was slow in arriving and before the experiments were started, Franklin had left for Costa Rica. He returned to learn that Cady had found that many salts dissolve in ammonia to form conducting solutions, although the pure solvent still further resembles water in being practically a non-conductor.

These results, obtained with simple apparatus designed and built with his own hands, for the first time aroused Franklin's latent research instincts. No longer was the literature to be searched for interesting experiments worthy of repetition. The facts recorded therein were to be used as foundations for new information to be discovered by himself and his co-workers.

The years from 1897 to 1903 were richly fruitful for the new research team which was soon enlarged by the weaning of C. A. Kraus from the Physics Department. There seemed to be no limits to the work which Franklin's aroused imagination now saw immediately ahead. Typical titles of papers based in this productive period are "Liquid Ammonia as a Solvent"; "Determination of the Molecular Rise of the Boiling Point of Liquid Ammonia"; "Metathetic Reactions Between Certain Salts In Liquid Ammonia"; "Electrical Conductivity of Liquid Ammonia Solutions"; "Concentration Cells in Liquid Ammonia."

In the fall of 1903, this team of productive research men, each outstanding in his own way, was broken up. Kraus had left for M. I. T., Franklin was to go West to Stanford, and Cady was to remain at Kansas for his entire professional career.

Franklin's evaluation of the two junior partners is of interest. He said many times that Kraus was the most skillful glass blower and manipulator in all of the laboratory arts whom he had known. I dare to question the first part of this opinion; Kraus might equal but certainly could not excel Franklin as an artist and artisan in the designing and working of the old German soft glass. Chemists of today who are accustomed to placing a piece of cold Pyrex tubing directly into the flame of an oxygen-gas blast lamp can have no appreciation of the problem involved in the construction of one of the intricate cells used in some of the ammonia work. The patience of Job and the manipulative skill of a master were needed and these Franklin had.

The later research record of Kraus speaks for itself; an outstanding pupil graduated into an outstanding and productive research professor.

Cady was rated by Franklin as his most brilliant student and co-worker, and we believe that this was a fair evaluation. However, it is worthy of note that his most productive and active research years were spent under Franklin's stimulating guidance.

In 1903, Franklin left Kansas for Stanford University to fill the chair of organic chemistry left vacant by the death of Professor Richardson. Stanford was a rich school in those pre-earthquake days, and David Starr Jordan was adding outstanding research men to his faculty when he could find them. The change was a happy one. Franklin had been preceded in his western journey by several Kansas friends, and one of these, Vernon Kellogg, was instrumental in persuading him to accept the Stanford offer. The university lay in a beautiful setting. Rolling foothills which began at the edge of the campus soon merged into the coastal mountains and beyond these lay the Pacific Ocean only twenty miles from the university. While the Coast Ranges were comparatively low, the higher and much more rugged and scenic Sierras were only a hundred miles to the east. We can be sure that to Franklin, not the least of the attractions of this western wonderland were the mountains which he loved so well.

While Franklin's work at Kansas was more spectacularly interesting, because of the greater emphasis placed on physical-chemical measurements, the purely chemical work which was largely done at Stanford was much the more important. To quote Alexander Findlay, "From their earlier experiments . . . Franklin and his collaborators were led to an exhaustive examination of the parallelism between the chemical behavior of derivatives of ammonia dissolved in liquid ammonia and the behavior of derivatives of water, aquo-compounds as Franklin called them, in aqueous solution. The investigation of the behavior of the former class of compounds, the ammono compounds, to use Franklin's nomenclature, constitutes the chief and most characteristic contribution of Franklin to chemistry."

The record of this contribution is embodied in his monograph on the "Nitrogen System of Compounds." In this, his detailed classification, of the organic compounds of nitrogen as belonging to the ammonia system, has made the book a classic and a most stimulating guide to further investigations by others. Franklin wrote slowly and most painstakingly; hence this monograph was rewritten many times and was over ten years in preparation.

The step by step reports of progress in his forty years of research are contained in eighty-seven papers of which less than half bear his name due to his generosity toward the pupils who were his collaborators.

Franklin, as we have seen, was a great experimentalist, and the few who were fortunate enough to be accepted by him as a collaborator will insist that he was without a peer as a teacher of graduate students. Every one of these men acquired a

skill in laboratory technique which was far above the average, each learned to think independently and, in addition, learned to view his own experimental results with that critical skepticism which is the true measure of a scientist.

His lectures in organic chemistry were models of clear and orderly thinking though Franklin never acquired the smooth and polished delivery which was characteristic of Stieglitz. His own experimental interest and belief in teaching by example made his lectures unusually instructive because of the many elaborate and skillfully done demonstrations which illustrated them.

He had an infinite capacity for making lifelong friends, and these were of all ages from babes in arms to emeritus professors. The Christmas lectures which, like Faraday, he enjoyed giving to the children of his friends and colleagues were elaborately illustrated with demonstrations to fit the occasion and the audience. (I dare say that many a middle-aged matron of today has in her jewel box a glass ring, with a "red" stone, which was made by Dr. Franklin just for her during one of these lectures.)

To the end of his days, he was a welcome and honored guest in the home of every former student and associate in this and other lands. He delighted in talking of his own work and pleasures and equally enjoyed listening to the exploits of others.

From the beginning of his professional career until the year of his death, he was a regular attendant at meetings of the American Chemical Society, and of all the honors that he received, he valued his election to the presidency of this society the most highly.

His wife, Effie Scott Franklin, who was a student at Kansas at the time of her marriage in 1897, died in 1931 and the older of two sons, Charles Scott Franklin, was killed in an airplane accident in 1928. The two surviving children are also worthy of their parents. Dr. Anna Franklin Barnett is a happy wife and mother and a practicing physician as well. John Curtis Franklin, an electrical engineer, is now Manager of Oak Ridge Directed Operations for the Atomic Energy Commission.

# Substituted Sulfaquinoxalines. III. Extension of the Glyoxalate Synthesis of 2-Aminoquinoxaline[1]

BY F. J. WOLF, KARL PFISTER, 3RD, R. H. BEUTEL, R. M. WILSON, JR., C. A. ROBINSON[2a] AND J. R. STEVENS[2b]

The preparation of 2-aminoquinoxaline by the glyoxalate synthesis[3] offered a convenient method for procuring substituted 2-aminoquinoxalines and the corresponding sulfonamido derivatives, of which a series was desired for antimalarial testing.[4] In this paper sixteen 2-sulfanilamidoquinoxaline derivatives bearing substituents in the benzenoid ring are reported. As shown in the accompanying

equations, the requisite 2-aminoquinoxalines were prepared by condensing butyl glyoxalate with the corresponding *o*-phenylenediamine (R = alkyl, alkoxy, halogen, nitro, carboxy or sulfonic acid group) to give a 2-hydroxyquinoxaline, which was then chlorinated and aminated.

The necessary diamines were obtained by reduction of the corresponding nitroanilines or dinitro compounds. In some cases these diamines were converted without isolation into the hydroxyquinoxalines by addition of butyl glyoxalate to the reaction mixture resulting from the reduction. Generally, however, the diamines were isolated and purified as the neutral sulfates. The reaction with butyl glyoxalate performed in water or water–ethanol gave the 2-hydroxyquinoxalines in good yields. These compounds are high-melting solids, insoluble in most organic solvents, but soluble in dilute ammonium or sodium hydroxide.

Chlorination of the hydroxy compounds was achieved by treatment with phosphorus chlorides (usually phosphorus pentachloride in phosphorus oxychloride). The products were purified to white to yellow solids by recrystallization from ligroin or benzene. At this stage the isomers resulting from condensation of the unsymmetrical diamines with butyl glyoxalate in the two possible ways were separated by fractional crystallization. The pure chloroquinoxalines were aminated with liquid ammonia, usually in methanol solution, at temperatures and reaction times that varied widely for optimum yields with the differently substituted chloroquinoxalines. The amines are weakly basic, pale yellow compounds, soluble in warm dilute hydrochloric acid and conveniently crystallized from benzene or benzene–ethanol solutions.

The reactivity of the amino group in the differently substituted compounds (as indicated by the ease of reaction with *p*-acetylaminobenzenesulfonyl chloride) varied considerably, and in the cases of substitution of the benzene nucleus with strongly meta-directing groups (nitro, carboxy and sulfonic acid) the condensation failed under the usual conditions. Sulfonamides of the nitro compounds were obtained from the reaction of the chloro derivatives with *p*-acetylaminobenzenesulfonamide, while the carboxy derivatives were converted into the esters, and these reacted with *p*-acetylaminobenzenesulfonyl chloride. No sulfonamides were obtained from the sulfonic acid derivatives.

As noted above, the isomeric pairs that resulted when the diamines were unsymmetrically substituted were separated as the 2-chloroquinoxalines. Attempts to separate the isomeric 2-hydroxy or 2-amino compounds were unsuccessful. Furthermore, since the sulfonamides were used for pharmacological screening, no attempt was made to identify the isomers. Two isomers were observed in every case with the exception of the 6(or 7)-carboxylic acid. However, of three vicinally substituted diamines, two gave only one of the isomeric quinoxalines in appreciable quantity.

The compounds prepared are listed in the following tables. The higher melting isomeric chloro derivative has been arbitrarily labelled a, and the subsequent derivatives are related to the chloro isomers. A paper by Platt (*J. Chem. Soc.*, 1310 (1948)) which appeared after this contribution was in press describes the preparation by an ambiguous method of both 2-hydroxy-6-methylquinoxaline and 2-hydroxy-7-methylquinoxaline and their respective chloro and amino derivatives. A comparison of melting points indicates that our 2-chloro-6-(or 7)-methylquinoxaline a is in fact 2-chloro-6-methylquinoxaline.

## Experimental

### Substituted *o*-Nitroanilines

The compounds used were either purchased or obtained by standard preparation according to procedures in the literature. However, a new method of synthesis of 2-nitro-6-chloroaniline was developed using the method described in the literature for the preparation of 2-nitro-6-bromoaniline.[5]

[a] Mixtures of isomers were not separated, although purification may have resulted in enrichment of one isomer. [b] These products consist of a mixture of both possible substituted 2-hydroxyquinoxalines. [c] *Anal.* Calcd.: N, 17.50. Found: N, 17.45. [d] *Anal.* Calcd.: N, 15.99. Found: N, 15.63. [e] These products consist of 5- or 8-substituted 2-hydroxyquinoxalines. [f] These derivatives were not analyzed, but were converted directly into the corresponding chloro derivatives (Table II). [g] These products consist of 6- or 7-substituted 2-hydroxyquinoxalines.

**2-Nitro-6-chloroaniline.**—A solution of 100 g. of *o*-nitroaniline in 100 ml. of concentrated sulfuric acid and 275 ml. of 20% oleum was warmed at 160° for five minutes. The mixture was poured into 2 kg. of ice and water, and a solution of 50 g. of chlorine in 700 ml. of glacial acetic acid was added at 0–5° while the mixture was mechanically stirred. The mixture was allowed to stand twenty-four hours at room temperature and then filtered. The insoluble material (2–8 g.) was discarded and the filtrate transferred to 5-liter round-bottom flask equipped with a thermometer immersed in the liquid, a steam inlet, a condenser for downward distillation and an electric heating mantle. The mixture was gradually heated to 135°. At this temperature most of the acetic acid has distilled, and the product begins to steam distil. Dry steam was introduced and the product steam distilled. The temperature of the contents of the flask gradually rises to 150° during the distillation. Toward the end of the distillation the mixture foams badly, and the introduction of an anti-foam agent is helpful. The distillate (approximately 5 l.) was filtered and the product recrystallized from Skellysolve B. The product, 36.3 g. (29% yield), melts at 72–73°.

### Substituted *o*-Phenylenediamines

Most of the diamines used have been previously prepared by various methods. The two methods used in the experiments were reduction with iron and hydrochloric acid and catalytic reduction. The product was generally isolated as the neutral sulfate by adding sulfuric acid to the alcohol solutions obtained from the reduction until no more precipitate was obtained. The sulfate salts were found to be non-hygroscopic, stable derivatives and could be purified by recrystallization from water or ethanol–water. The preparation of 3-chloro-1,2-diaminobenzene has not been previously described.

**3-Chloro-1,2-diaminobenzene Sulfate.**—A mixture of 37 g. of crude 2,3-dinitrochlorobenzene, 840 ml. of ethanol, 56 ml. of water and 72 g. of iron powder was warmed to 50°, and 11.5 ml. of concentrated hydrochloric acid was added at a rate sufficient to maintain gentle refluxing.

(6) Microanalyses were kindly performed by R. N. Boos, W. H. Humphrey, E. Thornton, L. Rosalsky and E. Miess of these Laboratories.

[a] The isomers are designated a, for the higher melting and b, for the lower melting. Therefore, compounds labeled 6- are either 6- or 7- substituted 2-chloroquinoxalines, those labeled 5- are either 5- or 8- substituted 2-chloroquinoxalines, etc. The subsequent products are labeled a or b referring to the chloro compound from which they were derived. [b] *Anal.* Calcd.: N, 15.68. Found: N, 15.08. [c] *Anal.* Calcd.: N, 15.68. Found: N, 15.59. [d] *Anal.* Calcd.: N, 13.42. Found: N, 13.97. [e] *Anal.* Calcd.: N, 11.48. Found: N, 11.8. [f] *Anal.* Calcd.: N, 22.17. Found: N, 21.70. [g] The mixture which was obtained melted at 85–87° and was not analyzed. Separation of isomers was very difficult, but a small amount of material, m. p. 115–117°, was isolated and had the analysis listed. [h] This product is a mixture of both possible isomers.

After the addition was complete, the mixture was refluxed one hour, neutralized with sodium hydroxide and filtered through Supercel. The filtrate was treated dropwise with 50% sulfuric acid until a permanent pink tinge developed. The precipitated diamine sulfate was filtered, washed with alcohol and ether and dried. The product, shiny platelets which turn purplish on the edges on drying, weighed 33.0 g. (94% yield). The product was obtained in similar yield when the 2-nitro-6-chloroaniline was thus reduced.

### Substituted 2-Hydroxyquinoxalines

The general procedure is illustrated below.

**2-Hydroxy-5(or 8)-chloroquinoxaline.**—A suspension of 33.0 g. of 2,3-diaminochlorobenzene sulfate in 350 ml. of water and 140 ml. of 95% ethanol was neutralized by the cautious addition of sodium bicarbonate. Butyl glyoxalate, 18.3 g., was added and the mixture refluxed two hours. The solution was cooled and filtered, yielding crude product (29.3 g.). The crude product was purified by dissolving in 2.5 *N* sodium hydroxide, treating with decolorizing charcoal, and precipitating by acidification with acetic acid (24.4 g., 79% yield), m. p. 310°.

### Substituted 2-Chloroquinoxalines

The chloro compounds were prepared by chlorination of the hydroxy compounds with phosphorus chlorides. The isomers obtained were separated by fractional crystallization.

**2-Chloro-6(and 7)-bromoquinoxaline.**—A mixture of 89.5 g. of 2-hydroxy-6(and 7)-bromoquinoxaline, 63 g. of

[a] From the reaction of the corresponding chloro compound with acetylsulfanilamide in the presence of potassium carbonate and copper powder. [b] From the reduction of the corresponding nitro compound.

phosphorus pentachloride and 200 ml. of phosphorus oxychloride was heated on the steam-bath and stirred for one hour. The dark brown solution was slowly poured onto 1.5 kg. of ice and filtered. The wet precipitate was taken up in 2 l. of hot ethanol, treated with decolorizing charcoal, concentrated to 600 ml., cooled and filtered. The crude mixture of isomers, 80 g., was dissolved in 1.5 l. of hot Skellysolve B. On cooling, substantially pure isomer, a, m. p. 148–150 (26 g. 27% yield) was obtained. The mother liquor was concentrated to 1 l., cooled and filtered, yielding a mixture, m. p. 110–135° (12 g., 13.2% yield). The filtrate concentrated to 100 ml. yielded on cooling material melting at 117–119° (30 g. 31% yield, total yield 71%). Recrystallization of the first fraction yielded a product, m. p. 152–153.5°, and the last fraction yielded a product, m. p. 118–120°.

**2-Chloroquinoxaline-6(and 7)-Sulfonyl Chloride.**—A mixture of 2-hydroxyquinoxaline-6(and 7)-sulfonic acid (143.7 g.), phosphorus pentachloride (396 g.) and phosphorus oxychloride (443 ml.) was refluxed for one and one-half hours. The nearly clear solution was cooled and poured on ice while the mixture was stirred vigorously. When all the phosphorus halides were decomposed the crude product was filtered, washed with water and

[a] I. Deacetylation carried out with ethanolic hydrogen chloride. II. Deacetylation carried out with aqueous sodium hydroxide.

dried, yielding crude product, m. p. 92–120° (124.3 g., 74.8%).

This mixture was separated with rather poor recovery by crystallization from benzene–ligroin mixtures to give equal amounts of the two isomers.

Isomer a crystallized as large colorless prisms from ligroin, m. p. 127–128°; isomer b was obtained as dendritic clusters of tiny colorless needles from ligroin, m. p. 98–98.5°.

**2-Chloroquinoxaline-6(or 7)-sulfonamide, b.**—Fifteen grams of 2-chloroquinoxaline-6(or 7) sulfonylchloride b was added to 250 ml. of concd. ammonia and the mixture heated on the steam-bath for five minutes. After standing overnight, the slurry was filtered and washed with water. The residue was purified by dissolving in 5% sodium hydroxide, treating with charcoal and precipitating with dilute acetic acid, yielding product, m. p. 225–235° (5.7 g., 41%). Crystallization of this material from glacial acetic acid gave prisms of m. p. 238–240° dec.

**2-Chloroquinoxaline-6(or 7)-sulfonamide, a.**—Fifteen grams of 2-chloroquinoxaline-6(or 7)-sulfonyl chloride, a, was converted into the sulfonamide as described above. After crystallization from glacial acetic acid, the product weighed 11.3 g. (81.5%), m. p. 251–253 with dec.

**2-Chloroquinoxaline-6(or 7)-carboxamide.**—A mixture of 30 g. of 2-chloroquinoxaline-6(or 7)-carboxylic acid, 66 g. of phosphorus pentachloride and 60 ml. of phosphorus oxychloride was heated two hours at 120°. The clear solution was concentrated to dryness *in vacuo* and the residue dissolved in 400 ml. of toluene. After treatment with decolorizing charcoal, the solution was concentrated *in vacuo* to about one-quarter of the initial volume. Five grams of the crude chloro acid chloride that separated was added in portions to 50 ml. of concentrated aqueous ammonia at room temperature. After allowing to stand one hour, the mixture was filtered yielding 2-chloro-6(or 7)-carbamidoquinoxaline (4.28 g.). Crystallization from methanol yielded material, m. p. 229.5°.

**2-Chloroquinoxaline-6(or 7)-carboxylic Acid.**—The mixture obtained by chlorinating 92 g. of 2-chloro-6(or 7)-carboxyquinoxaline, was poured into water and the resultant suspension stirred overnight. The crude product was dissolved in dilute sodium hydroxide and precipitated by acidification with dilute hydrochloric acid. Recrystallization of the crude, air-dried product from 500 ml. of isopropyl alcohol yielded material, m. p. 210–212° (75 g., 72% yield).

### Substituted 2-Aminoquinoxalines

In general, anhydrous ammonia was added to a solution or suspension of the chloro compound in methanol or ethanol and the mixture heated in a bomb under the conditions specified in Table III.

**2-Amino-5(or 8)-chloroquinoxaline.**—A mixture of 21 g. of 2, 5(or 8)-dichloroquinoxaline, 300 ml. of ethanol and 50 ml. of liquid ammonia was heated at 120° for three hours. The mixture was concentrated to dryness *in vacuo* and the residue dissolved in 250 ml. of hot 2.5 *N* hydrochloric acid and filtered from insoluble material, 0.3 g. The hot acid solution was treated with Darco G-60 (5 g.) and the product precipitated by adding a slight excess of 2.5 *N* sodium hydroxide. The flocculent precipitate was collected, air-dried and recrystallized from ethanol yielding light yellow granules, m. p. 218–220°, 10 g. Concentration of the mother liquor yielded a solid, (4.5 g., total yield 68%). A sample recrystallized from benzene was obtained as bright yellow platelets, m. p. 219–220°.

**2-Aminoquinoxaline-6(or 7)-sulfonic Acid, a.**—Hydrolysis of 2-chloroquinoxaline-6(or 7)-sulfonyl chloride a (19.5 g.) was accomplished by warming the compound on the steam-bath with a slight excess of 1 *N* sodium hydroxide. The nearly clear solution that resulted after fifteen minutes was filtered, made acid to litmus with hydrochloric acid and concentrated to dryness *in vacuo*.

The mixture of 2-chloroquinoxaline-6(or 7)-sulfonic acid a and salt thus obtained was suspended in 300 ml. of methanol and 60 cc. liquid ammonia and heated under pressure at 115° for fifteen hours. After the amination, the mixture was concentrated to dryness, and the residue was dissolved in the minimum quantity of water, treated with charcoal, filtered and made strongly acid with concd. hydrochloric acid. The white precipitate of 2-aminoquinoxaline-6(or 7)-sulfonic acid hydrochloride was collected, washed with 10% hydrochloric acid and dried, weight 6.0 g. (35.3% from the dichloro compound). Crystallization of this material from water yielded product with m. p. over 300°.

**2-Amino-6(or 7)-carbomethoxyquinoxaline.**—A solution of 10 g. of 2-amino-6(or 7)-carboxyquinoxaline (obtained by the usual aminating procedure) in 100 ml. of methanol containing 6 g. of anhydrous hydrogen chloride was heated at reflux two and one-half hours. The mixture was concentrated to dryness *in vacuo*. The residue was dissolved in warm water and the crude product precipitated by the addition of dilute ammonia water. The crude product, 8

g., m. p. 190–213°, was recrystallized three times from dioxane yielding a product that melts at 248.5°.

### Substituted 2-N⁴-Acetylsulfanilamidoquinoxalines

The amines were dissolved or suspended in pyridine and *p*-acetylaminobenzenesulfonyl chloride added while the mixture was stirred.

**2-N⁴-Acetylsulfanilamido-5(or 8)-chloroquinoxaline.**—To a mixture of 11.7 g. of the amine in 60 ml. of dry pyridine was added 16.7 g. of *p*-acetylaminobenzene sulfonyl chloride in four portions at ten-minute intervals, During the addition, the mixture warmed up to 35°. After being stirred for one hour, the resultant clear yellow solution was heated on a water-bath at 65° for one-half hour. The mixture was then poured into 800 ml. of hot water and the product, which crystallized when the mixture was stirred, was filtered and air dried. The crude product, 20.0 g., was dissolved in 250 ml. of 1.3 *N* sodium hydroxide and filtered; 4.45 g. of insoluble material, m. p. 208–210°, was obtained. The filtrate was acidified with glacial acetic acid yielding light yellow amorphous material, m. p. 245–252° (14.7 g., 62% yield). The analytical sample was crystallized from glacial acetic acid, m. p. 252–255°.

**2-N⁴-Acetylsulfanilamido-6(or 7)-carboxamidoquinoxaline.**—A mixture of 1.08 g. of 2-chloro-6(or 7)-carbamidoquinoxaline, 1.07 g. of acetylsulfanilamide, 0.65 g. of potassium carbonate and 50 mg. of copper powder in a Pyrex test-tube was stirred and heated at 180–190° in an oil-bath for fifteen minutes. The dark mixture was extracted with 10 cc. of 10% sodium hydroxide, filtered from the chloro compound that had not reacted and precipitated by acidification with dilute acetic acid. The oil that separated solidified on trituration with isopropyl alcohol. Recrystallization from glacial acetic acid yielded product, m. p. 277° about 500 mg.

### Sulfonamides

The acetyl derivatives were hydrolyzed by boiling with aqueous sodium hydroxide or ethanolic hydrogen chloride.

**2-Sulfanilamido-5(or 8)-chloroquinoxaline.**—A solution of 11.95 g. of the acetyl compound in 75 ml. of 2.5 *N* sodium hydroxide was heated for one-half hour on a steam-bath. The crude product, 10.25 g., 97% yield, was precipitated by neutralization with acetic acid. The crude product, m. p. 210–213°, was purified in 87% recovery by dissolving in hot 5 *N* ammonium hydroxide, treating with charcoal and precipitating with acetic acid, m. p. 213–215°.

**Acknowledgment.**—The authors are indebted to Dr. R. T. Major and Dr. Max Tishler for their kind encouragement and advice.

## Summary

The preparation of sixteen substituted derivatives of 2-sulfanilamidoquinoxaline is described, as well as the preparation of seventy-four other new quinoxaline compounds.

# 2-Acyloxyacetylthiophenes

BY FRANK KIPNIS,* HAROLD SOLOWAY AND JOHN ORNFELT

During synthetic work on substances containing the thiophene ring, it became desirable to prepare 2-hydroxyacetylthiophene (I) and a series of

I, R = OH III, R = Br
II, R = OCOR′

esters (II) derived therefrom. The intermediate which seemed to offer most promise was bromoacetylthiophene (III) which had been prepared by Brunswig[1] by the addition of bromine to a solution of 2-acetylthiophene in carbon disulfide stirred with a stream of carbon dioxide. In the present work, it was found more convenient to prepare this compound by treatment of the ketone in carbon tetrachloride with bromine in the presence of iron filings as catalyst.

By hydrolysis of the bromine compound with sodium formate in methanol,[2] 2-hydroxyacetylthiophene was prepared in fair yield. The esters, which are related to the phenacyl compounds, were prepared by several methods which gave acceptable yields. In view of the ready availability of 2-acetylthiophene[3] and 2-bromoacetylthiophene, it may be indicated that the esters would probably serve as suitable derivatives for carboxylic acids, supplementing those derived from the phenacyl halides.

## Experimental

**2-Bromoacetylthiophene (III).**—To a 1000-ml. interjoint flask fitted with a sealed stirrer, reflux condenser with drying tube, dropping funnel and thermometer, was added 42 g. (0.33 mole) of 2-acetylthiophene, 300 ml. of dry carbon tetrachloride and a few iron filings. The mixture was stirred and heated on the water-bath to 60° (internal) and then the bath was removed. A solution of 53.5 g. (0.67 atom) of bromine in 100 ml. of carbon tetrachloride was then added at such a rate that gentle refluxing occurred (about twenty minutes). The solution was refluxed for an additional thirty minutes, at the end of which time evolution of hydrogen bromide had ceased and the bromine coloration was absent. The volatiles were removed by distillation under slightly reduced pressure, and the residue was fractionated through a 30-cm. Vigreux column at 95–98° (1.5 mm.) to give 55 g. (80% yield) of a slightly yellow, extremely lachrymatory oil ($n^{20}$D 1.6258) which solidified below room temperature. The product was rather unstable at room temperature, but could be stored without decomposition at −10°. In agreement with Brunswig,[1] bromoacetylthiophene on treatment with alcoholic ammonia gave a carmine coloration, followed by a deep red-blue color on standing.

**2-Hydroxyacetylthiophene (I).**—In a 500-ml. 3-neck flask fitted with a sealed stirrer, reflux condenser and drying tube was placed 20.5 g. (0.1 mole) of 2-bromoacetylthiophene, 13.6 g. (0.2 mole) of anhydrous sodium formate and 180 ml. of absolute methanol. The stirrer was started and the solution was refluxed for ten hours. The volatiles were distilled at slightly reduced pressure, acetone

| $COC_4H_3O$ (furoyl) | 43 | 93.5 | Hexane | $C_{11}H_8O_4S$ | 55.92 | 3.41 | 13.57 | 56.07 | 3.54 | 13.04 |

[a] Analyses by Oakwold Laboratories, Alexandria, Virginia. [b] B. p. 113–114° (3 mm.).

was added to the residue to complete the precipitation of inorganic salts, the mixture was filtered, the filtrate stripped and the residue fractionated at 93–95° (3 mm.) to give 5.4 g. (38% yield) of an oil which solidified on standing. The crystalline material was twice recrystallized from hexane to give colorless plates melting at 73–74°.[4]

**2-Acetoxyacetylthiophene** (II, R′ = $CH_3$).—A mixture of 16.4 g. (0.08 mole) of 2-bromoacetylthiophene, 13 g. (0.16 mole) of anhydrous sodium acetate and 200 ml. of glacial acetic acid was refluxed with stirring for ten hours. At the end of that time, the mixture was cooled, diluted to 1500 ml. with ice water and extracted three times with 150 ml. of ether. The solvent layer was washed with 10% sodium carbonate solution until neutral and then with 50 ml. of saturated sodium chloride solution, dried with calcium sulfate and filtered from the desiccant. The ether was stripped and the residue distilled at 113–114° (3 mm.) to give 8 g. (55% yield) of a light yellow oil.

**2-Benzoyloxyacetylthiophene** (II, R′ = $C_6H_5$).—Directions are given for the benzoyl compound, but the furoyl and the cinnamoyl derivatives have been prepared in the same way, and other esters could undoubtedly be synthesized in a similar manner. It may be noted that ethanol may replace ethylene glycol as a solvent, but consistently higher yields have been achieved with the latter.

(4) All melting points were taken with a Fisher–Johns apparatus.

A mixture of 16 g. (0.11 mole) of sodium benzoate in 40 ml. of water was made slightly acid to litmus with 10% hydrochloric acid and then 200 ml. of ethylene glycol was added, together with 20.5 g. (0.1 mole) of 2-bromoacetylthiophene. After refluxing for twelve hours, the cooled mixture was poured into an excess of 4% sodium bicarbonate solution with stirring, causing the separation of a solid which was removed by filtration. The precipitate was washed thoroughly with bicarbonate solution, air-dried and recrystallized, first from heptane and then from carbon tetrachloride (Norite) to give 19.7 g. (80% yield) of white crystals melting at 95–96°.

The properties and analyses of the compounds prepared are noted in Table I.

## Summary

2-Bromoacetylthiophene has been prepared in 80% yield by treatment of 2-acetylthiophene with bromine in the presence of catalytic quantities of iron filings.

From this bromoketone, it was possible to synthesize the α-ketol and a series of α-ketol esters.

# 4-Hydroxybenzene-1,2,3-tricarboxylic Acid, 5-Hydroxybenzene-1,2,4-tricarboxylic Acid and their Derivatives

BY C. A. BUEHLER, R. BEECHER SPEES[1] AND PHILLIP A. SANGUINETTI[2]

In the identification of the degradation products of 6-hydroxymethyl-1,3-benzodioxan-5-carboxylic acid lactone,[3] it was necessary to synthesize 4-hydroxybenzene-1,2,3-tricarboxylic acid, 5-hydroxybenzene-1,2,4-tricarboxylic acid, the two methoxy trimethyl esters and the two methoxy tricarboxylic acids as possible reference compounds. The syntheses of the 5-hydroxy acid and its derivatives were accomplished by the scheme

$$C_6H_3(CH_3)_3(1,2,4) \longrightarrow \underset{\text{I}}{} C_6H_2SO_2OH(CH_3)_3(1,2,4,5) \longrightarrow$$

$$C_6H_2(COOH)_3OH(1,2,4,5) \longrightarrow$$
III

$$C_6H_2(COOCH_3)_3OCH_3(1,2,4,5) \longrightarrow$$
IV

$$C_6H_2(COOH)_3OCH_3(1,2,4,5)$$
V

Pseudocumene, I, gave the 5-sulfonic acid, II, in good yield by treatment with concentrated sulfuric acid. This sulfonic acid on oxidation with potassium permanganate followed by alkaline fusion produced the hydroxytricarboxylic acid, III, in 55% yield. Treatment with diazomethane gave the methoxytrimethyl ester, IV, which on saponification yielded the methoxy acid, V.

The 4-hydroxy acid was synthesized in a similar manner from hemimellitene (1,2,3-trimethylbenzene). Sulfonation gave the 4-sulfonic acid

(1) Present address: Northern Illinois College of Optometry, Chicago, Illinois.

(3) Buehler, Harris, Shacklett and Block, THIS JOURNAL, 68, 574 (1946).

in good yield and oxidation followed by alkaline fusion produced the hydroxy acid in 33% yield. The 4-methoxy ester was obtained as above, but saponification with 15% aqueous sodium hydroxide for as long as twelve hours failed to yield the pure 4-methoxy tricarboxylic acid, perhaps because of steric hindrance. To obtain this acid it was necessary to convert the 4-sulfonic acid into the 4-phenol (yield 30%). The methyl ether of the latter gave what was probably 2-methyl-4-methoxybenzene-1,3-dicarboxylic acid by heating with aqueous potassium permanganate for five hours since the acid did not form an anhydride at 220°, but by heating for a longer period 4-methoxybenzene-1,2,3-tricarboxylic acid (crude form) was obtained in 30% yield.

An examination of the two series of derivatives indicates that the methoxy esters are to be preferred as reference compounds.

## Experimental

All melting points and boiling points are uncorrected.

**Pseudocumene (I).**—4-Amino-1,3-dimethylbenzene, 393.8 g., was converted by the method of Smith and Lund[4] into 70.2 g. of the hydrocarbon, b. p. 68.5–69° (22–22.5 mm.) and $n^{24}D$ 1.5031 (Smith and Lund give b. p. 68–68.5 (22 mm.) and $n^{24}D$ 1.5032).

**Pseudocumene-5-sulfonic Acid (II).**—Pseudocumene, 8 cc., was sulfonated by the method of Smith and Cass[5] to give 11.8 g. of purified acid, m. p. 111–112° after softening at 108° (Smith and Cass give 110–111°).

**5-Hydroxybenzene-1,2,4-tricarboxylic Acid (III).**—This acid was synthesized by a procedure essentially that of the French and German Patents.[6] Pseudocumene-5-sulfonic acid, 10 g., and 4 g. of sodium hydroxide were dissolved in 250 cc. of water and the solution was heated to 90–100°, after which 47.1 g. of pulverized potassium permanganate was added, with stirring, at such a rate as to prevent boiling. The oxidation was continued for twenty-four hours more at this temperature, after which the solution was decolorized by the cautious addition of alcohol. The precipitated manganese dioxide was filtered off by suction and extracted twice with 150-cc. portions of boiling water.

The combined filtrates were evaporated to dryness with occasional stirring to prevent caking and the pulverized residue, after being mixed with 40 g. of potassium hydroxide and about 5 cc. of water, was fused with occasional stirring at 200–220° for from four to five hours in a nickel crucible. The melt was then mixed with 60 cc. of water and the mixture in a beaker was acidified cautiously with concentrated hydrochloric acid. Water, 150 cc. more, was added and the solution was heated to boiling (if all the salts did not dissolve, sufficient concentrated hydrochloric acid was added to effect solution). To aid in the filtration for the removal of silica shredded filter paper was added. The filtrate was then evaporated to dryness to remove hydrochloric acid since 5-hydroxybenzene-1,2,4-tricarboxylic acid, in contrast to the inorganic salts, is more soluble in acid than in neutral solution. Treatment of the residue with 270 cc. of boiling water gave a mixture which, when cooled in the refrigerator, produced more solids. Purification by solution in 60 cc. of hot 5% hydrochloric acid solution followed by treatment with 1 g. of Norite and cooling yielded 7.2 g., m. p. 238° with effervescence. Two more crystallizations from 5% hydrochloric acid solution and drying *in vacuo* over calcium chloride gave the hydrated acid, m. p. 239.5–240° with effervescence (French and German patents[6] give 240° with effervescence), which gives a red color with ferric chloride.

*Anal.* Calcd. for $C_9H_6O_7 \cdot 2H_2O$: C, 41.23; H, 3.84; neut. equiv., 87.4; loss of weight on drying, 13.74. Found: C, 41.36, 41.28; H, 4.12, 4.05; neut. equiv., 87.1; loss of weight on drying, 13.79, 13.79.

Heating at around 102° for three hours gave the anhydrous acid, m. p. 240° with effervescence.

*Anal.* Calcd. for $C_9H_6O_7$: C, 47.80; H, 2.67; neut. equiv., 75.4. Found: C, 48.10, 48.03; H, 2.77, 2.86; neut. equiv., 75.2, 75.1.

**Trimethyl-5-methoxybenzene-1,2,4-tricarboxylate (IV).**—5-Hydroxytrimellitic acid in ethanol at 0° was methylated with diazomethane in ether in the usual manner. The product crystallized from ligroin melted at 62.5–63.0°.

*Anal.* Calcd. for $C_{13}H_{14}O_7$: C, 55.32; H, 5.00. Found: C, 55.75, 56.03; H, 5.09, 5.08.

**5-Methoxybenzene-1,2,4-tricarboxylic Acid (V).**—The trimethyl ester was saponified with 5% aqueous sodium hydroxide solution to give a product, m. p. 224–225° with effervescence.

*Anal.* Calcd. for $C_{10}H_8O_7$: C, 50.01; H, 3.36; neut. equiv., 80.7. Found: C, 49.67, 49.75; H, 3.72, 3.54; neut. equiv., 79.8, 79.9.

**Hemimellitene.**—This hydrocarbon was prepared by two methods: (1) Benzyl chloride, b. p. 172–175°, 1416 g., was converted by the method of Smith and Spillane[7] into 77.4 g. of the hydrocarbon, b. p. 171.5–172.2° (741 mm.) and $n^{20}D$ 1.5130 (Smith and Spillane give b. p. 172.2–172.5° (741.4 mm.) and $n^{20}D$ 1.5130).

(2) *o*-Xylene was chloromethylated to give a mixture of 2,3-dimethylbenzyl chloride and 3,4-dimethylbenzyl chloride, which mixture was converted into pseudocumene and hemimellitene by forming the Grignard reagents and hydrolyzing. The hydrocarbons were separated by fractional distillation to give a product, b. p. 175–176° (740.5 mm.).[8]

**Hemimellitene-4-sulfonic Acid.**—Hemimellitene, 8 cc., was shaken with 16 cc. of concentrated sulfuric acid in a glass-stoppered flask until solution was complete (ten to fifteen minutes). This solution was added in 5-cc. portions, with stirring, to 32 cc. of cold concentrated hydrochloric acid, with cooling after each addition. Precipitation resulted, and after final cooling the solid was filtered dry by suction and crystallized twice from 100-cc. portions of cold 20% hydrochloric acid solution to give 11.5 g. of white plates, m. p. 115° (von Auwers and Wieners[9] give 111–114°).

**4-Hydroxybenzene-1,2,3-tricarboxylic Acid.**—This acid was prepared by a method similar to that used for 5-hydroxybenzene-1,2,4-tricarboxylic acid.[6] Hemimellitene-4-sulfonic acid, 10 g., was subjected to like treatment up to the point at which the filtrate was evaporated to dryness to remove hydrochloric acid. Then, upon the addition of 270 cc. of boiling water to the residue followed by heating for a short time, not all of the mono-potassium salt dissolved, but this amount of water was sufficient to dissolve the inorganic salts. Cooling in the refrigerator gave an additional amount of solid, the total of which, when crystallized five times from 40-cc. portions of 10% hydrochloric acid and dried in a vacuum desiccator, amounted to 4 g. and melted at 205–206° with effervescence.

*Anal.* Calcd. for $C_9H_6O_7 \cdot 1H_2O$: loss of weight on heating, 6.55. Found: 6.76, 6.89.

Heating at 102° for three hours gave the anhydrous acid.

*Anal.* Calcd. for $C_9H_6O_7$: C, 47.80; H, 2.67; neut. equiv., 76. Found: C, 48.28, 48.18; H, 2.89, 2.89; neut. equiv., 75.3, 75.0.

(8) We are indebted to Mr. Comer Shacklett of this Laboratory for the hemimellitene prepared by this preferred procedure. Details of the method will be published by him later. This product is the purer, the Bureau of Standards value, A.P.I. Res. Project 44 at NBS; "Selected Values of Properties of Hydrocarbons" Table 5a, dated June 30, 1945, for pure hemimellitene being176.15°(760 mm.).

(9) von Auwers and Wieners, *Ber.*, **58**, 2815 (1925).

**Trimethyl 4-Hydroxybenzene-1,2,3-tricarboxylate.**—The mother liquor from which the 4-hydroxy acid precipitated and the filtrates from the crystallization of the final product were combined and evaporated to dryness with occasional stirring. The pulverized residue in 500 cc. of dry methanol was saturated with hydrogen chloride and the mixture was refluxed for twenty-two hours while hydrogen chloride was introduced. Recovery in the usual manner and crystallization from 50% methanol gave 1.0 g. of white needles, m. p. 85.5–86°, which produce a red color with aqueous ferric chloride.

*Anal.* Calcd. for $C_{12}H_{12}O_7$: C, 53.73; H, 4.51. Found: C, 53.92, 53.99; H, 4.64, 4.84.

**Trimethyl 4-Methoxybenzene-1,2,3-tricarboxylate.**—The 4-hydroxy acid, 5 g., was methylated with diazomethane in the usual manner. The recovered product crystallized from methanol, 4.2 g., melted at 91.0–92.0°.

*Anal.* Calcd. for $C_{13}H_{14}O_7$: C, 55.32, H, 5.00. Found: C, 55.22, 55.45; H, 5.15, 5.21.

**4-Hydroxy-1,2,3-trimethylbenzene.**—This phenol was prepared by a modification of the method of von Auwers and Wieners[9] as follows: In a nickel crucible 120 g. of potassium hydroxide was heated to 250° at which time 65 g. of hemimellitene-4-sulfonic acid was added slowly with stirring while the temperature was allowed to rise to 325°. At this point a dark oil separated on top of the fused mixture. Upon cooling, the mixture was dissolved in 400 cc. of water and the solution was acidified with sulfuric acid, after which the phenol was removed by steam distillation. Extraction with ether and evaporation gave 13.5 g. of product. One crystallization from petroleum ether gave long white needles, m. p. 76–77° (von Auwers and Wieners obtained two crystalline forms: one on cooling the liquid, m. p. 69°; a second on crystallizing from solvents, m. p. 81°).

**4-Methoxyhemimellitene.**—4-Hydroxyhemimellitene, 14.7 g., was methylated with dimethyl sulfate and sodium hydroxide to give 13.1 g. of a colorless oil, b. p. 216–218° (728 mm.). Fractionation using an Anschütz thermometer produced a sample for analysis, b. p. 215.5–216.5° (740 mm.), $n^{20}D$ 1.5200.

*Anal.* Calcd. for $C_{10}H_{14}O$: C, 79.95; H, 9.39. Found: C, 79.76, 79.72; H, 9.22, 9.39.

**2(?)-Methyl-4-methoxybenzene-1,3-dicarboxylic Acid.**—This procedure was a modification of that given by Grewe[10] as follows: In a 3-liter, three-necked flask, equipped with an agitator, a separatory funnel and a reflux condenser, 13.1 g. of 4-methoxyhemimellitene was suspended in 50 cc. of 10% aqueous sodium hydroxide solution. While the suspension was agitated vigorously on a steam-bath, a solution of 114 g. of potassium permanganate dissolved in 1760 cc. of water was added over a three-hour period and the mixture was allowed to react for two hours longer. Methanol was then added to reduce the excess of permanganate and after filtering the filtrate was concentrated to 300 cc. Acidification, evaporation to dryness and extraction with 350 cc. of acetone followed by evaporation gave 4.1 g. of a slightly yellow product. Several crystallizations from water produced small white crystals, m. p. 216.0–216.5°. No anhydride was formed when this acid was heated to 220° for fifteen minutes.

*Anal.* Calcd. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80; neut. equiv., 105.1. Found: C, 57.05, 56.90; H, 4.60, 4.70; neut. equiv., 105.9.

**4-Methoxybenzene-1,2,3-tricarboxylic Acid.**—For a more strenuous oxidation procedure that given by Wilds and Djerassi[11] was modified as follows: In the apparatus described above, 4 g. of 4-methoxyhemimellitene was suspended in 324 cc. of 5% aqueous potassium hydroxide solution. While the suspension was heated on a steam-bath and agitated vigorously, 600 cc. of 0.35 *M* aqueous potassium permanganate solution was allowed to drop into the flask over a five-hour period. The mixture was allowed to react at this temperature until the purple color had disappeared, after which 25 cc. more of the permanganate solution was added over an hour period. When the color of permanganate had disappeared, another 25 cc. of the permanganate solution was added, and this process was repeated until a total of 725 cc. of the oxidizing solution had been added. At the end the excess permanganate was removed by the addition of sodium bisulfite and the mixture was filtered.

The most satisfactory method to remove the acid from the filtrate, concentrated to 500 cc., was that of Schultze.[12] After acidification with concentrated sulfuric acid, this concentrate was extracted twice with 200-cc. portions of ether (since the desired acid is insoluble in ether, only ether-soluble impurities are removed). The water layer was then saturated with sodium sulfate and extracted seven times with 250-cc. portions of ethyl acetate. Upon evaporating the combined portions of ethyl acetate to dryness, 2 g. of crude acid was obtained. Several crystallizations from small amounts of water gave 0.5 g. of white crystals, m. p. 215.0–216.0° with previous softening.

Crystallization from glacial acetic acid gave a product whose melting point was practically identical, but its analysis and neutral equivalent indicated that some anhydride formation had occurred.

*Anal.* Calcd. for $C_{10}H_8O_7$: C, 50.00; H, 3.36; neut. equiv., 80.0. Found: C, 49.96, 49.98; H, 3.27, 3.30; neut. equiv., 79.8.

## Summary

4-Hydroxybenzene-1,2-3-tricarboxylic acid and 5-hydroxybenzene-1,2,4-tricarboxylic acid have been synthesized from hemimellitene and pseudocumene, respectively. In addition, the methoxytrimethyl esters, the methoxytricarboxylic acids and several miscellaneous derivatives have been prepared. The methoxytrimethyl esters are to be preferred as reference compounds.

# Reactions of Per Acids. I. The Reaction of Perbenzoic Acid with Some Simple Ketones

BY S. L. FRIESS[1]

It has been shown by previous investigators that per acids are capable of converting acetyl substituents on the steroid nucleus into acetate groups, in moderately good yields. For example, Marker[2a] and co-workers demonstrated that a mixture of acetic, sulfuric and persulfuric acids could convert allopregnanol-3($\beta$)-one-20 into a mixture of epimeric carbinols, presumably by way of the monoacetates. These carbinols were subsequently oxidized to androstanedione-3,17. Further work by Marker[2b] showed that allopregnanone-20 would be converted by persulfuric acid into a mixture of the compound possessing a 17-acetate grouping, and allopregnanol-21-one-20, corresponding to oxidation at carbon 21.

Subsequent work by Reichstein[3] using perbenzoic acid as the oxidizing agent indicated that the acetate of allopregnanol-3-one-20 could be converted into the corresponding diacetate, which in turn was characterized by saponification to the crystalline androstanediol-3($\beta$),17($\alpha$).

Most recently, Sarett[4] has shown that in certain instances relatively high yields may be obtained on oxidation of 17-acetyl steroids to the corresponding 17-acetates, using perbenzoic acid in chloroform solution. A specific example of the reactions cited in this work is the perbenzoic acid oxidation of pregnane-3($\alpha$)-ol-11,20-dione acetate in 85% yield, corrected for recovery of starting material, to the compound etiocholane-3($\alpha$),17($\alpha$)-diol-11-one diacetate.

In an effort to determine the general utility of this novel reaction, it was considered expedient to test it on somewhat less complicated systems than those found among the steroids. For this purpose, each member of the varied set of simple methyl ketones shown in formulas I-V was subjected to the action of perbenzoic acid in moist chloroform solution, at 23–26°, for a fixed reaction time of ten days.

| | R—$COCH_3$ | | R—O—$COCH_3$ |
|---|---|---|---|
| I. | R = cyclohexyl | VI. | R = cyclohexyl |
| II. | R = phenyl | VII. | R = phenyl |
| III. | R = cyclopropyl | VIII. | R = $\beta$-naphthyl |
| IV. | R = $\beta$-naphthyl | | |
| V. | R = mesityl | | |

It was found that the reaction of perbenzoic acid with a methyl ketone proceeds quite smoothly for the compounds cyclohexyl methyl ketone, acetophenone and $\beta$-acetonaphthone, resulting in the corresponding acetates VI, VII and VIII, respectively, in yields of 67, 63 and 67% based on ketone. This demonstrates quite clearly that the reaction is not confined to these alicyclic systems dealt with in the steroids, but is equally applicable to aromatic systems in the benzene and naphthalene series.

When cyclopropyl methyl ketone (III) was subjected to the action of perbenzoic acid in moist chloroform, however, the expected oxidation did not occur, and indeed only 10% of the theoretically required amount of perbenzoic acid was consumed during the standard reaction period. Furthermore, it would seem that the recovery of 36% of the starting material, unchanged, indicates that the lack of reaction is not to be attributed solely to the possible destruction of the ketone in solution before reaction with perbenzoic acid can occur, but rather to the non-reactivity of the ketone itself.

Having extended the reaction to aromatic systems, it was also considered desirable to ascertain whether the effective action of perbenzoic acid is restricted solely to methyl ketones. To investigate this point, propiophenone was subjected to the action of the per acid under the standard reaction conditions adopted in this work. It was found again that the reaction occurred easily, with the production of the single compound phenyl propionate in 73% yield as based on ketone.

Finally, to determine the possible effect of bulky ortho substituents on the course of the reaction, acetomesitylene (V) was sent through the customary oxidation procedure. It was found that 107% of the required amount of perbenzoic acid was consumed, but the complex reaction product has not been completely analyzed. Further work on this reaction is in progress.

Also in progress and contemplated are further studies on the generality of the reaction, and stereochemical and rate studies on the mechanism of the oxidation. Postulation of a reaction mechanism will await completion of this work.

## Experimental

**General Procedure.**—To 0.10 mole of the pure ketone was added about 315 ml. of a standardized, moist chloroform solution containing approximately 0.12 mole of perbenzoic acid. The resulting cloudy solution was swirled at intervals, and allowed to stand in the dark at 23–26° for ten days. An aliquot was then titrated for residual oxidizing agent in the customary way.[5] A titration was also made on a portion of the stock perbenzoic acid solution which had been subjected to these conditions, to

[a] Corrected for approximate degree of spontaneous decomposition of per acid. [b] Based on ketone and corrected for recovered ketone. [c] M. p. of the β-naphthol itself; not converted to urethan. [d] No mesitol could be detected upon attempted saponification with base.

determine the extent of spontaneous decomposition of the per acid during this time interval.

The chloroform solution was then shaken with dilute sodium carbonate solution to remove the benzoic and residual perbenzoic acids, and this treatment followed by a water wash. The chloroform was then distilled off, and the residual product separated into ketonic and non-ketonic fractions by the use, where possible, of Girard Reagent T. The ketonic fraction, when liquid, was converted to its semicarbazone for purification and identification, while the non-ketonic ester fraction was generally distilled directly under reduced pressure.

A portion of each ester fraction was saponified with base, and the resulting alcohol or phenol converted into its α-naphthylurethan for final identification purposes. In all cases, only a single α-naphthylurethan was obtained from each ester product.

The data obtained from the reactions studied are shown in Table I.

## Summary

The reaction of perbenzoic acid in moist chloroform solution with cyclohexyl methyl ketone, acetophenone and β-acetonaphthone for ten day periods at room temperature furnishes cyclohexyl acetate, phenyl acetate and β-naphthyl acetate, respectively, in yields approximating 65%.

The reaction of perbenzoic acid with cyclopropylmethyl ketone under these conditions does not occur.

Propiophenone reacts smoothly under these conditions to furnish the single product phenyl propionate in 73% yield.

# Reaction of Hydroxyaldehydes with Ethyl Orthoformate. I. Hydroxypivaldehyde

BY ELLIOT R. ALEXANDER AND ELLIOT N. MARVELL[1]

During another investigation the preparation of hydroxypivaldehyde diethyl acetal (II) was attempted by allowing hydroxypivaldehyde (I) to react with ethyl orthoformate.[2] Instead of the expected hydroxy acetal (II), the only product

which could be isolated from the reaction mixture was 3,3-diethoxy-2,2-dimethylpropyl formate (III).

The structure of III was established by saponification of the ester with potassium hydroxide in dry ethanol. Potassium formate was isolated and a new compound was formed which had the correct molar refractivity and analysis for the hydroxy acetal (II). In addition, the structure for the formate ester (III) is supported by an infrared analysis (which showed the presence of an ester group but no hydroxyl group), by the correct molecular refractivity and by a molecular weight determination.

The formation of the ester (III) during the reaction was surprising. An examination of the literature has revealed that apparently the simultaneous formation of acetal and ester is novel in type. One explanation might be that an ester interchange occurred between the hydroxy acetal and ethyl formate or ethyl orthoformate. Experiment, however, has ruled out either of these possi-

(1) Present address: Oregon State College, Corvallis, Oregon.

(2) Claisen, *Ber.*, **29**, 1007 (1896).

bilities. When the hydroxy acetal (II) was treated with ethyl formate or ethyl orthoformate under conditions identical to those used for the preparation of 3,3-diethoxy-2,2-dimethylpropyl formate (III), a very complex mixture of products was formed but no ester could be isolated.

We, therefore, believe that the ester is formed not by a secondary process from the hydroxy acetal but as a result of the direct interaction of ethyl orthoformate with the hydroxy aldehyde. The scope and implications of the reaction are being investigated.

## Experimental[3]

**Reaction of Hydroxypivaldehyde with Ethyl Orthoformate.**—A mixture of 51.0 g. (0.5 mole) of hydroxypivaldehyde,[4] 75.0 g. (0.52 mole) of ethyl orthoformate, 75 ml. of dry ethanol and 1.0 g. of dry ammonium chloride was boiled under reflux for thirty minutes. The volatile products were removed by distilling the reaction mixture until the temperature of the vapors reached 80°. The residual material was washed with two 50-ml. portions of distilled water and the washings were extracted twice with 50-ml. portions of ether. The water washed product and the ether extracts were then combined and dried over anhydrous magnesium sulfate. After evaporation of the ether, the product was distilled through an eight-inch electrically-heated column packed with glass helices. Distillation yielded 31.0 g. (32%) of 3,3-diethoxy-2,2-dimethylpropyl formate, b. p. 93–94° (13 mm.), $n^{20}D$ 1.4200, $d^{20}_{20}$ 0.9633. An infrared absorption spectrum indicated the presence of a carbonyl group, ether linkages, and the absence of a hydroxyl group.[5]

*Anal.*[6] Calcd. for $C_{10}H_{20}O_4$: C, 58.80; H, 9.94; MR 53.60; mol. wt., 204. Found: C, 58.90; H, 10.05; MR, 53.33; mol. wt., 203.

**Preparation of Hydroxypivaldehyde Diethyl Acetal.**—To a solution prepared from 7.0 g. (0.1 mole) of potassium hydroxide in 75 ml. of dry ethanol was added 20.0 g. (0.1 mole) of 3,3-diethoxy-2,2-dimethylpropyl formate. The mixture became warm, turned light yellow, and a flocculent white solid precipitated. Distilled water (1.5 ml.) was added and the mixture was boiled under reflux for three hours. After removing as much alcohol as possible on the steam-bath, the mixture was cooled, and 100 ml. of ether was added. Potassium formate precipitated and was removed by suction filtration. After drying on a clay plate the salt melted at 162–165°. A mixed melting point with an authentic sample melted at 164–165°.[7] After removing the ether from the filtrate, distillation yielded 14.5 g. (84%) of hydroxypivaldehyde diethylacetal, b. p. 55° (1.0 mm.), $n^{20}D$ 1.4259, $d^{20}_{20}$ 0.9335.

*Anal.* Calcd. for $C_9H_{22}O_3$: C, 61.33; H, 11.44; MR, 48.58. Found: C, 61.43; H, 11.48; MR, 48.36.

**Reaction of Hydroxypivaldehyde Diethyl Acetal with Ethyl Orthoformate.**—Hydroxypivaldehyde diethylacetal (10.0 g., 0.057 mole) was treated with ethyl orthoformate under conditions identical with those described for the reaction of hydroxypivaldehyde with ethyl orthoformate. After drying and removing the ether it was attempted to distill the reaction mixture as before. A small amount of ethyl orthoformate and some material boiling at 85–185° (1.0 mm.) was obtained but the major part of the reaction mixture remained in the distilling flask. No pure components could be separated from the volatile portion on redistillation. The high boiling point of this material showed that no hydroxypivaldehyde diethylacetal nor 3,3-diethoxy-2,2-dimethylpropyl formate could have been present.

**Reaction of Hydroxypivaldehyde Diethyl Acetal with Ethyl Formate.**—Freshly prepared hydroxypivaldehyde diethyl acetal (10.0 g., 0.057 mole) was treated with ethyl formate (4.2 g., 0.057 mole) under conditions identical with those described for the reaction of hydroxypivaldehyde with ethyl orthoformate. After removal of the ether, 4.4 g. of ethyl formate (b. p. 52–54°) was recovered which must have contained a small amount of alcohol. On attempted distillation only a clear tough resin was obtained.

## Summary

When ethyl orthoformate is allowed to react with hydroxypivaldehyde the only product which can be isolated is 3,3-diethoxy-2,2-dimethylpropyl formate. This product arises from the direct interaction of the hydroxyaldehyde with ethyl orthoformate and not as a secondary reaction product of hydroxypivaldehyde diethylacetal.

[CONTRIBUTION FROM THE RESEARCH LABORATORIES OF THE CORN PRODUCTS REFINING COMPANY]

# Osmotic Pressure Studies on Corn Amylose

BY F. C. CLEVELAND AND R. W. KERR

The average molecular magnitude of the two fractions of starch still is a matter of some uncertainty. Even for the amylose fraction of corn starch, which has probably received more attention than any other starch component, estimations of size have been made which vary by 100%, or more. On the basis of sedimentation and diffusion studies, Fox[1] set a minimum value of 540 glucose units by the use of the acetate of a subfraction of corn amylose in methyl acetate solutions. Dumbrow[2] used a similar product and obtained a value of 375 by similar methods. Foster and Hixon[3] calculated that the $DP_n$ for corn amylose was 260 from osmotic pressure measurements of the acetate in chloroform. Principally from viscosity measurements by Foster and Hixon,[4] Foster[5] has estimated that corn amylose, extracted

(5) J. E. Foster, Dissertation, Iowa State College, Ames, Iowa, 1943.

from the starch by water at 75°, has a chain length of 175 glucose units. Foster and Hixon used the starch fraction dissolved in ethylenediamine. Meyer, Bernfeld and Hohenemser[6] obtained a value of 270 by osmotic pressure measurements in tetrachloroethane of the acetate of amylose prepared by extensively extracting corn starch with hot water. Caesar, Gruenhut and Cushing[7] have recently reported a value of 220 for corn amylose, using the nitrate in ethyl acetate according to the isopiestic method of Barger.

Precise work in fundamental starch chemistry necessitates having a more accurate knowledge of the size of starch components than is currently available. Work based on improperly prepared fractions and their derivatives and on methods which lack a rigorous derivation may be eliminated from consideration. Even so, the remaining work leads to ambiguous conclusions. A series of osmotic pressure measurements made on the same sample of a carefully prepared corn amylose acetate in three solvents, chloroform, 2,4-pentanedione and pyridine, are reported below. These results are given to point out the magnitude of the problem and to establish perhaps a basis for the interpretation and correlation of available data on other physical measurements which have been reported.

## Experimental

**Preparation of Corn A-Fraction (Corn Amylose).**—Defatted corn starch was treated according to the method of Schoch[8] by using Pentasol to precipitate the amylose from an autoclaved sol. The product was recovered by means of a super-centrifuge, redissolved in hot water and recrystallized by the addition of butanol. The yield was 20.8% by weight. The amount of iodine absorbed by the product was measured potentiometrically by Schoch's[9] modification of the method originated by Bates, French and Rundle.[10] This value was found to be 19.2% and indicates exceptionally high purity.

**Preparation of the Acetyl Derivative.**—Acetylation was performed according to a modification of the method of Mullen and Pacsu.[11] The starch fraction was dispersed in hot aqueous pyridine, the water removed by distillation of the pyridine–water azeotrope and then acetic anhydride was added which accomplished the major part of the acetylation. The modification consisted of adding fused sodium acetate at this point and refluxing for two periods each of one hour on separate days. After recovery of the product by pouring the reaction solution into a large volume of water, the material was disintegrated by wet grinding for a few seconds in a Waring Blendor. The acetate was recovered by filtration and washed five times with 100 times its weight of water, each washing involving a forty-eight-hour soaking period in the wash water. The yield was 97% and the acetyl content, measured by the method of Murray, Staud and Gray,[12] was 44.8%.

(12) T. F. Murray, C. J. Staud and H. LeB. Gray, *Ind. Eng. Chem., Anal. Ed.*, **3**, 269 (1931).

**Osmotic Pressure Measurements.**—Osmotic pressure measurements were made in a cell substantially as described by Fuoss and Mead.[13] The cell was placed in a wooden box and completely surrounded by cotton waste except for the protruding capillary tubes, filling tubes and valves. A thermometer was fastened directly to the metal cell. The assembly was then placed within a glass windowed cabinet provided with heating and cooling coils, air circulation and a mercury thermoregulator. The temperature of the cell was maintained at 30.00 ± 0.05°. Liquid levels in the capillaries were measured by use of a Gaertner Model M-908 cathetometer with an accuracy of ±0.05 mm. The dynamic method for determining osmotic pressures described by Fuoss and Mead[13] was used. These results were in good agreement with frequent determinations by the static method when chloroform and pentanedione were used as solvents. In the case of pyridine, movement of solvent was so slow that measurements based on early dynamic readings created an appreciable error and static measurements were employed entirely. In several determinations with pyridine the results of the static tests at twenty-four hours were checked again at seventy-two hours. No further increase in pressure was observed after the first twenty-four hours.

Uncoated, du Pont No. 450 cellophane, pretreated as described below, was used for membranes. Treatment consisted of soaking the membrane for from six to twenty-four hours in a series of solvent mixtures

Water (50°)
50% water–50% ethyl alcohol
95% ethyl alcohol
50% ethyl alcohol–50% amyl alcohol
100% amyl alcohol
75% amyl alcohol–25% solvent
50% amyl alcohol–50% solvent
25% amyl alcohol–75% solvent
100% solvent

All solvents used were purified by usual procedures starting with reagent grade liquids. Chloroform was distilled over calcium chloride and gave a neutral reaction. 2,4-Pentanedione was purified according to the method of Denoon.[14] As prepared, its reaction was neutral, but the liquid gave a slight acid reaction when exposed to air. Pyridine was refluxed and distilled over barium oxide.

The treated membranes were tested for permeability to the amylose acetates by evaporation of the liquid in the solvent side of the osmometer. In no case was a non-volatile residue obtained.

In preparing solutions, a standard procedure was adopted unless otherwise noted. The acetate was wet with part of the solvent and allowed to stand in a flask overnight. The next morning the flask was heated for fifteen minutes at 55°. For pyridine a temperature of 95° was used. The flask was cooled to 30° and the solution made up to volume.

In setting up the cell, solutions of least concentration were used first with new membranes. After use, the cell was drained, rinsed with solvent and then washed three times with the next higher concentration. A new membrane was used at the beginning of each series. In no case was the membrane found to be permeable to the amylose acetate samples. Some adsorption of the amylose acetate on the cellophane membrane was noted. This was particularly true in very dilute solutions (of the order of 0.05 to 0.20 g. per 100 ml.) and very low osmotic pressures were obtained. Accordingly, measurements were made at concentrations of 0.35 g. per 100 ml. and higher and then only after several prolonged soakings and washings with solutions of the concentration under study.

The osmotic pressures observed were expressed as cm. head of water, divided by the concentration in grams per 100 ml. and these values were plotted against concentration. The curve was extrapolated to zero concentration

and the value $[\pi/C]_{c=0}$ determined. Molecular weights were calculated as $DP_n$ values from the equation

$$DP_n = \frac{RT}{[\pi/C]_{c=0} \times M} = \frac{2.57 \times 10^5}{[\pi/C]_{c=0} \times 288}$$

wherein

$R$ is the gas constant at 30°
$T$ is the absolute temperature
$M$ is the molar weight of an anhydro glucose triacetate group
$\pi$ is the osmotic pressure expressed as cm. head of water

## Discussion of Results

The results of osmotic pressure measurements on corn amylose acetate in solutions of chloroform, pentanedione and pyridine are shown in Fig. 1, and calculated; apparent $DP_n$ values are 455, 675 and 1370, respectively (Table I). All of the liquids employed are good solvents for the acetate, using "good" in the ordinary sense, when comparison is made with other solvents which have been used and reported for amylose and other carbohydrate esters, such solvents for example as methyl acetate, ethyl acetate, tetrachloroethane and benzene. The rate of solution was reasonably high, particularly in the case of chloroform and pentanedione. The solutions were sparkling clear and remained so after standing at room temperatures for several days. In the case of pyridine the observation was made, however, that on prolonged standing, *e.g.*, thirty days or more, solutions containing 1% of corn amylose acetate began to precipitate a gel-like material on the bottom of the flask.

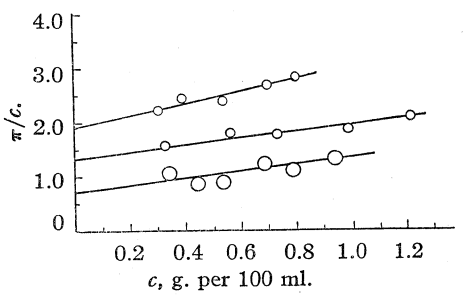

Fig. 1.—Osmotic pressure measurements of the acetate of corn amylose (no. 27) in: chloroform (top curve), 2,4-pentanedione (middle curve), pyridine (bottom curve).

It is well known that the amyloses are polydisperse.[15,16,17] Accordingly, one may expect some variation between samples when substantially the same procedure is used for isolation owing to minor variations in technique and the possibility of a subfractionating effect during repeated recrystallizations of the product. Another sample of corn amylose (no. 45), gave a value of 495 when the acetate was used in chloroform. Corn amylose prepared by butanol precipitation and recrystallization from aqueous butanol ($C$ 1/13), and previously used to prepare subfractions,[17] was converted into the acetate and from osmotic pressure measurements in chloroform a $DP_n$ of 435 was calculated in this solvent.

TABLE I

APPARENT $DP_n$ VALUES FOR CORN AMYLOSE ACETATE SAMPLES IN VARIOUS SOLVENTS AT 30°

| Sample | $DP_n$ in chloroform | $DP_n$ in pentanedione | $DP_n$ in pyridine |
|---|---|---|---|
| Corn amylose (no. 27)[a] | 455 | 675 | 1370 |
| Corn amylose (no. 45)[a] | 495 | ... | |
| Corn amylose (no. C 1/13)[b] | 435 | ... | |
| Corn amylose subfraction I | 250 | 370 | |
| Corn amylose subfraction II | 390 | 575 | |
| Corn amylose subfraction III | 525 | 795 | |
| Corn amylose subfraction IV | 675 | ... | |
| Corn crystalline amylose | 225 | 465 | |

[a] Pentasol precipitated. [b] Butanol precipitated.

Four subfractions of the amylose sample, $C$ 1/13, were prepared by ethylenediamine–ethyl ether phase separation technique.[17] These subfractions were acetylated and osmotic pressure measurements made in chloroform and in pentanedione solutions at 30°. The results for calculated $DP_n$ values are shown in Table I. Considerable variation, over 100%, was found in the chain lengths of the amylose subfractions. Again, higher values, about 50% higher, were found when pentanedione was used than when chloroform was employed as the solvent.

A corn amylose fraction, called corn crystalline amylose,[16] prepared by extracting corn starch with water at 75° and crystallizing the product from the extract by the addition of butanol, formed an acetate which had an apparent $DP_n$ of 225 in chloroform and 465 in pentanedione. This product is of the same type studied by Dumbrow[2] in methyl acetate solution. Foster[5] estimated a $DP$ of 175 for this fraction from viscosity measurements in ethylenediamine, as stated above.

The great variation in length of the amylose chains comprising any one sample no doubt explains in part the different values obtained when different systems are used for the measurement of average $DP$ values. It would be expected that osmotic pressure measurements from which number average molecular weights are calculated would give different results for corn amylose than viscosity or light-scattering data which are functions of weight-average molecular weight. Normally expected variations between samples would account for some discrepancy among the results of several investigators using the same system of measurement. However, these considerations do not account for the very large differences between the results, above reported, and presented in Table I when the same samples were used in the same apparatus and the solvent employed was the only variable. These data suggest that amylose derivatives are associated in organic solvents, to different extents, depending on the solvent.

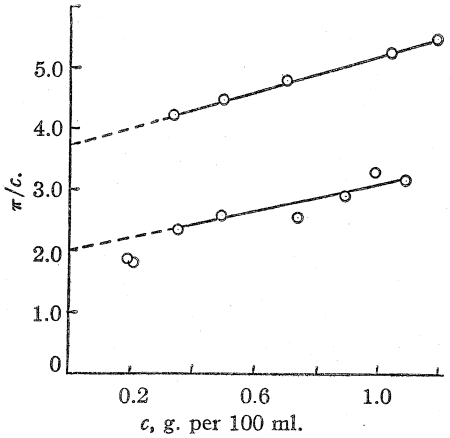

Fig. 2.—Osmotic pressure measurements, acetate of corn crystalline amylose in: chloroform (top curve), 2,4-pentanedione (bottom curve).

Doty, Wagner and Singer[18] have called attention to the fact that polymers may not be completely dissociated in solution and that the simple, difficultly refutable assumption that we are dealing with molecular dispersions in physical measurements on high polymer solutions is not always justified. This work deals principally with polyvinyl chloride polymers or co-polymers with the acetate, and the conclusions are limited by the consideration that linear organic halogen compounds might be expected to associate because of electronegative halogens. One would also expect the carbohydrates which have many hydroxyl groups along their chains to associate, for which reason they are usually derivatized for physical studies. However, carbohydrate esters, such as cellulose acetate, were shown by Doty and his coworkers also to give different osmotically determined molecular weights in acetone and in methyl "cellosolve." Cellulose acetate fraction 9 of Sookne and Harris[19] was found to have a molecular weight of 53,000 in acetone and 74,400 in methyl "cellosolve."

We had available a portion of this fraction 9 and found that its number average molecular weight in chloroform[20] at 30° was 47,600. This result invites drawing the general conclusion that linear carbohydrate acetates are associated to different degrees in various solvents and that association is least in chloroform.

Steurer[21] and others have proposed from the great difference in osmotic pressure of ethyl cellulose in the two solvents, chloroform and benzene, that the lower osmotic pressure curve for benzene solutions, relating $\pi/C$ to $C$, turns abruptly upward as infinite dilution is approached and at zero concentration $\pi/C$ equals the value for that of chloroform solutions. Possibly this is so. However, it should be noted that at concentrations of 0.1 g. per 100 ml. and less, the experimental error and inherent errors become very large and data taken in this concentration range are less reliable. Accordingly, we have made few observations at very low concentrations, but of those that were taken in pentanedione, the majority of values fell below rather than above the curve extrapolated from more reproducible values.[22] We have attributed these lower osmotic pressure values at low concentration to the effect of adsorption of solute by the new membrane. On the other hand, if one reuses cellophane membranes for very dilute solutions which have previously been employed at solute concentrations in the range of 0.3 to 1.2 g. per 100 ml., then one obtains, with amylose acetate at least, abnormally high osmotic pressures.

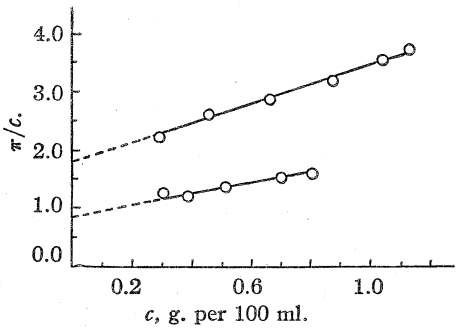

Fig. 3.—Osmotic pressure measurements in chloroform of the acetates of: corn amylose, no. 45 (top curve); tapioca amylose (bottom curve).

Even were curves obtained in some solvents which showed a radical change in slope from positive to negative within the concentration range below 0.1 gram per 100 ml., one could hardly expect to extrapolate these curves with any degree of certainty and the conclusion would still follow that the improper choice of solvent may lead to an inaccurate estimate of molecular weight. Furthermore, such data would not be inconsistent with the view that the solute associated more in these solvents than in those which gave a straight line relationship at some higher osmotic pressure level.

The association noted for corn amylose acetate in pentanedione and pyridine appears to be exaggerated for starch molecules, both linear and branched, which have a *DP* greater than that of the corn amylose samples. For example, Foster and Hixon[3] and F. Horan[23] observed that the amylose fraction from potato starch formed an acetate which swelled and only partially dissolved, even in chloroform. Tapioca amylose acetate (Pentasol precipitable fraction) appears to be very nearly the limit in respect to molecular size for visual solubility in chloroform, or rather lack of visual insolubility. The acetate swells at first and then appears finally to give a homogeneous dis-

persion which is optically void on heating to 55°. The apparent $DP_n$ in chloroform was found to be 1050 at 30°. The effect was even more pronounced in the case of corn amylopectin acetate (fraction not precipitated by Pentasol). During acetylation of this fraction, the reaction mixture set to a gel when the ratio of carbohydrate to pyridine plus acetic anhydride was 2 to 100 and it was necessary to reduce this ratio to 1 to 100 in order to obtain a fluid medium and to complete the acetylation. The triacetate remained insoluble, for the most part, even with prolonged boiling in chloroform or mixtures of chloroform and alcohol. However, it was found that corn amylopectin subfraction III[16] forms a triacetate which dissolves in chloroform and for which a $DP_n$ value of 635 was found. The acetates of subfractions of higher molecular weight were only partially soluble. These experiments leave no doubt of the very great association which can exist between these carbohydrate molecules (or molecular entanglement), particularly in very high molecular weight ranges and which may operate to some extent even in the low molecular weight ranges.

The reluctance of carbohydrate derivatives to disperse molecularly in organic solvents leaves open to question the results of all physical measurements of molecular weight which involve a study of solutions whether the method consists of osmotic pressure, viscosity, light scattering or sedimentation measurements. It is believed that the extent of dissociation depends not only on the solvent which is employed but possibly also on the temperatures used and on the type of starch derivative, and that these considerations explain in part at least the wide spread in values reported in the past for the chain length of corn amylose.

For the present in fundamental studies it would seem wise to adopt the use of a readily prepared derivative, such as the acetate, and a solvent such as chloroform which gives a low order of molecular weight values by osmotic pressure measurements and a definite procedure in respect to temperature and time, until these values can be checked by a completely independent method. Boiling temperatures are suggested for preparing the solutions and 30° for measurement.

## Conclusions

The apparent $DP_n$ values for the acetates of corn amylose and its subfractions have been calculated from osmotic pressure determinations using selected solvents. Of those used, chloroform gave the lowest $DP_n$ values; the acetate of one corn amylose sample prepared by Pentasol precipitation was found to have a $DP_n$ of 455 and another 495. The acetate of a butanol precipitated corn amylose had a $DP_n$ of 435. Subfractions of the latter varied in $DP_n$ between 250 and 675.

Higher values for $DP_n$ were found in other solvents tried and this may be explained as being due to association of the acetates in these solvents. Starch acetate samples tend to become visibly insoluble, or partly insoluble in organic solvents as the $DP$ exceeds that of corn amylose. Tapioca amylose acetate appeared to be very nearly the limit in respect to molecular size for solubility in chloroform and showed a $DP_n$ of 1050 in this solvent.

# The Preparation of Boron Hydrides by the Reduction of Boron Halides

BY DALLAS T. HURD

It recently (1945) has been found that boron hydrides, specifically diborane and diborane monohalides, can be synthesized by the reduction of boron halide vapor with hydrogen in the presence of metals[1] at elevated temperatures.

In addition it has been discovered that the hydrides of the alkali and alkaline earth metals will reduce gaseous boron halides to diborane at temperatures above about 200°.[2]

## Experimental

**A. Reductions Involving Metals.—1.** Boron trichloride gas[3] and hydrogen in *ca.* 1:3 ratio were passed through a vertical bed of −20 mesh aluminum granules in a 1″ Pyrex tube heated to 350°. After a short induction period aluminum chloride was observed subliming out of the reaction zone and the gas issuing from the reactor became spontaneously inflammable, burning with a green flame.

Chemical tests on samples of the exit gas indicated the presence of boron hydrides. These included the standard tests such as the decolorization of hanging drops of permanganate solution, formation of chocolate brown precipitate on paper soaked in silver nitrate solution, formation of hydrogen bubbles in hanging water droplets, as well as other chemical reactions characteristic of the boranes. The exit gas gave negative results on all of these tests until the temperature necessary for reaction had been reached.

To study the reaction in more detail a larger apparatus was designed (Fig. 1) comprising a reactor tube $2^1/_2$ in. in diameter, heated in a cylindrical furnace, followed by a trap to collect the aluminum chloride formed during the reaction and by traps at −80 and −190° to collect the reaction products. The side arm leading from the reactor to the aluminum chloride trap was kept warm electrically to avoid deposition of the halide in the tube. The boron chloride and hydrogen were metered in through rotameters, the hydrogen being purified in a conventional set-up. The

(1) A general criterion for the metal is that it be more electropositive than boron.

(2) Mention should be made of the reactions in ether solution between boron halides and the hydrides of electropositive metals to yield boron hydrides discovered by H. I. Schlesinger and his coworkers at Chicago, Ill.

(3) Boron trichloride supplied by the Cooper Metallurgical Laboratories, Cleveland, Ohio; purity over 98%.

reaction temperature was followed by a thermocouple embedded in the charge of aluminum.

Upon distillation of the condensed products following a run it was observed that the material in the trap at −190° was mostly diborane together with some hydrogen chloride. The greater portion of the boron hydride was collected at −80° as diborane monochloride ($B_2H_5Cl$) along with excess boron trichloride. Hydrolytic analyses of the distillation fraction boiling at −92.5° established the identity of the principal reaction product as diborane.

A number of experiments were made in this and in similar but smaller apparatus with various ratios of gaseous reactants and at temperatures ranging from 300 to 500°. Representative data are tabulated in Fig. 2. The products initially were analyzed by slow distillation in a Podbielniak automatic still at atmospheric pressure.[4] (With this procedure the unstable diborane monochloride is decomposed into diborane and boron chloride during the distillation.) Later a method for determining the amount of diborane by direct hydrolysis of samples of the exit gas was employed.

In no case were the higher hydrides of boron found in the condensed products in amounts sufficient to be detected. There was evidence, however, that small quantities of solid boranes such as $B_{10}H_{14}$ were caught in the first trap along with the aluminum chloride.

The reaction apparently did not proceed at temperatures much below about 300°.

Upon removal of the tube from the furnace following a reaction, the granular aluminum charge frequently was found to be coated with a dark blue deposit. This blue deposit, readily soluble in dilute hydrochloric acid, conceivably may be connected with the mechanism of the reaction as an active intermediate since its character and amount did not seem to change with variation of the reaction time even in long runs where channeling of the charge due to removal of aluminum would occur. The rapidity with which the aluminum was dissolved by dilute hydrochloric acid indicated also that the usual oxide coating on the metal had been removed by the reaction.

Several analyses of used reactor charges were made by dissolving weighed samples in hydrochloric acid and weighing the insoluble residue as free boron. These indicated that only a very small percentage of the boron trichloride passing through the reactor was lost by reactions to form free boron. Except in the runs at very high temperatures where as much as 5% loss might be encountered, the amount of free boron generally was less than 1%.

Material balances on a number of the runs showed that in general the over-all loss of boron in the reactor was quite low. For example, 18 g. of boron trichloride together with hydrogen in 1–6 mole ratio was charged to the reactor at 360° during the extraction of a sample from the portion of the run measured. This amount of boron chloride is equivalent to 1.66 g. of boron. Collected in the sample trap was 13.5 g. of boron trichloride and 0.47 g. of diborane (after distillation) representing an amount of boron equal to about 1.60 g.

It was found advantageous to purify and dry the hydrogen used, not from any marked improvement in the reaction as a result, but because it avoided the plugging of lines and loss of material resulting from the hydrolysis of boron trichloride to boric oxide by traces of water.

Several types of aluminum were tried with no marked difference in performance except for a general increase in the conversion with the surface area of the metal. With very fine material, however, channeling and a resulting loss of contact area was encountered.

2. Magnesium, zinc and sodium (molten) behaved similarly toward mixtures of boron trichloride and hydrogen although the first two gave poorer yields than aluminum. There is reason to believe, however, that with a suitable method of providing contact between molten sodium and the gaseous reactants, good yields of diborane could be obtained.

3. Boron trifluoride and hydrogen in about 1:2 ratio were passed through heated magnesium powder. At about 375° a violent reaction ensued and the temperature of the charge rose rapidly. Small amounts of diborane were detected in the exit gas and some of this material was condensed and distilled. Upon completion of the experiment it was seen that the reaction must have been very exothermic since the charge was blackened and local overheating had warped the glass of the reactor tube. This very vigorous reaction and low yield also were encountered in trying to produce reaction of boron fluoride and hydrogen over aluminum.

(4) Distillation analyses were made by Dr. L. V. McCarty.

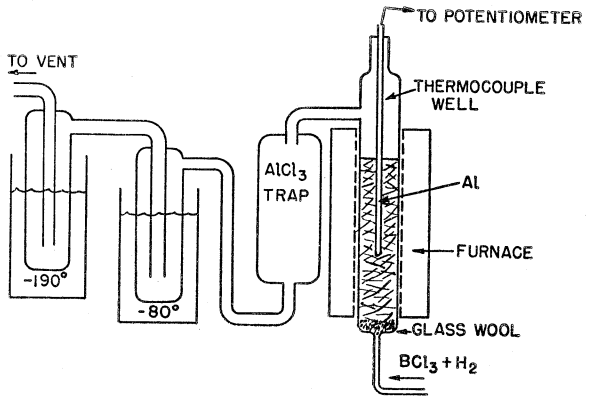

Fig. 1.—Diborane apparatus.

4. An experiment in which hydrogen was bubbled through boron tribromide at 25° and into a charge of granular aluminum at 250° produced aluminum bromide and small amounts of diborane. The yield was not high in the one reaction attempted.

**B. Reductions with Metal Hydrides.**—1. A charge of powdered sodium hydride[5] was placed in an inclined 1" Pyrex tube and a mixture of boron fluoride and hydrogen in *ca.* 1:2 ratio was passed through the charge while the temperature gradually was increased. At about 180° boron fluoride disappeared entirely from the exit gas and the presence of considerable quantities of diborane was confirmed. It later was shown that the presence of hydrogen was necessary to sweep the diborane product out of the hot zone to avoid pyrolysis. An experiment using nitrogen in place of hydrogen gave similar results so it is questionable whether either gas had any direct effect on the reaction.

The reaction was halted by the plugging of the reactor tube and it was found upon opening the furnace that much of the gray sodium hydride had been changed to a white salt, presumably either sodium fluoride or sodium borofluoride. No perceptible darkening of the charge which might indicate the deposition of free boron was observed.

Although no quantitative data as to the conversion of boron fluoride to diborane were obtained it seems quite likely, considering the total disappearance of boron fluoride from the exit gas, the amount of diborane produced, and the absence of pyrolysis products in the reactor, that the yield was high. With a suitable method of contacting gases with solids this method for the preparation of diborane may be of interest. There is the possibility, however, depending upon the reaction conditions, of losing boron fluoride by converting sodium fluoride to sodium borofluoride.

2. Boron trichloride and hydrogen passed through a charge of powdered sodium hydride at 200–220° reacted to produce diborane in the exit gas and sodium chloride in the charge. Both of these materials were identified by chemical tests. Boron trichloride alone passed rapidly over heated sodium hydride gave faint tests for diborane in the exit gas but the reaction was very exothermic and much darkening of the charge was noted. In all of these runs the tubes plugged quite rapidly due to build-up of sodium chloride in the charge.

(5) Sodium hydride generously supplied by the du Pont Electrochemicals Dept., Niagara Falls, N. Y.

Boron trichloride and hydrogen also reacted with crushed calcium hydride to produce spontaneously inflammable gaseous products which responded to the conventional tests for diborane. Calcium chloride was formed in the charge.

3. It is of interest to note in passing that some chemical evidence has been obtained for the formation of boron hydrides in the violent reaction that ensues upon heating mixtures of powdered anhydrous boric oxide and lithium hydride or sodium hydride. This hardly seems desirable as a preparative method, however.

## Discussion

It indeed appears surprising that a substance as thermally unstable as diborane can be synthesized under conditions that ordinarily would result in a rather rapid pyrolysis of this material. Several factors, however, may explain why so little pyrolysis actually does occur and why the losses of boron are small.

The actual contact time during which a unit of gas remained at elevated temperatures was in most cases rather short (Table I). This would tend to minimize pyrolysis losses. Also, there generally has been present in the reaction zone a large excess of hydrogen over the amount actually needed for the formation of boron–hydrogen compounds. Although the effect of hydrogen in inhibiting the decomposition of hydroborons at room temperature is well known, it well may be that this effect is not operative at elevated temperatures and the hydrogen may be effective largely by diluting the diborane product.

TABLE I

DIBORANE PREPARATIONS

| | T, °C. | $H_2$/$BCl_3$ | C. T.[a] | $Al_{size}$ | Condensed product, mole per cent. $B_2H_6$ | HCl | $BCl_3$ | Conversion, %[b] |

| 6 | 500 | 6–1 | 4″ | −30 | 6.7 | 0.9 | 92.4 | 12.5 |
| 7 | 450 | 6–1 | 6″ | −30 | 17.2 | 3.9 | 78.9 | 30 |

[a] C.T. Calculated contact time in hot zone, 1″ dia. reactor. [b] Per cent. $BCl_3$ converted to $B_2H_6$, assuming no boron loss in the reactor.

In addition it may be possible that more stable monoboron compounds, *e. g.*, $BHCl_2$, $BH_2Cl$, may be the primary products of a stepwise reaction and that these transient compounds later undergo rearrangement into diborane and boron trichloride when out of the reactor hot zone.

In the runs where boron fluoride was used no inflammation was noticed even though large quantities of diborane were present at times in the exit gas. This may indicate either that diborane monofluoride ($B_2H_5F$) is not formed in the reaction or is not spontaneously inflammable if it is formed.

Reasoning from the experiments with metal hydrides, the reduction of boron halides with hydrogen over metals similarly may appear at first glance to involve the initial formation of reactive hydrides on the surface of the metal followed by replacement reactions. There is, however, little direct evidence to support this over other possible mechanisms, and at the present time the exact nature of the reaction is not known.

## Summary

Diborane and diborane monohalides have been produced by the reduction of boron halides with hydrogen over active metals at elevated temperatures.

The reaction of gaseous boron halides with active metal hydrides also has been found to produce diborane.

# Liquid–Liquid Solubility of Perfluoromethylcyclohexane with Benzene, Carbon Tetrachloride, Chlorobenzene, Chloroform and Toluene

BY J. H. HILDEBRAND AND D. R. F. COCHRAN

The extraordinary solvent properties of fluorocarbons which have come to light during the last few years have been considered in two recent papers from this Laboratory, one by R. L. Scott,[1] who gave "solubility parameters" for a number of fluorocarbons and showed their general harmony with available solubility data, and another by Benesi and Hildebrand[2] who reported a figure for the solubility of iodine in normal perfluoroheptane at 25° and showed that the remarkably small solubility, only 0.007 the solubility in an ideal solution, does not overstrain existing solubility theory for regular solutions.[3] This instance of the adequacy of theory to cope with an extreme departure from Raoult's law encouraged us to measure other fluorocarbon solubilities in the expectation that they would have much more than merely empirical value and could be used in connection with refinements in the general theory.

The large molal volumes of the fluorocarbons compared with the corresponding hydrocarbons leads to unusually low "internal pressures" or "cohesive energy densities," while their high

molecular weights aid in maintaining them in the liquid state; the net result of which is to make many of their solutions with ordinary liquid hydrocarbons deviate from Raoult's law to such an extent as to form two liquid phases, a state of affairs comparatively rare among non-polar liquids. Since liquid–liquid solubilities are easily determined, we have used this means of further comparing theory with experiment.

**Materials.**—We are indebted to the Jackson Laboratory, du Pont de Nemours Co., for the supply of perfluoromethylcyclohexane. The benzene, "reagent grade, thiophene free," showed no color with concentrated sulfuric acid. It was dried with calcium chloride and distilled. The carbon tetrachloride, "reagent grade," was washed with concentrated sulfuric acid, then with water, and dried over calcium chloride. The chloroform, also "reagent grade," was washed successively with concentrated sulfuric acid, sodium carbonate aq., water, and dried over calcium chloride. The toluene was that used by Benesi and Hildebrand.[2] The chlorobenzene, "reagent grade," was dried over phosphorus pentoxide and distilled. All the above distilled within 0.1°.

**Procedure.**—The two liquids were measured by means of a carefully calibrated pipet made of 2-mm. capillary tubing into tubes 10 cm. long and 7 mm. diameter through capillary stems at right angles. The liquids were frozen in liquid nitrogen after introduction and sealed in. These tubes were heated above the consolute temperatures in a water-bath for 0 to 90° and in sulfuric acid for the range 90 to 130°. On slowly lowering the temperature while rocking a tube, the unmixing temperature of a solution could be accurately determined.

**Results.**—Table I gives the consolute temperatures of the different solutions together with the corresponding volume fractions of the fluorocarbon as measured at 25°, and the corresponding mole fractions. These temperatures are plotted against mole fraction in Fig. 1 and against volume fraction in Fig. 2. In Table II are given the critical mixing temperatures read from the maxima of these curves, also the critical compositions determined by aid of the assumption of rectilinear diameter, as in the analogous case of liquid–gas equilibrium.

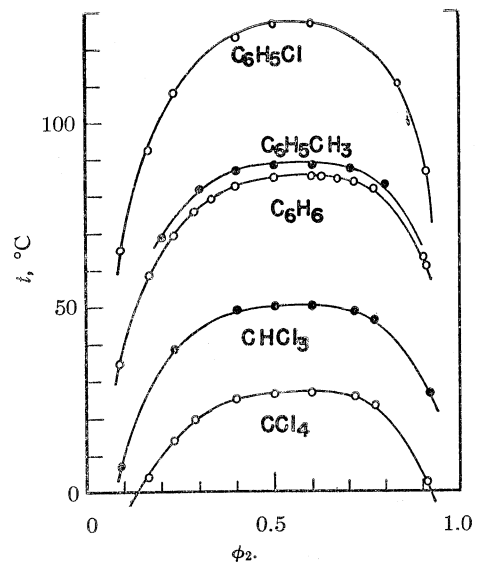

Fig. 2.—Consolute temperatures of perfluoromethylcyclohexane solutions *vs.* volume fraction of second component.

TABLE II

COMPARISON BETWEEN OBSERVED AND CALCULATED VALUES OF CRITICAL COMPOSITIONS AND TEMPERATURES FOR SOLUTIONS OF PERFLUOROMETHYLCYCLOHEXANE (COMPONENT 1)

| | v cc., 25° | Crit. $x_2$ obs. | Crit. $x_2$ calcd. | $T_c$ obs. | $T_c$ calcd. | $\delta_2$ | $\delta_1$ calcd. |
|---|---|---|---|---|---|---|---|
| $C_6F_{11}CF_3$ | 195 | | | | | | |
| $CCl_4$ | 97 | 0.70 | 0.74 | 300.0 | 269 | 8.6[1] | 5.8 |
| $CHCl_3$ | 81 | .74 | .78 | 323.5 | 325 | 9.0[a] | 6.0 |
| $C_6H_6$ | 89 | .73 | .76 | 358.5 | 360 | 9.15[1] | 6.0 |
| $C_6H_5CH_3$ | 102 | .69 | .71 | 362.0 | 324 | 8.9[1] | 5.8 |
| $C_6H_5Cl$ | 107 | .69 | .72 | 400.0 | 464 | 9.5[1] | 6.3 |

[a] This value is consistent with the solvent power of chloroform for other substances; the value of $(\Delta E^v/v)^{1/2}$ is 9.3. See J. H. Hildebrand, "A Critique of the Theory of Solubility of Non-electrolytes," *Chem. Revs.*, in press.

**Comparison with Theory.**—The regular solution equations[4] for liquid–liquid solubility are as follows, for the mole fraction at the critical point and the critical temperature, respectively

$$x_1 = \frac{(v_1^2 + v_2^2 - v_1v_2)^{1/2} - v_1}{v_2 - v_1} \qquad (1)$$

and

$$RT_c = \frac{2x_1x_2v_1^2v_2^2}{(x_1v_1 + x_2v_2)^3}(\delta_1 - \delta_2)^2 \qquad (2)$$

where the v's denote molal volumes, $x$'s mole fractions, and $\delta$'s are what we have been calling the "solubility parameters," which are ordinarily the square root of the energies of vaporization per cc., *i. e.*, $\delta = (\Delta E^v/v)^{1/2}$. In this paper we shall distinguish the fluorocarbon by the subscript 1.

It has been pointed out that eqn. 1 yields values of the critical composition not far from those obtained by the simpler assumption that the maximum occurs at equal volume fractions, *i. e.*, $\delta_1 = \delta_2 = 0.5$, as shown in Fig. 2. The curves are so flat at the top that this may suffice for ordinary purposes. It has been pointed out, further, that eqn. 2 yields values of $T_c$ not seriously different from a greatly simplified equation

$$4RT_c = (v_1 + v_2)(\delta_1 - \delta_2)^2 \qquad (3)$$

In Table II can be seen comparisons between observed and calculated values of the critical compositions and temperatures. The "observed" values of $x_2$ were taken from the solubility curves by aid of the assumption of rectilinear diameter, as in gas–liquid density curves. The curves are so flat around the maximum that these values are subject to an error of at least ±0.02. The "calculated" values were obtained from Equation 1 by substituting the molal volumes for 25°, given in the first column of figures. It would be preferable to use the molal volumes at the critical temperatures, but since we lack some of the necessary density data and in view of the uncertainty in fixing the "observed" values, a closer check is hardly to be desired.

We have found that values of $\delta_1 - \delta_2$ calculated from $T_c$ by eqn. 3 agree within a few per cent., *i. e.*, well within the limit of the unavoidable errors and uncertainties of the method, with those derived by aid of the more complicated eqns. 1 and 2, therefore eqn. 3 has been used in the following calculations. Substituting the observed values of $T_c$ and the v's for 25° gives $\delta_2 - \delta_1$, which, subtracted from the $\delta_2$-values in the next to the last column gives the calculated values of $\delta_1$ for perfluoromethylcyclohexane given in the last column. In so calculating we have neglected the effect of temperature upon both $\delta_1$ and $\delta_2$ and on this account alone we should not expect uniform values for $\delta_1$ "calculated." In addition, the dipole moments of chloroform and chlorobenzene might be expected to cause some disturbance. It is sufficient to find that these values of $\delta_1$ for the fluorocarbon derived from solubility data agree well with the value 6.0 at 25° set by Scott[1] long before this work was undertaken. Reversing the calculation, we have calculated $T_c$ for each solution using this value of $\delta_1$ in combination with the $\delta_2$-values given in the table. It will be seen that while the result is far from precise it has value, nevertheless, in giving the general region in which two liquid phases can coexist. The high critical temperature with toluene is not what its $\delta$-value, less than that of benzene, would lead us to expect. A similar reversal has been noted by Hildebrand and Jenks[5] in the solubilities of sulfur in these two liquids. An explanation of such facts must await refinements in the theory as well as additional data, such as partial molal volumes.

## Summary

Liquid–liquid solubility curves have been determined for binary mixtures of perfluoromethylcyclohexane with five other liquids, giving the following results for the critical solution temperatures in °C. and the mole fractions of the second components: carbon tetrachloride, 26.8°, 0.70; chloroform, 50.3°, 0.74; benzene, 85.3°, 0.73; toluene, 88.8°, 0.69; chlorobenzene, 126.8°, 0.69.

These values agree within the usual limits of error with those calculated by aid of the equations for regular solutions and the value 6.0, previously derived by Scott for the "solubility parameter" (the square root of the energy of vaporization per cc.) of the fluorocarbon.

# The Kinetics of the Oxidation of 2-Deuteropropanol-2 by Chromic Acid

BY F. H. WESTHEIMER AND NICHOLAS NICOLAIDES

The rate of the chromic acid oxidation of isopropyl alcohol to acetone has been shown to be proportional to the concentrations of isopropyl alcohol and the acid chromate ion, and proportional to the square of the concentration of hydrogen ion.[1] Although these kinetics fix the composition of the activated complex in the oxidation, they leave unanswered many questions concerning the mechanism. Specifically, they do not show whether the oxidative attack upon the alcohol molecule is at the secondary hydrogen atom, at the hydroxyl hydrogen atom,[2] or elsewhere. This question can be answered by studying the rate of oxidation of 2-deuteropropanol-2.

Both experimental and theoretical considerations show that, if the deuterium atom of 2-deuteropropanol-2 is removed in the rate-controlling step of the oxidation, the 2-deuteroalcohol will be oxidized much less rapidly than the corresponding hydrogen compound. On the other hand, if the rate determining step does not involve the removal of this deuterium atom, the oxidation rates for the hydrogen and deuterium compounds should be almost if not exactly identical. This test for the direct removal of a hydrogen atom depends upon the fact that C–H and C–D bonds differ in their zero-point energies. The method is completely general[3]; it has been strikingly applied by Reitz[4] in a study of the rate of enolization of acetone and of the deuteroacetones. In the present work, it has been found that 2-deuteropropanol-2 is oxidized by chromic acid only about one-sixth as fast as is ordinary isopropyl alcohol; it follows unambiguously that the secondary hydrogen atom is removed during the rate controlling step of the reaction.

## Experimental

**Deuterium.**—The deuterium for these experiments was made by vaporizing 12.1 g. of Norwegian heavy water (Norsk Hydro Elektrish Kvaelstofaktieselskat 99.73% $D_2O$; $d^{20}_4$ 1.10516) over Grignard magnesium heated electrically to 490 ± 25° in a heavy-walled combustion tube.[5] The resulting deuterium gas was passed through alkaline permanganate and stored over a saturated solution of sodium sulfate.

**2-Deuteropropanol-2.**—2-Deuteropropanol-2 was made by the catalytic deuteration of acetone according to the directions of Anderson and MacNaughton.[6] Eighty-six grams of acetone (J. T. Baker reagent grade, previously dried with potassium carbonate and distilled) was deuterated with 10.8 liters of deuterium gas, by means of 1.62 g. of Adams catalyst promoted with a few crystals of ferrous chloride. The deuteration required five days, during which time the catalyst was reactivated several times by briefly stirring the reaction mixture in air.

The reaction mixture was then fractionated through a small Podbielniak column (about 25 theoretical plates) to remove the large excess of acetone. When all the acetone had been removed, 54 cc. of water was added in order to exchange the hydroxylic deuterium of the isopropyl alcohol with the hydrogen of the water. Then the distillation (through the same column) was resumed. The fraction collected was 15 g. of the azeotropic mixture of isopropyl alcohol and water. Some of this azeotrope was used directly for rate measurements; some was re-equilibrated with water. The latter portion was prepared by adding 8.5 g. of the azeotrope to 100 g. of water, and then redistilling the mixture through the same Podbielniak column. The composition of the azeotrope was calculated as 90.1% deuteroisopropyl alcohol and 9.9% water from the combustion analysis of the material. (Microanalysis by Wm. Saschek, C, 53.40; H, 12.82.) Both portions of the azeotrope (that equilibrated once and that equilibrated twice) had the same rate of oxidation.

The work of Anderson and MacNaughton[6] suggests that in the deuteration all the deuterium gas is taken up at the carbonyl group, and the resulting product should be pure $CH_3\underset{D}{C}(OD)-CH_3$. If this were the fact, the product after equilibration with water should have been pure $CH_3\underset{D}{C}(OH)-CH_3$. Regrettably, however, the isopropyl alcohol which we prepared was a mixture containing only about 55% of the desired 2-deuteroalcohol. Fortunately the qualitative

| D-IV | .005520 | .2138 | .1082 | .40 | | 1.47 | |

[a] In those experiments prefixed with the letter "D," the isopropyl alcohol used contained 55% deuterium on the central carbon atom. [b] The symbol $k_{DI}$ represents the rate constant for the isotopically impure 2-deuteropropanol-2.

conclusions here reached (see the discussion) do not depend upon the isotopic purity of the alcohol used. (The mixture of isopropyl alcohol and deuteroisopropyl alcohol used for the oxidations is hereafter called isotopically impure deuteroisopropyl alcohol, or, when the meaning is clear, simply "2-deuteropropanol-2"). The material was analyzed for deuterium by burning a sample in air on a sintered glass wick and determining by a float method the density of the water formed. The procedure of Brown and Eberly[7] was followed, and was found to be reliable to within 0.01 mole per cent. of the deuterium oxide in the water analyzed. In one experiment 0.4855 g. of the azeotrope was mixed with 1.3085 g. of pure, dry, ordinary isopropyl alcohol; before combustion the mixture was dried over lime and distilled. The water formed contained 2.01 mole per cent. deuterium oxide, corresponding to 0.65 gram atom of deuterium per mole of the (isotopically impure) 2-deuteropropanol-2.

Evidently the "2-deuteropropanol-2" contained a fairly large proportion of ordinary isopropyl alcohol, with hydrogen rather than deuterium on the center carbon atom. This hydrogen could not have come from the heavy water, which was of good quality (the residual heavy water left over from the investigation had a density, $d^{20}_4$, of 1.1040, corresponding[8] to 98.7 mole per cent. deuterium oxide); neither could the hydrogen have come from water vapor in the deuterium gas, since the latter was dried over calcium chloride before use. But hydrogen–deuterium exchange does occur between acetone or isopropyl alcohol and deuterium gas at room temperature in the presence of platinum black,[9] and therefore this exchange may have occurred here in the presence of Adams catalyst. A small amount (0.1 g. atom per mole) of deuterium was observed (see below) in the acetone obtained by oxidation of the deuterated isopropyl alcohol here prepared. If exchange occurred with all the acetone used in the hydrogenation to the extent of 0.1 g. atom per mole, this exchange would be sufficient to supply the hydrogen needed to form the isotopically impure isopropyl alcohol actually obtained. Extensive further research will be needed to decide whether the method of preparation of the catalyst and other experimental details control the extent of the exchange, or whether such exchange is inevitable in hydrogenations over Adams catalyst, although, because of the limited extent of exchange, it sometimes escapes notice. In any event, it was necessary to find how much of the deuterium was attached to the secondary carbon atom, and how much occurred in the methyl groups. The isotopically impure 2-deuteropropanol-2 was therefore oxidized to acetone. The oxidation method of Anderson[10] (where rather concentrated sulfuric acid is employed) was abandoned in favor of the gentler Oppenauer method.[11] Four and two-tenths cc. of the deuteroisopropyl alcohol and 16 g. of fluorenone (Eastman Kodak Co. m. p. 80.5–81.5°) were refluxed for six hours with 1.7 g. of aluminum tertiary butoxide[12] in 70 cc. of dry toluene. The reaction mixture was fractionated through a 50-theoretical plate Piros-Glover micro still. The resulting acetone was burned, and found to contain 0.105 gram atom of deuterium per mole. The deuteroisopropyl alcohol used therefore contained about 65.0 − 10.5 = 54.5% of the desired $CH_3\overset{OH}{\underset{D}{C}}—CH_3$.

The calculation just given is based on the assumption that little or no exchange occurs during Oppenauer oxidation. To test this assumption, ordinary acetone (6.9 g.) was put back into the reaction mixture from which the (deuterium-containing) acetone and isopropyl alcohol had been removed by fractionation. The mixture was refluxed and distilled under the conditions employed in the oxidation of the isopropyl alcohol. The recovered acetone contained only 0.01 gram atom of deuterium per mole. This finding indicates that the exchange with deuterium during the Oppenauer reaction is negligible.

**Rate Determinations.**—The oxidation rates for isopropyl alcohol and the (isotopically impure) 2-deuteropropanol-2 were determined at 40° by the methods and equations of Westheimer and Novick.[1] The analytical method, however, differed from theirs. Instead of titrating the unreacted chromic acid, the quantity remaining in solution was determined spectrophotometrically with a Beckman Quartz Spectrophotometer, model DU. It was found that all the chromic acid solutions used had an absorption maximum close to 3500 Å.; at this wave length, chromic ion absorbs hardly at all. Despite the equilibrium[1,13] between $HCrO_4^-$ and $Cr_2O_7^=$ ions, solutions of chromic acid within the range of acidity used very nearly obey Beer's law. Nevertheless, an empirical standardization curve was prepared. The samples withdrawn from the reaction mixture were pipetted into a standard solution of sodium acetate such that the resulting buffer had an acetic acid–acetate ion ratio of one to 0.18. Blank experiments showed that, in this buffer, the rate of oxidation of isopropyl alcohol was negligible. These buffered solutions were then examined spectrophotometrically.

**Results.**—The kinetic results obtained as described are shown in Table I. The figures for isopropyl alcohol agree well with those of Westheimer and Novick. The ratio of the oxidation rates for isopropyl alcohol and the isotopically impure 2-deuteropropanol-2 was uniformly about 1.9.

In all the experiments hitherto cited, the concentration of alcohol greatly exceeded that of the chromic acid, and the former was therefore essentially constant during any individual rate determination. For this reason, the rate constant during any one experiment did not "drift," despite the fact that isotopically impure material (55% 2-deuteropropanol-2 and 45% isopropyl alcohol) was used. A few experiments were made with equivalent concentrations of ordinary isopropyl alcohol (or isotopically impure 2-deuteropropanol-2) and chromic acid. Here the rate constant for the oxidation of ordinary isopropyl alcohol was

essentially constant, whereas that for the oxidation of the isotopically impure deuteroisopropyl alcohol decreased during the course of the experiment. This drift was to be expected. Since isopropyl alcohol reacts faster than does the corresponding deutero compound, the latter forms the bulk of the residual material left toward the end of any oxidation.

It was possible to calculate for this latter type of experiment the chromic acid concentration anticipated at various reaction times (see Appendix and Table II). The first column of the table gives the times at which samples were withdrawn; the observed chromic acid concentrations of these samples are given in column three. The second column gives the fourth order rate constants, determined by the equation of Westheimer and Novick; the drift is obvious. Column four gives the chromic acid concentrations computed for various times on the basis of an assumed ratio (4.5) for the rate constants of the oxidations of ordinary and 2-deuteropropanol-2; column five gives the concentrations similarly computed on the basis of another assumed ratio (6). A few readings taken very early in the experiments and a few taken beyond the point of 90% reaction were erratic; these have been omitted from the table.

## Discussion

The experiments here reported prove beyond doubt that 2-deuteropropanol-2 reacts with chromic acid much more slowly than does ordinary isopropyl alcohol. Since the deuterated material here used contained only 55% of 2-deuteropropanol-2, the exact ratio of the oxidation rates must be calculated on the (almost certain) assumptions (1) that the isopropyl alcohol and the 2-deuteropropanol-2 react independently, and (2) that deuterium in the methyl groups has little if any effect upon the oxidation rate. Calculations made on this basis indicate that pure isopropyl alcohol should be oxidized about 6.7 times as rapidly as pure 2-deuteropropanol-2; this value is roughly consistent with the rate ratio of about 5 obtained from the data (presented in Table II) for experiments in which the initial chromic acid and alcohol concentrations were equivalent. The rate ratio calculated from experiments with 55% 2-deuteropropanol-2 is likely to be somewhat in error. Although the probable error in the rate constants is small (of the order of 2%), the possible errors in the deuterium analysis and the questionable distribution of deuterium between the secondary carbon atom and the methyl groups make the computed oxidation rate for 2-deuteropropanol-2 somewhat uncertain. This uncertainty is such that the ratio of the rate of oxidation of the pure 2-deuteropropanol-2 to that of isopropyl alcohol should probably be written as $0.17 \pm 0.05$. Such uncertainty is, however, irrelevant for the conclusion here drawn. For if 2-deuteropropanol-2 is oxidized much more slowly than is ordinary isopropyl alcohol, it follows that the carbon to secondary hydrogen bond (or carbon to secondary deuterium bond) is broken in the rate determining step of the reaction.

## Appendix

The data in Table II were obtained by use of the equations derived below. In these equations, the symbols $b'$, $c'$, $K'$ have the meanings previously[1] assigned to them. The initial concentration of the ordinary isopropyl alcohol is represented by $a_H$, that which has reacted is represented by $x$; the initial concentration of the 2-deuteropropanol-2 is represented by $a_D$, that which has reacted is represented by $y$. The fourth order rate constant for the decrease in concentration of chromic acid during the oxidation of ordinary isopropyl alcohol is represented by $k_H$ rather than by $k$. The corresponding constant for decrease during the oxidation of the deuteroalcohol is $k_D$. Since the stoichiometry of the reaction demands that three molecules of alcohol react for every two of chromic acid, the rate constants for the decrease of the concentration of isopropyl alcohol and deuteropropanol-2 are respectively $3/2\ k_H$ and $3/2\ k_D$. It follows that

$$dx/dt = 3/8\ k_H\ (a_H - x)\ \{-K' + \sqrt{K'^2 + 8K'\ [b' - 2/3\ (x + y)]}\}\ [c - 8/3\ (x + y)]^2 \quad (1)$$

$$dy/dt = 3/8\ k_D\ (a_D - y)\ \{-K' + \sqrt{K'^2 + 8K'\ [b' - 2/3\ (x + y)]}\}\ [c - 8/3\ (x + y)]^2 \quad (2)$$

$$dy/dx = k_D\ (a_D - y)/k_H\ (a_H - x) \quad (3)$$

Equation (3) when integrated yields (4)

$$y = a_D - \frac{a_D}{\left(1 - \frac{x}{a_H}\right)^{k_H/k_D}} \quad (4)$$

From eqn. (4), the value of $y$ corresponding to any value of $x$ can be found for any assumed value of $k_H/k_D$. When the values of $y$ corresponding to various values of $x$ are inserted into eqn. (1), this equation can be graphically integrated. This graphical integration gives the theoretical relation between the amount of alcohol (or chromic acid) consumed and the reaction time for the particular value of $k_H/k_D$ used. The values thus computed are presented in Table II.

## Summary

1. When Adams catalyst, activated by ferrous chloride, is used, the deuteration of acetone is accompanied by some hydrogen–deuterium exchange. The product here obtained was a mixture containing 55% of 2-deuteropropanol-2.

2. The rate of chromic acid oxidation of this product was only 52% of that of ordinary isopropyl alcohol. On the basis of this result, it is calculated that the rate of chromic acid oxidation of pure 2-deuteropropanol-2 should be about one-sixth that of pure isopropyl alcohol.

3. The lower rate of oxidation of the 2-deutero compound (which arises from differences between the zero point energies of the C–H and C–D bonds) proves that the secondary hydrogen (or deuterium) in isopropyl alcohol is removed in the rate controlling step of the chromic acid oxidation.

# 1-Cyano-2,6-diphenyl-4-hydroxycyclohexane and Some Related Compounds[1]

BY C. S. MARVEL AND ALLEN C. MOORE[2]

1-Cyano-2,6-diphenyl-4-hydroxycyclohexane (VI) was needed for another synthetic problem and it seemed probable that it could be produced readily by the addition of ethyl cyanoacetate to dibenzalacetone followed by hydrolysis, decarboxylation and reduction.

Kohler and Helmkamp[3] have prepared 1-cyano-2,6-diphenyl-4-cyclohexanone (I) by the addition of methyl cyanoacetate to dibenzalacetone followed by hydrolysis and decarboxylation of the addition product (II, R = $CH_3$). In our work the addition of ethyl cyanoacetate to dibenzalacetone ran smoothly in the presence of sodium ethoxide

I

to give an 88% yield of the cyclic cyanoester (II R = $C_2H_5$). Difficulty was experienced in hydrolysis of the ethyl ester although the methyl ester had not been difficult to hydrolyze.[3] It seemed probable that reduction of the carbonyl group would stabilize the cyclohexane ring so no reversal of the Michael reaction would occur under the conditions of alkaline hydrolysis. Accordingly, the keto ester (II, R = $C_2H_5$) was reduced by the Meerwein–Ponndorf–Verley method.[4] This reduction did not give the simple hydroxy compound but two other products. One was crystalline and proved to be a lactone (III). The other was a non-crystalline polyester (IV). The formation of lactones in this reaction is not unusual.[4] The lactone (III) was undoubtedly formed from the hydroxy ester intermediate with the *cis*-configuration for these groups and the polyester therefore was probably derived from the *trans*-isomer. Hydrolysis of this glassy material gave a 63% yield of the free acid (V) which did not readily form a lactone and this further confirms its *trans*-structure with respect to hydroxyl and carboxyl groups.

When the cyanolactone (III) was refluxed for three hours with 40% aqueous sodium hydroxide, the lactone ring was opened and decarboxylation occurred, giving an 80% yield of the hydroxy nitrile (VI). Decarboxylation of the free acid (V) also gave the hydroxynitrile (VI), in 50% yield. By continuing the alkaline hydrolysis of the cyanolactone for a total of thirty-one hours, there was obtained a 94% yield of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid (VII).

It became evident, from examination of the hydroxy acid (VII) derived from the hydroxynitrile (VI), that the acid had the *cis*-configuration. Thus, the hydroxy acid formed a second lactone (VIII) with ease, in 79% yield, when heated at its melting point. The action of such reagents as acetic anhydride, acetyl chloride and *p*-toluenesulfonyl chloride also brought about lactone formation. By contrast, the strictly analogous *trans*-4-hydroxycyclohexane-1-carboxylic acid prepared by Perkin[5] showed no tendency to yield a lactone when distilled, or when treated with hot 25% sulfuric acid.

When it is considered that the hydroxyl and carboxyl groups of the precursor of the cyanolactone (III) must have been *cis* with respect to one another, it follows that the nitrile and hydroxyl groups must have been in the *trans* configuration originally. It is clear then, that an inversion must have occurred to give a product (VII) of *cis* configuration. This inversion might have occurred during the opening of the lactone ring,[6,7] during

(1) This investigation was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program.

decarboxylation, or during hydrolysis of the nitrile group. An exact interpretation of the site of inversion does not appear to be possible on the basis of the present facts since the configuration of the phenyl groups with respect to one another and with respect to the nitrile is not definitely known.

If one assumes, however, that the most plausible form of II is one in which the two phenyl groups and the nitrile are *cis* with respect to one another, then an inversion at carbon 4 during hydrolysis of the lactone (III) would serve to explain the foregoing data. This would, of course, necessitate the anomalous assumption that the alcohol C–O bond must have been broken, instead of the ester C–O bond.

If, on the other hand, one assumes that no inversion occurred at carbon 4, it becomes more difficult to explain why the same hydroxy nitrile (VI) was obtained by decarboxylation of the hydroxy acid (V) and the lactone (III).

Under the drastic alkaline conditions used to effect hydrolysis and decarboxylation of the lactone (III), racemization of the nitrile group of the hydroxy nitrile (VI) might be anticipated. That this clearly did not occur is probably best explained by the assumption that the two phenyl groups being in *cis* configuration hindered free approach to one side of the cyclohexane ring. Hence, in the event that an intermediate imino tautomer formed after the loss of carbon dioxide by the initial hydrolysis product of the lactone (III), the shift of the proton would probably be restricted so that retention or inversion rather than racemization would be favored.

Methylation of the hydroxynitrile (VI) was brought about by a modification of Purdie's technique for alkylating sugars,[8] in which benzene was substituted for the usual alcoholic solvent. A yield of 66% of 1-cyano-2,6-diphenyl-4-methoxycyclohexane (IX) was thus obtained. When this methoxynitrile was subjected to the same conditions used previously to hydrolyze the hydroxynitrile, no reaction occurred. Hot 50% sulfuric acid also failed to bring about a reaction, yet when the strength was increased to 75%, the hot acid appeared to cause extensive decomposition and nothing could be isolated from the mixture. Similar results were obtained with cold concentrated sulfuric acid. By refluxing the methoxynitrile (IX) for two days with saturated alcoholic potassium hydroxide, it was eventually possible to isolate a very small yield of 2,6-diphenyl-4-methoxycyclohexane-1-carboxylic acid (X). This greatly increased stability of the nitrile group following methylation of the hydroxyl is very difficult to explain since there appears to be no reason to assume that an increase in hindrance of the nitrile should occur.

The *p*-toluenesulfonic ester of the hydroxynitrile (VI) was prepared in 84% yield by modification of a procedure used previously for preparing cholesteryl *p*-toluenesulfonate.[9] This ester appeared to be completely inert in the presence of boiling methanol[10] which would have been expected to bring about ether formation. The *p*-toluenesulfonate ester did react when it was refluxed in alcoholic solution with sodium methoxide to produce a small yield of $\Delta^1$- and/or $\Delta^2$-1-cyano-2,6-diphenylcyclohexene.

Acetylation of the hydroxynitrile gave an 85% yield of 4-acetoxy-1-cyano-2,6-diphenylcyclohexane which, oddly enough, melted in the same range, 140–143°, as both the hydroxynitrile and its *p*-toluenesulfonate. Hydrolysis of the acetoxynitrile by hot 40% aqueous sodium hydroxide gave the lactone of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid (VIII).

The hydroxynitrile reacted with phosphorus

pentachloride and thionyl chloride in the presence of pyridine to give small yields of a chloronitrile, m. p. 150°, of unknown configuration.

## Experimental

**Ethyl 1-Cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylate (II, R = $C_2H_5$).**—One hundred and three grams (0.44 mole) of recrystallized dibenzalacetone, m. p. 110–111°, and 58.6 g. (0.52 mole) of ethyl cyanoacetate were mixed with 1500 cc. of dry ethyl ether in a 2000-cc. Erlenmeyer flask and the mixture swirled until maximum solution had been effected.

A solution of sodium ethoxide was prepared by allowing 1.5 g. of clean, freshly-cut sodium to react with 50 cc. of absolute ethanol, then diluting with 50 cc. of dry ether.

While the ether mixture of the reactants was swirled, the sodium ethoxide solution was added dropwise intermittently until the tendency toward turbidity had ceased and a clear yellow solution resulted (10–20 cc. of catalyst solution was usually required). The reaction mixture became warm at this point, and small, feathery, white needles began to form. Additional catalyst solution was added dropwise with swirling, and the mixture transferred to a beaker. Under continued stirring, the mixture set up to a semi-solid mass. This was diluted with about 200 cc. of dry ether, stirred again, then set aside for thirty minutes in the ice-box. The solid was collected on a filter, pressed by a rubber dam, and finally washed twice with dry ether. The white material, after air-drying overnight, weighed 116 g., a yield of 76%, m. p. 132–134°. When the ethereal filtrate was concentrated, a second crop of solid weighing 18 g. was obtained, bringing the over-all yield to 134 g., or 88% of theoretical. Complete removal of solvent from the mother liquor left a thick brown oil weighing 17 g.

After two recrystallizations of a portion of the first crop from absolute ethanol, the melting point remained constant at 137–138°. The white compound failed to take up bromine, indicating that ring closure must have occurred.

*Anal.*[11] Calcd. for $C_{22}H_{21}O_3N$: C, 76.08; H, 6.06; N, 4.03. Found: C, 76.08; H, 5.94; N, 3.97.

The infrared absorption spectra[12] showed a very weak band at 2250 cm.$^{-1}$, the nitrile region, and strong bands at 1724 cm.$^{-1}$ and 1736 cm.$^{-1}$, the keto and ester group regions, respectively.

**1-Cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylic Acid (II, R = H).**—To a solution of 173 g. (0.5 mole) of ethyl 1-cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylate in 2 l. of hot ethanol, there was added 75 g. of potassium hydroxide in one liter of distilled water. The mixture was refluxed on the steam cone for nineteen hours, then the resulting wine-red reaction mixture was carefully neutralized while hot with dilute (1:2) hydrochloric acid. The clear, light yellow, neutral solution was concentrated to 2 l. and added dropwise, with stirring, to 2 l. of hot water. The mixture was warmed until most of the turbidity disappeared, then the dissolved portion was decanted from a brown, gummy insoluble residue. The gum solidified and, when dry, weighed 57 g.

The dissolved portion was treated with Darco, filtered, then added while hot to one liter of a stirred solution of dilute (1:2) hydrochloric acid. An off-white solid settled out readily and was removed on a filter, washed with water, and dried overnight at 80°. The product thus obtained melted with decomposition at 201° and weighed 66 g., a yield of 41% of theoretical.

A portion of this solid was recrystallized twice from benzene, then again from aqueous ethanol, giving a solid melting at 219–220° with rapid decomposition.

*Anal.* Calcd. for $C_{20}H_{17}O_3N$: C, 75.24; H, 5.33; N, 4.39. Found: C, 74.66; H, 5.48; N, 4.36.

1-Cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylic acid has been previously reported[3]; however, no melting point was recorded and the compound analyzed contained acetone of crystallization.

**Attempted Decarboxylation of 1-Cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylic Acid.**—Twenty-six grams (0.082 mole) of 1-cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylic acid, m. p. 208–209° dec., was heated under reduced pressure at 200–210° in an oil-bath until effervescence had ceased. The brown melt was cooled, then dissolved in ethanol and treated with Darco. A buff solid separated from the filtrate. After one recrystallization from ethanol, and two recrystallizations from benzene, this material melted with decomposition at 203–209°, indicating that it was most probably starting material. The filtrate could not be induced to yield any crystals.

**1-Cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic Acid, δ-Lactone (III).**—A solution of 260 g. (0.75 mole) of ethyl 1-cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylate in 1340 cc. of hot isopropyl alcohol was mixed while warm with 274 g. (1.34 moles) of freshly distilled aluminum isopropoxide. A gelatinous precipitate separated. The mixture, in a 3-l., round-bottomed flask, was refluxed under an 18-in. bead-packed column, mounted with a partial take-off type distillation head. Distillate was taken off slowly as reflux continued for approximately twenty-four hours, or until the distillate repeatedly failed to give a positive test for acetone with 2,4-dinitrophenylhydrazine.[4] The alcohol was then removed by distillation until the volume was reduced to about one-half that of the original. The mixture remaining was then transferred to a beaker surrounded by ice, and when cold, acidified with approximately one liter of dilute hydrochloric acid (220 cc. concentrated acid to 1100 cc. of water). The mixture was stirred and let stand until all gelatinous material had dissolved. If, at this point two layers resulted, additional isopropyl alcohol was added with stirring until only one liquid phase remained. After standing in the ice-box to allow for complete sedimentation, the liquid portion was carefully decanted, leaving a slurry of white granular crystals. This was diluted with 50% aqueous isopropyl alcohol containing some hydrochloric acid, and the solid removed on a filter. The crystals were washed on the filter, first with more acidified aqueous isopropyl, alcohol then with cold isopropyl alcohol and finally with water. The product, after drying at 80° for three hours, was a fine white crystalline powder, m. p. 226–227°, weighing 110 g. or 48.5%. Recrystallization from acetone gave a solid melting at 227–228°.

*Anal.* Calcd. for $C_{20}H_{17}O_2N$: C, 79.18; H, 5.65; N, 4.62. Found: C, 79.45; H, 5.63; N, 4.74.

The infrared absorption spectra showed a very weak band at 2265 cm.$^{-1}$, the nitrile region, and a strong band at 1766 cm.$^{-1}$, the lactone region.

In a run similar to the one above, the decanted solution was combined with washings and then concentrated until two layers formed. These were separated and the bottom layer extracted twice with benzene. The top layer was diluted with benzene, then separated. The combined benzene extract was washed with water, with dilute hydrochloric acid, then with dilute sodium hydroxide solution, and finally with water again. The extract was separated, stirred with anhydrous sodium sulfate, then boiled with Darco, and filtered while hot. Solvent was completely removed on the steam cone, vacuum being applied after the substance became rather viscous. A thick, light brown sirup remained, which solidified to a clear glass when cooled. All attempts to crystallize this substance failed. From 434 g. (1.25 moles) of ethyl 1-cyano-2,6-diphenyl-4-ketocyclohexane-1-carboxylate, there was obtained 240 g. of this non-crystalline residue.

**1-Cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic Acid (V).**—Two hundred and fourteen grams (0.613 mole, calculated as ethyl 1-cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylate) of the non-crystalline residue from the reduction described above, was dissolved in one liter of 95% ethanol, a solution of 67 g. (1.2 moles) of potassium hydroxide in 100 cc. of water was added, and the mixture refluxed for two hours. The cooled reaction

(11) All microanalyses were done by the Clark Microanalytical Laboratories.

(12) We are indebted to Mrs. J. L. Johnson for the infrared absorption data and its interpretation.

mixture was acidified with concentrated hydrochloric acid, boiled with Norit, filtered and the alcohol removed. The resulting gum was washed with water to remove sodium chloride, and then dissolved in hot benzene. White granular crystals, which deposited out of the cooled solution, were removed on a filter and desiccated under vacuum. There was thus obtained 125 g. of solid, m. p. 189–190° dec., a yield of 63% of theoretical. After two recrystallizations from 25–35% aqueous ethanol, the product melted at 204° dec.

*Anal.* Calcd. for $C_{20}H_{19}O_3N$: C, 74.75; H, 5.96; N, 4.36. Found: C, 74.36, 74.99; H, 5.74, 5.50; N, 4.36.

The infrared absorption spectra showed a weak band at 2247 cm.$^{-1}$, the nitrile region, and strong bands at 1750 cm.$^{-1}$ and 3445 cm.$^{-1}$, the carboxyl and hydroxyl regions, respectively. The lower melting product, 189–190° dec., showed extra bands at 2260 cm.$^{-1}$, 1717 cm.$^{-1}$, and 3362 cm.$^{-1}$. Removal of solvent from the mother liquor left a viscous brown oil weighing 61 g.

**Attempted Hydrolysis of 1-Cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic Acid, δ-Lactone.** (A).—Two grams (0.007 mole) of the δ-lactone was dissolved in a solution of 10 g. of potassium hydroxide in 100 cc. of ethanol. After being boiled with Norit, the solution was filtered and mixed with 200 cc. of water, cooled and added with stirring to 300 cc. of 1:5 hydrochloric acid. The milky suspension which resulted was allowed to settle overnight in the ice-box. A white solid separated and this was removed on a filter and air-dried. The solid, weighing approximately 1 g., was recrystallized from ethanol, giving well-defined crystals, m. p. 225–226°. A mixed melt with the starting material showed no depression.

In the absence of potassium hydroxide, 2 g. of crystalline δ-lactone failed to dissolve in 100 cc. of ethanol.

(B).—Approximately 1–2 g. of the δ-lactone was powdered and dissolved with stirring in cold concentrated sulfuric acid. Careful dilution of this solution with water gave a white precipitate which was removed on a filter. The solid thus obtained, after being washed with water and air-dried, melted at 225° and showed no depression in a mixed melt with the starting material.

**1-Cyano-2,6-diphenyl-4-hydroxycyclohexane (VI)** (A).—One hundred grams (0.33 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid, δ-lactone was refluxed with 1000 g. of 40% aqueous sodium hydroxide for three hours. At the end of the heating period, ammonia was first noted at the top of the reflux condenser. The reaction mixture was allowed to cool and the hardened organic layer was separated and washed with water. The solid was dissolved in ethanol, and the hot solution was treated with Darco, then filtered. Chilling brought out granular crystals which were removed on a filter and dried by vacuum desiccation. Sixty-three grams of solid, melting at 130–135°, and a second crop of 10 g., melting at 140–142°, were obtained. The total of 73 g. represents a yield of 80% of theoretical. Recrystallization of the solid from ethanol gave well-defined crystals, melting at 143–144°.

*Anal.* Calcd. for $C_{19}H_{19}ON$: C, 82.28; H, 6.91; N, 5.05. Found: C, 82.20; H, 6.70; N, 5.15.

The infrared absorption spectra showed a weak band at 2260 cm.$^{-1}$, the nitrile region, and a strong band at 3440 cm.$^{-1}$, the hydroxyl region.

Following the above method it was sometimes observed that the product resulting showed a melting range of 120–125°. Thus, in a representative case, there was obtained from 150 g. (0.495 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid, δ-lactone, 109 g. of solid melting at 120–125°, a yield of 80%. Recrystallization of this from 95% ethanol gave granular crystals melting at the same temperature. Doubling the volume of ethanol was without effect, so the solution was made alkaline with 2–5 g. of potassium hydroxide, boiled with Darco and filtered. The solid which was deposited melted in the same range, 120–125°.

The investigation of other solvents failed to indicate one better than ethanol.

(B).—A solution of 16 g. (0.05 mole) of recrystallized 1-cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid, m. p. 202° dec., in 125 cc. of crude quinoline was refluxed for one hour to effect decarboxylation. The cooled reaction mixture, after acidification with 500 cc. of 1:1 hydrochloric acid, was extracted twice with benzene and the resulting benzene extracts combined and treated with Norit. Following filtration, the solvent was removed, leaving a brown oil which was dissolved in ethanol and treated with Norit and Darco, then filtered. From the chilled solution there was obtained 6 g. of crystals, m. p. 142–143°, and a second crop of 1 g., m. p. 122–125°. The total of 7 g. represents a yield of 50% of theoretical.

**2,6-Diphenyl-4-hydroxycyclohexane-1-carboxylic Acid** (VII).—A mixture of 70 g. (0.23 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid, δ-lactone, and 1000 g. of 40% aqueous sodium hydroxide was refluxed for thirty-one hours. At the end of the heating period, *i.e.*, when ammonia ceased to be evolved, a gummy upper layer remained in the flask. This solidified when cool and was removed, washed with water and dissolved in ethanol. After being filtered, the warm solution was carefully neutralized with hydrochloric acid, then boiled, and again filtered to remove sodium chloride.

The alkali portion of the original reaction mixture was diluted with an equal volume of water, then carefully acidified with concentrated hydrochloric acid. The resulting solid was removed on a filter, and the wet cake, consisting chiefly of hydrated silica, was extracted with hot ethanol. After removal of the ethanol-insoluble material on a filter, the solution was combined with the one prepared initially.

The alcoholic solution was boiled with Norit, filtered, then concentrated somewhat to insure ease of crystallization. Chilling brought out fine, white needles, which were removed on a filter and dried in a vacuum desiccator. A second crop of crystals was obtained by concentrating and chilling the mother liquor. The first crop, weighing 58 g., melted at 172–173° dec., and the second crop, weighing 6 g., melted at 157–168° dec. The total of 64 g. represents a 94% yield.

After two recrystallizations from water containing 10% ethanol, the solid melted at 173–174° dec.

*Anal.* Calcd. for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80. Found: C, 76.97; H, 7.00.

The infrared absorption spectra showed strong bands at 1708 cm.$^{-1}$, the carboxyl region, and at 3365 cm.$^{-1}$, the hydroxyl region.

**2,6-Diphenyl-4-hydroxycyclohexane-1-carboxylic Acid, δ-Lactone** (VIII).—Twenty-five grams (0.084 mole) of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid was warmed at 135° under reduced pressure for approximately thirty minutes. The temperature was then raised to 170° for about twenty minutes (*i.e.*, until effervescence had ceased). After the light brown product had cooled somewhat, it was taken up in ethanol, decolorized with Darco, filtered and cooled until crystals formed. The white needles which deposited were removed on a filter, and the mother liquor concentrated to recover a second crop. By this means there was obtained a total of 18.5 g. of solid, m. p. 125–126°, 79% of theoretical.

After two recrystallizations from absolute ethanol, the solid melted at 126–127°.

*Anal.* Calcd. for $C_{19}H_{18}O_2$: C, 82.01; H, 6.48. Found: C, 81.95; H, 6.54.

The infrared absorption spectra showed a strong band at 1755 cm.$^{-1}$, the lactone region.

A solution of 6 g. (0.02 mole) of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid in 20 cc. of acetic anhydride was refluxed for five hours. The acetic anhydride was removed under reduced pressure and the solid residue dissolved in ethanol and decolorized with Norit. Fine white needles, m. p. 125°, were obtained from the cooled filtrate. A mixed melt with the δ-lactone, m. p. 125–126°, showed no depression.

To a solution of 5 g. (0.017 mole) of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid in 25 cc. of dry pyridine there was added, with caution, 2.6 cc. (3.84 g., 0.034

mole) of acetyl chloride. The mixture was allowed to stand overnight, then was diluted with water and extracted with chloroform. After the extract was dried over anhydrous sodium sulfate, the chloroform was removed and the residual oil dissolved in ethanol and the solution chilled. Crystals, m. p. 123°, were removed on a filter, Recrystallization from ethanol gave a solid melting at 124–125°. A mixed melt with the δ-lactone showed no depression.

To a solution of 5 g. (0.017 mole) of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid in 15 cc. of dry pyridine, there was added 6.85 g. (0.036 mole) of *p*-toluenesulfonyl chloride. The mixture, which became quite hot, was allowed to stand overnight. The crystalline mass which was formed was diluted with ethanol to effect solution, then enough water was added dropwise to induce recrystallization. Two and one-half grams of solid was removed on a filter and recrystallized, giving needles, m. p. 125°. A mixed melt with the δ-lactone showed no depression.

**1-Cyano-2,6-diphenyl-4-methoxycyclohexane (IX).**—The method used by Purdie and Irvine[8] in the alkylation of sugars, was followed with modification. To a solution of 10 g. (0.036 mole) of recrystallized 1-cyano-2,6-diphenyl-4-hydroxycyclohexane, m. p. 142–143°, in 100 cc. of dry benzene in a 500-cc., three-necked, round-bottomed flask, fitted with Hershberg stirrer, and cold finger-type condenser, was added 22.5 cc. (51.3 g., 0.36 mole) of methyl iodide, and 5–10 g. of a 30-g. portion of freshly prepared silver oxide. Two cubic centimeters of methanol was added, the stirrer was started, and the mixture was brought to reflux. The rest of the silver oxide was added in three or four approximately equal-sized batches at two-hour intervals. Reflux was maintained for an over-all period of ten hours.

The hot mixture was filtered to remove the silver residues, and these were washed on the filter with hot benzene, then transferred to a beaker and boiled with fresh benzene. The combined benzene extracts were decolorized with Darco, then evaporated. The residual oil was taken up in absolute ethanol, from which white plates separated immediately. Seven grams of crystalline solid, m. p. 105–106°, was obtained, a yield of 66.5%. The second crop from the concentrated mother liquor weighed less than 0.5 g. A portion of the concentrated mother liquor weighed less than 0.5 g. A portion of the product, after two recrystallizations from absolute ethanol, gave hexagonal plates, m. p. 106–107°.

*Anal.* Calcd. for $C_{20}H_{21}ON$: C, 82.43; H, 7.27; N, 4.81. Found: C, 82.38; H, 7.49; N, 4.85.

The infrared absorption spectra showed a weak band at 2247 cm.$^{-1}$, the nitrile region, and a strong band at 1104 cm.$^{-1}$, the ether C–O region.

**Attempted Hydrolysis of 1-Cyano-2,6-diphenyl-4-methoxycyclohexane. (A).**—A mixture of 2 g. (0.007 mole) of 1-cyano-2,6-diphenyl-4-methoxycyclohexane, m. p. 103–105°, and 50 g. of 40% aqueous sodium hydroxide was refluxed for twenty-four hours. After the mixture was cooled, the organic portion was separated and dissolved in 95% ethanol, treated with Darco, and the solution filtered. The filtrate was acidified with concentrated hydrochloric acid, boiled, again filtered, and finally concentrated. A solid which separated from the chilled solution was collected on a filter, air-dried, and recrystallized from ethanol, giving material melting at 103–104°. A mixed melt with the starting material showed no depression.

(B).—Five grams (0.017 mole) of the methoxynitrile, m. p. 101–103°, was added in small portions to 50 cc. of 75% sulfuric acid at 140–150°. The mixture became orange and all the organic material appeared to disperse after one-half hour. Heating was continued, with frequent shaking, for a total of one hour. The acid mixture, when poured onto cracked ice, deposited a yellow precipitate which was removed on a filter and dissolved in ethanol. After treatment with Norit, the solution was filtered, concentrated, and the resulting oil dissolved in dilute aqueous sodium hydroxide. Acidification of the orange solution with 1:1 hydrochloric acid failed to cause any precipitation.

(C).—A mixture of 2 g. (0.007 mole) of the methoxynitrile and 76 cc. of 50% sulfuric acid was refluxed for five hours. After the mixture had cooled, the solidified organic layer was separated, dissolved in ethanol, treated with Darco and the solution filtered. Crystals which separated from the chilled concentrated solution were collected on a filter and air-dried. In this manner there was obtained approximately 1 g. of material, m. p. 102–104°, which failed to show any depression in a mixed melt with a sample of starting material.

(D).—One gram of the powdered methoxynitrile was added slowly to 50 cc. of cold concentrated sulfuric acid over a period of fifteen to twenty minutes. The solid went into solution, imparting a brown coloration to the acid. While surrounded by ice, the mixture was carefully diluted by dropping in chipped ice until precipitation occurred. The gum which resulted was dissolved in ethanol, from which it failed to crystallize. After removal of the solvent, the concentrate was warmed with dilute aqueous sodium hydroxide, and the solution obtained treated with Darco and filtered. Acidification of the alkaline filtrate failed to cause precipitation.

**2,6-Diphenyl-4-methoxycyclohexane-1-carboxylic Acid (X).**—A solution of 4 g. (0.014 mole) of 1-cyano-2,6-diphenyl-4-methoxycyclohexane in 100 cc. of saturated alcoholic potassium hydroxide was refluxed for forty-eight hours. Ammonia was evolved and a small amount of an insoluble layer formed at the bottom of the flask. The reaction mixture was diluted with an equal volume of water, acidified with concentrated hydrochloric acid, then extracted twice with benzene. After treatment of the benzene extract with Norit and filtering, the solvent was removed completely, leaving a clear yellow oil which was then dissolved in ethanol, again treated with Norit and filtered. The clear yellow solution ultimately deposited crystals which were removed on a filter and air-dried. There was thus obtained 0.5 g. of solid melting at 176–178°. After two recrystallizations from absolute ethanol, crystalline rectangular parallelepipeds melting at 186–187° were obtained.

*Anal.* Calcd. $C_{20}H_{22}O_3$: C, 77.39; H, 7.15. Found: C, 77.18; H, 7.09.

The infrared absorption spectra showed strong bands at 1730 cm.$^{-1}$, the carboxyl region, and at 1128 cm.$^{-1}$, the ether C–O region.

***p*-Toluenesulfonate of 1-Cyano-2,6-diphenyl-4-hydroxycyclohexane.**—The procedure followed was a modification of the method used by Wallis, Fernholz and Gephart[9] for the preparation of cholesteryl *p*-toluenesulfonate. Five grams (0.018 mole) of recrystallized 1-cyano-2,6-diphenyl-4-hydroxycyclohexane was dissolved in 15 cc. of anhydrous pyridine and 6.85 g. (0.036 mole) of *p*-toluenesulfonyl chloride added. The solution immediately became hot and fumes were evolved. After standing at room temperature overnight, large needles had separated and the liquid portion had become sirupy. Absolute ethanol (about 20 cc.) was added dropwise to the stirred solution to induce crystallization again. The crystals were removed on a filter and dried by vacuum desiccation. There was thus obtained 6.5 g. of solid melting at 133–134°, a yield of 84% of theoretical.

Recrystallization from ethanol gave long white needles, melting at 140–142°. A mixture of starting material, m. p. 140–142°, and recrystallized product, showed a melting point depression of 20°. A sodium fusion test for sulfur was clearly positive.

*Anal.* Calcd. for $C_{26}H_{25}NO_3S$: C, 72.36; H, 5.84; N, 3.25. Found: C, 72.52; H, 5.68; N, 3.27.

The infrared absorption spectra showed a very weak band at 2247 cm.$^{-1}$, the nitrile region, and strong bands at 1180 cm.$^{-1}$, and 1193 cm.$^{-1}$, the sulfonyl region.

The ester was recovered unchanged after being refluxed with methanol for three hours.

**Reaction of *p*-Toluenesulfonate of 1-Cyano-2,6-diphenyl-4-hydroxycyclohexane with Sodium Methoxide.**—A solution of sodium methoxide, prepared by dissolving 1.5 g. of sodium in 30 cc. of methanol, was added to 8 g.

(0.019 mole) of the *p*-toluenesulfonate in 125 cc. of absolute ethanol, and the mixture refluxed for twenty-three hours. Glistening white plates were deposited during the reflux period. The reaction mixture, after careful acidification with concentrated hydrochloric acid, was chilled and the crystals removed on a filter. Washing of the filtered solid with water left only a small portion of water-insoluble material, which was then dissolved in ethanol and combined with the initial filtrate. As this solution, when chilled, showed a tendency to deposit more water-soluble plates, the solvent was completely removed and the residual semi-solid boiled for one-half hour with dilute aqueous sodium hydroxide solution. The organic material was separated from the cooled mixture and redissolved in ethanol, treated with Darco, filtered and finally chilled. The fine white needles resulting were removed on a filter and after air-drying, weighed approximately 1 g. The material thus obtained sintered at 185° but failed to show a definite melting point. After three recrystallizations from ethanol, a solid melting sharply at 207–208° was obtained.

*Anal.* Calcd. for $C_{19}H_{17}N$: C, 87.99; H, 6.61; N, 5.40. Found: C, 88.37; H, 6.44; N, 5.47.

The infrared absorption spectra of the 185° product showed twinned weak bands at 2217 cm.$^{-1}$ and 2247 cm.$^{-1}$, which indicate a conjugated nitrile group. The recrystallized material showed less of the second band at 2217 cm.$^{-1}$ and a more prominent band at 1585 cm.$^{-1}$, the conjugated phenyl frequency.

These data, together with the observation that the product reacted slowly to decolorize bromine in carbon tetrachloride, indicated that the compound was a mixture of $\Delta^1$- and $\Delta^2$-1-cyano-2,6-diphenylcyclohexene.

Similar results were obtained when the *p*-toluenesulfonates were refluxed in ethanol with sodium ethoxide for eighty minutes.

**4-Acetoxy-1-cyano-2,6-diphenylcyclohexane.**—A solution of 20 g. (0.072 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane in 200 cc. of acetic anhydride was refluxed for six hours. The acetic anhydride was distilled off under reduced pressure and the solid residue dissolved in ethanol, decolorized with Norit and filtered. Chilling brought out long white needles which were removed on a filter and dried by vacuum desiccation. There was thus obtained 19.5 g. of material melting at 141–142°, a yield of 85% of theoretical.

Two recrystallizations from absolute ethanol failed to raise the melting point. A mixed melt with starting material, m. p. 140–141°, showed a depression of 40°.

*Anal.* Calcd. for $C_{21}H_{21}O_2N$: C, 78.97; H, 6.63; N, 4.39. Found: C, 79.08; H, 6.55; N, 4.23.

The infrared absorption spectra showed a weak band at 2247 cm.$^{-1}$, the nitrile region, and a strong band at 1723 cm.$^{-1}$, the ester region.

**Hydrolysis of 4-Acetoxy-1-cyano-2,6-diphenylcyclohexane.**—A mixture of 2 g. (0.006 mole) of the acetoxynitrile and 50 g. of 40% aqueous sodium hydroxide was refluxed for twenty-four hours. When the mixture had cooled, the hardened organic layer was separated, washed with water, dissolved in ethanol and the solution treated with Darco and filtered. After acidification with concentrated hydrochloric acid, the solution was boiled and again filtered. Crystals which deposited from the cooled solution were collected on a filter and air-dried. The solid thus obtained melted at 125° and showed no depression in a mixed melt with a sample of 2,6-diphenyl-4-hydroxycyclohexane-1-carboxylic acid, δ-lactone.

**4-Chloro-1-cyano-2,6-diphenylcyclohexane. (A).**—Four grams (0.019 mole) of phosphorus pentachloride was added to a solution of 5 g. (0.018 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane in 125 cc. of dry benzene, and the mixture was refluxed for twenty-four hours. The warm reaction mixture was then shaken with an equal volume of water, separated, and shaken with an equal volume of 5% aqueous sodium hydroxide. Following separation, the solution was stirred with anhydrous sodium sulfate, filtered and the solvent removed. The residual oil, after being boiled for one hour with water, was dissolved in ethanol, treated with Norit, and the solution filtered. Chilling caused the deposition of prismatic needles which were then removed on a filter and air-dried. In this manner approximately 1.5 g. of solid was separated, which, after recrystallization from ethanol, melted at 150°. The yield was 26%.

*Anal.* Calcd. for $C_{19}H_{18}NCl$: C, 77.14; H, 6.13; N, 4.74. Found: C, 77.27; H, 5.97; N, 4.68.

(B).—Two cubic centimeters (3.3 g., 0.028 mole) of thionyl chloride was added to a solution of 5 g. (0.018 mole) of 1-cyano-2,6-diphenyl-4-hydroxycyclohexane in 100 cc. of dry benzene and 10 cc. of dry pyridine. A white precipitate formed immediately. During the subsequent reflux period of twenty-four hours, the white precipitate dissolved and sulfur dioxide was evolved. The reaction mixture was shaken twice with water, then filtered and the solvent removed, leaving a brown oil which was warmed with water for one hour, then separated, dissolved in ethanol, treated with Darco and the solution finally filtered. Chilling brought out a white solid which was collected on a filter and air-dried. There was thus obtained 1 g. of material melting at 143–145°, a yield of 19%. After recrystallization from absolute ethanol, the solid melted at 149–150° and showed no depression in a mixed melt with a sample of 4-chloro-1-cyano-2,6-diphenylcyclohexane.

## Summary

1-Cyano-2,6-diphenyl-4-hydroxycyclohexane has been synthesized. An interesting case of *cis–trans* inversion during the hydrolysis and decarboxylation of a cyanolactone has been observed. 1-Cyano-2,6-diphenyl-4-hydroxycyclohexane hydrolyzes with ease but its methyl ether requires rigorous conditions to effect hydrolysis of the nitrile group.

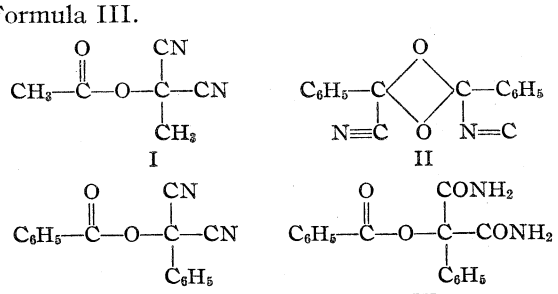
# Benzoyl Cyanide Dimer and the Addition of Benzoyl Cyanide to Aromatic Aldehydes[1]



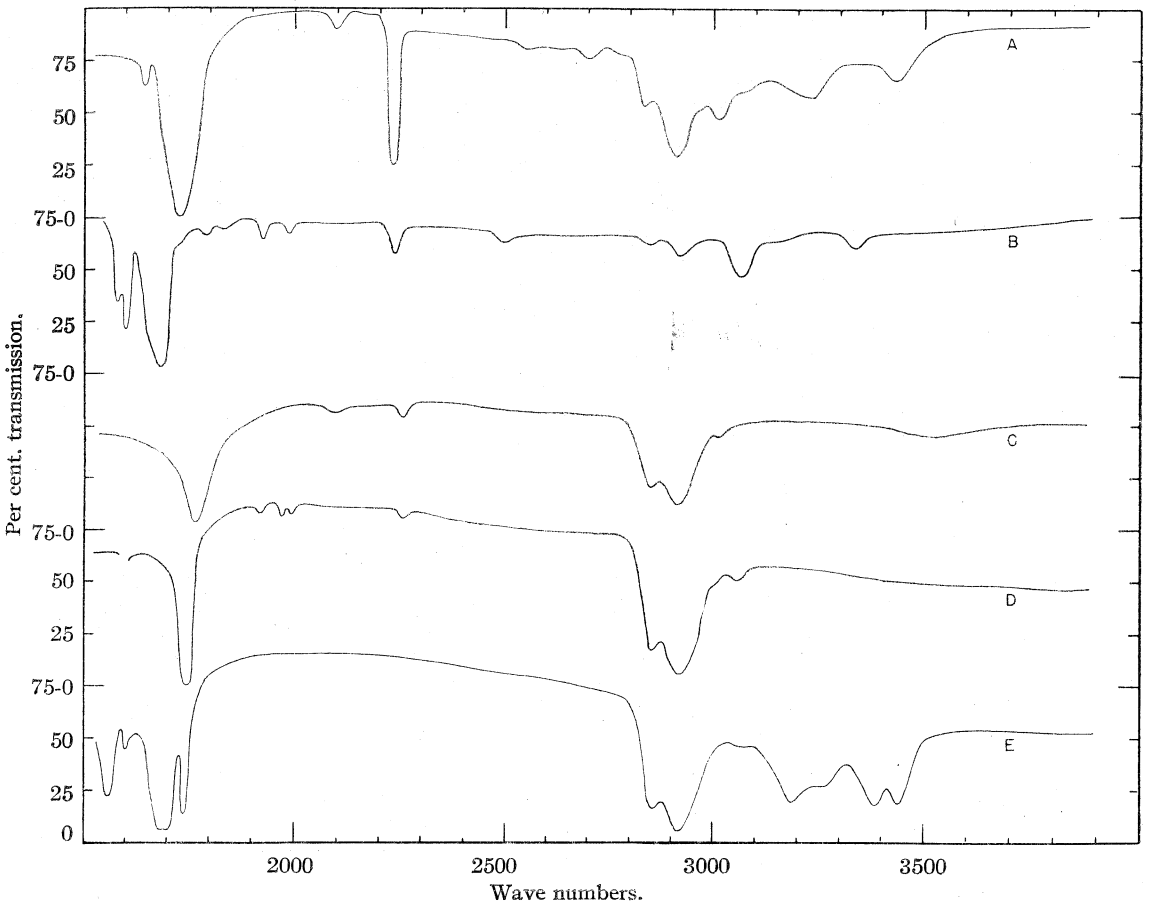
BY C. S. MARVEL, NEAL O. BRACE, FOIL A. MILLER AND AGATHA ROBERTS JOHNSON

While acetyl cyanide and benzoyl cyanide dimers are well characterized compounds, the structure of the latter has not been definitely determined. Brunner[2] assigned Formula I to acetyl cyanide dimer and this structure has been accepted by later workers.[3,4] Diels and Pillow[5] have suggested quite a different type of structure for benzoyl cyanide dimer (Formula II).

We isolated these two dimers as by-products in a reaction we were studying and became interested in their structures and the way in which they were formed. Since the formula for benzoyl cyanide dimer seemed to be less satisfactory than that of the acetyl cyanide dimer, we have re-examined this material and find that it is better described by Formula III.

Figs. 1a and b.—Infrared absorption spectra: A, acetyl cyanide [0.025 mm. liquid cell]; B, benzoyl cyanide [crystalline melt between rocksalt plates]; C, acetyl cyanide dimer; D, benzoyl cyanide dimer; E, diamide from benzoyl cyanide dimer. [These samples were prepared by grinding the crystalline compounds with paraffin oil to reduce light scattering. Absorptions due to the C–H frequencies of the paraffin oil occur at 2920, 2855, 1459 and 1378 cm.$^{-1}$ and partially mask the C–H frequencies of the compounds.]

(1) This investigation was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation in connection with the Government Synthetic Rubber Program.



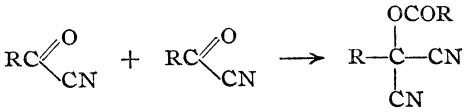
(2) Brunner, *Monatsh.*, **15**, 747 (1894).

(3) Bardroff, *ibid.*, **33**, 859 (1912).

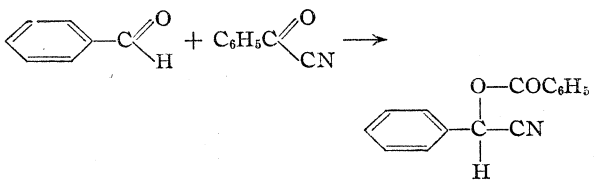
(4) Johnson and Newton, U. S. Patent 2,395,930 (1946); *C. A.*, **40**, 4078 (1946).

(5) Diels and Pillow, *Ber.*, **41**, 1893 (1908).

Diels and Pillow[5] suggested the nitrile–isonitrile structure (II) because they obtained only a monoamide on hydrolysis. We have found that a diamide (IV) can be obtained, and it is a sharper melting compound than the monoamide previously described.[5] Bardroff[3] had similarly prepared the diamide of acetyl cyanide dimer and proved its structure. He recognized that the structure postulated by Diels and Pillow[5] for benzoyl cyanide dimer was not satisfactory, but he did not attempt to relate the structure of this compound to that of acetyl cyanide dimer.



Infrared spectroscopic examination of acetyl cyanide dimer and benzoyl cyanide dimer show they are much alike in structure, and there is no evidence for a four-membered ring containing two oxygen atoms in the latter. Comparison of the spectra (Figs. 1a and b, curves C and D) of the two dimers indicates that they have analogous structures. Both show weak C≡N absorption (2256 cm.$^{-1}$) and strong C=O stretching frequencies (1746 and 1767 cm.$^{-1}$). The fact that the C=O band of the benzoyl cyanide dimer is 20 cm.$^{-1}$ lower than that of the acetyl cyanide dimer indicates that it is conjugated with the phenyl group. In the spectrum of the diamide of the benzoyl cyanide dimer (Figs. 1a and b, curve E) the C≡N absorption is absent and strong amide C=O absorption (1675–1700 cm.$^{-1}$) appears in addition to the C=O frequency found in the original compound. A complex series of N–H stretching frequencies also appear between 3190 and 3450 cm.$^{-1}$. Both these spectra (Figs. 1a and b, curves D and E) show the characteristic carbon-carbon stretching frequencies of the phenyl group, at 1493 and 1602 cm.$^{-1}$. The presence of two strong bands around 700 cm.$^{-1}$, where the mono-substituted phenyl group absorbs, indicates two types of mono-substitution, *e. g.* $C_6H_5C(=O)-$ and $C_6H_5-\underset{|}{\overset{|}{C}}-$. The remainder of the strong absorption bands in the spectra (from 800–1400 cm.$^{-1}$) are due to vibrations of C—O, C—C, C—N linkages and extensive parts of the molecules. These frequencies are too greatly affected by slight changes in structure to be of any value in interpretation.



The infrared absorption curves of acetyl (Figs. 1a and b, curve A) and benzoyl (Figs. 1a and b, curve B) cyanide both show a C≡N stretching frequency at 2235 cm.$^{-1}$ and ketone C=O around 1700 cm.$^{-1}$. This is at a lower frequency in the benzoyl where it is more highly conjugated. Characteristic phenyl frequencies appear in curve

B at 1600, 1580, 1490 cm.$^{-1}$ and at 700 cm.$^{-1}$ for the mono-substituted phenyl group. As is typical of methyl ketones, except acetone, the acetyl cyanide absorbs in the $CH_3$ region (1370 cm.$^{-1}$) and has a strong band around 1170 and one between 700 and 800 cm.$^{-1}$.

The dimers thus have the structure that might be expected if one acyl cyanide molecule adds to the carbonyl group of another molecule. A reaction of this general type for acyl halides and aldehydes was reported by Adams and his students[6]

some years ago. It has now been found that benzoyl cyanide will indeed add to the active carbonyl group of an aromatic aldehyde in the presence of catalytic amounts of aqueous potassium hydroxide. This furnishes a convenient method of converting an aromatic aldehyde to the benzoate of the corresponding cyanohydrin.

The reaction works well with benzaldehyde and anisaldehyde, but thus far we have not extended it to aliphatic aldehydes or to any ketone. It is obvious that for the reaction to go well the carbonyl compound used with an acyl cyanide must have a more active carbonyl group than the acyl cyanide itself.

## Experimental

**Acetyl Cyanide Dimer and Benzoyl Cyanide Dimer.**—$\alpha$-Acetoxy-$\alpha$-methylmalononitrile was obtained by high vacuum distillation of the residue of a reaction employing acetic anhydride and aqueous potassium cyanide as clear liquid, b. p. 82° (6 mm.), which on cooling solidified to a white solid, m. p. 69°, having an odor reminiscent of hydrogen cyanide and acetic acid. The solid was crystallized from aqueous alcohol solution. Brunner[2] gives the melting point for acetyl cyanide dimer as 69°.

*Anal.* Calcd. for $C_6H_6O_2N_2$: C, 52.17; H, 4.38; N, 20.29. Found:[7] C, 52.01; H, 4.18; N, 20.28.

Similarly, $\alpha$-benzoyloxy-$\alpha$-phenylmalononitrile was obtained by high vacuum distillation of the residue of a reaction employing benzoyl chloride and aqueous potassium cyanide as a yellow, viscous liquid, b. p. 150° (1 mm.), which solidified on cooling to a white solid, m. p. 95°. The solid was recrystallized from alcohol, m. p. 95°.

*Anal.* Calcd. for $C_{16}H_{10}O_2N_2$: C, 73.30; H, 3.85; N, 10.64. Found: C, 72.76; H, 3.66; N, 10.48.

(6) Adams and Vollweiler, THIS JOURNAL, **40**, 1732 (1918); Adams and French, *ibid.*, **43**, 651 (1921); Adams and Ulich, *ibid.*, **43**, 660 (1921).

(7) We are indebted to Mr. H. S. Clark, Clark Microanalytical Laboratory, for all microanalyses reported in this communication.

**$\alpha$-Phenyl-$\alpha$-benzoyloxymalonamide.**—Two grams of $\alpha$-benzoyloxy-$\alpha$-phenylmalononitrile was placed in a 125-ml. erlenmeyer flask and dissolved in 10 ml. of concentrated sulfuric acid. As a few drops of water were added, the temperature rose to 85°. The flask was cooled in an ice-bath, and a white solid separated out as 100 ml. of water was slowly added with stirring. The solid was collected on a Buchner funnel and washed with cold water. The material was recrystallized from 100 ml. of benzene containing a small amount of alcohol. The recrystallized material, after drying at 55°, melted at 185–190°. After further recrystallization from benzene containing a little alcohol and ether, the solid melted at 203.5–204.5° (uncor.).

*Anal.* Calcd. for $C_{16}H_{14}O_4N_2$: C, 64.42; H, 4.73; N, 9.39. Found: C, 64.60; H, 4.90; N, 9.20.

**Acetyl Cyanide and Benzoyl Cyanide.**—Acetyl cyanide was prepared from cuprous cyanide and acetyl bromide according to the directions given by Migrdichian[8] and benzoyl cyanide by the method given in "Organic Syntheses."[9]

**Benzoate of *p*-Methoxybenzaldehyde Cyanohydrin.**—Three grams (0.023 mole) of benzoyl cyanide and 3 g. (0.023 mole) of anisaldehyde were mixed in a 50-ml. glass-stoppered bottle, and 6 ml. of 10% aqueous potassium hydroxide solution was added. The bottle was shaken about ten minutes. An emulsion formed first, and later a viscous yellow oil settled out. The aqueous layer was decanted and the residual oil crystallized from alcohol. There was obtained 2.8 g. (46%) of a solid, m. p. 64–65°; the mother liquor contained additional material which did not crystallize. Recrystallization of the solid did not change the melting point.

A mixed melting point determination with an authentic sample of the benzoate of *p*-methoxybenzaldehyde cyanohydrin (m. p. 64–65°) prepared by the method of Francis and Davis[10] showed no depression. These authors gave the value of 66–67° for the melting point of this compound.

*Anal.* Calcd. for $C_{16}H_{13}O_3N$: C, 71.91; H, 4.86; N, 5.24. Found: C, 72.09; H, 4.78; N, 5.14.

**Benzoate of Benzaldehyde Cyanohydrin.**—In a 50-ml. glass-stoppered bottle were placed 2 g. (0.015 mole) of benzoyl cyanide, 1.6 g. (0.015 mole) of benzaldehyde and 6 ml. of 5% aqueous potassium hydroxide. The bottle was shaken for about fifteen minutes and a white solid ball formed. The aqueous solution was decanted, and the solid was recrystallized from alcohol. There was obtained 0.45 g. of the benzoate of benzaldehyde cyanohydrin, m. p. 59°, and 0.3 g. of a white solid, m. p. 121° (probably benzoic acid). From the mother liquor there was obtained by further evaporation 1.3 g. of solid, m. p. 54–55°, making a total yield of 49%. Recrystallization of the material melting at 59° did not change its melting point.

*Anal.* Calcd. for $C_{15}H_{11}NO_2$: C, 75.93; H, 4.67; N, 5.90. Found: C, 76.03; H, 4.73; N, 5.91.

Francis and Davis[10] report the melting point of the benzoate ester of benzaldehyde cyanohydrin as 63–64°.

## Summary

Benzoyl cyanide dimer has been shown to be $\alpha$-benzoyloxy-$\alpha$-phenylmalononitrile. It is apparently formed by one molecule of benzoyl cyanide adding to the carbonyl group of another. This view is favored by the fact that benzoyl cyanide adds readily to aromatic aldehydes to give the benzoate of the corresponding cyanohydrin.

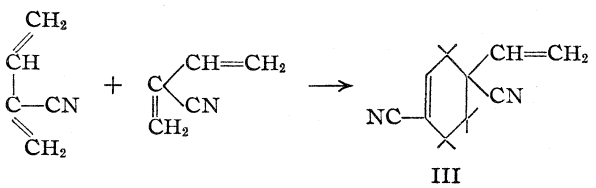
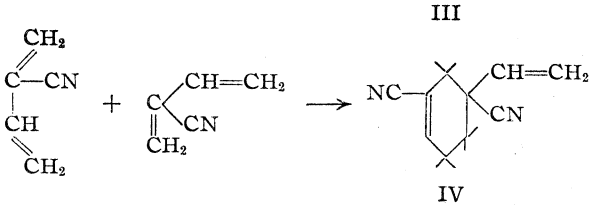
# The Dimer of 2-Cyano-1,3-butadiene[1]



BY C. S. MARVEL AND NEAL O. BRACE

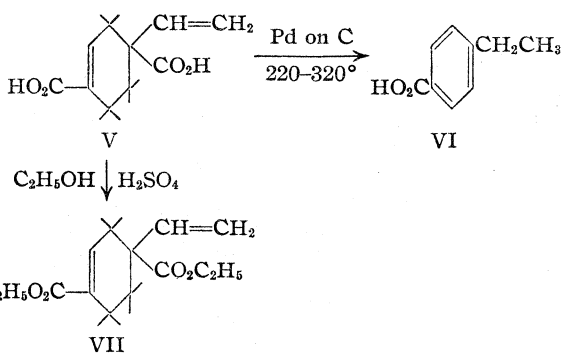
Dimerization is a reaction characteristic of 1,3-butadiene and its derivatives. Thus, it was not surprising to find that 2-cyano-1,3-butadiene on standing in an ice-box, even though picric acid was present, gradually changed to a low-melting solid. The closely related 2-chloro-1,3-butadiene has been shown to yield two dimers, the first a cyclohexene derivative (I)[2,3] and the second a cycloöctadiene derivative (II).[3] Hence we have considered similar possibilities for the structure of the dimer of the cyano derivative.



I II

Although there are several possible dimers, the Diels–Alder type of dimerization seems somewhat more probable in the case of 2-cyano-1,3-butadiene since there is present a common dieneophilic group. The Diels–Alder type of self-addition could produce either of two isomeric cyclohexene derivatives III or IV depending on the relative positions of the substituents in the final ring.

III



IV

The crude solid obtained from 2-cyano-1,3-butadiene, prepared by cracking the acetate of methyl vinyl ketone cyanohydrin,[4] melted at 30–40°. Purification by evaporation of monomer and crystallization of the solid residue gave long, thin plates which had a melting point of 55°. The melting point was not changed by further purification. Analysis and molecular weight determinations showed this compound was a dimer of the original diene. No other dimer was identified although small amounts may have been present in the residues.

The dimer showed two carbon–carbon double bonds by catalytic hydrogenation. The first mole of hydrogen was absorbed very rapidly and the second mole was added more slowly. Saponification with aqueous alkali gave a single acid (V) with a neutral equivalent of 100.4. This acid also contains two double bonds as shown by catalytic hydrogenation. It gave a diester (VII) with ethyl alcohol. This unsaturated dibasic acid was heated with palladium-on-charcoal containing a little copper chromite catalyst.[5] Carbon dioxide and hydrogen were evolved and a low yield of pure *p*-ethylbenzoic acid (VI) was isolated from the solid residue. No other dehydrogenation product was found.

The isolation of this acid is evidence that the dimer of 2-cyano-1,3-butadiene which we have isolated is best represented by formula III.

V VI VII

Further confirmatory evidence for the structures assigned has been obtained from the infrared spectra[6] of the dimer and of the diester (VII) (see Figs. 1a and b). The infrared absorption curves show two different nitrile absorption maxima, *i. e.*, 2220 (conjugated) and 2243 cm.$^{-1}$ (unconjugated) for the dimer of 2-cyano-1,3-butadiene (III) (curve A), and two different ester carbonyl absorption maxima, 1715 (conjugated) and 1730 cm.$^{-1}$ (unconjugated) for the diester (VII) (curve B) as well as conjugated and unconjugated double bond absorption maxima for both compounds, 1639 and 1649 cm.$^{-1}$ for the dimer (III) and 1636 and 1654 cm.$^{-1}$ for the diester (VII). A structure analogous to either of the 2-chloro-1,3-butadiene dimers (I or II) would have both nitrile groups conjugated with a double bond and would show only one absorption maximum in the nitrile

(6) We are indebted to Dr. Foil A. Miller and Mrs. J. L. Johnson for the infrared absorption curves and for their interpretation.

Infrared absorption spectra: Figs. 1a and b.—Curve A, dimer of 2-cyano-1,3-butadiene (run as crystalline melt between two rocksalt plates); curve B, diester (run as a liquid in an 0.025 mm. rocksalt cell).

frequency band of the infrared absorption spectrum.

The molar refractivity of the diester (VII) as calculated from the physical data is 0.34 higher than the figure obtained using the values given in the tables[7] for atomic refractivities. This exaltation may be attributed to one conjugated ester group but is hardly large enough to indicate two conjugated ester groups.

## Experimental

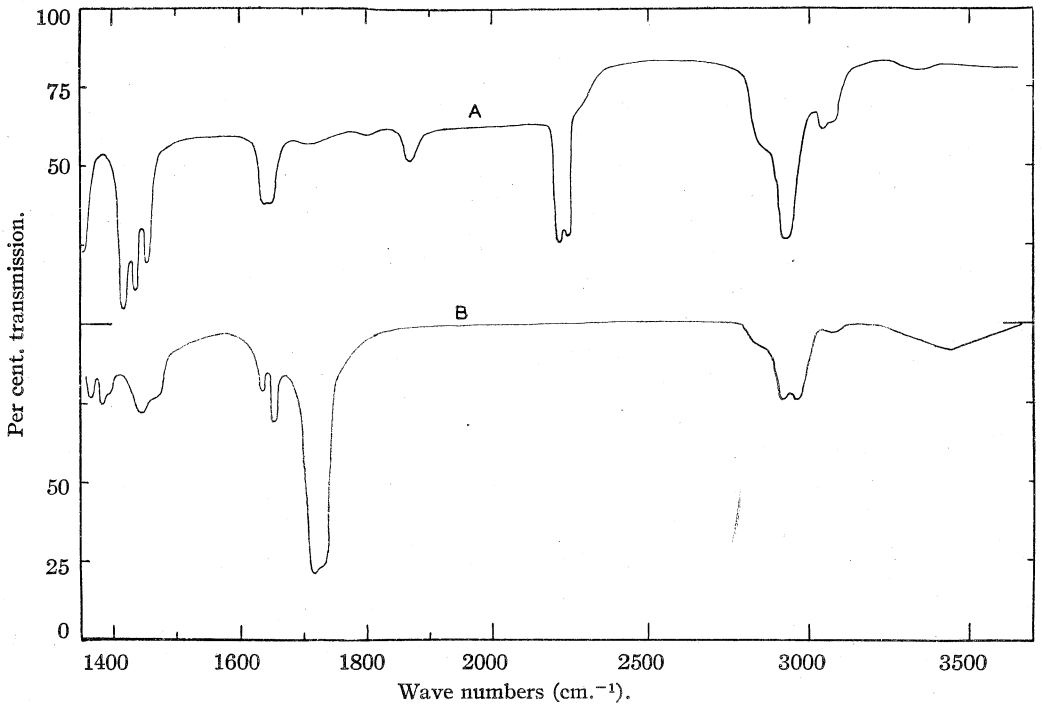
**Dimer of 2-Cyano-1,3-butadiene.**—A sample of 57 g. of 2-cyano-1,3-butadiene, containing a little picric acid as polymerization inhibitor, when stored at 5° for about three months solidified to the extent of about 75%. When warmed to room temperature the solid dissolved, but after the excess monomer was removed by distillation the residual viscous oil (*ca.* 40 g.) crystallized when cooled, m. p. range 30–40°.

In another instance, the solid residue remaining in a bottle of 2-cyano-1,3-butadiene (containing picric acid as inhibitor) which had been stored in an ice-box for about six months was scraped out and placed in a small ground-glass distilling flask. The dimer was distilled under high vacuum through an 8-in., helix-packed column. There was obtained 4.2 g. of liquid, b. p. 110–112° (1 mm.), which solidified on standing to a white solid, m. p. range 30–40°. A brown, semi-viscous liquid which remained in the flask became spongy when cooled but was interspersed with crystallites. The material darkened on standing. An analysis of the liquid, b. p. 110–112° (1 mm.), was obtained.

*Anal.* Calcd. for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; N, 17.71. Found:[8] C, 74.46; H, 5.94; N, 16.74.

This compound was dissolved in alcohol, treated with Darco, and filtered. The filtrate was evaporated and a few milliliters of water added until the solution began to get cloudy at 50°. When cooled to room temperature, the solution was seeded with a small crystal previously isolated and placed in the ice-box. The mass of crystals which formed was collected on a Buchner funnel, washed with very dilute alcohol, and air-dried, m. p. 54–54.5°. Further similar treatment of the filtrate (omitting the Darco) yielded three more crops of crystals. The third crop, which melted over the range of 44–51°, was contaminated with some residual oil, but the fourth crop was colorless and melted at 54–55°. In another experiment crystals were obtained which melted at 55–56°. Analysis of this crystalline material, in contrast to the compound which had merely been distilled, agreed well with the theoretical for a dimer.

*Anal.* Calcd. for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; N, 17.71; mol. wt., 158.2. Found: C, 75.92; H, 6.53; N, 17.67; mol. wt. (cryoscopic) in acetic acid, 146; in benzene (ebulloscopic), 141.



The dimer is soluble in dioxane, absolute ethanol, acetic acid, acetone, benzene and ether, gives a cloudy solution with methanol, and is insoluble in water, cyclohexane and Skellysolve B. The dimer in acetone solution decolorized dilute potassium permanganate solution rapidly.

**Hydrogenation of 2-Cyano-1,3-butadiene Dimer.**—In a ground-glass hydrogenation bottle were placed 0.1547 g. of 10% palladium-on-charcoal and 30 cc. of absolute methanol. The bottle was placed in the quantitative hydrogenation apparatus and evacuated and filled twice with hydrogen. Shaking was begun while the volume, temperature and pressure of the hydrogen was noted. The catalyst absorbed 6 cc. of hydrogen at 27° and 742 mm. pressure in seven minutes but absorbed no more hydrogen with shaking an additional twenty minutes.

The reduced catalyst was collected on a Hirsch funnel with suction and washed with 200 cc. of absolute methanol to remove the last traces of chloride ion, keeping the pyrophoric catalyst moist. The catalyst was transferred to the hydrogenation bottle, 0.3635 g. (0.00230 mole) of

(7) Shriner and Fuson, "Identification of Organic Compounds," 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1940, p. 107.

(8) The microanalyses reported in this work were done by the Clark Microanalytical Laboratory, Urbana, Illinois.

recrystallized dimer (m. p. 53–55°) was added, and the solid washed down with 30 cc. of absolute methanol. The bottle was placed in the hydrogenation apparatus, evacuated and filled with hydrogen three times, and shaking was begun at 28° and 742 mm. In seven minutes the compound absorbed 58 cc. of hydrogen. This is the amount required by 0.00230 mole for one double bond. The hydrogenation rate then became slower, and a total of 116 cc. of hydrogen (30° and 742 mm.) was absorbed by the compound over a period of seven hours. The amount calculated for 0.00230 mole for two double bonds is 117.0 cc. at 29° and 742 mm.

The catalyst was filtered and the methanol evaporated. The residue was taken up with 95% ethanol and heated on the water-bath at 50° while water was added drop by drop until the solution began to get cloudy. The solution was placed in the ice-box. The reduced material separated as an oil. No crystalline isomer was separated from the mixture.

**Saponification of the Dimer of 2-Cyano-1,3-butadiene.**—Four and one-half grams (0.0286 mole) of the crude solid was heated under reflux with 6.7 g. (0.12 mole) potassium hydroxide in 30 cc. of water. During the heating ammonia was liberated. An additional 0.5 g. of potassium hydroxide was added and refluxing was continued for four hours. No more ammonia could be detected at the top of the reflux condenser. One gram of Darco was added to the resulting orange solution and the mixture was then filtered. The solution was cooled in ice and acidified with 50% sulfuric acid. The precipitated acid was collected on a Buchner funnel, redissolved in 95% ethanol, and concentrated some by evaporation. Then water was added and the solution was allowed to crystallize at room temperature. The first crop of crystals, silvery-white leaflets, amounted to 0.3 g.; m. p. 235–236° (sintered 230°). By further evaporation of the filtrate and crystallization from dilute alcohol solution a total of 2.6 g. of solid (*ca.* 50%), m. p. 235–236°, was collected. A portion of material was lost.

In a second experiment 3.6595 g. of the dimer was saponified by heating with 15 g. of sodium hydroxide in 50 cc. of water over a period of fourteen and one-half hours. The alkaline solution was added slowly with very rapid stirring to a solution of 41.5 cc. of 12 *N* hydrochloric acid and 50 cc. of water in a 250-cc. beaker. The precipitated acid was collected on a Buchner funnel, washed with distilled water and dried in an oven at 55° for two hours, m. p. 231–232° (sintered 229°). The yield was 3.0881 g. or 70.5%. The acid was recrystallized from alcohol–water solution, m. p. 235°.

*Anal.* Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17; neutral. equiv., 98.1. Found: C, 60.80, 60.73; H, 6.11, 6.34; neutral. equiv., 100.4.

This acid was soluble in alcohol and hot water, and sparingly soluble in ether, benzene and acetone. It decolorized dilute potassium permanganate solution when dissolved in 95% ethanol. It did not decolorize bromine in carbon tetrachloride solution.

**Determination of the Number of Double Bonds in the Unsaturated Acid by Hydrogenation.**—A hydrogenation apparatus designed to measure quantitatively the amount of hydrogen taken up by an unsaturated compound was used in this experiment. There were placed in the reduction bottle 50 cc. of absolute ethanol, 0.5 g. of 10% palladium-on-charcoal and 0.1962 g. (0.001 mole) of the unsaturated acid. The system was evacuated and filled with hydrogen twice, the volume of hydrogen at 737 mm. and 23.8° was noted and shaking begun. In one minute 53.5 cc. of hydrogen was absorbed before stopping the shaker. The gas buret was refilled and shaking was resumed. In the next hour and twenty minutes, 42.9 cc. of hydrogen at 23° and 742 mm. was absorbed, making a total of 96.4 cc. of hydrogen.

In a blank determination, 0.500 g. of 10% palladium-on-charcoal in 50 cc. of absolute alcohol took up 40 ± 2 cc. of hydrogen at 22° and 749 mm. pressure. This is equivalent to 42 cc. at 742 mm. and 23°. In other words, the unsaturated compound itself absorbed 54 ± 2 cc. of hydrogen. The amount calculated for two double bonds is 50.0 cc. at 23.8° and 742 mm.

**Dehydrogenation of the Unsaturated Acid with Palladium-on-Charcoal.**—In an 18 × 150 mm. Pyrex test-tube were placed 1.00 g. (0.00510 mole) of the unsaturated acid, 0.100 g. of 10% palladium-on-charcoal catalyst, and 0.01 g. of copper chromite catalyst. The materials were mixed and the test-tube closed with a one-hole rubber stopper fitted with a 6-in. length of glass tubing. The tube was connected by means of rubber tubing to a U-shaped capil-

lary glass tubing immersed in a pan of water and extending part way up into a 50-cc. buret filled with water and standing in the water.

The evolved gas was collected in the buret and the volume, temperature, and pressure of the gas noted as the dehydrogenation was carried out. As one buret became filled with gas another was put in its place.

The test tube was placed in a Wood's metal-bath heated with a Bunsen burner to an initial temperature of 220°. Gas bubbles began to appear after a few minutes of heating and, as they began to slacken, the temperature of the bath was raised over a period of four hours. The final temperature was 320°. A total volume of 163.5 cc. of gas at standard temperature and pressure (corrected for water vapor pressure) was collected. The theoretical amount of hydrogen at standard temperature and pressure is 114 cc. for 0.00510 mole. An equal amount of carbon dioxide should be evolved, and this explains the excess over the theory for hydrogen. Most of the carbon dioxide was lost by solution in the water over which the gas was collected.

The residue in the test-tube was extracted with ether. The ether solution was filtered and evaporated. The oily residue solidified on cooling. It was dissolved in alcohol, treated with Darco, and filtered. Two successive attempts at crystallization by adding water to the hot solution and cooling yielded only gummy precipitates. The alcohol solution was transferred to a 10-cc. distilling flask, the alcohol removed, and the residue subjected to distillation at reduced pressure. Only a drop or two collected in the side-arm (b. p. 145–150° (19 mm.)), but when the distilling flask cooled, solid crystals appeared on the sides. The crystals, which were removed, amounted to 0.053 g., m. p. 98–105°. After recrystallization from alcohol–water solution, the melting point was 112°. The literature gives 110–111°[9] and 112–113°[10] for the melting point of *p*-ethylbenzoic acid. *m*-Ethylbenzoic acid is reported to melt at 47°.[11]

*Anal.* Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71. Found: C, 71.50; H, 6.99.

**Esterification of the Unsaturated Dibasic Acid.**—In a 50-cc., ground-glass, round-bottom flask attached to a 2-ft., water-cooled condenser were placed 0.98 g. (0.005 mole) of the unsaturated acid (m. p. 235°), 5 cc. of absolute alcohol (0.085 mole) and 2 drops of concentrated sulfuric acid. The reactants were refluxed on the steam-bath for four hours. Then 10 cc. of benzene was added, the water-cooled condenser replaced by a 10-in. Vigreux column and a total reflux-partial take-off head and the solution heated under practically total reflux as the azeotropic mixture of alcohol, benzene, and water was taken off at 65–72° over a period of four and one-half hours. The remaining traces of benzene and alcohol were removed by distillation under water pump pressure.

The residue was dissolved in 50 cc. of distilled ether and washed three times with 15-cc. portions of 5% aqueous potassium hydroxide solution, dried over anhydrous sodium sulfate, filtered, and distilled under reduced pressure in a 10-cc. distilling flask. The ester boiled at 131–133° (3 mm.) and amounted to 15–20 drops; $n^{20}D$ 1.4801[12]; $d^{20}_4$ 1.0639[12]; $M_D$ calcd. 67.04; $M_D$ found 67.38 (exaltation of 0.34).

The ester was soluble in alcohol, ether and chloroform. It was insoluble in dilute potassium hydroxide and 10% sodium bicarbonate solution. The ester decolorized dilute aqueous potassium permanganate solution but did not decolorize bromine in chloroform solution.

*Anal.* Calcd. for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99. Found: C, 66.54; H, 7.95.

Acidification of the potassium hydroxide wash solution with concentrated hydrochloric acid gave 0.128 g. of recovered acid, m. p. 233–234°.

## Summary

2-Cyano-1,3-butadiene dimerizes on standing at 5° in the presence of a trace of picric acid to yield a solid whose structure is that of the Diels–Alder condensation product, 1-vinyl-1,4-dicyano-$\Delta^4$-cyclohexene. Proof of the six-membered ring structure was obtained by converting the dimer to an unsaturated dibasic acid which was dehydrogenated and decarboxylated to *p*-ethylbenzoic acid.

The infrared absorption spectra of the dimer and of the diester prepared from it indicate the presence of a conjugated and an unconjugated nitrile group and ester group, respectively, thus confirming the structure assigned on the basis of degradation. No evidence for an eight-membered dimer was noted. Smaller amounts of other dimers may have been lost in working up the mixture.

# Orthoesters and Related Compounds from Malono- and Succinonitriles

By S. M. McElvain and Juel P. Schroeder[1]

The study of the preparation of orthoesters from nitriles, which has been in progress for some time in this Laboratory[2] in connection with work on the ketene acetals, has been extended to malono- and succinonitriles. The present paper reports the preparation and alcoholysis of the various iminoester hydrochlorides that may be obtained from these dinitriles and describes certain related products resulting from these reactions.

(1) Wisconsin Alumni Research Foundation Research Assistant, 1946–47; University Fellow, 1947–48.

(2) McElvain and (a) Nelson, This Journal, **64**, 1825 (1942); (b) Clarke, *ibid.*, **69**, 2661 (1947); (c) Stevens, *ibid.*, **69**, 2663 (1947).

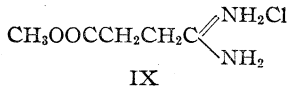
Treatment of each of these dinitriles with equivalent amounts of methanol and hydrogen chloride gave the monoimino salts (I and III) readily and methanolysis of these salts gave good yields of the corresponding cyanoörthoesters (II and IV). In the case of II it was necessary to remove all traces of acid from the reaction product with aqueous sodium carbonate solution before distillation to prevent the pyrolysis of the orthoester to cyanoketene dimethylacetal.

Attempts to convert II to the corresponding iminoester with equivalent amounts of methanol

$$CH_2(CN)_2 \xrightarrow{94\%} CNCH_2C(OCH_3)=NH_2Cl \xrightarrow{65\%} CNCH_2C(OCH_3)_3$$
I II

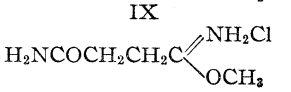
$$(CH_2CN)_2 \xrightarrow{80\%} CN(CH_2)_2C(OCH_3)=NH_2Cl \xrightarrow{77\%} CN(CH_2)_2C(OCH_3)_3$$
III IV

and hydrogen chloride gave none of the iminoester hydrochloride but instead the corresponding normal esters in the yields shown



$$II \xrightarrow[HCl]{CH_3OH} \underset{73\%}{CNCH_2COOCH_3} + \underset{21\%}{CH_2(COOCH_3)_2} + \underset{18\%}{NH_4Cl}$$

It appears that most of the hydrogen chloride was consumed in cleavage of II to the cyano-ester, methanol and methyl chloride before it reacted with nitrile and methanol to give the iminoester hydrochloride. The orthoester IV showed a similar tendency to be cleaved by hydrogen chloride prior to reaction of the nitrile group. In an attempt to prepare the diorthoesters directly from the dinitriles, each of the latter was dissolved in sufficient methanol to retain the intermediate salts (I and III) in solution and treated with two equivalents of hydrogen chloride. From these reactions also normal esters were the sole reaction products.



These results indicate that orthoesters of malonic and succinic acids cannot be prepared by a stepwise alcoholysis of the corresponding nitriles. Consequently, their preparation from the di-iminoester hydrochlorides was undertaken. The preparation of diethyl iminomalonate dihydrochloride (VI) in high yields has been reported[3] from the reaction of malononitrile with equivalent amounts of ethanol and hydrogen chloride *in ether solution*. This preparation could not be duplicated in the present work using either methanol or ethanol; instead, the only reaction products obtained were the monohydrochlorides corresponding to I or mixtures of the mono and dihydrochlorides, which precipitated from the reaction mixture. However, the preparation of the di-iminoester salt (VI) in quantitative yield was accomplished by treating the nitrile and alcohol in dioxane solution with a large excess of hydrogen chloride. The melting point of VI (119–120°) so obtained did not correspond to that (138°) previously reported,[3a] but its structure was shown beyond doubt by its halogen content and by its pyrolysis to ethyl chloride (93%) and malonamide (81%). Attempts to prepare the homologous methyl iminoester salt by this procedure gave a mixture of I and V. However, the use of a mixture of chloroform and dioxane as solvent gave V in reasonably pure form. The preparation of the di-iminoester salt VIII from succinonitrile has been reported.[4] Both VII and VIII were readily prepared in practically quantitative yields in the present work using dioxane as a solvent.

$$ClNH_2=(RO)C(CH_2)_nC(OR)=NH_2Cl$$

V. R is $CH_3$, $n$ is 1
VI. R is $C_2H_5$, $n$ is 1
VII. R is $CH_3$, $n$ is 2
VIII. R is $C_2H_5$, $n$ is 2

IX

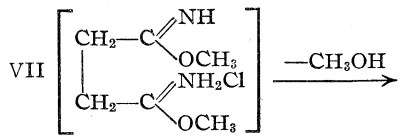
X

Methanolysis of VII by the procedures used for the cyanoörthoesters II and IV gave dimethyl succinate (45%), ammonium chloride (57%), and β-carbomethoxypropionamidine hydrochloride,[5] IX (36%). The structure of the latter compound was proved by the following synthesis, which eliminates the alternative isomeric structure (X) that might conceivably be a product of this reaction.

$$CH_3OOCCH_2CH_2CN \xrightarrow[HCl]{CH_3OH} CH_3OOCCH_2CH_2C(OCH_3)=NH_2Cl \xrightarrow{NH_3} IX$$

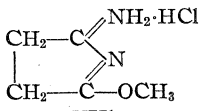
Alkaline hydrolysis converts the amidine salt (IX) to ammonia and succinic acid; acid hydrolysis converts it to β-carboxypropionamidine, which, as the free base, appears to exist as an inner salt, judging from its high melting point and insolubility in water and other inert solvents.

An attempt to prepare the free base from the di-iminoester hydrochloride VII furnished some insight into the mechanism by which IX is formed during the alcoholysis of VII. When VII was treated with an excess of aqueous sodium bicarbonate solution, a clear solution[6] resulted and only one of the hydrochloride functions was decomposed, as shown by the amount of carbon dioxide evolved. When this solution was acidified and subjected to mild hydrolysis for several hours, β-carboxypropionamidine (56%), succinimide (25%) and succinic acid (12%) were isolated. From these results it would appear that the bicarbonate converted VII to a monohydrochloride VIIa, which by loss of methanol passed into the cyclic amidino-ester hydrochloride (VIIb), the structure of which accounts for the failure of the weaker alkali to neutralize but one of the hydrochloride functions of VII as well as the water-solubility of the resulting product. The compounds isolated from the acidic hydrolysis of the half-



(3) (a) Houben and Blaise, Houben, "Die Methoden der organischen Chemie," 3rd Ed., Vol. VI, p. 436; (b) Kenner, Lythgoe, Todd and Topham, *J. Chem. Soc.*, 574 (1943).

(4) Pinner, *Ber.*, **16**, 352 (1883). No yield of VIII was reported; this method used ether as a solvent and it started with a two-phase system (succinonitrile is sparingly soluble in ether) which was reported to change, as the hydrogen chloride was absorbed, to a homogeneous solution, from which the salt finally precipitated.



(5) Pinner, ref. 4, noted the concurrent formation of an amidine salt and an ester during the pyrolysis of ethyl iminoformate hydrochloride.

(6) With sodium hydroxide solution a resinous product was precipitated; Pinner (ref. 4), who attempted to isolate the free base of VIII with similar results, assumed that the clear solution obtained was due to the water solubility of the free base.

neutralized solution of VII would be expected from the intermediate cyclic salt VIIb. From these observations it seems reasonable to conclude that IX is formed during the methanolysis of VII *via* the intermediate iminoester VIIb.

VIIa

VIIb

The isolation of normal esters instead of orthoesters in the above alcoholyses indicated that the latter esters were being destroyed during the removal of the alcohol from the alcoholysis solution prior to the alkaline wash. This supposition was confirmed when the two orthoesters XI and XII were obtained by the procedure[2b] in which the solution, resulting from the alcoholysis of VII, was neutralized with sodium methoxide prior to the removal of the alcohol. In this manner methyl ortho-β-carbomethoxypropionate (XI) and methyl orthosuccinate (XII) were obtained in 11 and 15% yields, respectively.

$CH_3OOCCH_2CH_2C(OCH_3)_3$ XI $(CH_3O)_3CCH_2CH_2C(OCH_3)_3$ XII

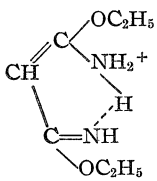
The ester XI, which may be obtained in much higher yield (63%) from methyl β-cyanopropionate, is a liquid with marked stability to heat; for example, no change was noted in a sample after refluxing (b. p. 210°) for one and one-half hours. This is in marked contrast to the β-cyano-orthoester (IV) which slowly but steadily loses methanol under similar conditions. The di-orthoester XII is a crystalline solid, m. p. 50–51°. It loses methanol slowly on heating and is converted to a high-boiling, viscous oil which was not studied further.

An attempt was made to obtain the diorthoester XII from the trichloroörthoester XIII, which was prepared in good yields from γ,γ,γ-trichlorobutyronitrile. However, XIII failed to undergo a replacement reaction with sodium methoxide; instead it was dehydrohalogenated to a product which gave analytical data approximating those calculated for the structure XIV.

$$\underset{\text{XIII}}{Cl_3CCH_2CH_2C(OCH_3)_3} \xrightarrow{NaOCH_3} \underset{\text{XIV}}{ClC{\equiv}CCH_2C(OCH_3)_3}$$

The preparation of ethyl orthocarbethoxyacetate (XV), a malonic ester corresponding to XI, was accomplished from ethyl cyanoacetate using the same procedure that proved successful for II.[7]

(7) In this connection it is of interest to note that Reitter and Weindel (*Ber.*, **40**, 3358 (1907)) reported that the alcoholysis of ethyl carbiminoethoxyacetate hydrochloride yielded carbethoxyketene diethylacetal instead of the expected orthoester (*cf.* also ref. 10).



However, the alcoholysis of the diiminoester hydrochloride VI by the procedure that produced XI and XII in the succinic series failed to yield either XV or ethyl orthomalonate (XVI). Instead, ethyl malonate, carbethoxyacetamide, ethyl cyanoiminoacetate (XVII) and ethyl orthocarbiminoethoxyacetate (XVIII) were the products isolated from the reaction.

$C_2H_5OOCCH_2C(OC_2H_5)_3$ XV $(C_2H_5O)_3CCH_2C(OC_2H_5)_3$ XVI

$CNCH_2C(OC_2H_5){=}NH$ XVII $CNCH{=}C(OC_2H_5){-}NH_2$ XVIIa

$HN{=}(C_2H_5O)CCH_2C(OC_2H_5)_3$ XVIII

A singular feature of this alcoholysis was the separation of only 50–55% of the expected ammonium chloride, regardless of the time (twenty to one hundred thirty hours) allowed for the alcoholysis. However, the alcoholic solution from which the ammonium chloride was filtered still contained sufficient hydrochloride salt to require 0.5 of an equivalent of sodium ethoxide (25%) for neutralization after correction for the dissolved ammonium chloride. This fact, the relatively low yield of ammonium chloride, together with the isolation of such products as XVII and XVIII, suggest that a considerable portion of the dihydrochloride VI, which is very insoluble in alcohol, is converted to a more soluble monohydrochloride,[8] which resists alcoholysis by virtue of the resonance stabilization of the ene-amine form of its cation

The neutralization of this cation by sodium ethoxide would produce XVII.[9] The iminoesterorthoester (XVIII) could be formed by the partial alcoholysis of VI and possibly also by the slower alcoholysis of the above cation of the monohydrochloride.

The exaltation of the molar and specific refractivities of ethyl cyanoiminoacetate indicate that it exists in the ene-amine from (XVIIa) as does the corresponding carbiminoethoxyester,[10] $C_2H_5OOC{-}CH{=}C(OC_2H_5)NH_2$.

(8) This conclusion is indicated by the fact that the dihydrochloride (21.5 g.) goes into solution immediately when treated with the same amount (250 ml.) of alcohol containing sufficient pyridine (7.4 g.) to neutralize one of the hydrochloride functions. One reaction by which a monohydrochloride might be formed during alcoholysis is through cleavage of an orthoester by the dihydrochloride: $RC(OC_2H_5)_3 + CH_2(C(OC_2H_5){=}NH_2Cl)_2 \rightarrow RCOOC_2H_5 + C_2H_5Cl + C_2H_5OH + HN{=}(C_2H_5O)CCH_2C(OC_2H_2){=}NH_2Cl$. This reaction is under investigation in this Laboratory.

(9) Neutralization of the dihydrochloride (VI) with sodium ethoxide yields XVII also; with aqueous sodium carbonate, however, VI is converted to diethyl iminomalonate.

[a] Reported by Reitter and Weindel.[7] [b] Product separated as an oil which crystallized after decantation of the supernatant liquid and washing the precipitate with ether. [c] Two moles of the alcohol corresponding to R′ per mole of nitrile used and the solution saturated with hydrochloric acid. [d] A mixture of 15 ml. of chloroform and 15 ml. of dioxane as solvent; when dioxane alone was used as the solvent the product was contaminated with methyl cyanoiminoacetate hydrochloride. [e] This amount of dioxane was required to cause a homogeneous solution of the nitrile in the alcohol. [f] Reported by Pinner, ref. 4.

## Experimental

**Nitriles.**—Malononitrile was prepared by the method of Surrey,[11] succinonitrile by that of Fauconnier,[12] γ,γ,γ-trichlorobutyronitrile by that of Bruson, *et al.*[13] Ethyl cyanoacetate was purchased from the Eastman Kodak Company. Methyl β-cyanopropionate was prepared in the following manner. A mixture of 66.5 g. of methyl β-cyanoiminopropionate hydrochloride (see Table I) and 100 ml. of water was swirled until solution was complete. This process was accompanied by marked cooling; after about two minutes, the solution evolved considerable heat and the ester began to separate. The mixture was allowed to stand at room temperature overnight after which the product was extracted with ether and dried over potassium carbonate. Distillation gave a yield of 38.2 g. (75%) of methyl β-cyanopropionate,[14] b. p. 93–103° (8 mm.), which was collected almost entirely at 95–97°.

**Preparation of the Iminoester Hydrochlorides.**—The general method of preparation described by Pinner[15] was used throughout this work. Strict precautions were always taken to ensure that the reagents were anhydrous and were protected from atmospheric moisture during the reaction. The nitrile and an equimolar quantity of the alcohol were dissolved in an inert solvent, the solution cooled in ice-water, and then treated with dry hydrogen chloride. Pinner and most of the previous workers in this Laboratory used ether as the inert solvent. In the present work anhydrous dioxane was found to be an excellent solvent for the preparation of certain of these salts because of a combination of desirable properties. First, it is a much better solvent for malononitrile and succinonitrile than is ether, *e. g.*, 75 ml. of ether per gram of succinonitrile is necessary to produce a homogeneous solution; however, a mixture of 0.6 ml. of dioxane and 5 ml. of ether dissolves 1 g. of this nitrile. Secondly, the iminoester hydrochlorides precipitate much more slowly from the dioxane than from ether.

The delayed precipitation of the salts from dioxane had two advantages: (a) in the preparation of di-iminoester dihydrochlorides it permitted both nitrile groups to react before any precipitation occurred and (b) it prevented clogging of the gas inlet tube by an early precipitation of the salt. Recently, anhydrous chloroform has been found to exert a similar solvent action on iminoester hydrochlorides and has been used in their preparation.[16] With this solvent, however, these salts often do not precipitate on standing, but must be recovered by evaporation of the solvent. Unfortunately, chloroform is a poor solvent for hydrogen chloride and experience in the present work has shown that a 1:1 mixture of chloroform and dioxane is for this reason a better solvent. This mixed solvent had to be used for the preparation of dimethyl iminomalonate dihydrochloride (V).

The pertinent data concerning the iminoester hydrochlorides prepared in this work are summarized in Table I.

**Ethyl Cyanoiminoacetate.**—To an ice-cooled mixture of 200 ml. of 40% aqueous potassium carbonate and 200 ml. of ether in a separatory funnel was added 26.5 g. (0.178 mole) of ethyl cyanoiminoacetate hydrochloride. The mixture was shaken for one minute and the ether layer separated and poured over anhydrous potassium carbonate. A little ice-water and 100 cc. of cold ether were added to the aqueous layer and the extraction procedure repeated as above. After two additional extractions, the combined extracts were decanted on to a fresh portion of drying agent and allowed to stand several hours. The ether was carefully evaporated on the steam-bath in a stream of dry air and the residue dried to constant weight in the vacuum desiccator. The yield of slightly impure, tan ethyl cyanoiminoacetate, m. p. 75–77°, was 19.4 g. (97%). Recrystallization from ether gave beautiful, white plates, m. p. 78–79°, b. p. 102–103° (10 mm.).

*Anal.* Calcd. for $C_5H_8N_2O$: $C_2H_5O$, 40.2; N, 25.0. Found: $C_2H_5O$, 40.8; N, 24.8.

In order to estimate the molar refraction, the densities and refractive indices at 25° were determined for known mixtures of ethyl cyanoiminoacetate with dioxane and with pyridine. These values were plotted against the corresponding concentrations and the straight lines obtained were extrapolated to 100% iminoester. The values thus obtained were: $n^{25}D$ 1.501 (with dioxane), 1.510 (with pyridine), average 1.506; $d^{25}_4$ 1.063 (with dioxane), 1.060 (with pyridine), average 1.062. $M_D$, calcd. for XVII 28.71, for XVIIa 29.71; found: 31.36. Thus the molar exaltation of XVIIa is 1.65, and the specific exaltation 1.47, which are comparable to the corresponding values of 1.80 and 1.13 reported[10] for ethyl carbethoxyiminoacetate.

Ethyl cyanoiminoacetate also was obtained from diethyl iminomalonate dihydrochloride (VI) in the following manner. To a solution of 4.1 g. (0.06 mole) of sodium ethoxide in 50 ml. of absolute ethanol containing phenolphthalein

as an indicator was added 6.9 g. (0.03 mole) of diethyl iminomalonate dihydrochloride. The mixture warmed slightly and the red color of the indicator disappeared. An additional 2 ml. of the sodium ethoxide solution was added to restore the alkalinity of the mixture and the latter was stirred for ten minutes. The precipitated sodium chloride was filtered by suction and the filtrate concentrated. Distillation of the residue gave 1.8 g. (54%) of ethyl cyanoiminoacetate, b. p. 101–102° (10 mm.), which crystallized on cooling. Recrystallization from ether gave the pure iminoester, m. p. 79–80°

When a warm solution of 5.6 g. (0.05 mole) of ethyl cyanoiminoacetate in 20 ml. of anhydrous benzene was mixed with a warm solution of 5.0 g. (0.051 mole) of freshly distilled maleic anhydride in 10 ml. of dry benzene, the mixture heated spontaneously and had to be cooled under the tap; a voluminous precipitate began to separate immediately and after digestion for fifteen minutes on the steam-bath the mixture was cooled and filtered. The yield of crude **ethyl N-(β-carboxyacrylyl)-cyanoiminoacetate**, m. p. 132–134° dec., was 10.4 g. (99%). Recrystallization from either acetone or dioxane gave 5.3 g. of a light yellow product, m. p. 141–142° dec. An additional recrystallization from dioxane yielded 4.1 g. of the pure material, m. p. 152–152.5° dec.; neutral equiv., 203 216 (calcd. 210).

*Anal.* Calcd. for $C_9H_{10}N_2O_4$: N, 13.3; $C_2H_5O$, 21.4. Found: N, 13.2; $C_2H_5O$, 20.4.

**Diethyl Iminomalonate.**—This di-iminoester was obtained in 44% yield by treatment of the salt VI with a cold, saturated aqueous solution of potassium carbonate and immediate extraction with ether. After drying over sodium sulfate, it distilled as a colorless liquid, b. p. 62–63° (0.4 mm.); $n^{25}D$ 1.4530, $d^{25}_4$ 1.011. Houben and Blaise[3a] reported this iminoester to boil at 58° (0.2 mm.), but gave no yield or analytical data for it.

*Anal.* Calcd. for $C_7H_{14}N_2O_2$: N, 17.7. Found: N, 17.9.

On standing this iminoester discolored rapidly and, after several weeks, became a dark brown semi-solid mass.

**Pyrolysis of Diethyl Iminomalonate Dihydrochloride (VI).**—When 2.5 g. of VI was heated in a bath at 150–160°, 1.3 g. (93%) of ethyl chloride, b. p. 12°, was condensed in a trap immersed in a Dry Ice–alcohol mixture. Recrystallization of the pyrolysis residue from absolute alcohol gave 0.9 g. (81%) of malonamide, m. p. 170–172°.

**Attempted Preparation of Dimethyl Iminosuccinate.**—When dimethyl iminosuccinate dihydrochloride was treated with cold, aqueous sodium carbonate or sodium bicarbonate and the mixture shaken with ether, a negligible amount of liquid was found in the ether layer.[6] Stronger bases such as sodium hydroxide or potassium carbonate yielded only resinous material in the ether layer and a dark-colored aqueous phase. The following experiments were performed in order to explain this anomalous behavior.

A mixture of 4.1535 g. of dimethyl iminosuccinate dihydrochloride and 8.0 g. of sodium bicarbonate was placed in a 200-ml. round-bottomed flask immersed in ice-water and equipped with a dropping funnel and delivery tube. On addition of 10 ml. of ice-water from the funnel, carbon dioxide was evolved and collected over mineral oil. The yield of carbon dioxide thus obtained amounted to 42.8% based on complete neutralization of the dihydrochloride. The residue was acidified with dilute nitric acid and the quantity of chloride ion determined. A 6.8% loss of chloride ion indicated the formation of this amount of methyl chloride. The combined yield of carbon dioxide and methyl chloride was, therefore, 49.6%, indicating that only one hydrochloride group per molecule had been neutralized.

To 200 ml. of ice-cooled 10% aqueous sodium carbonate was added 15.5 g. (0.071 mole) of dimethyl iminosuccinate dihydrochloride. The clear solution was acidified with 75 ml. of concentrated hydrochloric acid and evaporated nearly to dryness at a temperature of 50–70° in a stream of dry air. The slightly moist, solid residue was extracted with four 50-ml. portions of boiling acetone. To the acetone-insoluble residue was added 35 ml. of concentrated hydrochloric acid in 100 ml. of water and the evaporative hydrolysis repeated over a period of three hours. After acetone extraction of the residue, the latter was subjected to a third hydrolysis. The amounts of brown, crystalline solid extracted in each of these three acetone treatments were: (1) 10.5 g., (2) 1.5 g. and (3) 0.5 g.

The extracted material was dissolved in water, and sodium bicarbonate added until no further effervescence occurred. The white precipitate which had separated during this neutralization was filtered off and identified as β-carboxypropionamidine, m. p. 255.5° dec.; the yield was 4.6 g. (56%). This product was identical with that prepared from β-carbomethoxypropionamidine hydrochloride (see below). The filtrate was evaporated to dryness and extracted with boiling acetone to yield 1.8 g. (25.5%) of succinimide, m. p. 121.5–124°, which was separated from a small amount of inorganic contaminant by extraction with ether. Recrystallization from absolute ethanol gave the pure imide, m. p. 125–126°. The residue from this acetone extraction was acidified with hydrochloric acid and evaporated to dryness. Extraction with acetone removed a solid, which was recrystallized from water to give 1.0 g. (12%) of succinic acid, m. p. 185–186°.

**Preparation of Orthoesters.**—The following preparation of methyl orthocyanoacetate illustrates the method by which the monoiminoester hydrochlorides of Table I were converted to the corresponding orthoesters; following this preparation are descriptions of procedures used with the di-iminoester dihydrochlorides, VII and VI.

**Methyl Orthocyanoacetate (II).**—A mixture of 385 g. (2.85 moles) of methyl cyanoiminoacetate hydrochloride and 3 l. of absolute methanol was shaken until the salt had dissolved. This process was accompanied by marked cooling. After three hours ammonium chloride began to separate and the reaction appeared to be complete after standing overnight at room temperature. The methanol was removed by distillation through a fifteen-inch Vigreux column. Severe bumping invariably accompanied distillation of the methanol in the conventional manner due to the ammonium chloride that continued to separate. The bumping could be avoided by blowing a gentle stream of *dry* air through the mixture as it was heated on the steam-bath at such a rate that the temperature of the vapors was about 50°. When all the methanol had been removed, the residue was cooled and 500 ml. of dry ether added. The mixture was filtered by suction and the white solid residue washed with 200 ml. of dry ether. Extraction of the solid with hot absolute alcohol dissolved 38.3 g. (16%) of cyanoacetamide, m. p. 110–115°, and left a residue of 114.5 g. (75%) of ammonium chloride. The crude amide was recrystallized from water and the purified material melted at 118–119°.

The ether filtrate and washings from the ether-insoluble solid were combined and washed with a saturated aqueous solution of sodium carbonate. After drying over solid potassium carbonate, the ether layer was distilled to yield 269 g. (65%) of methyl orthocyanoacetate.

**Methyl Orthosuccinate (XII) and Methyl Ortho-β-carbomethoxypropionate (XI).**—A slurry of 38.0 g. (0.175 mole) of dimethyl iminosuccinate dihydrochloride in 250 ml. of absolute methanol was stirred mechanically for forty-two hours while immersed in a bath held at 13–15°. The resulting light green mixture was made alkaline to phenolphthalein with methanolic sodium methoxide and allowed to stand for one hour. The methanol then was distilled under reduced pressure and 200 ml. of anhydrous ether added to the residue. The precipitated solid was filtered and washed with dry ether, after which the filtrate and washings were evaporated to 50 ml. and more solid filtered and washed as before. The filtrate and washings were concentrated and distilled. After collecting a forerun, b. p. 82–104° (5 mm.), a fraction, b. p. 104–108° (5 mm.), which crystallized on standing and melted at 48–50°, was collected. Two recrystallizations from ethyl acetate, which required cooling in a Dry Ice–acetone mixture, gave pure methyl orthosuccinate, m. p. 50–51°. On cooling the forerun, b. p. 82–104° (5 mm.), in ice, additional

[a] Alcoholysis solution neutralized with sodium ethoxide before removal of alcohol; when the alcohol was removed before neutralization as in the preparation of II, the yield was 36%. [b] This orthoester was freed of normal ester by treatment with aqueous ammonia (sp. gr. 0.90). [c] Calcd.: Cl, 42.3. Found: Cl, 42.7. [d] This compound melts at 50–51°; the $n^{25}D$ was determined on the supercooled liquid.

orthoester was obtained and redistillation of the filtrate from this crop provided still more. The total yield of methyl orthosuccinate was 6.4 g. (15%).

From this second distillation of the forerun, b. p. 82–104°, 3.7 g. (11%) of XI, b. p. 91–98° (6 mm.), was obtained.

**Alcoholysis of Diethyl Iminomalonate Dihydrochloride (VI).**—A mixture of 107 g. (0.46 mole) of this salt and 1300 ml. of absolute ethanol was stirred in a bath held at 40°. The salt was quite insoluble in the alcohol and disappeared very slowly. After twenty-one hours, the precipitate of ammonium chloride (18.2 g., 0.34 mole) was filtered off and the filtrate titrated to the phenolphthalein end-point with 168 ml. (0.365 mole) of 2.173 *N* ethanolic sodium ethoxide. Thus the total amount of hydrochloride salts still present in the solution and as precipitated ammonium chloride was 0.705 mole or 77% of the ionic chlorine of the original iminoester hydrochloride. (In a similar run the ionic chlorine in this alcoholic solution was determined by titration with standard silver nitrate; the soluble chloride together with that precipitated as ammonium chloride was found to be 80% of that present in the iminoester salt used, which is in good agreement with the value obtained by neutralization with alkali.) The amount of ammonium chloride which dissolves in 1300 ml. of absolute ethanol is 7.9 g. so that the total yield of that salt was estimated to be 26.1 g. (53%).

The neutralized reaction mixture was made distinctly alkaline by addition of 5 ml. of the alcoholic sodium ethoxide solution and the precipitated sodium chloride removed by filtration. The filtrate was refluxed under a condenser which was connected to a trap immersed in a Dry Ice–alcohol mixture. After fifteen minutes a liquid had collected in the trap; on fractionation it yielded 3.5 g. (6%) of ethyl chloride, b. p. 12–15°, and small amounts of ammonia and ethanol. The alcohol then was distilled at about 100 mm. from the reaction mixture through an efficient column after which the following fractions were collected: (a) 25.0 g. of liquid boiling below 110° (2 mm.) and (b) 12.7 g. (21%) of carbethoxyacetamide, b. p. 130–135° (2 mm.), which was obtained as an oil that crystallized completely on seeding with an authentic sample of the amide. Washing with ether gave white crystals, m. p. 48–49°, which contained 34.5% ethoxyl and 10.8% nitrogen (calcd. 34.4 and 10.7%, respectively). The non-volatile residue from the distillation amounted to 22.0 g.

Fraction (a) was taken up in 400 ml. of 60–68° petroleum ether and the mixture allowed to stand in the refrigerator overnight. Filtration removed 2.4 g. (5%) of crude ethyl cyanoiminoacetate, which after recrystallization from ethyl acetate melted at 78–79°.

The petroleum ether filtrate from the iminoester was fractionated into: (1) 6.9 g. (9%) of diethyl malonate, b. p. 81–90° (4 mm.); (2) 3.4 g., b. p. 90–100° (4 mm.); (3) 8.4 g. (8%) of **ethyl orthocarbiminoethoxyacetate** (XVIII), b. p. 100–105° (4 mm.); and (4) 1.4 g. of residual oil. Redistillation of fraction (3) gave the pure iminoester-orthoester, b. p. 94–95° (3 mm.), the properties and analysis of which are listed in Table II. The identity of this compound was further established by treatment of 1.2 g. of fraction (3) in ice-cooled ether with an ether solution of anhydrous hydrogen chloride of known concentration. The addition of 0.8 mole of hydrogen chloride per mole of nitrogen present caused heat evolution but no precipitation; however, further addition of the reagent up to 2.0 moles per mole of nitrogen caused a separation of a white solid which was not increased by further addition of hydrogen chloride. The precipitate was filtered off and found to be 0.9 g. (90%) of ethyl carbethoxyiminoacetate hydrochloride, m. p. 92–94° dec. (reported,[10] 99–101° dec.), which contained 17.7% chlorine (calcd. 18.1%). Since the melting point did not agree with the value reported in the literature, the salt was further characterized by pyrolysis of a 1.0-g. sample to 0.2 g. (60%) of ethyl chloride, b. p. 11–12°, and 0.7 g. of residual oil which crystallized on seeding with carbethoxyacetamide. Recrystallization from ether gave the pure amide, m. p. 49–50°.

A similar treatment of fraction (2) with hydrogen chloride gave an 80% yield of ethyl carbethoxyiminoacetate hydrochloride indicating that this fraction also was largely XVIII.

Low yields of ammonium chloride were obtained invariably in the alcoholysis of diethyl iminomalonate dihydrochloride. Thus, at 30° the yields were 56, 50 and 53.5% for reaction periods of sixty-five, eighty and one hundred and thirty hours, respectively, while at 50° a yield of only 56% was obtained after twenty-one hours.

**Alcoholysis of Diethyl Iminomalonate Dihydrochloride in the Presence of Pyridine.**—To a solution of 7.4 g. (0.094 mole) of anhydrous pyridine in 250 ml. of absolute ethanol was added 21.5 g. (0.093 mole) of diethyl iminomalonate dihydrochloride (VI). After five minutes of shaking the salt had dissolved completely. The solution was heated under reflux in a bath at 40° for twenty-seven hours. During this time no ethyl chloride was collected in a trap provided for that purpose and only a small amount of crystalline solid precipitated.

The reaction mixture was titrated to the phenolphthalein end-point with 2.173 *N* ethanolic sodium ethoxide and required 78.5 ml. (92%) for neutralization. The precipitated sodium chloride was filtered off and the alcohol distilled from the filtrate through an efficient column at about 100 mm. pressure. Fractionation of the residue gave: (a) 0.9 g. (4%) of XVIII; (b) 0.8 g. (7%) of carbethoxyacetamide; and (c) 6.4 g. of a non-volatile tar. Fraction (a) showed only a slight opalescence in 60–68° petroleum ether, indicating that very little ethyl cyanoiminoacetate was present.

The properties and analyses of the orthoesters prepared by the above procedures are summarized in Table II.

When the alcoholic solution resulting from the methanolysis of dimethyl iminosuccinate dihydrochloride (VII) was distilled without the addition of sodium methoxide, a viscous, yellow oil remained as a residue. After trituration with dry ether, the oil was dissolved in water and this solution extracted with ether. From the combined ether extracts a 45% yield of dimethyl succinate was isolated. The aqueous solution was evaporated to dryness, extracted with boiling absolute ethanol and the insoluble ammonium chlo-

ride filtered off. Evaporation of the alcohol filtrate left a 36% yield of crude **β-carbomethoxypropionamidine hydrochloride (IX)**, which after recrystallization from absolute ethanol melted at 131–132°.

*Anal.* Calcd. for $C_5H_{11}ClN_2O_2$: Cl, 21.3; N, 16.8; $CH_3O$, 18.6. Found: Cl, 21.3; N, 16.7; $CH_3O$, 17.6.

This amidine salt was also prepared in the following manner: A mixture of 16.5 g. (0.091 mole) of methyl β-carbomethoxyiminopropionate hydrochloride and 20 ml. of absolute methanol was placed in a 200-ml. flask and the lumps of the salt broken up with a glass rod. Then a solution of 1.7 g. (0.10 mole) of ammonia in 12 ml. of methanol was added and the mixture swirled. There was an immediate heavy precipitation of a white solid which quickly redissolved. The mixture was kept at room temperature by cooling in an ice-bath. After standing for thirty minutes the solution was evaporated on the steam-bath in a stream of dry air and finally dried in a vacuum desiccator over sulfuric acid. The crystalline product, m. p. 126–128°, weighed 15.1 g. (99%). Recrystallization from absolute ethanol gave pure β-carbomethoxypropionamidine hydrochloride, m. p. 131–132°.

A solution of 0.54 g. of β-carbomethoxypropionamidine hydrochloride in 15 ml. of concentrated hydrochloric acid was heated at 95–100° for one hour. Evaporation of the aqueous acid under diminished pressure left 0.51 g. of crude β-carboxypropionamidine hydrochloride, m. p. 131–137°. Titration of this salt with standard alkali gave 0.305 g. (80%) of β-carboxypropionamidine, m. p. 258–260° dec.

*Anal.* Calcd. for $C_4H_8N_2O_2$: N, 24.1. Found: N, 24.2.

Evaporation of a solution of this amidine in dilute hydrochloric acid left β-carboxypropionamidine hydrochloride, m. p. 138–140°.

*Anal.* Calcd. for $C_4H_9ClN_2O_2$: Cl, 23.3; N, 18.4. Found: Cl, 23.6; N, 18.8.

**Methyl Ortho-β-carbamylpropionate.**—A mixture of 2 g. of methyl ortho-β-carbomethoxypropionate (XI) and 10 ml. of aqueous ammonia (sp. gr. 0.90) was stirred at room temperature until a clear solution was obtained (one-half hour). The resulting solution was extracted with chloroform and dried over Drierite. Evaporation of the solvent left 1.5 g. (82%) of methyl ortho-β-carboxamidopropionate, m. p. 90–94°. After washing with petroleum ether (b. p. 60–68°), this product melted at 94–97°.

*Anal.* Calcd. for $C_7H_{15}NO_4$: N, 7.91. Found: N, 7.85.

This compound is quite sensitive to recrystallization, yielding β-carbomethoxypropionamide when it was recrystallized from the ordinary organic solvents. This product was obtained also when the aqueous ammoniacal solution was evaporated to dryness under diminished pressure.

In contrast to the facile reaction of XI with aqueous ammonia, ethyl orthocarbethoxyacetate did not dissolve in aqueous ammonia even after forty-eight hours of efficient stirring. After this time approximately 75% of the unchanged orthoester was recovered.

**Reaction of Hydrogen Chloride with the Cyano-orthoesters II and IV.**—A solution of 11.6 g. (0.08 mole) of methyl orthocyanoacetate (II) in 2.56 g. (0.08 mole) of anhydrous methanol was cooled in ice while 2.9 g. (0.08 mole) of dry hydrogen chloride was introduced. The clear solution was placed in a refrigerator for one week during which a white solid slowly precipitated. Dry ether was added and the mixture placed in the refrigerator for an additional day. Filtration separated 0.66 g. of ammonium chloride. Distillation of the filtrate yielded 2.2 g. (21%) of dimethyl malonate and 5.8 g. (73%) of methyl cyanoacetate. From the distillation residue an additional 0.11 g. of ammonium chloride was separated, raising the total yield of this product to 0.77 g. (18%).

Dry hydrogen chloride was passed into a 6.2-g. sample of methyl ortho-β-cyanopropionate (IV). The liquid became hot and a small quantity of white solid separated. After saturation with the gas, the liquid was distilled to yield 4.1 g. (93%) of methyl β-cyanopropionate, b. p. 97–99° (9 mm.); 0.7 g. (56%) of methanol was collected in the cold trap.

**Reaction of Sodium Methoxide with Methyl Ortho-γ,γ,γ-trichlorobutyrate (XIII).**—A methanolic solution of sodium methoxide was prepared by dissolving 3.5 g. (0.15 atom) of sodium in 37.5 ml. of absolute methanol. On the addition of 12.6 g. (0.05 mole) of XIII the mixture heated and became dark brown. After standing overnight, 150 ml. of anhydrous ether was added and the white precipitate filtered off. The chloride and titratable alkali contents of this solid indicated that it consisted of 2.9 g. (33% yield) of sodium chloride and a trace of sodium methoxide. The solvents were removed from the filtrate at reduced pressure and the residue was distilled. It boiled over a wide range (44–85° (4–5 mm.)) and all of the fractions collected decolorized a bromine in carbon tetrachloride solution readily indicating that dehydrohalogenation had occurred. The largest fraction (2.4 g.) was a colorless liquid, b. p. 62–73° (5–4 mm.), $n^{25}D$ 1.4550, $d^{25}_4$ 1.1435. This material had the correct analysis and molar refraction for **1-chioro-4,4,4-trimethoxybutyne-1.**

*Anal.* Calcd. for $C_7H_{11}ClO_3$: Cl, 19.9; $CH_3O$, 52.1. Found: Cl, 19.8; $CH_3O$, 53.5.

## Summary

The preparation of cyano-orthoesters from malono- and succinonitriles *via* the mono-iminoester hydrochloride is described. Hydrogen chloride in alcohol solution cleaves each of these orthoesters to the normal ester before it converts the cyano group to the iminoester hydrochloride.

Succinonitrile has been converted *via* the di-iminoester hydrochloride to the ester-orthoester, $(CH_3O)_3CCH_2CH_2COOCH_3$, and the di-orthoester, $(CH_3O)_3CCH_2CH_2C(OCH_3)_3$, of succinic acid. Under the same conditions of reaction, malonitrile yields ethyl orthocarbiminoethoxyacetate. An explanation for this behavior is suggested.

The preparation and properties of a number of related compounds, including ethyl orthocarbethoxyacetate, are described.

# Ketene Acetals. XX. The Preparation and Properties of Cyanoketene Acetals. Some Novel Benzylation Reactions

BY S. M. MCELVAIN AND JUEL P. SCHROEDER[1]

In previous papers of this series benzylations of ketene diethylacetal[2] (I) and various alkyl- and phenylketene dimethylacetals[3] (VII) with benzyl bromide were reported. In each of these alkylations the reaction proceeded to the formation of disubstituted acetic esters (VI and IX), *i.e.*, the unsubstituted ketene acetal was dibenzylated, presumably through the intermediate ketene acetal IV (R = $C_6H_5CH_2$), while the monosubstituted ketene acetals (VII, X is *n*-propyl, *n*-heptyl or phenyl) yielded only monobenzylated products

$$CH_2{=}C(OC_2H_5)_2 \xrightarrow{RBr} [RCH_2{-}CBr(OC_2H_5)_2] \longrightarrow RCH_2COOC_2H_5 + C_2H_5Br$$
I II III

$$RCH{=}C(OC_2H_5)_2 \xrightarrow{RBr} [R_2CHCBr(OC_2H_5)_2] \longrightarrow R_2CHCOOC_2H_5 + C_2H_5Br$$
IV V VI

$$XCH{=}C(OCH_3)_2 + RBr \longrightarrow [XCHR{-}CBr(OCH_3)_2] \longrightarrow XCHRCOOCH_3 + CH_3Br$$
VII VIII IX

Inasmuch as there appeared to be no tendency for the intermediate VIII to lose hydrogen bromide as did II, even when X is phenyl, it seemed of interest to study the benzylation behavior of a ketene acetal containing the more negative cyano substituent.

Cyanoketene dimethylacetal (XI), as well as the homologous diethylacetal, was prepared by the pyrolysis of the corresponding orthoester (X). This pyrolysis is catalyzed by a trace of acid[4] as is the reverse reaction, the addition of alcohol to the ketene acetal

$$CNCH_2C(OCH_3)_3 \underset{}{\overset{H^+}{\rightleftharpoons}} CNCH{=}C(OCH_3)_2 + CH_3OH$$
X XI

The reaction proceeds to the ketene acetal when X is heated and the alcohol removed by distillation; the orthoester is re-formed from its components at room temperature, but can be isolated only after the removal of all traces of the acid catalyst.[4]

Because of the tendency of ketene diethylacetals to lose ethylene on heating,[5] the reactions subsequently reported were carried out with cyanoketene *dimethyl*acetal (XI). This compound is a solid, m. p. 41–42°, which is surprisingly inert toward water; indeed, it may be recrystallized from this solvent. It dissolves in methanol with noticeable cooling. However, when a drop of hydrochloric acid is added to either an aqueous or methanolic solution of XI, the solution becomes warm and the ketene acetal is converted to methyl cyanoacetate or methyl orthocyanoacetate (X). Also, XI reacts with aniline, in a manner similar to ketene diethylacetal,[6] to yield methyl N-phenylcyanoiminoacetate, $CNCH_2C(OCH_3){=}NC_6H_5$.

A rapid reaction occurred when cyanoketene dimethylacetal (XI) was heated with one equivalent of benzyl bromide at 160–170°. Within thirty minutes, 97% of the halogen of the benzyl bromide was evolved as methyl bromide and distillation of the remaining reaction mixture yielded methyl cyanoacetate (XVI) (31%), methyl benzylcyanoacetate (XIII) (21%) and methyl dibenzylcyanoacetate (XV) (26%). It is apparent

$$[C_6H_5CH_2CHCNCBr(OCH_3)_2] \longrightarrow C_6H_5CH_2CHCNCOOCH_3 + CH_3Br$$
XII XIII

$$C_6H_5CH_2C(CN){=}C(OCH_3)_2 \xrightarrow{C_6H_5CH_2Br} (C_6H_5CH_2)_2CCNCOOCH_3 + CH_3Br$$
XIV XV

from these results that the cyano substituent causes the intermediate (XII), which corresponds to VIII and presumably is formed by the addition of benzyl bromide to XI, to undergo pyrolysis to the disubstituted ketene acetal (XIV) as well as to the monobenzylated ester (XIII). Further benzylation of XIV converts it to the trisubstituted acetic ester (XV). The methyl cyanoacetate (XVI) present in the reaction mixture results from the action of the hydrogen bromide lost by XII on cyanoketene acetal.[7]

$$CNCH{=}C(OCH_3)_2 + HBr \longrightarrow CNCH_2COOCH_3 + CH_3Br$$
XVI

When cyanoketene acetal was heated with *two* equivalents of benzyl bromide at 170–180°, a steady evolution of methyl bromide continued

(6) Barnes, Kundiger and McElvain, *ibid.*, **62**, 1281 (1940).

(7) Obviously, hydrogen bromide could convert XIV to XIII by a similar reaction, but the ratio of reaction products indicates that it is primarily the ketene acetal XI that combines with this acid.

after one equivalent of this halide had been collected. After five hours of heating the yield of methyl bromide amounted to 82% (of two equivalents); during this time carbon dioxide (30%) also was evolved. As the heating continued, the yield of the latter product increased until it reached (after twenty-six hours) 96% of the theoretical; in this time the yield of methyl bromide rose to 87%. Fractionation of the remaining reaction mixture yielded benzyl bromide (5%), hydrocinnamonitrile XVII (7%), dibenzylacetonitrile XVIII (43%), together with small amounts of toluene and stilbene. All attempts to isolate the expected tribenzylacetonitrile (XIX) from the products of this run were unsuccessful. From another run, which was interrupted after 65% of the theoretical amount of carbon dioxide had been evolved, a 22% yield of benzyl dibenzylcyanoacetate (XX) was obtained.[8] In this run tribenzylacetamide was obtained by treatment of certain of the higher boiling fractions with 50% sulfuric acid.

When the reaction was interrupted before any appreciable evolution of carbon dioxide had occurred (one and one-half hours), 1.24 equivalent (62%) of methyl bromide was collected and benzyl bromide (28%), XVI (20%), XIII (11%), XV (3%), benzyl cyanoacetate (8%), XXI (19%) and XX (10%) were separated from the reaction mixture.

$C_6H_5CH_2CH_2CN$ XVII $(C_6H_5CH_2)_2CHCN$ XVIII $(C_6H_5CH_2)_3CCN$ XIX

$(C_6H_5CH_2)_2CCNCOOCH_2C_6H_5$ XX

$C_6H_5CH_2CHCNCOOCH_2C_6H_5$ XXI

From these results it appeared that the second equivalent of benzyl bromide had reacted further with one or all of methyl esters (XIII, XV and XVI) produced in the initial reaction of the halide with cyanoketene dimethylacetal, converting them to methyl bromide and the corresponding benzyl esters, the latter of which then lost carbon dioxide to yield the nitriles, XVII, XVIII and XIX. The order in which the methyl bromide and carbon dioxide were formed in the reaction together with the isolation of XX from both of the interrupted runs not only seemed to justify this conclusion, but to point to a study of the reaction of benzyl bromide with the individual methyl esters.

A mixture of methyl cyanoacetate (XVI) and benzyl bromide remained apparently unchanged at 170–180° for two hours before any methyl bromide appeared, and after twenty-four hours only a 17% yield of this bromide was collected. After forty-eight hours of heating, an 81% yield of methyl bromide and a 64% yield of carbon dioxide were obtained. However, distillation of the remaining material gave only a small amount of benzyl bromide; the main reaction product was an undistillable tar.

Methyl dibenzylcyanoacetate (XV) gave no evidence of reaction when heated with benzyl bromide; after twenty-two hours, both reactants were recovered unchanged. Methyl benzylcyanoacetate (XIII) had an induction period of one and one-half hours before it reacted with benzyl bromide, but after twenty hours at 170–180°, methyl bromide and carbon dioxide were obtained in 60 and 64% yields, respectively. The other products isolated from this reaction were XVII (19%), XXI (41%) and XX (3%).

The relatively high yield of XXI from XIII indicated that the former ester was probably the key intermediate in the decarboxylation reaction. This supposition was strengthened by the results obtained in an attempt to prepare XXI by an alcohol exchange between an excess of benzyl alcohol and methyl benzylcyanoacetate (XIII). When these reactants were heated together in the presence of a small amount of sodium benzyloxide, the theoretical quantity of methanol distilled out. However, distillation of the remaining reaction mixture was accompanied by loss of carbon dioxide, and XVII (23%), XVIII (39%), XIX (7%) and XX (5%) were the products isolated.[9] When this reaction was repeated and the alkaline catalyst removed after the distillation of the methanol and excess benzyl alcohol, the reaction products were XVIII (14%), the desired ester XXI (13%) and XX (26%).

The presence of XX among the products of this alcohol-exchange reaction indicates that benzyl alcohol functioned as a benzylating agent as did benzyl bromide in certain of the previously described reactions. It appears also that it was the benzyl ester XXI rather than the original methyl ester XIII that was further benzylated, because the yield of XX was much lower in the reaction in which considerable decarboxylation of XXI to XVII—and possibly also to XVIII—had occurred.

From the results described above it is evident that cyanoketene dimethyl acetal reacts with one equivalent of benzyl bromide, probably by an ionic mechanism, to produce the methyl esters XIII, XV and XVI. In the presence of two equivalents of the bromide, however, the reaction apparently takes a different course: the conversion of the primary intermediate XII to XV is suppressed (very little of XV was found among the reaction products although it was shown to be stable to the reaction conditions), and the formation of XIII is favored. This latter ester is then converted by

(8) From one of the earlier runs dibenzyl ether and N-benzylhydrocinnamamide, $C_6H_5CH_2CH_2CONHCH_2C_6H_5$, also were isolated in small amounts. These products, however, were found to be due to the presence of benzyl alcohol in the benzyl bromide, as they did not appear when an alcohol-free bromide was used.

(9) A similar alcohol exchange between benzyl alcohol and ethyl cyanoacetate gave 25% of benzyl cyanoacetate and 5.5% of XXI. During the distillation of these esters, a considerable amount of benzyl alcohol was formed, which, together with the large amount of tar that remained, indicated that benzyl cyanoacetate was suffering intermolecular loss of benzyl alcohol. This reaction is being investigated further.

the excess benzyl bromide to methyl bromide and the benzyl ester XXI, which then undergoes further benzylation and/or decarboxylation, probably *via* a series of free radical interchanges

$$XXI \longrightarrow C_6H_5CH_2CHCNCOO\cdot + \cdot CH_2C_6H_5$$
$$C_6H_5CH_2\cdot + XXI \longrightarrow XX + H\cdot$$
$$C_6H_5CH_2CHCNCOO\cdot \longrightarrow C_6H_5CH_2\dot{C}HCN + CO_2$$
$$C_6H_5CH_2\dot{C}HCN + H\cdot \text{ (or } H{-}C{\equiv}) \longrightarrow XVII$$
$$C_6H_5CH_2\dot{C}HCN + C_6H_5CH_2\cdot \longrightarrow XVIII$$
$$XX \longrightarrow (C_6H_5CH_2)_2CCNCOO\cdot + \cdot CH_2C_6H_5$$
$$(C_6H_5CH_2)_2CCNCOO\cdot \longrightarrow (C_6H_5CH_2)_2\dot{C}CN + CO_2$$
$$(C_6H_5CH_2)_2\dot{C}CN + H\cdot \text{ (or } HC{\equiv}) \longrightarrow XVIII$$
$$(C_6H_5CH_2)_2\dot{C}CN + C_6H_5CH_2\cdot \longrightarrow XIX$$

The presence of toluene and stilbene among the products of this reaction lend further support to the free radical interpretation of this reaction.

It is possible that the nitriles XVII, XVIII and XIX may be formed also by an ionic mechanism involving a concurrent intramolecular rearrangement and loss of carbon dioxide from a benzyl ester, *e.g.*, XXI → XVIII

$$C_6H_5CH_2CH(CN){-}C{=}O \longrightarrow C_6H_5CH_2\underset{C_6H_5CH_2}{\overset{|}{C}}HCN + CO_2$$

However, further work will be required to establish either of these reaction mechanisms.

## Experimental

**Cyanoketene Dimethylacetal (XI).**—In a 50-cc. flask equipped with a six-inch Vigreux column 14.7 g. of methyl orthocyanoacetate[4] was heated in a metal-bath maintained at 220–225°, whereupon 2.7 g. of methanol, b. p. 63–66°, distilled rapidly. The pyrolysis was stopped when the rate of methanol distillation dropped and the residue in the flask became dark. Distillation of this residue under reduced pressure gave an additional 0.25 g. of methanol in the cold trap, bringing the yield to 2.95 g. (90%), 2.65 g. of forerun, b. p. 90–127° (11 mm.), and 7.85 g. of cyanoketene dimethylacetal, b. p. 127–128° (11 mm.), m. p. 41.5–42°, $n^{50}D$ 1.4630, $d^{50}_4$ 1.055.

*Anal.* Calcd. for $C_5H_7NO_2$: N, 12.4; $CH_3O$, 54.9. Found: N, 12.6; $CH_3O$, 54.1.

The residue from the distillation amounted to 1.1 g. of a red tar, which was brittle at room temperature and was completely soluble in concentrated hydrochloric acid.

From the forerun 1.65 g. (17%) of methyl cyanoacetate and an additional 1 g. of XI was obtained on fractionation. The presence of approximately this amount of XI in the lower boiling fraction was indicated by its refractive index.[10] The total yield of XI was 8.85 g. (77%).

The above pyrolysis requires careful attention. Insufficient heating produced low yields of methanol and ketene acetal while an excessively long pyrolysis period resulted in increased tar formation and, consequently, low yields of the desired product. For example, in a run in which a yield of only 78% of methanol was obtained, the amount of tar formed was negligible but, correspondingly, the yield of ketene acetal was 68%. On the other hand, a run in which a quantitative yield of methanol was obtained produced considerably more tar and only 36% of ketene acetal.

(10) In order to make the latter calculation it was necessary to estimate $n^{20}D$ of the ketene acetal, which is a solid at 20° and could not be supercooled to that temperature. The value $n^{20}D$ 1.4774, was obtained by plotting the refractive indices at 20° of known mixtures of dioxane and the ketene acetal against composition and extrapolating the resulting straight line to 100% ketene acetal.

Cyanoketene dimethylacetal crystallizes in beautiful rectangular prisms. It is insoluble in cold water and dilute alkali but is soluble in the ordinary organic solvents and in concentrated sulfuric acid. It readily decolorizes a solution of bromine in carbon tetrachloride. It shows a remarkable inertness toward water as compared to other ketene acetals. For example, a few crystals were shaken with 5 ml. of distilled water for several minutes without apparent change. On warming to about 70°, however, the compound melted and finally dissolved. When the solution was cooled to room temperature an oil separated which quickly crystallized and was filtered off. This proved to be the unchanged ketene acetal, m. p. 41–42°, mixed m. p. 42–42.5°.

The compound dissolved in dilute hydrochloric acid with evolution of heat. Extraction of the solution with ether and evaporation of the extract, after drying over Drierite, left a residue of methyl cyanoacetate, b. p. 210°, $n^{20}D$ 1.4192, which was readily converted by concentrated aqueous ammonia to cyanoacetamide, m. p. 117–119°.

Solution of 4.0 g. of cyanoketene dimethylacetal in 30 ml. of absolute methanol was accompanied by cooling to 17°. When a thermometer moistened with concentrated hydrochloric acid was inserted in the solution the temperature rose immediately to 29°. After several minutes sodium bicarbonate was added and, after stirring, the supernatant liquid was decanted and distilled at reduced pressure. The yield of methyl orthocyanoacetate,[4] b. p. 90–93° (8 mm.), $n^{20}D$ 1.4232, was 4.2 g. (81%).

A solution of 5.2 g. (0.046 mole) of cyanoketene dimethylacetal and 4.3 g. (0.046 mole) of aniline was heated for fifteen hours on the steam-bath under a reflux condenser. Distillation under reduced pressure gave: 0.7 g. (48%) of methanol (cold-trap) and 5.9 g. of liquid which boiled over a wide range. The principal fraction was 3.6 g. (45%) of **methyl N-phenylcyanoiminoacetate**, b. p. 132–136° (4 mm.), $n^{25}D$ 1.5380, $d^{25}_4$ 1.097.

*Anal.* Calcd. for $C_{10}H_{10}N_2O$: N, 16.1; $CH_3O$, 17.8. Found: N, 15.7; $CH_3O$, 17.7.

**Cyanoketene Diethylacetal.**—To 4.00 g. of ethyl orthocyanoacetate[4] was added one drop of 85% phosphoric acid and the mixture distilled. After 0.8 g. of forerun, b. p. 125–145° (20 mm.); $n^{20}D$ 1.4378, 2.0 g. (66%) of cyanoketene diethylacetal, b. p. 145–146° (20 mm.); m. p. 37–38°, $n^{20}D$ 1.4621 (supercooled liquid), $n^{40}D$ 1.4536, was collected.

*Anal.* Calcd. for $C_7H_{11}NO_2$: N, 9.9; $C_2H_5O$, 63.8. Found: N, 9.8; $C_2H_5O$, 63.7.

A yield of 1.05 g. (quantitative) of ethanol was found in the cold-trap after the distillation.

A thermometer moistened with concentrated hydrochloric acid was inserted into a solution of 1.60 g. of this ketene acetal in 3.0 ml. of absolute ethanol. On stirring, the temperature rose from 26 to 39°. Fifty mg. of anhydrous potassium carbonate was added and the mixture distilled, yielding 1.46 g. (69%) of ethyl orthocyanoacetate,[4] b. p. 111–118° (19 mm.), $n^{20}D$ 1.4218.

**The Reaction of Cyanoketene Dimethylacetal with One Equivalent of Benzyl Bromide.**—A mixture of 68.4 g. (0.4 mole) of benzyl bromide and 45.2 g. (0.4 mole) of cyanoketene dimethylacetal was placed in a Claisen flask fitted with a condenser and receiving flask. To the receiving flask was connected a trap protected from atmospheric moisture and immersed in a mixture of Dry Ice and acetone.

The mixture was slowly heated until the bath temperature reached 174°. At this point there was such a vigorous evolution of gas that the bath was cooled to 160°. When ebullition had practically ceased (thirty minutes) the bath was lowered. A total of 39.5 g. of liquid had condensed in the trap of which 37.0 g. (97%) proved to be methyl bromide, b. p. 4°; the remainder was benzyl bromide, which had been swept over by the rapidly evolved methyl bromide.

The residual red oil in the flask was distilled and the following fractions collected: (a) 12.1 g. (31%) of methyl cyanoacetate, b. p. 59–65° (0.5 mm.); (b) 0.2 g., b. p.

65–112° (0.5 mm.); (c) 12.0 g., b. p. 112–129° (0.5 mm.); (d) 8.8 g., b. p. 129–180° (0.5 mm.); (e) 11.8 g., b. p. 180–200° (0.9 mm.); (f) 14.4 g., b. p. 200° (0.9 mm.) –205° (2 mm.). The residual tar weighed 10.4 g.

Redistillation of fractions (c) and (d) gave 14.0 g. of **methyl benzylcyanoacetate** (XIII), b. p. 115–123° (0.5 mm.). Careful refractionation yielded a middle cut of the pure ester, b. p. 114–115° (0.1 mm.), $n^{25}D$ 1.5119, $d^{25}_4$ 1.105.

*Anal.* Calcd. for $C_{11}H_{11}NO_2$: $CH_3O$, 16.4; N, 7.4. Found: $CH_3O$, 15.8; N, 7.2.

The ester was hydrolyzed to benzylcyanoacetic acid, m. p. 101–102°, by the method used[11] for the ethyl ester.

Two smaller, higher-boiling fractions were also collected following the methyl benzylcyanoacetate. The last one and the residue in the distilling flask solidified on cooling. Fraction (e) also solidified on standing to a crystalline mass, m. p. 64–67°. This was combined with the solid products just mentioned and the mixture recrystallized from alcohol to give 11.0 g. of methyl dibenzylcyanoacetate (XV), m. p. 78–79° (reported[12] 78–79°), methoxyl content 11.4% (calcd. 11.1%), nitrogen content 5.2% (calcd. 5.0%). This ester was hydrolyzed in 20% aqueous potassium hydroxide to dibenzylcyanoacetic acid, m. p. 188–189° dec. (reported, 188–189°,[13] 194–195°[12]), neut. equiv., 269 (calcd. 265), nitrogen content 5.4% (calcd. 5.3%). Since one melting point reported in the literature disagreed with the value obtained, the ester was characterized further by hydrolysis in 50% sulfuric acid (by volume) to give ammonia and dibenzylacetic acid, m. p. 87–88°, neut. equiv. 230 (calcd. 240).

The remaining material, *i.e.*, fraction (f), the mother liquor from the recrystallization of (e) and the high boiling liquid obtained in the purification of methyl benzylcyanoacetate, was subjected to a systematic purification scheme involving fractionation followed by recrystallization of those portions boiling in the range 170–200° (0.5 mm.). The process was then repeated on the mother liquors. In this manner an additional 10.0 g. of methyl dibenzylcyanoacetate boiling in the range indicated was obtained. Also an additional 2.0 g. of crude methyl benzylcyanoacetate, b. p. 110–123° (0.2 mm.), $n^{25}D$ 1.5257, was obtained, bringing the total yield of that compound to 16.0 g. (21%).

The material remaining from the above isolations was distilled and two fractions collected: (g) b. p. 192–225° (0.2 mm.) and (h) b. p. 219–250° (0.2 mm.). Fraction (h) solidified and, after recrystallization from ethanol, yielded 0.3 g. of benzyl dibenzylcyanoacetate (see below), m. p. 91–91.5°. The mother liquor from these recrystallizations were combined with (g) and evaporated to a constant weight of 3.7 g. Saponification of this material left 0.7 g. unsaponified. From the alkaline solution 2.1 g. of crude dibenzylcyanoacetic acid was obtained, which calculated as the methyl ester brought the total yield of the latter product to 29.3 g. (26%).

**The Reaction of Cyanoketene Dimethylacetal with Two Equivalents of Benzyl Bromide.**—A mixture of 41.5 g. (0.37 mole) of cyanoketene dimethylacetal and 126.0 g. (0.74 mole) of benzyl bromide was placed in a Claisen flask provided with a condenser and receiving flask. To the latter was connected an absorption train consisting of a wash bottle containing 50% aqueous potassium hydroxide followed by a calcium chloride tube and, finally, a cold trap protected from atmospheric moisture and immersed in a mixture of Dry Ice and alcohol.

The mixture was heated slowly by means of an oil-bath and when the temperature of the bath reached 170° a vigorous evolution of gas began. This subsided after forty-five minutes but mild ebullition continued quite steadily for eight hours. The reaction was allowed to continue for fifteen hours at 170–180°. At this time gas evolution had practically ceased and 47.0 g. (67%) of methyl bromide had collected in the cold-trap. The aqueous alkali had gained in weight by 10.5 g. (65% yield as carbon dioxide). Acidification of a portion of the solution liberated a gas which gave a heavy precipitate when bubbled through lime-water; another portion of this alkaline solution showed no significant content of bromide ion.

The clear, red residue was distilled and the following fractions were collected: (a) 12.3 g., b. p. 50–160° (1 mm.), (b) 25.2 g., b. p. 160–198° (1 mm.), (c) 19.8 g., b. p. 198–252° (1 mm.), (d) 12.9 g., b. p. 252–265° (1 mm.) and (e) 4.6 g. collected at full-oil-pump vacuum but accompanied by so much decomposition that the pressure was too high to measure on a McLeod gage. The tarry residue weighed 10.0 g.

Fraction (a) was refractionated to give (1) 6.1 g. (5%) of benzyl bromide, b. p. 39–45° (0.5 mm.), $n^{25}D$ 1.5639; (2) an intermediate fraction of 0.7 g., b. p. 45–75° (0.5 mm.); (3) 2.8 g. (6%) of hydrocinnamonitrile, b. p. 75–78° (0.4 mm.), $n^{25}D$ 1.5228; and (4) an afterrun of 0.4 g., b. p. 78–85° (0.5 mm.). The residue (2.0 g.) solidified on cooling.

Fractionation of (c) and (d) yielded 6.1 g. of liquid which boiled almost entirely at 160–190° (0.2 mm.) and solidified on cooling. This was combined with (b) which also had solidified and with the solid residue from the distillation of (a), and the resulting mixture was recrystallized from ethanol to give 18.6 g. of dibenzylacetonitrile (XVIII), m. p. 91–91.5° (reported,[14] 89–91°). The major product of the redistillation of (c) and (d) was 24.0 g. of light amber oil which was collected in four fractions boiling at 190–245° (0.2 mm.). All four crystallized on standing and recrystallization of each from ethanol gave **benzyl dibenzylcyanoacetate** (XX), m. p. 91–92°, saponification equiv. 340 (calcd. 355).

*Anal.* Calcd. for $C_{24}H_{21}NO_2$: C, 81.1; H, 5.9; N, 3.95. Found: C, 81.4; H, 6.1; N, 3.96.

Saponification of this ester in 10% aqueous sodium hydroxide produced benzyl alcohol, b. p. 204°; m. p. of 3,5-dinitrobenzoate, 113.5–114°, and dibenzylcyanoacetic acid,[13] m. p. 189–191°, neut. equiv. 272 (calcd. 265).

A 3.0-g. sample of the ester was hydrolyzed in refluxing 50% (by volume) sulfuric acid, and after making the solution basic it was distilled until the ammonia was removed. Extraction of the remaining alkaline residue with ether gave 1.3 g. of a neutral, semi-crystalline product. Acidification of the aqueous layer gave 1.6 g. of oil, from which dibenzylacetic acid, m. p. 87–88°, neut. equiv. 243, was isolated by distillation at reduced pressure and subsequent recrystallization from petroleum ether. The neutral product was likewise distilled. The light yellow distillate crystallized on cooling and repeated recrystallization from 60–68° petroleum ether gave silky crystals, m. p. 132.5–134°. This compound had the correct analysis for **tribenzylacetamide.**

*Anal.* Calcd. for $C_{23}H_{23}NO$: C, 83.8; H, 7.0; N, 4.25. Found: C, 83.8; H, 7.1; N, 4.68.

This product probably resulted from the hydration of the cyano group of benzyl dibenzylcyanoacetate (XX), followed by loss of carbon dioxide from the resulting amide. It seems unlikely that it was formed directly from tribenzylacetonitrile (XIX), as this compound (see below) was found to be extremely stable to hydration with sulfuric acid.

The deep red residue from the distillation of (c) and (d) was added to (e) and the mixture subjected to vacuum sublimation. A small quantity of solid and 1.2 g. of clear, red oil were obtained. The residue was a dark red tar from which nothing could be isolated. The oil, from its carbon and hydrogen content, appeared to be impure benzyl dibenzylcyanoacetate. The crystalline sublimate after recrystallization from ethanol yielded 0.4 g. of stilbene, m. p. 123–124°; dibromide,[15] m. p. 237–237.5°.

The mother liquor from the recrystallization of dibenzylacetonitrile was distilled and collected in three fractions: (f) b. p. 59–150° (0.4 mm.); (g) b. p. 150–181° (0.4 mm.); and (h) b. p. 181–225° (0.4 mm.). Refractiona-

tion of (f) gave 0.3 g. of dibenzyl ether, b. p. 111–116° (0.1 mm.), $n^{25}D$ 1.5580, which gave a characteristic heavy precipitate of yellow-green resin with concentrated sulfuric acid. Recrystallization of (g) from ethanol gave 1.3 g. of dibenzylacetonitrile while similar treatment of (h) yielded 0.6 g. of benzyl dibenzylcyanoacetate. The mother liquor from the latter was distilled; the portion boiling at 171–220° (0.5 mm.) solidified and was recrystallized from 60–68° petroleum ether. The yield of N-benzylhydrocinnamamide,[16] m. p. 81–83°, mixed m. p. 81–84°, was 1.2 g. (1%). The yields of both this product and dibenzyl ether were due to benzyl alcohol and were negligible when benzyl bromide,[17] $n^{25}D$ 1.5730, was used.

The remaining mother liquors were subjected to a systematic scheme of purification involving alternate fractionations and recrystallizations. In this manner an additional 2.1 g. of dibenzylacetonitrile, 0.6 g. of benzyl dibenzylcyanoacetate and 8.0 g. of oil, b. p. 187–238° (0.2 mm.), which had a nitrogen content of 5.6%, were obtained. Treatment of this latter fraction with hot 10% aqueous sodium hydroxide for five hours gave 0.6 g. of benzyl alcohol and 2.0 g. of dibenzylcyanoacetic acid; 5.1 g. remained unsaponified (hydrolysis of the same quantity of benzyl dibenzylcyanoacetate under identical conditions left only 5% unsaponified). The unsaponified material was subjected to refluxing 50% (by volume) sulfuric acid. This treatment produced 0.6 g. of a neutral solid, m. p. 122–128°, mixed m. p. with tribenzylacetamide 127–131°. The other products were ammonia and 1.8 g. of ether-soluble, acidic oil which, on sublimation, gave 0.1 g. of hydrocinnamic acid, m. p. 45–47°, neutral equiv. 154 (calcd. 150). The high-boiling residue had a neutral equivalent of 236 and, therefore, appeared to be crude dibenzylacetic acid (neut. equiv. 240).

These results indicated that the 8 g. of oil, which was subjected to saponification, was a mixture of approximately 3 g. of benzyl dibenzylcyanoacetate, 4 g. of dibenzylacetonitrile and 1 g. of tribenzylacetonitrile. Such a mixture would contain 5.2% nitrogen and leave the 5 g. of the alkali-inert nitriles unchanged after saponification of the ester.

The yields of *pure* dibenzylacetonitrile and benzyl dibenzyl cyanoacetate finally obtained were 21.9 g. (27%) and 13.0 g. (10%), respectively. However, since this experiment was designed to give information as to the course of the reaction, the more significant yields are those of the crude materials which make possible a relatively complete material balance. The failure to find but traces of other products in these crudes emphasizes their quantitative significance. The yield of crude dibenzylacetonitrile boiling almost entirely at 160° (0.2 mm.) to 190° (1 mm.) and which solidified on standing was 33.3 g. (41%) and of benzyl dibenzylcyanoacetate, b. p. 190–245° (0.2 mm.), was 29.9 g. less 1.2 g. of N-benzylhydrocinnamamide which was isolated from this fraction, or 28.7 g. (22%). In another run the yield of dibenzylacetonitrile was 43.5%.

**Quantitative Determination of the Carbon Dioxide and Methyl Bromide Evolved in the Reaction of Cyanoketene Acetal and Benzyl Bromide.**—A mixture of 11.3 g. (0.10 mole) of the ketene acetal and 34.2 g. (0.20 mole) of benzyl bromide was heated in a bath maintained at 170–180° and the amounts of methyl bromide (cold-trap) and carbon dioxide (absorption bulbs containing 50% aqueous potassium hydroxide solution) determined periodically. The results are summarized in Table I.

The products obtained from the residue were: (a) 0.9 g. (2.5%) of unchanged benzyl bromide, (b) 0.9 g. (7%) of hydrocinnamonitrile, (c) 9.5 g. (43%) of dibenzylacetonitrile, (d) 5.6 g. of viscous oil, b. p. 220–240° (1 mm.), (e) 0.3 g. of stilbene and (f) 4.1 g. of tarry residue. The condensate in the cold trap was 0.5 g. of toluene, b. p. 100–110°, 2,4-dinitro derivative, m. p. 70–70.5°.

Because of the high yield of carbon dioxide it was thought that (d) was tribenzylacetonitrile, and the fact that saponification of this fraction gave only small quantities of benzyl alcohol also indicated this possibility. However, all attempts to isolate this nitrile from the unsaponified material were unsuccessful.

TABLE I

YIELDS OF METHYL BROMIDE AND CARBON DIOXIDE FROM CYANOKETENE ACETAL (0.10 MOLE) AND BENZYL BROMIDE (0.20 MOLE)

| Time, hr. | $CH_3Br$, mole | $CO_2$, mole |
|---|---|---|
| 1 | 0.091 | 0.004 |
| 3 | .146 | .016 |
| 5 | .164 | .030 |
| 16 | .174 | .085 |
| 23 | .175 | .093 |
| 26 | .176 | .096 |
| 37 | .176 | .103[a] |

[a] A semi-quantitative determination of the carbonate present in the absorption tube was made by acidification of an aliquot of the solution and passing the liberated gas into a barium hydroxide solution. A 90% yield of barium carbonate was obtained. A titration of another aliquot of this solution, after acidification with nitric acid, against silver nitrate showed sufficient bromide ion to account for the discrepancy between the amount of carbon dioxide obtained in the absorption bulbs and that obtained as barium carbonate.

**Interrupted Reaction of Cyanoketene Dimethylacetal with Two Equivalents of Benzyl Bromide.**—A mixture of 31.5 g. (0.28 mole) of cyanoketene dimethylacetal and 96.0 g. (0.56 mole) of benzyl bromide was placed in a Claisen flask connected to the absorption train described above and heated at 170–175° for one and one-half hours. During this time 33.0 g. (62%) of methyl bromide was evolved, but the carbon dioxide-trap did not show any gain in weight. The residue was fractionated into: (a) 31.9 g., b. p. 83–84° (15 mm.); (b) 0.6 g., b. p. 46–108° (0.3 mm.); (c) 9.7 g., b. p. 108–122° (0.3 mm.); (d) 0.7 g., b. p. 122–154° (0.3 mm.); (e) 7.8 g. of a thick oil, b. p. 154–163° (0.3 mm.); (f) 24.6 g. of very viscous amber-colored oil, b. p. 177° (0.6 mm.) to 240° (2.5 mm.). Some decomposition during the distillation of (f) was apparent from the pressure rise and fuming which occurred. The tarry residue amounted to 8.5 g.

The refractive index and nitrogen and methoxyl content showed (a) to consist of 26.5 g. of benzyl bromide and 5.4 g. (19.5%) of methyl cyanoacetate (XVI). Fraction (c) contained 10.0% methoxyl and 7.3% nitrogen and gave a positive test for the benzoxy group with concentrated sulfuric acid. When 3.6 g. of (c) was shaken with 25 ml. of 10% aqueous sodium hydroxide the mixture warmed slightly and the oil dissolved. Extraction with ether gave 1.0 g. of benzyl alcohol; acidification of the aqueous residue gave a liquid acid, which was extracted with ether. After drying and evaporation of the solvent, the acid solidified; recrystallization from benzene gave pure benzylcyanoacetic acid, m. p. 101–102°. The aqueous solution, from which this product had been extracted, was evaporated under 20–30 mm. in a bath at 60–70° to a semi-crystalline residue. This was extracted with ether and the extract evaporated to dryness and allowed to stand over concentrated sulfuric acid in a desiccator overnight. The product was 0.3 g. of hygroscopic crystals which, after drying between filter papers, proved to be cyanoacetic acid, m. p. 60–66°. These results show that (c) was a mixture of methyl benzylcyanoacetate and benzyl cyanoacetate in the proportions 3:2 (based on the methoxyl content of (c)). The nitrogen value is in satisfactory agreement with

(16) Mohr, *J. prakt. Chem.*, [2] **71**, 235 (1905).

(17) Benzyl bromide was prepared by allowing a solution of benzyl alcohol in sufficient 48% hydrobromic acid to contain approximately 2.3 equivalents of hydrogen bromide to stand at room temperature. After two days 83–87% yields of benzyl bromide, $n^{25}D$ 1.5700, were obtained. This product, however, contained sufficient benzyl alcohol to give the products noted. The benzyl bromide, $n^{25}D$ 1.5730, was obtained from an alcohol–acid reaction mixture that had stood for two weeks.

this composition (calcd. N, 7.6; found N, 7.2), but the refractive index of such a mixture is 1.530 instead of the observed 1.515. This indicates the presence in the mixture of still another component of lower refractive index than that of either of these esters. Assuming the methoxyl value to be due solely to methyl benzylcyanoacetate, fraction (c) contained 5.9 g. (11%) of that ester. As to the benzyl cyanoacetate, the data indicate only that the maximum yield of that ester was 3.8 g. (8%).

On standing, fraction (e) partially crystallized. Recrystallization from alcohol gave 2.5 g. of methyl dibenzylcyanoacetate (XV), m. p. 76–79°. Further recrystallization raised the melting point to 79–80°, and a mixed melting point with an authentic sample showed no depression. Fraction (f) also partially crystallized on standing. It was treated with ethanol and the insoluble crystals (4.8 g.) of benzyl dibenzylcyanoacetate (XX), m. p. 90–91°, filtered off.

The alcoholic mother liquors from the recrystallizations of (e) and (f) were combined and distilled. After 1.8 g. of forerun, b. p. 67–165° (1 mm.), there was obtained 14.2 g. (19%) of benzyl benzylcyanoacetate (XXI), b. p. 165–195° (1 mm.), $n^{25}D$ 1.5550, which boiled almost entirely at 182–188° (1 mm.). Following this, 2.1 g. of an intermediate fraction, b. p. 195–205° (1 mm.), and 5.4 g. of benzyl dibenzylcyanoacetate, b. p. 210–240° (1.5 mm.), were collected. The latter ester was obtained as a red oil which was taken up in ethanol, seeded and the mixture allowed to stand overnight in the refrigerator; 2.0 g. of relatively pure ester, m. p. 89–90°, separated. Recrystallization from ethanol raised the melting point to 91–92°. The total yield of crude benzyl dibenzylcyanoacetate was 10.2 g. (10%).

**The Reaction of Methyl Cyanoacetates with Benzyl Bromide.** (a) **Methyl Cyanoacetate.**—A mixture of 10.5 g. (0.11 mole) of this ester and 36.8 g. (0.22 mole) of benzyl bromide was heated in an apparatus similar to the one used for the reaction of cyanoketene dimethylacetal and two moles of benzyl bromide. The heating-bath was held at 170–180° throughout the experiment. During the first two and one-half hours there was no reaction but at the end of that time a very slow evolution of gas commenced. The rate of evolution increased very gradually, finally reached a maximum after thirty hours and then slowly subsided until, after forty-seven hours, no more gas was being given off. The system was swept out for fifteen minutes with nitrogen before the products were examined. The yield of methyl bromide, b. p. 4–5°, condensed in the cold trap was 8.2 g. (81%) (after twenty-four hours the yield was 17%). The aqueous potassium hydroxide had gained 3.0 g., which represented a yield of 64% of carbon dioxide. The residue in the flask was distilled at reduced pressure but underwent decomposition (heavy fuming). The distillate consisted of 6.3 g. of benzyl bromide, b. p. 52–70° (1 mm.), and 5.8 g. of liquid, b. p. 70° (1 mm.), 195° (2 mm.), which was not investigated. The principal product was 16 g. of a black, tarry residue.

(b) **Methyl Dibenzylcyanoacetate.**—A mixture of 11.0 g. (0.04 mole) of this ester and 13.5 g. (0.08 mole) of benzyl bromide was heated at 170–180° for twenty-two hours without any apparent reaction. During this time the flask and contents lost no weight and on distillation there were obtained 11.5 g. of benzyl bromide, b. p. 92–97° (22 mm.), 10.4 g. of the original ester, b. p. 185–205° (0.1 mm.), and 1.6 g. of tar residue.

(c) **Methyl Benzylcyanoacetate.**—A mixture of 10.0 g. (0.053 mole) of this ester and 18.2 g. (0.106 mole) of benzyl bromide was heated at 170–180°. No apparent reaction occurred until one and one-half hours had elapsed when a slow evolution of gas commenced. The rate of evolution increased slowly over a period of several hours but had decreased after eleven hours and after twenty hours had ceased altogether. The yields of methyl bromide and carbon dioxide were 60 and 64%, respectively.

The residue was fractionated and the following fractions collected: (a) 9.3 g. of unreacted benzyl bromide, b. p. 92–102° (23 mm.); (b) 1.3 g. (19%) of hydrocinnamonitrile, b. p. 86–98° (0.1 mm.), $n^{25}D$ 1.5242; (c) 5.8 g. (41%) of benzyl benzylcyanoacetate, b. p. 160–190° (0.1 mm.), $n^{25}D$ 1.5530; (d) 2.9 g. of a viscous oil, b. p. 200–230° (1 mm.); and (e) 1.0 g. of tar as residue.

Fraction (d) was dissolved in ethanol and seeded with a crystal of benzyl dibenzylcyanoacetate (XX). On standing in a refrigerator for several days, 0.6 g. (3%) of crystalline XX separated from the solution.

**The Reaction of Cyanoacetic Esters with Benzyl Alcohol.** (a) **Ethyl Cyanoacetate.**—To a solution of 0.3 g. of metallic sodium in 100 ml. of anhydrous benzyl alcohol was added 20.0 g. (0.18 mole) of ethyl cyanoacetate. The clear solution was heated in an oil-bath and when the bath temperature reached 110° a gelatinous precipitate began to separate. At a bath temperature of 170° a rapid evolution of ethanol began and continued for about ten minutes. Heating at 170–175° (bath temperature) was continued for an additional five minutes, after which time distillation of alcohol had practically ceased. Redistillation of the distillate gave 7.6 g. (92%) of ethanol and 0.2 g. of benzyl alcohol.

The excess benzyl alcohol was distilled from the residue at a pressure of 2 mm. and the residual red oil extracted with two 100-ml. portions of anhydrous ether. Finally, the ether-insoluble semi-solid which remained was taken up in cold water containing sodium chloride to prevent emulsification. This mixture was extracted repeatedly with ether and the ether solution combined with the previous ether extracts. This combined extract was washed repeatedly with the dilute aqueous sodium chloride solution, dried over Drierite, after which the ether was evaporated and the residue distilled. The first fraction collected boiled at 65–152° (1.5 mm.). Further distillation was accompanied by marked decomposition which was apparent from the copious fumes and a rise in pressure. A second fraction was collected during this decomposition at a vapor temperature of 152–200°. The undistillable residue weighed 5.9 g.

Redistillation of the first fraction gave 1.4 g. of forerun, b. p. 60–127° (1 mm.), and 6.7 g. of **benzyl cyanoacetate**, b. p. 127–137° (1 mm.). The latter portion of this fraction was selected for analysis and proved to be the pure ester, b. p. 131–137° (1 mm.); $n^{25}D$ 1.5188; $d^{25}_4$ 1.139.

*Anal.* Calcd. for $C_{10}H_9NO_2$: C, 68.6; H, 5.2; N, 8.0. Found: C, 68.6; H, 5.4; N, 7.6.

The second fraction was fractionated to yield: 1.7 g. of benzyl alcohol, b. p. 64–65° (1.5 mm.); 0.5 g. of an intermediate fraction, b. p. 65–131° (1.5 mm.); 1.1 g. of benzyl cyanoacetate, b. p. 131–141° (1.5 mm.); and 2.6 g. (5.5%) of benzyl benzylcyanoacetate, b. p. 175–195° (1.5 mm.). The total yield of benzyl cyanoacetate was 7.8 g. (25%). The combined residues from the second distillations weighed only 0.3 g.

Attempts to avoid the formation of large amounts of tar in this reaction by the use of no catalyst or an acid catalyst were unsuccessful. In the former instance, no reaction occurred up to 190°. Catalysts such as sulfuric acid, oxalic acid and sulfosalicylic acid caused only sluggish reaction, the yields of alcohol at the end of two hours heating at 180–200° being of the order of only 50%.

(b) **Methyl Benzylcyanoacetate.**—To a solution of 0.3 g. of metallic sodium in 100 ml. of benzyl alcohol was added 22.2 g. (0.118 mole) of methyl benzylcyanoacetate. The mixture was heated at 180–195° for twenty minutes; 4.0 ml. of methanol was collected. The excess benzyl alcohol was distilled at reduced pressure (1.5 mm.) and during this operation an additional 0.5 ml. of methanol collected in the cold trap (total yield, 94%). To the residue was added 150 ml. of anhydrous ether and the precipitated sodium salt removed by filtration. The filtrate was washed with cold water until the washings were no longer alkaline to phenolphthalein and then dried over Drierite. Fractionation of the ether solution yielded: (a) 2.8 g. of forerun, b. p. 55–93° (1 mm.); (b) 3.7 g. (14%) of dibenzylacetonitrile, b. p. 150–175° (1 mm.); (c) 3.9 g. (12.5%) of benzyl benzylcyanoacetate, b. p. 175–188° (1 mm.); and (d) 10.8 g. (26%) of benzyl dibenzylcyanoacetate, b. p. 220–230° (1 mm.).

Recrystallization of (b) and (d) from ethanol gave pure

dibenzylacetonitrile, m. p. 91–92°, and benzyl dibenzylcyanoacetate, m. p. 91–92°, respectively. A center cut from (c) was pure **benzyl benzylcyanoacetate** (XXI), b. p. 180–183° (1 mm.), $n^{25}D$ 1.5533, $d^{25}_4$ 1.124.

*Anal.* Calcd. for $C_{17}H_{15}NO_2$: C, 77.0; H, 5.7; N, 5.3. Found: C, 77.5; H, 5.7; N, 5.3.

From a similar run of 0.13 mole of methyl benzylcyanoacetate, in which the alkaline catalyst was not removed, a partial decarboxylation occurred during the distillation as indicated by an increase in the pressure and a gain in weight of an Ascarite tube in the system. The products of this run were: (a) 3.9 g. (23%) of hydrocinnamonitrile, b. p. 78–92° (1 mm.); (b) 8.0 g. of dibenzylacetonitrile, b. p. 158–170° (1 mm.); and (c) 8.0 g. of an oil, b. p. 180–220° (1 mm.), which crystallized on cooling. Recrystallization of (b) from ethanol gave pure dibenzylacetonitrile, m. p. 91–92°. Extraction of (c) with ether left 2.9 g. (7%) of **tribenzylacetonitrile** (XIX), m. p. 210–217°, which after recrystallization from a chloroform–alcohol mixture gave white needles, m. p. 222–223.5°.

*Anal.* Calcd. for $C_{23}H_{21}N$: C, 88.7; H, 6.8; N, 4.5. Found: C, 88.1; H, 7.0; N, 4.5.

Tribenzylacetonitrile is insoluble in cold, concentrated sulfuric acid, but dissolves when the acid is warmed to 95–100° to give a pale yellow solution, which yields no precipitate on dilution with water. The nitrile (XIX) is recovered unchanged after heating with 75% (by volume) sulfuric acid at 100–125° for five minutes or with refluxing 50% sulfuric acid for fourteen hours; under the former set of conditions dibenzylacetonitrile (XVIII) is converted in good yield to dibenzylacetamide, which, after recrystallization from ethanol–water, melts at 127–129°.

The ether extract from which XIX was separated was distilled and gave an additional 3.2 g. of dibenzylacetonitrile (total yield, 39%) and 2.5 g. (5%) of benzyl dibenzylcyanoacetate, b. p. 200–220° (0.7 mm.), which crystallized on standing and which after recrystallization from ethanol melted at 91–92°.

## Summary

Cyanoketene dimethyl- and diethylacetals have been prepared by the pyrolysis of the corresponding orthoesters and certain of their properties and reactions reported.

With one equivalent of benzyl bromide the dimethylacetal gives methyl dibenzylcyanoacetate as one of the reaction products, showing that the negative cyano substituent makes possible the replacement of the single methylene hydrogen of the acetal.

In the presence of a second equivalent of benzyl bromide the reaction continues with the methyl esters produced by the first equivalent to yield benzyl esters of mono- and dibenzylcyanoacetates, which lose carbon dioxide to yield mono-, di- and tribenzylacetonitriles.

These novel benzylation reactions are also shown to occur with these methyl esters and benzyl alcohol.

# Ketimines and Acylketimines Related to Amidone[1]

BY L. C. CHENEY, R. R. SMITH AND S. B. BINKLEY

Because of the great importance of morphine and related opium alkaloids in medicine and the associated problem of liability to drug addiction, it is not surprising that information pertaining to the discovery of the potent analgesic drug, amidone (I)[2a,b] has already stimulated rather extensive chemical and clinical investigation.[3–18]

Inasmuch as it has been reported[19] that nuclear substitution of the two phenyl groups in amidone does not enhance analgesic potency or lead to more desirable activity, attention has been focused in this Laboratory on other structural modifications, including the synthesis of certain carbinols, esters,[20] ketimines and acylated ketimines related to amidone. Several examples of the latter class have been described by other investigators[7,12,17] since the completion of this work.

Although ketimines are commonly dealt with as unstable intermediates in the synthesis of ketones by means of the Grignard reagent[21] and the Hoesch and Hoesch–Houben syntheses, few, if any, imines or acylimines of physiologically active ketones appear to have been studied pharmacologically. Our interest was initially aroused in this class of compounds when the remarkably stable isoamidone imine (II)[12,17] was unexpectedly isolated while carrying out the synthesis of amidone in essential accordance

with the original procedure.[1] For the sake of convenience lithium amide was advantageously substituted for sodium amide in the condensation of diphenylacetonitrile with 1-dimethylamino-2 chloropropane. The oily reaction product proved

I

II

III

to be a mixture of isomeric nitriles[12,18] which yielded amidone (I) and isoamidone imine (II) on treatment with ethylmagnesium bromide followed by hydrolysis in accordance with the original directions.[1] In order to ensure complete hydrolysis, the ketimine (II) was refluxed with constant boiling hydrochloric acid for thirty-six hours, whereupon isoamidone (III)[7,8,10,17] was obtained in quantitative yield. The preparation of the dihydrochloride and the acetyl derivative completed the characterization of isoamidone imine.

It is noteworthy that ketimines of the isoamidone series are not appreciably hydrolyzed under the drastic conditions imposed by the German procedure for the preparation of amidone, for sufficient heat is evolved to volatilize practically all of the xylene used as the solvent when the Grignard reaction product is poured into the dilute hydrochloric acid. Other examples of sterically hindered, stable ketimines, however, can be found in the literature. Typical examples are the ketimines of trichloroacetomesitylene[22] and 1,2-diphenyl-2-methyl-1-propanone.[23]

The less sterically hindered and consequently less stable ketimines were isolated in favorable yields by conducting the hydrolysis of the bromomagnesium salt in the cold with ammonium chloride. The imines were then extracted with ether from basic solution and purified by distillation *in vacuo*. They are all low-melting solids or viscous yellow oils, some of which gradually evolve ammonia on standing at room temperature. Precipitation of the ketimines from ethereal solution with hydrogen chloride produced hygroscopic acidic salts which melted over a wide range with the evolution of gas. Cloke[24] has noted a similar phenomenon in working with other ketimines. The acylketimines were prepared by treating a benzene solution of the imine with the appropriate acid chloride or, alternatively, by adopting the general procedure of Moureau and Mignonac[25] and adding dropwise the acid chloride directly to the cold bromomagnesium salt of the ketimine.

## Experimental

**Preparation and Separation of 4-Dimethylamino-2,2-diphenyl-3-methylbutyronitrile and 4-Dimethylamino-2,2-diphenylvaleronitrile.**—The following procedure is believed to offer some advantages over the published method.[12] To a well-stirred suspension of 36.3 g. (1.58 moles) of lithium amide in 285 ml. of dry benzene there was added 278 g. (1.44 moles) of diphenylacetonitrile over a period of twenty minutes while the temperature was maintained at 45–50°. After the addition was completed, the mixture was heated at 45–50° for one and one-half hours. It was then cooled to 20–25° and 181.1 g. (1.49 moles) of 1-dimethylamino-2-chloropropane[1] was added. The mixture was stirred for one hour and then heated gradually until a vigorous reaction ensued with the evolution of ammonia. Heating was discontinued until the reaction moderated, whereupon the mixture was refluxed for an additional two hours, then cooled and poured into 800 ml. of water. The benzene layer was separated, washed twice with water and extracted with 6 *N* hydrochloric acid until a precipitate no longer formed in a sample of extract when made basic. The combined extracts were washed once with ether, made strongly alkaline with sodium hydroxide solution and extracted with a total of 700 ml. of ether in three portions. After the combined ether extracts were washed with water and saturated salt solution, they were dried over anhydrous potassium carbonate and the filtered solution was concentrated and cooled to induce crystallization of the higher melting nitrile, which was collected by filtration. Further concentration and cooling led to the total isolation of 187.5 g. (46.8% yield) of 4-dimethylamino-2,2-diphenylvaleronitrile,[12,13] m. p. 90–91°.

The removal of residual ether left a viscous yellow-brown oil which was dissolved in 200 ml. of absolute alcohol, and treated with an excess of absolute alcoholic hydrogen chloride. Small white crystals of the aminonitrile hydrochloride (145.5 g.), m. p. 222–225°, separated. Recrystallization from absolute alcohol (350 ml.) elevated the melting point to 225–226°. The purified hydrochloride (119.4 g.) was dissolved in water, made alkaline with ammonium hydroxide and extracted with ether. The ether extract was washed with water, dried over potassium carbonate, and solvent was removed to obtain 103.2 g. (25.8% yield) of 4-dimethylamino-2,2-diphenyl-3-methylbutyronitrile,[12,13] in the form of a colorless oil which crystallized on scratching and cooling to melt at 67.5–69°. The structure of each isomer has been definitely established.[12]

Repeated attempts to detect the presence of a third aminonitrile, the precursor of Isoamidone I,[7,17] as a product of the alkylation were unsuccessful.

The other alkylations of diphenylacetonitrile were conducted in accordance with the above procedure. When isomeric aminonitriles were not involved, the product was readily purified by distillation through a Vigreux column.

**6-Dimethylamino-4,4-diphenyl-5-methyl-3-hexanone (Isoamidone) (III) Hydrochloride[7,10,17] Monohydrate.**—4-Dimethylamino-2,2-diphenyl-3-methylbutyronitrile was converted into isoamidone imine (II)[12,17] in accordance with the general procedure described for the preparation of ketimines. The product, b. p. 148–153° at 1 mm., was obtained in 76.7% yield. Treatment of an isopropyl alcohol solution of the base with one equivalent of hydrogen chloride followed by dilution with ether precipitated a monohydrochloride monohydrate of II which melted at 89–142°, dec., after being dried in the air. The anhydrous monohydrochloride of II, m. p. 151–152°, was obtained by heating a sample of the hydrate *in vacuo*, first at 61° for two hours, and then at 81° for three hours.

A mixture of 10 g. (0.0275 mole) of the monohydrochloride monohydrate of II was refluxed for thirty-six hours with 90 ml. of concentrated hydrochloric acid. The solution was cooled in ice and made strongly alkaline by the addition of 50 g. of sodium hydroxide dissolved in 145 ml. of water. Prolonged cooling and scratching with a glass rod failed to crystallize the oily base. It was therefore extracted with 400 ml. of ether and the washed extract was dried for four hours over anhydrous potas-

sium carbonate. To the cooled filtered solution there was added an excess of absolute alcoholic hydrogen chloride. After the white hydrochloride which precipitated was collected and dried *in vacuo* overnight over phosphorus pentoxide, it melted at 119–122° and weighed 9.8 g. The melting point was not altered by recrystallization of a sample from dilute hydrochloric acid by the addition of a saturated solution of sodium chloride. Analyses disclosed that the compound, in spite of its subjection to the drying agents, was actually the monohydrate.

*Anal.* Calcd. for $C_{21}H_{28}NOCl \cdot H_2O$: C, 69.4; H, 8.33; N, 3.87. Found: C, 68.9; H, 8.23; N, 3.83.

Following recrystallization of the monohydrate from ethyl acetate and desiccation over phosphorus pentoxide, the salt melted at 155–158° with previous softening but still contained water. The anhydrous material has been reported to melt at 190–193°.[17]

**4,4-Diphenyl-6-(4-morpholinyl)-3-iminohexane (412-10H).**—The general procedure employed for the preparation of the ketimines is illustrated by the following typical example. To the well-stirred solution of ethylmagnesium bromide prepared in the customary manner from 13.4 g. (0.544 mole) of magnesium turnings, 67.9 g. (0.62 mole) of ethyl bromide and 115 ml. of anhydrous ether, there was added during a period of fifteen minutes a solution of 84.9 g. (0.277 mole) of 2,2-diphenyl-4-(4-morpholinyl)-butyronitrile dissolved in 91 ml. of dry xylene. The mixture was stirred and refluxed for four and one-half hours, during which time a greenish gray precipitate formed. A nitrogen atmosphere was provided throughout the reaction. The thick suspension was cooled, diluted with about 100 ml. of ether to facilitate the transfer and poured slowly into a stirred, cooled mixture composed of 150 g. of ice and 300 ml. of water. Following completion of the hydrolysis, 150 ml. of concentrated ammonium hydroxide was added, the ether phase was separated and the aqueous layer extracted twice with 200-ml. portions of ether. The combined ethereal extracts were washed with water and dried over anhydrous potassium carbonate. After the removal of the solvent, distillation through a short Vigreux column afforded 73.8 g. (79.2%) of the ketimine as a pale yellow viscous oil, b. p. 198–202° at less than 1 mm. It separated from ether in the form of colorless crystals, m. p. 85–86.5°.

**6-Dimethylamino-4,4-diphenyl-5-methyl-3-(acetylimino)-hexane Hydrochloride[17] (C-14719B).**—A cold aqueous solution of 3 g. (0.00875 mole) of II monohydrochloride was made alkaline with 20% sodium hydroxide solution and extracted with 50 ml. of benzene. The benzene layer was washed with water, dried over anhydrous potassium carbonate and filtered. Treatment of the solution with 10.5 ml. of a molar solution of acetyl chloride in benzene (a 20% excess) caused a precipitate to form. After refluxing the mixture for two hours, solvent was distilled under reduced pressure and the white residue was boiled with 25 ml. of ethyl acetate, cooled and filtered to obtain 3 g. (89% yield) of fine white crystals, m. p. 214–215°. A sample was dissolved in hot absolute alcohol and precipitated with ether without changing the melting point.

**6-Dimethylamino-4,4-diphenyl-3-(propionylimino)-heptane Hydrochloride (489-43H).**—An ethereal solution of ethylmagnesium bromide prepared from 4.9 g. (0.2 mole) of magnesium, 115 ml. of dry ether and 24.5 g. (0.225 mole) of ethyl bromide in a nitrogen atmosphere was treated with 30 g. (0.108 mole) of 4-dimethylamino-2,2-diphenylvaleronitrile dissolved in 200 ml. of dry xylene and the stirred mixture was refluxed for four and one-half hours. The resulting suspension was chilled in an ice–salt-bath throughout the dropwise addition of 20.8 g. (0.224 mole) of propionyl chloride dissolved in 50 ml. of ether. After standing overnight the yellow-green suspension was stirred into a mixture of 300 g. of ice, 150 g. of ammonium chloride and 150 ml. of water. When all solid had dissolved, the solution was made alkaline with ammonium hydroxide, which caused the precipitation of 5.9 g. of the free acylimine, m. p. 142–145°. Upon treatment of the washed and dried ether layer with hydrogen chloride, 31 g. of hydrochloride precipitated which was dissolved in water and converted into 11.3 g. of the crude base, m. p. 139–144°, by the addition of ammonia. Recrystallization of the combined fractions from 65 ml. of ethanol produced 14.2 g. (35% yield) of the pure base, m. p. 146–147°.

The hydrochloride was prepared by dissolving 13.2 g. of the base in 20 ml. of warm benzene, diluting with 200 ml. of dry ether and bubbling an excess of hydrogen chloride into the solution. The strongly acidic salt (15 g.) which precipitated was boiled under reflux with 140 ml. of anhydrous ethyl acetate until no more hydrogen chloride was evolved. Cooling, filtration and desiccation over phosphorus pentoxide afforded 9.3 g. of small white crystals, m. p. 202–203°.

### Pharmacology

The pharmacological evaluation of these compounds was conducted by Dr. Carl C. Pfeiffer of the University of Illinois Medical School and the preliminary data are presented here with his permission. White mice injected intraperitoneally were used for the toxicity determinations. A modified Wolff–Hardy technique applied to guinea pigs was used to measure minimal subcutaneous analgesic dosage. Activity index is the mouse $LD_{50}$ divided by the guinea pig analgesic dose, a device which serves as an effective basis for comparison.

From the tabulation it can be observed that in both the amidone and isoamidone series the order of decreasing toxicity and increasing activity index is ketone:ketimine:acetylketimine. Owing to comparable potency and significantly lower toxicity, all of the tabulated ketimines and their acyl derivatives possess as high or more favorable activity indices than those of amidone and isoamidone. With reference to the acylated ketimines, the amidone side chain confers highest potency and index when the acyl group is acetyl. Conversely, in the case of the β-morpholinylethyl compounds the propionyl group is more effective than the acetyl.

It should be mentioned that since the *levo*-isomer of amidone has been shown to be the pharmacologically active form,[2,10] one should expect the *l*-isomer of amidone imine and its acyl derivative to be approximately twice as potent as the tabulated values. Since the intermediate nitrile can be resolved without difficulty,[10] the synthesis of these optically active forms appears practicable.

**Acknowledgments.**—The authors are indebted to Dr. Carl C. Pfeiffer for the pharmacological data and to Mr. Richard M. Downing for the microanalyses.

## Summary

Some representative ketimines and acylated ketimines related to amidone have been described. Preliminary pharmacological data indicate that these compounds are potent analgesic drugs which are less toxic than the corresponding ketones.

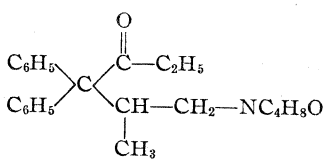
# Analgesic Carbinols and Esters Related to Amidone (Methadon)[1]



BY MERRILL E. SPEETER, WENDELL M. BYRD, LEE C. CHENEY AND S. B. BINKLEY

A number of ketones and imines related to the potent analgesic Amidone (Methadon) have been prepared[2,3,4,5,6,7,8] but no modifications of the Amidone structure involving other variations in the ketone moiety of the molecule have been reported. The present paper deals with the reduction of Amidone and a number of related ketones, esters and acids to carbinols. Since esterification of the carbinols potentiated the activity in a number of cases, a variety of carbinol derivatives was prepared.

The synthesis of the parent ketones in most cases was carried out using already established procedures.[2,6] When isomers were expected, hydrolysis of the Grignard reaction in the last step paralleled the original German procedure,[2] and isolation of the ketones and imines was accomplished through a combination of recrystallization and distillation methods. The morpholinyl analogs of Amidone and Isoamidone were assigned structures (I) and (II) through consideration of the

I

II

similarities of the isolation procedures for these compounds to the isolation of the corresponding dimethylamino derivatives. The ketone II, isolated in part as the imine, was given the Isoamidone structure while ketone I, which separated as a highly insoluble hydrobromide salt, was assigned the Amidone structure. No degradative studies were carried out to definitely establish the position of the methyl group.[9]

Amidone was readily reduced catalytically by the use of Adams platinum oxide catalyst, but not with palladium. Isoamidone was resistant to all attempts at catalytic hydrogenation under a number of different conditions. The same resistance toward catalytic reduction conditions was shown by the morpholinyl analogs of Amidone I and Isoamidone II. The compound believed to have the structure represented by I was readily reduced by the same conditions employed for Amidone. Compound II was recovered unchanged from all catalytic reduction experiments. This behavior toward reduction of the "iso" forms of these members of the Amidone series is apparently related to steric factors. It was found that lithium aluminum hydride reduces Amidone, Isoamidone and the morpholinyl analogs in good yield.

Reduction of Amidone and the related branched chain compounds introduces a second asymmetric carbon atom in the molecule, making two diastereoisomeric pairs possible. One pure compound was isolated from the reduction of Amidone in sufficiently high yield (98%) to indicate that another isomer, if formed at all, is formed only in small amounts. The same compound was isolated from both the catalytic and lithium aluminum hydride reductions.

The primary alcohols and their esters in the Amidone series were prepared through the lithium aluminum hydride reductions of the appropriate ester or acid. 2,2-Diphenyl-4-(N-morpholinyl)-1-butanol was obtained in 85% yield from the corresponding ethyl $\gamma$-N-morpholinyl-$\alpha,\alpha$-diphenyl butyrate. Reduction of $\gamma$-dimethylamino-$\alpha,\alpha$-diphenylvaleric acid with lithium aluminum hydride proceeded in poor yield because of the low solubility of the acid in ether.

The general method for preparation of the esters involved refluxing of the carbinol in ethyl acetate with an excess of the acyl halide. It was found that some of the esters were hydrolyzed on attempted recrystallization from alcohols although a number of esters in the morpholinyl series, and esters of the higher molecular weight acids were stable in boiling alcohol.

**Pharmacology.**—In Table I physical constants on a number of ketones related to Amidone are given together with pharmacological data. Dr. Pfeiffer and co-workers have found the $LD_{50}$ for

(1) Presented in part before the Division of Medicinal Chemistry of the American Chemical Society, Chicago, Illinois, April 19–23, 1948.

[a] See footnotes to Table II for data on methods of pharmacological evaluation and comparison data with Amidone and Isoamidone.

Amidone intraperitoneally in the mouse to be 28.6 ± 2 mg./kg. while the minimal analgesic dose subcutaneously in the guinea pig is 12.5 mg./kg. It is thus apparent that several of the morpholinyl ketones and esters are nearly as potent as Amidone on a weight basis and much less toxic.

The pharmacological data summarized in Table II establish several generalizations for these series. In all cases the alcohols are less toxic than the corresponding ketones; however, the analgesic activity of the carbinols is unpredictable, being undetectable in some cases. The acetate esters are uniformly more analgesic and more toxic than the parent ketones. The increase in analgesic potency of the acetate esters over the ketones is in all cases sufficient to produce a marked increase in the activity index in spite of the increased toxicity.

[a] Intraperitoneal LD/50 in the mouse in mg./kg. The pharmacological data were obtained by Dr. Carl C. Pfeiffer and coworkers of the University of Illinois Medical School. These data were presented in part at the Federation Meetings, Atlantic City, March 15–19, 1948. See *Federation Proceedings*, **7**, 255 (1948). [b] Subcutaneous analgesic dose in the guinea pig in mg./kg. [c] For comparison the activity index for Amidone by the same pharmacological methods is 2.3, for Isoamidone 3.1 (Pfeiffer and co-workers). [d] No analgesia or toxicity found. [e] In this compound one phenyl ring has been reduced to cyclohexyl. [f] The product was obtained as an oil, b. p. 150–153° (1 mm.). [g] Inactive at 75 mg./kg.

**Acknowledgments.**—We wish to express our appreciation to Mr. R. M. Downing for the microanalyses recorded herein. We also wish to thank Dr. Carl Pfeiffer of the University of Illinois Medical School for permission to present the pharmacological data.

## Experimental

**Preparation of Substituted Acetonitriles.**—Diphenylacetonitrile was purchased commercially[10] while the intermediate dialkylaminoalkyl halides were prepared according to literature methods or minor modifications thereof.[2] Published procedures for the preparation of the dialkylaminoalkylacetonitriles[2] were used with the substitution in all cases of lithium amide[11] for sodium amide.

**2,2-Diphenyl-4-(N-morpholinyl)-valeronitrile and 2,2-Diphenyl-3-methyl-4-(N-morpholinyl)-butyronitrile.**—The mixed nitriles were obtained in 90% yield through the condensation of 1-(N-morpholinyl)-2-chloropropane[12] with diphenylacetonitrile. On standing the heavy oil partially crystallized. A portion of these crystals melted at 100–102° after two recrystallizations from ethanol.

*Anal.* Calcd. for $C_{21}H_{24}N_2O$: C, 78.75; H, 7.55. Found: C, 78.60; H, 7.03.

**Preparation of Ketones.**—The ketones were prepared through Grignard reactions on the nitriles or through hydrolysis of imines isolated from the Grignard reactions.[4,8]

**4,4-Diphenyl-6-(N-morpholinyl)-3-heptanone and 4,4-Diphenyl-5-methyl-6-(N-morpholinyl)-3-iminohexane.**—A solution of 320 g. (1.0 mole) of the isomeric nitriles, from the previous reaction, in 400 ml. of dry xylene was added to a solution of ethylmagnesium bromide prepared from 49 g. (2 g. atoms) of magnesium and 218 g. (2 moles) of ethyl bromide in 500 ml. of anhydrous ether. All operations were carried out under nitrogen in a three-necked flask using a mercury-seal stirrer. After the addition of the nitriles the mixture was refluxed for six hours. The green reaction mixture was then poured as rapidly as possible into a 4-liter beaker containing 1 liter of water and 500 ml. of concentrated hydrochloric acid. The hydrolysis was exceedingly vigorous and the ether and xylene were vaporized. When the mixture had cooled somewhat, 500 ml. of benzene was added whereupon three layers separated. In a few hours the heavy, red middle layer sank to the bottom and began to crystallize. After forty-eight hours the brown solid was filtered, and washed with ether; yield 300 g. (calcd. yield of one isomer 216 g.). After recrystallization from 1500 ml. of water, the product weighed 235 g. and after recrystallization from 2500 ml. of isopropanol 171 g.; m. p. 230–231°, yield of ketone I, 79.3%. Analysis established that the compound was the hydrobromide salt of the ketone.

The acid layer from the hydrolysis of the Grignard reaction was made basic and extracted with benzene. The extracts were dried over potassium carbonate and concentrated. The heavy oil which separated was dissolved in hot Skellysolve C; the cooled solution deposited crystals, m. p. 104–105°. From the nitrogen analysis and the rapid reaction of the material with acetyl chloride the compound was considered to be 6-morpholinyl-5-methyl-4,4-diphenyl-3-iminohexane, the imine of II.

*Anal.* Calcd. for $C_{23}H_{30}N_2O$: N, 7.99. Found: N, 8.03.

**Acetylation of 6-Morpholinyl-5-methyl-4,4-diphenyl-3-iminohexane.**—Five grams of the imine was dissolved in 50 ml. of benzene and 5 ml. of acetyl chloride added. After a few minutes the mixture began to deposit crystals. The crystals were filtered after three hours and recrystallized from ethyl acetate. The yield of 6-morpholinyl-5-methyl-4,4-diphenyl-3-acetyliminohexane hydrochloride was 4 g.; m. p. 223–224°.

*Anal.* Calcd. for $C_{25}H_{32}N_2O_2 \cdot HCl$: C, 69.95; H, 7.76. Found: C, 69.50; H, 7.90.

**Hydrolysis of 6-Morpholinyl-5-methyl-4,4-diphenyl-3-iminohexane.**—Two grams of the imine was refluxed for sixteen hours in 50 ml. of constant-boiling hydrochloric acid. The acid was distilled under reduced pressure and the residue made basic. The oil was extracted with ether and the ether solution dried and concentrated. The oily residue was dissolved in hot ethanol. The 6-morpholinyl-5-methyl-4,4-diphenyl-3-hexanone which separated from the cold solution melted at 139–140°.

*Anal.* Calcd. for $C_{23}H_{29}NO_2$: C, 78.58; H, 8.34. Found: C, 78.80; H, 7.90.

**Investigation of Mother Liquors from Ketone I Recrystallization.**—To obtain the ketone II present, the filtrates from the water recrystallization of I were made basic, and the heavy oil which separated dissolved in hot ethanol. The cooled solution deposited crystals which were recrystallized from Skellysolve C, m. p. 139–140°, undepressed with previously obtained ketone II. Additional amounts of ketone II were isolated from isopropyl alcohol recrystallization mother liquors of I. The mother liquors were concentrated, and the oily mixture of ketone and imine hydrolyzed with concentrated hydrochloric acid. The oil liberated through addition of alkali was extracted and distilled, after removal of solvent; b. p. 187–190° (1.6 mm.), m. p. 138–140°. The total yield of ketone II was 75 g. or 42%.

**γ-Dimethylamino-α,α-diphenylvaleric Acid.**—A mixture of 49.5 g. (0.178 mole) of 4-dimethylamino-2,2-diphenylvaleronitrile and 150 ml. of 70% sulfuric acid was heated at 150° for five hours, cooled and poured into water. The precipitated acid was filtered, dissolved in dilute alkali, and the filtered solution made slightly acidic. The precipitated acid was recrystallized from methyl isobutyl ketone and then from water; m. p. 200–201°.

**Carbinols.**—The following preparation illustrates the general method used for the catalytic reduction of the ketones.

Ten grams (0.03 mole) of Amidone hydrochloride was dissolved in 100 ml. of distilled water and 0.5 g. of Adams platinum oxide catalyst[13] added. The compound was then hydrogenated at room temperature under an initial hydrogen pressure of 55 pounds. After two hours the calculated amount of hydrogen was absorbed. The catalyst was filtered, the filtrate made basic and the oil was taken up into ether. The dried ether solution was saturated with dry hydrogen chloride and the oil which first separated soon crystallized. The precipitated material melted at 206–207°. Recrystallization from isopropyl alcohol or methyl isobutyl ketone gave well formed plates or prisms which melted at 195–196°. Prolonged drying at 100° under reduced pressure did not raise this value. The compound is evidently dimorphic.

*Anal.* Calcd. for $C_{21}H_{29}NO \cdot HCl$: N, 4.03. Found: N, 3.99.

**6-Dimethylamino-5-methyl-4,4-diphenyl-3-hexanol.**—This reaction illustrates the general method used for lithium aluminum hydride[14] reductions.[15] A solution of 18.5 g. (0.06 mole) of Isoamidone base in 300 ml. of ether was shaken for three hours with potassium hydroxide pellets to remove last traces of moisture. The dry solution was then added to a solution of 2.5 g. (0.067 mole) of lithium aluminum hydride in 300 ml. of anhydrous ether. The reaction was mildly exothermic, and the mixture refluxed gently. The mixture was refluxed for twelve hours, cooled in an ice-bath, and 200 ml. of 10% aqueous sodium hydroxide added dropwise. The ether layer was decanted and the aqueous layer extracted with ether. The combined ether solutions were washed with water and dried over potassium carbonate. After removal of the ether the oily residue crystal-

(15) Nystrom and Brown, THIS JOURNAL, **69**, 1197 (1947).

lized. The crude yield was quantitative. The solid was recrystallized from Skellysolve C and melted at 108–110°.

**6-Dimethylamino-4-cyclohexyl-4-phenyl-3-hexanol.**—Ten grams (0.03 mole) of Amidone was dissolved in 60 ml. of glacial acetic acid and 1 g. of platinum oxide catalyst added. This mixture was shaken at 50–60° with an initial hydrogen pressure of 55 lb. During a seventy-two-hour period, the amount of hydrogen absorbed was somewhat more than that calculated for the complete hydrogenation of one benzene ring and reduction of the ketone to the carbinol. At this stage addition of fresh catalyst caused no additional absorption of hydrogen. The catalyst was filtered, and the filtrate concentrated under reduced pressure. The residue was made basic and extracted into ether. The solvent was removed from the dried extract and the residue distilled; b. p. 150–153° (1 mm.). Although a crystalline phosphate was obtained, all other salts prepared were oils.

**6-Dimethylamino-4,4-diphenyl-3-acetoxyheptane Hydrochloride.**—A mixture of 19 g. (0.061 mole) of Amidone carbinol, 250 ml. of anhydrous ethyl acetate and 7.8 g. (0.100 mole) of acetyl chloride was refluxed for two hours, and then cooled in an ice-bath. The precipitated crystals were recrystallized from ethyl acetate; yield 21.5 g. (90%), m. p. 213–214°.

**6-Dimethylamino-4,4-diphenyl-3-(N-phenylcarbamyloxy)-heptane Hydrochloride**—Ten g. (0.033 mole) of Amidone carbinol was dissolved in ether and 6.7 g. (0.06 mole) of phenyl isocyanate added. After four hours a small quantity of diphenylurea had separated from the reaction mixture. The ether solution was decanted, and the diphenylurea recrystallized from ethanol; mixed m. p. 238–239°. The ether solution was extracted with 300 ml. of 4 *N* hydrochloric acid. After some time the crystalline hydrochloride separated from the extract, m. p. 150–151° after recrystallization from equal parts of methanol and hydrochloric acid.

## Summary

1. Data on a number of ketones related to Amidone are presented.

2. The reduction of the ketones with lithium aluminum hydride and by catalytic hydrogenation is described.

3. Esters, carbonates and carbamates prepared from the carbinols are presented.

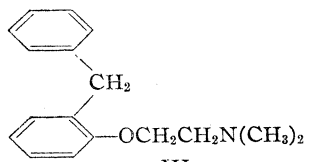
# Alkylaminoalkyl Ethers of the Benzylphenols

BY L. C. CHENEY, RICHARD R. SMITH AND S. B. BINKLEY



In 1937 Bovet and Staub reported that a series of phenol ethers synthesized by E. Fourneau exerted a protective action against histamine intoxication[1] and anaphylactic shock[2] in guinea pigs. This discovery initiated the ensuing numerous pharmacological investigations of synthetic compounds which have been admirably reviewed by Loew.[3] The more extensive work of Staub[4] suggested that in general the ortho-substituted phenol ethers manifested higher antihistaminic activity than their para and meta isomers. Although the thymol derivative 929F (I) was selected as the most promising compound of this class, toxicity and untoward side-effects militated against its clinical usefulness.

I

II

III

In 1945 Loew and his colleagues[5] announced their discovery of the potent antihistaminic action of benzohydryl β-dimethylaminoethyl ether (Benadryl) (II) synthesized by Rieveschl and Huber.[6]

Inasmuch as none of the Fourneau phenoxyethylamines investigated,[1,2,4] were substituted by a benzyl group, it was considered of interest to prepare 2-benzylphenyl β-dimethylaminoethyl ether (III) for pharmacological evaluation, especially since III is an isomer and vinylog of Benadryl (II). The present paper describes the preparation of II, its 4-isomer, certain homologs and salts thereof.

Pharmacological assays which will be reported elsewhere indicate that III (C-5581H) is to date more promising medicinally than any of the tabulated homologs. Its water-soluble hydrochloride is relatively non-toxic and it elicits a high order of antihistaminic and local anesthetic activity in animals. Clinical tests are in progress.

With the exception of the two hydrogenated derivatives (489-1 and 489-2), all of the com-

pounds in Table I were prepared by two general procedures. Method A consisted in condensing sodium benzylphenate with the appropriate aminoalkyl chloride. It is of interest that method A gave a low yield of 518-14 owing to the formation of considerable quantities of low-boiling material which was not investigated. Consequently method B, wherein an ω-bromoalkyl ether of a benzylphenol is caused to react with a particular amine, proved to be the procedure of choice for the synthesis of an ether bearing a secondary amino group.

Because of the marked tendency of the free dialkylaminoalkyl chlorides to polymerize when heated in the presence of polar solvents, the method developed by Dalgliesh[7] for the synthesis of 929F (I) proved less satisfactory than the use of toluene as a solvent. For the same reason sodium or sodium hydride was selected instead of sodium alkoxides for preparing the sodium salts of the phenols. A nitrogen atmosphere guarded against oxidation.

## Experimental[8]

**The Benzylphenols.**—Pure 2-benzylphenol required for this series was first prepared by the method of Claisen[9] in yields ranging from 25 to 35%, a procedure advantageous in the sense that practically none of the 4-isomer is produced. The residues did contain, however, appreciable amounts of the strongly cryptophenolic 2,6-dibenzylphenol,[9,10] which served for the preparation of compound 489-27 (Table I). When larger quantities of 2-benzylphenol were required it proved advantageous to separate the isomeric benzylphenols in commercially available "Santophen 7"[11] by utilizing the marked difference in the water solubility of their barium salts. The procedure is based on a Bayer patent.[12] Another patented method of separating the isomers was not thoroughly investigated. It takes advantage of the remarkably high solubility of the alkali salts of 2-benzylphenol in an inert, non-aqueous organic solvent such as xylene.[13]

**Separation of 2-Benzylphenol from 4-Benzylphenol in "Santophen 7."**[11,12]—To a boiling solution of 1950 g. of technical grade barium hydroxide octahydrate in 7.5 liters of water contained in a 12-l. round-bottom flask was added 1500 g. of molten "Santophen 7." The mixture was boiled for ten to twelve minutes and then cooled to 10–12°. The insoluble barium 4-benzylphenate was collected in a large Büchner funnel and sucked as dry as possible by the use of a rubber dam. The cake was broken up and digested with occasional stirring on the steam-bath for at least two hours with sufficient 6 *N* hydrochloric acid (*ca.* 1300 ml.) to render the medium strongly acidic (*p*H 2). Crude 4-benzylphenol, m. p. 81–84°, crystallized on cooling and stirring. One crystallization from carbon tetrachloride afforded pure 4-benzylphenol, m. p. 84°.

The original filtrate containing the soluble barium 2-benzylphenate was promptly acidified to *p*H 2 (to avoid the formation of purple oxidation products) with about 650 ml. of concentrated hydrochloric acid while cooling and stirring the mixture. It was found expedient to seed the oily product to induce crystallization. When the temperature sank below 8°, the light-brown crystals were collected by suction and dissolved in two liters of hot benzene. The solution was then transferred to a separatory funnel, the water was withdrawn and the benzene layer was washed with two 500-ml. portions of water for the removal of residual inorganic salt. Azeotropic distillation of the water and benzene was then continued until approximately 375 ml. of benzene remained in the flask, whereupon the warm benzene solution was poured into 1500 ml. of petroleum ether (b. p. 77–115°). Cooling and filtration yielded 582 to 654 g. of practically colorless 2-benzylphenol, m. p. 51.5–53°.

**The Dialkylaminoalkyl Chlorides.**—Treatment of the commercially available amino alcohols with thionyl chloride in benzene solution[14] afforded practically quantitative yields of the corresponding chloride hydrochlorides. In general the free bases were not distilled, but rather prepared from a 20 or 30% excess of the salt shortly before use. Dry toluene solutions of the bases appear to be quite stable at room temperature. The Amidone intermediates, 1-dimethylamino-2-propanol and 1-dimethylamino-2-chloropropane, required for 338-19A and B were prepared satisfactorily as originally described[15]; also the I. G. Farbenindustrie procedures[16] for the preparation of β-1-piperidylethyl chloride and the corresponding alcohol produced excellent results.

β-Cyclohexylaminoethyl chloride hydrochloride, m. p. 219–219.5°, an intermediate for 518-14, was prepared in 97.5% yield by Dr. W. B. Wheatley from N-cyclohexylethanolamine.[17] *Anal.* Calcd. for $C_8H_{17}NCl_2$: C, 48.5; H, 8.7; N, 7.1. Found: C, 48.7; H, 8.7; N, 7.0.

**Method A. 2-Benzylphenyl β-Dimethylaminoethyl Ether (C-5581H) (III) Hydrochloride.**—Twelve hundred and ten grams (8.4 moles) of β-dimethylaminoethyl chloride hydrochloride[14] was covered with 1 liter of toluene and cooled in an ice-bath. Into the well-stirred suspension was slowly added a cold solution of 400 g. (10 moles) of sodium hydroxide dissolved in 400 ml. of water. The toluene solution of the base was decanted and the aqueous mixture was extracted further by decantation with 1 liter of toluene divided into five portions. (In the event an emulsion forms at this point, the addition of a relatively large quantity of anhydrous potassium carbonate permits filtration.) The combined extracts were dried overnight (or at least two hours on the mechanical shaker) over anhydrous potassium carbonate. Into a twelve-liter three-neck flask equipped with a sealed stirrer, dropping funnel and reflux condenser were placed 1 liter of dry toluene and 138 g. (6.0 moles) of sodium, and a dry nitrogen atmosphere was provided. A Glas-Col heating mantle was utilized to heat the toluene to boiling. When the sodium had melted the stirrer was started and a solution of 1159 g. (6.3 moles) of 2-benzylphenol (dried over phosphorus pentoxide) in 2360 ml. of dry toluene was added *via* dropping funnel at such a rate as to maintain vigorous boiling without external heating. After the addition was complete the mixture was refluxed and stirred until all of the sodium had dissolved. The previously prepared toluene solution of β-dimethylaminoethyl chloride was then added rapidly through the dropping funnel and the stirred mixture was boiled under reflux for seventeen hours. Steam distillation then served to remove the toluene and to volatilize or polymerize excess β-dimethylaminoethyl chloride. The oily product was extracted from the cooled aqueous phase with approximately 3 liters of ether. Combined ether extracts were washed with 20% sodium hydroxide solution, then with a saturated solution of sodium chloride and dried over anhydrous potassium carbonate. Distillation of the product through a twelve-inch Vigreux column afforded 1444 g. (94.3%

[a] Yield of pure hydrochloride. [b] The structure of the selective hydrogenation product was not established. [c] Geometrical isomers were not isolated. [d] The low yield is ascribed to the escape of methylamine from the pressure bottle.

yield based on the sodium) of colorless oil, b. p. 141–144° at less than 1 mm.

The hydrochloride was precipitated quantitatively from ether solution by means of commercial hydrogen chloride. Recrystallization from methyl isobutyl ketone produced 1457 g. (88.3% yield) of colorless crystals, m. p. 119–120°.

**Method B. 2-Benzylphenyl β-Isopropylaminoethyl Ether Hydrochloride (489-9).**—Under an atmosphere of dry nitrogen a solution of 193.4 g. (1.05 moles) of 2-benzylphenol in 200 ml. of dry toluene was added dropwise to a stirred, boiling suspension of 24.0 g. (1.0 mole) of sodium hydride (du Pont) in 100 ml. of dry toluene. After all of the sodium hydride had reacted, 563.6 g. (3 moles) of ethylene bromide was added and the mixture was refluxed for sixty hours. The reaction product, which was still strongly alkaline, was washed successively with water, 20% sodium hydroxide solution, saturated salt solution and then dried over anhydrous magnesium sulfate. After nearly all of the toluene had been distilled under reduced pressure the product crystallized. Recrystallization from isopropyl alcohol produced 142.4 g. (48.8% yield) of crude 2-benzylphenyl β-bromoethyl ether, m. p. 82–85°, which contained a high carbon impurity.

*Anal.* Calcd. for $C_{15}H_{15}BrO$: C, 62.0; H, 5.20. Found: C, 64.4; H, 5.23.

Into a well-cooled solution of 56.3 g. (0.193 mole) of the above crude bromo ether in 80 ml. of dioxane contained in a pressure bottle was slowly poured 34.2 g. (0.58 mole) of isopropylamine. The bottle was sealed and heated in the steam cone overnight (seventeen hours). The light yellow solid which remained after removal of the solvent and excess isopropylamine under reduced pressure was treated with an excess of sodium hydroxide and the liberated base was taken up in ether. Upon shaking the ether extract with 6 *N* hydrochloric acid, the hydrochloride precipitated. After recrystallization from water 47.7 g. (81.2% yield based on the crude bromoethyl ether) of white crystals, m. p. 174–175°, were obtained.

Crude 2-benzylphenyl γ-bromopropyl ether, m. p. 137–163°, was prepared in a 60% yield by the method described for the above β-bromoethyl homolog. For those syntheses involving amines boiling above 100° the use of a pressure bottle was not required. The bromo ether was refluxed overnight with a large excess of the appropriate amine.

**2-Benzylphenyl β-Dimethylaminoisopropyl Ether (339-19A) and 2-Benzylphenyl β-Dimethylaminopropyl Ether (338-19B).**—To a solution of sodium methoxide prepared from 6.9 g. (0.3 mole) of sodium and 117 ml. of absolute methanol was added 55.2 g. (0.3 mole) of 2-benzylphenol. Following removal of excess methanol under reduced pressure, the sodium 2-benzylphenate was dissolved in 180 ml. of dry toluene and refluxed with a large excess (59.5 g.) of freshly distilled 1-dimethylamino-2-chloropropane[15] under an atmosphere of nitrogen for five and one-half hours. The basic material was extracted with dilute hydrochloric acid. Combined acid extracts were made strongly basic with alkali and extracted with ether. The ether solution was washed thoroughly with water, dried over potassium carbonate and distilled through a twelve-inch Vigreux column to obtain two fractions: $F_1$, b. p. 148–152°, (27.5 g.) and $F_2$, b. p. 152.5–157°, (19.4 g.) at less than 1 mm. Both fractions were dissolved in ether and precipitated with dry hydrogen chloride. $F_1$ yielded 33.5 g. of hydrochloride, m. p. 80–132°, which afforded 7.4 g. of product, m. p. 168–169°, on recrystallization from acetone. The hydrochloride from $F_2$ weighed 23.5 g. and melted at 73–84°. Treatment with hot acetone produced 5.4 g. of material, m. p. 161–164°. On boiling the two fractions with a large volume of acetone 10.4 g. of the less soluble isomer, m. p. 170–171.5°, was obtained in pure form. The acetone mother liquors were concentrated to dryness and the gummy residue (29.6 g.) was recrystallized twice from ethyl acetate to obtain 23.0 g. of the lower melting isomer, m. p. 75–80°. The structures of these anticipated isomers derived from the halide utilized in the original synthesis of Amidone[15] have been assigned by analogy with the physical properties of Amidone and Isoamidone.[18]

**2-Cyclohexylmethylcyclohexyl β-Dimethylaminoethyl Ether (489-1) Hydrochloride.**—Twenty-five and five-tenths grams (0.10 mole) of 2-benzylphenyl β-dimethylaminoethyl ether was dissolved in 100 ml. of glacial acetic acid. One gram of Adams platinum catalyst and 6 ml. of concentrated sulfuric acid were added and the compound was hydrogenated under a gage pressure of 50 lb. of hydrogen and a temperature of 60° until 0.6 mole of hydrogen was taken up. The catalyst was filtered off and the filtrate was allowed to stand until a duplicate preparation was carried out. After removing the acetic acid from the combined filtrates under reduced pressure, the residue was taken up in 150 ml. of water, made alkaline with 20% sodium hydroxide solution, and extracted into ether. The

(18) For pertinent references see Cheney, Smith and Binkley, THIS JOURNAL, **71**, 53 (1949).

ether solution was washed with water and then dried over anhydrous potassium carbonate. The hydrochloride was precipitated with dry hydrogen chloride to obtain 7.1 g. of product, m. p. 128–129°, which afforded 6.6 g. of material which melted at 128.5–129° after recrystallization from ethyl acetate. On concentrating the ether solution and recrystallizing the residue from ethyl acetate 4.9 g. of additional material was obtained. The over-all yield therefore was 31.5%.

**Hexahydro-2-benzylphenyl β-Dimethylaminoethyl Ether (489-2) Hydrochloride.**—The same quantities and procedure were used as described for 489-1 with the exception that the hydrogenation was interrupted when only one-half as much hydrogen had been taken up. From the partial reduction of 51 g. (0.2 mole) of C-5581H there was obtained 41.9 g. of material melting over the range 117–150°. Two recrystallizations from acetone led to the isolation of 15.3 g. (25.7% yield) of white crystals melting at 169–170°.

**Acknowledgment.**—The authors wish to thank Mr. Richard M. Downing for the microanalyses and the assistance of Messrs. L. E. Lorensen and H. J. Reiche and Dr. W. B. Wheatley is gratefully acknowledged.

## Summary

1. The preparation of 2-benzylphenol and 4-benzylphenol is described.

2. Twenty dialkylaminoalkyl ethers of the benzylphenols and their hydrochlorides are reported.

3. 2-Benzylphenyl β-dimethylaminoethyl ether hydrochloride manifests potent antihistaminic and local anesthetic activity.

SYRACUSE, NEW YORK RECEIVED JULY 28, 1948

# β-Dimethylaminoethyl Ethers of Substituted 2-Benzylphenols

BY W. B. WHEATLEY, L. C. CHENEY AND S. B. BINKLEY

It has been observed that 2-benzylphenyl β-dimethylaminoethyl ether hydrochloride (I) possesses greater antihistaminic activity when tested

I

II

in guinea pigs than Benadryl (II).[1] Therefore the synthesis of β-dimethylaminoethyl ethers of various substituted 2-benzylphenols was undertaken in order to ascertain whether substitution enhances the antihistaminic activity of the parent compound. In this paper is described a number of new basic ethers related to I, all incorporating the β-dimethylaminoethyl group, but with substitutions in the 2-benzylphenyl portion of the molecule.

In general the basic ethers were prepared by heating together the substituted sodium 2-benzylphenolate and β-dimethylaminoethyl chloride in an inert solvent such as toluene. The products were isolated by standard procedures and converted to the hydrochlorides by saturation of the ether solution of the amines with dry hydrogen chloride. These hydrochlorides are white crystalline compounds, most of which are quite soluble in water.

A survey of the literature reveals that 2-benzylphenol may be prepared in a number of ways. Phenol may be condensed with benzyl chloride alone[2] or with either benzyl chloride or the alcohol in the presence of a variety of catalysts[3] to yield a mixture of 2- and 4-benzylphenols together with traces of benzyl phenyl ether. On the other hand, the use of sodium phenolate and benzyl chloride yields the 2-isomer almost exclusively.[4] A considerable amount of ether is formed, but it can be removed easily by extraction, whereas the separation of 2- and 4-benzylphenols requires more involved procedures.[2,5] For this reason, the method of Claisen, *et al.*,[4] was used to prepare the intermediate substituted 2-benzylphenols (see Table I). Several of those prepared from sodium phenolate and a substituted benzyl chloride were treated with barium hydroxide[5a] in order to insure complete removal of the 4-isomer, but as the amount of 4-isomers appeared to be negligible, this treatment was omitted in later preparations. Sodium hydride, which has recently become available commercially, was employed exclusively to prepare the sodium phenolates, both in the Claisen reaction and in the Williamson ether synthesis. It was found that in the quantities used in the laboratory, sodium hydride is more conveniently handled than sodium, and reacts rapidly and completely with phenolic compounds.

[a] The yields in the table represent the once-distilled products, which were treated as described in the experimental reaction to remove any 4-isomer which may have been present. [b] Recrystallized from cyclohexane. [c] Recrystallized from benzene–Skellysolve B.

**Pharmacology.**—Preliminary pharmacological data indicate that none of the compounds herein reported is as active against histamine-induced spasm in guinea pigs as I. A more complete report of the pharmacology of these compounds will be published elsewhere.

## Experimental[6]

**Preparation of Substituted 2-Benzylphenols.**—In a typical experiment, a solution of 138 g. (1.0 mole) of *p*-ethoxyphenol in 250 cc. of warm toluene was added gradually to a stirred suspension of 24 g. (1.0 mole) of sodium hydride in 150 cc. of toluene, under a nitrogen atmosphere. To the resulting suspension, stirred and maintained at gentle reflux, was added dropwise 140 g. (1.1 moles) of benzyl chloride. After five hours of vigorous refluxing, the reaction mixture was cooled and hydrolyzed with dilute hydrochloric acid. The aqueous layer was discarded and the toluene layer washed in turn with water and saturated sodium bicarbonate solution. The toluene solution was then extracted several times with Claisen alkali; the basic extracts acidified with hydrochloric acid and the liberated phenolic material taken up in ether. Evaporation of the ether left an oil which was distilled *in vacuo*, giving a forerun of recovered *p*-ethoxyphenol, followed by 95.8 g. (42%) of 4-ethoxy-2-benzylphenol, a light yellow oil boiling at 165–167° (1 mm.). In an alternative method of working up the reaction, the toluene solution obtained following hydrolysis was stripped of solvent and the residue taken up in approximately four times its volume of Claisen alkali. The neutral material was removed by extraction with Skellysolve C; acidification of the basic solution gave the phenolic fraction, which was extracted and distilled as described above.

Compounds III–VI, X and XI (Table I) were used in the next step without further purification while VII, VIII and IX were treated with barium hydroxide as described below. In order to separate a mixture of 2- and 4-benzylphenols, one mole of the mixture is dissolved in a boiling solution of 0.75 mole of barium hydroxide octahydrate in 900 cc. of water, boiled ten minutes, then cooled and filtered.[5a] Acidification of the filtrate gives the 2-isomer, which may be distilled or recrystallized. It was found that with substituted 2-benzylphenols, the separation of the insoluble barium salt is best carried out at different temperatures, depending on the particular compound. The temperatures at which the separations were done are as follows: VIII, 50°; IX, 10°. The solution of barium salt of VII formed two layers at 80°; the small lower layer was removed and acidified to give the 2-isomer.

Those compounds with substituents in the phenol ring were prepared from the substituted sodium phenolate and benzyl chloride; the others from sodium phenolate and the substituted benzyl chloride (α-bromoethylbenzene was used to synthesize X). In addition to those phenols listed in Table I, there was prepared a number of other substituted 2-benzylphenols, which have been described in the literature: 2-benzyl-4-cresol,[4] 2-benzohydrylphenol,[4] 2-benzoylphenol,[7] 2-(4′-bromobenzyl)-phenol,[8] 4-chloro-2-benzylphenol,[9] 6-chloro-2-benzylphenol,[9] 4-chloro-2-(4′-chlorobenzyl)-phenol,[9] 4,6-dichloro-2-benzylphenol[10] and 2-(2′,3′ and 4′-chlorobenzyl)-phenols.[2]

In one case it was shown that an increase in reaction temperature increased the yield of benzylated phenol. The reaction of 4-chlorobenzyl chloride with sodium phenolate in toluene gave the desired 2-(4′-chlorobenzyl)-phenol in 29% yield; in xylene, 40% yield.

**Preparation of Substituted 2-Benzylphenyl β-Dimethylaminoethyl Ethers.**—The following is a typical example. To a well-stirred, ice-cold suspension of 37 g. (0.26 mole) of β-dimethylaminoethyl chloride hydrochloride[11] in 50 cc. of toluene were added slowly 30 cc. of a 56% potassium hydroxide solution; the mixture was stirred for about fifteen minutes, then the toluene layer decanted. The aqueous sludge was stirred with two successive 50-cc. of portions of toluene and the combined toluene decantates dried by shaking over anhydrous potassium carbonate for four hours. To a suspension of 4.8 g. (0.2 mole) of sodium hydride in 200 cc. of toluene, under a nitrogen atmosphere, was added gradually a solution of 39.6 g. (0.2 mole) of 2-benzyl-4-cresol in 100 cc. of toluene. After completion of the addition, the mixture was refluxed for thirty minutes. To the resulting clear yellow solution, maintained at gentle reflux, was added dropwise the above-described toluene solution of β-dimethylaminoethyl chloride. Precipitation of sodium chloride began almost immediately. After seven hours of refluxing, the mixture was cooled and water added. The toluene layer was washed with 10% potassium hydroxide solution, dried, stripped and the residue distilled *in vacuo*, giving 47.8 g. (89% yield) of 2-benzyl-4-tolyl β-dimethylaminoethyl ether, b. p. 168–174° (3 mm.). The basic ether was converted to its hydrochloride by saturating an ice-cold ether solution of the amine with dry hydrogen chloride. The insoluble hydrochloride was collected by filtration, and recrystallized from isopropyl alcohol–Skellysolve B.

Since crystalline hydrochlorides of 518–19 and 551–43 (Table II) could not be obtained readily, the basic ethers were dissolved in cold 95% ethanol and ethyl acetate, respectively, and the calculated amount of concentrated nitric acid added. Dilution with ether caused precipitation of the crystalline nitrates, which were collected and recrystallized.

[g] A double melting point was observed, the lower at 141.0–143.0°. The lower melting form was converted to the higher by fusion and seeding with a crystal of the higher melting form. [h] Melting point, formula and analysis of the nitrate.

**2-(α-Hydroxybenzyl)-phenyl β-Dimethylaminoethyl Ether Hydrochloride.**—Twenty grams (0.075 mole) of the hydrochloride of 490-12 was dissolved in 100 cc. of absolute ethanol and hydrogenated over Adams platinum oxide catalyst at three atmospheres pressure. After 2.75 hours, the theoretical amount of hydrogen had been absorbed. The catalyst was removed by filtration, the filtrate diluted with ether and the precipitated amine salt (14.0 g., 70% yield) recrystallized from a mixture of isopropyl alcohol and methyl isobutyl ketone.

**Acknowledgment.**—Dr. E. C. Horning of the University of Pennsylvania kindly supplied samples of *p*-isopropylbenzyl chloride and 2,3-dimethoxybenzyl alcohol. Microanalyses were performed by Mr. Richard M. Downing. Mr. William E. Fitzgibbon carried out certain reactions reported herein.

## Summary

1. The synthesis of a number of new substituted 2-benzylphenols is reported.

2. The synthesis of a series of β-dimethylaminoethyl ethers of substituted 2-benzylphenols is reported.

3. Preliminary pharmacological data indicate that some of these basic ether hydrochlorides prevent histamine-induced asthma in guinea pigs.

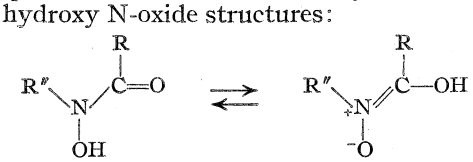
# Analogs of Aspergillic Acid. I. The Tautomerism of the Hydroxypyridine-N-oxides[1]

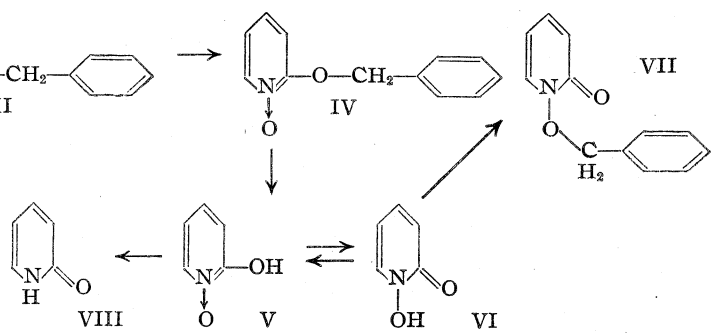
BY ELLIOTT SHAW

A structural study of aspergillic acid, an antibiotic produced by the mold, *Aspergillus flavus*,[2] led to the conclusion[3] that the substance is a 1-hydroxy-3,6-dialkyl-2-pyrazone (I). The acidic properties are thus attributable to a cyclic hydroxamic grouping. Like the more familiar acyclic hydroxamic acids, aspergillic acid can be reduced



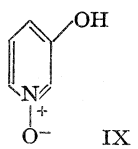
I

II



by chemical agents with loss of one oxygen atom to a neutral substance (II) which no longer gives a deep red color with ferric chloride and does not form a copper salt. Of considerable importance is the fact that this change is also accompanied by loss of antibacterial properties. The hydroxamic acid grouping, therefore, seems to be an essential feature of the molecule for biological activity, a conclusion supported by the observation that certain simpler hydroxamic acids not related to pyrazine derivatives also inhibit bacterial growth.[4]

This novel occurrence of a hydroxamic acid grouping in a natural product, together with the possibility of developing synthetically a new series of antibacterial agents, led us to undertake the preparation of cyclic hydroxamic acids. The only examples of this type encountered in the literature are a few N-hydroxy-2-quinolones obtained by a synthesis of quite limited application, *i. e.*, partial reduction of ethyl *o*-nitrocinnamates with cyclization taking place at the *o*-hydroxylamino ester stage.[5,6] It seemed likely that more general methods of preparation might be developed by a study of a postulated tautomerism of hydroxamic acid and hydroxy N-oxide structures:



The existence of such a tetrad system has been indicated[7] in the case of N-hydroxyphthalimidine by the formation of the isomeric O-ethers.

The pyridine series was chosen for the initial studies because of the accessibility of intermediates. 2-Benzyloxypyridine (III) was prepared and, by means of perbenzoic acid, converted to its N-oxide (IV), an ether of tautomeric structure (V). The oxide dissolves in aqueous hydrochloric acid with rapid separation of benzyl chloride, and a crystalline acid, $pK = 5.9$, corresponding to (V) or (VI) can be isolated from the solution. The acid forms a copper salt and gives a deep red color with ferric chloride—characteristic, classic properties of hydroxamic acid. However, similar behavior could be expected of the tautomeric hydroxypyridine N-oxide (V) in which the positively charged nitrogen in the amine oxide semi-polar bond would facilitate ionization by an inductive effect. For example, 3-hydroxypyridine N-oxide (IX) was prepared and found to be quite acidic, $pK = 6.4$ compared to $pK = 8.6$ for 3-hydroxypyridine itself. For this isomer, no tautomeric structure comparable to a hydroxamic acid (as in VI) can be formulated.

III IV V VI VII VIII

IX

However, in the 2-pyridyl series it is necessary to conclude from the spectroscopic data described below that the acid obtained on debenzylation of the amine oxide (IV) is not the corresponding hydroxyoxide (V) but a hydroxamic acid (VI). The tautomeric system involved was defined chemically by the preparation of the benzyl ethers corresponding to both forms, (IV) and (VII), and by their conversion on reductive debenzylation to a single acid m. p. 150° (VI).

The N-benzyloxy ether (VII) was formed as the only non-acidic product when the sodium

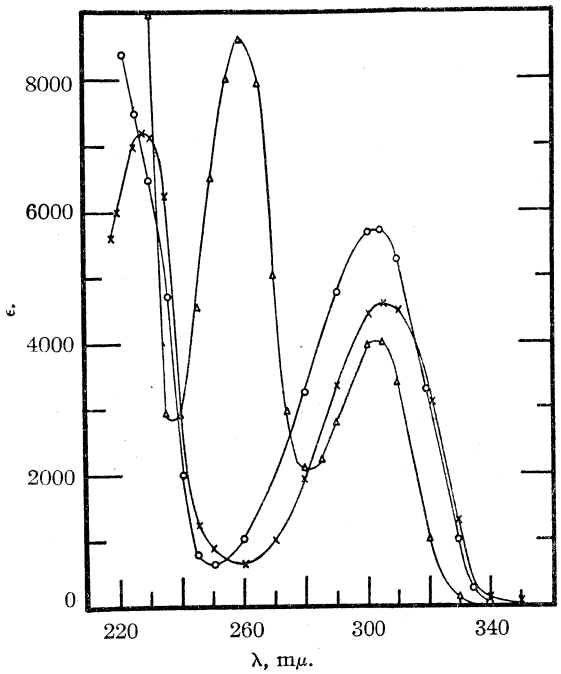

Fig. 1.—Ultraviolet absorption spectra in ethanol: -Δ-Δ-Δ-, 2-benzyloxypyridine N-oxide; -X-X-X, N-hydroxy-2-pyridone; -O-O-O-, N-benzyloxy-2-pyridone.

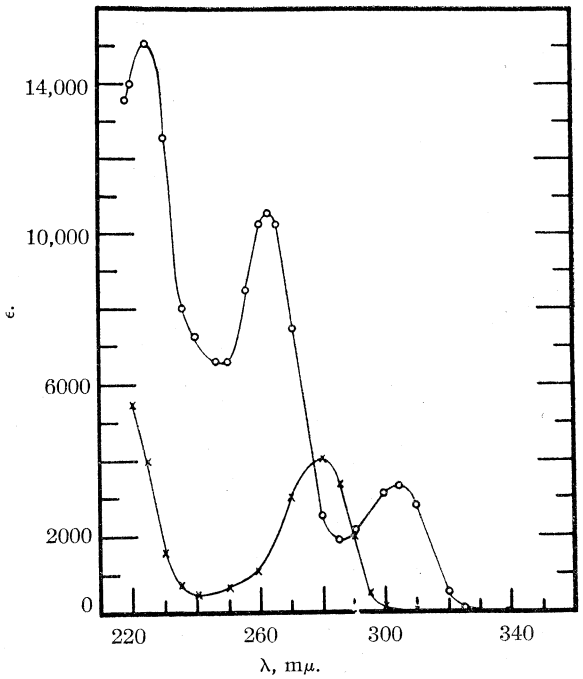

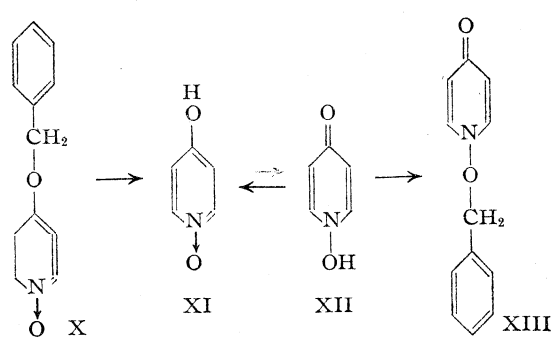

Fig. 2.—Ultraviolet absorption spectra in ethanol: -X-X-X, 3-hydroxypyridine; -O-O-O-, 3-hydroxypyridine N-oxide.

salt of the acid m. p. 150° was treated with benzyl chloride. This ether differs from its isomer (IV) not only in lack of basicity, but also in its resistance to hot, aqueous hydrochloric acid. That it is the more stable isomer is indicated by its isolation, in small quantities, from the hydrochloric acid debenzylation of (IV) apparently due to an isomerization of (IV) to (VII).

In the ultraviolet region, the spectra of the acids (V–VI) in ethanol shows two maxima ($\lambda$ = 228 m$\mu$, $\epsilon$ = 7,200 and $\lambda$ = 305 m$\mu$, $\epsilon$ = 4,600) corresponding rather well to those in the spectrum of 2-pyridone ($\lambda$ = 227 m$\mu$, $\epsilon$ = 7,300 and $\lambda$ = 300 m$\mu$, $\epsilon$ = 5,000). 2-Pyridone is itself considered[8,9] to be in the amide rather than in the hydroxypyridine form, preferably expressed[9] as a dipolar modification. Additional evidence in favor of a hydroxamic acid structure (VI) for the acid is found in a comparison of its spectrum with those of the benzyl ethers of the tautomeric forms shown in Fig. 1. The absorption characteristics for the acid differ markedly from those of the amine oxide (IV) and are in better agreement with the spectrum of the N-benzyloxy isomer (VII). The maximum at 260 m$\mu$ for 2-benzyloxypyridine N-oxide (Fig. 1) is apparently related to the N-oxide configuration. A similar peak is found in the spectrum of 3-hydroxypyridine N-oxide (Fig. 2) at 263 m$\mu$, both substances in ethanol. Further, pyridine N-oxide, measured conveniently in water by neutralizing the hydrochloride prepared by the method of Meisenheimer[10] absorbs mainly at 255 m$\mu$, $\epsilon$ = 9,000; when measured also in water, the spectrum of 3-hydroxypyridine N-oxide shows a shift of the maximum at 263 m$\mu$ (ethanol) to 255 m$\mu$ and, like pyridine N-oxide, exhibits diminishing intensity, as the *p*H drops from 5 to 1, without a change in the wave length of the maximum. Specific absorption in this region is significantly absent from the spectrum in water or ethanol of the acid m. p. 150°, on observation in agreement with the assignment of a hydroxamic acid (VI) rather than a pyridine oxide structure (V) to the substance.

To complete the study of the isomeric hydroxypyridine N-oxides, the 4-pyridyl analog was prepared. As in the 2-pyridyl series, tautomerism with a hydroxamic acid structure was anticipated (XI–XII). 4-Benzyloxypyridine was converted to the N-oxide (X) which, when reduced cata-

(8) Specker and Gawrosch, *Ber.*, **75**, 1345 (1942).

lytically, gave an acid m. p. 238–240°, $pK = 5.9$. A new benzyl ether, undoubtedly XIII was obtained from the sodium salt of the acid on treatment with benzyl chloride. A comparison of the ultraviolet absorption spectra of the acid (XI–XII) and the isomeric benzyl ethers offers no information as to the state of the tautomerism since all three substances show maximum absorption in the same region, 268–270 mμ (Fig. 3).[11]

Of the three isomeric pyridine acids described, only N-hydroxy-2-pyridone has significant antibacterial activity.

## Experimental[12]

**2-Benzyloxypyridine N-Oxide (IV).**—2-Benzyloxypyridine (37 g.) was added to a chloroform solution of perbenzoic acid (1.5 equivalents) and the mixture left standing at room temperature in a loosely stoppered flask. After three days the solution was washed successively with aqueous sodium carbonate and water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The crystalline residue was thinned with a mixture of ethyl acetate and hexane for filtration, yielding 18 g. (45%) of product m. p. 99–102°. This material was satisfactory for the next step. An analytical sample was obtained by recrystallization from ethyl acetate and hexane and melted at 103–106°.

*Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.96. Found: C, 71.66; H, 5.74; N, 6.88.

**N-Hydroxy-2-pyridone (VI).**—(A) By hydrochloric acid debenzylation: 2-Benzyloxypyridine N-oxide (4.3 g.) was boiled for ten minutes with 15 ml. of 20% hydrochloric acid under a reflux condenser provided with a take-off to remove benzyl chloride. The turbid solution was then taken to dryness *in vacuo* and recrystallized from benzene containing a small amount of methanol. There was obtained 1.6 g. (68%) of product melting at 145–147°. A recrystallization from ethyl acetate brought the m. p. to 149–150°.

*Anal.* Calcd. for $C_5H_5O_2N$: C, 54.05; H, 4.54; N, 12.61. Found: C, 53.94; H, 4.62; N, 12.55.

N-Hydroxy-2-pyridone gives a deep red color with ferric chloride in alcohol solution or a precipitate in aqueous solution. The copper salt melts at 298° (dec.).

*Anal.* Calcd. for $(C_5H_4O_2N)_2Cu$: N, 9.87. Found: N, 9.73.

From the mother liquor in the above debenzylation a small neutral fraction was obtained by combining the benzene and ethyl acetate filtrates, extracting acidic material with aqueous alkali, and concentrating the organic layer. Colorless crystals were obtained, m. p. 83–84°, isomeric with the starting material.

*Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.96. Found: C, 71.56; H, 5.60; N, 6.97.

(B) By catalytic reduction: 2-Benzyloxypyridine N-oxide (25 g.) was shaken in 100 ml. of ethanol with 750 mg. of palladium catalyst (5% on charcoal) at an initial pressure of 50 lb. of hydrogen. The reduction was complete in about five minutes. Concentration of the filtered solution gave 9.5 g. (69%) of N-hydroxy-2-pyridone, m. p. 150°.

**N-Benzyloxy-2-pyridone (VII).**—N-Hydroxy-2-pyridone (3.25 g.) was added to a solution of sodium (0.75 g.) in 45 ml. of ethanol. The resultant suspension of sodium salt was refluxed with benzyl chloride (4.18 g.) for three hours. The filtrate was concentrated to a small volume, taken up in chloroform, and washed with dilute sodium hydroxide solution to remove unreacted starting acid. The dried organic layer on evaporation left a crystalline neutral residue of 3.8 g. (70%) melting at 85–86°. The melting point was unchanged by recrystallization from ethyl acetate and hexane. This material is identical with that obtained from the mother liquors of the hydrochloric acid debenzylation of 2-benzyloxypyridine N-oxide as described above.

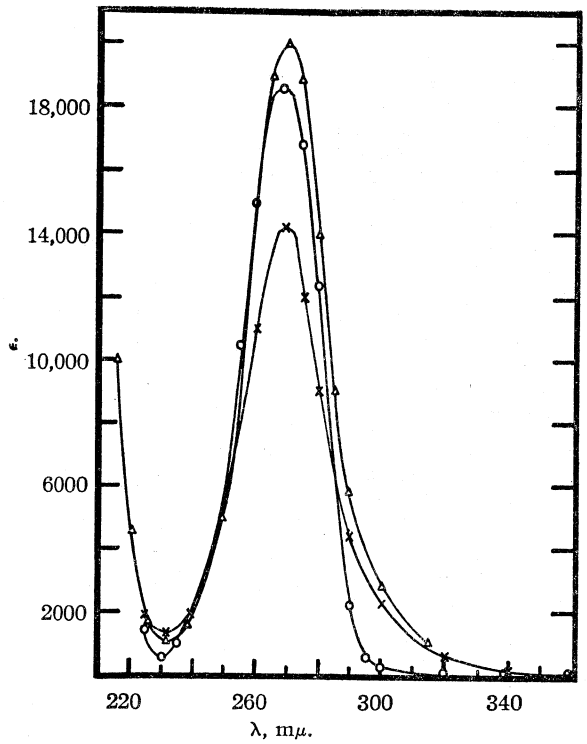

Fig. 3.—Ultraviolet absorption spectra in ethanol: -Δ-Δ-Δ-, 4-benzyloxypyridine N-oxide; X-X-X, N-hydroxy-γ-pyridone or tautomer; -O-O-O, N-benzyloxy-γ-pyridone.

**Reduction of N-Hydroxy-2-pyridone to 2-Pyridone.**—Red phosphorus (1 g.) and iodine (0.5 g.) were left standing for ten minutes in 25 ml. of glacial acetic acid. N-Hydroxy-2-pyridone (2 g.) in 30 ml. of glacial acetic acid was added and the solution refluxed for two and one-half hours. The reaction was worked up although the reduction was not yet complete judging by the persistence of a ferric chloride color test. The filtrate was taken to dryness and the residue extracted with boiling ethyl acetate. The addition of picric acid (5.5 g. in 50 ml. of alcohol) precipitated 2.5 g. of picrate (43%) identical with the picrate prepared from an authentic sample of 2-pyridone and melting at 170–172°.

*Anal.* Calcd. for $C_{11}H_8O_8N_4$: C, 40.75: H, 2.49; N, 17.28. Found: C, 40.75; H, 2.60; N, 17.31.

**3-Hydroxypyridine N-Oxide (IX).**—3-Hydroxypyridine oxidized quite readily with perbenzoic acid (1.5 equivalents in chloroform), the product crystallizing out overnight, m. p. 188–190°, (65%). Recrystallization from methanol raised the m. p. slightly to 189–191°.

*Anal.* Calcd. for $C_5H_5O_2N$: C, 54.05; H, 4.54; N, 12.61. Found: C, 53.93; H, 4.68; N, 12.54.

**4-Benzyloxypyridine.**—4-Pyridylpyridinium dichloride[13] (65 g.) was dissolved in 150 ml. of hot benzyl alcohol and added to a solution of sodium (13 g.) in 250 ml. of benzyl alcohol. The suspension was refluxed for four hours, poured into water, and extracted with ether. Fractionation of the residue obtained from concentration of the dried ether extract gave an oil b. p. 147–160° (4 mm.). On redis-

(11) The coöperation of Dr. Nettie H. Coy of the Division of Development, E. R. Squibb and Sons, in providing the spectroscopic measurements cited in this paper is acknowledged.

(12) All melting points are uncorrected. Microanalyses were carried out by Mr. J. F. Alicino.

tillation there was obtained 11.5 g. (22%) of product, b. p. 155–160° (4 mm.). The free base could be crystallized from hexane, m. p. 55–56°.

*Anal.* Calcd. for $C_{12}H_{11}ON$: C, 77.81; H, 5.98; N, 7.56. Found: C, 78.22; H, 5.84; N, 7.42.

A picrate of the base melted at 150–151°.

*Anal.* Calcd. for $C_{12}H_{11}ON \cdot C_6H_3O_7N_3$: C, 52.18; H, 3.45. Found: C, 52.22; H, 3.40.

**4-Benzyloxypyridine N-Oxide (X).**—The oxide was prepared from the base by means of perbenzoic acid as described above for the 2-isomer and melted at 178–179°.

*Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.96. Found: C, 71.57; H, 5.42; N, 6.62.

The amine oxide formed a picrate readily in alcoholic solution, m. p. 123–124°.

*Anal.* Calcd. for $C_{12}H_{11}O_2N \cdot C_6H_3O_7N_3$: C, 50.24; H, 3.30. Found: C, 49.84; H, 3.29.

**N-Hydroxy-4-pyridone (XI–XII).**—4-Benzyloxypyridine N-oxide (1 g.) was catalytically reduced with 150 mg. of palladium (5% on charcoal) as described for the 2-isomer. The filtrate was concentrated to a small volume, depositing 345 mg., 68%, m. p. 243–244°. The acid gives no precipitate with ferric chloride but produces an orange color. The preparation of this compound by another method has been described[14] but no m. p. is given.

*Anal.* Calcd. for $C_5H_5O_2N$: C, 54.05; H, 4.54; N, 12.61. Found: C, 54.47; H, 4.81; N, 12.20.

(14) Ost, *J. prakt. Chem.*, [2] **29**, 379 (1884).

**N-Benzyloxy-4-pyridone (XIII).**—N-Hydroxy-4-pyridone (47 mg.) was added to a solution of sodium (9.7 mg.) in alcohol and refluxed with benzyl chloride (53.6 mg.) for one hour. The mixture was partitioned between ethyl acetate and alkali. The organic layer on evaporation left a residue of 73 mg. After recrystallization from ethyl acetate and hexane, the material melted 112–113°.

*Anal.* Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51. Found: C, 71.80; H, 5.60.

The picrate of this benzyl ether melted at 164° and depresses the melting point of the picrate of 4-benzyloxypyridine N-oxide.

*Anal.* Calcd. for $C_{12}H_{11}O_2N \cdot C_6H_3O_7N_3$: C, 50.24; H, 3.30. Found: C, 50.33; H, 3.65.

**Acknowledgment.**—The author is indebted to Mr. W. A. Lott for his interest and encouragement.

## Summary

The synthesis of N-hydroxy-2-pyridone, a cyclic hydroxamic acid, is described. The acid is in tautomeric relationship with 2-hydroxypyridine N-oxide.

Isomeric acids of the 3- and of the 4-pyridyl series also have been prepared.

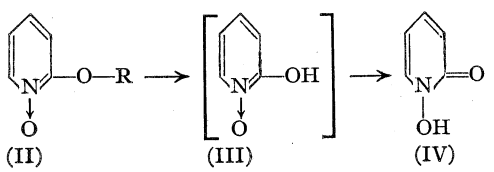
# Analogs of Aspergillic Acid. II. Various Antibacterial Heterocyclic Hydroxamic Acids[1]

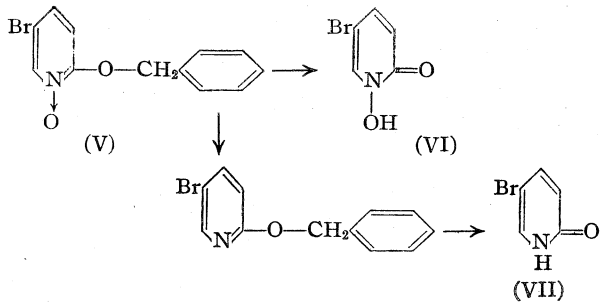


BY W. A. LOTT AND ELLIOTT SHAW

Attempts to develop synthetic methods for introducing into heterocyclic rings the hydroxamic acid grouping present in aspergillic acid (I) led to a

(I)

preparation for N-hydroxy-2-pyridone (IV).[2] The

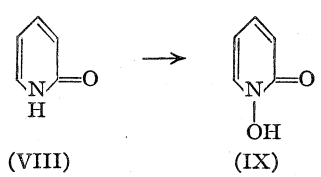


(II) (III) (IV)

synthesis was achieved by conversion of a 2-pyridyl ether to its N-oxide (II), followed by de-alkylation. The 3- and 4-pyridyl derivatives were also prepared[2] but, of these position isomers, only N-hydroxy-2-pyridone showed antibacterial activity, an observation which encouraged the extension of synthetic work to the preparation of additional heterocyclic hydroxamic acids. New methods have been developed. The synthetic acids exceed, in some instances, the *in vitro* antibacterial activity of aspergillic acid.

The hydroxamic acid grouping in N-hydroxy-2-pyridone (IV) is quite stable chemically, resisting the action of boiling aqueous acid or cleavage of the N–O bond by catalytic reduction (Pd), ammonium sulfide, or stannous chloride. In these respects, the grouping bears no resemblance to N-oxides. It is apparent that the amine oxide (II, R = benzyl) is converted to the hydroxamic acid (IV) successfully due to a more rapid initial attack at the ether linkage, by hydrochloric acid or catalytic reduction, than at the N–O bond which subsequently gains increased resistance to reduction by a tautomeric shift (III → IV) to the hydroxamic acid structure.[2] A similar series of reactions led to a 4-methyl derivative of (IV) in good yields. However, when the substituent was bromine in the 5-position, reduction or treatment of the N-oxide (V) with hydrochloric acid led to 5-bromopyridone (VII) as the main product. In the hydrochloric acid debenzylation, for example, the ratio of pyridone to hydroxamic acid isolated (VI) was 3:1. In this case, in contrast to

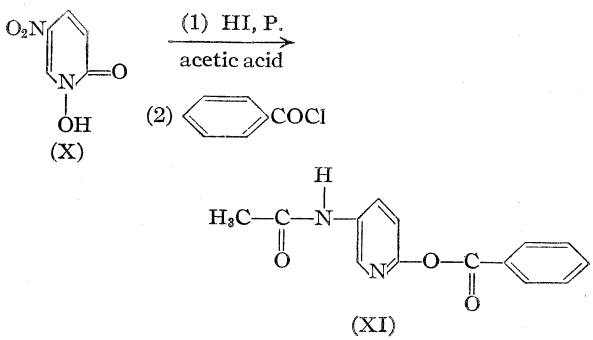
(1) Presented before the Division of Organic Chemistry at the 112th Meeting of the American Chemical Society, New York, N. Y., September, 1947.



(2) Shaw, THIS JOURNAL, **71**, 67 (1949).

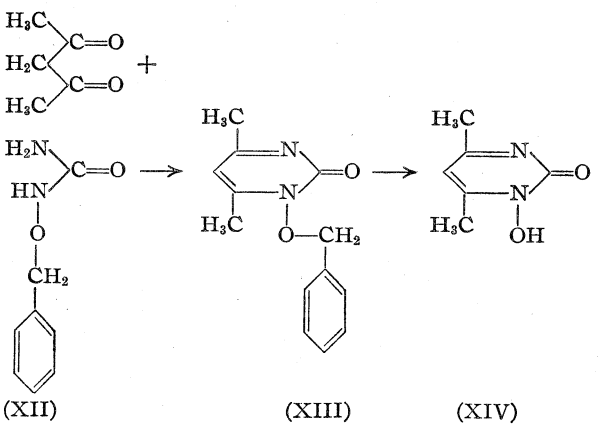
those cited above, the initial attack is mainly at the amine oxide bond.

When attempts were made to apply the above synthesis to the preparation of cyclic quinoline hydroxamic acids, difficulty was encountered in the formation of the intermediate amine oxides. Treatment of 2-benzyloxyquinoline and 2-benzyloxy-4-methylquinoline with perbenzoic acid did not lead to satisfactory oxidations. The problem has been attacked by other methods, to be reported later.



The direct oxidation of amides to hydroxamic acids by means of hydrogen peroxide and ferric chloride has been reported.[3] The conversion of

(VIII) (IX)



2-pyridone (VIII) to N-hydroxy-2-pyridone (IX) bears a formal resemblance to such a change. This oxidation has been achieved. Persulfuric acid, perbenzoic acid, and performic acid have been tried, but of these only perbenzoic acid gave satisfactory results. 5-Bromopyridone (VII) was also conveniently oxidized in yields of 15–20% to the corresponding hydroxamic acid (VI) and, in view of the poor results obtained in the initial synthetic approach to this acid (V → VI), the direct oxidation offers the best method of preparation. In the quinoline series, however, less than a 1% yield of N-hydroxy-2-quinolone was obtained on treatment of carbostyril with perbenzoic acid.

The stability of the hydroxamic acid grouping in N-hydroxy-2-pyridone (IV) has been described above. It was found that the nucleus in this compound undergoes substitution with ease. Nitration in glacial acetic acid gave a nitro compound identified as N-hydroxy-5-nitro-2-pyridone (X). Reduction with hydriodic acid in glacial acetic acid followed by benzoylation of the product led to the same acetamidopyridyl benzoate (XI) produced from 5-nitro-2-pyridone under similar conditions. Bromination gave a mixture of brominated acids from which was isolated a monobromo derivative different from the known 5- and 6-bromo acids and which is considered to be N-hydroxy-3-bromopyridone. 2-Pyridone itself undergoes substitution in the 3- and 5-positions.[4,5]

(X) (XI)

For the preparation of a hydroxamic acid in the pyrimidine series, benzyloxyurea (XII) was condensed with acetylacetone and the resultant N-benzyloxypyrimidone (XIII) cleaved by catalytic hydrogenation to 1-hydroxy-4,6-dimethyl-2-pyrimidone (XIV).

(XII) (XIII) (XIV)

The *in vitro* antibacterial activities of a group of the synthetic hydroxamic acids are compared with aspergillic acid in Table I.

The values given indicate the concentrations necessary to prevent growth of the organisms.[6] It is significant that the common structural feature of these antibacterial agents is the cyclic hydroxamic acid grouping capable of chelating metals. A number of structurally related compounds have been tested which have some of the features of the active compounds but are incomplete as hydroxamic acids, *viz.*, pyridine N-oxide and 2-pyridone; these are not active *in vitro*. Furthermore, "vinylogs" of hydroxamic acids such as N-hydroxy-4-pyridone[2] (XV) and N-hydroxy-7-chloro-4-quinolone (XVI) which have an acidity comparable to their isomeric N-hydroxy-2-pyridone and -2-quinolone derivatives but, unlike the latter, do not form precipitates with metallic ions are inactive

(6) We are indebted to Drs. Rake and Donovick of the Division of Microbiology, The Squibb Institute for Medical Research, for these results. The activities were measured by a dilution method accurate to ±15%.

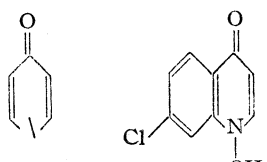

TABLE I

THE *in vitro* ANTIBACTERIAL ACTIVITIES OF SOME SYNTHETIC HYDROXAMIC ACIDS AND THE ANTIBIOTIC, ASPERGILLIC ACID

| | Minimal inhibiting concentration mg./ml. | | |
|---|---|---|---|
| | *Staphylococcus aureus* P209[a] | *Klebsiella pneumoniae*[a] | *Mycobacterium smegmatis*[b] |
| Aspergillic acid | 0.021 | 0.030 | 0.023 |
| N-Hydroxy-2-pyridone | .003 | .043 | .035 |
| N-Hydroxy-4-methyl-2-pyridone | .041 | .045 | .041 |
| N-Hydroxy-3-bromo-2-pyridone | .013 | > .25 | .05 |
| N-Hydroxy-5-bromo-2-pyridone | .005 | .09 | .017 |
| N-Hydroxy-6-bromo-2-pyridone | .011 | .19 | .19 |
| N-Hydroxy-5-nitro-2-pyridone | .14 | .90 | .45 |
| N-Hydroxy-2-quinolone | .0012 | .019 | .013 |
| N-Hydroxy-4,6-dimethyl-2-pyrimidone | .21 | .95 | .44 |

[a] Tested in yeast beef broth. [b] Tested in modified Kirchner's medium.

*in vitro*. It seems probable, therefore, that the compounds in Table I are antibacterial due to their ability to combine with, and deprive microorganisms of, metabolically essential metals. A

(XV) (XVI)

correlation between antibacterial activity and chelating power has been demonstrated[7] in a series of 8-hydroxyquinoline derivatives. With respect to aspergillic acid, Goth has observed that the addition of ferric ion diminishes the *in vitro* activity of the antibiotic.[8]

## Experimental[9]

**2-Bromo-4-methylpyridine and 2,5-Dibromopyridine.**—The 2-bromopyridines were prepared from the corresponding 2-aminopyridines by an adaptation of the method of Craig.[10] In an externally cooled 3-neck flask provided with stirrer, thermometer and dropping funnel, 2-amino-4-methylpyridine (81 g.) was dissolved with cooling in 48% hydrobromic acid (630 ml.). After the addition of 115 ml. of bromine, a solution of sodium nitrite (130 g.) in water (190 ml.) was gradually introduced below 0°. Stirring was then continued for an hour after which the solution was made alkaline with 50% sodium hydroxide and treated with sodium sulfite (100 g.). The mixture was steam distilled, and the oily 2-bromo-4-methylpyridine extracted from the distillate with ether. Fractionation of the dried extract gave 99 g., 77%, b. p. 220–222°.[11] When 2-amino-5-bromopyridine[12] was treated in the same way, 2,5-dibromopyridine, m. p. 92–96°, was obtained as a white solid in the steam distillate, 40%.

**Pyridyl and Quinolyl Benzyl Ethers.**—In the formation of N-hydroxy-2-pyridone (IV) from the N-oxide of a 2-pyridyl ether (II), the ethyl ether was as easily cleaved with hydrochloric acid as the benzyl ether. However, in subsequent applications of the method, the benzyl ether was used because of the additional method of cleavage by hydrogenolysis. The benzyl ethers were prepared from the corresponding bromopyridines and chloroquinolines essentially by the method of Renshaw and Conn.[13] The halogen derivatives were refluxed for two hours with a slight excess of sodium benzylate in benzyl alcohol, poured into water, and extracted with ether. The dried ether–benzyl alcohol layer was concentrated and fractionated *in vacuo*. In those cases resulting in a crystalline product, hexane was used for recrystallization before analysis.

**2-Benzyloxy-4-methylpyridine,** 50% yield, b. p. 142–145° at 5 mm. *Anal.* Calcd. for $C_{13}H_{13}ON$: C, 78.39; H, 6.53; N, 7.03. Found: C, 78.03; H, 6.85; N, 7.18.

**A picrate formed in alcohol,** m. p. 140–141°. *Anal.* Calcd. for $C_{19}H_{16}N_4O_8$: C, 53.27; H, 3.73; N, 13.08. Found: C, 53.63; H, 3.68; N, 12.99.

**2-Benzyloxy-5-bromopyridine,** 71% yield, b. p. 178–185° at 14 mm., m. p. 56–58°. *Anal.* Calcd. for $C_{12}H_{10}ONBr$: C, 54.50; H, 3.79; N, 5.30. Found: C, 54.10; H, 3.85; N, 5.30.

**A picrate** was obtained, m. p. 107–109°. *Anal.* Calcd. for $C_{18}H_{13}O_8N_4Br$: N, 11.34. Found: N, 11.72.

**2-Benzyloxyquinoline,** 86% yield, b. p. 196–197° at 2 mm., m. p. 46–47°. *Anal.* Calcd. for $C_{16}H_{13}ON$: C, 81.67; H, 5.57; N, 5.95. Found: C, 82.04; H, 6.10; N, 5.76.

**2-Benzyloxy-4-methylquinoline,** 68% yield, b. p. 174–176° at 1 mm., m. p. 52–56°. *Anal.* Calcd. for $C_{17}H_{15}ON$: C, 81.85; H, 6.02; N, 5.62. Found: C, 81.37; H, 5.94; N, 5.46.

**The base gave a picrate,** m. p. 149–150°. *Anal.* Calcd. for $C_{23}H_{18}O_8N_4$: C, 57.70; H, 3.76; N, 11.72. Found: C, 57.32; H, 4.04; N, 11.70.

**4-Benzyloxy-7-chloroquinoline,** 57% yield, m. p. 100–101°, recrystallized from benzene. *Anal.* Calcd. for $C_{16}H_{12}ONCl$: C, 71.24; H, 4.49; N, 5.19. Found: C, 70.92; H, 4.54; N, 5.17

**N-Oxides.**—The pyridyl and quinolyl benzyl ethers were left standing at room temperature with a chloroform solution containing 1.5 equivalents of perbenzoic acid.[14] After several days, when potassium iodide titration showed disappearance of most of the perbenzoic acid, the solution was washed with aqueous sodium carbonate and water. The chloroform layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to a small volume. The resultant crystals were drained from adhering oil on a filter and recrystallized from ethyl acetate.

**2-Benzyloxy-4-methylpyridine N-oxide** was thus obtained in a yield of 53%, m. p. 81–82°. *Anal.* Calcd. for $C_{13}H_{13}O_2N$: C, 72.53; H, 6.08; N, 6.51. Found: C, 72.61; H, 6.14; N, 6.72.

**2-Benzyloxy-5-bromopyridine N-oxide,** 25% yield, m. p. 127–128°. *Anal.* Calcd. for $C_{12}H_{10}O_2NBr$: C, 51.40; H, 3.57; N, 5.00. Found: C, 51.59; H, 4.03; N, 5.02.

**4-Benzyloxy-7-chloroquinoline N-oxide** required a modification of the above procedure for its isolation. Concentration of the carbonate-washed chloroform solution gave a benzoic acid salt from which the oxide was obtained by trituration with dilute sodium hydroxide and extraction with chloroform, m. p. 163°, 65% yield. *Anal.* Calcd. for $C_{16}H_{12}O_2NCl$: C, 67.25; H, 4.24; N, 4.89. Found: C, 67.11; H, 4.35; N, 5.11.

**N-Hydroxy-4-methyl-2-pyridone.**—The benzyl ether N-oxide was treated with aqueous hydrochloric acid as previ-

(13) Renshaw and Conn, THIS JOURNAL, **59**, 297 (1937).

(14) "Organic Syntheses," Coll. Vol. I, 431 (1941).

ously described[2] and led to the hydroxamic acid, m. p. 129–130°, 75% yield. *Anal.* Calcd. for $C_6H_7O_2N$: C, 57.58; H, 5.63; N, 11.18. Found: C, 57.51; H, 5.89; N, 11.17.

**Action of Aqueous Hydrochloric Acid on 2-Benzyloxy-5-bromopyridine N-Oxide.**—The oxide (7 g.) was refluxed for ten minutes with 20% hydrochloric acid (35 ml.) during which time the benzyl chloride formed was condensed and removed. The aqueous residue was taken to dryness *in vacuo* and the resultant crystalline mixture, dissolved in ethyl acetate–butanol (1:1), was extracted with aqueous sodium carbonate. When the aqueous layer was acidified and taken to dryness, extraction with absolute alcohol gave the hydroxamic acid, N-hydroxy-5-bromo-2-pyridone, m. p. 137–139°, 13%. *Anal.* Calcd. for $C_5H_4O_2NBr$: C, 31.60; H, 2.12; N, 7.37. Found: C, 31.65; H, 2.59; N, 7.35.

The ethyl acetate–butanol fraction from the above partition on concentration led to 5-bromo-2-pyridone, 40%, m. p. 179–181°, identical with an authentic sample.[15]

**N-Hydroxy-7-chloro-4-quinolone.**—4-Benzyloxy-7-chloroquinoline N-oxide (10 g.) was reduced with hydrogen at fifty pounds initial pressure in 100 ml. of absolute ethanol and 0.5 g. 5% palladium-on-carbon. The product crystallized out and was separated from the catalyst by solution in dilute sodium hydroxide and reprecipitation with acid, 5 g., m. p. 262°, 73%. Recrystallization from glacial acetic acid did not alter the melting point. The acid gives an orange color with ferric chloride but forms no precipitate. *Anal.* Calcd. for $C_9H_6O_2NCl$: C, 55.26; H, 3.09; N, 7.16. Found: C, 55.53; H, 3.32; N, 7.37.

**Direct Oxidation of 2-Pyridones to Hydroxamic Acids.**—The 2-pyridone was left standing at room temperature with a chloroform solution of perbenzoic acid containing a 50% excess of the oxidizing agent. After about one week at room temperature, the solution was taken to dryness and desiccated to a dry powder. This residue was triturated with ether and filtered several times to remove benzoic acid. The insoluble portion was recrystallized from benzene. N-Hydroxy-2-pyridone and N-hydroxy-5-bromo-2-pyridone were obtained in this way in yields of 15 and 18%, respectively, and were identical with the acids obtained from the 2-benzyloxypyridyl N-oxides. 6-Bromo-2-pyridone[16] under the above conditions produced N-hydroxy-6-bromo-2-pyridone, m. p. 155–157°, 19% yield. *Anal.* Calcd. for $C_5H_4O_2NBr$: C, 31.60; H, 2.12; N, 7.37. Found: C, 32.02; H, 2.22; N, 7.17.

5-Nitro-2-pyridone was not oxidized by perbenzoic acid at room temperature, judging by the absence of a ferric chloride coloration. Carbostyril (7 g.) produced 0.2 g. of N-hydroxy-2-quinolone, m. p. 189–191°, isolated as the fraction insoluble in aqueous bicarbonate and soluble in carbonate. The acid did not depress the melting point of the material prepared by the method of Friedländer.[17]

**N-Hydroxy-5-nitro-2-pyridone.**—N-Hydroxy-2-pyridone (3.1 g.) was dissolved in glacial acetic acid (15 ml.); concentrated nitric acid (2 ml., d. 1.42) was added with cooling. The product rapidly crystallized out; 2.8 g., 67% yield, m. p. 198–199°, unchanged on recrystallization from glacial acetic acid. *Anal.* Calcd. for $C_5H_4O_4N_2$: C, 38.47; H, 2.59; N, 17.95. Found: C, 38.09; H, 2.34; N, 17.75.

The nitro derivative (1.5 g.) was refluxed in glacial acetic acid (20 ml.) with concentrated hydriodic acid (1.5 ml., sp. gr. 1.7) and red phosphorus (1 g.). Since the hydroxamic acid grouping was not completely reduced (ferric chloride color) after three hours, a second portion of hydriodic acid was added and the refluxing continued for an hour longer. On concentration of the filtrate, yellow crystals of an hydriodide were obtained, 0.95 g. The hydriodide was dissolved in pyridine (15 ml.) and shaken in a stoppered flask with benzoyl chloride (1 ml.). After fifteen minutes, the mixture was poured into water and concentrated under reduced pressure. The derivative, 0.2 g., was recrystallized from ethyl acetate and hexane and melted at 149–150°.

When 5-nitro-2-pyridone was treated in the same way, an identical benzoate (XI) was obtained, indicating that nitration of the hydroxamic acid had produced a 5-nitro derivative. 5-Amino-2-pyridone forms di-acyl derivatives.[18] *Anal.* Calcd. for $C_{14}H_{12}N_2O_3$: C, 65.60; H, 4.72; N, 10.93. Found: C, 65.77; H, 4.73; N, 10.60.

**N-Hydroxy-3-bromo-2-pyridone.**—To a solution of N-hydroxy-2-pyridone (3 g.) in glacial acetic acid (15 ml.) was added a solution of bromine (4.3 g.) in the same solvent (20 ml.). After two hours at room temperature, the solution was filtered and taken to dryness *in vacuo*. The residue was clearly a mixture from which the initial crop of crystals from ethyl acetate, 0.7 g., m. p. 208–209°, was the only pure fraction isolated. *Anal.* Calcd. for $C_5H_4O_2NBr$: C, 31.60; H, 2.12; N, 7.37. Found: C, 31.48; H, 2.27; N, 7.46.

An hydriodic acid reduction was carried out as described above for the nitration product, and led to the pyridone, m. p. 183–184° (alcohol). *Anal.* Calcd. for $C_5H_4ONBr$: C, 34.51; H, 2.30; N, 8.04. Found: C, 34.74; H, 2.58; N, 7.89.

**1-Benzyloxy-4,6-dimethyl-2-pyrimidone.**—N-Benzyloxyurea[19] was dissolved in absolute alcohol (200 ml.) in a flask provided with a stirrer; acetylacetone (12.6 g.) and concentrated sulfuric acid (13.8 ml.) were added. After one hour, crystallization was induced by scratching and chilling. With the addition of ether, a 51% yield of the pyrimidine sulfate was obtained. The free base separated on treatment of the salt with aqueous alkali, m. p. 130–131° (from water). *Anal.* Calcd. for $C_{13}H_{14}O_2N_2$: C, 67.80; H, 6.12; N, 12.16. Found: C, 68.03; H, 6.24; N, 12.14.

**N-Hydroxy-4,6-dimethyl-2-pyrimidone.**—The benzyl ether (11.5 g.) was shaken with palladium-on-charcoal-5% (1.0 g.) in the atmosphere of hydrogen at an initial pressure of 50 lb. Reduction was rapid. When the theoretical amount of hydrogen had been taken up, the shaking was stopped. The hydroxamic acid was crystallized from the filtrate with the addition of ether; 6.5 g., 90%, m. p. 185–186°. There was no change in melting point on recrystallization from ether. *Anal.* Calcd. for $C_6H_8N_2O_2$: C, 51.42; H, 5.75; N, 19.99. Found: C, 51.27; H, 5.88; N, 19.68.

## Summary

The synthesis of a number of heterocyclic compounds containing the hydroxamic acid grouping, —N(OH)—C(=O)—, in the ring is described. Such acids have, in general, antibacterial action *in vitro*.

# Certain Derivatives of 2-Aminobenzothiazole

BY FLAVEN E. JOHNSON[1] AND CLIFF S. HAMILTON

Alkyl aryl and heterocyclic aryl sulfones containing a *p*-amino group have shown marked bacteriostatic[2] and antitubercular[3] activity. This is particularly true of derivatives containing the thiazole ring.[4] Sulfides and sulfoxides have also shown chemotherapeutical activity.[5] The present investigation was undertaken to embody the above characteristics in one compound by synthesizing sulfur containing derivatives of 2-aminobenzothiazole, for example 6-methylmercapto-2-aminobenzothiazole (V).

V

4-Methylmercaptonitrobenzene (II) was prepared by a series of conventional methods, reduced to the amine and converted to 4-methylmercaptophenylthiourea (IV). Oxidation of IV with bromine gave 2-amino-6-methylmercaptobenzothiazole (V) in good yields. After protecting the amino group compound V was oxidized to 2-amino-6-methylsulfonylbenzothiazole (VIII) in excellent yields.

2-Amino-6-methylsulfonylbenzothiazole was also prepared by oxidizing compound II to 4-methylsulfonylnitrobenzene (IX), reducing it to the amine and treating the compound obtained with ammonium thiocyanate, then with bromine to give a low yield of compound VIII. This synthesis proved that the mercapto sulfur and not the ring sulfur was undergoing oxidation.

Conversion of compound VIII to 2-chloro-6-methylsulfonyl-benzothiazole (XI) proceeded smoothly employing a modified Sandmeyer reaction. An attempt to use the same reaction on compound V produced two products, 2-chloro-6-methylsulfinylbenzothiazole (XVI) at 0° and 2-chloro-6-methylmercaptobenzothiazole (XXI) at −20°. Compounds XVI and XXI were later oxidized to XI by means of hydrogen peroxide.

Chloro compounds XI, XVI and XXI were all successfully condensed with benzylamine, piperidine, δ-diethylaminobutylamine and γ-diethylaminopropylamine to produce the remainder of the compounds shown in the accompanying tables.

All of the sulfone derivatives and a representative member of the sulfoxide and sulfide series have been submitted for pharmacological screen testing.

## Experimental

**Sodium *p*-Nitrothiophenate (I).**—This compound was prepared according to the procedure of Stacy[6] using a 75% ethanol–water solution as the reaction medium. The solution was kept at reflux temperature during the entire reaction to yield 84% of the desired salt.

**4-Methylmercaptonitrobenzene (II).**—The procedure as employed by Waldron and Reid[7] was used to prepare the compound in 70–75% yields; m. p., 68–69°, lit.[7] 67° and 71°.

**4-Methylmercaptoaniline Hydrochloride (III).**—4-Methylmercaptonitrobenzene (45 g., 0.32 mole) was reduced in three runs (15 g. each), by means of hydrogen and Raney nickel in acetone solution. Six hours were required for complete reduction and the product was isolated as a salt by passing dry hydrogen chloride gas through the solution. The product removed by filtration weighed 44.5 g. (94%) and was identified by formation of the benzoyl derivative; m. p. 176–178°, lit.[8] 177–178°.

**4-Methylmercaptophenylthiourea (IV).**—The method used was that of Wertheim[9]; yield 86%, m. p. 200–201°, lit.[9] 198–199°.

**2-Amino-6-methylmercaptobenzothiazole (V).**—4-Methylmercaptophenylthiourea (58 g., 0.29 mole) was suspended in 200 ml. of dry chloroform in a 500-ml. round-bottomed flask. Liquid bromine (58 g., 0.362 mole) in dry chloroform (100 ml.) was carefully added. The reaction flask was placed under a reflux condenser provided with a trap to catch hydrogen bromide vapors and carefully warmed for forty minutes. The solvent was then decanted and fresh chloroform added followed by twenty minutes of heating. The solid which remained was decanted free of solvent and dried. The yellow amorphous material was triturated with sulfurous acid solution and washed with water. The hydrobromide salt obtained was dissolved in 1.5 l. of hot water, filtered free of impurities and made alkaline with ammonium hydroxide. The solid separating on cooling was recrystallized from 50% ethanol–water solution; yield, 51.2 g. (89.5%) of light tan plates melting at 150–151°.

**2-Acetamido-6-methylmercaptobenzothiazole (VI).**—2-Amino-6-methylmercaptobenzothiazole (15 g., 0.8 mole) was dissolved by warming in technical grade acetic anhydride and treated in the conventional manner to obtain 18.1 g. (99%) of cream-colored crystals, which recrystallized from 95% ethanol and had a m. p. of 198–200°.

*Anal.* Calcd. for $C_{10}H_{10}N_2OS_2$: N, 11.75. Found: N, 12.03.

**2-Acetamido-6-methylsulfonylbenzothiazole (VII).**—2-Acetamido-6-methylmercaptobenzothiazole (18.1 g., 0.8 mole) was dissolved in 340 ml. of glacial acetic acid by warming on a steam-bath. Hydrogen peroxide solution (60 ml., 30%) in glacial acetic acid (40 ml.) was added and the mixture warmed to 80° on a steam-bath. After standing at room temperature for one hour the reaction solution was placed in the refrigerator overnight. The white fluffy crystals that separated were removed by filtration, washed with water and dried; yield 15.7 g. (76.5%), m. p. 305–307°.

*Anal.* Calcd. for $C_{10}H_{10}N_2O_3S_2$: N, 10.36. Found: N, 10.52.

**2-Amino-6-methylsulfonylbenzothiazole (VIII) (Method I).**—2-Acetamido-6-methylsulfonylbenzothiazole (15.7 g., 0.6 mole) was heated at reflux temperature with hydrochloric acid (4 *N*, 240 ml.) for thirty minutes. The white

[a] Dihydrochlorides. [b] Analyzed as a dipicrate which has a m. p. of 163–165°.

solid was completely dissolved by this time so the solution was filtered and carefully neutralized with ammonium hydroxide while still hot. The crystals that separated were recrystallized from 95% ethanol; yield 12 g. (91%) of white needles, m. p. 224–226°.

**4-Methylsulfonylnitrobenzene (IX).**—4-Methylmercaptonitrobenzene (2.0 g., 0.012 mole) was placed in glacial acetic acid (15 ml.) and hydrogen peroxide (30%, 10 ml.) was added. The solution was warmed on a steam-bath until all the mercapto compound went into solution. The mixture was allowed to stand at room temperature for one hour and then placed in the refrigerator overnight. The long yellow needles that separated were filtered yielding 1.85 g. (79%), m. p. 142°, lit. 136° and 142.5°.[6]

**4-Methylsulfonylaniline Hydrochloride (X).**—4-Methylsulfonylnitrobenzene (7.1 g., 0.035 mole) was reduced using Raney nickel and hydrogen in acetone solution. After complete reduction the solution was filtered free of catalyst and saturated with dry hydrogen chloride; yield 6.3 g. (86.5%). Some of the hydrochloride was converted to the amine producing a light yellow solid; m. p. 136–137°.[6]

**2-Amino-6-methylsulfonylbenzothiazole (VIII). (Method II).**—4-Methylsulfonylaniline hydrochloride (4.05 g., 0.024 mole) was treated with ammonium thiocyanate (1.8 g., 0.024 mole) in a water solution analogous to the preparation of compound IV. The impure solid thus obtained was treated with bromine and chloroform in a manner analogous to the preparation of compound V; yield 0.5 g. (9.1%), m. p. 223–225°. A mixed melting point determination with compound VIII prepared by Method I gave no appreciable depression of the melting temperature.

**2-Chloro-6-methylsulfonylbenzothiazole (XI).**—2-Amino-6-methylsulfonylbenzothiazole (4 g., 0.02 mole) was dissolved by warming and stirring in 87% phosphoric acid (43 ml.). The solution was cooled externally to 0° and concentrated nitric acid (18 ml.) was added with stirring. A solution of sodium nitrite (1.43 g., 0.02 mole) in water (3.6 ml.) was added to the lower portion of the well-stirred mixture. After standing for ten minutes the viscous diazonium solution was poured in a thin stream into concentrated hydrochloric acid (75 ml.) containing cuprous chloride (3 g., 0.02 mole). After the evolution of

nitrogen had ceased, the mixture was diluted to three times its volume and allowed to stand for one hour. The solid which formed was removed by filtration and recrystallized using charcoal from 95% ethanol (100 ml.); yield 2.4 g. (48%) of white needles, m. p. 189–190°.

**2-Chloro-6-methylsulfinylbenzothiazole (XVI).**—2-Amino-6-methylmercaptobenzothiazole (5 g., 0.03 mole) was dissolved by heating in 87% phosphoric acid (75 ml.). The solution was then cooled to 0° by means of an ice-bath. Cold concentrated nitric acid (25 ml.) was added with rapid stirring. A solution of sodium nitrite (2 g. in 5 ml. of water, 0.03 mole) was then added to the lower portion of the well-stirred acid medium. The deep red viscous diazonium mixture which formed was then poured in a small stream into concentrated hydrochloric acid (100 ml.) containing cuprous chloride (5.0 g., 0.03 mole). As soon as evolution of nitrogen ceased the mixture was stirred for an additional fifteen minutes and diluted to three times its volume. The diluted solution was extracted four times with benzene (100-ml. portions). The benzene was dried over anhydrous sodium sulfate and evaporated to dryness. The resulting orange solid was recrystallized, employing charcoal, from hot water (150 ml.); yield 2 g. (34%) of white fluffy crystals, m. p. 112–113°.

**2-Chloro-6-methylmercaptobenzothiazole (XXI).**—Identical conditions and amounts were employed as in the preparation of compound XVI with the exception that the diazotization was carried out at −20 instead of 0° using an acetone–Dry Ice-bath. The product was extracted with benzene and obtained in the solid form as before. The yellow material was transferred in two portions to a small fractionating column and distilled under reduced pressure. A yellow oil distilled over at 138–142° (3 mm.). This product was recrystallized, using charcoal, from hot petroleum ether; yield 1.5 g. (28%) of white crystals, m. p. 51–52°.

The condensations of amines with chloro compounds were carried out in a slightly over two mole excess of the amine so that the excess amine would form a salt with the hydrogen chloride eliminated. The method employed for isolation of the product was based on the fact that all the amines reacting were more soluble in water than the condensed products. The following preparations illustrate the procedure used.

**2-(Benzylamino)-6-methylsulfonylbenzothiazole (XIV).**—2-Chloro-6-methylsulfonylbenzothiazole (0.75 g., 0.003 mole) and benzylamine (0.86 g., 0.008 mole) reacted together in a 25-ml. round-bottomed flask equipped with a water condenser. Although some heat was evolved at once the mixture was heated at 150° for four hours in an oil-bath to complete the reaction. Upon cooling the reaction mixture solidified. The crystals which formed were washed thoroughly with dilute ammonium hydroxide and water to remove excess benzylamine. The solid that remained was recrystallized from ethyl acetate; yield 0.93 g. of fine white crystals, m. p. 220°.

**2-(δ-Diethylaminobutylamino)-6-methylmercaptobenzothiazole Dihydrochloride (XXII).**—2-Chloro-6-methylmercaptobenzothiazole (0.25 g., 0.001 mole) and δ-diethylaminobutylamine (0.43 g., 0.003 mole) reacted together on a steam-bath for twenty-two hours. The resulting liquid was mixed thoroughly with dilute ammonium hydroxide and extracted with three portions of diethyl ether (25 ml.). The combined solutions were washed three times with water (25 ml.), dried over anhydrous sodium sulfate and dry hydrogen chloride gas added until an oil separated. The oil was recrystallized, using charcoal, from methanol and anhydrous diethyl ether; yield 0.35 g. of a light brown solid.

## Summary

1. 2-Amino-6-methylsulfonylbenzothiazole and 2-amino-6-methylmercaptobenzothiazole have been prepared from *p*-nitrochlorobenzene in good yields.

2. The above compounds were converted to the corresponding 2-chloro compounds producing in addition 2-chloro-6-methylsulfinylbenzothiazole.

3. All three chloro compounds were successfully condensed with benzylamine, piperidine, δ-diethylaminobutylamine and γ-diethylaminopropylamine.

# Some β-Amino-α-chloroacrylonitriles

BY JOHN G. ERICKSON

Except for a few β-aminoacrylonitriles prepared by Moureu and Lazennec,[1] no compounds of this class have been reported. The French workers prepared their compounds by the addition of various primary and secondary amines to several α,β-acetylenic nitriles.

Here we wish to report the preparation of a number of β-amino-α-chloroacrylonitriles (II) by the reaction of α,β-dichloroacrylonitrile (I) with ammonia and aliphatic and aromatic primary and secondary amines.

$$\underset{\text{I}}{\text{ClCH=CCN}} + \text{RR'NH} \longrightarrow \underset{\text{II}}{\text{RR'NCH=CCN}} + \text{HCl}$$

(Cl on the α-carbon in both I and II)

The reactions were carried out in alcohol or benzene solutions at or near room temperature. An acid acceptor, which was either a tertiary amine or an excess of the ammonia or amine being used in the reactions, was always present to neutralize the hydrogen chloride eliminated in the reactions.

The β-amino-α-chloroacrylonitriles are, in general, unstable. Although they may usually be distilled, even at high temperatures, without serious decomposition, those compounds which are liquids at room temperature slowly darken and decompose upon standing. The solid compounds appear to be relatively stable at room temperature. Of the liquid β-amino-α-chloroacrylonitriles, those derived from secondary amines are less stable than those derived from primary amines. The nature of the decomposition is not clear.

Attempts to confirm the structures of these compounds by conversion to known compounds failed, presumably because the chlorine in these

After twenty hours, the mixture was poured into water and extracted with benzene. The benzene extract was distilled. Calcd. for $C_{13}H_{23}N_2Cl$: iodine number (cg. of $I_2$ per g.), 105. Found: 106. [d] Addition carried out over forty-five minutes in 100 cc. of ethanol at 30–35°. Product washed up as in preceding run and crystallized from ethyl acetate. [e] Addition carried out in 50 cc. of methanol. Little heat was evolved. After twenty hours, the mixture was poured into water. The product was filtered off and crystallized from cold methanol (hot methanol caused decomposition) to give a light orange solid. [f] Addition carried out over two hours in 100 cc. of methanol at 20–30°. Product worked up as in third and fourth runs. Calcd. for $C_{11}H_{19}N_2Cl$: Cl, 16.51; iodine number, 118; found: Cl, 16.05; iodine number, 114. [g] Addition carried out over fifteen minutes in 100 cc. of methanol at 35°. Product worked up as in third, fourth and sixth runs.

compounds is very tightly bound. However, the assigned structures of these compounds are substantiated by a study of the infrared absorption spectrum of β-amino-α-chloroacrylonitrile (II, R=R'=H) which shows, among others, absorption bands at 3500–3200 cm.$^{-1}$, 3070 and 1650 cm.$^{-1}$, and 2210 cm.$^{-1}$, attributable, respectively, to the structural features, —$NH_2$, H—C=C, and —CN. These features are all found in structure III.

III IV V

The isomeric structure, IV, resulting from replacement of the α-chlorine in I, although it possesses the structural features indicated by the infrared absorption spectrum, does not seem likely, since immediate rearrangement to the ketimine structure, V, would be expected. The existence of stable enamine forms, such as III, is also found in the closely related β-aminocrotonic esters. Replacement of the β-chlorine in I rather than the α-chlorine also seems the more likely since I may be regarded as a substituted vinylog of cyanogen chloride and since chlorine atoms alpha to nitrile groups appear to possess lowered activity, at least in certain reactions.[2]

**Acknowledgment.**—The author is indebted to Dr. R. C. Gore of the Physics Division of these Laboratories for the determination and interpretation of the infrared absorption spectrum of β-amino-α-chloroacrylonitrile.

## Experimental

**General Procedure.**—Table I summarizes the results obtained. In each run, α,β-dichloroacrylonitrile (I) was added to a solution of amine and acid acceptor in some suitable solvent. The temperature of the reaction mixture was controlled by the use of a cooling bath. After standing at room temperature for a period of time after the addition, the reaction mixtures were worked up, usually being poured into water, extracted with benzene and distilled. Besides analyses for nitrogen, corroborative chlorine analyses and iodine number determinations were done in several cases.

## Summary

β-Amino-α-chloroacrylonitrile and several of its N-substitution products have been prepared by the reaction of α,β-dichloroacrylonitrile with ammonia and various primary and secondary aliphatic and aromatic amines.

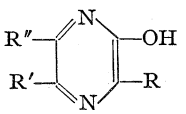
# Pyrazines and Related Compounds. I. A New Synthesis of Hydroxypyrazines

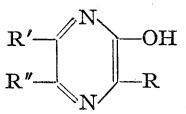
BY REUBEN G. JONES

A new general synthesis of hydroxypyrazines (I) has been devised which involves the condensation of 1,2-dicarbonyl compounds with α-amino acid amides



(I)

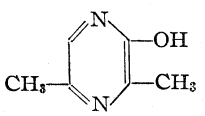
This appears to be a direct and convenient method for the preparation of hydroxypyrazines which, heretofore, have been obtained in poor yields and by laborious procedures.[1] It also appears to be one of the few satisfactory methods for preparing compounds containing the isolated pyrazine nucleus.[2]



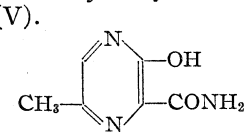
In starting out to explore this reaction the first condensations were carried out with glyoxal and aminomalonamide. When these compounds were mixed in water solution and allowed to stand, or warmed, dark brown reaction products resulted from which no pure materials could be isolated. It was then found that in the presence of base, preferably one equivalent of sodium or potassium hydroxide, glyoxal and aminomalonamide reacted rapidly to form the sodium or potassium salt of 2-hydroxy-3-carboxamidopyrazine. Under these conditions aminomalonamide was also found to condense readily with other 1,2-diketones and ketoaldehydes to give high yields of substituted hydroxycarboxamidopyrazines. Subsequently it was found that diacetyl reacted with aminomalonamide in the absence of any added base to give a practically quantitative yield of 2-hydroxy-3-carboxamido-5,6-dimethylpyrazine. In one experiment in which a solid glyoxal polymer was heated in water with aminomalonamide, several drops of aqueous sodium hydroxide was sufficient to bring about condensation.

In order to determine the scope of the reaction glyoxal, methylglyoxal, diacetyl, phenylglyoxal and benzil were condensed with a number of typical α-amino acid amides. The results of these experiments are summarized in Table I. Usually, when the reagents were mixed at room temperature, reaction took place immediately with the evolution of heat and the formation of black intractable tars. The reactions were suitably controlled, however, to yield the desired pyrazine compounds by operating at temperatures of about −10 to −20°. For the most part the reactions were carried out in water or methanol solution and with the use of one equivalent of aqueous sodium hydroxide. However, other solvents and bases may be used. For example, methionine amide and diacetyl were allowed to react in dry chloroform solution using one equivalent of piperidine to give a 70% yield of 2-hydroxy-3-(β-methylmercaptoethyl)-5,6-dimethylpyrazine. Hydroxypyrazine, the parent member of the series, was obtained in good yield by the condensation of glycine amide with glyoxal.

The condensation of an α-amino acid amide with an unsymmetrical dicarbonyl compound might be expected to yield a mixture of the two possible isomeric hydroxypyrazines (II and III).

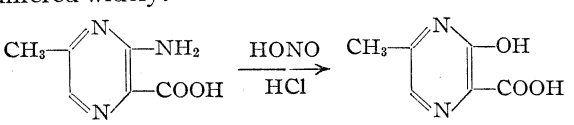


(II)



(III)

However, in each case where methylglyoxal or phenylglyoxal has been condensed with an α-amino acid amide, only one compound has been isolated. The melting point of the product from the reaction of methylglyoxal with alanine amide differed from that of the known 2-hydroxy-3,6-dimethylpyrazine.[1b] Therefore, the compound must be 2-hydroxy-3,5-dimethylpyrazine (IV).



(IV)

Methylglyoxal and aminomalonamide underwent reaction to yield 2-hydroxy-5-methyl-3-pyrazinecarboxamide (V).

(V)

Proof of structure (V) was obtained by hydrolyzing to the acid and comparing the melting point with that of 2-hydroxy-6-methyl-3-pyrazinecarboxylic acid (VI). The latter was synthesized from the known 2-amino-6-methyl-3-pyrazinecarboxylic acid.[3] The melting points of the two acids differed widely.

[a] Previously prepared by a different method, see McDonald and Ellingson, THIS JOURNAL, **69**, 1034 (1947). [b] Structure not proved. [c] Previously prepared by a different method, see ref. 1c. [d] Previously prepared by a different method, see ref. 1a.

The structures of the hydroxypyrazines obtained from the reaction of phenylglyoxal with alanine amide and with aminomalonamide are now under investigation. It is hoped that these and other studies currently under way will provide an insight into the mechanism of the reaction.

## Experimental

**α-Amino Acid Amides.**—Aminomalonamide,[4] m. p. 187–188° (dec.), separated in 97% yield by allowing a solution of aminomalonic ester[5] in seven volumes of absolute alcohol saturated with ammonia to stand at room temperature seven days. The yellow to orange colored product was pure enough for the condensation with dicarbonyl compounds.

*Anal.* Calcd. for $C_3H_7N_3O_2$: N, 35.88. Found: N, 35.83.

Glycine amide and *dl*-alanine amide were prepared by treating the corresponding amino acid ethyl esters with ten volumes of saturated absolute alcoholic ammonia instead of liquid ammonia as described by Koenigs and Mylo.[6] The reaction with glycine ethyl ester was allowed to proceed for four days and then worked up[6] to give a 38% yield of amide. With a longer reaction time the yield was lower. In the preparation of alanine amide the reaction mixture stood for thirty days before it was worked up to give a 63% yield of amide and 17% of unchanged ester.

A solution of *l*-tyrosine ethyl ester in absolute alcoholic ammonia was allowed to stand for ten days. When the solution was evaporated to dryness, unchanged tyrosine ethyl ester was quantitatively recovered. Tyrosine amide was obtained in 90% yield from tyrosine ethyl ester and liquid ammonia as described by Koenigs and Mylo.[6]

For the preparation of *dl*-methionine amide a solution of 287 g. (1.62 moles) of *dl*-methionine ethyl ester, b. p. 132° (14 mm.), in two liters of absolute alcohol saturated at 0° with ammonia was allowed to stand in a closed flask for thirty days. The clear solution was evaporated in vacuum at about 40° until all alcohol appeared to have been removed. The residual semicrystalline mass was treated with one liter of anhydrous ether and cooled to 0°. The snow-white crystalline product was collected on a filter, washed with dry ether and dried in vacuum: The ether filtrate was distilled to yield 57 g. (20%) of unreacted methionine ethyl ester. The yield of amide was 175 g. (93% based on unrecovered ester); m. p. 48–49°. A sample for analysis was dissolved in chloroform, the solution filtered, and evaporated in vacuum.

*Anal.* Calcd. for $C_5H_{12}N_2OS$: C, 40.51; H, 8.17. Found: C, 40.66; H, 8.14.

α-Aminophenylacetamide was prepared in 88% yield by allowing a solution of ethyl α-aminophenylacetate in seven volumes of absolute alcoholic ammonia to stand at room temperature for two weeks. The product was isolated as described above for methionine amide; m. p. 128–129°.

*Anal.* Calcd. for $C_8H_{10}N_2O$: N, 18.66. Found: N, 18.32.

Samples of the amino acid amides were kept in the refrigerator for several months without decomposition. At room temperature, however, alanine amide and especially glycine amide lost ammonia and changed to the diketopiperazines.

**Condensations with Aminomalonamide.**—To 25 g. (0.166 mole) of 40% aqueous glyoxal solution diluted with 25 ml. of water was added 11.7 g. (0.10 mole) of finely powdered aminomalonamide. The mixture was cooled in an ice–salt-bath, and with stirring 10 ml. (0.125 mole) of 12.5 *N* sodium hydroxide solution was added dropwise while the temperature was maintained below 10°. The resulting solution was allowed to stand at room temperature, and after a few minutes it had set to a semisolid mass of finely-divided crystals (sodium salt of 2-hydroxy-3-carboxamidopyrazine). After several hours, 10 ml. of glacial-acetic acid was added with stirring. The precipitate of 2-hydroxy-3-carboxamidopyrazine was collected on a filter,

(6) Koenigs and Mylo, *Ber.*, **41**, 4427 (1908).

washed with water, then with acetone and air dried. The yield of crude product was 12.5 g. (90% based on aminomalonamide). A sample for analysis was recrystallized from water and dried at 150° for several hours (see Table I).

The yields were lower when the reaction was conducted at higher temperatures or when smaller proportions of glyoxal were used. Potassium hydroxide or diethylamine was used in place of the sodium hydroxide with equally good results. Also, solid glyoxal polymer or glyoxal sodium bisulfite could be substituted for aqueous glyoxal solution.

Diacetyl was condensed with aminomalonamide in the manner described above for glyoxal. Later it was discovered that diacetyl reacted with powdered aminomalonamide in water suspension without any basic catalyst to give a practically quantitative yield of 2-hydroxy-3-carboxamido-5,6-dimethylpyrazine. This compound was very sparingly soluble in water, acetic acid or alcohol, but readily soluble in pyridine.

The condensation of aminomalonamide with methylglyoxal proceeded best when an excess of the amide was used.[7] A solution of 36 g. (0.50 mole) of freshly prepared methylglyoxal[8] (b. p. 60–64° at 50 mm.) in 50 ml. of water was cooled to −20° and 60 g. (0.51 mole) of finely powdered aminomalonamide was added. With stirring, 40 ml. (0.50 mole) of 12.5 *N* sodium hydroxide solution was added dropwise while the temperature was kept below 0°. The mixture was then allowed to stand at room temperature for eighteen hours before it was acidified with 50 ml. of 12 *N* hydrochloric acid. After standing for an additional two days, the mixture was chilled, and the 2-hydroxy-3-carboxamido-5-methylpyrazine was collected on a filter, washed with a little water and air dried. The yield was 45 g. (59%). For analysis the compound was recrystallized from water in which it appeared to be appreciably soluble.

A mixture of 21 g. (0.10 mole) of benzil and 11.7 g. (0.10 mole) of powdered aminomalonamide in 350 ml. of 50% aqueous alcohol was heated to about 70° and 10 ml. (0.125 mole) of 12.5 *N* sodium hydroxide solution was added with stirring. A clear brown solution formed and then suddenly it became almost solid with crystalline precipitate. The cooled mixture was filtered, and the solid was washed by suspension in 300 ml. of acetone. This sodium salt was very sparingly soluble in all of the common solvents, including boiling water. It was suspended in 200 ml. of acetone and treated with 20 ml. of concentrated hydrochloric acid. The resulting almost-clear solution was diluted with 500 ml. of water to precipitate 2-hydroxy-3-carboxamido-5,6-diphenylpyrazine as an oil which soon crystallized. The compound was readily recrystallized from acetone–petroleum ether, acetone–water or alcohol–water.

**Condensations with Glycine Amide, Alanine Amide, Methionine Amide and α-Aminophenylacetamide.**—The following typical experiment will illustrate the method used for the preparation of most of the compounds in Table I.

A solution of 8.8 g. (0.10 mole) of alanine amide in 50 ml. of methanol was cooled to −30° and to it was added a solution of 24 g. (0.10 mole) of commercial 30% methylglyoxal in 25 ml. of methanol also precooled to −30°. With stirring, 10 ml. (0.125 mole) of 12.5 *N* aqueous sodium hydroxide solution was added dropwise while the temperature was maintained below −10°. The mixture was allowed to stand in the refrigerator at −5° for two hours, then at room temperature for several hours. To the mixture was added 10 ml. of 12 *N* hydrochloric acid followed by 5 g. of solid sodium bicarbonate to neutralize any excess acid, and the whole was evaporated to dryness in vacuum on the steam-bath. The residue was extracted with three 100-ml. portions of boiling chloroform. Evaporation in vacuum of the chloroform left 8.5 g. of gummy solid. This was recrystallized successively from 25-ml., 15-ml. and 10-ml. portions of ethyl acetate to yield 3.5 g. of white crystals, m. p. 144–146°. The ethyl acetate mother liquors were evaporated and cooled, and after several recrystallizations there was eventually obtained an additional 1.7 g. of pure product making the total yield 5.2 g. (42%). A small sample recrystallized from acetone melted at 145–146° and a sample sublimed in vacuum also melted at 145–146°.

*Anal.* Calcd. for $C_6H_8N_2O$: C, 58.05; H, 6.50; N, 22.57. Found: C, 58.33; H, 6.57; N, 22.42.

The melting point of the known 2-hydroxy-3,6-dimethylpyrazine is reported[1b] to be 210–211°. This difference in melting point in conjunction with the analytical data proves that the present compound must be 2-hydroxy-3,5-dimethylpyrazine.

The condensation of glycine amide with benzil was carried out in *hot* methanol solution.

**Hydroxypyrazine.**—To a solution of 12 ml. of 12.5 *N* sodium hydroxide in 50 ml. of methanol cooled to −20° was added 7.4 g. (0.10 mole) of glycine amide in 20 ml. of methanol. Then with stirring 30 g. (0.15 mole) of 30% aqueous glyoxal was added slowly while the temperature was maintained below −10°. After the solution had stood at room temperature for two hours, 15 ml. of acetic acid was added, and the mixture was evaporated to dryness under vacuum on the steam-bath. The residue was exhaustively extracted with acetone, and after evaporation of the acetone extract there was obtained 8.1 g. (84% yield) of crude hydroxypyrazine, m. p., 140–150°. This product was difficult to purify, but, eventually, after three recrystallizations from absolute alcohol using liberal quantities of activated carbon there was obtained 4.6 g. (48% yield) of pure hydroxypyrazine, m. p. 187–189°, and mixed m. p. with an authentic sample,[3] 187–189°.

**Condensation with Tyrosine Amide.**—The following example is typical. To a suspension of 8.5 g. (0.05 mole) of tyrosine amide in 50 ml. of methanol at −20° was added 12 g. (0.06 mole) of 30% aqueous glyoxal followed by 9 ml. (0.11 mole) of 12.5 *N* sodium hydroxide solution. The mixture was removed from the cooling-bath and allowed to stand overnight at room temperature. With stirring, 10 ml. of 12 *N* hydrochloric acid and 10 ml. of water were added and the solution was chilled to 0°. The white crystalline precipitate of 2-hydroxy-3-(*p*-hydroxybenzyl)-pyrazine (Table I) was collected on a filter, washed with water and air dried. It was recrystallized from methanol–ethyl acetate or methanol–water.

**2-Hydroxy-5,6-dimethyl-3-pyrazinoic Acid.**—A suspension of 11.5 g. (0.069 mole) of 2-hydroxy-3-carboxamido-5,6-dimethylpyrazine in 75 ml. of 3 *N* sodium hydroxide solution was heated on the steam-bath for several hours. Ammonia was evolved, and a clear brown solution formed. The solution was acidified with excess (25 ml.) concentrated hydrochloric acid and chilled to 0°. The crystalline precipitate was collected and air dried. It weighed 9.0 g. (79% yield). A sample was recrystallized from water; m. p. 172–174° (dec.).

*Anal.* Calcd. for $C_7H_8N_2O_3$: N, 16.66. Found: N, 16.86.

In the same way 2-hydroxy-3-carboxamidopyrazine was hydrolyzed to 2-hydroxy-3-pyrazinoic acid in 84% yield; m. p. 218–220°. The mixed melting point with a specimen prepared by the method of Weijlard, Tishler and Erickson[3] was also 218–220°.

**2-Hydroxy-5-methyl-3-pyrazinoic Acid.**—A suspension of 20 g. (0.13 mole) of crude 2-hydroxy-3-carboxamido-5-methylpyrazine in 75 ml. of 5 *N* sodium hydroxide solution was heated on the steam-bath for sixteen hours. The resulting solution was acidified and chilled to yield 6.0 g. (30%) of 2-hydroxy-5-methyl-3-pyrazinoic acid. A sample was recrystallized from water, in which it was appreciably soluble.

*Anal.* Calcd. for $C_6H_6N_2O_3$: C, 46.75; H, 3.92; N, 18.18. Found: C, 46.79; H, 3.99; N, 18.52.

The recrystallized compound melted with decomposition at 155–157°. Authentic 2-hydroxy-6-methyl-3-pyrazin-

(7) Very small yields of the desired 2-hydroxy-3-carboxamide-5-methylpyrazine were obtained when methylglyoxal was used in excess. With commercial 30% methylglyoxal (obtained from Carbide and Carbon Chemicals Corporation) the best yields of pyrazine compound were only 25 to 30%.

(8) Riley, Morley and Friend, *J. Chem. Soc.*, 1875 (1932).

oic acid (see below) melted and decomposed at 182–183°, and a mixture of the two melted and decomposed over the range 150–155°.

**2-Hydroxy-6-methyl-3-pyrazinoic Acid.**—A solution of 3.5 g. (0.023 mole) of 2-amino-6-methyl-3-pyrazinoic acid[3] in 100 ml. of 1.00 *N* hydrochloric acid was cooled to 10° and with stirring 4.5 g. (0.065 mole) of solid sodium nitrite was added in small portions. The solution stood at room temperature for one hour, and then it was heated at 70° for one-half hour. With stirring 3.0 g. (0.035 mole) of sodium bicarbonate was added, and the solution was evaporated to dryness in vacuum. The residue was extracted with 150 ml. of hot absolute alcohol, the alcohol solution was evaporated to 25 ml., and 200 ml. of dry ether was added. The resulting brown hygroscopic precipitate was recrystallized from 20 ml. of water to give 1.2 g. of tan powder. This was recrystallized from 4 ml. of water using carbon to decolorize, and 0.8 g. of light tan crystals were obtained; m. p. 183–184° (dec.).

*Anal.* Calcd. for $C_6H_6N_2O_3$: C, 46.75; H, 3.92; N, 18.18. Found: C, 47.04; H, 4.23; N, 18.65.

## Summary

A new pyrazine synthesis has been evolved in which 1,2-dicarbonyl compounds are caused to condense with α-amino acid amides to yield substituted hydroxypyrazines.

# The Catalytic Hydrogenation of the Benzene Nucleus. IV. The Hydrogenation of Methyl-substituted Benzoic Acids

BY HILTON A. SMITH AND JAMES A. STANFIELD

## Introduction

In an earlier paper[1] it was demonstrated that for the polymethylbenzenes the rate of catalytic hydrogenation of the benzene nucleus was governed not only by the number of substituents but also by their position. Those compounds which were symmetrically substituted reacted much faster than did others with the same number of substituents. Evidence that this was a question of symmetrical substitution and not of symmetry in the molecule itself was found in the fact that *p*-cymene hydrogenated more rapidly than did isopropylbenzene.

In order to study this matter further, a number of compounds have now been prepared which have both methyl groups and carboxyl groups attached to a benzene ring. With such compounds it should be possible to confirm the evidence that symmetrical substitution rather than molecular symmetry is the important factor.

## Experimental

**Benzoic, ortho-, meta- and para-toluic acids** were all obtained from the Eastman Kodak Company and were Eastman best grade materials.

**2,3-Dimethylbenzoic acid** was prepared from 3-nitro-1,2-dimethylbenzene. The nitro group was reduced with iron and hydrochloric acid[2] to form the amino compound, which was then converted to 3-iodo-1,2-dimethylbenzene.[3] This was then converted to 2,3-dimethylbenzoic acid using an adaptation of the Grignard reaction.[4]

**2,4-Dimethylbenzoic acid** was prepared by diazotization of the corresponding amino compound followed by treatment of the diazonium salt with potassium iodide.[5] The iodo compound was converted to the acid by treatment of the corresponding Grignard reagent with carbon dioxide.

**2,5-Dimethylbenzoic acid** was prepared by bromination of *p*-xylene[6] which was then converted to the acid by carbonation of the corresponding Grignard reagent.

**2,6-Dimethylbenzoic acid** was prepared from 2-amino-1,3-dimethylbenzene using the same general procedure as that employed in the preparation of the 2,3-dimethylbenzoic acid.

**3,4-Dimethylbenzoic acid** was prepared from *o*-xylene in a manner analogous to that used for the 2,5-dimethylbenzoic acid.

**3,5-Dimethylbenzoic acid** was prepared from mesitylene by oxidation with dilute nitric acid.[7]

**2,3,4-Trimethylbenzoic acid** was prepared; 3-iodo-1,2-dimethylbenzene was treated with magnesium and dimethyl sulfate to form hemimellitene in the same manner as that used in the preparation of isodurene.[8] The hydrocarbon was converted to 2,3,4-trimethylbenzaldehyde through the action of zinc cyanide in the presence of hydrogen chloride gas and aluminum chloride.[9] The aldehyde was then oxidized to the desired acid by means of a 20% permanganate solution.

**2,4,5-Trimethylbenzoic acid** was prepared by bromination of pseudocumene[10] followed by a Grignard reaction similar to that used in the preparation of 2,3-dimethylbenzoic acid.

**2,4,6-Trimethylbenzoic acid** was prepared from bromomesitylene by means of a Grignard synthesis.

**2,3,6-Trimethylbenzoic acid** was prepared from pseudocumene.[10] The pseudocumene was first sulfonated to form pseudocumenesulfonic acid-5[11] which was then brominated. This bromination to form a mixture of 5-bromopseudocumene and 3-bromopseudocumenesulfonic acid-5 has been previously carried out by Smith and Kiess[12] but the procedure was sufficiently modified to warrant description: 136 grams of pseudocumenesulfonic acid-5 ($C_6H_2(CH_3)_3SO_3H \cdot 1.5H_2O$) was suspended in 300 ml. of 20% hydrochloric acid solution; 122 g. of bromine suspended in 56

ml. of 20% hydrochloric acid was added to the cooled sulfonic acid suspension. The resulting jelly-like mass was stirred for several hours, and then allowed to stand overnight. The 5-bromopseudocumene together with some of the sulfonated material was removed by extraction with ether. The extract was washed with sodium bicarbonate until all acidic materials were removed. The ether was then removed by evaporation and the solid bromopseudocumene recrystallized from ethanol; 60 g. (50%) of white crystals, melting at 71–72° was obtained. In addition, 56 g. (33%) of 3-bromopseudocumenesulfonic acid-5 was recovered.

TABLE I

PHYSICAL CONSTANTS OF ACIDS HYDROGENATED

| Acid | Corr.[a] M. p., °C. | Neutral equivalent Found | Neutral equivalent Theoretical |
|---|---|---|---|
| Benzoic | 121.6–121.8 | 122.2 | 122.0 |
| *o*-Toluic | 106.0–107.0 | 136.2 | 136.1 |
| *m*-Toluic | 114.4–115.0 | 135.8 | 136.1 |
| *p*-Toluic | 182.0–183.0 | 136.3 | 136.1 |
| 2,3-Dimethylbenzoic | 144.5–144.8 | 150.7 | 150.2 |
| 2,4-Dimethylbenzoic | 125.4–125.8 | 150.3 | 150.2 |
| 2,5-Dimethylbenzoic | 133.8–134.1 | 150.4 | 150.2 |
| 2,6-Dimethylbenzoic | 115.8–116.2 | 150.0 | 150.2 |
| 3,4-Dimethylbenzoic | 167.4–168.2 | 149.7 | 150.2 |
| 3,5-Dimethylbenzoic | 171.6–172.0 | 150.2 | 150.2 |
| 2,3,4-Trimethylbenzoic | 166.6–167.4 | 164.5 | 164.2 |
| 2,3,6-Trimethylbenzoic | 102.4–102.8 | 164.4 | 164.2 |
| 2,4,5-Trimethylbenzoic | 150.8–151.2 | 164.6 | 164.2 |
| 2,4,6-Trimethylbenzoic | 157.0–158.0 | 164.4 | 164.2 |
| 2,3,4,6-Tetramethylbenzoic | 169.4–170.0 | 178.5 | 178.2 |
| 2,3,5,6-Tetramethylbenzoic | 179.4–180.0 | 178.3 | 178.2 |
| 2,3,4,5,6-Pentamethylbenzoic | 211.0–211.6 | 192.0 | 192.2 |

[a] All melting points have been corrected for emergent thermometer stem.

**2,3,4,6-Tetramethylbenzoic acid** was prepared using bromomesitylene as a starting material. This was converted to isodurene by the action of dimethyl sulfate on the corresponding Grignard reagent.[8] The isodurene was then brominated to form 4-bromo-1,2,3,5-tetramethylbenzene, which was then converted to 2,3,4,6-tetramethylbenzoic acid by the usual Grignard procedure.

**2,3,5,6-Tetramethylbenzoic acid** was obtained by brominating durene to form 3-bromo-1,2,4,5-tetramethylbenzene which was then converted to the desired acid by a Grignard procedure.

**2,3,4,5,6-Pentamethylbenzoic acid** was prepared by bromination of pentamethylbenzene followed by a Grignard synthesis.[4] The latter was somewhat complicated by the insolubility of both the magnesium complex in ether and the sodium salt of the acid in water. However, good yields (60%) were obtained.

It was necessary that all of these acids be very pure before hydrogenation was attempted. They were recrystallized several times; the solvent for the final crystallization was usually Eastman best grade cyclohexane. Occasionally this solvent was shaken with Raney nickel before use. Neutral equivalents of all acids were determined by titration with standard base. Table I gives the melting points and neutral equivalents of the acids.

As in earlier work, the acetic acid solvent was prepared by fractionation in a five-foot helix-packed still, and the platinum catalyst was either prepared by standard methods[14] or was a commercial sample. The hydrogenations were carried out in a low pressure Parr catalytic reduction apparatus in the manner previously described.[15] For the slower runs, the standard hydrogen reservoir tank (4.02 l.) was replaced by a smaller one (0.875 l.); 50 ml. of glacial acetic acid was used as solvent for each run. This solvent was purified before use by fractionation.

After each hydrogenation was complete, the platinum catalyst was recovered from the solution by filtration. Most of the solvent was then removed by distillation. If the product was a liquid or low-melting solid, it was purified by distillation through a 10-inch Vigreux column. If the product was of sufficiently high melting point so that good crystals could be obtained, the warm liquid from which the excess solvent had been removed was poured into water, and the crystals removed by filtration. The physical constants of the products are given in Table II.

TABLE II

PRODUCTS ISOLATED FROM HYDROGENATION

| Cyclohexanecarboxylic acid derivative | B. p. cor.[a] °C. | Mm. | M. p., cor.[a] | Neutral equivalent Found | Neutral equivalent Theory | $n^{20}D$ | Per cent. recovery |
|---|---|---|---|---|---|---|---|
| 2-Methyl- | 241.7–241.9 | 760 | | 141.9 | 142.1 | .... | 91 |
| 3-Methyl- | 143.5–143.8 | 21 | | 142.4 | 142.1 | 1.4570 | 93 |

| 2,3,4,6-Tetramethyl-[b] | | | 43.8–44.8 | 184.0 | 184.2 | | 85 |
| 2,3,5,6-Tetramethyl-[b] | | | 137.6–138.6 | 184.7 | 184.2 | | 87 |
| 2,3,4,5,6-Pentamethyl-[b] | | | 129.1–130.2 | 198.4 | 198.2 | | 78 |

[a] All melting and boiling points have been corrected for emergent thermometer stem. [b] New compounds.

The 5-bromopseudocumene was converted to 3-bromopseudocumenesulfonic acid-5 by the action of fuming sulfuric acid,[13] and subsequently hydrolyzed to form 3-bromopseudocumene. 2,3,6-Trimethylbenzoic acid was prepared from this bromide by a Grignard synthesis.

## Experimental Calculations and Results

It was established, as in previous work, that the hydrogenation reaction was first order with respect to hydrogen pressure, zero order with respect to the hydrogen acceptor, and directly proportional to the amount of catalyst used. This is also true for the compounds studied here, as is shown by Table III. These rate constants are calculated from the equation

$$\log \frac{p^0_{H_2}}{p_{H_2}} = \frac{kt}{2.303\ V}$$

by plotting log $p^0_{H_2}/p_{H_2}$ against $t$, and multiplying the slope of the line thus obtained by 2.303 $V$.[16] These constants all referred to one gram of standard catalyst at 30°[15,17] are given in Table IV. The table also includes constants for corresponding polymethylbenzenes.

TABLE III

EFFECT OF VARIABLES ON RATE OF HYDROGENATION OF METHYL-SUBSTITUTED BENZOIC ACIDS

| Acid | Moles | Grams of catalyst | Initial pressure (p. s. i.) | $k°_{30} \times 10^4$ |
|---|---|---|---|---|
| *o*-Toluic | 0.025 | 0.2000 | 64.7 | 312[a] |
| *o*-Toluic | .025 | .2000 | 17.9 | 319 |
| 2,3,5,6-Tetramethylbenzoic | .05 | .2000 | 64.7 | 35.6 |
| 2,3,5,6-Tetramethylbenzoic | .05 | .1000 | 64.7 | 34.8 |
| 2,4-Dimethylbenzoic | .03 | .2000 | 64.5 | 289 |
| 2,4-Dimethylbenzoic | .01 | .2000 | 65.0 | 291 |

[a] The units of all rate constants are liters × grams$^{-1}$ × min.$^{-1}$.

## Discussion

An examination of Table IV shows at once that the same trend is found in the reaction rate constants for the methyl-substituted benzoic acids as was found in the polymethylbenzenes. In general, the greater the number of substituents found on the benzene ring, the slower is the rate constant. However, whenever the number of substituents is the same, the position of substitution becomes important. In all cases, the most symmetrically substituted molecules hydrogenate faster. This confirms the idea that symmetrical substitution rather than molecular symmetry is the important factor in influencing the rate.

In the last column of Table IV is given the ratio of the rate constants for the corresponding methyl-substituted benzoic acids and polymethylbenzenes. This ratio, which indicates the effect of substitution of a carboxyl group for a methyl group, is fairly constant, the only noteworthy exception being the ratio of the rate constants for pentamethylbenzoic acid and hexamethylbenzene. This acid hydrogenates somewhat more readily than was anticipated. No explanation for this fact can be offered at the present time.

(16) Fuzek and Smith, THIS JOURNAL, **70**, 3743 (1948).

(17) These constants, $k°_{30}$, differ from those previously published by a factor of 4.43.

TABLE IV

COMPARISON OF RATE CONSTANTS WITH PREVIOUS DATA

| Methylbenzene | $k°_{30} \times 10^4$[b] | Corresponding methylbenzoic acid | $k°_{30} \times 10^4$ | Ratio of rate constants[a] |
|---|---|---|---|---|
| Toluene | 1800 | Benzoic | 1120 | 1.6 |
| *o*-Xylene | 932 | 2-Methyl- | 312 | 3.0 |
| *m*-Xylene | 1434 | 3-Methyl- | 813 | 1.8 |
| *p*-Xylene | 1882 | 4-Methyl- | 942 | 2.0 |
| Hemimellitene | 417 | 2,6-Dimethyl- | 200 | 2.1 |
| Hemimellitene | 417 | 2,3-Dimethyl- | 186 | 2.2 |
| Pseudocumene | 847 | 2,5-Dimethyl | 404 | 2.1 |
| Pseudocumene | 847 | 2,4-Dimethyl- | 289 | 2.9 |
| Pseudocumene | 847 | 3,4-Dimethyl | 350 | 2.4 |
| Mesitylene | 1680 | 3,5-Dimethyl- | 641 | 2.6 |
| Prehnitene | 282 | 2,3,4-Trimethyl- | 83.6 | 3.3 |
| Prehnitene | 282 | 2,3,6-Trimethyl- | 77.4 | 3.6 |
| Isodurene | 332 | 2,4,6-Trimethyl- | 209 | 1.6 |
| Durene | 529 | 2,4,5-Trimethyl- | 211 | 2.5 |
| Pentamethylbenzene | 103 | 2,3,4,6-Tetramethyl- | 61.3 | 1.7 |
| Pentamethylbenzene | 103 | 2,3,5,6-Tetramethyl- | 35.2 | 2.9 |
| Hexamethylbenzene | 18 | 2,3,4,5,6-Pentamethyl- | 23.2 | 0.8 |
| | | | Av. | 2.3 |

[a] The ratio of the rate constants is obtained by dividing the constant of the second column by the constant of the fourth column. The units of all rate constants are liters × grams$^{-1}$ × min.$^{-1}$. [b] Calculated from the data of Smith and Pennekamp (ref. 1) by multiplying the rate constants previously reported by 4.43. The value for hexamethylbenzene has been revised due to errors in previous calculation.

## Summary

A study has been made of the kinetics of catalytic hydrogenation of a number of methyl-substituted benzoic acids. The reactions were carried out at low pressures, in acetic acid solution, using Adams platinum catalyst. First-order reaction rate constants, all referred to one gram of standard platinum oxide, are given.

It has been demonstrated that the substitution of a carboxyl group for a methyl group cuts the rate of hydrogenation approximately in half. It has also been demonstrated that compounds with symmetrical substitution generally hydrogenate more readily than corresponding unsymmetrically substituted compounds.

# The Ultraviolet Absorption Spectra of Organic Sulfur Compounds. I. Compounds Containing the Sulfide Function[1]

BY EDWARD A. FEHNEL[2] AND MARVIN CARMACK

In connection with a study of the chemistry of certain organic sulfur compounds in this Laboratory, we have frequently had occasion to determine the ultraviolet absorption spectra of compounds containing the sulfide or sulfone functions. Since surprisingly little has been published concerning the absorption spectra of simple organic compounds of this type,[3] we have undertaken an extensive investigation of the absorption spectra of model compounds containing these functions for the purpose of providing data which should prove useful in structure determinations. The present paper describes the results obtained with aliphatic and aromatic sulfides, mercaptals and mercaptoles, alkoxysulfides, ketosulfides and carbalkoxysulfides. Further data on sulfones, nuclearly-substituted aromatic sulfides and sulfones, and heterocyclic sulfur compounds will appear in subsequent publications.

On the basis of the limited information heretofore available on the spectroscopic properties of the sulfide function, it has been stated that —$\ddot{S}$— is a resonance insulator with properties much like those of —$\ddot{O}$— and —$CH_2$—.[4] We have now observed an unusual type of conjugation between chromophores in compounds in which the sulfide function and another function such as a carbonyl, carbalkoxyl, vinyl, phenyl or second sulfide function are both attached to the same carbon atom. These observations lead to some interesting conclusions regarding the correlation of absorption spectra with structure in these types of compounds. A discussion of the theoretical aspects of the problem has been reserved until after a description of the spectra themselves.

**Aliphatic Sulfides.**—Alkyl sulfides in ethanol solution exhibit a narrow absorption band of rather high intensity (log $\epsilon \sim 3$) in the neighborhood of 210 m$\mu$ (Figs. 1–3). A gradual displacement of the maximum toward longer wave lengths and higher intensities is observed as the $\alpha$-hydrogen atoms are successively replaced by methyl groups in the series: methyl sulfide, ethyl sulfide, isopropyl sulfide and *t*-butyl sulfide (Fig. 1). A shoulder which appears on the long wave length side of the curves for methyl sulfide, ethyl sulfide (Figs. 1 and 2), *n*-butyl sulfide (Figs. 3 and 4) and pentamethylene sulfide (Fig. 5) in the region 225–235 m$\mu$ is considerably reduced in the curve for isopropyl sulfide and disappears in the curve for *t*-butyl sulfide. This shoulder is shifted 10 m$\mu$ toward longer wave lengths in the spectrum of tetramethylene sulfide, while the peak at 210 m$\mu$ is broadened and reduced in intensity as compared with the next higher homolog, pentamethylene sulfide (Fig. 5). The differences between the spectra of the latter two compounds presumably have a stereochemical basis and will be considered further in connection with our study of the spectra of heterocyclic sulfur compounds.

**Mercaptals and Mercaptoles.**—The marked optical interaction exhibited by compounds in which two sulfide functions are attached to a common carbon atom is illustrated in Figs. 2 and 3. In the spectra of the mercaptals a new peak (log $\epsilon \sim 2.8$) appears in the region 235–240 m$\mu$. Alkylation of the central carbon atom, as in 2,2-bis-(*n*-butylmercapto)-propane (Fig. 3), has only the effect of intensifying this new absorption band somewhat. As might be expected from the multiplicity of functional units, *sym*-trithiane (Fig. 2) has a spectrum similar to, but uniformly more intense than, those of the simple mercaptals. In contrast to these results, ethanol solutions of trioxane, the oxygen analog of *sym*-trithiane, are completely transparent throughout the region observable with the instrument and solvent used (down to ~208 m$\mu$).

The spectra of bis-(*n*-butylmercapto)-methane and *sym*-trithiane were determined in both ethanol and anhydrous dioxane, and the results, shown in Fig. 6, indicate only a very slight influence of the solvent on the position of the new peak in the region 235–240 m$\mu$. This band is not, therefore, attributable to dissociation or to chemical reaction with a hydroxylated solvent.

That there exists a profound difference in the spectral behavior of sulfur and oxygen was shown by replacing one of the sulfur atoms of a mercaptal with an oxygen atom in the monothioacetal, *n*-$C_4H_9SCH_2OC_2H_5$ (Fig. 4). It will be noted that the replacement of sulfur with oxygen not only results in the disappearance of the peak at 236 m$\mu$ but suppresses the intensity of absorption below that of even the simple alkyl

sulfides. A similar effect is observed in the spectra of the dimethoxysulfide, $CH_3OCH_2SCH_2OCH_3$, and of *n*-$C_4H_9SCH_2CH_2OC_2H_5$ (Fig. 4).

When two sulfide functions are separated by two methylene groups, as in 1,2-bis-(*n*-butylmercapto)-ethane (Fig. 3), the chromophores are effectively insulated from each other, and the spectrum is similar to that calculated for a simple monosulfide at twice the molar concentration.

A comparison of the relative effect of $-CH_2-$, $-\ddot{O}-$, and $-\ddot{S}-$ in six-membered rings is shown in Fig. 5 in the spectra of pentamethylene sulfide, 1,4-thioxane and 1,4-dithiane. Little difference is observed in the effect of sulfur and oxygen when either of these is separated from a sulfide function by two carbon atoms, in marked contrast to the unique behavior observed when only a single carbon atom intervenes between two sulfide functions.

**Allyl Sulfide.**—An example of the effect of having a vinyl group and a sulfide function attached to the same carbon atom is provided by the spectrum of allyl sulfide (Fig. 2). The curve, which consists of a broad absorption band having a maximum at 221 mμ, differs markedly from those of both non-conjugated alkadienes[5] (*e.g.*, 1,5-hexadiene, $\lambda_{max.} < 200$ mμ) and simple sulfides.

**Aromatic Sulfides.**—The ultraviolet absorption spectra of a number of typical aryl and aralkyl sulfides are illustrated in Figs. 7–11. Considerable interaction between sulfur and an attached benzene ring is evident in the spectra of phenyl sulfide (Fig. 9), benzyl phenyl sulfide (Fig. 9) and the phenyl alkyl sulfides (Figs. 7 and 8), all of which differ markedly from the spectra of simple benzenoid hydrocarbons such as toluene (Fig. 8). A smoothing out of the benzenoid fine structure and a great intensification of the absorption throughout are features which appear to be characteristic of the phenylmercapto group. However, a progressive change in the position of the long wave length maximum is noted when the α-hydrogen atoms in the phenyl alkyl sulfides (Fig. 7) are replaced stepwise by alkyl groups in the series: phenyl methyl sulfide ($\lambda_{max.}$ 254 mμ), phenyl ethyl sulfide ($\lambda_{max.}$ 256 mμ), phenyl isopropyl sulfide ($\lambda_{max.}$ 258 mμ), and phenyl *t*-butyl sulfide ($\lambda_{max.}$ 266 mμ). Simultaneously with the shift of the maxima toward longer wave lengths, a downward trend in intensities is observed (log ε: 3.98, 3.90, 3.75, 3.19, resp.). Progressive changes are likewise noted in the shoulder in the region 270–290 mμ and in the short wave length peaks at 200–220 mμ.

The effect of interposing one or more methylene

groups between the sulfide function and the benzene ring is illustrated in the curves for the homologous series: phenyl ethyl sulfide, benzyl ethyl sulfide, and phenethyl ethyl sulfide (Fig. 8). Although the spectrum of benzyl ethyl sulfide is less intense than that of phenyl ethyl sulfide, considerable interaction between the sulfur atom and the aromatic nucleus in the former compound is indicated by the development of a prominent shoulder at 235–240 mμ (log ε ~2.9). In this same region a minimum appears in the curve for phenethyl ethyl sulfide, which is essentially a summation of the spectra of an alkyl benzene and an alkyl sulfide. Analogous relationships, on a somewhat higher level of absorption, are observed with the corresponding series of symmetrical aryl-substituted sulfides: phenyl sulfide, benzyl sulfide and phenethyl sulfide (Fig. 9).

In contrast to the striking changes brought about in the absorption spectra of the alkyl sulfides by the attachment of a second alkylmercapto group to an α-carbon atom, there appears to be little evidence of interaction between the sulfide functions in the bis-(phenylmercapto)-methanes, $C_6H_5SCH_2SC_6H_5$ and $C_6H_5SC(CH_3)_2SC_6H_5$ (Fig. 10). The spectrum of the first compound is approximately that of phenyl ethyl sulfide at twice the molar concentration, and the spectrum of the second is similarly related to the curve for phenyl *t*-butyl sulfide. When one of the hydrogen atoms on the central carbon atom of a bis-(alkylmercapto)-methane is replaced by a phenyl group, as in $CH_3SCH(C_6H_5)SCH_3$ (Fig. 8), the resultant spectrum closely resembles that of benzyl ethyl sulfide except that the molar extinction values are uniformly about twice as large (0.3 log unit higher) in the case of the mercaptal.

The effect of substitution of oxygen in the alkyl portion of the aromatic sulfides is shown in the curves for $C_6H_5SCH_2OCH_3$ and $C_6H_5CH_2SCH_2OCH_3$ (Fig. 11). Here again oxygen exerts a suppressive effect on the absorption similar to that observed with the aliphatic alkoxysulfides.

**Ketosulfides.**—The aliphatic β-ketosulfides, ethylmercaptoacetone and α-ethylmercaptoisopropyl methyl ketone (Fig. 12), exhibit absorption maxima in approximately the same regions of the spectrum ($\lambda_{max.}$ 295–300 mμ and 240–245 mμ) as the aliphatic α,β-unsaturated ketones ($\lambda_{max.}$ 310–350 mμ and 230–250 mμ).[6] This conjugative effect disappears when the sulfide function and the carbonyl function are separated by two methylene groups, as in β-ethylmercaptoethyl methyl ketone (Fig. 12), the spectrum of which is essentially a summation of the spectra of a simple ketone and an alkyl sulfide. The presence of a well-developed peak at 235 mμ in the spectrum of tetrahydro-1,4-thiapyrone (Fig. 12) is somewhat surprising, but the absorption curve for this compound is very similar to that of an acyclic γ-ketosulfide at longer wave lengths.

The absorption spectra of several typical phenyl-substituted ketosulfides are shown in Figs. 13 and 14. Attachment of an alkylmercapto group to the α-carbon atom of a phenyl alkyl ketone, as in ω-ethylmercaptoacetophenone (Fig. 13), causes a pronounced bathochromic and hyperchromic displacement of the long wave length

(6) For a discussion of the spectra of the α,β-unsaturated ketones, see Woodward, THIS JOURNAL, **63**, 1123 (1941); **64**, 76 (1942).

portion of the curve. Substitution of an alkylmercapto group on a β-carbon atom, as in β-ethylmercaptopropiophenone (Fig. 13), has little effect upon the characteristic absorption of the benzoyl chromophore, and the resultant spectrum is almost identical with that of a phenyl alkyl ketone. The spectra of the α-phenylmercaptoketones, phenylmercaptoacetone and α-phenylmercaptoisopropyl methyl ketone (Fig. 14), appear to be approximately summations of the spectra of an aliphatic ketone and an appropriately substituted phenyl alkyl sulfide (phenyl ethyl sulfide and phenyl *t*-butyl sulfide, respectively).

**Carbalkoxysulfides.**—The spectra of several α- and β-carbalkoxysulfides are shown in Fig. 15. Strong interaction between the sulfide func-

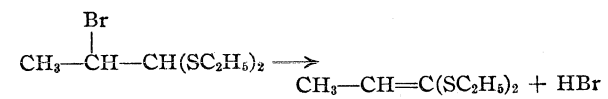
tion and the carbalkoxyl group in α-carbalkoxysulfides is indicated by the appearance of an absorption band at 247 mμ (log ε 2.54) in the spectrum of ethyl *n*-butylmercaptoacetate. The interpolation of a second methylene group between the sulfide and carbalkoxyl functions, as in methyl β-*n*-butylmercaptopropionate and methyl β-thiodipropionate, effectively insulates the chromophores from each other, with the result that the spectra of β-carbalkoxysulfides differ only slightly from those of simple alkyl sulfides. An ethoxyl group in the α-position of an ester has only a slight bathochromic effect on the absorption of the weakly chromophoric carbalkoxyl group, as shown in the comparison of the spectra of ethyl acetate and ethyl ethoxyacetate (Fig. 15).



## Discussion

The absorption of visible and near-ultraviolet radiation (800–200 mμ) by organic compounds is usually associated with a separation of electrical charge arising from the polarization of the π-orbital electrons of a system of multiple bonds.[7] A closely related phenomenon is the absorption of radiation in the far-ultraviolet region of the spectrum by molecules containing atoms with unshared pairs of valence electrons, which, like one of the electron pairs in a double bond, enter a π orbital in the molecule and interact more or less readily with electromagnetic vibrations of sufficiently high energy. Although absorption bands due solely to this process can generally be observed only at wave lengths below 200 mμ, the near-ultraviolet bands in the spectra of alkyl derivatives of such highly polarizable atoms as sulfur, bromine and iodine have been attributed to the excitation of these non-bonding electrons.[8] The displacement of these bands toward longer wave lengths with increasing alkyl substitution on the α-carbon atom has been ascribed to the accumulation on the sulfur and halogen atoms of a negative charge induced by the electron-releasing alkyl groups.[8b]

While this interpretation accounts satisfactorily for the absorption bands of the simple alkyl sulfides in the neighborhood of 210 mμ it fails to explain the extensive optical interaction which we have observed in the case of the alkylmercaptals and alkylmercaptoles. The appearance of a new long wave length band in the spectra of these compounds cannot be due to an inductive effect acting through the central carbon atom, since the $-I$ effect of each sulfur atom would be expected to put the π electrons of the other sulfur atom under additional constraint, thereby decreasing the normal absorption associated with each sulfide function. This is the observed result when one of the sulfur atoms is replaced by oxygen in the monothioacetals. The disappearance of the long wave length band and the return of the spectrum to the alkyl sulfide type when a second carbon atom is introduced into the molecule between the two sulfide functions also argues against an interpretation in terms of an inductive effect.

When absorption of visible or ultraviolet light by a polyfunctional molecule differs markedly from a summation of the spectra of the individual chromophores (*i.e.*, by exhibiting large bathochromic and hyperchromic displacements of the absorption bands characteristic of the component chromophores, or by the appearance of entirely new bands), the effect is generally regarded as evidence for the conjugation of the chromophoric groups. Since many of the polyfunctional sulfides show the optical behavior characteristic of conjugated systems, it is of interest from the theoretical point of view to deduce what modes of polarization are possible and probable in these compounds and to evaluate their effects on the optical properties of the system.

Two types of electronic interaction appear to be possible in the mercaptal system: (1) hyperconjugation involving the valence bonds of the central carbon atom, with attendant expansion of the valence shell of the sulfur atoms; and (2) direct interaction of the electronic fields of the two sulfur atoms through space. The hyperconjugation of C–H and C–C bonds with other groups has been discussed in connection with a number of physico-chemical problems, including its effect on absorption spectra.[9] It has been specifically suggested in connection with mercaptals by Rothstein[10] to account for the observed mobility of hydrogen attached to the central carbon atom in these compounds, as for example, in the spontaneous elimination of hydrogen bromide from 2-bromo-1,1-bis-(ethylmercapto)-propane, where the apparent proton-releasing

effect of sulfur is attributed to resonance forms in which sulfur has an expanded valence shell.[11]

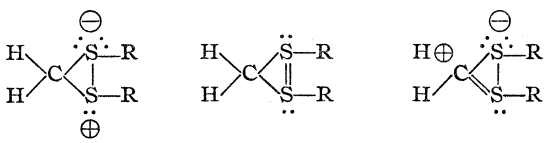
(10) Rothstein, *J. Chem. Soc.*, 1550, 1553, 1558 (1940).

(11) An expansion of the valence shell of sulfur in the sulfide function has also been proposed by Schomaker and Pauling [THIS JOURNAL, **61**, 1769 (1939)] to account for the observed value of the dipole moment of thiophene. It was found necessary to assume approximately a 10% contribution by structures of types a, b, and c, in

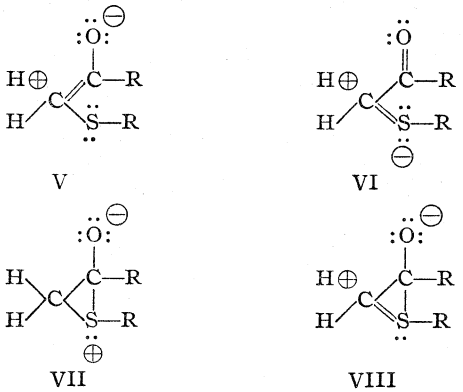


which the sulfur atom expands its valence shell to a decet.

Ia Ib Ic

Woodward and Eastman[12] have recently pointed out that Rothstein's mechanism would also account for the formation of 2-carbomethoxy-3-ketotetrahydrothiophene as the major product in the Dieckmann cyclization of $\alpha,\beta'$-dicarbomethoxymethylethyl sulfide at low temperatures.

The type of polarization represented by structures Ia and Ic might be considered to afford an adequate explanation for the development of a new peak in the region 235–240 m$\mu$ in the spectra of the alkylmercaptals and alkylmercaptoles. It is of interest to note, however, that the possibilities for polarized resonance forms are not exhausted by the structures postulated by Rothstein if one accepts the original assumption that the sulfide function can behave as either a donor or an acceptor of electrons. For example, there seems to be no reason for excluding the possibility of direct interaction of the electronic systems of the two sulfur atoms, involving a transfer of charge from one sulfur atom to the other and giving rise to polarizations along the line of centers of these atoms. Such interactions, illustrated in formulas II and III, imply the existence of transient three-membered rings. In addition, still other resonance forms (formula IV) can be



(two forms) (four forms)

II III IV

written which involve the simultaneous operation of this effect and the hyperconjugative effect proposed by Rothstein.[13]

That direct interaction may occur between the two sulfur atoms in the alkylmercaptals and alkylmercaptoles seems to be supported by the resemblance of the spectra of these compounds to those of the alkyl disulfides, RSSR, in which two sulfur atoms are joined by primary valence bonds.[14] The marked difference in the optical behavior of the mercaptals and monothioacetals is also consistent with this interpretation; while the oxygen atom can exert an inductive effect upon the sulfur atom, it cannot be considered to participate in resonance involving expansion of its valence shell to accommodate more than eight electrons.

Resonance forms embodying similar assumptions can be written for the $\beta$-ketosulfides, $\alpha$-carbalkoxysulfides, benzyl sulfides, and allyl sulfides. Thus, contributions from structures such as V–VIII might account for the characteristic absorption spectra of the $\beta$-ketosulfides.

V VI

VII VIII

In 1,2-bis-(alkylmercapto)-ethanes and $\gamma$-ketosulfides, little, if any, direct interaction between the functional groups would be anticipated, since these groups would, on the average, be widely separated in space. Possible exceptions might be found in cyclic compounds, such as 1,4-dithiane and tetrahydro-1,4-thiapyrone, in which the 1,4-atoms are restricted to relatively feeble oscillations between the positions corresponding to "chair" and "boat" forms of the rings and, as a result, are always in close proximity to each other.[15] It is interesting to note that the spectra of 1,4-dithiane and tetrahydro-1,4-thiapyrone differ from those of their acyclic analogs, and it is very probable that these differences are attributable to direct interaction between the 1,4-atoms.

When the sulfide function is attached directly to a benzene ring, a much larger number of modes of polarization are possible than in the case of the aliphatic sulfides. By analogy with the corresponding phenyl ethers, structures in which sulfur behaves as an electron donor with respect to the benzene ring would be expected to contribute heavily to the resonance in all phenylmercapto derivatives. If, however, the sulfur atom is also capable of accepting electrons from the aromatic nucleus, additional resonance structures can be

(12) Woodward and Eastman, THIS JOURNAL, **68**, 2229 (1946).

(13) The possible participation of cyclic structures such as II, III and IV depends not only upon the ability of sulfur to donate *and accept* electrons, but also upon the ability of the two sulfur atoms to approach each other sufficiently closely to interact. That such three-membered rings are not a stereochemical impossibility is indicated by considerable recent work on the role of neighboring groups in nucleophilic displacement reactions [*cf.* Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., New York, N. Y., 1940, pp. 176–178; Winstein and Buckles, THIS JOURNAL, **64**, 2780 (1942), and succeeding papers; Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, p. 242]. Studies on the mechanism of replacement of halogen in mustard gas have shown specifically that the sulfur atom may be involved in three-membered rings [*cf.* Gilman and Philips, *Science*, **103**, 409 (1946); Fuson, Price and Burness, *J. Org. Chem.*, **11**, 475 (1946)].

(14) Ethyl disulfide has an absorption band with a maximum at 249 m$\mu$ (log $\epsilon$ 2.63) [Ley and Arends, *Z. physik. Chem.*, **B15**, 311 (1932)].

(15) The close approach of the 1,4-atoms of these compounds in all possible configurations of the rings is only fully appreciated after an examination of the scale models; *e. g.*, Stuart or Fisher-Hirschfelder molecular models.

written which are not possible with the analogous oxygen compounds. The progressive changes observed in the spectra of the phenyl alkyl sulfides with increasing alkylation of the $\alpha$-carbon atom might result either from changes in the relative importance of resonance contributions by structures of these two types, or from steric effects, or from a combination of both these factors. A study of the absorption spectra of various nuclearly-substituted phenyl sulfides is being undertaken to provide additional data on this aspect of the problem, and the results will be described in a subsequent communication.

Regardless of the directional character of the polarization within the phenylmercapto group, it is evident that the resonance within this system is considerable, and it is not surprising, therefore, to find that the sulfur atom in this combination shows little or no tendency to interact with other functional groups attached to the $\alpha$-carbon atom. We can thus account for the fact that the attachment of a second phenylmercapto group or an acetyl group in this position on a phenyl alkyl sulfide fails to give rise to new absorption bands or to cause any appreciable displacement of the maxima characteristic of the parent sulfide.

An obvious implication of these concepts is that the unique properties postulated for the sulfide function on spectroscopic grounds should be reflected in the chemical reactivity of compounds containing this function. Several examples of the activation of methylene groups by adjacent alkylmercapto groups have been referred to[10,12] above, and other unusual properties of thio compounds have been reported which might be satisfactorily explained on the basis of these concepts. Further work is planned along chemical and physico-chemical lines suggested by the spectroscopic data.

## Experimental[16]

**Ultraviolet Absorption Measurements.**—The ultraviolet absorption spectra were determined with a Beckman quartz spectrophotometer, Model DU, using an approximately constant spectral band width of *ca.* 1 m$\mu$ down to wave lengths in the neighborhood of 220 m$\mu$. Readings at shorter wave lengths were obtained by using the 0.1 switch position and balancing the galvanometer for 100% transmission with the solvent in position before the phototube. The wave lengths and logarithms of the molar extinction coefficients at the absorption maxima and at prominent points of inflection are listed in Table I.

**Preparation of Compounds.**—Most of the previously known compounds were prepared by methods described in the literature or were obtained from commercial supply houses; source references are given in Table I. With several exceptions which are noted below, all compounds were purified by two or more redistillations or recrystallizations immediately before determination of the spectra. The physical constants for all previously known compounds except phenethyl sulfide (see below) checked those recorded in the literature.

bis-(Phenylmercapto)-methane,[17] 2,2-bis-(phenylmercapto)-propane,[18] and $\alpha,\alpha$-bis-(methylmercapto)-toluene,[19] decomposed so readily on heating that it was not found possible to purify the crude products by distillation, even at very low pressures. To obtain the pure compounds, large excesses of the sulfhydryl intermediates were employed in the preparations, and the crude oils

***t*-Butyl Sulfide.**[23]—A mixture of 225 g. of concentrated sulfuric acid and 65 g. of water was cooled in an ice-bath, and 50.4 g. (0.60 mole) of *t*-butyl alcohol was added at such a rate that the temperature of the mixture did not exceed 10°. After addition of the alcohol was complete, stirring and cooling were continued while 27.0 g. (0.30 mole) of *t*-butyl mercaptan was added dropwise over a thirty-minute period. The ice-bath was then removed and the mixture was allowed to warm to room temperature. The product was separated by pouring the reaction mixture into 500 g. of ice, extracting with ether, drying the combined extracts over anhydrous magnesium sulfate, and fractionally distilling the ether solution. After removal of the ether, a fraction boiling at 60–65° and consisting mostly of unreacted mercaptan was obtained; recovery, 7.1 g. The crude *t*-butyl sulfide boiled at 144–149°; yield, 27.9 g. (87%, taking the recovered mercaptan into account). Redistillation afforded pure material boiling at 148–149°.

**Phenethyl sulfide** was prepared by a modification of the method of Bermejo and Herrera,[24] using sodium sulfide nonahydrate instead of potassium sulfide. The product was a colorless oil, b. p. 190–192° at 8 mm. (yield, 67%), which crystallized when cooled in a Dry Ice–acetone mixture but remelted again below room temperature[25]; the earlier investigators[24] reported a melting point of 92°.

*Anal.* Calcd. for $C_{16}H_{18}S$: C, 79.27; H, 7.48. Found: C, 79.11; H, 7.35.

**Phenethyl Ethyl Sulfide.**—A solution of 13.6 g. (0.22 mole) of ethyl mercaptan and 8.8 g. (0.22 mole) of sodium hydroxide in 100 ml. of ethanol was heated to boiling, and 31.0 g. (0.22 mole) of phenethyl chloride was added dropwise at such a rate as to maintain refluxing without the application of external heat. The mixture was then refluxed for another thirty minutes after which most of the solvent was removed by distillation, the residue was diluted with several times its volume of water, and the layers were separated. The upper layer was washed with water, dried over anhydrous magnesium sulfate, and distilled under diminished pressure to yield 29.5 g. (81%) of colorless oil, b. p. 96–98° at 4 mm. This material was redistilled and the middle fraction, b. p. 96° at 4 mm., was taken for the spectrum determination.

*Anal.* Calcd. for $C_{10}H_{14}S$: C, 72.22; H, 8.49. Found: C, 72.27; H, 8.54.

**β-*n*-Butylmercaptoethyl Ethyl Ether.**—A solution of 45 g. (0.50 mole) of *n*-butyl mercaptan and 20 g. (0.50 mole) of sodium hydroxide in 200 ml. of ethanol was treated with 76.5 g. (0.50 mole) of 2-bromoethyl ethyl ether and worked up exactly as in the procedure above. Distillation of the crude product at reduced pressure gave 57.8 g. (71%) of colorless oil, b. p. 103–108° at 31 mm. The spectral sample was taken from the middle fraction of a second distillation; b. p. 105–106° at 30 mm.

*Anal.* Calcd. for $C_8H_{18}OS$: C, 59.20; H, 11.18. Found: C, 59.32; H, 11.34.

**Benzylmercaptomethyl Methyl Ether.**—A solution of 52.0 g. (0.42 mole) of benzyl mercaptan and 16.8 g. (0.42 mole) of sodium hydroxide in 200 ml. of ethanol was treated with 33.5 g. (0.42 mole) of chloromethyl methyl ether and worked up as above. Fractional distillation of the crude product afforded 11.7 g. (17%) of colorless oil, b. p. 128–133° at 19 mm. On redistillation most of this sample boiled at 128° at 18 mm.

*Anal.* Calcd. for $C_9H_{12}OS$: C, 64.23; H, 7.19. Found: C, 64.33; H, 7.11.

**α-Ethylmercaptoisopropyl methyl ketone** was prepared by an adaptation of the method for ethylmercaptoacetone,[26] using α-bromoisopropyl methyl ketone instead of chloroacetone. The crude product was obtained as a colorless oil, b. p. 64–67° at 15 mm., yield 73%. On redistillation most of this material boiled at 65–66° at 15 mm.

*Anal.* Calcd. for $C_7H_{14}OS$: C, 57.50; H, 9.65. Found: C, 57.51; H, 9.59.

**β-Ethylmercaptoethyl methyl ketone** was obtained by the dropwise addition of 8.7 g. (0.14 mole) of ethyl mercaptan in which a bit of sodium had been dissolved to 12.8 g. (0.18 mole) of methyl vinyl ketone, and distillation of the crude product at reduced pressure; yield, 10.9 g. (61%) of colorless oil, b. p. 78–79° at 10 mm.

*Anal.* Calcd. for $C_6H_{12}OS$: C, 54.51; H, 9.15. Found: C, 54.58; H, 9.01.

**β-Ethylmercaptopropiophenone** was prepared in a similar manner from 17.5 g. (0.13 mole) of phenyl vinyl ketone and 9.3 g. (0.15 mole) of ethyl mercaptan. The crude product solidified on standing overnight and was recrystallized from aqueous ethanol (Norit) to yield 13.4 g. (53%) of colorless microcrystalline powder, m. p. 46–47°.

*Anal.* Calcd. for $C_{11}H_{14}OS$: C, 67.99; H, 7.26. Found: C, 68.13; H, 7.17.

**α-Phenylmercaptoisopropyl methyl ketone** was prepared by an adaptation of the method for phenylmercaptoacetone,[26] using α-bromoisopropyl methyl ketone instead of chloroacetone. The crude product was obtained as a colorless oil, b. p. 115–117° at 5 mm., yield 65%. On redistillation most of this material boiled at 102° at 3 mm.

*Anal.* Calcd. for $C_{11}H_{14}OS$: C, 67.99; H, 7.26. Found: C, 67.88; H, 7.13.

**Methyl β-*n*-butylmercaptopropionate** was obtained by the cautious addition of 27.9 g. (0.31 mole) of *n*-butyl mercaptan, in which a bit of sodium had been dissolved, to 25.8 g. (0.30 mole) of methyl acrylate, and distillation of the crude product at reduced pressure; yield, 42.8 g. (81%) of almost colorless oil, b. p. 118–119° at 19 mm. Redistillation of this material afforded the pure compound as a colorless oil, b. p. 118° at 19 mm.

*Anal.* Calcd. for $C_8H_{16}O_2S$: C, 54.50; H, 9.15. Found: C, 54.30; H, 9.10.

## Summary

The ultraviolet absorption spectra are reported for forty-four organic compounds containing the sulfide function, including alkyl, aryl and aralkyl sulfides, mercaptals and mercaptoles, 1,2-bis-(alkylmercapto)-ethanes, alkoxysulfides, ketosulfides and carbalkoxysulfides. The prepara-

(23) Jones and Reid, *ibid.*, **60**, 2452 (1938), obtained a 6% yield of this compound as a by-product in the addition of hydrogen sulfide to isobutylene at 180° in the presence of sulfur.

(24) Bermejo and Herrera, *Congr. intern. quim. pura y aplicada 9th Congr., Madrid*, **4**, 238 (1934); *C. A.*, **30**, 3418 (1936).

(25) Oxidation of this product with excess 30% hydrogen peroxide in acetic acid gave the sulfone as colorless leaflets, m. p. 99–100° after recrystallization from aqueous ethanol; reported[24] m. p. for phenethyl sulfone 101°.

(26) Table I, source ref. 21.

tion of a number of new sulfides and a greatly improved method for the preparation of *t*-butyl sulfide are described.

Considerable optical interaction is observed when the sulfide function is attached to a benzene ring or to a carbon atom bearing a carbonyl, carbalkoxyl, phenyl, vinyl or alkylmercapto group. The apparent conjugative effect of the sulfide function in these compounds is not destroyed by alkylation of the central carbon atom, but when two methylene groups intervene between the functional groups, the absorption spectra are essentially summations of the spectra of the component chromophores.

An attempt is made to account for the interaction of the sulfide function with a second similar function or with an unsaturated group attached to the same carbon atom by assuming the formation of three-membered rings stabilized by resonance among forms in which sulfur has an expanded valence shell.

# Ultrasonic Investigation of Molecular Properties of Liquids. III.[1] Linear Polymethylsiloxanes[2]

BY ALFRED WEISSLER

Certain aspects of the relation between molecular structure and sound velocity in liquids may be studied by means of a polymer series. This has already been done (using four or five members of each series) in the cases of the polyethylene glycols,[3] polychlorotrifluoroethylene,[4] and polyisobutylenes.[5] The last is of special interest because it was in highly viscous polyisobutylenes that Mason found the first unquestionable example of sound velocity dispersion in liquids.

A polymer series in which the liquid state persists up to high molecular weights is the linear polydimethylsiloxanes,[6,7] of type formula

$$(CH_3)_3Si-\left[-O-\underset{CH_3}{\overset{CH_3}{Si}}-\right]_n-O-Si(CH_3)_3$$

where $n$ may vary from zero up to several hundred. These materials offer an opportunity for more extensive investigations than the three series mentioned above, where members of moderate molecular weight are already solids. In the present work, the velocity of sound, density and refractive index (D light) at 30° were measured for fourteen linear polydimethylsiloxanes, and the results were used to calculate adiabatic compressibility, ratio of specific heats and molecular weight.

## Experimental

The polymers used were those sold by Dow Corning under the name Silicone Fluids DC 500 and 200, viscosity grades from 0.65 to 1000 centistokes. Higher members are polymerization mixtures with the volatiles removed, but the first four fluids are chemical individuals—the dimer, trimer, tetramer and pentamer, respectively. A few measurements were also made on two partially phenylated polymethylsiloxane fluids, of the DC 700 and 702 series.

Sound velocity in these liquids was measured by means of the one-megacycle ultrasonic interferometer previously described.[1] Refractive indices were determined with an Abbe refractometer.

## Results and Discussion

The values of sound velocity listed in Table I are lower than for most organic liquids, except that replacing methyl groups by phenyls raises the velocity, as in the 700 and 702 fluids. Figure 1 is a semilogarithmic plot of the data, which shows

TABLE I

PHYSICAL PROPERTIES OF LINEAR POLYMETHYLSILOXANES (DOW CORNING SILICONE FLUIDS)

| Fluid | Velocity (meters/sec.) at 30.0° | Velocity (meters/sec.) at 50.7° | Temp. coeff. (meters/second/degree) | Refractive index (D) | Density, g./ml. |

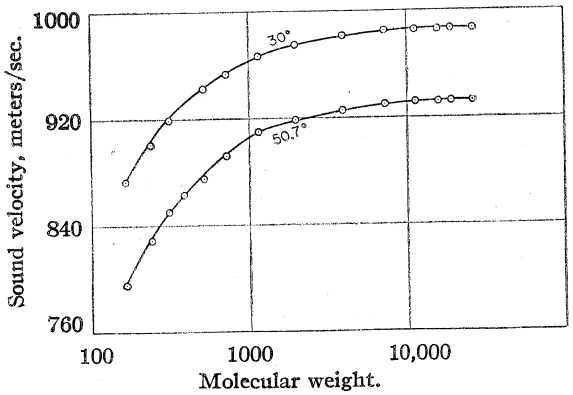

Fig. 1.—Sound velocity in the polydimethylsiloxane fluids.

that the velocity in polydimethylsiloxanes at first increases rapidly with molecular weight, but then levels off in the region of molcular weight 20,000. A similar leveling-off for the higher members is apparent in the refractive indices and densities.

Supplementary measurements at 50.7° showed that the rate of change of sound velocity with temperature decreases from −3.8 to −2.6 meters/second/degree as one goes from the lowest to the highest member (Table I). Such slopes are normal for liquids,[8] in contrast to the unusually flat viscosity–temperature slopes for which these silicone fluids are noted.

**Adiabatic Compressibility.**—From the sound velocity $v$ and density $d$, the adiabatic compressibility $K_{ad}$ is readily calculated by means of the equation

$$K_{ad} = 1/v^2d \qquad (1)$$

Table II reveals that the compressibilities so obtained are unusually high. This correlates with other characteristic properties of the silicones: low cohesive forces, low boiling points, and X-ray evidence[9] for large-amplitude oscillations of the methyl groups which sweep out umbrella-like surfaces.

The densities at 50.7°, required in eqn. (1), were computed with the aid of the thermal expansion coefficients supplied by the manufacturer.[10]

**Ratio of Specific Heats.**—The isothermal compressibility $K_{is}$ can be calculated from the relation

$$K_{is} = K_{ad} + T\alpha^2/c_pd \qquad (2)$$

where $T$ is the absolute temperature, $\alpha$ the coefficient of thermal expansion, and $c_p$ the specific heat at constant pressure. The values of $c_p$ at 30° for the first nine fluids were determined by electrical heating in a simple vacuum-bottle calorimeter,[11] with no attempt at high precision; they ranged from 0.45 calorie/gram for the 0.65 cs. fluid, to 0.39 calorie/gram for the 50 cs. fluid.

In Table II, the isothermal compressibilities calculated in this way are seen to be unusually high. A novel use of this property is in an aircraft landing gear developed in Great Britain, in which the spring action results from the compressibility of a silicone fluid.[12]

TABLE II

COMPRESSIBILITY OF LINEAR POLYMETHYLSILOXANES

| Fluid | Adiabatic compressibility ($10^{-12}$ sq. cm./dyne) at 30° | Adiabatic compressibility ($10^{-12}$ sq. cm./dyne) at 50.7° | Isothermal compressibility at 30° ($10^{-12}$ sq. cm./dyne) | Ratio of specific heats |
|---|---|---|---|---|
| 500–0.65 cs. | 174.1 | 219.5 | 228.7 | 1.31 |
| 1.0 | 151.7 | 186.4 | 196.4 | 1.29 |
| 1.5 | 140.4 | 169.7 | 176.6 | 1.26 |
| 2.0 | 133.3 | 160.0 | 165.9 | 1.24 |
| 3.0 | 126.4 | 151.2 | 155.5 | 1.22 |
| 5.0 | 121.0 | 141.9 | 145.6 | 1.20 |
| 10 | 115.2 | 133.2 | 136.6 | 1.19 |
| 20 | 111.6 | 128.8 | 132.3 | 1.18 |
| 50 | 108.8 | 125.1 | 128.3 | 1.18 |
| 200–100 | 107.6 | 123.4 | | |
| 200 | 107.1 | 122.5 | | |
| 350 | 106.8 | 122.1 | | |
| 500 | 106.7 | 122.0 | | |
| 1000 | 106.5 | 121.7 | | |
| 702–27 | 61.5 | | | |
| 700–50 | 91.3 | | | |

Also listed in Table II is the ratio of specific heats $\gamma$, which is equal to the ratio of isothermal to adiabatic compressibilities

$$\gamma = c_p/c_v = K_{is}/K_{ad} \qquad (3)$$

This ratio decreases monotonically as the molecular weight increases. Such a result is expected, because of the greater number of degrees of freedom in more complex molecules.

**Molecular Weight.**—An empirical method[3] for determining molecular weight $M$ within a polymer series (from sound velocity, density, and refractive index $n$) utilizes the equation

$$M = \frac{Bd}{v^{1/3} - A\left(\frac{n^2-1}{n^2+2}\right)} \qquad (4)$$

where $A$ and $B$ are two empirical constants characteristic of the series. For the polydimethylsiloxanes, these constants were evaluated at 40.885 and 48.10, respectively.

Equation (4) yielded the molecular weights listed in Table III, which have an average accuracy[13] of 5% for the first twelve of the fluids. It is

(12) T. K. Cordes, *Engineer's Digest*, March, 1946.

(13) The "theoretical" molecular weights are those kindly furnished by Dr. A. J. Barry of the Dow Chemical Co. in a personal communication. See also *J. Appl. Phys.*, **17**, 1020 (1946). Dr. Barry points out that his figures are not to be regarded as precise standards, because two fluids may have identical viscosities but different number average molecular weights, due to variations in polymerization technique.

evident that the results fall off in accuracy for values above about 15,000, because the computation then involves a very small difference between the two terms in the denominator of eqn. (4).

TABLE III

DETERMINATION OF MOLECULAR WEIGHTS OF POLYDIMETHYLSILOXANES BY THE SOUND VELOCITY METHOD

$$M = \frac{48.10d}{v^{1/3} - 40.855\left(\frac{n^2-1}{n^2+2}\right)}$$

| Fluid | Theoretical molecular weight | Found molecular weight | Deviation, % |
|---|---|---|---|
| 0.65 cs. | 162.2 | 141.0 | −13.1 |
| 1.0 | 236.3 | 233.7 | − 1.1 |
| 1.5 | 310.4 | 316.9 | + 2.1 |
| 2.0 | 384.5 | 371.6 | − 3.3 |
| 3.0 | 520 | 554 | + 6.5 |
| 5.0 | 720 | 753 | + 4.6 |
| 10 | 1,160 | 1,208 | + 4.1 |
| 20 | 1,970 | 1,971 | + 0.1 |
| 50 | 3,900 | 4,170 | + 6.9 |
| 100 | 7,100 | 7,680 | + 8.2 |
| 200 | 11,200 | 11,560 | + 3.2 |
| 350 | 15,800 | 15,440 | − 2.3 |
| 500 | 19,000 | 23,100 | +21.5 |
| 1000 | 26,500 | 23,200 | −12.5 |

In a paper that came to attention after this work was completed, Warrick[14] has shown how similar results may be obtained from refractive index and density data alone.

**Molar Sound Velocity Increments.**—Just as in the familiar case of molar refraction, the molar sound velocity $R = v^{1/3}M/d$ of a compound may be calculated by summing the increments[15] for each atom in the molecule, or alternatively for each bond in the molecule. No velocity increment involving silicon has previously been reported. Using the present data on the first four polymers and a value of 95.2 for the C–H bond, the bond increment for silicon–carbon is here determined as 35.4, and that for silicon–oxygen as 61.5. These figures give truly additive molar sound velocities, in which the deviations from experimental values are only a few tenths of a per cent.

Attempts to calculate an atomic increment for silicon gave values of 129, 122, 120 and 117, respectively, for the first four liquids. A corresponding lack of constancy in the atomic *refraction* increments for silicon in these same compounds has been reported[14]; it was necessary to use *bond* refraction increments, again, in order to attain an additive system. This situation was tentatively attributed to wide variations in the ionic character of the bonds in organosilicon compounds.

**Acknowledgment.**—The assistance of Patricia E. Mortell in the measurements of sound velocity is hereby gratefully acknowledged.

## Summary

The variation of sound velocity with molecular weight has been studied in a series of 14 polydimethylsiloxanes, at 30 and 50.7°. These fluids were found to possess remarkably high compressibilities.

Bond increments for the molar sound velocity have been determined for the silicon–carbon and silicon–oxygen bonds.

# Properties of Electrolytic Solutions. XXXVI. Effect of Addition Agents on the Conductance of Long Chain Salts[1]

BY GEORGE L. BROWN,[2] PHILIP F. GRIEGER[3] AND CHARLES A. KRAUS

## I. Introduction

In previous papers of this series, it has been shown that the addition of methanol to aqueous solutions of long chain salts has marked effect on their properties in the critical region and at higher concentrations.[4]

The present study was undertaken for the purpose of determining the effect of additives in somewhat greater detail in order to ascertain the generality of the phenomena and some of the underlying factors that influence observed results. The present, like the several preceding investigations, has been exploratory in nature. A high precision is not claimed for the results; nevertheless, it is believed that, in the critical region, they are not seriously in error. Precision measurements in the dilute region are now under way in this Laboratory, and the results will be communicated in due course.

The effect of additions of methanol, isopropyl alcohol and *t*-butanol on the conductance of dodecylammonium chloride in water was measured at several concentrations of the additives.

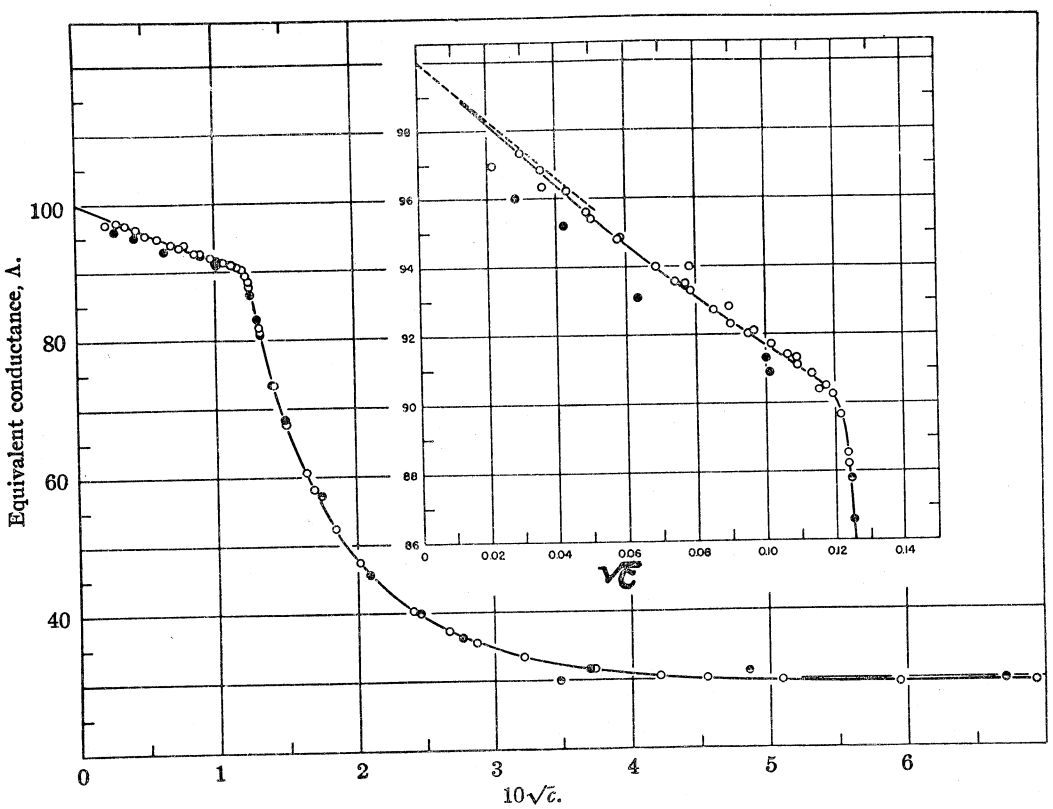

Fig. 1.—Dodecylammonium chloride in water at 25°: ○, this investigation; ●, Ralston and Eggenberger; ◓, Ralston, Hoerr and Hoffman. Dotted line on insert has theoretical slope.

More interesting, perhaps, are the results upon addition of methanol and tertiary butanol to solutions of octadecylpyridonium iodate and hexadecylpyridonium iodate; each of these two salts exhibits a maximum in pure water.[5]

Measurements were also carried out with dodecylammonium chloride in a 24.65% methanol–water mixture to which were added varying proportions of dodecanol: from 0.044 to 0.651 mole of dodecanol per mole of salt. The reason for carrying out the measurements in a methanol–water mixture was to increase the solubility of dodecanol.

The conductance of aqueous solutions of the hydrochlorides of two diamines having ten carbon atoms connecting the ammonium groups was measured for the purpose of determining whether or not they exhibit the usual properties of long chain salts.

## II. Experimental

**1. Apparatus and Procedure.**—These were substantially the same as those described in earlier papers of this series.[4] All measurements were carried out at 25 ± 0.01°.

**2. Solvents.**—Freshly distilled water was employed having a specific conductance of $1 \times 10^{-6}$ mho, or lower.

Methanol, after standing over lime, was decanted onto activated alumina pellets and, after refluxing, was distilled in a packed column. Middle and later fractions, excepting the last, had a conductance varying from $1 \times 10^{-7}$ to $0.3 \times 10^{-7}$.

Isopropyl alcohol, commercial Petrohol, was treated after the manner of methanol. Solvent having a specific conductance of $4 \times 10^{-9}$ was readily obtained. The density at 25° was found to be 0.7856 as against 0.7805 as given in the literature.[6] This may indicate the presence of some higher alcohols as impurities. For the purpose in hand, these could have little effect on the results obtained.

*t*-Butanol was purified by distillation. Its refractive index, $n^{25}D$, was found to be 1.3865.

Dodecanol was used as supplied by the dealer, without purification; it had a negligible specific conductance.

**3. Salts: Dodecylammonium Chloride.**—Hydrogen chloride was passed through a solution of the amine (purified by distillation, m. p., 27.9–28.2°) in diethyl cellosolve. The product, after filtration, was twice recrystallized from diethylcellosolve. It was finally recrystallized from absolute ethanol and washed with acetone; m. p. (sealed tube) 182.3°; chlorine: found, 15.95 ± 0.02; theory, 15.985%.

Hexadecylpyridonium iodate was prepared by metathesis of the iodide with freshly prepared silver iodate in ethanol. After filtration, the salt was precipitated by addition of acetone and recrystallized four times from an acetone–ethanol mixture; iodate: found, 36.6 and 37.2%; calcd., 36.5%. Difficulty was experienced in the analyses due to absorption of iodine by the hexadecylpyridonium iodide which precipitated upon addition of potassium iodide.

Octadecylpyridonium iodate was prepared like the corresponding hexadecyl compound; iodate: found, 34.31 and 34.68%; calcd., 34.49%.

1-N-Morpholino-10-N′-piperidinodecane dihydrochloride and di-*n*-propylamino-10-N-piperidinodecane dihydrochloride were made from the corresponding amines which were kindly furnished by Dr. N. J. Leonard, of the Univer-

(5) Brown, Grieger, Evers and Kraus, THIS JOURNAL, **69**, 1835 (1947).

(6) Brunel, *ibid.*, **45**, 1334 (1923).

sity of Illinois. Preparation and analysis of the amines are described by Price, Guthrie, Herbrandson and Peel.[7] Analyses of the salts are as follows: morpholino salt, chlorine: found, 18.55%; calcd., 18.50%; dipropyl salt, chlorine: found, 17.85%; calcd., 17.85%.

## III. Results

The results of measurements with dodecylammonium chloride in water and mixtures containing varying amounts of tertiary butanol, isopropyl alcohol and methanol, respectively, are presented in Table I. The square root of concentration, in moles per liter of solution, appears in the first column and the corresponding value of the equivalent conductance in the second column. Results are shown graphically in Figs. 1, 2 and 3.

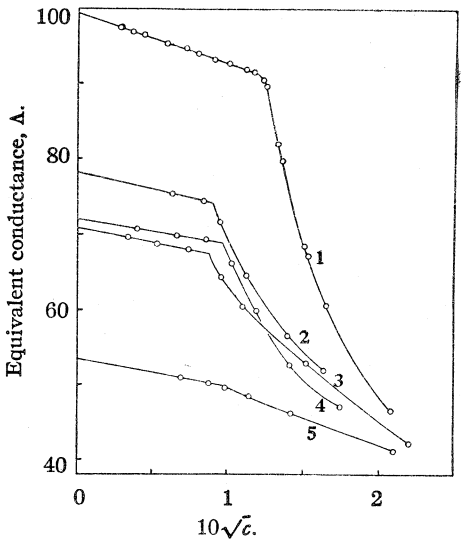

Fig. 2.—Dodecylammonium chloride in alcohol–water mixtures at 25°: (1) water, (2) 5.66% *t*-butanol, (3) 7.88% *t*-butanol, (4) 8.00% isopropanol, (5) 16.19% isopropanol.

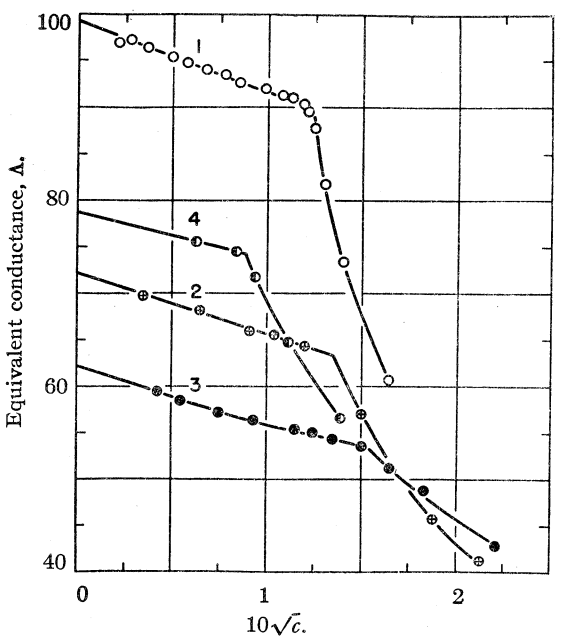

Fig. 3.—Dodecylammonium chloride in methanol–water mixtures at 25°: methanol, %: (1) 0.0, (2) 16.19, (3) 24.65; butanol, %, (4) 5.66.

(7) Price, Guthrie, Herbrandson and Peel, *J. Org. Chem.*, **11**, 281 (1946).

The results for octadecylpyridonium iodate in pure water and in the presence of methanol and *t*-butanol, and for hexadecylpyridonium iodate in water and in the presence of *t*-butanol, are similarly given in Table II. The results are shown graphically in Fig. 4.

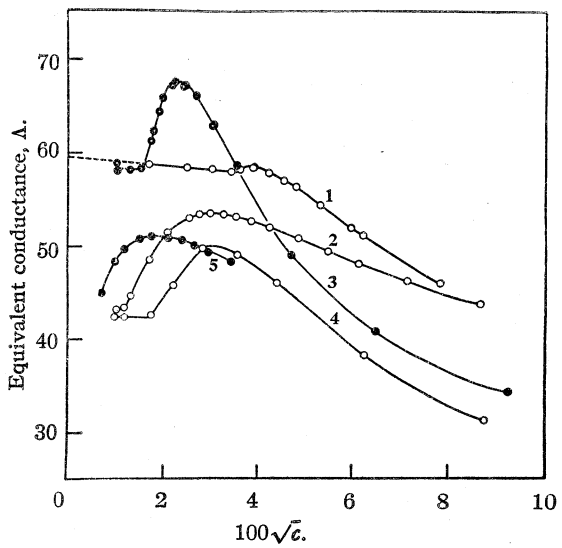

Fig. 4.—Hexadecylpyridonium iodate in: (1) water, (2) 7.94% *t*-butanol; octadecylpyridonium iodate in: (3) water, (4) 16.18% methanol, (5) 10.15% *t*-butanol.

In Table III are presented the results for dodecylammonium chloride in a 24.65% methanol–water mixture to which were added 0.110, 0.261 and 0.651 mole of dodecanol per mole of salt, respectively. Measurements were also carried out with mixtures containing, respectively, 0.044 and 0.246 mole of dodecanol per mole of salt. These values are shown in Fig. 5 along with those for which numerical data are given in the table.

The results for the diammonium salts are shown graphically in Fig. 6.

Except in the case of solutions of dodecylammonium chloride and the diammonium salts in water, solution densities were taken equal to solvent densities. The densities of aqueous solutions of dodecylammonium chloride at 25° were computed from the equation of Ralston and Hoerr.[8]

Values of the specific conductance, $\kappa_0$, the density, $d$, and the dielectric constant, $D$, for the solvent mixture are given at the head of each table. The composition of the solvent mixtures is given in weight per cent. of additive.

(8) Ralston and Hoerr, THIS JOURNAL, **64**, 772 (1942).

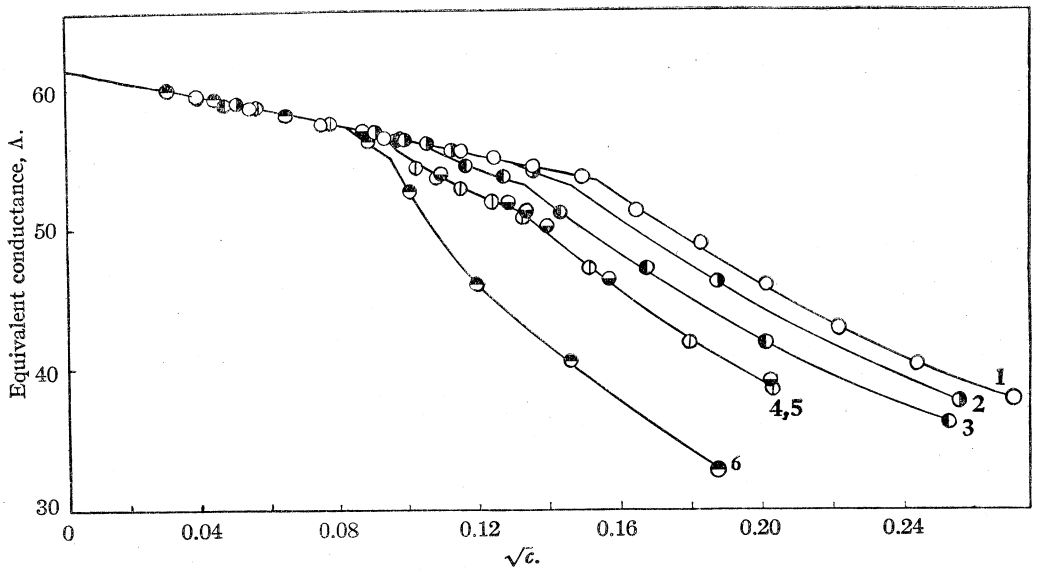

Fig. 5.—Dodecylammonium chloride in 24.65% methanol on addition of following moles of dodecanol per mole salt: (1) 0.0, (2) 0.044, (3) 0.111, (4) 0.246, (5) 0.261, (6) 0.651.

## IV. Discussion

**1. Conductance of Dodecylammonium Chloride in Water at 25°.**—In Fig. 1, the equivalent conductance of dodecylammonium chloride is plotted as a function of the square root of concentration. The results of Ralston and his coworkers are also shown for comparison. As may be seen from inspection of the figure, our results are in excellent agreement with those of Ralston and Eggenberger[9] at concentrations higher than the critical and are in fair agreement at lower concentrations. Our results are also in fair agreement with those of Ralston, Hoerr and Hoffman[10] at concentrations greater than critical.

The results of the present investigations are not sufficiently precise to establish definitely the form of the conductance curve below the breakpoint. For example, the solvent correction is about 1 and 10% at concentrations of $10^{-3}$ and $10^{-4}$, respectively. They indicate, however, that Λ is not a linear function of $\sqrt{c}$ up to the breakpoint, since an upward curvature is noticeable. Below $3 \times 10^{-3}$, the curve approximates the Onsager slope (*viz.*, 83) within the experimental error.

| 14.34 | 51.02 | 10.81 | 53.51 | 11.92 | 45.92 |
| 16.76 | 47.06 | 11.48 | 52.76 | 14.60 | 40.48 |
| 20.12 | 41.76 | 12.37 | 51.79 | 18.75 | 32.74 |
| 25.28 | 36.17 | 13.27 | 50.66 | | |
| | | 15.11 | 47.03 | | |
| | | 17.94 | 41.76 | | |
| | | 20.29 | 38.49 | | |

The critical concentration lies between 1.42 and $1.44 \times 10^{-2}$. Ralston, Hoerr and Hoffman[11] give $1.30 \times 10^{-2}$. Corrin and Harkins,[12] using the indicator method, found values ranging between 1.24 and $1.36 \times 10^{-2}$, depending upon the dye used.

**2. Effect of Alcohols on Dodecylammonium Chloride in Aqueous Solution.**—As appears from the earlier work of Evers[4] and of Grieger,[4] the hexadecyl and octadecyl quaternary ammonium salts, as used by them, show a marked shift of the breakpoint toward higher concentrations on addition of methanol. The same is true of solutions of dodecylammonium chloride as appears from Fig. 3. Whether or not there is an initial recession of the break point concentration on addition of small amounts of methanol is uncertain, but it may be inferred that, if it occurs at all, it is very small.

The effect of different alcohols on the breakpoint concentration of dodecylammonium chloride is of interest. The effect is shown graphically in Figs. 2 and 3 and the values are given in Table IV.

TABLE IV

EFFECT OF ALCOHOLS ON BREAKPOINT CONCENTRATION, $C_b$, OF DODECYLAMMONIUM CHLORIDE IN WATER

| Alcohol | % Alcohol | $C_b \times 10^2$ |
|---|---|---|
| ..... | 0.0 | 1.4 |
| Methanol | 16.2 | 3.1 |
| Methanol | 24.7 | 5.2 |
| Isopropyl | 8.0 | 0.92 |
| Isopropyl | 16.2 | 1.04 |
| *t*-Butanol | 5.7 | 0.79 |
| *t*-Butanol | 7.9 | 0.74 |

It will be noted that for dodecylammonium chloride, as for quaternary hexadecyl and octadecyl compounds, the addition of methanol causes an increase in the breakpoint concentration. Isopropyl alcohol, on the other hand, causes a marked decrease of the critical concentration. Thus, 16% of methanol raises the breakpoint from $1.4 \times 10^{-2}$ to $3.1 \times 10^{-2}$, while 16% of isopropyl lowers it to $1.04 \times 10^{-2}$. The decrement, in the case of *t*-butanol, is even greater the breakpoint falling to $0.74 \times 10^{-2}$ for 8% of this alcohol as against $0.92 \times 10^{-2}$ for 8% of isopropyl alcohol.

(11) Measurements by P. F. Grieger.

(12) Corrin and Harkins, THIS JOURNAL, 69, 683 (1947).

The breakpoint concentration passes through a minimum on addition of isopropyl alcohol but in the case of *t*-butanol, the concentration is still decreasing as far as the highest content of alcohol measured. Ralston and Hoerr[13] have determined the effect of ethanol on the breakpoint of dodecylammonium chloride. They found little change on initial addition and a marked shift toward higher concentration for larger additions.

It is, thus, evident that the effect of an added alcohol on the breakpoint concentration is markedly dependent on the number of carbon atoms in the alcohol.

**3. Hexadecyl- and Octadecylpyridonium Iodate.**—These two salts are remarkable in that both exhibit a maximum in their conductance curves in pure water.[14] The results are shown graphically in Fig. 4, curves 1 and 3. In curves 2, 4 and 5 are shown the results obtained on adding tertiary butanol and methanol.

For convenience in discussion, numerical values are given in Table V for some of the variables that characterize the curves of Fig. 4. The concentration at which the curve begins to rise above the straight line in dilute solution is termed the "risepoint."

TABLE V

CHARACTERISTIC VALUES FOR CURVES OF FIGURE 4

| Solvent mixture | Λ Risepoint | Λ Max. | Rise, % | $c \times 10^4$ Risepoint | $c \times 10^4$ Max. |
|---|---|---|---|---|---|
| **Hexadecylpyridonium Iodate** | | | | | |
| Water | 58.0 | 58.6 | 1 | 9.9 | 16 |
| 7.9% Butanol | 43.3 | 53.5 | 24 | 1.35 | 9 |
| **Octadecylpyridonium Iodate** | | | | | |
| Water | 57.8 | 67.6 | 17 | 0.9 | 5 |
| 16.2% Methanol | 42.6 | 49.8 | 16 | 2.9 | 8 |

These two salts are of particular interest in that they enable us to study the effect of various factors on the maximum phenomenon in water. The addition of two carbon atoms to the hexadecyl chain decreases the risepoint concentration to one-tenth that of the hexadecyl compound. The rise at the maximum is increased from 1 to 17% and the concentration of the maximum is reduced in the ratio of 3 to 1. It is apparent that the maximum phenomenon is very sensitive to the length of the hydrocarbon chain.

On addition of 16% methanol to the solution of the octadecyl compound, no great change occurs; the conductance increase at the maximum is not appreciably altered, the risepoint and the maximum are shifted toward higher concentrations. In 10% *t*-butanol, the risepoint concentration could not be determined but it appears from curve 5 that it is not far from $0.5 \times 10^{-4}$. The value of Λ at the maximum is 51 and the limiting conductance of octadecylpyridonium iodate, based on the conductance of this salt in water and potassium iodate in water and in the butanol–water mixture[15] is 40. Thus, the height of the maximum in water and in the 10% *t*-butanol mixtures is approximately the same. Although the measurements were carried to a concentration of only $10^{-3}$, it is evident that the bow of the maximum is much broader in 10% *t*-butanol than in water.

On addition of *t*-butanol to a solution of the hexadecyl compound, the conductance curve is greatly altered. The increase of κ at the maximum rises from 1 to 24% and the bow of the maximum is widened toward both lower and higher concentrations. The risepoint is shifted to lower concentration in the ratio of 7 to 1 and the maximum is shifted in the same direction in the ratio of 2 to 1.

**4. Dodecylammonium Chloride on Addition of Dodecanol.**—Measurements were carried out with five different proportions of dodecanol to salt in a 25.64% methanol–water mixture; the results for three of them are presented in Table III, while all are shown graphically in Fig. 5. Two series were carried out for nearly the same proportion of alcohol to salt; the results are in good agreement as may be seen from curves 4 and 5 of the figure.

With increasing proportion of dodecanol, the breakpoint recedes to lower concentration. Breakpoint values are presented in Table VI.

TABLE VI

BREAKPOINT CONCENTRATIONS FOR DODECYLAMMONIUM CHLORIDE ON ADDITION OF DODECANOL IN 25.64% METHANOL–WATER MIXTURE

| Moles dodecanol per mole salt | 0.0 | 0.044 | 0.111 | 0.261 | 0.651 |
|---|---|---|---|---|---|
| Breakpoint concn. $\times 10^2$ | 2.37 | 1.69 | 1.08 | 0.83 | 0.69 |

The breakpoint concentration is markedly lowered (to 1/3) on addition of 0.651 mole of dodecanol per mole of salt. More significant, perhaps, is the fact that at concentrations below the breakpoint, the conductance values are the same as in the pure solvent mixture, regardless of the proportion of dodecanol. This indicates that below the breakpoint, the salt behaves like a normal electrolyte and is unaffected by the dodecanol. This result is at variance with those obtained by Ralston and Hoerr[16] for dodecylammonium chloride in aqueous solutions on addition of methyllauramide, dodecane and lauronitrile. These authors found only a slight depression in the breakpoint concentration on making the additions, while they found the conductance to be strongly (and rather uniformly) depressed at all salt concentrations, even below the breakpoint. For a given addition agent, the conductance was found to be independent of the amount of non-electrolyte added.

(13) Ralston and Hoerr, THIS JOURNAL, **68**, 2460 (1946).

(14) Recently, Ralston, Eggenberger and Du Brow, *ibid.*, **70**, 977 (1948), found that the equivalent conductance of didodecyldimethylammonium chloride in water passes through a maximum in the neighborhood of $C = 10^{-4}$.

(15) Unreported measurements by P. F. Grieger.

(16) Ralston and Hoerr, THIS JOURNAL, **69**, 883 (1947).

More recently, Ralston and Eggenberger[17] have reported that the equivalent conductance of dodecylammonium chloride in water and in water saturated with a number of sparingly soluble organic non-electrolytes (hydrocarbons, alcohols, etc.) is the same at concentrations less than the critical.

As the concentration of dodecylammonium chloride is increased above that of the breakpoint in the presence of dodecanol, there occurs a change in the character of the curves which may be of the nature of a second breakpoint. This is best shown by curves 4 and 5 for 0.246 and 0.261 mole of dodecanol per mole of salt. The two series are in good agreement, and there is little doubt that, at a certain concentration, the course of the curves undergoes a marked change. At concentrations above the "second breakpoint," the curves are all convex to the concentration axis, and they parallel one another rather closely.

It is of interest to note that for 0.044 and 0.111 mole of dodecanol per mole of salt, the solutions remained homogeneous over the entire range of concentration. For 0.26 mole of dodecanol, the solution became cloudy at the second breakpoint, the cloudiness increasing up to the first breakpoint; thereafter, the cloudiness decreased with dilution. For 0.65 mole of dodecanol, the solution was cloudy, although stable, over the whole range of concentration. The reproducibility of the results leaves little doubt that, in these solutions, we are dealing with a system in equilibrium. The fact that below the breakpoint the curves coincide for all proportions of alcohol to salt is strong evidence that under these conditions the two (alcohol and salt) are not associated.

**5. Salts of Doubly Charged Long Chain Ions.**—It was of interest to determine whether salts with two ions connected by a hydrocarbon chain would exhibit properties similar to those of uni-univalent long chain salts. Measurements were carried out with 1-N-morphine 10-N′-piperidinodecane dihydrochloride and di-N-propyl-10-N-piperidinodecane dihydrochloride. The results are shown graphically in Fig. 6 along with the conductance curve for decylammonium chloride at 20° as determined by Ralston and Hoerr.[18] As may be seen from the figure, the conductance curves for the diammonium salts exhibit no singularities up to 0.25 *N*. It may be concluded that these salts do not exhibit the properties of ordinary long chain electrolytes over the concentration range measured, at least not so far as conductance is concerned.

## V. Summary

1. The effect of isopropyl alcohol and *t*-butanol on the conductance of dodecylammonium chloride in aqueous solution has been determined and compared with that of methanol.

2. It has been found that octadecylpyridonium and hexadecylpyridonium iodate exhibit a maximum in their conductance curves in aqueous solution; the maximum is much the more pronounced for the octadecyl compound.

3. The effect of methanol and *t*-butanol on the conductance of the octadecyl compound in aqueous solution has been determined as has also that of *t*-butanol on solutions of the hexadecyl compound. The effect of butanol in the case of the latter compound is very pronounced.

4. The effect of dodecanol on the conductance of solutions of dodecylammonium chloride in a 25.64% methanol–water mixture has been studied. The breakpoint concentration is lowered on addition of dodecanol; at concentrations below the breakpoint, the conductance is unaffected by addition of dodecanol. There are indications of a second break at concentrations above that of the normal breakpoint.

5. The conductance of the two diammonium salts with ten carbon atoms between the ionic groups follows the course of a normal electrolyte as far as measured (0.25 *N*).

# Activity of Cadmium Iodide in Deuterium Oxide

BY EVAN C. NOONAN[1]

Many salts have been found to be less soluble in deuterium oxide than in protium oxide. Provided the solid phase is not hydrated the activities of the electrolyte in both solvents must be identical at saturation, *i. e.*

$$(A) \qquad m_H\gamma_H = m'_D\gamma'_D$$

In this expression $m_H$ and $m'_D$ represent the concentrations in terms of moles of salt per 55.507 moles of solvent, $\gamma_H$ is the conventional stoichiometric mean ionic activity coefficient in water whose value is unity at infinite dilution, while $\gamma'_D$ is a relative activity coefficient defined by the above equation. The value $\gamma'_D$ at infinite dilution in $D_2O$ is not unity; it combines the change in standard state in passing from $H_2O$ to $D_2O$ with the conventional activity coefficient in $D_2O$. Although $\gamma'_D$ was termed an absolute activity coefficient by La Mer and Noonan[2] this designation is somewhat misleading since it is not referred to an absolute standard state. While the relative activity coefficient defined in this way could be used to describe the behavior of a given salt in any pair of solvents it is of particular value in the case of protium and deuterium oxides since the molecular volumes and dielectric constants of these solvents are nearly identical, and contributions to the change in standard state from these sources may usually be neglected. Any pronounced differences in activity effects between $H_2O$ and $D_2O$ can be directly compared, and are of interest since important factors of electrolytic behavior may be revealed which are not accounted for by present theories.

It has been suggested[3] that the macromolecular structure of water is responsible for solubility differences of salts in $H_2O$ and $D_2O$. The greatest effects should therefore be observed at the highest dilutions, since the structure of the solution would then approach that of the undisturbed solvent. Only limited information is obtainable from solubility determinations in this region; activity data for salts in heavy water as a function of concentration are therefore desirable.

Eddy and Menzies[4] found that cadmium iodide was 26% less soluble in heavy water than in light water at 25°, indicating that further study of this salt might prove profitable. Bates[5] determined thermodynamic properties of cadmium iodide using the cell

$$(B) \qquad Cd\text{–}Hg(2\ phase)/CdI_2(m\ in\ H_2O)/AgI\text{–}Ag$$

Information obtained from measurements on a similar cell using $H_2O$–$D_2O$ mixtures as the solvent is the subject of this paper.

## Experimental

**A. Preparation of Materials: Deuterium oxide** was purified before each determination by consecutive vacuum distillation from alkaline permanganate and then from a crystal of potassium dichromate or chromic anhydride. Water treated in this manner was found to have a conductance of $2 \times 10^{-6}$ mho or better.

**Cadmium iodide** was purified by the method of Baxter and Hartman for cadmium chloride.[6] A C.P. grade of cadmium iodide was fused in a glass vessel, cooled, dissolved in distilled water and filtered from an insoluble residue. The solution was then evaporated and the process repeated for a total of five times. The resulting salt was recrystallized twice.

**Cadmium Amalgam.**—An 800-g. sample of cadmium metal was distilled three times in vacuum using an all glass apparatus. The distillate amounted to 300 g. and carefully purified mercury was distilled upon it to give a saturated amalgam. During the course of the experiments, this amalgam was found to be awkward to use with the micro equipment involved and became contaminated with stopcock grease. It was then filtered through sintered glass and divided into two portions, one of which was diluted with mercury to yield a single phase amalgam. All these operations were carried out in vacuum or under an atmosphere of nitrogen.

**Silver Iodide Electrodes.**—These were made by the thermal method recommended by Bates.[5]

**B. Apparatus and Procedure.**—A 16-ml. pyrex pycnometer fitted with platinum electrodes was used to determine the density and conductivity of heavy water. Ground glass joints were used on the pycnometer, cell, weighing flasks and on all parts which came into contact with the heavy water solutions. All apparatus other than the pycnometer was carefully cleaned, steamed and dried before use. All parts of the apparatus were pyrex except the silver iodide electrode supports which were made of hard Jena glass.

Solutions for each cell were made up from 16 ml. of heavy water and the appropriate amount of dry salt. For the 0.1 molal solutions, the amount of water was adjusted with a 0.25-ml. hypodermic syringe calibrated to 0.01 ml. The three least concentrated solutions were made by diluting a stock solution. All solutions were evacuated to remove dissolved air and a nitrogen atmosphere substituted in the weighing flasks. The usual corrections were applied for the buoyancy of air.

The cell employed was equipped with two silver iodide and two cadmium-amalgam electrodes. Total volume of the cell was about 10 ml., and it was filled using vacuum technique. Voltage readings were taken over a six–twelve hour period with a suitably equipped Leeds and Northrup Type K potentiometer. Temperature was controlled at $25 \pm 0.01°$ as measured with a B. S. calibrated thermometer.

A special cell was built to measure the e. m. f. of the 2-phase cadmium amalgam *versus* the dilute amalgam actually employed for the cadmium iodide cells. Two electrodes for each amalgam concentration were used, and the cell was filled with an aqueous solution of purified cadmium sulfate of undetermined concentration.

**C. Experimental Results.**—Deuterium contents of the heavy water mixtures were computed from the density increment over unity at

(6) Baxter and Hartman, *ibid.*, **37**, 120 (1915).

25° and the $d^{25}_{25}$ value for heavy water of 1.10764 as determined by Stokland, Ronaess and Tronstad.[7] The total moles of water species were used to compute the molality which is uniformly expressed as moles of salt per 55.507 moles of water.

All cells were made using a single phase amalgam which was 0.00239 volt positive to a 2-phase cadmium amalgam at 25° and observed values were increased by this figure to give the e. m. f. of the cell

(C) Cd–Hg(2 phase)/$CdI_2(m'$ in $H_2O$, $D_2O$)/AgI–Ag

Results of measurements of the e. m. f. of the above cell at 0.1 $m'$ (moles of salt per 55.507 moles of total water species) as a function of deuterium content are presented in Table I. Values for light water were interpolated from the data of Bates[5] using large-scale plots of $-\log\gamma_H$ *vs.* $m^{1/2}$ and the electromotive force equation at 25° given as (D).

$$(D) \qquad E = 0.18280 - 0.088716 \log \gamma_H m_H$$

Good agreement was obtained between the check runs in protium water and the original data of Bates. The voltage decrease of the cells made with deuterium water is nearly a linear effect of the deuterium content. Deviations from linear variation are given in the last column of Table I, and it appears that there may be a slight sag just beyond the experimental error. A slightly sagged curve was observed in a similar study of the thermodynamics of potassium chloride in protium and deuterium oxide.[2] For this work cells involving liquid junctions were employed and isotopic water species may have been transferred across the boundary. Apparently, whatever the nature of the solvation effects on cadmium iodide in protium-deuterium oxide mixtures, the amount of HDO present is not important. This is decidedly not true for the hydrochloric acid cell made in heavy water, for the value of $E_H - E_D$ passes through a maximum,[8] the effect being associated with the various isotopic hydronium ions formed.

TABLE I

ELECTROMOTIVE FORCE OF THE CELL Cd–Hg(2 PHASE)/$CdI_2(0.1m')$/AgI–Ag AT 25° AS A FUNCTION OF THE DEUTERIUM CONTENT OF THE SOLVENT

| $D_2O$, % | $m'$ | $E_{H_2O,\ D_2O}$ obs., volts | $E_{H_2O} - E_{H_2O,\ D_2O}$ volts | Deviation from linearity, millivolts |

## Discussion of Results

The data obtained in heavy water are not sufficiently comprehensive to permit the evaluation of the standard molal potential in pure $D_2O$ nor the calculation of conventional activity coefficients in this solvent. However, the relative activity coefficient, $\gamma'_D$, defined in equation (A) may be obtained in the following manner. For the light water cell the e. m. f. is represented as

$$(E) \qquad E_H = E^0_H - RT/2F \ln 4(m_H\gamma_H)^3$$

(E) while for the deuterium oxide cell on the modified molal scale, $m'$, (F) holds. If $E^0_H$ is arbitrarily

$$(F) \qquad E_D = E'^0_D - RT/2F \ln 4(m'_D\gamma'_D)^3$$

set equal to $E'^0_D$ and if $m_H = m'_D$ then equations (E) and (F) can be combined to give (G). At

$$(G) \qquad E_H - E_D = 3RT/2F \ln (\gamma'_D/\gamma_H)$$

25° this equation can be further simplified to (H).

$$(H) \qquad (E_H - E_D)/0.0088716 + \log \gamma_H = \log \gamma'_D$$

Table II summarizes the results obtained at various concentrations, $m'$, of cadmium iodide for cell (C). In all cases $m'$ is given as the moles of salt per 55.507 moles of total water species. The observed potential of cell (C) is listed in the column headed $E_{H_2O,\ D_2O}$, obs. The heading $E_{H_2O} - E_{D_2O}$ refers to the difference between the e. m. f. of cell (B) in water (data of Bates) and the observed value of cell (C) extrapolated to pure deuterium oxide. Stoichiometric mean ionic activity coefficients, $\gamma_H$, taken from the data of Bates, were used to compute the listed values of $\gamma'_D$.

Figure 1 is a plot of the activity ratio, $a_D/a_H$ (which is equivalent to $(\gamma'_D)^3/(\gamma_H)^3$), *versus* the square root of molality, $m'$. It may be seen that there is a slight linear change with molality down to 0.06 $m'$; below that concentration the activity ratio rises sharply. Although the experimental error increases in this region the results indicate a very real trend. The most interesting area appears to be at dilutions beyond those reported in this paper (0.006 $m'$).

At 0.1 $m'$ the value for the partial molal free energy change when 1 mole of cadmium iodide

(7) Stokland, Ronaess and Tronstad, *Trans. Faraday Soc.*, **35**, 312 (1938).

(8) Noonan and La Mer, *J. Phys. Chem.*, **43**, 247 (1939).

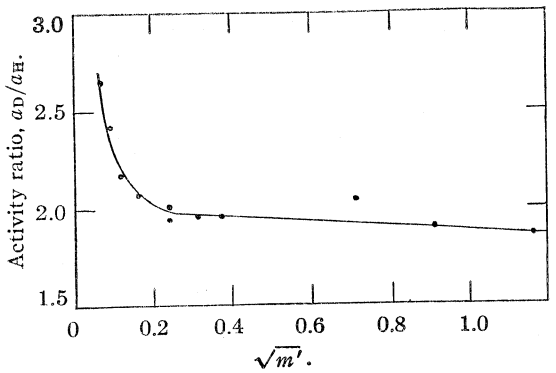

Fig. 1.—Activity ratio of cadmium iodide in heavy and light water at 25° as a function of concentration.

is transferred isothermally and reversibly from pure deuterium oxide solution to pure protium oxide solution is −398 cal. This may be compared with about −225 cal. for a similar transfer of potassium chloride.[2]

**Correction for Differences in Molar Volume.**—Because a mole of $D_2O$ occupies 0.36% more volume than a mole of $H_2O$ at 25° a correction should be applied for the electrical work obtained on isothermally and reversibly expanding the ionic assembly in light water to the volume it would occupy in heavy water. Using the appropriate e.m.f. equation for a cadmium iodide concentration cell, and assuming that the density and activity coefficients of the solutions do not change over a range of 0.36% variation in molality, it will be found that the value is 0.00014 volt. This correction should be added to the difference, $E_H - E_D$. It is about the order of the experimental error in measuring the most concentrated solutions and was neglected in treating the results.

## Summary and Conclusions

1. The e.m.f. of cell (C) has been determined

(C) Cd–Hg(2 phase)/$CdI_2$($m'$ in $H_2O$, $D_2O$)/AgI–Ag

at 25° as a function of concentration, $m'$, of cadmium iodide in terms of moles of salt per 55.507 moles of total water species. By combining the results with light water data, relative stoichiometric mean ionic acitivity coefficients, $\gamma_D$, in deuterium oxide have been computed. The value of this activity coefficient is not unity at infinite dilution, but it affords a comparison of the activity behavior of cadmium iodide in the isotopic solvents.

2. At 0.1 $m'$ the e.m.f. of cell (C) was found to be nearly a linear function of the deuterium content of the solvent.

# Adsorption of Gas Mixtures. Nitrogen–Oxygen on Anatase

BY JAMES R. ARNOLD[1]

The data on multilayer adsorption of gas mixtures[2] are limited in quantity compared to those available on single gases. Moreover, the studies which have been made have employed chiefly charcoal and silica gel as adsorbents. These substances, while industrially important, are not suitable for fundamental studies, since the phenomena of multilayer adsorption and capillary condensation occur simultaneously on their surfaces. A further limitation of some of the studies[3] is the choice of pairs of adsorbates for which large deviations from additive properties, *e. g.*, Raoult's law, are to be expected. Such data are peculiar to the system studied, and cannot yield generally useful information.

Hill[4] has recently generalized the Brunauer–Emmett–Teller (BET) theory[2,5] to mixtures of gases, for which no or moderate deviations from Raoult's law occur. This extension brings out the important fact that any statistical theory of adsorption can be generalized to give adsorption isotherms for such mixtures. Since the added assumption involved in the generalization will not introduce a large error, for a well-chosen pair of gases, the degree of agreement obtained between gas mixture data and the extended theory will provide evidence for or against the original theory. It will be shown below that the present study provides strong evidence against at least one of the postulates of the BET theory, and indications in favor of a quite different model.

The system chosen for this study was the gas pair nitrogen–oxygen on the adsorbent anatase ($TiO_2$). The two gases have convenient vapor pressures at liquid nitrogen temperature, and their phase diagrams at this temperature show small deviations from Raoult's law. The analysis can be made readily by a direct method. The adsorbent is one which has been extensively studied,[6,7] and consists of single crystals, free from

microscopic flaws and fissures, so that capillary condensation is minimized.

The usual technique for taking mixture adsorption data consists of varying gas composition at constant pressure in a static system. A flow method, in which data are taken over a range of pressures for a few definite gas compositions, has a double advantage. First, the time taken to reach equilibrium is greatly reduced by the elimination of diffusion block and, second, the isotherm equations come out in particularly simple form. This method was used in the present work.

## Experimental

**Materials.**—The anatase used in this study was supplied through the kindness of Professor W. D. Harkins. It was degassed under high vacuum at 300° before each run, and as frequently as necessary during the course of a run. Measurement of the area of a 3-g. sample, using nitrogen as adsorbate, in a multibulb apparatus of standard type[8] gave a value of 13.73 sq. meters/gram for its specific area, in good agreement with values obtained elsewhere.[6,7] The area of a 1.294-g. sample measured with the flow apparatus described below was 13.81 sq. meters/gram.

Five tanks of nitrogen–oxygen mixtures, containing 14.9, 29.8, 50.2, 70.2 and 85.3% oxygen, respectively, were obtained from the Linde Air Products Co. They were certified to contain less than 0.1% argon, and only traces of other non-condensable impurities. The nitrogen and oxygen used for the single gas isotherms were Air Reduction Co. Prepurified and Electrolytic grades, respectively.

The gases were passed over "Dehydrite" (magnesium perchlorate) to remove water, and used without further purification.

**Apparatus and Procedure.**—The measurements were made in the flow apparatus shown in Fig. 1. The detachable sample cell F has 2-mm. capillary leads to cut down dead space; the sample itself is about six inches below the surface of a liquid nitrogen bath. The anatase powder is prevented from blowing over by a loose-fitting glass ball-socket valve at the base of the bulb. The pretrap C consists of an identical sample of anatase in a liquid nitrogen bath, and serves to remove condensible impurities.

In operation, gas flows at the rate of 20 cc./min. through the capillary flowmeter A (maintained at slightly above atmospheric pressure), through the Hoke needle valve B, the pretrap C, the cell F, the Hoke needle valve H, and finally through the stopcock P to a Nelson roughing pump. The needle valves B and H allow the pressure in the cell system to be set at any desired value (as read on the manometer D). The time necessary for the adsorbed gas to come into equilibrium with the given mixture at a given pressure was tested in a series of preliminary experiments. A running time of eight to ten minutes was found to be sufficient, except at very low pressures, where the flow rate had to be decreased to prevent excessive pressure drops in the line, and at pressures near the condensation pressure, where especially large volumes of gas were taken up. The running time used in the actual measurements was approximately thirty minutes.

At the end of this period valves B and H are closed simultaneously, and the pressure read on manometer D. The temperature was read on a nitrogen vapor pressure thermometer[9] with bulb immersed in the bath surrounding F. Data used for calibration were those of Dodge and Dunbar.[10] Stopcocks E and G are then closed, valve H opened, and the system evacuated through stopcock N. The analytical train, consisting of Toepler pump K, measuring bulb L, and reaction bulb M, is also evacuated.

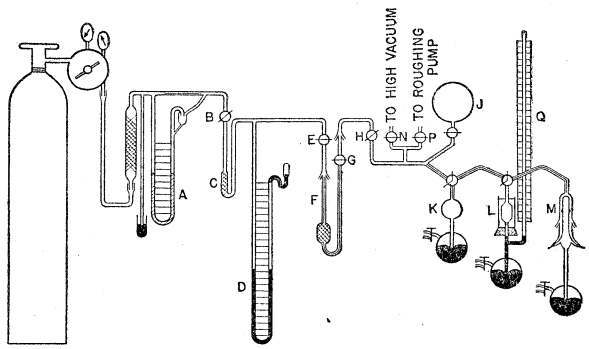

Fig. 1.—Diagram of flow apparatus.

Stopcock N is then closed, G opened, the liquid nitrogen bath removed, and the gas in the cell transferred with the Toepler pump to the measuring bulb L. The gas pressure, measured with manometer Q, the known volume of bulb L, and dead space of the cell F, permit the calculation of the total amount adsorbed at the given pressure and gas composition. After mixing to insure homogeneity, an aliquot of the gas is measured in L and transferred to the analytical bulb M. Smaller samples of gas are used entire.

The reactive element in M is an iron-plated platinum wire (after Lambert and Peel[11]), heated electrically to bright red heat. Two one-minute passes usually suffice for complete reaction, after which the gas is transferred back to bulb L, the residual pressure representing the nitrogen content of the sample. From this value the amount of each gas adsorbed can be calculated. After several analyses the wire is restored to activity by reduction with hydrogen. This method of analysis is quite satisfactory in practice, though a small correction (a few tenths per cent.) was necessary for residual gases in the electrolytically plated iron. The method is reproducible to 0.1%. It is necessary to replace the plated wire occasionally, as it burns out after prolonged use.

To begin a new point, stopcock G is closed, and the liquid nitrogen bath placed around cell F. Stopcock E is then opened. As points on an isotherm of a given gas composition are taken in more or less random order, the pressure in the cell might now be either greater or less than the final running pressure. Thus the points on the isotherm include indiscriminately "adsorption" and "desorption" points. The fact that the isotherm points showed no scatter due to this effect was a further check that the points represent equilibrium. Valves B and H are then roughly adjusted, stopcock P opened, followed by stopcock G, and the valves adjusted until the desired pressure is reached.

Each mixture isotherm consists of 40 to 50 points taken as described above. The pure gas isotherms were determined in the same way, omitting the analysis. The lowest pressure at which the apparatus gave reliable results was 2–3 mm.

The points on the pure gas isotherms below 1 mm. pressure were measured in a static system, using a three-range calibrated McLeod gage in place of the usual gas buret, with the sample contained in the detachable cell F. Thermal transpiration causes an error in pressure readings at these low pressures; the maximum possible error is a factor of $\sqrt{T_1/T_2} = \sqrt{298/78} = 1.95$. Correction for this effect was made according to Loeb.[12] The theory given is not exact, so that residual errors in pressure of 10–20% may be expected. The resulting errors in amount adsorbed are negligible.

## Results and Discussion

The isotherms obtained for the two pure gases and the five mixtures are shown in Figs. 2–8. The

pressure $p_0$ is the saturation vapor pressure of the liquid phase in equilibrium with gas of the given composition at 78.2°K. The composition and vapor pressure of these liquid phases are given in Table I. It may be seen that Raoult's law is obeyed in this system within a few per cent.

In examining the pure gas isotherms, we note that in the region of moderate to high $p/p_0$, the two curves are nearly superimposable. In the low pressure region, however (inserts, Figs. 2 and 3), the adsorption of nitrogen greatly exceeds that of oxygen.

The mixed adsorption isotherms show a number of striking features. First, we note the close resemblance between the total gas isotherms and those for the pure gases. In fact, except for a small difference in scale, all seven total gas isotherms can be nearly superposed (except below $p/p_0$ = 0.01, where there are no mixture data). At the highest pressures, the adsorbed phase is much

[a] Dodge and Davis, THIS JOURNAL, 49, 591 (1927).

richer in oxygen, the more condensable gas, than is the gas phase, its composition approaching that of the bulk liquid asymptotically as $p$ approaches $p_0$. This behavior is to be expected unless there is a first order phase transition at $p_0$ between the adsorbed and liquid phases. At low pressures, corresponding to low surface coverage, the adsorbed phase becomes poorer in oxygen than the gas phase. This characteristic may be seen most readily in Fig. 6. At the lowest pressure measured, the adsorbed phase contains 23% nitrogen, compared to 77% at the highest pressure. Considering the generally parallel features of the two pure gas isotherms, the specificity of the surface for nitrogen adsorption is an apparent anomaly.

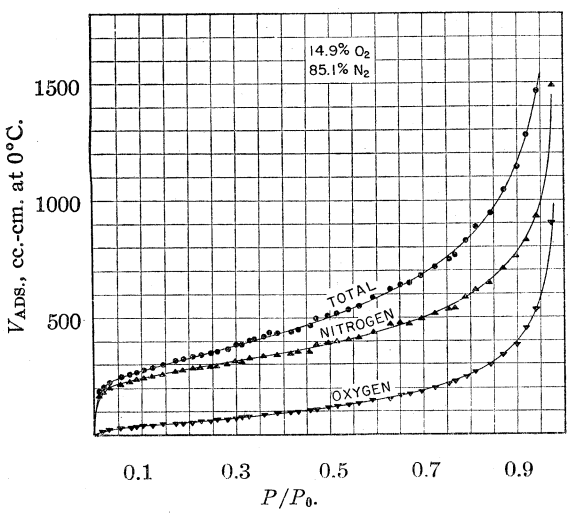

Fig. 4.—14.9% oxygen, 85.1% nitrogen isotherms. ▲, nitrogen; ▼, oxygen; ●, total gas adsorbed. The designations are the same in succeeding figures.

Another qualitative feature may be noted in the oxygen-rich mixtures, Figs. 7 and 8. In these isotherms the adsorption of nitrogen is almost independent of pressure over a considerable range of pressure.

**Comparison with Extended BET Theory. The Total Gas Isotherms.**—We shall use

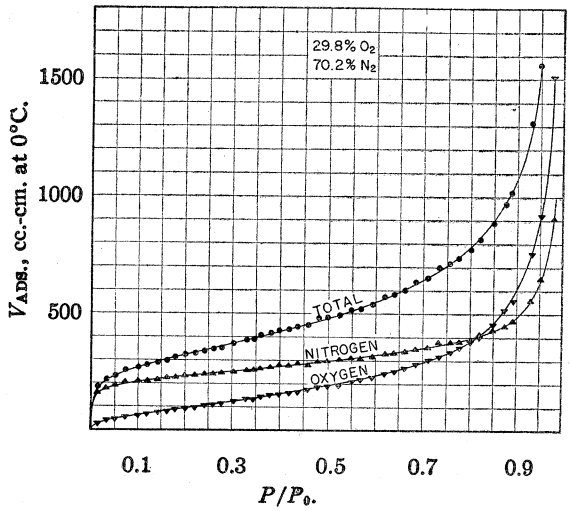

Fig. 5.—29.8% Oxygen, 70.2% nitrogen isotherm.

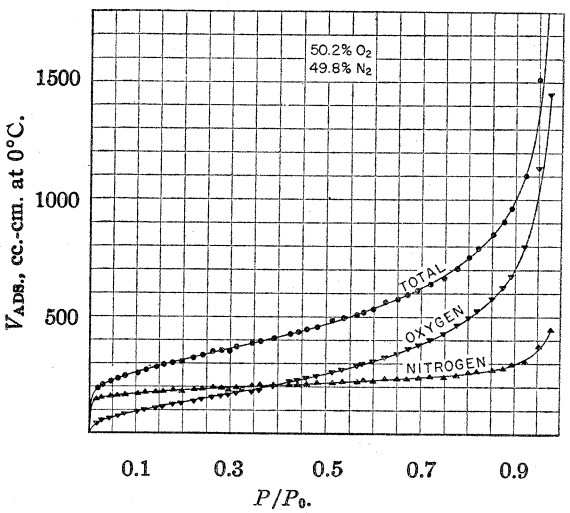

Fig. 6.—50.2% Oxygen, 49.8% nitrogen isotherm.

Hill's[4] eqn. (38), under the condition that Raoult's law is obeyed. Raoult's law, it may be noted, can be derived rigorously from statistical mechanics only on the assumption that the molecular area (or volume) is the same.[13] The error introduced by moderate differences in molecular size is small, however. We shall restate the equation in the form

$$\frac{v_1}{v_m} = \frac{cxX}{1 + cxY} \qquad (1)$$

letting

$$c = \frac{x_1c_1 + x_2c_2}{x_1 + x_2},\ x = x_1 + x_2,\ x_1 = y_1p/p_{10}$$

where

$p$ = gas pressure
$y_1$ = mole fraction of component 1 in gas phase
$p_{10}$ = vapor pressure of (pure) component 1

(13) Fowler, "Statistical Mechanics," Cambridge Univ. Press, Cambridge, England, 1936, p. 532.

$c_1$ = $c$ (after Brunauer, Emmett and Teller) for component 1, as determined from the pure gas isotherm
$v_1$ = volume of component 1 adsorbed from the mixture
$v_m$ = volume adsorbed corresponding to one monolayer

with similar definitions for component 2.

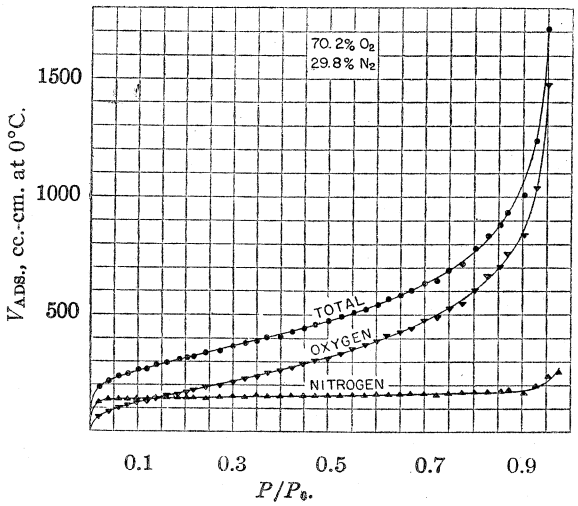

Fig. 7.—70.2% Oxygen, 29.8% nitrogen isotherm.

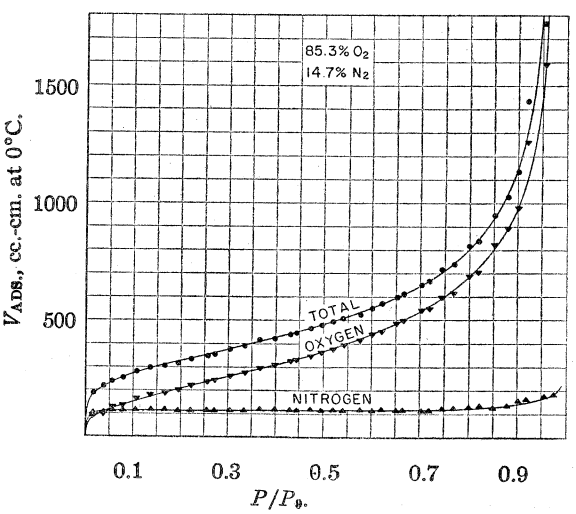

Fig. 8.—85.3% Oxygen, 14.7% nitrogen isotherm.

The two functions $X$ and $Y$ are given by Hill's eqns. (29) and (30), which we can restate as

$$X = \left[\frac{c_1x_1}{cx} + \frac{x_1}{(1 - x)}\right]\frac{1}{(1 - x)} \qquad (2)$$

$$Y = 1/(1 - x) \qquad (3)$$

Combining and simplifying

$$\frac{v_1}{v_m} = \frac{cx}{(1 - x)(1 - x + cx)}\left[\frac{c_1x_1(1 - x)}{cx} + x_1\right] \qquad (4a)$$

Likewise for component 2

$$\frac{v_2}{v_m} = \frac{cx}{(1 - x)(1 - x + cx)}\left[\frac{c_2x_2(1 - x)}{cx} + x_2\right] \qquad (4b)$$

The total gas adsorbed will then be

$$\frac{v_1 + v_2}{v_m} = \frac{cx}{(1 - x)(1 - x + cx)} \qquad (5)$$

This equation has the same form as the BET isotherm for a single gas.[5] That the terms have substantially the same significance may be seen by the following transformations. If the gas composition $y_1$ is held constant, the condensation pressure of the gas mixture will be given by

$$1/p_0 = y_1/p_{10} + y_2/p_{20} \qquad (6)$$

and

$$x = y_1 p/p_{10} + y_2 p/p_{20} = p/p_0 \qquad (7)$$

while $c$, the weighted mean of the $c$ values for the pure components, is likewise a constant over the whole pressure range.

It is apparent from Figs. 2 to 8 that the total gas isotherms for the various mixtures fit the BET eqn. (5) about as well as those for the pure gases. The BET constants, calculated from the isotherms by least squares, are given in Table II.

TABLE II

BET CONSTANTS FOR ISOTHERMS

| $y_2$, % | $v_m$, cc.-cm. | Mol. area, sq. Å. | $c$ | $c$ (from eqn. 1) |
|---|---|---|---|---|
| 0 | 312[a] | 16.2 | 143 | 143 |
| 14.9 | 273 | 18.5 | 94 | 112 |
| 29.8 | 266 | 19.0 | 92 | 95 |
| 50.2 | 261 | 19.4 | 86 | 83 |
| 70.2 | 261 | 19.4 | 90 | 77 |
| 85.3 | 267 | 18.9 | 83 | 74 |
| 100 | 288 | 17.5 | 72 | 72 |

[a] This value is somewhat uncertain due to non-linearity of the BET plot for this isotherm. $V_m$ may be as low as 288 cc.-cm.

The $p_0$'s used in calculating the constants, and in plotting Figs. 4 to 8, are the actual saturation pressures, not those calculated from Raoult's law. The difference in $c$ values by the two methods of calculation is at most 6%; the difference in molecular areas is negligible. The last column lists the $c$ values calculated from eqn. (1).

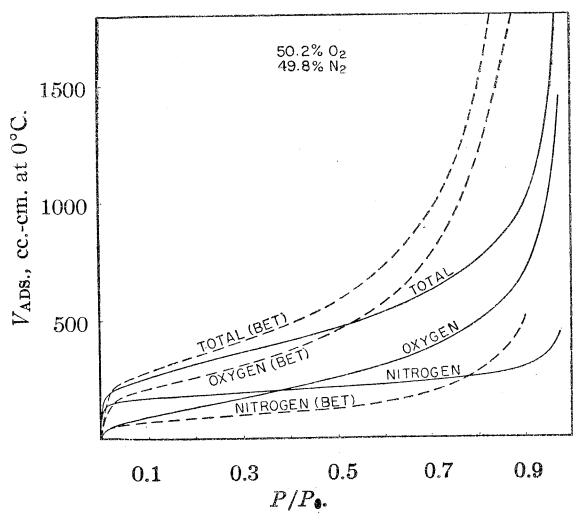

Fig. 9.—50.2% Oxygen isotherm: —, observed; - - - -, calculated from extended BET theory.

The range over which eqn. (5) holds for the mixtures is the same as that for the pure gases, namely, from $p/p_0 = 0.05$ to 0.30. The difference between the two sets of $c$ values is probably outside experimental error; it is too small, however, to cause more than minute deviations in the observed isotherms.

The $v_m$ values show strikingly the effect of molecular environment on molecular area in films of moderate thickness. We note that the observed value of the molecular area of oxygen on anatase (taking 16.2 sq. Å. for nitrogen as a reference value) is 17.5 sq. Å., compared with 13.2 sq. Å. calculated for liquid packing. This greater apparent area is common when other adsorbates are compared to nitrogen.[6,7] It has the fortunate effect, from our point of view, of bringing the two molecular areas into closer agreement. The areas for the mixtures are average areas per molecule of whatever species, it being impossible to treat the average molecular areas of nitrogen and oxygen separately. These areas turn out to be greater in every case than the molecular areas of either pure gas, and to pass through a smooth maximum between the 50.2 and 70.2% oxygen mixtures. The effect is far outside the experimental error, estimated at 0.5 to 1%. Moreover, it is independent of the correctness of the extended BET theory, since, as pointed out above, the isotherms are nearly superimposable except for a scale factor. Thus whatever point on the isotherm represents complete coverage of a monolayer, the relative values of $v_m$ in Table II will be preserved.

This effect is presumably associated with other signs of non-ideal behavior in these systems (see below).

**Component Isotherms.**—Figure 9 gives a comparison between the 50.2% oxygen isotherm (Fig. 6) and the isotherm predicted by the extended BET theory. Between $p/p_0 = 0.05$ and 0.30 the observed and calculated total gas isotherms run parallel, differing only by the scale factor discussed above. Above $p/p_0 = 0.30$ the predicted isotherm diverges increasingly in the direction of increased adsorption. This behavior exactly parallels that for the pure gas isotherms. When we compare the isotherms of the component gases in the moderate pressure region, however, we find a sharp discrepancy between theory and experiment. *The observed isotherms for the individual components, oxygen and nitrogen, differ from those calculated from the extended BET theory by more than a factor of two.* Instead of the observed highly selective adsorption of nitrogen at low pressures, the theory predicts only a small difference between the composition of the adsorbed phase below one monolayer surface coverage, and that of the bulk liquid. This discrepancy is equally apparent in all five mixture isotherms.

Returning to equations (4a) and (4b), we note that in the special case $c_1 = c_2 = c$

$$v_1/(v_1 + v_2) = x_1/(x_1 + x_2) = \frac{(y_1/p_{10})}{(y_1/p_{10} + (y_2/p_{20})} \quad (8)$$

That is, the composition of the adsorbed phase is equal to that of the bulk liquid, and is independent of $c$ and $x$. We can see from Table II that the difference between $c_1$ and $c_2$ is small, although in the right direction. In fact, the theory predicts a minimum oxygen concentration of 71% in the adsorbed phase, compared with 85% in the bulk liquid and 23% actually observed at $p/p_0 = 0.017$.

**Theoretical Discussion. The "Liquid Entropy" Model.**—Since the adsorbed phase is in equilibrium with gas at a lower pressure than the vapor pressure, we have from elementary thermodynamics

$$(\mu_A - \mu_L) = RT \ln (p/p_0) \quad (9)$$

that is, the partial molal free energy of the adsorbed phase is always less than that for the bulk liquid. This free energy difference (henceforth written $\Delta\mu_A$) can be considered as the sum of two terms

$$\Delta\mu_A = \overline{\Delta H}_A - T\overline{\Delta S}_A \quad (10)$$

In the simplest possible case of the BET theory, where $c = 1$, and $\Delta H_1 = 0$, $\overline{\Delta H}_A = 0$ over the whole isotherm and equation (10) reduces to

$$\Delta\mu_A = -T\overline{\Delta S}_A \quad (11)$$

That is, the partial molal entropy of the adsorbed phase is greater than that of the bulk liquid. In the usual type II BET isotherm $H_1 < H_L$ (these are negative quantities; the heat content of the adsorbed phase decreases with increasing heat of adsorption). $\overline{\Delta H}_A$ has its minimum value $\Delta H_1$ at zero pressure and coverage, and increases to zero at high coverage. Thus both heat and entropy contribute to adsorption in this case, but at least at high coverage, where the family of BET isotherms approach one another, the entropy term is the major contributor to the decreased free energy of the adsorbed phase, according to this theory. This entropy term may be loosely spoken of as "configurational entropy," thought of as arising from the large number of possible states for a BET adsorbed phase (see Hill's eqn. (4)), or the large amount of "disorder" in such a phase.

One of the basic assumptions of the BET theory is that a molecule may be adsorbed on another molecule with equal probability whether or not the lower or upper molecules have any nearest neighbors, *i. e.*, horizontal interactions are neglected. Thus the physical picture of the BET adsorbed phase at high coverage is of columns of molecules of various heights scattered at random, so that occasional columns of many molecules arise out of nearly bare areas. It has been pointed out, for example by Cassel,[14] that the van der Waals forces, which produce surface tension in liquids, will tend to draw these columns down and produce a smooth, ordered film. Hill's[15] calculations have shown the importance of this effect. This assumption, of the BET theory, together with the assumption of a constant $E_1$ which stands or falls with it, is its most obvious weakness.

The recent accurate heat measurements of Beebe and Kington[16] have permitted the calculation of the partial molal entropies of adsorption in a number of gas–solid systems, including the systems nitrogen–anatase and oxygen–anatase. In the systems studied the partial molal entropy of the adsorbed phase is uniformly *less* than that of the bulk liquid, approaching it closely at about $v/v_m = 1$ and above. The observed entropies have a minimum value about 4–5 e. u. less than that of the bulk liquid.

In light of these observations, a model is proposed based on the following assumptions: (1) the partial molal entropy of the adsorbed phase is constant and equal to that of the bulk liquid, for the pure gas isotherms; (2) if the sites for adsorption are arranged in order of decreasing heat of adsorption for component 1, they will also be in decreasing order for component 2; (3) for sites of a given heat of adsorption Raoult's law is obeyed. Assumption (1) is an approximation to the observed entropies of Beebe and Kington. Assumption (2) is a pure assumption in the region of low coverage, so long as the reason for the varying heat of adsorption is not known. In the region of multilayer adsorption, it must be approximately valid on purely geometrical grounds, since here the concept of "sites" gives way to that of "layers," the order of filling of which must be the same. The physical picture here, one frequently proposed before,[2] is of a smooth liquid-like film, the van der Waals field of the solid being superimposed on the liquid forces, and falling off fairly slowly with distance from the surface. Halsey, in a fundamental paper on the theory of adsorption,[17] has discussed this assumption extensively. As a consequence of assumptions (1) and (2), all sites of heat of adsorption $\Delta H_A$ fill at the pressure given by $\Delta H_A = RT \ln (p/p_0)$. If the first two assumptions are granted, the third becomes subject to experimental test. We shall refer to this set of assumptions as the "liquid entropy" (LE) model.

Calculation of a mixed adsorption isotherm then proceeds as follows. For any given set of sites, let the heats of adsorption for the two components be $\Delta H_{A1}$ and $\Delta H_{A2}$, and let the equilibrium pressures on the two pure gas isotherms be $p_1'$ and $p_2'$. Then the composition of the gas adsorbed on these sites is

$$r_1(v) = \frac{(y_1/p_1')}{(y_1/p_1') + (y_2/p_2')} \quad (12)$$

(14) Cassel, *J. Phys. Chem.*, **48**, 195 (1944).

(15) Hill, *J. Chem. Phys.*, **15**, 767 (1944).

(16) Beebe and Kington, THIS JOURNAL (in press). The author is greatly indebted to Drs. Beebe and Kington for making their data available to him before publication.

(17) Halsey, *J. Chem. Phys.*, **16**, 931(1948).

The equilibrium pressure is determined by

$$1/p = y_1/p_1' + y_2/p_2' \qquad (13)$$

The composition of the whole film at volume adsorbed $v$ and pressure $p$ is given by

$$R_1(v) = \frac{1}{v}\int_0^v r_1(v)\,dv \qquad (14)$$

$r_1(v)$ and $p(v)$ may be determined from the pure gas isotherms. These isotherms must be determined down to very low surface coverage. The integration of eqn. (14) is performed numerically.

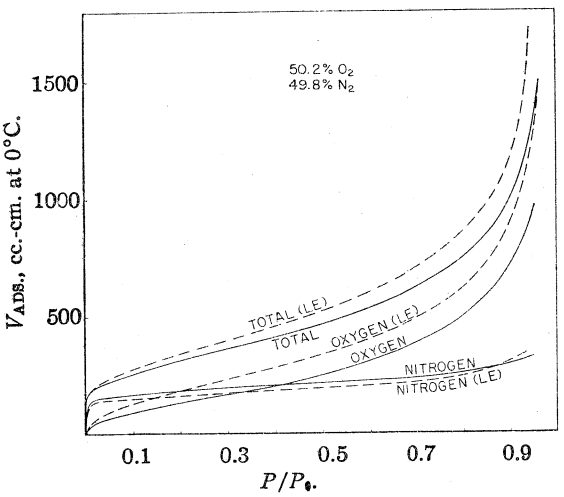

Fig. 10.—50.2% Oxygen isotherm: —, observed; - - - -, calculated from "liquid entropy" (LE) model.

The result of such a calculation for the 50.2% oxygen isotherm is shown in Fig. 10. The agreement is seen to be much better than that in Fig. 9. That this is so for the total gas isotherm reflects no credit on our model since the functions $p'(v)$ and $p_2'(v)$ are the observed isotherms (Figs. 2 and 3), while the pure gas isotherms used in eqns. (4) and (5) are the BET isotherms, which fit the experimental data only between $p/p_0 = 0.05$ and 0.30. For the component isotherms a real improvement is apparent. The composition of the adsorbed phase at $p/p_0 = 0.017$ is now 29% oxygen, compared to 71% on the BET model, and 23% actually observed. The discrepancy between calculated and observed isotherm is greater for oxygen than for nitrogen, the scale factor of the total gas isotherm tending to increase the discrepancy in the oxygen case, and reduce it in the nitrogen case.

Semi-quantitative agreement is likewise obtained with the isotherms for the other four gas mixtures.

In testing assumption (3) of our model, given the other two, we again encounter the scale factor of the total gas isotherm, as a positive deviation from Raoult's law, *i. e.*, greater pressure corresponding to a given surface coverage. The assumption of "regular solution" behavior, and the introduction of the scale factor as a measure of departure from ideality, would undoubtedly improve the calculations somewhat, bringing the total gas isotherms closely into line with predictions.

The use of the measured entropies of Beebe and Kington, instead of assumption (1), is also possible. The calculations become tedious, and assumption (3) can no longer hold at more than one temperature, or even at one temperature except by fortuitous cancellation of effects. Rough approximate calculations show improved agreement; more accurate entropy data, especially at low coverage, would probably be necessary for a real test of this method.

We may conclude that in this system, and probably in others where small deviations from Raoult's law are to be expected, the "liquid entropy" model gives semi-quantitative agreement with experiment. The data required for this model are simply the pure gas isotherms, over the whole range from low coverage to many-layer coverage. Determination of the total gas isotherms at constant gas composition will improve the agreement by allowing for "regular solution" behavior. Measurement of heats of adsorption, and use of observed rather than liquid entropies, will give further improvements. Since determination of the two pure gas isotherms is much less difficult and time-consuming than measurement of a series of gas mixture isotherms, the "liquid entropy" model will be a practical tool for predicting mixed adsorption behavior. The more exact methods, requiring data more difficult to determine, probably will not.

**Acknowledgments.**—The author is indebted to the National Research Council for the grant of a fellowship to pursue these studies, and to Harvard University for the generous provision of facilities and equipment. He is grateful to Professor George B. Kistiakowsky for his continued support and encouragement, and to Dr. Kistiakowsky, Professor Ralph A. Beebe, Dr. Henry A. Kierstead and Dr. George Halsey for a number of illuminating discussions, at various times and places.

## Summary

Adsorption isotherms at constant gas composition have been determined at 78.2°K. for five nitrogen–oxygen mixtures on Harkins' anatase. Isotherms for the two pure gases have also been determined. The isotherms show selective adsorption of nitrogen by this surface at low coverage.

Comparison with the extended BET theory shows qualitative disagreement, and provides evidence against at least one of the assumptions of the BET theory.

Use of a "liquid entropy" model gives semi-quantitative agreement with experiment.

This model allows the prediction of mixed adsorption behavior from the pure gas isotherms, for pairs of gases for which Raoult's law holds approximately.

# The Electric Moments of Some Aromatic Fluorine Compounds[1]

BY HENRY FREISER,[2] MARCUS E. HOBBS AND PAUL M. GROSS

The unusual and in some cases unique properties of organic fluorine compounds make an interpretation of these properties in terms of molecular structure of importance both because of the end use to which the compounds may be put and because of the insight that such an interpretation may lend to the relations of structure and properties. The present paper gives the results of determinations of the polar properties of a series of organic fluorine compounds in terms of the dipole moments and polarizabilities of the molecules and relates these values to the molecular structures involved.

TABLE IA

SUMMARY OF PHYSICAL PROPERTIES OF COMPOUNDS

| Compound | B. p. (cor.) °C. | Mm. | $n^{30}D$ | $d^{30}_4$ | | Analyses, % Calcd. | Found |

[a] Best grade obtained from Eastman Kodak Company. [b] No analysis data available, but physical properties check with those described by H. S. Booth, H. M. Elsey and P. E. Burchfield, THIS JOURNAL, **57**, 2066 (1935). [c] Obtained from Hooker Electrochemical Company and treated with boiling sodium bicarbonate solution until no tests for $Cl^-$ were obtained in the solution. This was followed by fractional distillation.

## Materials and Experimental Details

Most of the compounds used in these measurements were made in the Duke University Laboratories in connection with the research being carried on by Messrs. P. Tarrant, L. Rapoport, R. Kittila and G. West under the direction of Drs. L. A. Bigelow and C. K. Bradsher. Their syntheses will be described in other publications. The analyses reported in this section were made by Dr. Rose Davis.

Both the solvents and compounds to be measured were carefully purified. Liquids were purified by careful fractionation while solids were fractionally crystallized. In the absence of other data, constancy of boiling point or freezing point was used as a criterion of purity.

**Benzene.**—Jones and Laughlin best grade of benzene (did not discolor concentrated sulfuric acid) was dried over anhydrous sodium sulfate, then refluxed over sodium wire for six hours and finally distilled from sodium. Fractions boiling over 0.02° range were used in the measurements. After the benzene had been used for a measurement it was recovered by repeated fractionation from the higher boiling solute and finally redistilled from sodium until

(2) (a) Present address, University of Pittsburgh, Pittsburgh, Pennsylvania. (b) Part of a thesis of Henry Freiser submitted in partial fulfillment of the requirements of the Ph.D. degree in Chemistry at Duke University, June, 1944.

its b. p. was constant. This recovered benzene was also used for some of the measurements: b. p. 80.10–80.12° (cor.); $d^{30}_4$ 0.868143 (av.); $n^{30}D$ 1.49483.

**Heptane.**—"Technical" *n*-Heptane from the Phillips Petroleum Company was described by them as "possibly containing up to 4% branched hydrocarbons. The sulfur content is about 0.004% and no olefins are present." The heptane was purified by shaking it with successive portions of concentrated sulfuric acid until the acid remained colorless after four hours of shaking. The product was then washed with dilute sodium hydroxide and finally with water. It was dried over calcium chloride, refluxed for six hours over sodium wire from which the heptane was finally distilled. Fractions boiling over a 0.02° range were used. The heptane was recovered after each measurement in the same manner employed in benzene recovery and was used again in some of the measurements: b. p. 98.52–98.54° (cor.), $d^{30}_4$ 0.677431 (av.).

**1,3-bis-(Trichloromethyl)-benzene.**—Crystals already partly purified by Mr. G. West were further recrystallized from carbon tetrachloride and a cooling curve obtained: f. p. 38.8–39.0°.

*Anal.* Calcd.: Cl, 68.1. Found: Cl, 68.0.

All the other compounds used were liquids under ordinary conditions and were purified in the following manner. They were dried over drierite and then fractionally distilled through a nichrome wire-wound spiral column. A summary of their physical properties is given in Tables IA and IB. Where the analysis data are available, they are included.

The procedure has been described previously.[3] The dielectric constant measurements were made with an apparatus of the heterodyne beat type which has been described recently.[4]

## Results and Discussion

The experimental results of the electric moment determination are summarized in Table II. In this table $\mu_D$ is the value of the moment obtained by means of the usual Debye expression and $\mu_0$ is obtained from the Onsager equation[5] for a polar solute in a dilute solution of a non-polar solvent. The latter equation is

$$\lim \frac{\Delta\epsilon}{f_2} = \frac{M_2 d_1}{M_1 d_2}\frac{3\,\epsilon_1(n_2^2-\epsilon_1)}{(2\,\epsilon_1+n_2^2)} + \frac{4\pi N_A d_1}{3kTM_1}\left[\frac{\epsilon_1(n_2^2+2)\,\mu_0}{(2\,\epsilon_1+n_2^2)}\right]^2 \quad (1)$$

In this expression the subscripts 1 and 2 refer to solvent and solute, respectively. $\Delta\epsilon$ is the increment in the dielectric constant of the solution over that of the solvent, $f_2$ the mole fraction of the solute, $d$ the density, $n$ the refractive index which was taken for the sodium D lines, $M$ the molecular weight and the other symbols have the usual meaning. Since, in the low concentrations employed, the value of $\Delta\epsilon/f_2$ was constant within experimental error, the average value was employed in the calculations. $\mu_M$ was calculated using the empirical extrapolation equation of Müller[6] by insertion of the value $\mu_D$ calculated from the Debye dilute solution equation as the value of $\mu_{soln.}$

It can be seen from Table II that agreement between the dipole moment values calculated by the different methods is rather close in most cases, although the Müller value is always somewhat higher than $\mu_D$ as would be necessary because of the form of the Müller equation.[6]

The results of the Onsager calculations were in no better agreement with the gas values, where these were known, than were the Debye values. The Müller equation was somewhat better in this regard. Specifically, a comparison[7] may be made for the chlorobenzene gas value of 1.70*D* and the fluorobenzene gas value of 1.57*D*. While the Onsager moments deviated from the gas moments by about 0.10 debye unit, the Müller values agreed with those obtained from gas measure-

ments within experimental error. For the Müller equation good agreement is usually obtained in the cases of compounds measured in both solvents. This would indicate the internal consistency of Müller's equation but not its validity and it must be remembered that Müller's equation is empirical. Because of its empirical nature and consequent limitations it should be used only as an expedient for calculating moments when gas values are not available.

In many structural problems, the difference between the observed dipole moment of a molecule and the moment calculated on the basis of vector additivity of the group moments is of considerable interest. For the compounds measured in this study, these differences are fairly independent of the method of calculation used, provided that the same method is used for each molecule considered. Table III lists the results of such a computation.

TABLE III

DEVIATIONS FROM VECTOR ADDITION

| Compound | Δ Debye, *D* | Δ Onsager, *D* | Δ Müller, *D* |

| 4-Fluoro-1,3-bis-(trichloromethyl)-benzene | .09 | .05 | .09 |

The dipole moment of each molecule listed in Table III was calculated by vector addition of the bond moments using as component moments values obtained in the following manner: (1) the Debye value obtained in benzene, since for better comparison, measurements in the same solvent were chosen, (2) the average Onsager value and (3) the average value obtained by calculation using Müller's equation. In all cases, the values of the moments of chlorobenzene, fluorobenzene, benzotrifluoride and benzotrichloride were taken as being those of the C–Cl, C–F, C–$CF_3$, C–$CCl_3$ bonds, respectively. The values of the moments obtained in this manner were compared to the actual moments and the deviations listed in Table III. A positive deviation signifies that the measured moment is larger than that calculated by vector addition of the component bond moments. As shown in the table good agreement between the deviations is obtained in most of the cases. The lack of agreement for *o*-fluorochlorobenzene where the value of the deviation calculated by Müller's method is quite different from the other two is the only case where a serious discrepancy is noted. The reason for this discrepancy is not understood.

A general consideration of the origins within the solute molecule of such deviations as shown in Table III have been discussed elsewhere.[8] A cause for deviation extraneous to the solute molecule itself may arise from solvent effects. The theoretical aspects of this effect have been discussed by Frank and Sutton and others.[9] To illustrate the nature of the effect as discussed by Frank and Sutton consider a molecule in which the electric moments completely compensate; *i. e.*, *p*-dichlorobenzene. On the average, in the absence of a field, the solvent molecules arrange themselves in the vicinity of the polar bonds in such a way as to have the moments induced in them by the polar bonds completely cancel one another. In case the moments induced in the solvent molecules by the polar bonds lie in the direction of an imposed field these molecules will be bound more tightly to the solute molecule whereas the solvent molecules with their induced moment directions opposing the field are bound to the solute molecule less tightly than if the field were absent. The net effect of the above is that the solvated solute molecule shows an average electric moment in the direction of the field, *viz.*, an increased polarizability. Such an increased polarizability will, in the usual method of calculation of electric moments from solution measurements, lead to a calculated real dipole moment of the solute molecule. For future reference we will refer to this type of effect as a deviation originating from solvent effects.

Examination of Table III shows that for all of the disubstituted cases the para compounds exhibit a positive deviation and all ortho and meta substituted compounds show negative deviations from vector additivity. The explanation of this difference in sign may well lie in differences in the origins of the observed deviations. It is suggested that the para compounds show positive deviations because the predominating deviation effect is one originating in the solvent effects discussed above. The negative deviations for the ortho and meta cases may be most simply attributed to a preponderance of deviation effects arising from the inductive and space induction effects. However, it may be noted that both the space induction and inductive effects through the ring are expected to be rather small for the meta cases. The distance of separation of the groups minimizes the space effect and the inductive effects through the ring would probably be small if the

(8) Hobbs and Weith, THIS JOURNAL, **65**, 925 (1943).

(9) (a) Frank and Sutton, *Trans. Faraday Soc.*, **33**, 1307 (1937); (b) S. H. Bauer, *J. Chem. Phys.*, **4**, 458 (1936); (c) H. O. Jenkins, *J. Chem. Soc.*, 910 (1936).

effect is considered to be distributed equally on all carbon atoms of the ring. In the disubstituted cases the electric moments in general corroborate the structure of the isomers considered.

The cause for the observed deviations in the tri- and tetra-substituted compounds is difficult if not impossible to locate because of the complexity and undetermined magnitude of the factors which might cause such deviations. A rather simple consideration of the other reasonable isomers that might have been obtained in the method of preparation leads one to conclude that, in general, the observed moments, considered in light of the deviations from additivity are such as to corroborate the identity of the molecule involved.

In considering the influence of the polar substituents on physical characteristics one of the simplest evidences of this influence is found in Table IB where the values of the molar refraction, $R_D$, for the sodium D lines are shown. The calculated values are obtained by summing the atomic and bond components of the molecule and this value is compared with the observed value as calculated from the Lorenz–Lorentz expression, *viz.*

$$R_D = \frac{n^2_D - 1}{n^2_D + 2}\frac{M}{d}$$

The difference between $R_D$(obs.) and $R_D$(calcd.) might originate in an effect of the substituents on either the electrical volume fraction term, $(n^2 - 1)/(n^2 + 2)$, or the molar volume term, $M/d$ or on both terms. Thus the electronic transitions responsible for the refractive index may either increase or decrease their strengths, and/or new transitions may become accessible when substituents are attached to the ring. The effect of any of these potential changes on the value of $R_D$ would probably appear most prominently in the $(n^2 - 1)/(n^2 + 2)$ term. If, because of the repulsive or attractive fields of the substituents, the molar volume changes disproportionately to the $(n^2 - 1)/(n^2 + 2)$ term the value of $R_D$ will be affected in direct proportion to the lack of compensatory changes in these terms.

The only data presented which allow a simple evaluation of the relative effects of the above two terms are (1) *m*-chlorobenzotrifluoride and *p*-chlorobenzotrifluoride and (2) *m*-fluorobenzotrichloride and *p*-fluorobenzotrichloride. If we denote $(n^2 - 1)/(n^2 + 2)$ as $B$, then the following approximate expression may be derived from the equation for $R$ for the meta and para cases

$$(R_p - R_m) = B_pV_p - B_mV_m$$
$$\simeq B_p(V_p - V_m) + V_p(B_p - B_m) \qquad (2)$$

With division by $R_p$ we obtain

$$\frac{\Delta R_{p-m}}{R_p} \simeq \frac{\Delta V_{p-m}}{V_p} + \frac{\Delta B_{m-m}}{B_p} \qquad (3)$$

The values of $R$, $V$ and $B$ are given for the above compounds in Table IV.

TABLE IV

| | $R$, cc. | $V$, cc. | $B$ |
|---|---|---|---|
| *m*-Chlorobenzotrifluoride | 35.87 | 135.26 | 0.26521 |
| *p*-Chlorobenzotrifluoride | 36.04 | 135.94 | .26520 |
| *m*-Fluorobenzotrichloride | 45.85 | 148.18 | .30939 |
| *p*-Fluorobenzotrichloride | 45.92 | 148.41 | .30944 |

The values for the terms of eq. (3) taken from the experimental data are shown directly below.

| | $\frac{\Delta R_{p-m}}{R_p}$ | $\frac{\Delta B_{p-m}}{B_p}$ | $\frac{\Delta V_{p-m}}{V_p}$ |
|---|---|---|---|
| (*p*-*m*)-Chlorobenzotrifluoride | $4.7 \times 10^{-3}$ | $-0.6 \times 10^{-3}$ | $+5.0 \times 10^{-3}$ |
| (*p*-*m*)-Fluorobenzotrichloride | $1.5 \times 10^{-3}$ | $+0.2 \times 10^{-3}$ | $+1.6 \times 10^{-3}$ |

The discrepancy between $\Delta R_{p-m}/R_p$ and the sum of the other two terms is attributable to lack of precision in the value from which the various terms were obtained and to the approximations used in eq. (3). It is evident from these results that the major fraction of the difference in the $R$ values for the para and meta compounds resides in the molar volume term and as would be expected on the basis of the interdependence of $n$ and $V$ the two terms $\Delta V/V$ and $\Delta B/B$ may be of opposite sign. In general it may be concluded from these results that the repulsive fields of the electronegative atoms cause a volume change that is not compensated for by a corresponding change in $n$. In view of these results it may be suggested that the probable cause of the other large + $\Delta R_D$ values in Table IB lies in volume changes rather than changes in $B$.

Table IB contains only one serious negative $\Delta R_D$. This value of $-0.85$ for benzotrifluoride probably shows how significantly the large electronegativity of the $-CF_3$ group can influence the polarizability of the benzene ring. Some evidence for this may be obtained from the data shown for toluene and benzotrifluoride in Table V.

TABLE V

| Substance | 30°C. $R_D$ | 30°C. $V$ | $\frac{\Delta V(100)}{V}$ | $\frac{\Delta B(100)}{B}$ |
|---|---|---|---|---|
| Toluene | 31.06 | 107.58 | 0 | 0 |
| Benzotrifluoride | 29.65 | 124.58 | +15.8 | −17.6 |
| *m*-Xylene | 35.90 | 124.03 | 0 | 0 |
| 1,3-bis-(Trifluoromethyl)-benzene | 35.77 | 155.97 | +25.8 | −20.8 |

The $\Delta V/V$ and $\Delta B/B$ column data are obtained by using toluene as a reference for the first two cases and *m*-xylene for the latter two. It is evident from the data on toluene and benzotrifluoride that the negative value of $\Delta R_D$ for benzotrifluoride probably arises from the overcompensation of the positive volume change by a negative change in the $B$ term. This may be taken as indicative of a tightening of the ring electron

system in the benzotrifluoride molecule. This situation is apparently reversed when the cases of *m*-xylene and the 1,3-bis-(trifluoro)-compounds are considered, *viz.*, the fractional positive volume change exceeds the fractional negative change in *B*. It will be noted in Table IB that the values of $\Delta R_D$ are roughly constant for the *m*-fluoro and *m*-chloro compounds and the same applies to the *p*-compounds except for *p*-chlorobenzotrichloride. The latter compound has a rather low $\Delta R_D$ in view of the data on the other compounds of similar nature. It is notable that in all cases of the disubstituted compounds in which large + $\Delta R_D$ deviations occur one of the substituents is fluorine. This atom because of its small size, large electronegativity and low polarizability would give rise to a large coulombic repulsion for other bonded electronegative atoms and would have low compensatory attraction arising from dispersion forces. The larger chlorine atom has a lower electronegativity and a higher polarizability and as such might give rise to a smaller *relative* volume increment than would the fluorine atom.

The bonded fluorine atom should contribute to the London[10] dispersion forces about the same as bonded hydrogen atoms and yet in spite of the large dipole moment of benzotrifluoride and 1,3-bis-(trifluoromethyl)-benzene the boiling point of the former is roughly 8° lower than that of toluene and of the latter roughly 23° lower than that of *m*-xylene. The first order factor in determining boiling points in normal liquids is the force arising from the interaction of instantaneous atomic dipoles with dipoles induced in neighboring polarizable systems. Since in first approximation this force varies as $1/r^6$, it is evident that a very small change in *r* will have a considerable influence on the interaction energy, and in cases of systems of essentially the same distribution and magnitude of polarizability within a molecule it may be generally expected that the substance with largest intermolecular distances will have the lower boiling point. In the cases of *m*-xylene and 1,3-bis-(trifluoromethyl)-benzene the ratio of the average intermolecular separations at 30° is about 1/1.15 and for toluene and benzotrifluoride at 30° the ratio is about 1/1.10. The molar volume at the respective boiling points of the compounds would be more instructive in the above connection than the data at 30°; however, to the knowledge of the authors, such data are not available for the fluorine compounds. The fact that the substances listed with largest intermolecular distances are the lowest boiling of the pairs considered can hardly be regarded as coincidence although it is recognized that the entire line of reasoning relating to the boiling point and intermolecular distance has serious quantitative limitations.

## Summary

The electric moments of a number of organic fluorine compounds have been measured and discussed in relation to the structure of the molecules. The effect of fluorine on some physical characteristics of molecules is briefly considered.

# Allylic Rearrangements. XXIV. Abnormal Bimolecular Substitution. The Condensation of Butenyl and Pentenyl Chlorides with Sodium Malonic Ester

BY RICHARD E. KEPNER,[1a] S. WINSTEIN AND WILLIAM G. YOUNG

Recent work[1b,c] on nucleophilic displacement reactions of allylic systems has indicated that bimolecular ($S_N2$) reactions produce unrearranged products (eqn. 1). An abnormal bimolecular ($S_N2'$) mechanism (eqn. 2) has been proposed[2] and, while some of many conversions in the literature may involve this mechanism at least partly, no completely satisfactory evidence for its operation has so far appeared.

Thus many reported cases of reactions of allylic halides with nucleophilic reagents such as sodium malonic ester,[3] sodium acetoacetic ester,[4] sodium allyl benzene,[5] potassium phthalimide,[6] sodium

phenoxide[7] or the sodium enolates of ethyl isopropylidenemalonate and ethyl (1-methyl-propylidene)-cyanoacetate[8] afford no evidence for the operation of the $S_N2'$ mechanism because of either the lack of kinetic evidence, the use of impure allylic halides, the probability of allylic rearrangement during the reaction, or extreme difficulty in detecting the presence of small amounts of abnormal product in certain cases.

The reactions of allylidene chlorides[9] seemingly offered an example of the mechanism at first sight, but later work[10] has indicated that these reactions can best be explained by other means. Carroll[11] reported the formation of $CH_3COCH_2$-$CH_2CH{=}CHC_6H_5$ in the treatment of $\alpha$-phenylallyl alcohol with acetoacetic ester, and Wilson[12] has suggested that this rearranged product may result from the $S_N2'$ mechanism. However, Kimel and Cope[13] found that the observed product was formed by successive ester interchange and cyclic rearrangement of the unsaturated ester.

Bergmann[2c] claims that the abnormal bimolecular mechanism operates in the reaction of optically active $\alpha,\gamma$-dimethylallyl chloride with sodium malonic ester or sodium diphenylmethide, in this way accounting for the complete loss of optical activity. The same product results from either a normal or abnormal bimolecular attack on $\alpha,\gamma$-dimethylallyl chloride, and thus it was impossible for Bergmann to prove the operation of the $S_N2'$ mechanism from the structure of the product. In this article is reported some further work on displacement reactions of allylic halides which is pertinent to the question of the operation of an abnormal bimolecular mechanism. The conversions in question involved the action of sodium malonic ester on $\gamma$-methylallyl (I), $\alpha$-methylallyl (II), $\gamma$-ethylallyl (III) and $\alpha$-ethylallyl (IV) chlorides. These chlorides are similar to the one employed by Bergmann[2c] but normal and abnormal bimolecular mechanisms give different products.

The products of the displacement reactions were directly hydrogenated, saponified and decarboxylated to yield saturated monocarboxylic acids. The acids which may result from the butenyl chlorides are *n*-caproic acid (V) and $\beta$-methylvaleric acid (VI), and from the pentenyl chlorides are *n*-heptanoic acid (VII) and $\beta$-ethylvaleric acid (VIII). The acid product from each halide was carefully fractionated and various of the distillation fractions converted to benzyl amine salts to yield a semiquantitative estimate of the composition. The estimates thus obtained indicated less than 1% of abnormal product from each of the primary chlorides (I and III). With $\alpha$-methylallyl chloride (II), there was estimated 10% of abnormal product when the condensation with sodium malonic ester was carried out at the reflux temperature of the alcoholic solution and 6% when the condensation was carried out at room temperature. With $\alpha$-ethylallyl chloride (IV) the abnormal product was estimated at 23%.

The original chlorides (I–IV) were very carefully purified so that the production of abnormal products cannot be due to impurity of starting materials. Also, the chlorides are quite stable to thermal rearrangement, so this possible cause for production of abnormal products can be eliminated. It was shown by refractive index measurements that the pure chlorides without a solvent are unchanged after three hours at 80°. Actually, we should be concerned about rearrangements in ethanol, the solvent employed for the condensa-

tions. However, we should expect rearrangement in ethanol to be accompanied by very extensive solvolysis and this, as will be discussed shortly, is quite slow relative to the rate of the reaction with sodium malonic ester.

Ruling out impurity and rearrangement of the halides, there is still another conceivable mode of production of abnormal products besides the $S_N2'$ mechanism. This would be by way of a rate-determining ionization of the halide followed by very successful competition by malonic ester anion for the allyl carbonium ion. This we are able to rule out on the basis of kinetic experiments with α-ethylallyl chloride (IV), the halide which gave rise to the most abnormal product. The rate of solvolysis of this chloride in absolute ethanol and the rate of the condensation with diethyl malonate ion in absolute ethanol were both determined at 50.00°. The first order constant, $k_1$, observed for solvolysis of *ca.* 0.3 *M* chloride was $4.96 \times 10^{-4}$ hr.$^{-1}$, the same order of magnitude as that previously observed for α-methylallyl chloride,[14] $2.11 \times 10^{-4}$ hr.$^{-1}$ at 40°. The condensation of α-ethylallyl chloride with diethyl malonate ion gave excellent second-order kinetics, the results of a typical run being summarized in Table I and the results of several runs in Table II.

TABLE I

CONDENSATION OF α-ETHYLALLYL CHLORIDE WITH SODIUM MALONIC ESTER IN ABSOLUTE ETHANOL AT 50.00°

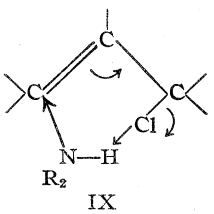
TABLE II

SUMMARY OF RATE CONSTANTS FOR THE REACTION OF α-ETHYLALLYL CHLORIDE WITH SODIUM MALONIC ESTER



| Run | α-EA-Cl, mole/liter | NaCH(COOEt)$_2$, mole/liter | $k_2$ |
|---|---|---|---|
| 1 | 0.3391 | 0.3586 | 0.349 |
| 2 | .3495 | .3268 | .366 |
| 3 | .1655 | .6279 | .325 |
| 4 | .6461 | .1625 | .357 |

From the second-order rate constant, $k_2$, listed in Tables I and II, it is clear that the bimolecular reaction with malonic ester anion is much faster than the first-order solvolysis. In fact, one can calculate[1a] for an experiment at 50° with initially 2 *M* reagents that at complete reaction only 0.5% of the α-ethylallyl chloride has reacted by a solvolytic first-order mechanism. Thus, even if solvent does not compete with malonic ester anion, a maximum of 0.5% abnormal product could be accounted for by a solvolytic mechanism.

It is clear from the above arguments that the abnormal product observed in the case of the secondary chlorides (II and IV) arises from a bimolecular displacement process involving attack on the γ-carbon atom. Similarly this must have contributed to the reaction of α,γ-dimethylallyl chloride studied by Bergmann, but one would hardly anticipate sufficient contribution to account for complete racemization.

Other pertinent cases of nucleophilic displacements with allylic compounds involve the action of amines on halides. Thus Meisenheimer and Link[15] found that α-ethylallyl chloride (IV) on treatment with diethylamine or methylaniline yielded abnormal products, the same ones derived from γ-ethylallyl chloride (III). Also, Webb has found in these laboratories that α-methylallyl chloride II yields, on reaction with diethylamine, an abnormal product identical with the one from γ-methylallyl chloride (I). While these reactions are being scrutinized further, the indications are that abnormal product arises from bimolecular processes involving attack on the γ-carbon atom.

In the case of the abnormal displacement reactions, it is still not clear to what extent a mechanism of the type symbolized in IX contributes.

IX

Just as this manuscript was being completed, Jones, Lacey and Smith[16] reported the formation of an abnormal product from the action of diethylamine on the halides X (R = H or *n*-$C_4H_9$).

$RC{\equiv}CCH{=}CHCHClCH_3$ X $\quad$ $RC{\equiv}CCH{=}CHCH_2Cl$ XI

Normal products were obtained with aniline, ammonia and ethylamine. The halides XI (R = H or *n*-$C_4H_9$) yielded normal products even with diethylamine. The case of the abnormal product may be analogous to the cases of Meisenheimer and Link and Webb. However, abnormal product from X may arise from isomerization of normal product since treatment of normal product from X (R = H) and ethylamine with ethyl bromide gives the abnormal product.

Among the factors favoring abnormal product formation, Jones, Lacey and Smith emphasize basic strength of the nucleophilic reagent, in this way accounting for the formation of abnormal product with only diethylamine (and not $NH_3$

(14) Young and Andrews, THIS JOURNAL, **66**, 421 (1944).

(15) Meisenheimer and Link, *Ann.*, **479**, 211 (1930).

(16) Jones, Lacey and Smith, *J. Chem. Soc.*, 940 (1946).

$C_2H_5NH_2$ or $C_6H_5NH_2$). We feel that in cases of competing modes of attack (in this case $\alpha$ *vs.* $\gamma$) by a *limited* series of reagents, the dependence of rate on basic strength for each mode will be different. Thus a correlation of the ratio of the two rates with basic strength may become possible for a *limited* series of reagents. However, on this basis we do not expect a sharp difference between diethylamine and the other amines employed by Jones and co-workers, for the gap in basic strength is large between aniline and ethylamine and small between ethylamine and diethylamine.

One factor which is certain to be serious in a case of competing attacks such as the present competition between $\alpha$- and $\gamma$-attacks is the steric one. Thus, primary halides will suffer $\alpha$-attack more rapidly than the secondary halides, at least partly or largely for steric reasons. It is interesting that on this basis alone, without considering resonance effects and steric effects in the $\gamma$-attacks, the general behavior of the various halides can be correlated. The primary halides I, III and XI (R = H or *n*-$C_4H_9$) give normal products and similarly Meisenheimer and Link[15] obtained normal product from cinnamyl chloride and ethylaniline. On the other hand, the secondary halides II, IV and X (R = H or *n*-$C_4H_9$) give partly or largely abnormal products with certain reagents.

## Experimental

**$\alpha$- and $\gamma$-Methylallyl Chlorides.**—A mixture of the chlorides was prepared from a mixture of the alcohols and purified by standard methods.[17] The chlorides used had the following properties: $\alpha$-methylallyl chloride, b. p. 63.2–63.5° (750 mm.), $n^{20}D$ 1.4151, and $\gamma$-methylallyl chloride, b. p. 58.5–59.0° (300 mm.), $n^{20}D$ 1.4351.

**$\alpha$- and $\gamma$-Ethylallyl Chlorides.**—The $\alpha$-ethylallyl alcohol, b. p. 113–113.5° (750 mm.), $n^{25}D$ 1.4223, $d^{25}_4$ 0.8344, used as a source of the allylic chlorides was prepared from ethylmagnesium bromide and acrolein according to the method of Delaby[18] as modified by Prevost.[19] The pentenyl chlorides were prepared from the $\alpha$-ethylallyl alcohol by means of phosphorus trichloride and pyridine at 0° using standard methods[17] and were fractionated through a 1.5 × 135 cm. helices packed column under reduced pressure. The properties of the chlorides[20] used were as follows: $\alpha$-ethylallyl chloride, b. p. 55.0° (200 mm.), $n^{20}D$ 1.4253, $n^{25}D$ 1.4229, $d^{25}_4$ 0.8933, $M_D$, obs. 29.81, calcd. 29.69, equiv. wt., obs. 104.6, 104.9, calcd. 104.6; $\gamma$-ethylallyl chloride, b. p. 71.8° (200 mm.), $n^{20}D$ 1.4404, $n^{25}D$ 1.4380, $d^{25}_4$ 0.9089, $M_D$, obs. 30.20, calcd. 29.69, equiv. wt., obs. 105.2, 105.7, calcd. 104.6.

***n*-Caproic Acid.**—This material was redistilled Eastman Kodak Company White Label material, b. p. 97.5–98.0° (10 mm.), $n^{20}D$ 1.4163. The benzylamine derivative was prepared according to the method of Buehler, Carson and Edds[21] and recrystallized from anhydrous ethyl acetate; m. p.[22] 71–71.5° (cor.).

*Anal.* Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48. Found: C, 69.97; H, 9.64.

**$\beta$-Methylvaleric Acid.**—Secondary butyl bromide, b. p. 89–90° (750 mm.), $n^{25}D$ 1.4345, prepared from redistilled Eastman Kodak Company White Label 2-butanol, b. p. 99.0° (750 mm.), by means of phosphorus tribromide and pyridine at 0°, was condensed with malonic ester, b. p. 104–5° (25 mm.), in absolute ethanol according to the general method of Gilman and Blatt.[23] The condensation product was isolated but not purified and then hydrolyzed and decarboxylated as described by Blatt[24] to give $\beta$-methylvaleric acid, b. p. 93–94° (13 mm.), $n^{20}D$ 1.4158. The benzylamine derivative was somewhat hygroscopic and melted at 66–67° (cor.) after several recrystallizations from a mixture of anhydrous ethyl acetate and low-boiling petroleum ether.

*Anal.* Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48. Found: C, 70.44; H, 9.52.

***n*-Heptanoic Acid.**—Hydrolysis of Eastman Kodak Company White Label heptanoic anhydride yielded *n*-heptanoic acid, b. p. 109–110° (10 mm.), $n^{20}D$ 1.4225. The benzylamine derivative, recrystallized from a mixture of anhydrous ethyl acetate and low boiling petroleum ether, melted at 66.0–66.5° (cor.).

*Anal.* Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77. Found: C, 71.72; H, 9.88.

**$\beta$-Ethylvaleric Acid.**—Diethylcarbinol, b. p. 115–115.2° (750 mm.), $n^{15}D$ 1.4126, prepared by the reaction of ethylmagnesium bromide with propionaldehyde, was converted to 3-bromopentane by treatment with phosphorus tribromide and pyridine at 0°. The 3-bromopentane, b. p. 116.5–116.8° (750 mm.), $n^{20}D$ 1.4444, was condensed with malonic ester[23] and the condensation product hydrolyzed and decarboxylated[24] to $\beta$-ethylvaleric acid, b. p. 104–105° (13 mm.), $n^{20}D$ 1.4250, in 40% over-all yield. The benzylamine derivative of $\beta$-ethylvaleric acid crystallized slowly from low boiling petroleum ether at room temperature. Since the derivative was extremely hygroscopic and difficult to handle the best melting point which could be obtained was 51–53°.

*Anal.* Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77. Found: C, 70.63; H, 10.11.

**Condensation of $\alpha$- and $\gamma$-Methylallyl and $\alpha$- and $\gamma$-Ethylallyl Chlorides with Sodium Malonic Ester.**—To a stirred solution of sodium ethoxide, prepared by adding 0.50 mole of freshly cut sodium to 250 ml. of absolute ethanol (99.96%), was added 0.50 mole of diethyl malonate, b. p. 104–105° (25 mm.), over a one-half hour period. To this stirred sodium malonic ester solution was added 0.50 mole of the allylic chloride over a one-half hour period and the mixture then refluxed for two hours to complete the condensation. The cooled reaction mixture was poured into 800 ml. of water, neutralized with carbon dioxide gas, and the condensation product isolated by extraction with diethyl ether. The diethyl ether was removed by distillation and the condensation product added to 100 ml. of 95% ethanol and reduced at atmospheric pressure using platinum oxide catalyst. The catalyst was removed by filtration and the reduction product hydrolyzed and decarboxylated as described by Blatt.[24] The organic acids were isolated by extraction with diethyl ether and then completely removed from the ether layer by extraction with sodium carbonate solution. The aqueous solution of the sodium salts was decolorized with carbon, filtered, and the resulting colorless solution acidified with sulfuric acid. The organic acids were again isolated by extraction with diethyl ether. The diethyl ether was removed by distillation and the organic acids were carefully fractionated into 2–3 g. fractions. A second run was made using $\alpha$-methylallyl chloride (Method 2) in which the condensation of the chloride with sodium malonic ester was completed by allowing the mixture to stand at room temperature for one week instead of refluxing for two hours.

(18) Delaby, *Compt. rend.*, **175**, 967 (1922).

(19) Prevost, *Ann. chim.*, [10] **10**, 113, 147 (1928).

(20) Prevost [*Compt. rend.*, **187**, 1052 (1928)] reported the following properties: $\alpha$-ethylallyl chloride, $n^{23}D$ 1.4224, $d^{23}_4$ 0.8966; $\gamma$-ethylallyl chloride, $n^{23}D$ 1.4347, $d^{23}_4$ 0.9095.

(21) Buehler, Carson and Edds, THIS JOURNAL, **57**, 2181 (1935).

(22) Buehler, Carson and Edds[21] reported the melting point of the benzylamine salt of *n*-caproic acid to be 51.7–52.7°.

(23) Gilman and Blatt, "Organic Syntheses," Coll. Vol. I, 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1941, p. 250.

(24) Blatt, "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 416.

The products from the condensations with α-methylallyl chloride (Method 1), α-methylallyl chloride (Method 2), γ-methylallyl chloride, α-ethylallyl chloride and γ-ethylallyl chloride absorbed 92, 88, 93.5, 93.5 and 100%, respectively, of the theoretical amount of hydrogen, and the over-all yields of the saturated monocarboxylic acids were 89, 76, 80, 80 and 74%, respectively.

Fractionation of the saturated acids from the first condensation with α-methylallyl chloride with the aid of an estimated 25-plate 0.9 × 85 cm. platinum gauze-packed column similar to one described by Bower and Cooke[25] yielded 22 fractions (2–3 g. each) with a distillation temperature variation of 89–91° (10 mm.) and refractive index variation of $n^{20}D$ 1.4155–1.4157. Benzylamine derivatives of various distillation fractions were prepared by addition of approximately 0.25 ml. of benzylamine to 0.25 ml. of the acid. The resulting solid mass of crystals was recrystallized from a minimum volume (approximately 1 ml.) of a 50% mixture of anhydrous ethyl acetate and low boiling petroleum ether. From the melting point data for these derivatives, summarized in Table III, the amount of *n*-caproic acid, the abnormal product, was estimated to be 10 ± 3% of the total acid obtained. The loss of benzylamine derivative in the small amount of mother liquor was low but some difference in the solubility of the derivative of the normal and the abnormal products was a source of some uncertainty in the analysis, estimated at ±3%.

TABLE III

MELTING POINTS OF BENZYLAMINE DERIVATIVES OF α-METHYLALLYL CHLORIDE PRODUCTS

| Distillation fraction | M. p., of benzylamine salt, °C. | Mixed m. p. with β-methylvaleric acid salt, m. p. 66–67° | Mixed m. p. with *n*-caproic acid salt, m. p. 71–71.5° |
|---|---|---|---|
| 2 | 66–67 | 66–67 | |
| 4 | 65–67 | 66–67 | |
| 12 | 66–67 | 66–67 | |
| 18 | 65.5–67 | 66–67 | 50–56 |
| 19 | 66–67 | 66–67 | 53–57 |
| 20 | 47–51 | 50–55 | 42–45 |
| 21 | 65–68 | 54–57 | 66–69 |
| 22 | 70–71 | 55–57 | 70–71 |

The second condensation with α-methylallyl chloride (Method 2) gave similar results and the amount of abnormal product was estimated by means of benzylamine derivatives to be 6 ± 3% of the total acid obtained.

Fractionation of the saturated acids from the condensation with α-ethylallyl chloride gave 21 fractions (2–3 g. each) with a distillation temperature variation of 100–108° (10 mm.). The refractive index of fractions 1–14 varied from $n^{20}D$ 1.4250–1.4254 and then decreased for fractions 15–17 until fractions 18–21 were constant at 1.4226. In this fractionation, the refractive indices, the boiling points and the odor all indicated the presence of *n*-heptanoic acid, the abnormal product, in fractions 15–21, inclusive. Benzylamine derivatives of various distillation fractions were prepared and recrystallized once from low-boiling petroleum ether and the minimum amount of anhydrous ethyl acetate necessary to dissolve the solid. From the melting point data for these derivatives, summarized in Table IV, the amount of *n*-heptanoic acid, the abnormal product, was estimated to be 23 ± 3% of the total acid obtained.

Investigation of the fractionated acids from the condensations with γ-methylallyl and γ-ethylallyl chlorides in a similar manner indicated that a generous estimate of the amount of abnormal product present in each case would be 1% of the total acid obtained.

**Kinetic Studies.**—The presence of a small amount of acidic impurity in the solutions resulted in a fast initial rate so that in each run the first determination was taken as a blank and the rate constants calculated assuming this to be zero time.

**(A) Solvolysis of α-Ethylallyl Chloride in Absolute Ethanol.**—A sample of α-ethylallyl chloride was weighed into a 100-ml. volumetric flask and diluted to volume with absolute ethanol (99.96%). Approximately 13 ml. of this solution was sealed into each of a series of tubes which were maintained at 50.00°. At certain time intervals tubes were withdrawn from the thermostat, cooled quickly in an ice-bath and 10.00-ml. aliquots titrated to the first definite phenolphthalein end-point with standard sodium hydroxide solution.

**(B) Condensation of α-Ethylallyl Chloride with Sodium Malonic Ester in Absolute Ethanol.**—To a weighed sample (approximately 0.034 mole) of α-ethylallyl chloride in a 100-ml. volumetric flask was added 85 ml. of 0.44 *M* alcoholic sodium malonic ester solution and the resulting mixture diluted to volume with absolute ethanol (99.96%). The solution was mixed thoroughly and 10.00-ml. aliquots sealed in test-tubes and placed in a thermostat at 50.00° as rapidly as possible. The samples were removed from the thermostat at intervals, cooled rapidly in an ice-bath and the contents of the tube washed quantitatively into an excess of standard alcoholic hydrochloric acid. The excess hydrochloric acid was then titrated with standard sodium hydroxide solution using brom thymol blue indicator. Determinations of the initial concentration of the sodium malonic ester in the reaction mixture by analyzing one aliquot when the samples were immersed in the thermostat and by analyzing another aliquot which had been heated fifteen hours at 80° to complete the reaction agreed within 0.3%.

## Summary

The products resulting from the condensation of sodium malonic ester with α- and γ-methylallyl and α- and γ-ethylallyl chlorides have been investigated. γ-Methylallyl and γ-ethylallyl chlorides reacted entirely to give products which would result from a normal bimolecular displacement. α-Methylallyl and α-ethylallyl chlorides reacted to give 10 and 23%, respectively, of the product which would result from an abnormal bimolecular displacement involving attack on the γ-carbon atom. Kinetic studies with α-ethylallyl chloride indicated that the abnormal product arises from a second-order reaction.

Abnormal bimolecular displacements are briefly discussed.

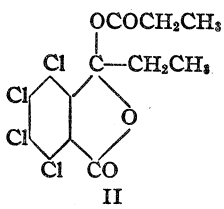
# Vinyl Aromatic Compounds. VI. Alkylidenephthalides and Related Compounds[1]

BY DAVID T. MOWRY, EUGENE L. RINGWALD AND MARY RENOLL[2]



The Gabriel modification of the Perkin reaction, in which phthalic anhydride is substituted for benzaldehyde, has been reviewed briefly.[3]

We have selected the preparation of 3-ethylidenephthalide from phthalic anhydride, propionic anhydride and sodium propionate,[4,5] for study as representative of the Gabriel method of alkylidenephthalide formation. Although Gottlieb[4] reported an 88% crude yield, we have found that only 40–50% could be isolated as a pure product having a melting point of 64–65°. 2-Methyl-1,3-indandione (I), m. p. 84°, has been identified as one of the by-products and was easily separated by virtue of its solubility in cold aqueous alkali. The principal impurity, however, was an oil which could not be satisfactorily separated and purified by crystallization or distillation.

I

II

In order to elucidate the nature of this by-product, tetrachlorophthalic anhydride was condensed with a 200% excess of propionic anhydride under similar conditions to give a mixture of products from which 10% of 3-ethylidene-4,5,6,7-tetrachlorophthalide, m. p. 161°, and 14% of a neutral substance, $C_{13}H_{10}O_4Cl_4$, m. p. 107–108°, were isolated by fractional crystallization. The neutral by-product was easily saponified to 2-propionyl-3,4,5,6-tetrachlorobenzoic acid, m. p. 178–180°, which was independently prepared from 3-ethylidene-4,5,6,7-tetrachlorophthalide. Hence, the by-product is probably 3-propionoxy-3-ethyl-4,5,6,7-tetrachlorophthalide (II) which may have been formed by the addition of propionic acid to the ethylidenephthalide. The oily by-product formed in the preparation of 3-ethylidenephthalide probably has an analogous structure.

The phthalic anhydride–propionic anhydride reaction conditions have been varied with respect to catalyst, reagent ratios, and reaction times. Using 1.1 moles of propionic anhydride, 0.5 mole of sodium propionate and a reaction time of five hours at 180° there was obtained an 80% yield of crude distilled product, b. p. 154–162° (11 mm.) and a 58% yield of pure 3-ethylidenephthalide, m. p. 64–65°. The use of potassium propionate gave similar results, while sodium acetate was markedly inferior. Pyridine did not catalyze the reaction, although this catalyst recently has been reported,[6] to be satisfactory for the condensation of phthalic anhydride with malonic acid. No improvement in yield was obtained by increasing the reaction time.

On standing for several months 3-ethylidenephthalide is slowly transformed to a sticky resinous material.[7] This appears to be a low molecular weight polymer, $(C_{10}H_8O_5)_x$, of considerably higher oxygen content than the monomeric substance. It forms phthalic anhydride on destructive distillation. This transformation is caused by atmospheric oxygen since samples of ethylidenephthalide stored for six months in sealed evacuated ampoules showed no evidence of change.

By similar techniques, phthalic anhydride has been condensed with butyric anhydride and heptanoic anhydride to give propylidene- and *n*-hexylidene-phthalides. Attempts to prepare cyanomethylenephthalide from cyanoacetic acid and phthalic anhydride have been unsuccessful.[8] Thiophthalic anhydride reacted normally with propionic anhydride to give 3-ethylidenethiophthalide, but maleic and dichloromaleic anhydride gave only intractable tars. 3-Benzal-4,5,6,7-tetrachlorophthalide has been prepared from phenylacetic acid and tetrachlorophthalic anhydride in 60% yield.

We have attempted to prepare the ethyl ester of phthalideneacetic acid by direct esterification using acid catalysts. However, a hydration and decarboxylation took place with the formation of ethyl *o*-acetylbenzoate. A similar hydration and decarboxylation is reported by Yale,[6] who prepared *o*-acetylbenzoic acid directly from phthalic anhydride and malonic acid in pyridine

solution. 3-Methylenephthalide may have been the intermediate since the crude distillate on some runs formed a glassy polymer on standing. The desired esters of phthalideneacetic acid were prepared in satisfactory yields by treating phthalideneacetyl chloride with methyl, ethyl and *n*-hexyl alcohols. However, an attempted esterification of the acid chloride with phenol by the Schotten–Baumann technique was unsuccessful.

## Experimental Part[9]

**3-Ethylidenephthalide.**—The following is a typical procedure for the preparation of ethylidenephthalide.[4,5] Phthalic anhydride (296 g., 2.0 moles) and propionic anhydride (286 g., 2.2 moles) were placed in a two-liter three-necked flask equipped with a stirrer, thermometer, reflux condenser and funnel for addition of solids. After heating to 150–160°, 96 g. (1.0 mole) of dry sodium propionate was added in four portions over a period of thirty minutes, taking care to allow the evolution of carbon dioxide to subside after each addition. After heating at slow reflux (170–180°) for five hours, the reaction was cooled somewhat and stirred vigorously with 700 cc. of hot water. The organic layer was taken up in 200 cc. of carbon tetrachloride and separated and washed with warm water. The product was then distilled to give 256 g. (80%) of crude ethylidenephthalide, b. p. 154–162° (11 mm.). Two recrystallizations from a mixture of benzene and hexane gave 130 g. of white crystals, m. p. 64–65°. An additional 55 g., m. p. 62–63° was obtained from the mother liquors, giving a total yield of 58%.

Extraction of the yellow oil remaining in the mother liquors with sodium hydroxide gave, after acidification, 12 g. (4%) of white crystals, b. p. 150° (17 mm.), m. p. 84–85°. This was 2-methyl-1,3-indandione, which Nathanson[10] prepared from sodium methylate and ethylidenephthalide.

The following table gives the crude (distilled) and pure (fraction melting above 60°) yields of ethylidenephthalide based on phthalic anhydride which were obtained under various conditions of catalyst concentration, reagent ratios, and reaction times at 170–180°.

| Phthalic anhydride, moles | Propionic anhydride moles | Sodium propionate, moles | Time, hr. | Crude yield, % | Pure yield, % |
|---|---|---|---|---|---|
| 1.0 | 1.1 | 0.1 | 5 | <5 | .. |
| 1.0 | 1.1 | .5 | 2 | 71 | 43 |
| 1.0 | 1.1 | .5 | 5 | 80 | 58 |
| 1.0 | 1.1 | .5[a] | 6 | 43 | 25 |
| 1.0 | 1.1 | .5[b] | 3 | 65 | 50 |
| 1.0 | 1.1 | .5[c] | 5 | 0[d] | .. |
| 1.0 | 1.1 | 1.0 | 5 | 75 | 50 |
| 1.0 | 1.1 | 1.0 | 24 | 78 | 46 |
| 1.0 | 1.5 | 0.5 | 3 | .. | 45 |
| 1.2 | 1.0 | 0.5 | 3 | 62 | 41 |

[a] Sodium acetate. [b] Potassium propionate. [c] Pyridine. [d] Essentially all the phthalic anhydride was recovered unchanged.

The gummy resinous material formed by ethylidenephthalide[7] on standing in contact with air at room temperature for several months was washed with hot benzene. The insoluble portion was a white powder which melted at 196–199°, and a 2% solution in dioxane had a specific viscosity at 25° of 0.067 compared to 0.018 for unchanged ethylidenephthalide. Analysis indicated that this low polymer contained considerably more oxygen than the monomer.

*Anal.* Calcd. for $(C_{10}H_8O_5)_x$: C, 57.7; H, 3.8. Calcd. for $(C_{10}H_8O_4)_x$: C, 62.5; H, 4.6. Found: C, 58.5; H, 3.97.

Destructive distillation of the crude gummy material was effected under vacuum using an open flame. About fifty weight per cent. of phthalic anhydride, m. p. 129–131° after recrystallization, was obtained in the distillate.

**3-Ethylidene-4,5,6,7-tetrachlorophthalide and 3-Ethyl-3-propionoxy-4,5,6,7-tetrachlorophthalide.**—One mole (286 g.) of tetrachlorophthalic anhydride and 390 g. (3.0 moles) of propionic anhydride were heated with stirring to 160°. Then 60 g. (0.63 mole) of sodium propionate was added in five portions over a period of one hour. The reaction was then refluxed for five hours before distilling off the excess propionic anhydride and propionic acid under reduced pressure. The residue was washed with 500 cc. of water at reflux, dissolved in a little carbon tetrachloride and separated. The organic layer was distilled and a fraction boiling at 210–230° (5–8 mm.) was collected. This was dissolved in hot acetone and cooled to give white crystals which were recrystallized once from acetone and again from a mixture of benzene and hexane. There was obtained 29 g. (10%) of 3-ethylidene-4,5,6,7-tetrachlorophthalide, m. p. 161–162°.

*Anal.* Calcd. for $C_{10}H_4O_2Cl_4$: C, 40.3; H, 1.34; Cl, 46.7. Found: C, 40.5; H, 1.54; Cl, 48.2.

The filtrate from the first acetone recrystallization was diluted with water and the resultant solid collected and recrystallized several times from dilute ethanol to give 51 g. (14%) of 3-ethyl-3-propionoxy-4,5,6,7-tetrachlorophthalide, white crystals, m. p. 107–108°.

*Anal.* Calcd. for $C_{13}H_{10}Cl_4O_4$: C, 42.0; H, 2.70; Cl, 38.2; mol. wt., 372. Found: C, 42.26; H, 2.78; Cl, 38.33; mol. wt. (Rast), 395.

Although this material was not soluble in aqueous alkali it instantly formed a reddish yellow solution in alcoholic sodium hydroxide. After warming for fifteen minutes it was acidified and the solid was recrystallized from dilute alcohol to give yellow crystals, m. p. 178–180°, which were soluble in sodium bicarbonate. This was 2-propionyl-3,4,-5,6-tetrachlorobenzoic acid and was identical with a sample prepared by the saponification of 3-ethylidene-4,5,6,7-tetrachlorophthalide.

*Anal.* Calcd. for $C_{10}H_6O_3Cl_4$: C, 38.0; H, 1.90. Found: C, 38.2; H, 2.09.

**3-Propylidenephthalide.**—Phthalic anhydride (296 g., 2.0 moles) was treated with butyric anhydride (348 g., 2.2 moles) in the presence of sodium butyrate (110 g., 1.0 mole) at 150–180° for five hours. The product was recovered as described above to give 217 g. (62%) of 3-propylidenephthalide, b. p. 142–145° (4.0 mm). Careful refractionation through a one-meter column packed with glass helices gave an analytical sample b. p. 143° (4 mm.), $n^{25}D$ 1.5859, f. p. 5°. Bromberg[11] reported b. p. 169–170° (12 mm.) for a product obtained in 41% yield.

**3-*n*-Hexylidenephthalide.**—This compound was prepared from 1.0 mole of phthalic anhydride, 1.1 moles of heptanoic anhydride and 0.5 mole of sodium heptanoate in the same manner as described for ethylidenephthalide. There was obtained a 54% yield of 3-*n*-hexylidenephthalide, b. p. 175–176° (5 mm.), $n^{25}D$ 1.5585, f. p. 5–6°.

*Anal.* Calcd. for $C_{14}H_{16}O_2$: C, 77.7; H, 7.41. Found: C, 77.42; H, 7.42.

**3-Ethylidenethiophthalide.**—Thiophthalic anhydride[12] (91 g., 0.55 mole, m. p. 108°) was treated with 170 g. (1.3 moles) of propionic anhydride and 53 g. (0.55 mole) of sodium propionate at 160° for three hours. The product was recovered in the usual fashion and boiled at 155–160° (6 mm.) with slight decomposition. The crude product was recrystallized twice from hexane to give 3-ethylidenethiophthalide, m. p. 56–57°, in 31% yield. The white crystals assumed an orange color on exposure to light.

*Anal.* Calcd. for $C_{10}H_8OS$: S, 18.2. Found: S, 18.43.

(9) Analyses by Oakwold Laboratories, Alexandria, Va. All melting points corrected.

(11) Bromberg, *Ber.*, **29**, 1436 (1896).

(12) Reissert and Holle, *Ber.*, **44**, 3029 (1911).

**3-Benzal-4,5,6,7-tetrachlorophthalide.**—The procedure of Weiss[13] for benzalphthalide was used. Phenylacetic acid (136 g., 1.0 mole), tetrachlorophthalic anhydride (238 g., 0.84 mole) and 3 g. of sodium acetate were heated at 230 to 260° for several hours using a short column and downward condenser to remove the water formed. The molten residue was then poured out and recrystallized from five liters of xylene. The product, 173 g. (53%) melted at 300°.

*Anal.* Calcd. for $C_{15}H_6O_2Cl_4$: C, 50.0; H, 1.67; Cl, 39.5. Found: C, 50.6; H, 2.26; Cl, 39.40.

**Ethyl Phthalideneacetate.**—Phthalideneacetic acid[14] (170 g., 0.9 mole) and 225 cc. of thionyl chloride were refluxed for four hours and the excess thionyl chloride was evaporated under water-pump vacuum. The resultant crystalline solid was broken up and treated with 300 cc. of cold absolute ethanol. After stirring for several hours the yellow solid was filtered and recrystallized from a mixture of benzene and hexane to give 90 g. (46%) of yellow crystals, m. p. 131–133°. The analytical sample after two more recrystallizations melted at 134–135°.

*Anal.* Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62; sapn. no., 218. Found: C, 66.33; H, 4.62; sapn. no., 212.

Earlier attempts to esterify phthalideneacetic acid directly with an excess of ethanol using sulfuric acid as a catalyst gave a good yield of ethyl *o*-acetylbenzoate, b. p. 112–115° (2 mm.), $n^{25}D$ 1.5122.

*Anal.* Calcd. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.32; sapn. no., 192. Found: C, 68.92; H, 6.55; sapn. no., 199.

Saponification of a small sample with alcoholic potassium hydroxide gave *o*-acetylbenzoic acid,[15] m. p. 115°. In one esterification run the crude distilled product having $n^{25}D$ 1.5238 was thought to contain some methylenephthalide since the material polymerized to an insoluble incompatible mass on standing at room temperature for several days.

**Methyl Phthalideneacetate.**—Treatment of phthalideneacetyl chloride with methanol at 5–10° in a similar fashion gave a 61% yield of the methyl ester, yellow crystals, m. p. 171–172° cor., after recrystallization from a mixture of benzene and hexane.

*Anal.* Calcd. for $C_{11}H_8O_4$: C, 64.7; H, 3.92. Found: C, 64.78; H, 4.12.

***n*-Hexyl Phthalideneacetate.**—Seventy grams of crude phthalideneacetyl chloride was treated with 250 cc. of *n*-hexanol at room temperature and warmed to 60° with stirring. The resultant oil was distilled twice to give 54 g. (59%) of a pale yellow oil, b. p. 208–210° (3 mm.).

*Anal.* Calcd. for $C_{16}H_{18}O_4$: C, 70.2; H, 6.58. Found: C, 69.92; H, 6.96.

## Summary

The preparation of 3-ethylidenephthalide from phthalic anhydride and propionic anhydride in the presence of sodium acetate has been studied and 2-methyl-1,3-indanedione has been isolated as a by-product. The formation of a second by-product, 3-ethyl-3-propionoxyphthalide, is inferred since an analogous compound has been isolated from a similar reaction using tetrachlorophthalic anhydride. 3-Propylidenephthalide, 3-*n*-hexylidenephthalide, 3-ethylidenethiophthalide, 3-ethylidene- and 3-benzal-4,5,6,7-tetrachlorophthalides, and the methyl, ethyl and hexyl esters of phthalideneacetic acid have been prepared and characterized.

# Reduction of Aldehydes, Ketones and Acid Chlorides by Sodium Borohydride

BY SAUL W. CHAIKIN AND WELDON G. BROWN

The successful use of lithium aluminum hydride as a reducing agent for organic compounds[1] has prompted the investigation of the reducing properties of other complex hydrides. The borohydrides of aluminum,[2] gallium,[3] beryllium,[4] lithium[5] and sodium[6] have been described. Of these, the sodium compound appeared to be of the greatest practical interest because it is potentially a cheaper material than lithium aluminum hydride and because a convenient preparative method is available.[6]

The reduction of various inorganic substrates by sodium trimethoxyborohydride, $NaBH(OCH_3)_3$, in aqueous solution has been studied by Sheft,[7] who also effected the reduction of carbon dioxide to formate. Previous studies on sodium borohydride, $NaBH_4$, as a reducing agent by Schlesinger, Schaeffer and collaborators[8] have been concerned with applications in the fields of inorganic and analytical chemistry, but have nevertheless served to indicate the potential value of the reagent in organic synthesis.

We find that the reduction of aldehydes and ketones by sodium borohydride follows the same pattern as with lithium aluminum hydride. The reactions occur rapidly at room temperature in most cases, although occasionally heating is required, and the corresponding alcohols are formed in comparable yields. Unsaturated aldehydes and ketones, in three examples studied, furnish the unsaturated alcohols.

The experimental techniques are quite different, for whereas lithium aluminum hydride must be used in non-hydroxylic solvents and must be rigorously protected from moisture, the reductions with sodium borohydride may be carried out in water or methanol solution. This represents a gain in convenience and economy, and suggests a possible further advantage in the reduction of ether-insoluble compounds, such as the sugars, for which lithium aluminum hydride is unsuitable.

However, a limitation is imposed by the difficultly hydrolyzable nature of the intermediate alkyl borates in certain cases. The *n*-alkyl borates are very rapidly hydrolyzed and thus, where the reduction of an aliphatic aldehyde is carried out in an aqueous solution of sodium borohydride, hydrolysis of the intermediate boron ester takes place concurrently. Other types undergo hydrolysis less readily,[9] and in the reduction of aromatic aldehydes and some of the ketones studied subsequent heating with alkali was necessary in order to liberate the alcohols. Stable complexes with boric acid are formed by α-hydroxy-acids[10] and by many polyhydroxy compounds[11] and the isolation of such products presents a problem which has not been satisfactorily solved. Thus pyruvic acid and glucose, although evidently reduced by sodium borohydride, form complexes from which boron-free reduction products could not be isolated.

The reduction of the carboxylate group of acids by sodium borohydride does not occur to any appreciable extent under the conditions described above for the reduction of carbonyl groups. Moreover, these conditions are not appropriate, because of the alkaline medium, for the reduction of easily hydrolyzable derivatives of carboxylic acids. Acid chlorides may be successfully reduced however by employing a suspension of sodium borohydride in dioxane or other inert solvent. The reaction is vigorous with aliphatic acid chlorides but aromatic acid chlorides require heating. Simple acid chlorides are converted to the alcohols in good yields but the results for unsaturated and other polyfunctional acid chlorides are less clean-cut.

Crotonyl chloride and cinnamoyl chloride evidently undergo reaction at the carbon–carbon double bonds as is shown by the isolation, in the latter case, of some hydrocinnamyl alcohol, and by the fact that in neither case was it possible to isolate any of the unsaturated alcohol. Analogous reactions of lithium aluminum hydride are known[1,12] and on the basis of this analogy it is assumed that the borohydride adds to the double bond forming a carbon–boron bond with the β-carbon atom. This bond, in contrast with the analogous aluminum compounds, is evidently highly resistant to hydrolytic fission. It is noteworthy that the reduction of cinnamaldehyde by sodium borohydride in methanol solution could not be forced beyond the cinnamyl alcohol state.

Under conditions favorable for the reduction of acid chlorides, sodium borohydride is without action on the esters and nitriles tested. Acids and acid anhydrides show only slight reduction on prolonged heating of the mixtures. It is with respect to these types that the milder reducing action of sodium borohydride, as compared with lithium aluminum hydride, is most clearly evident.

The lower reactivity of the borohydride is advantageous in permitting the selective reduction of acid chloride or carbonyl groups in the presence of other functional groups which, with lithium aluminum hydride, would also be reduced. This special application is perhaps most strikingly illustrated in the present work by the selective reduction at the carbonyl groups in levulinic acid, ω-bromoacetophenone[13] and *m*-nitrobenzaldehyde.

Although precise determinations of the stoichiometrical relationships have not been carried out the end-point in the strongly exothermic reaction of most aldehydes and ketones with sodium borohydride is easily recognizable. Semi-quantitative observations of this kind leave no doubt that four moles of the aldehyde or ketone react with one of the borohydride and the course of the reactions may be formulated as

$$4R_2CO + NaBH_4 = NaB(OCHR_2)_4 \quad (1)$$

$$NaB(OCHR_2)_4 + 2NaOH + H_2O = Na_2BO_3 + 4R_2CHOH \quad (2)$$

## Experimental

**Sodium Borohydride.**—The sodium borohydride used in this work was supplied to us through the kindness of Professor H. I. Schlesinger. Analysis, by measurement of the hydrogen gas evolved upon acidification of an aqueous solution, showed 90% sodium borohydride. It was kept in a screw-cap bottle which was opened intermittently with no special precautions to prevent access of atmospheric moisture; the rate of deterioration was less than 2% per year. Aqueous or methanolic solutions were prepared for immediate use by dissolving the required quantity to make a 10–15% solution. Aqueous solutions, stabilized by the addition of sodium hydroxide (0.2 *N*), showed less than 5% loss of activity in two weeks. A solution 6 *N* in sodium hydroxide showed only slight decomposition at 100°.

**Reduction of Aldehydes and Ketones.**—The order in which the reactants were combined was largely arbitrary except where special considerations indicated a preference. Alkali-sensitive compounds, *e. g.*, crotonaldehyde, were reduced by addition of the compound, dissolved in water or methanol, to a solution of the hydride in order to avoid prolonged contact of unreduced compound with alkali. Compounds of very low solubility, *e. g.*, benzil and dicyclohexyl ketone, were more conveniently reduced by adding a solution of the hydride to a suspension of the compound in methanol; in such cases the reaction mixtures became homogeneous as the reactions proceeded.

Two ketones, mesityl oxide and dicyclohexyl ketone, required heating to 60–70° to initiate reaction. More com-

(9) Scattergood, Miller and Gammon, THIS JOURNAL, **67**, 2150 (1945), have reported qualitative observations on the ease of hydrolysis of alkyl borates and have noted that a wide variation exists, secondary alkyl borates hydrolyzing less rapidly than primary with pronounced chain-branching effects in both types.

(11) Hermans, *Z. anorg. Chem.*, **142**, 83 (1925).

(12) Hochstein and Brown, THIS JOURNAL, **70**, 3484 (1948).

(13) This compound is reduced to methylphenylcarbinol by lithium aluminum hydride (unpublished work by Mr. Lloyd Trevoy).

monly, cooling was necessary to moderate the reactions and to maintain the temperature in the range 20–30°.

In order to avoid the acid-catalyzed decomposition of hydride which would otherwise be caused by the free acidic groups, the solutions of levulinic acid and of *m*-hydroxybenzaldehyde were neutralized by the addition of sodium hydroxide prior to reduction.

When necessary, to establish completeness of reaction, the presence of excess sodium borohydride was detected by adding one drop of the reaction mixture to 1 ml. of dilute acid, the immediate evolution of hydrogen constituting a positive test.

Striking color phenomena were observed during the course of the reduction of benzil. A reddish-purple color appeared on the first addition of hydride solution and persisted until about one third of the required amount of hydride had been added. Thereafter, until nearly the end of the addition of hydride, the color was discharged on each fresh addition of hydride, leaving the yellow color of benzil, and then slowly returned. After all of the hydride solution had been added the color was still yellow; on warming the mixture to 60° it became colorless. The crude product from this reduction melted over the range 124–131° and was evidently a mixture of *meso*- and *dl*-hydrobenzoin. By multiple recrystallizations from carbon tetrachloride and from mixtures of carbon tetrachloride and chloroform, following the procedure of Böeseken and Elsen,[14] ***meso***-hydrobenzoin, m. p. 137°, was isolated in 56% yield.

In the reduction of diacetyl no comparable color phenomena were observed. The yellow color of diacetyl disappeared when a quantity of hydride had been added which was sufficient to reduce one carbonyl group.

Our results for aldehydes and ketones are summarized in Table I.

**Reduction of Acid Chlorides.**—Dioxane, used in the reduction of acid chlorides, was purified by refluxing for twenty-four hours over calcium hydride followed by distillation, rejecting the forerun until a 1-ml. test sample showed no gas evolution when treated with a few milligrams of sodium borohydride. Diethyl carbitol was used instead of dioxane in those cases where the boiling point of the reduction product is near that of dioxane. The diethylcarbitol was a technical grade, purified by distillation.

The reduction of aliphatic acid chlorides was carried out by the regulated addition of the acid chloride, dissolved in dioxane if necessary, to a cooled suspension of sodium borohydride, in excess, in dioxane. The mixtures were heated on the steam-bath for a short time following the addition and then, after cooling, water was added. The addition of water invariably resulted in a vigorous exothermic reaction accompanied by the evolution of hydrogen gas in the amount of approximately four moles per mole of acid chloride taken. The evolution of hydrogen was probably caused by the acid, liberated in the hydrolysis of the intermediate complexes, acting upon the excess sodium borohydride. Isolation of the reduction products was accomplished by appropriate methods with the results shown in Table II.

TABLE I

REDUCTION OF ALDEHYDES AND KETONES

| Compound | Product | Yield, % | $n_D$ or m. p.,[a] °C. |
|---|---|---|---|
| **A. Reductions in Aqueous Solution** | | | |
| Acetonylacetone | Hexanediol-2,5 | 86 | 1.4453 |
| *n*-Butyraldehyde (C)[b] | *n*-Butanol | 85 | 1.3977 |
| Chloral hydrate | 2,2,2-Trichloroethanol | 61 | |
| Crotonaldehyde (C) | Crotyl alcohol | 85 | 1.4249 |
| Cyclopentanone | Cyclopentanol | 90 | 1.4520 |
| Diacetyl | Butanediol-2,3 | 62 | 1.4336 |
| Levulinic acid | γ-Valerolactone | 81 | 1.4319 |
| Mesityl oxide (C)[c] | 4-Methyl-3-pentenol-2[d] | 77 | 1.4310 |
| Methyl ethyl ketone | *s*-Butanol | 87 | 1.3956 |
| **B. Reductions in Methanol Solution** | | | |
| Anisaldehyde (C) | Anisyl alcohol | 96 | 24 |
| Benzil | Hydrobenzoin[e] | 89 | 124–131 |
| ω-Bromoacetophenone | Styrene bromohydrin | 71 | 1.5751 |
| Cinnamaldehyde | Cinnamyl alcohol | 97 | 32.5 |
| Dicyclohexyl ketone | Dicyclohexylcarbinol | 88 | 62 |
| *p*-Dimethylaminobenzaldehyde (C) | *p*-Dimethylaminobenzyl alcohol | 96 | 1.5775 |
| *m*-Hydroxybenzaldehyde (C) | *m*-Hydroxybenzyl alcohol | 93 | 64 |
| *m*-Nitrobenzaldehyde | *m*-Nitrobenzyl alcohol[f] | 82 | 30.5 |

[a] Melting points are given for solid products, refractive indices (at 25°) for liquid products. Other data pertaining to characterization are omitted except in special cases noted below. [b] The letter "C" designates the order of addition to be: compound added to solution of the borohydride, except where thus designated the order of addition was the opposite. [c] Mesityl oxide was purified by the procedure of Stross, Monger and de V. Finch [THIS JOURNAL, 69, 1627 (1947)]; b. p. 128.8–129°, $n^{24}D$ 1.4435. The reduction was carried out in a 2:1 water–methanol mixture. [d] B. p. 138–140°. Doeuvre [*Bull. soc. chim.*, 10, 371 (1943)] who prepared this compound in 25% yield by the Meerwein–Ponndorf reduction of mesityl oxide, reported b. p. 138–140°, $n^{15}D$ 1.4377. The 63% yield, given by Wilds ["Organic Reactions," Vol. II, Wiley & Sons, New York, N. Y., 1944, p. 209], is incorrectly quoted from earlier literature. [e] The stated yield pertains to a mixture of isomers (*cf.* text). [f] The compound was observed in two allotropic modifications, one melting at 15° and a stable form melting at 30.5°. The literature melting point is 27° [Staedel, *Ber.*, 27, 2112 (1894)].

TABLE II

REDUCTION OF ACID CHLORIDES

| Compound | Product | Yield, % | $n_D$ or m. p.[a] °C. |
|---|---|---|---|
| Benzoyl chloride | Benzyl alcohol | 76 | 1.5371 |
| *n*-Butyryl chloride | *n*-Butanol | 81 | 1.3979 |
| Cinnamoyl chloride | Hydrocinnamyl alcohol[b] | 12 | 1.5248 |
| Monoethyl succinate acid chloride | Butyrolactone[c] | 40 | |
| Palmitoyl chloride | Cetyl alcohol[d] | 87 | 47.5–49 |
| *o*-Phthalyl chloride | Phthalide[e] | 49 | 72 |
| | Phthalyl alcohol[e] | 15 | 59 |

[a] See footnote (*a*), Table I. [b] Identified through the 3,5-dinitrobenzoate, m. p. 91°. A major portion of the product consisted of an organic material containing boron not decomposed by hot alkali. [c] B. p. 87–87.5° (12 mm.). Chromic acid oxidation furnished succinic acid, m. p. 183–184.5°. [d] Reaction product hydrolyzed in hot dilute acid. [e] Identity of products verified by mixed melting points with authentic specimens.

In the case of aromatic acid chlorides, which were found not to react at room temperature, a modified procedure was followed in which the mixtures were heated on the steam-bath for one to two hours, and then were cooled in an ice-bath before adding water. Some difficulty with foaming during the first addition of water was experienced.

**Miscellaneous Experiments.**—The following compounds, heated with a dioxane or diethylcarbitol suspension of sodium borohydride for one hour, showed no evidence of reduction: ethyl butyrate, ethyl phenylacetate, benzyl cyanide, maleic acid. Partial reduction was observed under similar conditions with butyric acid, phthalic anhydride and succinic anhydride. Cinnamyl alcohol, refluxed for one hour with an alkaline methanol solution of sodium borohydride, was recovered unchanged.

The isolation of boron-free products was unsuccessful, although reduction obviously occurred, with pyruvic acid,

(14) Böeseken and Elsen, *Rec. trav. chim.*, 47, 694 (1928).

glucose, anthraquinone and crotonyl chloride. Acetylacetone evidently suffered cleavage prior to or during the reduction; isopropyl alcohol was isolated in 63% yield.

Solutions of benzene diazonium chloride exhibited a rapid and strongly exothermic reaction with sodium borohydride. Benzene, aniline and phenylhydrazine were isolated in relatively small yields. The course of the reaction was qualitatively similar in neutral and in strongly alkaline solutions.

**Acknowledgment.**—The support afforded by the Lindsay Light and Chemical Company through the award of a Fellowship to the junior author (S. W. C.) is gratefully acknowledged.

## Summary

Sodium borohydride, in water or methanol solution, is an effective reagent for the conversion of aldehydes and ketones to the corresponding alcohols. Its properties are compared with those of lithium aluminum hydride and it is shown to be superior in selective reductions. Acid chlorides are reduced to primary alcohols in non-aqueous media, but carboxylic acids, anhydrides, esters and nitriles are practically unaffected.

# Crystalline Derivatives of Isomaltose[1,2]

BY M. L. WOLFROM, L. W. GEORGES[3] AND I. L. MILLER[4]

In the course of our studies on the structure of starch it became desirable to have a reference compound made up of two D-glucose residues combined by a 6-$\alpha$-D-glucosyl linkage. Musculus,[5] Grimaux and Lefèvre[6] and Gautier[7] had prepared weakly reducing non-fermentable sirupy disaccharides by condensing D-glucose in the presence of acids. E. Fischer[8] in attempts to synthesize maltose, obtained a similar material which he called "isomaltose" and characterized as its phenylosazone (m. p. 158°). Georg and Pictet[9] prepared isomaltose according to the procedure of Fischer as modified by Friedrichs[10] and obtained a sirup which produced an amorphous acetate upon hot acetylation with acetic anhydride and sodium acetate. By means of a fractional precipitation procedure from ethanol the crude acetate was separated into three fractions: octaacetylgentiobiose, m. p. 190–195°; $\beta$-octaacetylisomaltose, amorphous, fusing at 72–77° and showing a rotation of $[\alpha]^{20}D$ +93.7° ($c$ 4.8); a small amount of a third fraction, amorphous and fusing at 115–123°. The $\beta$-octaacetylisomaltose was converted into amorphous $\alpha$-octaacetylisomaltose by heating with acetic anhydride and zinc chloride, $[\alpha]^{19}D$ +115.5° ($c$ 4.2). The free sugar exhibited a rotation of $[\alpha]^{23}D$ +104.6° (ten minutes), +99.7° (twenty-four hours) ($c$ 5.1, water), and produced a phenylosazone which melted at 160° and had a rotatory value of $[\alpha]^{23}D$ +23.1° ($c$ 1.2, methanol). Upon methylation of the free sugar with subsequent hydrolysis, Georg[11] obtained 2,3,-4-trimethyl-D-glucose and 2,3,4,6-tetramethyl-D-glucose indicating a 6-D-glucopyranosyl structure. Myrbäck[12] prepared "isomaltose" as a reversion product of D-glucose by the action of hydrochloric acid and by methylation studies confirmed Georg's observation that it is 6-$\alpha$-D-glucosyl-D-glucose. Berlin[13] has been able to isolate gentiobiose octaacetate from the "isomaltose" of Fischer. He believes that this preparation is a gross mixture containing gentiobiose. His observation is supported by Isaiev.[14] By acid hydrolysis and by Taka diastase treatment, Ahlborg and Myrbäck[15] obtained from corn starch a sirupy disaccharide which on methylation and hydrolysis yielded 2,3,4,6-tetramethyl-D-glucose and 2,3,4-trimethyl-D-glucose. It was thus established as an "isomaltose" derivative. Following the publication of our preliminary notice,[1] Montgomery, Weakley and Hilbert[16] hydrolyzed amylopectin (waxy corn starch) with a Taka diastase type of enzyme and isolated a disaccharide characterized by a crystalline octa-$p$-nitrobenzoate and by two isomeric crystalline octaacetates. One of the latter was shown to be identical with the product described herein by a direct comparison involving mixed melting point and comparative X-ray powder diffraction diagrams.

For a source of this disaccharide we turned to the synthetic polysaccharide dextran which is made from sucrose by the action of *Leuconstoc dextranicum*. Methylation studies[17,18] have shown that

this polysaccharide is bound at least to the extent of 90% by 6-α-D-glucopyranosyl linkages.

In this work we report the preparation of a disaccharide, isolated as its crystalline β-D-octaacetate (Fig. 1), by controlled acid hydrolysis of dextran under conditions which do not favor the production of reversion products. The isolation was effected by application of the acetate chromatographic techniques established in this Laboratory.[19] Molecular weight and acetyl determinations together with elementary analyses showed the acetate to be a disaccharide.

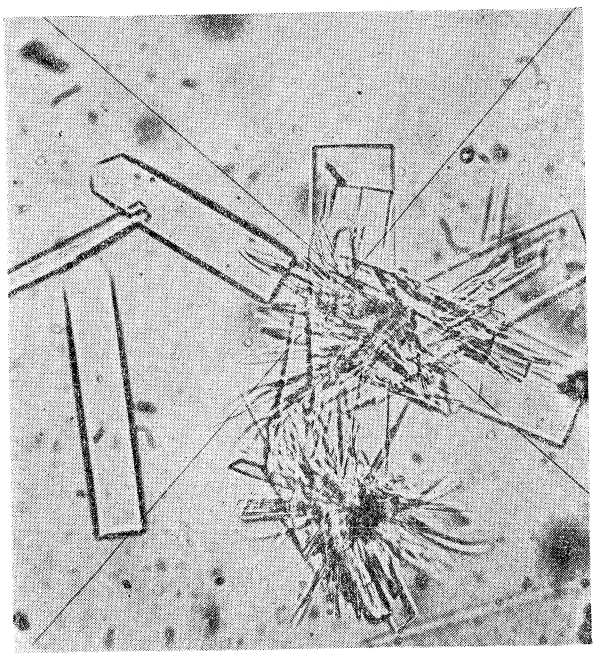

Fig. 1.—β-D-Isomaltose octaacetate.

The determined rotation of the disaccharide octaacetate is in close agreement with that of the amorphous acetate of Georg and Pictet[9] and with that predictable for a 6-α-D-glucopyranosyl disaccharide linkage by application of Hudson's rules of isorotation. The value may be calculated from the rotations of three known octaacetates containing 6-D-glycosyl linkages as follows

| | | |
|---|---|---|
| Gl + L + Gal | = 69,560 | (6-α-D-galactosyl-β-D-glucose octaacetate) (β-melibiose octaacetate) |
| −(Gl − L + Gal) | = 0 | (6-β-D-galactosyl-β-D-glucose octaacetate) |
| 2L | = 69,560 | |
| L | = 34,780 | |
| Gl − L + Gl′ | = −3,590 | (6-β-D-glucosyl-β-D-glucose octaacetate) (β-gentiobiose octaacetate) |
| + L | = 34,780 | |
| Gl + Gl′ | = 31,190 | |

(19) W. H. McNeely, W. W. Binkley and M. L. Wolfrom, THIS JOURNAL, **67**, 527 (1945).

| | | |
|---|---|---|
| Gl + L + Gl′ | = 31,190 + 34,780 = 65,970 | = (6-α-D-glucosyl-β-D-glucose octaacetate) (β-isomaltose octaacetate) |

$$[\alpha]_D = \frac{65,970}{678.6} = +97°$$

in which L, Gl, Gl′ and Gal represent portions of the molecular rotation due to the glycosyl carbon atom binding the disaccharide, the two acetylated pyranoid D-glucose entities and the pyranoid D-galactose entity, respectively.

Deacetylation of this crystalline acetate yielded the free reducing disaccharide in amorphous form with a specific rotation of $[\alpha]^{24}D$ +103.2° (water) in good agreement with the value of 104.6° cited by Georg and Pictet.[9] The disaccharide was not fermentable by yeast.

The crystalline disaccharide octaacetate was converted to the crystalline 6-α-D-glucopyranosyl-α-D-glucopyranosyl bromide heptaacetate and this in turn was transformed into the crystalline methyl 6-α-D-glucopyranosyl-β-D-glucopyranoside heptaacetate. Deacetylation of the latter compound yielded an amorphous glycoside which on periodate oxidation produced the data shown in Table I, which table also cites comparative oxidation data with the corresponding glycosides of the β-1,4-linked cellobiose and the β-1,6-linked gentiobiose. These data definitely establish the new glycoside as a methyl 6-α-D-glucopyranosyl-β-D-glucopyranoside. The ring structure in the nonreducing portion of the disaccharide and in both the D-glucose entities in the glycoside, octaacetate, and acetohalogen compound can be considered as established.

TABLE I

PERIODATE OXIDATION AT 25° OF THE METHYL GLYCOSIDES OF β-D-FORMS OF CELLOBIOSE, GENTIOBIOSE AND ISOMALTOSE

| Substance | Time, hr. | Oxidant consumed[a] | Formic acid formed |
|---|---|---|---|
| Methyl β-D-cellobiopyranoside | 8 | 3.01 | |
| | 10 | 3.02 | 1.05 |
| Methyl β-D-gentiobiopyranoside | 3 | 4.06 | |
| | 4.5 | 4.08 | 1.95 |
| Methyl 6-α-D-glucopyranosyl-β-D-glucopyranoside (Methyl β-D-isomaltoside)[b] | 3 | 4.02 | |
| | 4 | 4.04 | 1.91 |

[a] Eighteen:one (moles periodate:glycoside). [b] Prepared through its crystalline acetate and chromatographically homogeneous.

## Experimental

**6-α-D-Glucopyranosyl-β-D-glucopyranose Octaacetate.**—An amount of dextran (100 g.), prepared by the action of *Leuconostoc dextranicum* on sucrose[19] (rotation $[\alpha]_D$ +180° (*c* 1, water)), which is in agreement with the value reported by Peat[18]) was dissolved by shaking in 3 liters of 30% hydrochloric acid. The mixture was held at 24–26° and polarimetric readings were taken at intervals. When the rotation had dropped to $[\alpha]_D$ +105°, which required about twelve hours, the solution was poured into 15 liters of water, and the acid neutralized with basic lead carbonate. The precipitate was filtered and washed with

500 ml. of water. The lead ion was precipitated from the combined filtrate and washings with hydrogen sulfide and after filtration the solution was neutralized to a *p*H of 7.0 by the addition of sodium bicarbonate. The solution was concentrated to about 700 ml. under reduced pressure at 50°. The remainder of the ionic material was removed by passing the solution successively over Amberlite[20] resins IR-100 and IR-4. The solution and washings were concentrated to a sirup at 50° and this was dried to an amorphous powder by azeotropic distillation with absolute ethanol under reduced pressure.

Twenty grams of the amorphous hydrolyzate, 20 g. of freshly fused sodium acetate and 200 ml. of acetic anhydride were placed in a liter flask fitted with a reflux condenser and heated gradually by means of an oil-bath to 110–120° and held there until completion of the vigorous reaction. The reaction mixture was then cooled and poured into 2 liters of ice and water. When the oily layer had hardened to an amorphous solid, it was filtered and washed free of acetic acid with water; yield *ca.* 25 g.

Five grams of the above-described amorphous acetylated hydrolyzate of dextran was dissolved in 100 ml. of benzene and placed on a column of Magnesol[21]–Celite[22] (5:1 by wt.) (240 × 80 mm. in diam.[23]) and developed with 3000 ml. of benzene–ethanol (100:1 by vol.). The first zone near the bottom of the extruded column, as located by means of streak indicator (1 part of potassium permanganate, 10 parts of sodium hydroxide and 100 parts of water) contained β-D-glucose pentaacetate. The second zone located about one-third of a column length from the bottom contained the disaccharide octaacetate. It was cut out, eluted with 750 ml. of acetone and evaporated to a sirup; yield 0.5 g. Material (1.6 g.) obtained in this manner was dissolved in 50 ml. of benzene and placed on a column of Magnesol[21]–Celite[22] (5:1 by wt.) (240 × 43 mm.[23]) and developed with 1200 ml. of benzene–ethanol (100:1). The first significant zone from the bottom of the column was sectioned and eluted with 750 ml. of acetone to produce a sirup on solvent removal; yield 0.9 g. This material was crystallized from ethanol and was recrystallized from the same solvent; yield 0.7 g., m. p. 143–144°, $[\alpha]^{25}D$ +96.9° (*c* 2.7, chloroform).

*Anal.* Calcd. for $C_{12}H_{14}O_{11}(CH_3CO)_8$: C, 49.56; H, 5.63; $CH_3CO$, 11.78 ml. of 0.1 *N* NaOH per 100 mg.; mol. wt., 679. Found: C, 49.74; H, 5.67; $CH_3CO$, 11.86 ml.; mol. wt. (Rast), 680.

**6-α-D-Glucopyranosyl-D-glucose.**—Two grams of 6-α-D-glucopyranosyl-β-D-glucopyranose octaacetate was deacetylated according to the method of Isbell.[24] The acetate was dissolved in 40 ml. of absolute methanol and cooled to 0°. Barium methoxide (2.4 ml. of 0.4 *N*) was added to the solution and the whole kept at 0° for twenty-four hours. It was then diluted with 200 ml. of cold water and the ionic material removed by passing over Amberlite resins IR-100 and IR-4.[20] The effluent from the ion exchange columns was concentrated to a sirup under reduced pressure. The residual water was removed by repeatedly stirring with ethanol and evaporating to dryness in a vacuum desiccator. All attempts to crystallize the substance failed. It is a very hygroscopic solid; $[\alpha]^{24}D$ +103.2° (*c* 3.85, water). This material displayed only one zone when placed on Silene[25]–Celite[22] (5:1 by wt.) (240 mm. × 43 mm.[23]) and developed with 120 ml. of 90% dioxane. The free sugar is not fermented by bakers' yeast.

*Anal.* Calcd. for $C_{12}H_{22}O_{11}$: C, 42.10; H, 6.48. Found: C, 42.73; H, 7.10.

**6-α-D-Glucopyranosyl-α-D-glucopyranosyl Bromide Heptaacetate.**—Two grams of 6-α-D-glucopyranosyl-β-D-glucopyranose octaacetate was dissolved in 20 ml. of dry, freshly prepared, and ethanol-free chloroform. The solution was cooled in an ice–salt-bath and to it was added 5.2 ml. of dry glacial acetic acid containing 30–32% of hydrogen bromide. The mixture was allowed to stand at 0° for two hours after which it was poured into a separatory funnel containing cracked ice. The chloroform solution was washed four times with cold water and dried over anhydrous sodium sulfate. A sirup was obtained on solvent removal that was crystallized from absolute ethanol; m. p. 131–133°, $[\alpha]^{24}D$ +202° (*c* 1.75, chloroform).

*Anal.* Calcd. for $C_{26}H_{35}O_{17}Br$: C, 44.64; H, 5.04; Br, 11.41. Found: C, 44.74; H, 5.01; Br, 10.98.

**Methyl 6-α-D-Glucopyranosyl-β-D-glucopyranoside Heptaacetate.**—An amount of 0.19 g. of crystalline 6-α-D-glucopyranosyl-α-D-glucopyranosyl bromide heptaacetate was dissolved in 3 ml. of absolute methanol containing 0.2 g. of powdered Drierite, 0.2 g. of silver carbonate, 2 ml. of alcohol-free chloroform and a trace of iodine. The mixture was shaken overnight, filtered and evaporated to a sirup. The sirup was crystallized from ethanol–water and was recrystallized in the same manner; yield 0.06 g., m. p. 114–116°, $[\alpha]^{25}D$ +88.5° (*c* 2.0, chloroform).

*Anal.* Calcd. for $C_{26}H_{35}O_{17}(OCH_3)$: C, 49.84; H, 5.89; $OCH_3$, 4.77. Found: C, 49.97; H, 6.17; $OCH_3$, 4.96.

**Methyl 6-α-D-Glucopyranosyl-β-D-glucopyranoside.**—Methyl 6-α-D-glucopyranosyl-β-D-glucopyranoside heptaacetate (0.45 g.) was dissolved in 2.5 ml. of absolute methanol and heated under reflux for fifteen minutes with 0.2 ml. of 0.1 *N* sodium methoxide according to the method of Zemplén and Pacsu.[26] The reaction mixture was cooled and the methanol was removed under reduced pressure at 50–55°. The resulting sirup was dissolved in 5 ml. of water and the ionic material removed by passing the solution over Amberlite resins IR-100 and IR-4.[20] The effluent from the ion exchange columns was concentrated to a viscous sirup and the product was obtained as an amorphous solid by stirring in dioxane and concentrating under reduced pressure in a vacuum desiccator. This operation was repeated several times; yield 0.2 g., $[\alpha]^{24}D$ +50° (*c* 5.8, water).

*Anal.* Calcd. for $C_{12}H_{21}O_{10}(OCH_3)$: C, 43.82; H, 6.79; $OCH_3$, 8.71. Found: C, 44.11; H, 6.83; $OCH_3$, 8.68.

**Acknowledgment.**—We are pleased to acknowledge the advice of Professor Grant L. Stahly of the Department of Bacteriology of this University, in the preparation of the dextran.

## Summary

1. 6-α-D-Glucopyranosyl-β-D-glucopyranose octaacetate has been separated in crystalline condition by chromatographic methods from the acetylated hydrolyzate of dextran (from *Leuconostoc dextranicum*). This acetate was converted to the crystalline 6-α-D-glucopyranosyl-α-D-glucopyranosyl bromide heptaacetate.

2. 6-α-D-Glucopyranosyl-D-glucose and methyl 6-α-D-glucopyranosyl-β-D-glucopyranoside have been prepared in amorphous but chromatographically pure condition through their crystalline acetates and the 1,6-linkage established by periodate oxidation of the latter compound.

# Further Studies of the Action of Pancreatic Amylase: A Differentiation of the Products of the Hydrolysis of Potato Starch and of a Linear Fraction from Corn Starch[1]

BY ROSLYN B. ALFIN[1a] AND M. L. CALDWELL

Considerable information concerning the mechanism of the enzymic hydrolysis of starch may be obtained from investigations of the action of purified amylases upon different substrates. The work reported briefly here deals with studies of the action of highly purified maltase-free pancreatic amylase[1,2] upon unfractionated potato starch, Lintner soluble potato starch, and upon a linear fraction from corn starch. The linear substrate was kindly supplied by Dr. T. J. Schoch. It was hydrolyzed completely to fermentable sugar by beta amylase and corresponded to 94% "amylose"[3] by potentiometric titration.[4] The studies included comparisons of the rates of the hydrolysis of the different substrates as well as of the products formed from them.

## Experimental

The hydrolyses were carried out at 40° as previously described.[2] Portions of the reaction mixtures were removed at intervals during the hydrolyses and examined for total reducing value by iodometric titration.[5] The reducing values were converted into their equivalents of maltose or of glucose and are reported in terms of the percentage yield of maltose or of glucose that could be obtained theoretically from the substrate. Because they give stoichiometric values, iodometric titrations give a measure of the number of glucosidic linkages of the substrate that have been ruptured. Portions of the reaction mixtures were also examined at intervals during the hydrolyses for maltose and for glucose by a modification of the method of Somogyi[6,7] for the selective fermentation of these sugars by washed bakers yeast. Examination of mixtures of known concentrations of glucose and of maltose in the presence of starch showed that these sugars could be accounted for under the conditions of these experiments to within 2%. The reducing value of the reaction mixtures in excess of that due to glucose and maltose was attributed to unfermented reducing dextrins. According to Myrbäck,[8,9] conditions which permit the fermentation of maltose also permit some fermentation of any straight-chain trisaccharide which may be present. No attempt was made in this work to distinguish between maltose and such a trisaccharide.

Average degrees of polymerization have been calculated for the reducing dextrins from their weights and reducing values. In the early stages of the hydrolyses, the values for the average degrees of polymerization of the dextrins cannot be taken as absolute values. Iodometric methods are stoichiometric for reducing sugars of low molecular weights. The application of the method to dextrins formed in the earlier stages of the hydrolyses may introduce certain errors. However, this method seems to be the most satisfactory of those at present available by which to obtain an indication of the breakdown of the substrates.

No evidence of maltase activity was found in composite mixtures of the preparations of purified pancreatic amylase even when the highest concentrations used here reacted for twenty-four hours at 40° with 1% maltose under the conditions used for the hydrolysis of starch.[10] Similarly, attempts to cause the selective inactivation of amylase and of glucosidase (dextrinase) activities failed to give evidence of the presence of traces of carbohydrases other than amylase in the preparations of purified pancreatic amylase.[2] Therefore, the results reported here do not appear to be influenced to any significant extent by the action of contaminating carbohydrases.

## Results

**Rates of Hydrolysis.**—The typical data summarized in Table I show that Lintner soluble

$$DP = \frac{\text{weight of dextrins (mg.)}}{\text{reducing value as maltose (mg.)}} \times 2$$

potato starch and unfractionated potato starch were hydrolyzed at practically the same rates when treated with the same concentrations of pancreatic amylase under comparable conditions. On the other hand, the data given in Tables II and III show significant differences in the rates of the hydrolysis of the linear substrate and of unfractionated potato starch.

In the very early stages of the hydrolyses, in the presence of relatively low concentrations of amylase (Table III), unfractionated potato starch was hydrolyzed more rapidly than the linear substrate. However, after approximately 3% of the glucosidic linkages of the substrates had been broken, the linear substrate was hydrolyzed more rapidly than the unfractionated starch (Tables II and III). These results suggest that there are more points for attack by pancreatic amylase in the branched chain than in the straight-chain components of starch, but that the reducing dextrins formed from the branched chain components are hydrolyzed less rapidly by the amylase than are the reducing dextrins formed from the straight chain components.

Further study of the data given in Table III shows not only that pancreatic amylase hydrolyzes

the unfractionated starch and the linear substrate at different rates, but also that, for the same time intervals with the same concentration of amylase, the relative concentrations of the products formed from the two substrates differ.

A comparison of the products formed from the two substrates when equivalent numbers of glucosidic linkages had been ruptured is given in Table IV.

Examination of the data summarized in Tables III and IV shows that maltose was present in measurable concentrations from the very early stages of the hydrolysis. It was present in considerably larger concentrations in the hydrolyzates from the linear substrates than in those from potato starch whether the comparisons are made at the same time intervals with equal concentrations of amylase (after the first five minutes, Table III) or at equivalent stages in the hydrolyses of the two substrates (Table IV).

Glucose, also, was liberated by maltase-free pancreatic amylase from potato starch and from the linear components of corn starch although this sugar did not appear in the very early stages of the hydrolyses of these substrates. The data given in Table IV show that even after 15% of the glucosidic linkages of the substrates had been broken, only about 1% of glucose was present. Comparisons at the same time intervals with equal concentrations of amylase (Table III) and also at equivalent stages in the hydrolyses of the two substrates (Table IV) show that glucose appeared somewhat earlier and at equivalent hydrolysis was present in slightly larger concentrations in the hydrolyzates of potato starch than in those of the linear substrate. These differences in the concentrations of maltose and of glucose obtained from the two substrates suggest that the presence of 1,6-$\alpha$-D-glucosidic linkages in the branched chain components of starch interferes with the formation of maltose and favors the production of glucose by pancreatic amylase. This suggestion has received confirmation in subsequent studies with waxy maize starch, a branched chain substrate.[11]

The data given in Table IV also show that pancreatic amylase causes the rapid breakdown of both substrates to reducing dextrins of low average molecular weights and of relatively high reducing values. When the total reducing values of the hydrolyzates were equivalent to 50% theoretical maltose, reducing dextrins accounted for 57 and 45% of the total reducing value and for 81 and 75% by weight of the total products present in the hydrolyzates from the unfractionated starch and from the linear substrate, respectively. These findings are in accord with the observations of many investigators that pancreatic amylase causes a rapid decrease in the viscosities of its substrates and the rapid disappearance of products which give color with iodine. In the present studies, a clear red color with iodine was obtained when the reducing values of the reaction mixtures were equivalent to approximately 25% theoretical maltose. The achromic stage was reached at approximately 55% theoretical maltose.

Further study of the reducing dextrins (Tables III and IV) is of interest. During the early stages of the hydrolyses, the average molecular weights of the reducing dextrins liberated from the linear substrate were relatively high as compared to the average molecular weights of the dextrins from unfractionated potato starch. These findings again suggest that the branched chain components of starch offer more points of attack for pancreatic amylase than do the linear components. However, reducing dextrins were present in consistently lower concentrations in the hydrolyzates from the linear substrate than in those from the unfractionated starch. Therefore, the dextrins from the linear substrate appear to be hydrolyzed more readily than those from the branched chain components of starch.

Taken all together, the data lead to the conclusion that pancreatic amylase causes the random hydrolysis of both the branched and the linear components of starch.

Comparisons of the data obtained with unfractionated potato starch and with Lintner soluble potato starch, showed that a preliminary acid treatment of potato starch influences appreciably the course of the hydrolysis of starch by pancreatic amylase. As would be expected, the average molecular weights of the reducing dextrins were lower in the earlier stages of the hydrolysis of the acid treated, partially degraded starch. In the later stages of the hydrolyses, more maltose and smaller concentrations of residual dextrins of the same or of slightly higher average molecular weights were present in the hydrolyzates of Lintner soluble potato starch than in those of untreated potato starch.

## Summary and Conclusions

A study has been made of the action of purified maltase-free pancreatic amylase upon unfractionated potato starch, Lintner soluble potato starch and upon a linear fraction from corn starch.

No marked differences were observed in the rates of the hydrolysis of unfractionated potato starch, or of Lintner soluble potato starch when comparisons were based upon the total reducing values of the hydrolyzates obtained with the same concentrations of amylase reacting under comparable conditions.

On the other hand, marked differences were observed in the rates of hydrolysis of unfractionated potato starch and of the linear substrate.

The evidence indicates that there are more points for attack by pancreatic amylase in the branched chain components than in the linear components of starch but that the reducing dextrins formed from the branched chain components are hydrolyzed less readily by pancreatic amylase

(11) F. M. Mindell, A. L. Agnew and M. L. Caldwell, THIS JOURNAL, in press.

than are the reducing dextrins formed from the linear components. Marked differences were also found in the relative concentrations of the products formed by pancreatic amylase from unfractionated potato starch and from the linear substrate. These differences were observed whether the comparisons were made for the same time intervals with the same concentrations of amylase or at equivalent stages in the hydrolysis of the two substrates.

Maltose was present in measurable concentrations from the very early stages of the hydrolysis of unfractionated potato starch and of the linear substrate. However, this sugar was present in considerably higher concentrations in the hydrolyzates from the linear substrate than in those from potato starch whether comparisons are made at the same time intervals with equal concentrations of amylase or at equivalent stages in the hydrolysis of the two substrates.

Glucose was liberated by maltase-free pancreatic amylase from unfractionated potato starch and from the linear substrate although this sugar did not appear in the very early stages of the hydrolyses of these substrates. Comparisons made at the same time intervals with equal concentrations of amylase and also at equivalent stages in the hydrolyses of the two substrates show that glucose was liberated somewhat earlier and at equivalent hydrolysis was present in slightly larger concentrations in the hydrolyzates of potato starch than in those of the linear substrate.

A study of the results as a whole indicates that purified pancreatic amylase causes the random hydrolysis of both the straight and the branched chain components of starch.

# Pantothenic Acid Studies. VI. A Biologically Active Conjugate of Pantothenic Acid[1]

BY TSOO E. KING, I. GORDON FELS AND VERNON H. CHELDELIN

In a previous paper from this Laboratory[2] glutamic acid was reported to enhance the growth promoting property of pantothenic acid in certain strains of yeast. A related observation was made by Woolley,[3] who found that glutamic acid was very active in reversing the inhibitory effect of ketone analogs of pantothenic acid in organisms which require the preformed vitamin in the medium. Although the mechanism of these actions is at present obscure, it appeared possible that glutamic acid might conjugate with pantothenic acid or β-alanine (and possibly with pantoic acid in the proper linkage) to produce a substance which is more active for the growth of microörganisms. Since numerous possibilities exist for combinations of pantothenic acid, glutamic acid and β-alanine, their direct preparation was deferred in favor of biosynthesis of active materials by resting cells.

Glutamic acid was incubated in buffered saline with β-alanine or with pantothenic acid in the presence of resting yeast cells (*S. cerevisiae* L.M. strain, A.T.C.C. No. 9371). The resulting mixture showed extremely great activity, occasionally over a thousand times that of the β-alanine or pantothenic acid present, as measured in a pantothenic acid-free medium using L.M. yeast. The incubated product from β-alanine was always more active than that from pantothenic acid. However, the results were not consistent; in six of eighteen experiments no increase in activity was obtained, and the trend among the later experiments was toward increases of twofold or less. It was not possible to tell whether this was due to inconsistencies in synthesis of active material or to variable requirements by the assay organisms. It was therefore decided to seek another assay organism for the active principle, as well as new sources from which it might be isolated.

## Stimulation of Growth in *S. cerevisiae* 2190

Strain 2190 (National Collection of Cultures, London) was observed previously[4] to grow very feebly in a pantothenic acid containing medium which was satisfactory for the growth of sixteen other yeasts. The addition of glutamic acid improved the growth considerably, although further enhancement was obtained with yeast extract. The effects are summarized in Table I. The glutamic acid effect recalls the similar observation in strains L.M. and 2504.[2] However, strain 2190 was not stimulated by the mixture resulting from incubation with resting L.M. yeast cells. The extra stimulatory effect of yeast extract upon 2190 was also manifested by acid-hydrolyzed casein, as well as by amino acid mixtures containing no additional glutamic acid.

## The Response of Acetobacter suboxydans to Extracts of Natural Materials

Nachmansohn and Berman[5] have obtained active preparations of the coenzyme for acetylation of choline from heart tissue. In view of the fact that Lipmann and co-workers[6,7] showed this coenzyme (coenzyme A) to contain pantothenic acid, and in view of the failure of yeast 2190 to respond to the resting cell preparation, additional experiments were carried out with liver, yeast and heart extracts. The response of a given test organism to these extracts was measured in terms of pantothenic acid. The apparent pantothenic acid contents so obtained were checked by means of other assays using *L. arabinosus*, which utilized the intact vitamin, and by L.M. yeast, which, after hydrolysis of the preparations with 6 *N* hydrochloric acid for one hour, indicated the total β-alanine content. *A. suboxydans* was regarded as a preferred organism for study because of its relatively great sensitivity to pantoic acid[8] and the fact that *A. suboxydans* assays of certain tissues[8] frequently gave higher values than those obtained with *L. arabinosus*.

It was reported in a preliminary note[9] that when fresh liver or heart muscle was heated and brought to *p*H 4.5–5.0 to remove most of the protein, the filtrates from these preparations possessed considerably higher apparent pantothenic acid contents when assayed by *A. suboxydans* than when *L. arabinosus* or G.M. yeast was used. The activity of these extracts was far higher than could be accounted for by the pantothenic acid present, as measured by *L. arabinosus* after digestion with takadiastase and papain.[10] That the active material in these extracts contained pantothenic acid was strongly suggested by the fact that no compound is known to be able to substitute for the vitamin or the pantoic acid moiety in media in which it is lacking, and also by the observation that the β-alanine content increased upon hydrolysis. After six hours hydrolysis, the β-alanine values accounted for roughly half of the activity exhibited in *A. suboxydans*, and it was felt that the active principle was therefore about twice as effective as the free vitamin for this organism. The activity was thought to be due to a conjugated form of pantothenic acid which for convenience will be abbreviated PAC in the present paper.

When pantothenic acid (or pantoic acid[8]) was the limiting factor for growth of *A. suboxydans*, growth curves were sigmoidal in shape. The cultures containing adequate amounts of the vitamin grew rather slowly, requiring sixty to seventy hours to reach optical density values of 0.5 or greater. By contrast, the curves obtained with the conjugate were nearly straight and the rate of growth was much more rapid than in those containing pantothenic acid. As may be seen in Fig. 1, flasks containing pantothenic acid showed very little growth after twenty-four hours of incubation, whereas those containing the conjugate had already exhibited perceptible turbidity.

## Comparison of the Pantothenic Acid Conjugate with Coenzyme A. Acetylation Studies

**Sulfanilamide.**—Lipmann and co-workers[6] reported that coenzyme A possessed the ability to acetylate sulfanilamide in the presence of adenosine triphosphate (ATP) and an apoenzyme from pigeon liver. The question whether PAC is identical with coenzyme A can be answered by comparing the acetylating power of the

two preparations. The results in Table II show that the present conjugate is not active in the acetylation of sulfanilamide. The sample of Lipmann's preparation used contained about 11γ of pantothenic acid, while 15 mg. of PAC contained about 10 γ of pantothenic acid activity for *A. suboxydans*.

**Choline.**—Since Lipmann and Kaplan have shown[7] that coenzyme A is also active in the acetylation of choline (and is therefore presumably identical with Nachmansohn and Berman's coenzyme[5]), the PAC preparation was also examined for ability to acetylate choline under the conditions described by Nachmansohn and co-workers.[5,11] The results are summarized in Table III, where the samples of PAC used contained approximately 58 γ, 21 γ and 15 γ of pantothenic acid activity, respectively. From this table, it is apparent that PAC possessed no activity in the acetylation of choline. The slight response in sample No. 300 was probably not significant.

## The Behavior of Alkali toward the Pantothenic Acid Conjugate

Neal and Strong[12] reported the existence of an alkali-stable form of pantothenic acid which remained in pork liver after alkaline hydrolysis and which could be utilized with greater efficiency by lactic acid bacteria after takadiastase and papain digestion. Since preliminary experiments had indicated that PAC was somewhat more resistant to alkali than the free vitamin, the possible similarity of PAC and the alkali-stable factor was tested. This was accomplished in two ways: by determining the *A. suboxydans* activity of liver autoclaved with alkali, and by noting the extent of degradation of PAC concentrates by alkali and their possible conversion into alkali-stable residues.

The results in Table IV indicate that the conjugate is different from the alkali-stable factor, since heating of sample 701 with alkali destroyed virtually all of the activity for *A. suboxydans*. On the other hand, a small residue of activity remained both in sample 701 and in fresh pork liver. This could be due either to the presence of the alkali-stable form in these preparations or to its formation from PAC during hydrolysis. That this conversion actually takes place is indicated by the increased activity of sample 701 for *L. arabinosus* after treatment with alkali (*cf.* samples 3 and 4, 6 and 7 of Table IV). The Neal–Strong factor (or something biologically indistinguishable from it) may thus be considered as one of the degradation products of PAC.

## Comparison of the Conjugate with Blood Pantothenic Acid

Wright[13] noted that pantothenic acid existed in bound form in blood. The vitamin appeared to be combined to protein, since it could be precipitated by tungstic acid and could be released from combination by takadiastase digestion or by autoclaving for short periods. In contrast, PAC is not precipitated by tungstic acid, and is not destroyed by heat or enzymes under the above conditions.

[a] Since *A. suboxydans* is influenced by moderate concentrations of sodium chloride, a sufficient amount was added to equal that present after alkali hydrolysis and neutralization. [b] Samples treated under stated conditions, filtered; filtrates assayed for PA with *L. arabinosus* 17–5(10). [c] Samples treated under stated conditions, then digested with takadiastase and papain, filtered and assayed for PA (10). [d] The amount of NaCl present in samples (6) and (7) would not influence the growth of *A. suboxydans*.

## Properties of the Conjugate

Certain important properties of the conjugate have been observed in connection with concentration studies. Although the molecule appears to be fairly large as indicated by its failure to dialyze through cellophane into running distilled water over a sixty-hour period, it is not precipitated at all by the Folin–Wu tungstic acid reagent. The latter behavior suggests that it may be a polypeptide containing several acidic groups. The previous statement[9] that the conjugate appears to contain glutamic acid is in line with these observations. In addition, a preparation of intestinal phosphodiesterase was found to liberate pantothenic acid from the conjugate. This indicates the presence of phosphoric acid linkages in the conjugate.

The conjugate is only slightly precipitated by barium hydroxide under the conditions employed by Nachmansohn and Berman.[5] This is in contrast to their results with the coenzyme for choline acetylation. The precipitation with barium hydroxide has been used in spite of the large losses in activity, however, since it is a very effective agent for removing the impurities associated with the conjugate. Concentrations of over ten-fold in *A. suboxydans* activity are regularly obtained by this means.

Charcoal (Norite A), which can be used for the adsorption of free pantothenic acid or the diphosphate,[14] also adsorbs the conjugate. Adsorption is nearly complete when 10% by weight of charcoal is employed. On the other hand, attempts at elution have so far been unsuccessful. Lloyd's reagent is effective (60–80% adsorbed when 200% by weight is used), and elution with dilute ammonia is nearly quantitative. Combination of this treatment with tungstic acid precipitation regularly results in concentrations in activity of over twenty fold. Lloyd's reagent removes much extraneous coloring matter, so that the eluates possess a light yellow color. The ion exchange resins are also fairly effective in both acid and alkaline solutions (equal weights adsorb 50–80%), but weaker adsorbents such as corn starch and barium sulfate are of little value.

## Experimental Methods

The organisms used for testing β-alanine, pantothenic acid and PAC were *Saccharomyces cerevisiae*, strains L.M. and G.M., *Lactobacillus arabinosus* 17-5 and *Acetobacter suboxydans*, A.T.C.C. No. 621, respectively. All tests were performed using previously published methods.[2,8,10] "Free" pantothenic acid was determined by direct assay with *L. arabinosus*. Enzyme digestions were carried out with takadiastase and papain.[15]

The acetylation of sulfanilamide was performed according to Lipmann.[16]

Coenzyme A or PAC in proper concentrations were placed into the chambers of Warburg flasks, together with a salt mixture, sodium acetate, ATP, sulfanilamide and dialyzed pigeon liver. After shaking ninety minutes the residual sulfanilamide concentrations were determined by the method of Bratton and Marshall[17] in an electrophotometer.

The acetylation of choline in the presence of ATP was performed in a Warburg apparatus under an atmosphere of nitrogen with the same technique as used by Nachmansohn and co-workers.[5,11] The method for determining acetylcholine followed essentially Stephenson and Rowatt's modification[18] of Chang's method.[19] The standard acetylcholine solution was prepared immediately before use. A solution of eserine was likewise prepared in buffered frog Ringer's solution. The rectus abdominis muscle (frog) was excised and placed in a glass chamber of 30-ml. capacity with buffered Ringer's solution and aerated with a steady stream of oxygen bubbles for about one hour. The Ringer's solution was then drained off and replaced by eserinized buffered Ringer's solution and aerated for another hour. The muscle was then used for testing acetylcholine activity.

### Concentration Studies

Fresh pork heart was freed as much as possible from blood and connective tissue, passed several times through a fine meat grinder, and diluted with about twice its volume of water. Live steam was introduced and the mixture

was boiled for a few minutes. After cooling, the residue was removed by filtration, washed with water and discarded. The filtrate was brought to *p*H 4.0–4.5 with acetic acid, and after standing several hours at 5° was filtered again. The resulting filtrate was then precipitated either with 20–30 volumes of acetone, or with barium hydroxide until precipitation was complete and a slight excess of the alkali remained. The solid from the acetone precipitation was usually of a very dark color and contained a large percentage of protein. It was hygroscopic but would not redissolve completely in water. Since the volume of acetone required was so great, barium precipitation was usually employed.

The barium precipitate was separated by centrifugation and washed several times with water (*p*H 9.5–10.0) and finally with a small amount of distilled water. It was then decomposed with excess 0.5 *M* sodium sulfate. The filtrate after removal of barium sulfate was usually golden yellow in color, with *p*H approximately 10. This preparation, after precipitation with acetone, filtration and drying of the precipitate *in vacuo*, contained one to five $\gamma$ of pantothenic acid activity per mg. of organic solids.

By combining the above treatments with tungstic acid precipitation, adsorption with Lloyd reagent, and dialysis, concentrates containing up to 5% pantothenic acid activity have been obtained, based upon the total solid matter present. Further studies are in progress to accomplish the isolation of the pure conjugate.

**Acknowledgment.**—The authors wish to acknowledge with thanks, gifts of coenzyme A and alkaline phosphodiesterase from Drs. G. D. Novelli and F. Lippman, to Ruth S. Langdon and Eleanor C. Parsons for technical assistance, and to Dr. Rosalind Wulzen for helpful suggestions and the use of laboratory facilities for the testing of acetylcholine activity.

## Summary

A conjugate of pantothenic acid (abbr. PAC) has been obtained in partially purified form from pork heart. It appears to be roughly twice as active for the growth of *A. suboxydans* as is the free vitamin. Growth of this organism is also more rapid with the conjugate than with pantothenic acid. The present conjugate is different from coenzyme A, the alkali-stable form of pantothenic acid or the protein conjugate found in blood.

From the behavior toward tungstic acid and dialysis, PAC appears to be an acidic molecule of molecular size considerably greater than pantothenic acid. Studies are in progress to accomplish the isolation of the pure material.

# Streptomycin. IX.[1] The Stepwise Degradation of Mannosidostreptomycin

BY HOMER E. STAVELY[2] AND JOSEF FRIED

Streptomycin concentrates have been shown to contain in addition to streptomycin a second antibiotic substance which has been termed streptomycin B or mannosidostreptomycin.[1] The degradation of this substance to derivatives of streptidine, streptobiosamine and D-mannose has been the subject of a preliminary communication.[3] The present paper gives a detailed account of those findings and, moreover, presents experimental data showing that in mannosidostreptomycin D-mannose is attached glycosidically to the streptobiosamine moiety through one of the three free hydroxyl groups of N-methyl-L-glucosamine.

Mannosidostreptomycin was isolated in the pure state as the crystalline reineckate which was converted to an amorphous hydrochloride.[1] Analyses of these two salts indicated that this antibiotic is a triacidic base of the composition $C_{27}H_{49}O_{17}N_7$. The difference in composition, $C_6H_{10}O_5$, between this substance and streptomycin appeared to be due to one hexose unit attached to the latter with the loss of one molecule of water. This assumption was substantiated[4] by the following degradation reactions.

When a solution of mannosidostreptomycin in 1.3 *N* methanolic hydrogen chloride was allowed to stand at room temperature for two days and the residue from the methanol solution, after careful neutralization with silver carbonate, was acetylated, an amorphous material was obtained, which upon chromatography on alumina afforded the two anomers of methyl tetraacetyl-D-mannopyranoside, as well as methyl tetraacetyl streptobiosaminide dimethyl acetal[5] and octaacetyl streptidine,[6] the latter two substances identical with the products obtained by similar degradation of streptomycin.

Confirmatory evidence as to the presence of D-mannose, streptobiosamine and streptidine in

(4) The experimental evidence adduced in this paper does not permit any conclusions as to the position of attachment of the streptobiosamine moiety to streptidine in mannosidostreptomycin. It is most likely, however, that this linkage involves the 4-hydroxyl group of streptidine as has been shown to be the case in streptomycin by Kuehl, Peck, Hoffhine, Peel and Folkers, *ibid.*, **69**, 1234 (1947).

(5) N. G. Brink, F. A. Kuehl, Jr., E. H. Flynn and K. Folkers, *ibid.*, **68**, 2557 (1946).

mannosidostreptomycin was adduced by mercaptolysis. In using the anhydrous conditions described by Kuehl, Flynn, Brink and Folkers[7] for the mercaptolysis of streptomycin incomplete reaction was often observed. However, when aqueous hydrochloric acid[8] was substituted for the gaseous hydrogen chloride reaction was complete after fifteen hours of shaking at room temperature. Chromatography of the crude acetylated product yielded octaacetyl streptidine, ethyl tetraacetyl-β-thiostreptobiosaminide diethyl mercaptal[8] and the α- and β-forms of ethyl tetraacetyl-1-thio-D-mannopyranoside.[9]

Following the identification of the cleavage products obtained from mannosidostreptomycin our efforts were directed toward ascertaining the site of the linkage joining D-mannose to the remaining portion of the molecule. On the assumption that the linkage between streptobiosamine and streptidine is identical for the two streptomycins, D-mannose could be attached glycosidally through one of the three free hydroxyl groups of the N-methyl-L-glucosamine moiety, through the 2-,5- or 6-hydroxyl groups of streptidine or, least probably, through the tertiary hydroxyl group of streptose. Moreover, the possibility of a linkage involving one of the nitrogenous groups could not be disregarded. Evidence that the D-mannose moiety is attached to N-methyl-L-glucosamine was adduced by partial cleavage to a product in which the linkage between these two moieties had remained intact. Initial trials to effect such an incomplete degradation by methanolysis of dihydromannosidostreptomycin[1] using a low enough concentration of hydrogen chloride to leave approximately half the starting material unreacted led to complete cleavage of the remaining portion into α- and β-methyl D-mannopyranosides, methyl-α-dihydrostreptobiosaminide[10] and streptidine, all isolated as the crystalline acetyl derivatives. Suitable experimental conditions were finally arrived at on the basis of the following observations. When a solution of mannosidostreptomycin or its dihydro-derivative in 1 *N* sulfuric acid was allowed to stand at 45° for twenty hours streptidine sulfate monohydrate separated in almost quantitative yield, but no mannose was detectable among the reaction products upon addition of phenylhydrazine to the neutralized hydrolysate. On the other hand, a quantitative yield of mannose phenylhydrazone was obtained when the hydrolysis was conducted at 100° for one hour. These findings indicated that D-mannose is attached to the streptobiosamine moiety and not to streptidine. Removal of the sulfate and excess chloride ions from the solution obtained by hydrolysis of dihydromannosidostreptomycin at 45°, followed by lyophilization, afforded a crude amorphous material which was acetylated immediately and purified by chromatography. The resulting product, although amorphous, gave analytical figures in accord with those calculated for the nonaacetate of a trisaccharide, which has been designated dihydromannosidostreptobiosamine on the basis of its cleavage by methanolysis into the anomeric methyl D-mannopyranosides and methyl dihydrostreptobiosaminide, and on the basis of further evidence discussed below. A differential acetyl determination on this nonaacetate indicated that eight of the acetyl groups were attached to oxygen and the remaining one to nitrogen, ruling out the possibility that D-mannose is linked to streptobiosamine via the N-methylamino group.

The acetolysis procedure of Hann and Hudson[11] when applied to methyl pentaacetyl dihydrostreptobiosaminide resulted in the quantitative cleavage of this disaccharide into its component sugars,[12] only one of which (pentaacetyl N-methyl-L-glucosamine) was extractable from the neutralized reaction mixture by chloroform. Whereas the residue remaining after evaporation of this chloroform solution invariably crystallized, the analogous fraction obtained by acetolysis of the nonaacetate of dihydromannosidostreptobiosamine remained amorphgus even after chromatooraphic purification on alumina. Indications from analytical figures that this product represents the octaacetate of a disaccharide composed of D-mannose and N-methyl-β-L-glucosamine were confirmed by methanolysis and reacetylation, which readily afforded the two anomeric methyl tetraacetyl-D-mannopyranosides as well as methyl tetraacetyl-N-methyl-β-L-glucosaminide. The latter was identified by comparison with the product obtained by methanolysis and reacetylation of pentaacetyl N-methyl-α-L-glucosamine. On the basis of this cleavage reaction and of the above described degradation of dihydromannosidostreptobiosamine to derivatives of D-mannose and dihydrostreptobiosamine the amorphous acetolysis product is formulated as the octaacetate of a D-mannoside of N-methyl-L-glucosamine.

Information concerning the anomeric character of the glycosidic linkage between the two sugars can be derived from available data by the application of Hudson's rules of isorotation.[13] On the assumption that the linkage between streptobiosamine and streptidine is of the α-type, as has been shown for streptomycin,[14] the molecular rotation of mannosidostreptomycin can be expressed as $[M]_B = [M]_A + A_{St.} + B_{Man.}$, where $[M]_B$ and $[M]_A$ are the molecular rotations of mannosidostreptomycin and streptomycin, respectively, $A_{St.}$

the contribution of carbon atom one of D-mannose to the molecular rotation of mannosidostreptomycin, and $B_{Man.}$ the contribution of the basal chain of the mannose moiety as calculated from the molecular rotations of $\alpha$- and $\beta$-D-mannose ($A + B = +5380$, $-A + B = -2940$). $A_{St.}$, the quantity characteristic of the glycosidic linkage in question then becomes $A_{St.} = [M]_B - [M]_A - B_{Man.}$ or, after substitution of the experimental values, $A_{St.} = (871)(-47) - (691)(-86) - 1220 = +17180$. The positive numerical value for $A_{St.}$ and the fact that the mannose moiety in mannosidostreptomycin has the D-configuration indicate that the glycosidic linkage is of the $\alpha$-D type. The absolute value of 17180 is in reasonable agreement with the value for $A_{OMe}$ (14230) calculated from the molecular rotations of the two anomeric methyl D-mannopyranosides.

Experimental data establishing the exact site of the glycosidic linkage between D-mannose and the remaining portion of the molecule will be presented in a subsequent publication.

## Experimental[15]

**Methanolysis of Mannosidostreptomycin.**—Mannosidostreptomycin trihydrochloride[3](1.1 g.) was dissolved in 30 ml. of 1.3 *N* methanolic hydrogen chloride. After two days the spectrophotometric maltol assay[1] showed a decline from the original $\Delta E$ value of 126 to less than 3. An excess of silver carbonate was added to the flask and the mixture was stirred for four hours. After standing overnight the mixture was filtered and excess silver ion removed from the solution by means of hydrogen sulfide. After filtration through charcoal the filtrate was evaporated *in vacuo* and the residue (710 mg.) was acetylated in pyridine (5 ml.)-acetic anhydride (5 ml.) for twenty-four hours. After removal of the solvents *in vacuo* the residue was dissolved in chloroform, the solution washed with dilute hydrochloric acid, dilute sodium bicarbonate solution and water, and the chloroform extract dried over sodium sulfate. The residue from the chloroform solution was dried and extracted several times with dry ether, most of the streptidine octaacetate remaining undissolved. It was crystallized from ethanol, m. p. 255–257° (dec.).

*Anal.* Calcd. for $C_8H_{10}N_6O_4(COCH_3)_8$: N, 14.04. Found: N, 13.68.

The dried ether residue (874 mg.) was dissolved in benzene (25 ml.) and chromatographed on an acetic acid-washed alumina[16] column, 1.5 × 20 cm. The chromatogram was developed with 100 ml. of benzene. The first 25 ml. of eluate yielded 270 mg. of residue which crystallized from an ether solution on evaporation. It was recrystallized twice from ether–pentane, $[\alpha]^{24}D$ +49° (*c*, 1.1 in chloroform). The m. p. was 65–66°, not depressed on admixture of an authentic sample of methyl tetraacetyl-$\alpha$-D-mannopyranoside.

*Anal.* Calcd. for $C_7H_{10}O_6(CH_3CO)_4$: C, 49.72; H, 6.12; $CH_3O$, 8.56; acetyl, 47.5. Found: C, 50.01; H, 6.08; $CH_3O$, 8.98; acetyl, 47.7.

The succeeding 25 ml. of benzene contained 30 mg. of a substance which likewise crystallized from ether but which melted unsharply from 130 to 150° and was probably a mixture of the $\alpha$- and $\beta$-anomers of methyl tetraacetyl-D-mannopyranoside. Further elution with 50 ml. of benzene yielded only 22 mg., likewise crystalline from ether, melting from 100 to 110°.

The column was then eluted with a mixture of 70 ml. of benzene and 30 ml. of ether and the eluate collected in 20-ml. portions. The residues all crystallized from ether and melted unsharply between 100 and 125°. Elution with 50 ml. of ether then yielded 131 mg. of crystalline material which melted at 124–125° after two recrystallizations from ether–hexane; $[\alpha]^{25}D$ −122° (*c*, 0.56 in chloroform). There was no melting point depression on admixture of an authentic specimen of methyl tetraacetyl-$\alpha$-streptobiosaminide dimethyl acetal.

*Anal.* Calcd. for $C_{13}H_{18}NO_7(OCH_3)_3(COCH_3)_4$: C, 50.97; H, 6.95; N, 2.48; $CH_3O$, 16.5; O-acetyl, 22.9. Found: C, 51.01; H, 6.74; N, 2.60; $CH_3O$, 16.9; O-acetyl,[17] 23.2.

The material which had been eluted with 30% ether in benzene was combined with the residue from the methyl tetraacetyl-$\alpha$-streptobiosaminide dimethyl acetal mother liquor, dissolved in 15 ml. of benzene and rechromatographed on a column of alumina, 0.8 × 15 cm. Nothing could be eluted with benzene. Elution with 100 ml. of 30% ether in benzene afforded 62 mg. of a substance which attained a constant m. p. of 117–119° after several recrystallizations from ether–hexane. The specific rotation was −102°.

*Anal.* Found: C, 51.58; H, 6.98.

This product was probably a mixture of the $\alpha$- and $\beta$-anomers of methyl tetraacetyl streptobiosaminide dimethyl acetal.

Elution of the column with ether yielded a further quantity (87 mg.) of methyl tetraacetyl-$\alpha$-streptobiosaminide dimethyl acetal, m. p. 123–125°, $[\alpha]D$ −121°.

**Mercaptolysis of Mannosidostreptomycin.**—Mannosidostreptomycin (2.38 g.) was added to 10 ml. of ethyl mercaptan and 4.5 ml. of concentrated hydrochloric acid and the mixture was shaken vigorously for a period of eighteen hours at room temperature. The reagents were distilled off *in vacuo* at a bath temperature not exceeding 30° and the last traces of water were removed by twice distilling absolute alcohol off the residue. The latter was acetylated by shaking for sixteen hours with 25 ml. of pyridine and an equal volume of acetic anhydride. The dark red solution was concentrated to a sirup and the latter partitioned between ice-water and chloroform. The chloroform layer was washed with dilute hydrochloric acid, sodium bicarbonate and finally with water. After drying over sodium sulfate the chloroform extract was evaporated to dryness *in vacuo* and the residue taken up in 10 ml. of absolute alcohol. On standing in the refrigerator overnight the alcoholic solution deposited crystals, which were filtered off and washed with cold ethanol. The filtrate and washings were evaporated to dryness *in vacuo* and chromatographed as described below.

The crystals, which appeared to be a mixture, were extracted with warm ether. This treatment left undissolved a fraction which was difficultly soluble in most organic solvents. Recrystallization from a large volume of alcohol produced small needles which melted at 255–257°, and were identified as octaacetylstreptidine.

The combined ether extracts were evaporated to dryness and the crystalline residue was recrystallized three times from absolute alcohol. Prismatic needles, 110 mg., melting at 160–161°, were obtained. The melting point was raised to 161–162° by chromatography of a benzene solution of this material on alumina, followed by an additional recrystallization from alcohol, $[\alpha]^{25}D$ −67° (*c*, 0.51 in chloroform). The substance showed no depression in melting point when mixed with an authentic sample of ethyl tetraacetyl-1-thio-$\beta$-D-mannopyranoside.[9]

*Anal.* Calcd. for $C_8H_{12}O_5S(CH_3CO)_4$: C, 48.98; H, 6.17; S, 8.16; $CH_3CO$, 43.84. Found: C, 49.22; H, 5.91; S, 8.33; $CH_3CO$, 43.4.

(15) The melting points reported in this paper were taken in capillary tubes and have been corrected for stem exposure.

(16) The alumina used for all chromatograms reported in this paper was purchased from the Harshaw Chemical Company, Cleveland, Ohio. It was washed with dilute acetic acid and then washed repeatedly with distilled water until the *p*H of a water suspension of the alumina had risen to 6.0. It was then filtered and dried at 150° for thirty-six to forty-eight hours.

(17) J. F. Alicino, *Anal. Chem.*, **20**, 590 (1948).

The residue from the above alcoholic filtrate and washings was dissolved in 15 ml. of benzene and after the addition of an equal volume of hexane was chromatographed on a column containing 30 g. of alumina. A mixture of equal volumes of benzene and hexane eluted a crystalline fraction (100 mg.) which after several recrystallizations from hexane containing a small amount of ether melted at 107–108°, $[\alpha]^{24}D$ +94° (*c*, 1.06 in chloroform). These data are in accord[18] with the constants for ethyl tetraacetyl-1-thio-α-D-mannoside.[9] No melting point depression was observed on admixture of an authentic sample of the latter.

*Anal.* Calcd. for $C_8H_{12}O_5S(CH_3CO)_4$: C, 48.98; H, 6.17; S, 8.16; $CH_3CO$, 43.84; mol. wt., 392.4. Found: C, 48.91; H, 6.04; S, 8.17; $CH_3CO$, 44.2; mol. wt. (Rast), 378.

Subsequent elution of the alumina column with 850 ml. of benzene yielded a second crystalline substance (530 mg.), which after recrystallization from ether–hexane melted at 111–112°, $[\alpha]^{25}D$ −31° (*c*, 0.95 in chloroform). There was no depression in melting point when this substance was mixed with an authentic sample of ethyl tetraacetyl-β-thiostreptobiosaminide diethyl mercaptal. The latter has been reported[8] to have m. p. 111–111.5° and $[\alpha]^{28}D$ −29° (*c*, 3.0 in chloroform).

*Anal.* Calcd. for $C_{27}H_{45}NO_{11}S_3$: C, 49.44; H, 6.92; N, 2.14; S, 14.66. Found: C, 49.45; H, 7.01; N, 2.52; S, 14.81.

**Methanolysis of Dihydromannosidostreptomycin.**—A solution of 800 mg. of vacuum-dried dihydromannosidostreptomycin in 16 ml. of 0.8 *N* methanolic hydrogen chloride was allowed to stand at room temperature for forty hours. Upon addition of 32 ml. of anhydrous ether to this solution a copious precipitate formed, which was filtered, washed with ether and dried *in vacuo*. The dried powder weighed 610 mg. and had $[\alpha]^{25}D$ −46° (*c*, 1.51 in methanol). The ether–methanol filtrate was concentrated *in vacuo* to a thin sirup and precipitated with a large excess of ether. After two hours of standing in the refrigerator, the oily deposit was separated from the supernatant by decantation and dried *in vacuo*. A white powder (169 mg.) was obtained which had $[\alpha]^{26}D$ −77° (*c*, 1.05 in methanol). All but 11 mg. of this material was acetylated with 4 ml. of pyridine and 3 ml. of acetic anhydride and the resulting acetylation product chromatographed in benzene solution (10 ml.) on 7 g. of alumina. Benzene eluted an oil which crystallized readily when its ether solution was allowed to evaporate at room temperature. The material on recrystallization from absolute alcohol yielded prismatic needles which melted at 159.5–160.5° and had $[\alpha]^{24}D$ −50° (*c*, 0.68 in chloroform). The melting point of this substance was not depressed on admixture of an authentic sample of methyl tetraacetyl-β-D-mannopyranoside. The latter has been reported[19] to have m. p. 161° and $[\alpha]^{25}D$ −50.4° (*c*, 1.4 in chloroform).

*Anal.* Calcd. for $C_7H_{10}O_6(CH_3CO)_4$: C, 49.72; H, 6.12; $OCH_3$, 8.56; $CH_3CO$, 47.5. Found: C, 49.61; H, 6.08; $OCH_3$, 8.35; $CH_3CO$, 48.3.

Subsequent elution of the column with a mixture of equal volumes of benzene and ether gave fractions which crystallized spontaneously upon evaporation of the solvents *in vacuo*. Recrystallization from absolute alcohol yielded a product (m. p. 192–193°; $[\alpha]^{24}D$ −119° (*c*, 0.48 in chloroform)) which proved to be identical with an authentic sample of methyl pentaacetyl-α-dihydrostreptobiosaminide prepared from dihydrostreptomycin.

*Anal.* Calcd. for $C_{14}H_{22}NO_9(CH_3CO)_5$: C, 51.14; H, 6.62; O-acetyl, 30.6. Found: C, 51.10; H, 6.64; O-acetyl, 30.4.

(18) The specific rotation of ethyl tetraacetyl-1-thio-α-D-mannoside prepared directly from D-mannose is +104°. The difference between this value and the one obtained for the substance prepared from mannosidostreptomycin is probably due to the presence of a small amount of the β-anomer in the latter.

(19) T. L. Harris, E. L. Hirst and C. E. Wood, *J. Chem. Soc.*, 2108 (1932).

The vacuum-dried ether precipitate (610 mg.) described above was acetylated with 5 ml. of acetic anhydride and 10 ml. of pyridine. The resulting acetylation product was dissolved in 5 ml. of absolute alcohol and allowed to stand in the refrigerator overnight. A crystalline precipitate formed, which consisted for the most part of octaacetylstreptidine. It was separated off by centrifugation and extracted several times with small portions of dry ether. The combined alcohol–ether filtrates were evaporated to dryness and the residue chromatographed in benzene solution on alumina. The two crystalline fractions obtained from the column proved to be identical with those described above.

**Aqueous Acid Hydrolysis of Mannosidostreptomycin.**—A solution of 1.08 g. of crude mannosidostreptomycin hydrochloride in 20 ml. of 1 *N* sulfuric acid was heated to 45° for twenty-four hours. After standing in the refrigerator for one day streptidine sulfate (0.45 g., 92% of the theoretical amount) was removed by filtration and the sulfate ion was removed from the filtrate by the addition of excess barium carbonate. To the supernate 0.4 g. of phenylhydrazine hydrochloride and 0.6 g. of sodium acetate were added. After standing for four hours the slight precipitate which had formed was centrifuged, washed and dried. It weighed only 26 mg. and could not be crystallized. Increasing the time of hydrolysis to sixty-five hours did not change the result. A quantitative yield of D-mannose phenylhydrazone was obtained, when the reaction was conducted at 100° for one hour.[20]

**Nonaacetyl-dihydromannosidostreptobiosamine.**—A solution of 8.1 g. of dihydromannosidostreptomycin trihydrochloride in 160 ml. of 1 *N* sulfuric acid was kept at 45° for twenty hours. After standing in the refrigerator for two days 3.28 g. (96% of the theoretical amount) of streptidine sulfate was removed by filtration. A sample was analyzed after drying at 100° for two hours.

*Anal.* Calcd. for $C_8H_{18}O_4N_6 \cdot H_2SO_4 \cdot H_2O$: C, 25.40; H, 5.86; N, 22.20; S, 8.46. Found: C, 25.42; H, 5.73; N, 22.14; S, 8.33.

The filtrate was neutralized with barium hydroxide, the barium sulfate removed by filtration, and silver carbonate was added with shaking until the *p*H attained a value of 6 to 6.5. The supernatant liquid was immediately lyophylized and the resulting amorphous solid acetylated with pyridine (50 ml.)–acetic anhydride (30 ml.) for two days at room temperature. The solvents were then removed under reduced pressure and the residue taken up in chloroform, which was washed with dilute hydrochloric acid, dilute sodium bicarbonate solution and water, and dried over sodium sulfate. The dried residue from the chloroform solution was dissolved in benzene and chromatographed on an acetic acid-washed alumina column, 3 × 20 cm. Material eluted with benzene (200 ml.) weighed 0.83 g. and had a specific rotation of −93°. It was discarded. Subsequent elutions with benzene–ether mixtures, ether and ethyl acetate yielded fractions which all had specific rotations of −45° ± 7°, and these were combined. Since this material could not be induced to crystallize it was lyophylized from benzene solution to an amorphous powder, $[\alpha]^{25}D$ −48° (*c*, 1.05 in chloroform), which was dried at 60° *in vacuo*.

*Anal.* Calcd. for $C_{19}H_{26}O_{14}N(COCH_3)_9$: C, 50.51; H, 6.04; N, 1.59; O-acetyl, 39.2; total acetyl, 44.0. Found: C, 50.58; H, 6.15; N, 1.91; O-acetyl, 37.9; total acetyl, 44.7.

**Methanolysis of Nonaacetyl-dihydromannosidostreptobiosamine.**—The acetylated trisaccharide (320 mg.) was dissolved in 10 ml. of 1.5 *N* methanolic hydrogen chloride. After standing for two days the acid was removed by shaking with excess silver carbonate followed by centrifugation. The supernatant liquid was evaporated to dryness *in*

(20) This experiment was carried out by Mr. J. Kowald, and provides the basis for an analytical procedure for the determination of mannosidostreptomycin, a detailed account of which will be published shortly by Dr. E. T. Stiller and Mr. J. Kowald of the Division of Chemical Development.

*vacuo* and the residue acetylated overnight in pyridine (5.0 ml.)-acetic anhydride (3.0 ml.). The dried acetylation product (307 mg.) worked up as in the acetylations described above was extracted with benzene, leaving undissolved 46 mg. of crystals, which after recrystallization from acetone–pentane had a m. p. of 191–193°, not depressed on admixture of authentic methyl pentaacetyl-α-dihydrostreptobiosaminide.

The benzene solution was chromatographed on an acetic acid-washed alumina column, 1 × 18 cm. Elution with 75 ml. of benzene yielded 57 mg. of methyl tetraacetyl-α-D-mannopyranoside, m. p. 63–65°. Further elution with 50 ml. of 30% ether in benzene afforded first 26 mg. of a crystalline material which melted over a wide range, 60 to 140°, and then 26 mg. of methyl tetraacetyl-β-D-mannopyranoside which melted at 153–155° after recrystallization from ether–pentane. The m. p. of a mixture with an authentic sample of m. p. 160° was 153–157°. A further quantity of methyl pentaacetyl dihydrostreptobiosaminide, 85 mg., m. p. 188–191°, was obtained by elution with 50 ml. of ether.

**Acetolysis of Nonaacetyl-dihydromannosidostreptobiosamine.**—In a preliminary experiment 90 mg. of the acetylated trisaccharide was dissolved in a mixture of 7.0 ml. of acetic anhydride, 3.0 ml. of acetic acid and 0.1 ml. of concentrated sulfuric acid. The initial rotation, $[\alpha]^{25}D$ −48°, dropped to −19° in five hours and remained constant at −10° after sixteen hours. The solution was then poured into a beaker containing crushed ice and solid sodium bicarbonate and shaken and stirred vigorously until the acids were neutralized. Extraction with chloroform yielded 75 mg. of a residue which was taken up in benzene and chromatographed on an alumina column, 1 × 15 cm. Elution with 40% ether in benzene afforded pentaacetyl-N-methyl-L-glucosamine (11 mg., m. p. 156°), but the bulk of the material (51 mg.) could be eluted only with ether. Since it could not be induced to crystallize, it was lyophilized from benzene solution and dried at 60° *in vacuo*, $[\alpha]^{25}D$ −31° (*c*, 0.6 in methanol).

*Anal.* Calcd. for $C_{13}H_{17}O_{10}N(COCH_3)_3$: N, 2.03; O-acetyl, 43.6; total acetyl, 49.8. Found: N, 1.92; O-acetyl, 40.8; total acetyl, 51.6.

Subsequent acetolyses on a larger scale always gave as the principal product an amorphous material having $[\alpha]D$ −32 ± 2°. The small amounts of pentaacetyl-N-methyl-L-glucosamine were probably derived from the estimated 5–10% streptomycin present in the mannosidostreptomycin used for degradation.

**Methanolysis of Octaacetyl-D-mannosido-N-methyl-L-glucosamine.**—A solution of 360 mg. of the acetylated disaccharide in 20 ml. of 1.1 *N* methanolic hydrogen chloride was allowed to stand at room temperature for forty-eight hours, and the mixture of products was isolated and acetylated as described above for the methanolysis of mannosidostreptomycin.

The acetylation product was dissolved in 20 ml. of benzene and chromatographed on a column of alumina, 1 × 18 cm. Elution with benzene (100 ml.) gave 52 mg. of crude methyl tetraacetyl-α-D-mannopyranoside, which melted at 64–66° after recrystallization from ether–pentane. Further elution with 40% ether in benzene yielded successively 30 mg. of methyl tetraacetyl-β-D-mannopyranoside, m. p. 157–159°, and 93 mg. of a crystalline substance which melted at 106–108° after several recrystallizations from ether–pentane, $[\alpha]^{25}D$ −4.0° (*c*, 0.5 in ethanol).

*Anal.* Calcd. for $C_7H_{10}O_4N(COCH_3)_4(OCH_3)$: C, 51.19; H, 6.71; N, 3.73; $CH_3O$, 8.27; O-acetyl, 34.4. Found: C, 51.28; H, 6.71; N, 3.58; $CH_3O$, 8.06; O-acetyl, 35.7.

There was no depression in m. p. on admixture of methyl tetraacetyl-N-methyl-β-L-glucosaminide, m. p. 105–108°, which had been prepared by methanolysis and reacetylation of pentaacetyl-N-methyl-α-L-glucosamine.

**Methyl Tetraacetyl-N-methyl-β-L-glucosaminide.**—Pentaacetyl-N-methyl-α-L-glucosamine (140 mg.) was dissolved in 10 ml. of 1.1 *N* methanolic hydrogen chloride. After two days standing the solution was stirred with excess silver carbonate for thirty minutes, then filtered, and the filtrate evaporated to dryness *in vacuo*. The residue was acetylated overnight in acetic anhydride (2 ml.)-pyridine (2 ml.). The crude acetylation product was crystallized several times from ether–pentane, m. p. 103–105°, $[\alpha]^{25}D$ −4.2° (*c*, 0.5 in ethanol).

**Acknowledgment.**—The authors wish to express their appreciation to Dr. O. Wintersteiner for his interest and helpful advice in the course of this work. They are also indebted to Miss Mary Berestecki and Miss Doris E. Walz for their able technical assistance and to Mr. Joseph F. Alicino, Miss Anne C. Crickenberger and Miss Ruth Karitzky for the microanalytical determinations.

## Summary

Mannosidostreptomycin has been cleaved by methanolic hydrogen chloride to streptidine, methyl α-streptobiosaminide dimethyl acetal, and the α- and β-forms of methyl D-mannopyranoside, and by ethyl mercaptan–hydrochloric acid to the corresponding ethyl thio-derivatives. The cleavage products were isolated as the crystalline acetates.

Dihydromannosidostreptomycin has been degraded by methanolic hydrogen chloride to the α- and β-anomers of methyl D-mannopyranoside and methyl dihydrostreptobiosaminide, all isolated as the crystalline acetates.

Hydrolysis of dihydromannosidostreptomycin with 1 *N* sulfuric acid at 45° yielded streptidine sulfate and a trisaccharide, dihydromannosidostreptobiosamine, isolated as the amorphous nonaacetate. This product was cleaved by methanolic hydrogen chloride to methyl β-D-mannopyranoside and methyl α-dihydrostreptobiosaminide, both isolated as the crystalline acetates.

Acetolysis of nonaacetyl dihydromannosidostreptobiosamine gave a disaccharide acetate, octaacetyl mannosido-N-methyl-L-glucosamine, which was cleaved by methanolic hydrogen chloride to methyl β-D-mannopyranoside and methyl N-methyl-β-L-glucosaminide, both isolated as the crystalline tetraacetates.

The conclusion is drawn from these data that mannosidostreptomycin is a D-mannosido-N-methyl-α-L-glucosaminido-L-streptoside of streptidine. The linkage between the D-mannose and the N-methyl-L-glucosamine moieties appears to be α.

# Ethyl Thioglycosides of D-Mannose and D-Galactose and a New Synthesis of Styracitol

BY JOSEF FRIED AND DORIS E. WALZ

In the course of recent work on the structure of mannosidostreptomycin[1,2] two isomeric ethyl thiohexosides were obtained which were not identical with any of those described in the literature. The present work, originally undertaken for the purpose of identifying these two substances, has afforded a method for the preparation of ethyl thio-D-mannopyranosides and D-galactosides, as well as a new synthesis for styracitol (1,5-anhydromannitol).

The alkyl thioglycosides, in contrast to the well-explored sugar mercaptals, have met with but occasional interest and their study has been confined to derivatives of glucose and fructose. Schneider and Sepp[3] were the first to synthesize an ethyl thioglucoside, later shown to be the $\alpha$-furanoside,[4,5] by partial cleavage of glucose diethyl mercaptal with mercuric chloride. This substance has been found[6] to undergo an unusual sequence of reactions in the presence of 0.01 *N* hydrochloric acid. Under these conditions approximately one half of the material was converted into the $\beta$-furanoside and eventually into glucose and ethyl mercaptan, while the other half escaped the hydrolyzing effect of the acid by rearranging into the acid resistant pyranoid form. The ring shift resulted in the formation of ethyl $\alpha$-thioglucopyranoside which was isolated and characterized as the tetraacetate. Ethyl $\alpha$-thioglucopyranoside has also been prepared by the prolonged action of 22% hydrochloric acid on both glucose diethyl mercaptal and on an equimolecular mixture of glucose and ethyl mercaptan.[7,8] The fourth isomer, ethyl $\beta$-thioglucopyranoside, was prepared by Schneider and co-workers[9] according to the original Fischer method,[10] reaction of the potassium mercaptide with acetobromoglucose, and by the action of ethyl iodide on thioglucose.[11]

The formation of the two ethyl thiomannosides by mercaptolysis of mannosidostreptomycin[1,2] in the presence of concentrated hydrochloric acid suggested that simple glycosides might be mercaptolyzed in an analogous fashion. This was indeed found to be the case. Both $\alpha$- and $\beta$-methyl D-mannopyranoside on treatment with ethyl mercaptan and concentrated hydrochloric acid for eighteen hours at room temperature yielded after acetylation ethyl tetraacetyl-1-thio-$\beta$-D-mannopyranoside, $[\alpha]^{25}D$ $-67°$ and m. p. 161–162°. Methyl $\beta$-mannopyranoside yielded in addition a small amount of the $\alpha$-anomer ($[\alpha]^{25}D$ $+104°$; m. p. 107–108°). Better results from a preparative point of view were obtained when the above conditions were applied to the free sugar. Thus, when D-mannose was shaken with ethyl mercaptan and concentrated hydrochloric acid for eighteen hours at room temperature, and the resulting mixture after neutralization with sodium carbonate was evaporated to dryness *in vacuo*, the residue upon acetylation afforded a 32% yield of ethyl tetraacetyl-1-thio-$\beta$-D-mannopyranoside. Chromatography of the mother liquor yielded in addition a small amount of the $\alpha$-anomer. Catalytic deacetylation with barium methylate afforded the free $\alpha$- and $\beta$-ethyl thio-D-mannosides of which only the latter was obtained in crystalline form. Its properties are listed in Table I.

It is well known that the action of ethyl mercaptan and hydrochloric acid on D-mannose for a period of five minutes produces the diethyl mercaptal in 63% yield.[12] The absence of this substance from the products of the eighteen-hour reaction, as shown by careful chromatography of the mother liquor, after removal of the crystalline ethyl tetraacetyl-1-thio-$\beta$-D-mannopyranoside, indicated that the mercaptal is likely to be an intermediate in the formation of the thioglycosides.

The stability of the two ethyl thiomannosides toward strong acid suggested that they possess pyranoid ring structures. More definite proof, however, was sought by utilizing the demercaptalation reaction of Wolfrom and his collaborators,[13] using mercuric chloride and cadmium carbonate in methanol, in the hope of replacing the mercapto group of the more abundantly available $\beta$-anomer by methoxyl. In spite of the use of a large excess of mercuric chloride and a reaction time of twenty-four hours, the starting material was recovered unchanged. Conclusive evidence for the pyranose structure of ethyl 1-thio-$\beta$-D-mannoside was adduced by reductive desulfurization of the latter with Raney nickel, which afforded the 1,5-anhydrohexitol styracitol[14] in good yield. The 1,5-oxide structure of styracitol has been securely established by Zervas,[15] who succeeded in synthesizing this substance by catalytic reduction of tetra-

[a] P. Brigl, K. Gronemeier and A. Schulz, *Ber.*, **72**, 1052 (1939). [b] W. Schneider, J. Sepp and O. Stiehler, *ibid.*, 51, 220 (1918). [c] E. Pacsu and E. J. Wilson, Jr., THIS JOURNAL, **61**, 1450 (1939). [d] The specific rotations were determined at temperatures ranging from 24 to 27°.

acetyl-2-hydroxyglucal, followed by deacetylation.

The structure of styracitol has been the subject of considerable controversy. Evidence has been presented by several groups of workers supporting either the 1,5-anhydromannitol[16,17] or the 1,5-anhydrosorbitol[18,19] structure. The present synthesis leaves little doubt that the mannitol structure, which is overwhelmingly favored by previous evidence, is the correct one.

In applying the conditions for the preparation of the ethyl thio-D-mannosides to D-galactose we obtained, after acetylation and chromatographic purification, two crystalline ethyl tetraacetyl-1-thio-D-galactosides. Their properties as well as those of the crystalline ethyl thiogalactosides obtained after deacetylation are listed in Table I. In the last two columns of this table are also given the 2A and 2B values calculated from the molecular rotations on the basis of Hudson's rules of isorotation.[20] For the sake of comparison, the values for the two anomeric ethyl thio-D-glucopyranosides and their tetraacetates have also been included. The agreement between the 2A values calculated from the molecular rotations of the two thiogalactosides (76800) and their tetraacetates (88500) and those for the thioglucopyranosides (72500) and their tetraacetates (86030) appears to be close enough to warrant the conclusion that the two ethyl thiogalactosides are anomeric and possess pyranoid structures. The 2A value for the tetraacetyl-thio-D-mannosides (67000) shows the deviation characteristic of all mannose derivatives.[21]

An attempt to prepare the ethyl thioglycosides of L-arabinose in an analogous manner yielded only arabinose diethyl mercaptal. This result demonstrates the influence of stereo configuration on the reactivity of the sugar mercaptals rendering difficult any prediction as to the general applicability of the above procedure.

## Experimental[22]

**α- and β-Ethyl Tetraacetyl-1-thio-D-mannopyranosides.**—D-Mannose (5.0 g.) was added to ice-cold concentrated hydrochloric acid (20 ml.) and ethyl mercaptan (20 ml.), and the mixture was shaken for sixteen hours at room temperature. At the end of this period the excess ethyl mercaptan and part of the hydrochloric acid were removed *in vacuo* at a bath temperature not exceeding 30°. The residual acid solution (10 ml.) was diluted with water (10 ml.) and alcohol (10 ml.) and alkalinized by the addition of solid sodium carbonate to a *p*H of 8. During the addition of the sodium carbonate it was necessary to add water and alcohol in order to prevent the mixture from solidifying. The solvents were then removed *in vacuo* and the resulting residue dried by distilling absolute alcohol (60 ml.) from it. The dried residue was then acetylated by shaking overnight with pyridine (40 ml.)–acetic anhydride (40 ml.), and the acetylation mixture was concentrated *in vacuo* to a sirup. The latter was partitioned between ice-water and chloroform and the chloroform layer was washed with dilute acid, sodium bicarbonate and water. The dried chloroform solution upon removal of the solvent *in vacuo* yielded a brown sirup (10.7 g.) which crystallized on standing at room temperature. Crystallization was complete after two days at 4° after which time the crystalline mass was digested with a small amount of cold absolute alcohol and filtered by suction. The crystals, after washing with cold alcohol (3.24 g.), melted at 157–158°. Recrystallization from absolute alcohol raised the melting point to 161–162°; $[\alpha]^{24}D$ −67° (*c*, 0.67 in chloroform).

*Anal.* Calcd. for $C_{16}H_{24}O_9S$: C, 48.98; H, 6.17; S, 8.16; O-acetyl, 43.84. Found: C, 49.19; H, 5.98; S, 8.41; O-acetyl, 44.7.

The sirupy mother liquor from which the bulk of the ethyl tetraacetyl-1-thio-β-D-mannopyranoside had been removed by filtration was concentrated *in vacuo* and the alcohol-free oily residue (7.44 g.) was dissolved in a mixture of benzene (75 ml.) and hexane (185 ml.) for chromatography on alumina (100 g.). A mixture of 2 parts of benzene and 5 parts of hexane eluted at first (720 ml.) oily material, which was followed by a series of crystalline fractions. A total of 1270 ml. of the above solvent mixture eluted approximately 150 mg. of crystals which after several recrystallizations from ether–hexane melted at 107–108°; $[\alpha]^{25}D$ +104° (*c*, 0.88 in chloroform).

(22) The melting points reported in this paper were taken in capillary tubes and have been corrected for stem exposure.

*Anal.* Calcd. for $C_{16}H_{24}O_9S$: C, 48.98; H, 6.17; S, 8.16. Found: C, 49.07; H, 5.98; S, 8.43.

**Mercaptolysis of Methyl α-D-Mannopyranoside.**—Methyl α-D-mannopyranoside (400 mg.) was shaken with concentrated hydrochloric acid (2 ml.) and ethyl mercaptan (5 ml.) for eighteen hours at room temperature. The mixture was cooled to 0°, neutralized with concentrated ammonia and evaporated to dryness *in vacuo*. The thoroughly dried residue was acetylated with pyridine (10 ml.)–acetic anhydride (10 ml.), and the acetylation mixture was worked up as in the preceding experiment. Chromatography on alumina (25 g.) from benzene (10 ml.)-hexane (15 ml.), yielded crystals (40 mg.), eluted by equal volumes of benzene and ether, which melted at 159.5–161° and were identified as ethyl tetraacetyl 1-thio-β-D-mannoside.

**Mercaptolysis of Methyl β-D-Mannopyranoside.**—Methyl β-D-mannopyranoside (190 mg.) was mercaptolyzed as described for the α-anomer. Acetylation of the crude product yielded a semicrystalline residue which when taken up in cold absolute alcohol (1.5 ml.) yielded crystalline ethyl tetraacetyl-1-thio-β-D-mannopyranoside. The alcoholic mother liquor was freed from solvent *in vacuo*, dissolved in benzene (4 ml.) and hexane (4 ml.) and chromatographed on acetic acid washed alumina (7 g.). A mixture of benzene (140 ml.) and hexane (140 ml.) eluted material which crystallized readily on seeding with ethyl tetraacetyl-1-thio-α-D-mannoside. After two recrystallizations the melting point remained constant at 107–108°, and showed no depression on admixture of ethyl tetraacetyl-1-thio-α-D-mannoside

**Ethyl 1-Thio-β-D-mannopyranoside.**—Ethyl tetraacetyl-1-thio-β-D-mannopyranoside (500 mg.) was suspended in dry methanol (75 ml.) and a 0.9 *N* solution of barium methylate (1 ml.) was added. The mixture was allowed to stand at room temperature for sixteen hours with occasional shaking during the first hour. Carbon dioxide was then passed through the solution for ten minutes and the methanol was removed *in vacuo*. The residue was taken up in water, the precipitate of barium carbonate centrifuged off and the solution evaporated to dryness *in vacuo*. Upon addition of a few drops of absolute alcohol the residue crystallized rapidly. Recrystallization from absolute alcohol yielded clusters of prismatic needles (145 mg.), which melted at 118–119°; $[\alpha]^{25}D$ −83° (*c*, 0.6 in water).

*Anal.* Calcd. for $C_8H_{16}O_5S$: C, 42.85; H, 7.19; S, 14.27. Found: C, 42.71; H, 6.98; S, 14.37.

**Reductive Desulfurization of Ethyl Tetraacetyl-1-thio-β-D-mannopyranoside to Styracitol.**—A solution of ethyl tetraacetyl-1-thio-β-D-mannopyranoside (300 mg.) in absolute alcohol (20 ml.) was refluxed with Raney nickel[23] (4 ml.) for four hours. The mixture was diluted with alcohol (20 ml.) and the Raney nickel removed by centrifugation and subsequent gravity filtration of the turbid supernate. The nickel was washed with fresh portions of hot alcohol and the combined filtrates were evaporated to dryness *in vacuo*. The sirupy residue was deacetylated in methanol (45 ml.) with 0.9 *N* barium methylate (0.6 ml.) at 4° for sixteen hours. After removal of the barium as described in the preceding experiment, the residue was dissolved in a small amount of absolute alcohol and was seeded with authentic styracitol.[24] On cooling, crystals (70 mg.) were obtained, which after two recrystallizations from methanol melted at 155–156° and had $[\alpha]^{27}D$ −48° (*c*, 1.1 in water). There was no depression in melting point on admixture of the above authentic sample of styracitol of m. p. 155–156° and $[\alpha]^{26}D$ −50° (*c*, 1.0 in water).

*Anal.* Calcd. for $C_6H_{10}O_5$: C, 43.94; H, 7.37. Found: C, 44.01; H, 7.44.

An additional amount of crystals (30 mg.) was obtained on concentration of the ethanolic mother liquor. The total yield of crude crystalline product was 100 mg. or 80%.

**Attempted Replacement of the Ethylmercapto Group in Ethyl Tetraacetyl-1-thio-β-D-mannopyranoside by Methoxyl.**—To a solution of ethyl tetraacetyl-1-thio-β-D-mannopyranoside (200 mg., 0.51 millimole) in absolute methanol (4 ml.) was added mercuric chloride (775 mg., 2.85 millimoles) and cadmium carbonate (575 mg.). The mixture was refluxed for eighteen hours, taken up in chloroform (20 ml.), filtered, and extracted with water to remove the mercuric chloride. The chloroform solution was dried over sodium sulfate and evaporated to dryness *in vacuo*. The crystalline residue proved to be unchanged starting material.

**α- and β-Ethyl Tetraacetyl-1-thio-D-galactopyranosides.**—D-Galactose (5.0 g.) was treated with concentrated hydrochloric acid (20 ml.) and ethyl mercaptan (20 ml.) exactly as described above for D-mannose. Upon acetylation with pyridine (40 ml.)–acetic anhydride (40 ml.) a brown sirup (7.7 g.) was obtained, which crystallized only to a small extent on long standing. A portion of the sirup (6.67 g.) was therefore chromatographed on alumina (100 g.) from a benzene (67 ml.)–hexane (167 ml.) solution. Elution of the column with benzene–hexane (2:5) yielded at first a considerable amount of oily material. After 600 ml. of the eluant had passed through the column the succeeding 900 ml. of effluent, collected in 13 fractions of 70 ml., yielded on evaporation crystals melting at 107–108°. Since no depression in melting point was observed when the first and the thirteenth fraction were mixed, all the fractions were combined and recrystallized from ether–hexane. The resulting material (287 mg.) melted at 108–109° and had $[\alpha]^{26}D$ +218° (*c*, 1.18 in chloroform).

*Anal.* Calcd. for $C_{16}H_{24}O_9S$: C, 48.98; H, 6.17; S, 8.16; acetyl, 43.84. Found: C, 49.02; H, 6.10; S, 8.40; acetyl, 43.0.

Subsequent elution of the column with the same solvent mixture gave two fractions (240 ml. each) from which a small amount of the above crystalline material (m. p. 103–104°) was obtained on seeding. Continued elution with 1900 ml. of benzene–hexane yielded upon evaporation of the solvents a second crystalline substance, which after several recrystallizations from ether–hexane melted at 74–75° (114 mg.); $[\alpha]^{26}D$ −8.0 (*c*, 2.1 in chloroform).

*Anal.* Calcd. for $C_{16}H_{24}O_9S$: C, 48.98; H, 6.17; S, 8.16; acetyl, 43.84. Found: C, 48.91; H, 6.23; S, 8.53; acetyl, 44.1.

Elution with benzene (320 ml.) afforded a small amount of crystals (5.2 mg.), which melted at 141.5–142°. The substance contained no sulfur and was probably pentaacetyl-β-D-galactopyranose, which has been reported[25] to melt at 142°.

**Ethyl 1-Thio-α-D-galactopyranoside.**—Ethyl tetraacetyl-1-thio-α-D-galactopyranoside (130 mg.) was deacetylated in dry methanol solution (21 ml.) with 0.9 *N* barium methylate (0.28 ml.) as described above for ethyl thio-β-D-mannopyranoside. The residue, from which the barium had been removed, crystallized upon addition of absolute alcohol. On recrystallization from this solvent fine needles (49 mg.) were obtained which melted at 153.5–154° and had $[\alpha]^{27}D$ +320° (*c*, 0.55 in water).

*Anal.* Calcd. for $C_8H_{16}O_5S$: C, 42.85; H, 7.19; S, 14.27. Found: C, 42.81; H, 6.94; S, 14.55.

**Ethyl 1-Thio-β-D-galactopyranoside.**—Ethyl tetraacetyl-1-thio-β-D-galactopyranoside (60 mg.) was deacetylated as described in the preceding experiment. Since the barium-free residue could not be induced to crystallize it was dissolved in ethanol (0.5 ml.)–benzene (1.5 ml.) and chromatographed on alumina (1 g.). A mixture of alcohol (1 part) and benzene (3 parts) eluted at first (26 ml.) amorphous material, which was discarded. All subsequent fractions obtained with this solvent mixture (165 ml.) and with equal volumes of benzene and alcohol (300 ml.) crystallized on rubbing with ethyl acetate. The

(23) Similar yields were obtained with both freshly prepared and six-months-old Raney nickel.

(24) The authors wish to thank Dr. John T. Sheehan for kindly supplying them with a sample of pure styracitol isolated from *Styrax obassia*.

(25) E. Erwig and W. Koenig, *Ber.*, **22**, 2207 (1889).

combined fractions were recrystallized from a minimum of alcohol and ethyl acetate and yielded 13 mg. of long thin needles which melted at 121.5–122.5° and had $[\alpha]^{26}D$ −23.5° (*c*, 0.89 in water).

*Anal.* Calcd. for $C_8H_{16}O_5S$: C, 42.85; H, 7.19; S, 14.27. Found: C, 42.58; H, 6.77; S, 13.50.

**Reaction of L-Arabinose with Ethyl Mercaptan.**—L-Arabinose (2 g.) was treated with ethyl mercaptan (8 ml.) and hydrochloric acid (8 ml.) as described for methyl α-D-mannopyranoside. The dried neutralized residue was acetylated with pyridine (20 ml.)–acetic anhydride (20 ml.), the crude acetylation product dissolved in absolute alcohol (3 ml.), and the solution was allowed to stand in the refrigerator overnight. The resulting crystals (2.35 g.) were filtered and washed with cold alcohol. After two recrystallizations from 95% alcohol the crystals melted at 79–80° $[\alpha]^{27}D$ −27.0° (*c*, 1.6 in chloroform). These data are in accord with those given for tetraacetyl-L-arabinose diethyl mercaptal by Wolfrom and Newlin.[26]

*Anal.* Calcd. for $C_{17}H_{28}O_8S_2$: C, 48.11; H, 6.65; S, 15.08. Found: C, 48.27; H, 6.65; S, 15.27.

**Acknowledgment.**—The authors wish to thank Dr. Oskar Wintersteiner for helpful discussions during the course of this work and Mr. Joseph F. Alicino, Miss Anne C. Crickenberger and Miss Ruth Karitzky for the microanalytical determinations.

## Summary

α- and β-ethyl tetraacetyl-1-thio-D-mannopyranosides have been prepared by the prolonged action of ethyl mercaptan and hydrochloric acid on both D-mannose and methyl β-D-mannopyranoside. Methyl α-D-mannopyranoside yielded only the β-anomer. Ethyl 1-thio-β-D-mannopyranoside has been obtained in crystalline form.

Styracitol has been prepared from ethyl tetraacetyl-1-thio-β-D-mannopyranoside by desulfurization with Raney nickel.

α- and β-ethyl 1-thio-D-galactopyranosides and their tetraacetates have been prepared in crystalline form.

The action of ethyl mercaptan and hydrochloric acid on L-arabinose for eighteen hours led only to the diethyl mercaptal.

# The Reaction of Simple Antigens with Purified Antibody[1]

BY ARTHUR B. PARDEE[2] AND LINUS PAULING

Many biological reactions, including the interaction of antibodies and antigens, the effect of enzymes on their substrates, and the self-reproducing behavior of genes, are characterized by a high degree of specificity. The great problem of the nature of the forces responsible for this biological specificity is being attacked vigorously in many ways at the present time. During the past six years we have carried out a series of investigations[1] on the reactions of antisera with simple substances, extending and refining the work of Landsteiner.[3] The results obtained provide strong support for the concept that biological specificity is due to a detailed complementariness in surface configuration of the molecules involved (antigen and antibody) and that the forces which contribute to specific attraction of two molecules—van der Waals electronic forces, hydrogen bond forces, etc.—are in general short-range forces, effective over distances of a few Ångström units. The conclusion has been reached that the surface approximation of antibody and the haptenic groups of antigens is to within about 1 Å.

Much of our work has consisted of studies of the precipitation of an antiserum by a simple polyhaptenic substance. The observation that certain simple substances containing two or more haptenic groups would form precipitates with the homologous antiserum was made by Landsteiner and van der Scheer.[4] It was suggested by Landsteiner that the forces between dye molecules which favor the formation of colloidal solutions, that is, of polymerized aggregates, are responsible for the ready precipitability of these substances, many of which are dyes. We, however, have presented evidence that the presence of two or more haptenic groups in each molecule, making the formation of a framework possible, is responsible for their precipitability.

The suggestion that it is polymerization of these simple precipitating antigens that gives them their precipitating power has been revived by Boyd and Behnke,[5] who reported that they had found one of the simple antigens used by us to be highly (11-fold) polymerized in saline solution, and who stated that accordingly the results of our earlier investigations might not justify the

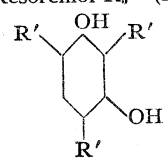
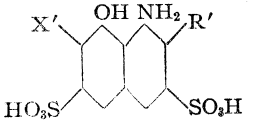
interpretation that we had given them. This criticism has been repeated by Kabat.[6]



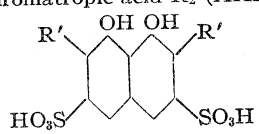
In the present paper we report the results of experiments on the interaction of simple precipitating antigens with purified antibody solutions. It has been found that the behavior of the simple antigens with purified antibody solutions is somewhat different from that with antiserum, the difference apparently being due to a rather strong non-specific combination of the dye molecules with the constituents of serum not present in purified antibody, presumably mainly albumin.[7,8] The effect of this combination seems to be to reduce the concentration of the free dye molecules to such an extent that in serum solution they react mainly in the monomeric form.

## Experimental



**Synthetic Antigens.**—The compounds used as synthetic antigens and their preparation have been described in previous papers except resorcinol-R$_3'$, which was prepared by Mr. A. L. Grossberg, by the method used for chloroglucinol-R$_3'$ (XI) with use of a different phenolic nucleus.[9,10]

R represents the *p*-azobenzenearsonic acid group, R′ the *p*-(*p*-azobenzeneazo)-benzenearsonic group, and X′ the *p*-(*p*-azobenzeneazo)-benzoic acid group.



Resorcinol-R$_3'$ (R$_3'$)

H-acid-R′X′ (R′X′)

Chromatropic acid-R$_2'$ (XXX)

**Antibodies and Other Substances.**—The anti-R serum was obtained from rabbits by the method previously described.[9]

Specifically purified anti-R antibody (referred to in this paper as purified antibody) was prepared by Prof. D. H. Campbell.[11] Various preparations using resorcinol-R$_3'$ as precipitant were pooled and used for the succeeding experiments.

The pneumococcus type I antibody used in some of the experiments was a commercial preparation, Lederle Refined and Concentrated Rabbit Globulin. The purified polysaccharide was prepared by Dr. J. E. Cushing, Jr.

The rabbit serum albumin was prepared by Dr. George A. Feigen, by a single salt precipitation.

**Salt and Buffer.**—All experiments were done in 0.9% sodium chloride solution, without buffer present unless otherwise noted. When a buffer is referred to as *x*F it is meant that the sum of all forms of the buffering material is *x* formula weights per liter.

**Precipitation Reaction; General Methods.**—Antigen and antibody at approximately the final *p*H were mixed and allowed to stand for one hour at room temperature and then for two to five days at 5°. (It was found that resorcinol-R$_3'$ gave the same amount of precipitate in two hours as in three days, and that the maximum turbidity under the conditions used was reached in ten minutes at room temperature.) After having been washed,[9] the precipitates were analyzed for antigen by adding 2.5 ml. of 1 *N* sodium hydroxide, making up to 5.5 ml. in a centrifuge tube, and reading the light absorption on a Beckman spectrophotometer at an appropriate wave length and slit width. Compound resorcinol-R$_3'$ was read at 500 mμ and 0.03 mm. slit width, and antigens XXX and R′X′ at 600 mμ and 0.04 mm. slit width. The first two compounds showed no tendency to fade over a period of several days in alkali or over several months in approximately neutral solution, but R′X′ faded about 20% in a day in alkali. The compounds reacted slowly with the soft glass bottles. The error in the colorimetric procedure is estimated at ±3% or less for samples containing more than $4 \times 10^{-9}$ moles of antigen, and is somewhat greater for smaller samples.

The same sample was then analyzed for protein by the modified Folin–Ciocalteu method.[12] A correction was made for the color of the antigen. To test the method ten triplicate analyses were run on purified antibody samples by both the modified Folin–Ciocalteu and the Nessler method by two analysts. The first method gave values which averaged 1.035 ± 0.035 times the second.

In some of the experiments with purified antibody the supernatant liquids were decanted from the centrifuged precipitates, both parts were analyzed, and the precipitates were corrected for the small amount of antigen and protein in the remaining supernatant liquid. In some of the later experiments only the precipitates were analyzed and the correction was calculated from the amount of reactants added.

The molecular weight of the antibody was taken as 160,000 for calculations.

## Results

Precipitates were analyzed both with and without washing, as described in the previous section. The amounts of precipitate and the mole ratios in the precipitate for the two procedures are compared in Table I and also in Table II. It can be seen that for the antigen used (XXX) the amount of precipitate washed away is 30 to 45% of the original amount; the ratio of antigen to antibody in the precipitate remains about the same, however. Only 10 to 15% of the precipitate with antigen resorcinol-R$_3'$ (at *p*H 6.9) was lost on washing.

It was found that the amount of precipitate obtained with antigen XXX and purified antibody at *p*H 7.6 and 8.1 was only slightly dependent on the volume of the reaction mixture, the amount of precipitate varying over about a 20% range for any given amounts of antigen and antibody on three-fold dilution with buffer solution. The mole ratio in the precipitate was essentially independent of the volume of the mixture. In contrast, a three-fold increase in the volume of a system containing antiserum and a simple poly-

[a] See note of Table I.

haptenic antigen[13] caused the amount of precipitate to decrease by 50%.

A number of experiments other than those reported in Table II were carried out in which varying amounts of purified antibody were added to a constant amount of antigen in a constant volume of solution. A 5 to 10% decrease in precipitated protein was noted at the largest amounts of antibody in every experiment. This effect of inhibition of precipitation by antibody excess is similar to but not nearly so marked as the effect in serum,[10] in which a four-fold increase in amount of antiserum above the optimum was found to decrease the amount of precipitate to a third of the maximum value.

Many precipitation experiments in which constant amounts of purified antibody were added to various amounts of antigen were carried out. The detailed results were in all cases similar to those reported in Table I, and their important features are summarized in Table III. Some experiments with added serum are also reported at the end of Table III for comparison. The first two columns give the antigen used and the *p*H of the system. A stands for antigen and B stands for antibody. Columns 3 to 5 have to do with conditions at the optimum, *i. e.*, the conditions which give the maximum amount of precipitate. Column 3 gives the per cent. of total antibody precipitated. The values in this column depend on the antigen, and, for resorcinol-R$'_3$, decrease with increasing *p*H. In the presence of serum an optimum is obtained at about *p*H 9.0.[14] The presence of serum greatly reduces the amount of precipitable antibody, especially in the case of antigen R'X', which gives no precipitate in serum.

TABLE III

SUMMARY OF PRECIPITATION EXPERIMENTS WITH PURIFIED ANTIBODY

| Antigen | *p*H | Per cent. of antibody pptd. at optimum | Mole ratio A/B in system at optimum | Mole ratio A/B in precipitate at optimum | A/B in precipitate at A = 0 |
|---|---|---|---|---|---|
| XXX | 8.1 | 73 | 1.8 | 1.3 | 0.9 |
| XXX | 8.1 | 58 | 1.5 | 1.8 | 1.1 |
| Resorcinol-R$'_3$ | 6.6 | 82 | 18 | 19 | 2.5 |
| Resorcinol-R' | 6.9 | 84 | 7.0 | 10 | 5.0 |
| Resorcinol-R$'_3$ | 7.6[a] | 76 | 5.1 | 5.0 | 1.1 |
| Resorcinol-R$'_3$ | 7.9 | 68 | 5.7 | 4.5 | 2.0 |
| Resorcinol-R$'_3$ | 8.7[b] | 63 | 6.0 | 7.0 | 1.5 |
| R'X' | 7.9[b] | 50 | 12 | 4.6 | 2.8 |
| XXX (in serum) | 8.1[b] | 19 | 7 | .. | ... |
| Resorcinol-R$'_3$ (in serum) | 8.5 | 36 | 5.1 | 2.2 | 2.0 |
| R'X' (in serum) | 8.3 | 0 | .. | .. | ... |

[a] This experiment was started at *p*H 9.9; when no precipitate appeared, the mixtures were acidified to *p*H 7.6. [b] 0.01 F Veronal buffer present. Mr. Leonard Lerman found no non-specific precipitation between resorcinol-R'$_3$ and normal rabbit γ-globulin under conditions similar to the above.

Column 4 gives the number of moles of antigen required per mole of antibody to form the maximum amount of precipitate. The antigen resorcinol-R$'_3$, which is more highly associated than the others,[15] requires a higher ratio, and the ratio is greater at lower *p*H. Antigen R'X' has a strikingly different ratio than the structurally similar compound XXX. The presence of serum has little effect on this ratio for resorcinol-R$'_3$ but a large effect for XXX.

The fifth column gives the mole ratio of antigen to antibody in the precipitate at the optimum. The values are similar to those in column 4 in the absence of serum, and decrease with increasing *p*H. The antigen R'X' is an exception, requiring a much higher ratio in the system than in the precipitate. Experiments in serum also show a lower antigen–antibody ratio in the precipitate than in the system, probably because much of the antigen is non-specifically combined with serum proteins.

(15) See the following paper, THIS JOURNAL, 71, 148 (1949).

The sixth column gives the mole ratio of antigen to antibody in the precipitate extrapolated to zero antigen–antibody ratio. This value can be obtained from either an experiment with variable antigen and constant antibody or an experiment with constant antigen and variable antibody. The values for the two types of experiment are the same within experimental error for antigen resorcinol-$R_3'$ and for XXX but are 4.0 and 2.8 for R'X'. The ratio is of interest because one would expect non-specific reactions of antigen with proteins, and also association, to be least important when there is a large excess of antibody in the system. Ideally the ratio should be unity according to the framework theory.[16] This is the value found for antigen XXX and approached by resorcinol-$R_3'$ as the *p*H is increased. In the experiment which was started at *p*H 9.9 and finished at *p*H 7.6 it appeared as if the antigen combined as a small aggregate at the higher *p*H and remained unassociated as the *p*H was decreased. Earlier experiments by Pressman[14] showed that if resorcinol-$R_3'$ were aged for even one hour at *p*H values below 9 before addition to antibody, the amount of precipitate was appreciably decreased below the optimum amount obtained with antigen kept above *p*H 9. R'X' has a higher limiting ratio than the structurally similar antigen XXX, indicating that R'X' is associated in the precipitate even at antigen–antibody ratios less than unity. If the values in the fifth and sixth columns of Table III agree, the non-specific effect in the purified antibody experiments is probably small. Experiments in serum all led to fairly low ratios.[10]

The shapes of the plots of amount of precipitate *vs.* amount of antigen added were generally similar. One quarter to one sixth of the optimum amount of antigen was required to give half the maximum amount of precipitate with purified antibody, and slightly more was required with antiserum. Generally about eight times the optimum amount of antigen was required to reduce the amount of precipitate to a half by antigen-excess inhibition. An exception was R'X', which required more than a fifteen-fold excess.

**The Effect of Addition of Serum or Serum Albumin.**—Normal rabbit serum was added to the purified antibody and precipitation tests were made, with the results reported in Table III. The effect of the serum was to reduce the amount of precipitate with antigens resorcinol-$R_3'$ and XXX, and to prevent precipitation with antigen R'X'. Serum albumin had the same effect as normal rabbit serum: it completely inhibited precipitation with R'X', and reduced the amount of precipitate obtained with antigen XXX. The tests in serum albumin were made at *p*H 6.2.

(16) L. Pauling, THIS JOURNAL, **62**, 2643 (1940); L. Pauling, D. Pressman, and C. Ikeda, *ibid.*, **64**, 3010 (1942).

**A Study of Non-specific Adsorption.**—To see how much antigen was held non-specifically to the precipitates in the purified antibody experiments, precipitations were carried out between purified pneumococcus polysaccharide type I and a commercial globulin preparation from rabbit serum, containing about 10% antibody precipitable by the polysaccharide. In the first four tubes of the series reported in Table IV the compound resorcinol-$R_3'$ was present at the time of precipitation of approximately optimal amounts of the reactants. In tubes 5 to 8 the precipitation was completed and then the supernatant liquid was replaced by solutions of resorcinol-$R_3'$. The results given in the table show that there is a very strong non-specific affinity of the precipitate for the simple antigen. That the antigen is not merely trapped in the precipitate is shown by the fact that the second four experiments gave ratios very similar to the first four. Although there is ten times as much protein in the solution as in the precipitate, the precipitate can hold 80% of the antigen. That the increase in precipitate with increasing amounts of antigen is a non-specific effect is shown by the ninth and tenth tubes of the table, in which no polysaccharide was present. Experiments with compound XXX and the pneumococcus polysaccharide system showed that the protein in the precipitate is more effective for non-specific combination than is the protein in solution for this compound also, and that the effect is not due to a difference in the type of protein, because in some experiments only a fraction of the antibody was precipitated and there was still preferential

TABLE IV

NON-SPECIFIC ADSORPTION OF COMPOUND RESORCINOL-$R_3'$

To $10^{-4}$ g. pneumococcus polysaccharide type I in 1 ml. saline there was added 1 ml. of saline containing 4.5 mg. of commercial anti-polysaccharide type I. The precipitation was done in the presence of 1 ml. of saline containing compound resorcinol-$R_3'$ in tubes 1–4, and the supernate of the precipitate was replaced by 3 ml. of saline containing compound resorcinol-$R_3'$ in tubes 5–8. Tubes 9 and 10 were controls, containing no polysaccharide. Final *p*H 8.0, no buffer, duplicate analyses

| | Resorcinol-$R_3'$ added moles × $10^9$ | Precipitated protein moles × $10^9$ | Mole ratio $\frac{R_3'}{\text{protein in precipitate}}$ | % of total resorcinol-$R_3'$ in precipitate |
|---|---|---|---|---|
| 1 | 400 | 3.7 | 12.0 | 11 |
| 2 | 85 | 3.3 | 8.8 | 34 |
| 3 | 22 | 2.9 | 4.8 | 63 |

| 6 | 85 | 2.6 | 9.5 | 29 |
| 7 | 22 | 2.8 | 5.7 | 72 |
| 8 | 7 | 2.6 | 2.1 | 78 |
| 9 | 85 | 0.3 | 30 | 11 |
| 10 | 22 | .2 | 14 | 14 |

A Referee suggests that it would be preferable to carry out this experiment with antibody prepared by more gentle methods because the Lederle product may have an altered affinity for haptens due to its method of preparation.

combination with the precipitate. Compound XXX was not bound as strongly as was resorcinol-$R'_3$. R'X' was bound to about the same extent as XXX.

These observations can perhaps best be explained by considering the precipitate to have a few locations where a dye-polymer molecule can attach itself very firmly, perhaps by combining with several protein molecules. Such sites would be absent in the protein in solution. Since only a few polymer molecules could go into these locations, the fraction of dye combined with the precipitate would be large when there was little dye in the system, and would become smaller when the dye was increased and the stronger locations were filled. Then the protein in the solution would compete successfully with the smaller amount of precipitate.

**Hapten Inhibition.**—Varying amounts of the strong hapten *p*-(*p*-hydroxybenzeneazo)-benzenearsonic acid were added to an optimal mixture of purified antibody and antigen XXX at *p*H 7.6 before precipitation had begun. This hapten, in 20-fold excess over the added antigen, was able to inhibit the precipitation almost completely, and gave a heterogeneity index[17] of $\sigma = 1.5$. A 50-fold excess of the weaker hapten benzenearsonic acid had almost no effect on the amount of precipitate obtained with purified antibody and resorcinol-$R'_3$. These results on hapten inhibition with purified antibody are closely similar to those obtained with antiserum.

## Discussion of Results

In our earlier work on the molecular ratio of antigen to antibody in the precipitate formed by dye antigens with hapten-homologous antiserum, values of about 1.2 for this ratio were found. These values indicate a valence of approximately 2 (2.4) for antibody if the dyes are assumed to be bivalent. The equality of the values found for trihaptenic and tetrahaptenic dyes with those for dihaptenic dyes was explained as resulting from steric hindrance of the large antibody molecules, which prevents more than two of the haptenic groups of the small dye molecules from being effective. A constant antigen-antibody ratio was obtained (to within about ±20%) even when the amount of dye added to a constant amount of antiserum was varied over a wide range, from antigen excess to antigen deficiency, and when the *p*H was varied from 7.6 to 9.2. Essentially the same results were obtained for seven dyes. The new results, obtained with different dyes and with purified antibody, are much different. A strong dependence of the ratio on the amount of antigen is observed, and the ratios are much higher than those found before, except in the antibody-excess region. The results found in the present investigation are of the nature to be expected in case that the dyes form aggregates that are taken up by the precipitate through non-specific adsorption. The amount of non-specific adsorption of resorcinol-$R'_3$ shown in Table IV is enough to account for the high values of the molecular ratio of dye and antibody reported in Tables I, II and III.

The limiting values of the molecular ratio extrapolated to zero dye concentration are approximately 1.0 for antigen XXX and somewhat larger for resorcinol-$R'_3$.

We believe that the difference between the results obtained with purified antibody and those obtained earlier with antiserum is due to the non-specific combination of the dye molecules with serum albumin or other constituents of serum not present in the purified antiserum,[7,8] and that in the presence of serum this effect causes the concentration of uncombined dye molecules to be so small as to keep the amount of aggregation down to a low value. It seems likely that the high values for the amount of dye in the precipitates formed with purified antibody are due largely to the inclusion of the aggregates in the precipitate through non-specific adsorption, and possibly also to some extent to their incorporation in the framework as effective precipitating antigens.

The results obtained with the antigen R'X' indicate that dimers or larger aggregates of this molecule are able to form a precipitate with anti-R serum, the precipitation being inhibited by the presence of serum. In our earlier investigation[10] we observed that a small amount of precipitate was formed by R'X' with some pools of anti-R serum; it is likely that these precipitates were due, not to cross-reaction, but to the presence of aggregates, these pools of antiserum perhaps containing smaller amounts of the complexing material than are usually present.

The conclusion that may be reached from the experimental results obtained is that the earlier work, carried out with serum, is presumably reliable, despite the tendency of the dyes to aggregate, because this tendency was counteracted by the presence of complexing materials in the serum. Moreover, the limiting molecular ratio found by extrapolation to antibody excess of the results obtained in the present investigation, with purified antibody, supports the molecular ratio of about 1 given by the earlier work. It would, however, be desirable, in order to carry conviction, for additional experiments to be made, with use of non-aggregating polyhaptenic precipitating antigens.

In the earlier studies it was found that non-aggregating polyhaptenic compounds (amides, rather than azo dyes) form precipitates with antisera, whereas the monohaptenic substances do not; however, analyses of the precipitates were not made because of the difficulties of determining the amount of the colorless precipitating antigens.

It may be pointed out that the quantitative hapten inhibition experiments reported in earlier

(17) L. Pauling, D. Pressman, and A. L. Grossberg, THIS JOURNAL, 66, 784 (1944).

papers of this series are not made unreliable by the phenomenon of aggregation of the precipitating antigen, for two reasons: first, the experiments were carried out in the presence of serum, which presumably inhibited the aggregation of the antigens; and second, the experiments all involve the comparison of the concentration of hapten required for a standard amount of inhibition (50%) with the concentration of a standard hapten producing the same effect, and this concentration ratio of the haptens, which do not themselves form aggregates, would be expected to be the same whether the test substance (the precipitating antigen) was aggregated or not.

The investigation reported in this paper was carried out with the aid of a grant from The Rockefeller Foundation. We wish to thank Professors Dan H. Campbell and Verner Schomaker, and Drs. David Pressman, Frank Lanni, J. E. Cushing, Jr., George Feigen and Stanley Swingle for advice in connection with the work and for providing some of the materials used. Mr. Dan Rice carried out many of the protein analyses.

## Summary

Experiments have been carried out on the precipitation under various conditions of specifically purified anti-azobenzenearsonic acid antibodies by three azo dyes, serving as precipitating antigens. The non-specific combination of the dyes with pneumococcus polysaccharide: antipolysaccharide precipitates has also been investigated.

In solution these dyes exist as monomeric molecules and as aggregates. The molecular ratio of dye to antibody in the precipitate was found in general to be much larger than in earlier experiments involving antiserum, and to depend greatly upon conditions of the precipitation, whereas the earlier ratio (approximately 1.2) was essentially independent of these conditions. The dye is also carried down in non-specific serological precipitates (pneumococcus polysaccharide:antipolysaccharide antibody), apparently through non-specific adsorption or entrapment in the precipitate. The large molecular ratio in the precipitate formed with the homologous antibody is probably due mainly to the non-specific adsorption of dye aggregates. It is suggested that the results obtained with antiserum, which seem not to be affected by aggregation of the dye molecules, are to be explained as resulting from the combination of the dye molecules with constituents of serum, mainly albumin, which are not present in the purified antibody, this combination keeping the concentration of free antibody low, and preventing the formation of appreciable amounts of the aggregates.

# The Degree of Association of Some Simple Antigens

BY ARTHUR B. PARDEE AND STANLEY M. SWINGLE

In the preceding paper, which considers the effect of serum on the precipitin reaction between certain simple polyhaptenic precipitating antigens and antibodies, it was assumed that the antigens could be associated into aggregates. This paper presents measurements on some simple antigens which, because of their size and color, may be expected to be associated to a measurable extent.

In their treatment of the precipitin reaction between antisera and simple polyhaptenic substances (hereafter called simple antigens), Pauling and coworkers were aware of the possibility that their simple antigens might be associated, but did not consider association important and neglected it. This was done because some of the simple antigens used by them were colorless[1] and hence almost certainly not associated and because a simple substance containing one haptenic group against one antiserum and another against another antiserum did not precipitate against either antiserum separately, as it should if it were polymerized, but did precipitate with the mixed antisera.[2]

Landsteiner[3] was the first to suggest that the precipitating power of simple antigens might be connected with their association. He observed that some of the simple antigens have structures similar to those of associating dyes.[4,5] Many dyes are associated in solution; the forces involved have been explained on the basis of the color-producing resonance in the conjugated structure.

Boyd and Behnke[6] published a note stating that one large and highly colored simple antigen was polymerized 11-fold in a saline solution.

## Experimental Methods

**Simple Antigens.**—All the synthetic antigens used in the present work, and their preparation, have been described in references[1,2,7,8]; the symbols used in those papers will be used here. R is *p*-azobenzenearsonic acid. R′ is *p*-(*p*-azobenzene)-azobenzenearsonic acid, and X′ is *p*-(*p*-azobenzene)-azobenzoic acid.

Chromotropic acid is 1,8-dihydroxynaphthalene-3,6-disulfonic acid and H-acid is 1-amino-8-napthol-3,6-disulfonic acid. The polyhaptenic substances used are VI, resorcinol-$R_3$; XI, phloroglucinol-$R'_3$; XII, 4,4′-bis-(azo-2,4-dihydroxy)-3,5-di-R′-biphenyl; XXXV, chromotropic acid-$X'_2$; XXX, chromotropic acid-$R'_2$; and R′-X′, chromotropic acid-R′X′. Other antigens are referred to by name.

**Free Diffusion.**—Aqueous solutions of the antigens in 0.9% sodium chloride buffered at *p*H 8.0 to 8.5 with 0.1 *M* veronal (unless otherwise noted) were studied at 1.3° in a Lamm-type[9] diffusion cell made of bakelite (some of the antigens precipitate with traces of metal ions). A light-absorption method similar to that of Tiselius and Gross[10] was used, except that a reference cell with five solutions of concentration 1/8, 1/6, 1/4, 1/2 and 3/4, the initial concentration was photographed simultaneously with the diffusion cell so that the positions of the corresponding concentrations in the diffusing column could be determined by a direct comparison of the photographic densities, corrected for a slight non-uniformity of illumination. Photographs were taken periodically until the diffusion was interrupted. The diffusion coefficient was calculated at each concentration by the formula $D = \{\Delta X\}^2 f(c_0/c)/t$, in which $\Delta X$ is the distance between the given concentration $c$ and the 1/2 concentration after time $t$, and $f(c_0/c)$ is a function whose value may be obtained from tables.[11] Values of $\{\Delta X\}^2/t$ were obtained from the slopes of plots of $\{\Delta X\}^2$ *vs.* $t$. These plots generally gave a straight line for each concentration. The position of the 1/2 concentration generally moved toward the high concentration end of the cell, indicating that $D$ decreases with increasing concentration.[12,13] A numerical average of the value of $D$ obtained at each concentration is reported in Table I.

**Porous Diaphragm Diffusion.**—For the measurements of diffusion through a porous diaphragm,[14] five cells of the usual simple design with Jena G3 or G4 disks were used with a volume of 25 ml. on each side of the disk. The cells were used interchangeably after an intercomparison with the antigen H acid-azo-benzene gave an average deviation of 4% for 27 measurements, with no significant differences among the five cells. The antigens were dissolved in a solution containing 0.9% NaCl + 0.1 *M* veronal buffer at *p*H 8.0 and were allowed to diffuse for two weeks, during which time samples were periodically withdrawn for analysis. Convective stirring was brought about by making the salt concentration in the bottom layer slightly lower than that in the top layer. Analyses were colorimetric and accurate to about 2%. Values of the diffusion coefficient reported in Table I are for determinations using any one of the cells and the equation

$$D = \frac{K}{t} \log \left( \frac{c_1 + c_2}{c_2 - c_1} \right)$$

in which $c_1$ is the final concentration in the dilute solution, $c_2$ is the final concentration in the more concentrated solution, and $K$ is the cell constant obtained by calibration with 0.15 *M* KCl ($D = 9.6 \times 10^{-6}$ cm.²/sec. at 1.3°).

TABLE I

DEGREE OF ASSOCIATION FROM DIFFUSION DATA

| | Concn.[a] × 10⁵ | Method[e] | $D$, cm.²/sec. × 10⁶ | $n^i$ |
|---|---|---|---|---|
| H-Acid-azo-benzene | 10 | *f* | 2.13 | 1.3 |
| | 10 | *f* | 2.36 | 1.0 |
| | 19 | *d* | 1.83 ± 0.07 | 2.0 |
| H-Acid-azo-benzoic acid | 80 | *d* | 2.08 ± 0.05 | 1.3 |
| XXX | 5 | *f* | 0.77 | 10 |
| | 5 | *f* | 0.82 | 7 |
| | 50 | *d* | 1.14 ± 0.06 | 3 |
| XXXV | 6.5[b] | *f* | 1.07 | 4 |
| | 6.5[c] | *f* | 1.20 | 3 |
| | 6.5[b] | *d* | 1.25 ± 0.02 | 2 |
| | 6.5[c] | *d* | 0.97 ± 0.03 | 6 |
| | 11[g] | *d* | 1.44 ± 0.15 | 0.8 |
| R′X′ | 15 | *d* | 0.95 ± 0.08 | 6 |
| | 15 | *d*[h] | 2.23 ± 0.16 | 7 |

| XII | 9.5 | *f* | 0.22 | 300[j] |
| | 9.5 | *f* | 0.20 | 400[j] |
| | 9.5 | *d* | Adsorbed by disk | |
| XI | 16 | *d* | Adsorbed by disk | |
| Phenol-phthalein | Satd. acid solution | *d* | 2.5 ± 0.60 | 1 |
| VI | 45 | *d* | 1.12 ± 0.05 | 4 |

[a] Concentrations are moles per liter in 0.9% saline + 0.1 *M* veronal buffer at *p*H 8.0 unless otherwise noted. [b] *p*H 10.0. [c] *p*H 7.5. [e] Diffusion by *f* free diffusion, or *d* porous diaphragm, all at 1.3° except as noted. [g] In ethanol. [h] At 35°. [i] The degree of association calculated from the Stokes–Einstein equation with an estimated shape correction. [j] Not corrected for shape.

**Osmotic Pressure.**—The osmotic pressures reported in Table II for two of the larger antigens were obtained with a simple osmometer consisting of a 15-ml. Cellophane sack tied to a 1-mm. capillary. The reported capillary rise is the value given by extrapolation to infinite time of a plot of rise *vs.* $1/t$. The other antigens leaked through the cellophane too rapidly for successful measurements, and less permeable membranes were too slow to equilibrate.

**Partition Coefficient.**—H-acid-azobenzene was found to have a measurable partition coefficient between water and *n*-butanol, the results of which indicate that this substance is associated to the same extent in both solvents, and is hence probably monomeric. On a plot of concentration in water *vs.* concentration in *n*-butanol, the experimental points fit the least squares line through the origin with an average deviation of ±4%, which is much better agreement than would be possible with even 25% dimerization in one solvent.

## Discussion

It is probable that the degree of association is dependent on the concentration, and that the values of diffusion coefficient reported here, being calculated in a simple manner, represent the coefficient at some intermediate concentration in the cell. The experimental data are not sufficiently complete or accurate to permit us to use a more refined treatment.[12,13] Values of $D$ from diffusion measurements at 1/8, 1/6 and 1/4 $c_0$ showed no consistent trend with concentration, but $D$ from 3/4 $c_0$ was generally 60 to 80% of the other three values.

An assumption of spherical shape is made in calculating a particle radius $r$ from the Stokes–Einstein equation,[15] $D = RT/6\pi Nr\eta$ in which $\eta$ is the viscosity of the solvent. Actually the particles, particularly the monomeric ones, must be quite elongated. Somewhat better particle volumes were calculated by multiplying the diffusion coefficient by a correction factor[16] to account for the higher frictional resistance. This correction is based on the assumption that the particles resemble ellipsoids of revolution of dimensions estimated from their known structure and the assumption that they polymerize side by side. Using for the partial specific volume the value 0.64 ml./g. as measured for compound XXX, in agreement with Robinson[4] for a different dye, values of the degree of association $n$ were calculated, as reported in Table I. The corrected values of $n$ are smaller than uncorrected values by factors varying from 1 to 0.4. The error in $n$ is seen to be more than three times the error in $D$, which may be large in itself, so that tests of the validity of the results are desirable. Several are available.

TABLE II

THE DEGREE OF ASSOCIATION FROM OSMOTIC PRESSURE DATA

| | Concn. × $10^5$ | Temp., °C. | Capillary rise, cm. | $n$ |
|---|---|---|---|---|
| XXX | 7 | 37.5 | 1.0 | 2 |
| | 7 | 37.5 | 1.2 | 2 |
| XII | 9.5 | 37.5 | 0.55 | 4 |
| | 9.5 | 37.5 | 0.7 | 5 |
| XI | 16 | 25 | Adsorbed by osmometer | |

For H-acid-azobenzene the values $n = 1$ and 1.3 from free diffusion and $n = 2$ from 27 porous diaphragm measurements may be compared with the partition experiments which showed this substance probably monomeric. Diffusion gave $n = 1$ for phenolphthalein, which is presumably monomeric in the colorless form, in which it lacks the resonating electrons necessary for association. Similarly, compounds XXXV and R′X′ in ethanol solution are probably monomeric, in agreement with the diffusion results, $n = 0.8$.

The osmotic pressure data are in poor agreement with the diffusion data, but nevertheless indicate some degree of association. Attempts to gain useful information by studying the changes in absorption spectrum with concentration showed that for compounds VI, VII, XI, XXX and XXXV there is no change, as is in general true for azo dyes,[17] except that in the presence of borate ions the spectra of XXX and XXXV change somewhat, an observation which has not been explained.

The measurement of Boyd and Behnke[6] ($n = 11$ for compound XI) seems reasonable. This compound was adsorbed by both the porous disk and the osmosis membrane, so that we were unable to obtain data for it.

This investigation was carried out with the aid of a grant from the Rockefeller Foundation. We wish to thank Dr. David Pressman for furnishing the synthetic antigens.

## Summary

We have carried out measurements on the association of a number of polyhaptenic simple substances. Some of these colored simple antigens are probably associated several-fold in saline solution. Diffusion measurements seem to give an approximate measure of the degree of association, at least for those compounds which are not too highly associated.

# The Structure and Chemistry of Actidione, an Antibiotic from Streptomyces Griseus[1]

BY EDMUND C. KORNFELD, REUBEN G. JONES AND THOMAS V. PARKE

Recently Ford and Leach[2a,b] of the Upjohn Research Laboratories reported the isolation from *Streptomyces griseus* of a new antibiotic substance which they named "Actidione."[3] This interesting material is highly active against most yeasts but is relatively inactive against other microörganisms. Subsequently, Leighty and Fortune of these Laboratories also isolated Actidione from Streptomycin residues, and we undertook a study designed to elucidate the chemical structure of the new antibiotic. A preliminary communication[4] regarding this work has been published, in which structure I was proposed. It is the purpose of the present paper to give the evidence upon which this formulation is based.

The empirical formula of Actidione as originally determined in these laboratories and also ascertained by the Upjohn workers[2a] is $C_{15}H_{23}NO_4$. Nitrogen analyses by either the Dumas or Kjeldahl methods gave concordant results. It was

(1) Presented before the Division of Organic Chemistry of the American Chemical Society at the Washington, D. C., meeting, 1948.

(2) (a) Ford and Leach, THIS JOURNAL, **70**, 1223 (1948). (b) Leach, Ford and Whiffen, *ibid.*, **69**, 474 (1947).

(3) The compound was given this name because it was originally believed to be a *di*ketone. However, the present work has shown the compound to be a *mono*ketone.

(4) Kornfeld and Jones, *Science*, **108**, 437 (1948).

then found that all of the nitrogen in Actidione was liberated as ammonia by simply boiling the compound with sodium hydroxide solution. This fact suggested the presence of an amide or imide grouping in Actidione. A determination of terminal methyl groups indicated that the molecule contained *two* such linkages.

Evidence for functional groups in Actidione was next sought, and it was found that the compound was easily converted to a *p*-nitrobenzoate and an acetate ($C_{17}H_{25}NO_5$).[2] Actidione also gave a qualitative test for primary or secondary alcoholic hydroxyl by the method of Fearon and Mitchell.[5] This test gives negative results with *tertiary* alcohols. The compound formed a monoxime[2] and a semicarbazone.[2] When subjected to catalytic reduction only *one* mole of hydrogen was absorbed, to yield dihydroactidione (II). The latter product was shown to be a *diol* by conversion to a diacetate ($C_{19}H_{29}NO_6$). However, it was not attacked by periodic acid, and, therefore, dihydroactidione was considered not to be a 1,2-diol. Actidione acetate, mentioned above, also underwent catalytic reduction to yield a dihydro derivative ($C_{17}H_{27}NO_5$). The dihydro compounds showed only end absorption in the ultraviolet, thus indicating that during the hydrogenation a carbonyl was reduced to a hydroxyl group.

Confirmation of the functional groups was found in further physical studies. The ultraviolet spectrum of Actidione (Fig. 1) showed a single maximum at 287 m$\mu$ ($\epsilon$ = 36.7), which is characteristic of a simple ketone group. The infrared spectrum (Fig. 3) contained bands at wave lengths which may be assigned to carbonyl (5.90 $\mu$) hydroxyl (2.80 $\mu$), C-methyl (7.28 $\mu$), >NH (3.00 $\mu$), aliphatic C–H (3.42 $\mu$) and others. A semiquantitative

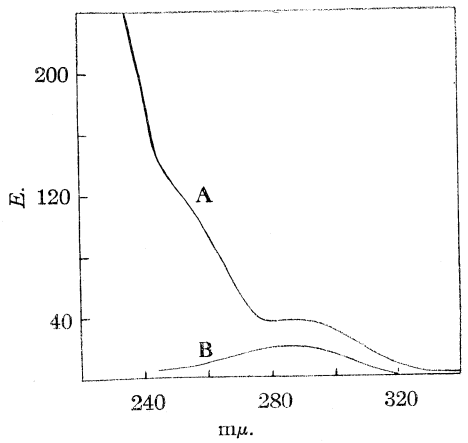

Fig. 1.—Ultraviolet absorption spectra of Actidione (A) and $C_8H_{14}O$ ketone (B) from Actidione.

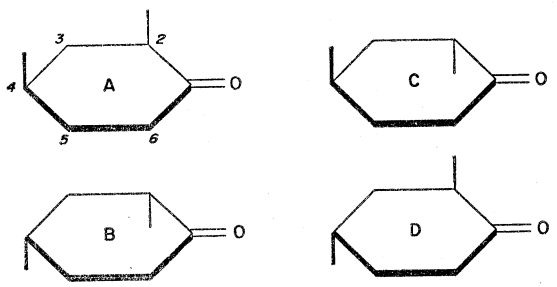
study of this spectrum in comparison with that of other compounds indicated that Actidione contained *three* carbonyl groups. Rapid electrometric titration in water showed no titratable group from *p*H 2 to *p*H 10. Beginning at about *p*H 10, however, a weakly acidic group was titrated with a mid-point or $pK'_\alpha$ of 11.2. Discussion of this titration data is presented later. Thus, in summary, it was indicated that Actidione had two terminal methyl groups, one hydroxyl group (primary or secondary), one ketone group and an amide or imide linkage.



Degradative studies were next undertaken to determine whether identifiable fragments of the molecule could be isolated. Ford, Leach and Whiffen[2] had already discovered that Actidione was extremely labile under basic conditions. We observed that exposure of the molecule to even one-hundredth normal alkali at room temperature resulted in rapid inactivation and cleavage to form, among other things, a fragrant, volatile liquid. This liquid was isolated with facility either by ether extraction of the alkaline degradation mixture or by steam distillation. It was found to be dextrorotatory and to have the empirical formula $C_8H_{14}O$ (III). The ultraviolet absorption spectrum (Fig. 1) had a single maximum at 284 mμ ($\epsilon$ = 20.2) characteristic of a carbonyl group. The presence of a carbonyl group was confirmed by the preparation of an oxime, semicarbazone, 2,4-dinitrophenylhydrazone, *p*-nitrophenylhydrazone and a bisulfite addition product. Upon catalytic reduction the compound absorbed *one* mole of hydrogen. Tests for an aldehyde group were negative, so the fragrant liquid was considered to be a *cyclic ketone*. A literature search revealed that there were at least three known cyclic ketones of the formula $C_8H_{14}O$ with physical properties hardly distinguishable from the natural degradation product (see Table I). Consequently, these three isomeric ketones were synthesized for comparison. The melting points of the semicarbazones were of little help in the identification be-

TABLE I[a]

| Ketone | B. p., °C. | $n_D$ | M. p., °C., of semicarbazone |
|---|---|---|---|
| $C_8H_{14}O$ from Actidione | 175–176 | 1.4435 | 212–214 |
| Isopropylcyclopentanone[15] | 173–174 | 1.4395 | 201–202 |
| 2,4-Dimethylcyclohexanone[17] | 175–176 | 1.4430 | 200–202 |
| 2,5-Dimethylcyclohexanone[19] | 174–176 | 1.4406 | 155–157 |

[a] Experimental values as determined in this Laboratory.

cause the natural product was optically active while the synthetic ketones were racemic. However, a comparison of the infrared spectra of the four compounds (Fig. 2) showed in a very convincing manner that the natural ketone was an optical isomer of 2,4-dimethylcyclohexanone (III). It may be noted that the spectra of the natural and synthetic 2,4-dimethylcyclohexanones are identical in every way, while marked differences are found in the spectra of the isomeric ketones. Additional confirmation of the identity of the natural degradation product was obtained by resolution of the synthetic *dl*-2,4-dimethylcyclohexanone. This was accomplished by fractional crystallization of the *l*-menthydrazones obtained from the *dl*-ketone. The least soluble *l*-menthydrazone was found to be identical with the *l*-menthydrazone of the natural dextrorotatory ketone. This identity was established by melting point, mixed melting point, optical rotation, and finally by comparison of the X-ray diffraction patterns (see Experimental). Of the four possible optical isomers of 2,4-dimethylcyclohexanone (A to D), A and B would have identical

infrared spectra as would also C and D.[6] The spectra of the *cis*- and *trans*-forms, however, would differ. Obviously, the natural and synthetic ketones must *both* be either all *cis* or all *trans* depending on which is the more stable, or each may consist of the same equilibrium proportion of *cis* and *trans* forms.

With the identification of the $C_8$ ketone from Actidione there remained yet seven carbon atoms to be accounted for. At this point certain evidence on hand suggested that Actidione might be a glutarimide derivative. In the first place, the infrared spectrum of Actidione, mentioned above, indicated the presence of *three* carbonyl groups. One had been identified as a simple ketonic linkage, so there remained *two* carbonyl groups which *could*

(6) Thompson and Sutherland, *Trans. Faraday Soc.*, **41**, 197 (1945).

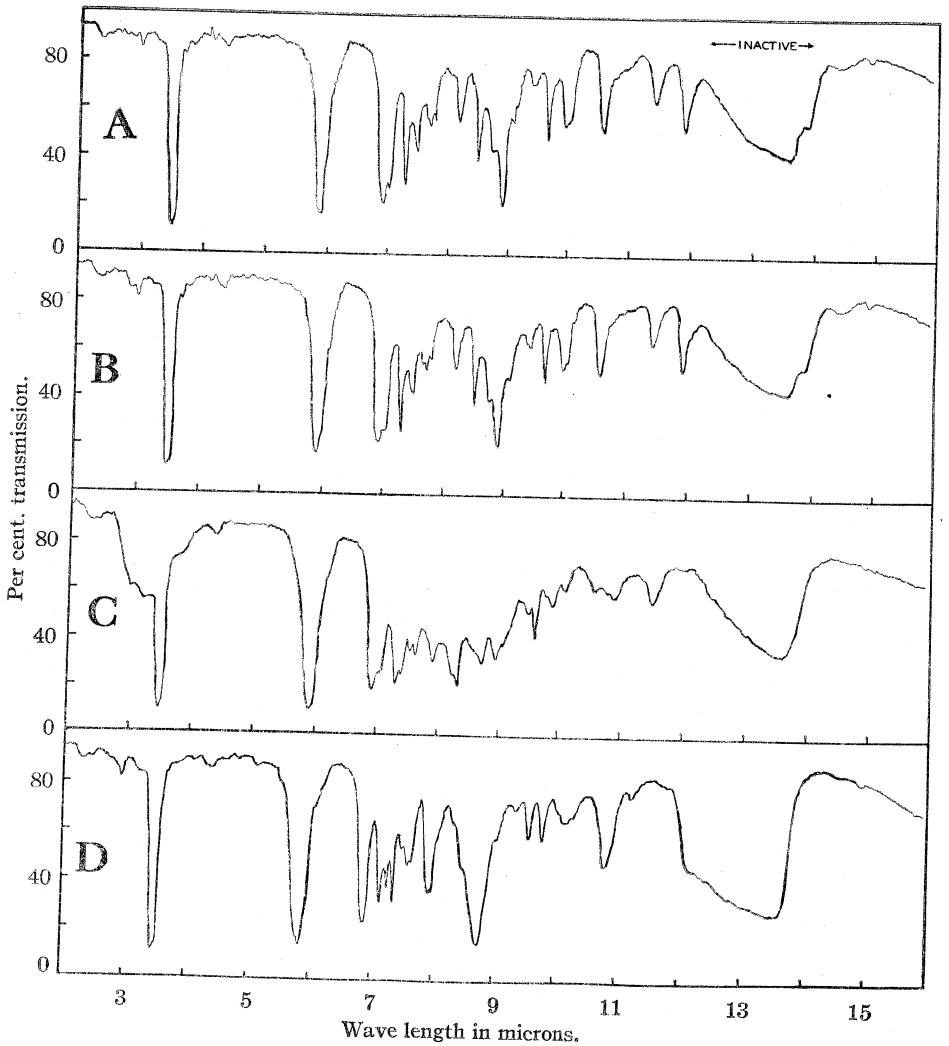


Fig. 2.—Infrared absorption spectra of $C_8H_{14}O$ from Actidione (A), 2,4-dimethylcyclohexanone (B), 2,5-dimethylcyclohexanone (C) and $\alpha$-isopropylcyclopentanone (D). Concentration, 20% in carbon tetrachloride; cell length, 0.132 mm. Inactive region is due to solvent absorption.

be accounted for by a cyclic imide structure. Furthermore, the weakly acidic character of Actidione ($pK'_\alpha$ 11.2) as revealed in the electrometric titration was consistent with a cyclic imide formulation. To confirm this point an electrometric titration of glutarimide was carried out, and it was found that the acidic >NH group had a $pK'_\alpha$ of 11.2, identical with that of Actidione. Succinimide, on the other hand, was found to have a $pK'_\alpha$ of 9.35. Having thus obtained evidence for the presence of a glutarimide ring system in Actidione it was of interest to determine the point of attachment of that ring to the other part of the Actidione molecule. Two model compounds, $\alpha$-ethylglutarimide and $\beta$-ethylglutarimide, were synthesized, and their infrared spectra were compared with that of Actidione (Fig. 3). Both Actidione and $\beta$-ethylglutarimide had bands at 8.75 $\mu$, while this band was completely missing in the spectrum of the $\alpha$-ethyl isomer. This was tentatively accepted as evidence that Actidione was a $\beta$-substituted glutarimide.

Substantial *chemical* evidence for a $\beta$-substituted glutarimide structure was sought next. Proof of the presence of a cyclic imide grouping was furnished when dihydroactidione (II) was allowed to react with diazomethane to form an N-methyl derivative (IV). This is a characteristic reaction of glutarimide.[7] That the methyl group was attached to nitrogen was demonstrated by alkaline degradation of the N-methyldihydroactidione to yield methylamine. When Actidione was degraded in alkaline solution and the ammonia and 2,4-dimethylcyclohexanone so formed were removed, the residue yielded a seven-carbon acidic fragment, presumably propionaldehyde-2,2-diacetic acid. This product was not obtained in pure condition but on oxidation it afforded

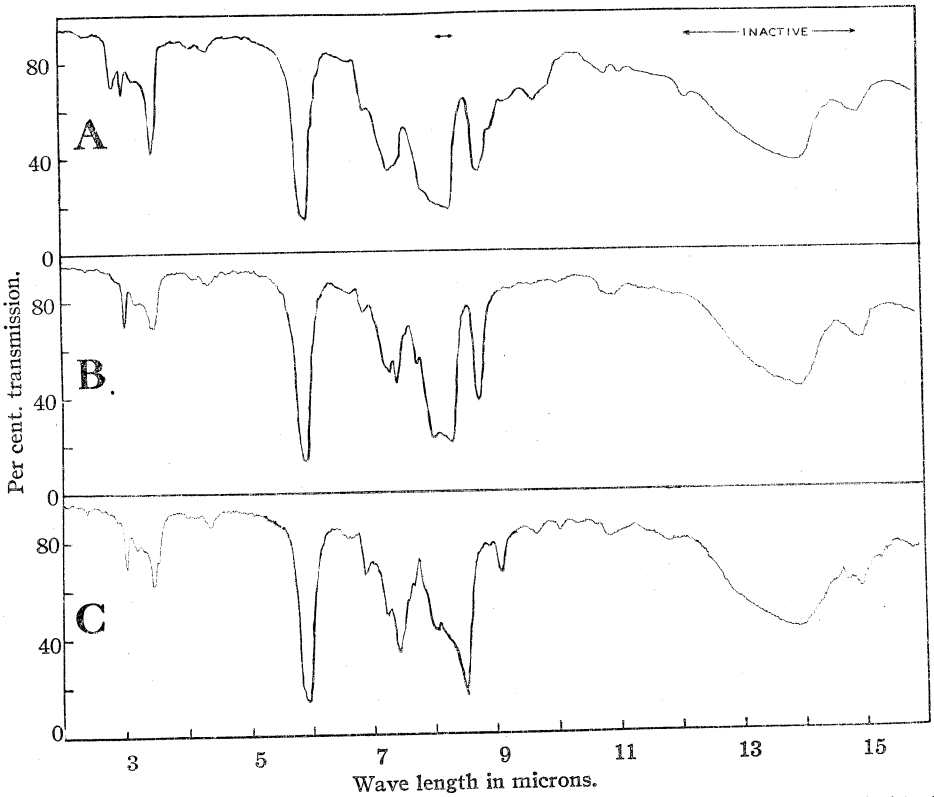

Fig. 3.—Infrared absorption spectra of Actidione (A), β-ethylglutarimide (B) and α-ethylglutarimide (C). Concentrations, 6.3%, 2.8% and 3.3%, respectively, in chloroform; cell length 0.132 mm. Inactive regions are due to solvent absorption.

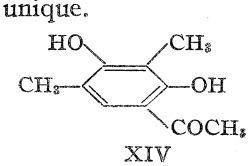
methanetriacetic acid (V), which was identified by a mixed melting point determination with an authentic sample, and by conversion to the tri-*p*-bromophenacyl ester. In another experiment Actidione was first oxidized by means of chromic acid to the diketone, dehydroactidione (VI), which was characterized as a *1,3* diketone by its ultraviolet absorption spectrum ($\lambda_{max.}$ 292 mμ; ε, 9910)[8] and by conversion to a copper complex. Dehydroactidione was then degraded in alkaline solution to form 2,4-dimethylcyclohexanone, ammonia, and methanetriacetic acid (V). This hydrolysis of the 1,3-diketone took place almost exclusively by fission of the carbon–carbon bond *exo*cyclic to the cyclohexanone ring.

On the basis of the evidence presented up to this point then, structure I may be proposed for Actidione. The hydrolytic cleavage of the antibiotic may be looked upon as a reverse aldol reaction accompanied by opening of the glutarimide ring. Additional confirmation in support of structure I was obtained by a number of further transformations and reactions.

As was mentioned above the propionaldehyde-2,2-diacetic acid formed on alkaline degradation of Actidione was not obtained analytically pure. A derivative of this aldehyde–diacid was obtained, however, when Actidione was allowed to react with benzylamine. Benzylamine caused an opening of the glutarimide ring accompanied by a reverse aldol fission of the molecule. This was followed by condensation of the resulting aldehyde with benzylamine. The end-product of this series of reactions was the derivative VII.

Thus far it had not been established whether the point of attachment of the seven-carbon section of the Actidione molecule was at the 2 or 6 position on the 2,4-dimethylcyclohexanone ring (III). Evidence proving linkage through the 6 position was obtained by dehydration of Actidione in the presence of phosphorus pentoxide to form anhydroactidione (VIII). This product, which had a typical α,β unsaturated ketone absorption spectra in the ultraviolet ($\lambda_{max.}$, 241 mμ; ε, 8250)[9] could not result if attachment had been at position 2. Catalytic reduction of anhydroactidione gave tetrahydroanhydroactidione (IX).



Several interesting transformations in the dihydroactidione (II) series were also carried out. Dihydroactidione was found to be stable to hydrolytic carbon–carbon cleavage because of the absence of the aldol configuration. Alkaline hydrolysis of this compound merely opened the glutarimide ring with elimination of ammonia.

(8) 2-Acetylcyclohexanone has $\lambda_{max.}$ = 290 mμ (ε = 8750).

(9) Woodward's rule (THIS JOURNAL, 64, 76 (1942)) predicts $\lambda_{max.}$ = 240 mμ.

On acidification of the hydrolysis mixture an acidic product, dihydroactidione acid, was isolated, which on the basis of its properties and reactions was formulated as the lactone acid (X). This acid formed a monomethyl ester (XI) on treatment with diazomethane, and the ester was converted by means of alcoholic ammonia to the diamide (XII). This diamide was also produced directly by the reaction of dihydroactidione (II) with ammonia, and it was reconverted by alkaline hydrolysis to dihydroactidione acid (X). When dihydroactidione acid (X) was treated with ammonia, the lactone ring was again opened to give the ammonium salt of a monoamide-acid which was isolated as the silver salt (XIII). Reaction of the lactone-acid (X) with two equivalents of alkali and two moles of *p*-bromophenacyl bromide gave a *di-p*-bromophenacyl ester. All of these transformations are adequately interpreted on the basis of the formulations presented.

Finally, it was of interest to discover if natural products similar to Actidione had been previously isolated. The literature reveals a mould metabolic product which has a skeletal arrangement resembling that of a portion of Actidione. Clavatol, a product isolated from *Aspergillus clavatus* by Hassall and Todd,[10] has the structure XIV. The glutarimide ring in Actidione, however, seems to be unique.

XIV

**Acknowledgments.**—The authors express their appreciation to Drs. W. W. Davis and R. B. Woodward for helpful discussions. Dr. Woodward was the first to suggest the possibility of a cyclic imide formula. We also thank Mr. R. A. Kern for some of the ultraviolet work, Mr. G. Vaughan for the X-ray diffraction data and Mr. W. L. Brown and Mr. H. L. Hunter for the microanalyses. We are especially indebted to Drs. J. H. Ford and B. E. Leach of the Upjohn Laboratories for their continued interest and for generously supplying part of the Actidione used in this work.

## Experimental[11]

**Purification of Actidione (I).**—Actidione was purified for analysis by repeated recrystallization from water containing a little methanol, from which it separated slowly, m. p. 119.5–121°, $[\alpha]^{29}D$ −3.38° (*c* = 9.47 in ethanol).

*Anal.* Calcd. for $C_{15}H_{23}NO_4$: C, 64.03; H, 8.24; N, 4.98. Found: C, 64.37; H, 8.55; N, 5.08. Nitrogen by Kjeldahl method, found: 5.11. Nitrogen by Kjeldahl method omitting acid digestion, found: 4.84. C-methyl determination,[12] found: 1.32. (Synthetic 2,4-dimethylcyclohexanone gave a value of 1.28).

**Isolation of Ammonia from Alkaline Degradation of Actidione.**—Actidione (5 g.) was dissolved in 100 ml. by 12 *N* sodium hydroxide solution. The solution was refluxed for one-half hour, and the evolved gas was absorbed in 25 ml. of ice-water. To this aqueous solution was added 1 g. of phenyl isothiocyanate, and the mixture was shaken well. Long prismatic crystals of phenylthiourea had separated from the solution after standing overnight, m. p. 157–158°. A mixed melting point with an authentic sample of phenylthiourea was also 157–158°.

**Actidione-*p*-nitrobenzoate.**—Actidione (1 g.) was dissolved in 3 ml. of dry pyridine, and 0.66 g. of *p*-nitrobenzoyl chloride was added. The mixture became warm and partly solidified. It was heated on a steam-bath until all solids were dissolved and was then cooled. Ice-water was added, and the aqueous phase was decanted. The residue was rubbed with a little ethanol, and the product was filtered, washed with ethanol, and dried; yield, 0.75 g. A sample was purified for analysis by recrystallization from aqueous dioxane, m. p. 215–220° (dec.).

*Anal.* Calcd. for $C_{22}H_{26}N_2O_7$: C, 61.38; H, 6.09; N, 6.51. Found: C, 61.13; H, 6.24; N, 6.53.

**Actidione Acetate.**—This was prepared by a method similar to that of Ford and Leach[2a]; m. p. after recrystallization from dilute ethanol, 150–152°.

*Anal.* Calcd. for $C_{17}H_{25}NO_5$: C, 63.14; H, 7.79; N, 4.33. Found: C, 63.56; H, 7.67; N, 4.50; C-methyl, 2.17.

**Reduction of Actidione Acetate.**—A small sample of the acetate was reduced catalytically in glacial acetic acid using platinum oxide as catalyst. Absorption of hydrogen ceased after 1.03 moles had been taken up. The catalyst was filtered, and the solvent was distilled *in vacuo*. The residue was recrystallized several times from dilute ethanol. Dihydroactidionemonoacetate was obtained as shiny needles, m. p. 169–171°.

*Anal.* Calcd. for $C_{17}H_{27}NO_5$: C, 62.75; H, 8.37; N, 4.31. Found: C, 63.10; H, 8.32; N, 4.26.

**Actidione Semicarbazone.**—This derivative was prepared by essentially the same method used by Ford and Leach.[2a] It was obtained as a hydrate, m. p. 187–188°.

*Anal.* Calcd. for $C_{16}H_{26}N_4O_4.H_2O$: C, 53.92; H, 7.92; N, 15.72. Found: C, 54.01; H, 7.89; N, 15.65, 15.75.

**Dihydroactidione (II).**—Actidione (3 g.) was reduced at atmospheric pressure in 40 ml. of glacial acetic acid using 1 g. of platinum oxide catalyst. Reduction was complete after 1.05 moles of hydrogen had been absorbed (two to three hours). The solution was filtered, and the acetic acid was removed *in vacuo*. The residue was recrystallized from water containing a little acetone; m. p. 137–139° after thorough drying *in vacuo*.

*Anal.* Calcd. for $C_{15}H_{25}NO_4$: C, 63.58; H, 8.89; N, 4.94. Found: C, 63.50; H, 8.88; N, 5.29.

Dihydroactidione was recovered unchanged after being exposed at room temperature to aqueous periodic acid for twenty-four hours.

**Dihydroactidione Diacetate.**—Dihydroactidione (II) (1.1 g.) was dissolved in a mixture of 20 ml. of acetic anhydride and 10 ml. of dry pyridine, and the solution was allowed to stand overnight. The solvents were then evaporated *in vacuo*, and the residue was stirred with dilute ethanol. The product which soon crystallized was purified by recrystallization from dilute methanol, m. p. 72–75°.

*Anal.* Calcd. for $C_{19}H_{29}NO_6$: C, 62.11; H, 7.96; N, 3.81. Found: C, 62.01; H, 7.90; N, 3.78; C-methyl, 3.44.

***d*-2,4-Dimethylcyclohexanone (III) by Alkaline Degradation of Actidione.**—Actidione (10 g.) was dissolved in 200 ml. of 20% sodium hydroxide solution, and about one-half of the solution was distilled. The distillate was saturated with sodium chloride and extracted with ether. The extracts were dried over sodium sulfate, and the ether

(10) Hassall and Todd, *J. Chem. Soc.*, 611 (1947).

(11) All melting points were taken on a Fisher-Johns melting point block and are corrected.

(12) Ginger, *J. Biol. Chem.*, **156**, 453 (1944).

was removed. The residue was distilled, b. p. 175–176°, yield, 3.0–3.5 g., $[\alpha]^{29}D$ +11.52° ($c$ = 5.417 in ethanol), $n^{25}D$ 1.4435.

*Anal.* Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.45; H, 11.08.

The 2,4-dinitrophenylhydrazone of *d*-2,4-dimethylcyclohexanone was obtained in the usual manner and was recrystallized from dilute dioxane, m. p. 169–172°.

*Anal.* Calcd. for $C_{14}H_{18}N_4O_4$: C, 54.89; H, 5.92; N, 18.29. Found: C, 54.64; H, 5.75; N, 18.76.

The *p*-nitrophenylhydrazone was prepared in ethanol using acetic acid as catalyst. The derivative separated as golden, matty needles from dilute ethanol, m. p. 152–153°.

*Anal.* Calcd. for $C_{14}H_{19}N_3O_2$: C, 64.34; H, 7.33; N, 16.08. Found: C, 64.33; H, 7.10; N, 15.82.

The oxime, prepared as usual, was sublimed for analysis, m. p. 48–51°.

*Anal.* Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92. Found: C, 68.71; H, 10.94; N, 10.32.

The semicarbazone was prepared and purified by recrystallization from dilute ethanol, m. p. 212–214°.

*Anal.* Calcd. for $C_9H_{17}N_3O$: C, 58.99; H, 9.35; N, 22.93. Found: C, 59.37; H, 9.47; N, 23.07.

The *l*-menthydrazone of *d*-2,4-dimethylcyclohexanone was prepared by the method of Woodward, Kohman and Harris[13] and was recrystallized from ethanol, m. p. 164–165°, $[\alpha]^{29}D$ −58.7° ($c$ = 1.524 in ethanol).

*Anal.* Calcd. for $C_{19}H_{34}N_2O_2$: N, 8.69. Found: N, 8.91.

**Resolution of Synthetic *dl*-2,4-Dimethylcyclohexanone.**—A solution of 10 g. of the pure ketone (see below), 17 g. of *l*-menthydrazide, 4 g. of sodium acetate, and 2 ml. of glacial acetic acid in 200 ml. of ethanol was refluxed for forty minutes. The solution was seeded with *d*-2,4-dimethylcyclohexanone-*l*-menthydrazone and was cooled overnight. The first crop of crystals weighed 5.2 g., m. p. 135–143°. After four recrystallizations from ethanol the melting point was 164–165° and showed no depression when mixed with the *d*-2,4-dimethylcyclohexanone-*l*-menthydrazone obtained above from the natural 2,4-dimethylcyclohexanone; $[\alpha]^{29}D$ −56.8° ($c$ = 1.54 in ethanol).

*Anal.* Calcd. for $C_{19}H_{34}N_2O_2$: N, 8.69. Found: N, 8.69.

**X-Ray Diffraction Identification of the Natural and Synthetic *d*-2,4-Dimethylcyclohexanone-1-menthydrazones.**—X-Ray powder patterns of the natural and synthetic *d*-2,4-dimethylcyclohexanone-*l*-menthydrazones were taken on a North American Philips Unit with a circular camera. The patterns obtained were identical. Calculated D values of identical lines on the two patterns were duplicated to an average error of ±0.01 Å. unit with a maximum deviation of 0.05 Å. unit. Relative intensities of the corresponding lines on the two patterns were identical.

**N-Methyldihydroactidione (IV).**—An ether solution of diazomethane was prepared from 5 g. of nitrosomethylurea, dried over potassium hydroxide, and filtered into a solution of 2.8 g. of dihydroactidione (II) in 40 ml. of methanol. The mixture was allowed to stand overnight and was then evaporated *in vacuo* to yield a colorless oil. Acetone and water were added, and after scratching the oil crystallized. The product was purified for analysis by recrystallization from aqueous acetone, m. p. 129–132°.

*Anal.* Calcd. for $C_{16}H_{27}NO_4$: C, 64.62; H, 9.15; N, 4.71. Found: C, 64.09; H, 8.91; N, 4.68.

**Alkaline Degradation of N-Methyldihydroactidione (IV).**—The N-methyl derivative (0.35 g.) was boiled in 2 ml. of water containing 0.5 g. of potassium hydroxide, and 1 ml. of distillate was collected under 1 ml. of ice-water. The aqueous solution containing the distillate was mixed with 0.1 g. of phenyl isothiocyanate, warmed to 40°, and shaken until the product crystallized. The N-methyl-N′-phenylthiourea was filtered, washed and dried, m. p. 119–121°. A mixed melting point with an authentic sample was also 119–121°.

The residue from the distillation was acidified with hydrochloric acid, and the product which separated was recrystallized from dilute ethanol. It was shown to be dihydroactidione acid (X) (see below) by melting point and mixed melting point determinations.

**Degradation of Actidione to Methanetriacetic Acid (V).**—Actidione (10 g.) was dissolved in a solution of 20 g. of sodium hydroxide in 100 ml. of water. The mixture was distilled until 150 ml. of distillate was collected, the original volume being kept constant by periodic addition of water. The residue was cooled and neutralized with 13.5 ml. of concentrated sulfuric acid. The solution was then cooled in an ice-bath while 3.74 g. of powdered potassium permanganate was added. The mixture was shaken until the permanganate color was discharged, after which it was warmed for a few minutes on a steam-bath, made just alkaline with sodium hydroxide and filtered to remove manganese dioxide. The filtrate was saturated with sodium sulfate, acidified with sulfuric acid and exhaustively extracted with ether. Evaporation of the ether left 4.8 g. of crude, sirupy methanetriacetic acid (V). The acid was dissolved in water and was added to an aqueous solution of excess lead acetate. The insoluble lead salt was filtered and washed with water. It was resuspended in water, and the mixture was saturated with hydrogen sulfide. Lead sulfide was removed by filtration, and the filtrate was concentrated *in vacuo* to a crude sirupy residue. Neutral equivalent, calcd. for methanetriacetic acid 63.4; found, 74.9. Part of the sirupy acid on long standing in ether solution crystallized to give methanetriacetic acid, m. p. 112–116°; a mixed m. p. with a sample of the synthetic acid was 114–117°. Another part of the crude acid (0.57 g.) was dissolved in 10 ml. of water and was neutralized with 0.636 g. of sodium bicarbonate. Ethanol (65 ml.) containing 2.12 g. of *p*-bromophenacyl bromide was added, and the mixture was refluxed for three and one-half hours. Most of the ethanol was removed by distillation *in vacuo*, and water was added. The gummy derivative which separated was taken up in dilute acetone. The product crystallized and was recrystallized twice from aqueous acetone, m. p. 110–112°. A mixed melting point with an authentic sample of methanetriacetic acid-tri-*p*-bromophenacyl-ester (m. p. 115–116°) was 112–115°.

**Benzylamine Reaction Product (VII) from Actidione.**—Three grams of actidione was warmed on a steam-bath for two hours with 7.5 ml. of benzylamine. The odor of 2,4-dimethylcyclohexanone was evident. The mixture was cooled, and the product was filtered and washed with chloroform; yield, 0.7 g. The derivative was recrystallized several times from methanol for analysis, m. p. 180–182°.

*Anal.* Calcd. for $C_{21}H_{25}N_3O_2$: C, 71.77; H, 7.17; N, 11.96. Found: C, 71.35; H, 6.75; N, 12.09.

**Oxidation of Actidione; Dehydroactidione (VI).**—Pure actidione (3 g.) was dissolved in 75 ml. of glacial acetic acid, and to this solution was added dropwise, during a period of ten minutes, a solution of 0.80 g. of 98% chromium trioxide in 10 ml. of water. The reaction mixture was allowed to stand at room temperature for two hours after which it was warmed for a few minutes on a steam-bath. The solvents were then removed completely *in vacuo*. Water was added to the residue, and the product was extracted with chloroform. The chloroform solution was washed with water, dried over sodium sulfate and evaporated *in vacuo*. The residue was recrystallized from dilute ethanol, m. p. 177–180°; yield, 0.8 g.

*Anal.* Calcd. for $C_{15}H_{21}NO_4$: C, 64.49; H, 7.58; N, 5.02. Found: C, 64.20; H, 7.39; N, 4.87.

On catalytic reduction of a small sample of dehydroactidione in glacial acetic acid using platinum oxide as

(13) Woodward, Kohman and Harris, THIS JOURNAL, **63**, 120 (1941).

catalyst 2.3 moles of hydrogen were absorbed. Separation of the resulting mixture of racemates of dihydroactidione in analytically pure condition has not been accomplished as yet.

**Copper Complex from Dehydroactidione.**—The diketone (VI) was dissolved in hot dilute ethanol, and the solution was filtered into an excess of aqueous copper acetate. The olive-green complex soon crystallized and was filtered and washed with water, ethanol and ether, m. p. 228–230° (dec.).

*Anal.* Calcd. for $C_{30}H_{40}N_2O_8Cu$: Cu, 10.25. Found: Cu, 10.20.

Under similar conditions no copper salts were formed with actidione, dihydroactidione or glutarimide.

**Alkaline Degradation of Dehydroactidione (VI).**—The diketone (VI) (2.3 g.) was dissolved in a solution of 4.6 g. of sodium hydroxide in 23 ml. of water. The solution was boiled, and 45 ml. of distillate was collected, while the volume of the hydrolysis mixture was kept constant by frequent addition of water. The distillate was mixed with 100 ml. of ethanol containing 1.6 g. of 2,4-dinitrophenylhydrazine. This solution was heated to boiling, and 2 ml. of concentrated hydrochloric acid was added. The mixture was boiled for a few minutes, cooled, and the derivative was filtered and washed with methanol. A 68% yield (1.7 g.) of 2,4-dimethylcyclohexanone-2,4-dinitrophenylhydrazone was thus obtained. The residue in the distillation flask was cooled and acidified with 5 ml. of concentrated sulfuric acid. The resulting solution was exaustively extracted with ether and the extract concentrated *in vacuo*. The crude sirup so obtained could not be induced to crystallize, so it was dissolved in 25 ml. of water containing 1 g. of Girard reagent P[14] and 1 ml. of acetic acid. The solution was refluxed for one-half hour, saturated with sodium sulfate, and again extracted continuously with ether overnight. Evaporation of the extract left 1.5 g. of sirup. On cooling an ether–nitromethane solution of the sirup overnight crystalline methanetriacetic acid (V) was obtained, m. p. 117–119°; mixed melting point with synthetic methanetriacetic acid, 119–121°.

*Anal.* Calcd. for $C_7H_{10}O_6$: C, 44.21; H, 5.30. Found: C, 44.50; H, 5.35.

Part of the crude acid above (0.8 g.) was neutralized with 11.15 ml. of 1 *N* sodium hydroxide solution and mixed with 100 ml. of ethanol and 3.1 g. of *p*-bromophenacyl bromide. The solution was refluxed for three hours, after which it was concentrated *in vacuo* to about half the original volume, and water was added. The gum which separated was washed with sodium bicarbonate solution, water and methanol. It was then taken up in acetone and methanol and cooled slowly. The crystalline product which separated was recrystallized from acetone–methanol, m. p. 115–116°. The mixed melting point with authentic methanetriacetic acid–tri-*p*-bromophenacyl ester was also 115–116°.

*Anal.* Calcd. for $C_{31}H_{25}Br_3O_9$: C, 47.65; H, 3.23; Br, 30.69. Found: C, 47.36; H, 3.09; Br, 30.32.

**Dehydration of Actidione; Anhydroactidione (VIII).**—Pure actidione (3 g.) dissolved in 100 ml. of dry benzene was mixed with 6 g. of phosphorus pentoxide. The mixture was heated slowly (15 min.) to boiling with frequent shaking and was then allowed to cool. The benzene solution was filtered, and the solvent was removed *in vacuo*. The residual colorless sirup was crystallized from benzene–petroleum ether; yield, 1.0 g. It was recrystallized for analysis from benzene–ether, m. p. 134–135°.

*Anal.* Calcd. for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32. Found: C, 68.53; H, 8.44; N, 5.48.

This product on warming in alkaline solution gave the volatile ketone, *d*-2,4-dimethylcyclohexanone (III).

**Reduction of Anhydroactidione (VIII).**—A small sample of anhydroactidione (VIII) on catalytic reduction in acetic acid using platinum oxide as catalyst absorbed 2.16 moles of hydrogen in one hour. The solvent was distilled *in vacuo*, and the crude tetrahydroanhydroactidione (IX) was purified by recrystallization from benzene–petroleum ether, m. p. 125–127°.

*Anal.* Calcd. for $C_{15}H_{25}NO_3$: C, 67.38; H, 9.43. Found: C, 67.57; H, 9.94.

**Alkaline Degradation of Dihydroactidione; Dihydroactidione Acid (X).**—Dihydroactidione (II) (1 g.) was dissolved in 10 ml. of 20% sodium hydroxide, and the solution was heated to boiling for five minutes. The reaction mixture was cooled, and 4.5 ml. of concentrated hydrochloric acid was added. The product which separated was filtered, washed with water and recrystallized from dilute ethanol; m. p. 180–183°, yield 85%.

*Anal.* Calcd. for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51; neut. equiv., 284.3. Found: C, 63.70; H, 8.71; neut. equiv., 284.0.

In an oxidation experiment using two-thirds mole (two equivalents) of potassium permanganate to one of dihydroactidione acid in dilute acetic acid, only unchanged starting material was isolated. This indicated the absence of a free secondary alcoholic group.

**Di-*p*-bromophenacyl Ester of Dihydroactidione Acid.**—One gram of the acid (X) was dissolved in 7.04 ml. of 1 *N* sodium hydroxide (two equivalents) and 60 ml. of ethanol, and 1.953 g. (two moles) of *p*-bromophenacyl bromide were added. The solution was refluxed for three hours and was then concentrated *in vacuo*. Water was added to the gelatinous product, and the solid was filtered, washed with water and methanol and dried; yield, 2.4 g. No suitable solvent for purification was found. The ester gelled out under all conditions tried, so the sample was dissolved in ethanol and precipitated with water, m. p. 130–135°.

*Anal.* Calcd. for $C_{31}H_{36}Br_2O_8$: C, 53.46; H, 5.21; Br, 22.95. Found: C, 53.39; H, 5.46; Br, 22.23.

**Methyl Ester of Dihydroactidione Acid (XI).**—Diazomethane was prepared in 20 ml. of ether from 2 g. of nitrosomethylurea. The solution was dried over potassium hydroxide and filtered onto 1.5 g. of dihydroactidione acid (X) in a few ml. of methanol. After standing for ten minutes the solution was filtered and concentrated *in vacuo*. The methyl ester which separated was crystallized from methanol–ether, m. p. 139–141°.

*Anal.* Calcd. for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78. Found: C, 64.40; H, 8.46.

**Diamide (XII) from the Methyl Ester of Dihydroactidione Acid.**—The filtrate from the preparation of the crystalline methyl ester above was treated with 30 ml. of methanol saturated with ammonia and allowed to stand overnight. The solvents were then distilled *in vacuo*, and the crude diamide was recrystallized from dioxane–methanol. The product melted at about 100° with loss of solvent of crystallization, resolidified and remelted at 165–168°. Analysis showed that the compound contained one molecule of dioxane of crystallization.

*Anal.* Calcd. for $C_{15}H_{28}N_2O_4 \cdot C_4H_8O_2$: C, 58.75; H, 9.34; N, 7.21; loss at 120°, 22.68. Found: C, 57.57; H, 8.89; N, 7.08; loss at 120°, 22.36.

The sample was then dried at 120° *in vacuo* and reanalyzed, m. p. 167–171°.

*Anal.* Calcd. for $C_{15}H_{28}N_2O_4$: C, 59.97; H, 9.39; N, 9.32. Found: C, 60.26; H, 8.99; N, 8.53.

**Diamide (XII) from Dihydroactidione.**—The dihydro compound (II) (2 g.) was dissolved in 30 ml. of methanol, and 30 ml. of liquid ammonia was added. The mixture was allowed to stand overnight after which the solvent was distilled *in vacuo*, and the residue was recrystallized twice from water. The colorless needles melted at about 100° with loss of water of hydration, resolidified and remelted at 174–177°.

*Anal.* (Dried at 25°.) Calcd. for $C_{15}H_{28}N_2O_4 \cdot 0.5H_2O$: C, 58.23; H, 9.45; N, 9.06. Found: C, 58.86; H, 10.18; N, 8.68.

(14) Girard, *Helv. Chim. Acta*, **19**, 1095 (1936).

A sample was then dried at 120° *in vacuo* and reanalyzed, m. p. 176–178°.

*Anal.* Calcd. for $C_{15}H_{28}N_2O_4$: C, 59.97; H, 9.39. Found: C, 59.64; H, 8.84.

A mixed melting point with the slightly less pure diamide (m. p. 167–171°) prepared from the methyl ester of dihydroactidione acid was 170–174°.

**Dihydroactidione Acid (X) from the Diamide (XII).**—The above diamide (0.15 g.) was boiled in a solution containing 0.25 g. of sodium hydroxide in 3 ml. of water until no more ammonia was evolved (five minutes). The mixture was cooled and acidified with hydrochloric acid. The product was filtered, washed and recrystallized from dilute ethanol, m. p. 179–183°. A mixed m. p. with dihydroactidione acid (X) was 180–183°.

**Silver Salt of the Amide Acid (XIII) Obtained from Dihydroactidione Acid.**—The dihydroacid (X) (1 g.) was mixed with 30 ml. of methanol and 50 ml. of liquid ammonia and allowed to stand for several days. The solvents were evaporated *in vacuo* leaving the amorphous ammonium salt of the amide acid, which was not obtained in crystalline condition. A portion was dissolved in water, filtered and the silver salt (XIII) precipitated with aqueous silver nitrate solution. The salt was collected on a filter and washed with water, m. p. 171–174°.

*Anal.* Calcd. for $C_{15}H_{26}AgNO_5$: N, 3.43; Ag, 26.43. Found: N, 3.17; Ag, 26.33.

**2-Isopropylcyclopentanone.**—This ketone was prepared by a modification of the method of Cornubert and Borrel.[15] Acetone was condensed with cyclopentanone to give isopropylidenecyclopentanone, b. p. 94–97° (32 mm.); yield, 20%. Catalytic hydrogenation of the unsaturated ketone to isopropylcyclopentanone was effected smoothly in the presence of 5% palladium–charcoal catalyst in glacial acetic acid. The product had a b. p. 172–174°; yield, 88%. It was purified by conversion in the usual fashion to the semicarbazone (m. p. 201–202°). Regeneration of the ketone was brought about by hydrolysis in 20% sulfuric acid. The pure ketone boiled at 173–173.5°, $n^{29}D$ 1.4395.

*Anal.* Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 75.82; H, 11.56.

***dl*-2,4-Dimethylcyclohexanone.**—1-Hydroxy-2,4-dimethylbenzene (145 g.) was hydrogenated in 100 ml. of glacial acetic acid in a 500-ml. steel bomb at 4000 pounds pressure at room temperature using 5 g. of platinum oxide catalyst.[16] The reduction was complete in one hour. The catalyst was filtered and the acetic acid was neutralized with aqueous sodium hydroxide solution. The 2,4-dimethylcyclohexanol was extracted with ether, and the extracts were dried over sodium sulfate. The ether was removed and the product distilled, b. p. 175–179°; yield, 60%.

The alcohol (183 g.) was then added to a solution of 135 ml. of concentrated sulfuric acid in 1500 ml. of water. The resulting mixture was warmed to 45°, and with vigorous stirring 291 g. of powdered potassium dichromate was added portionwise during a period of eleven to twelve minutes while the temperature was maintained at 42–48° by external cooling in ice water. The reaction mixture was stirred for one-half hour longer, after which the product was extracted with ether. The extracts were washed thoroughly with 5% sodium hydroxide and water and were dried over calcium chloride and distilled, b. p. 175–178°; yield, 79%. The ketone was purified in the usual manner by conversion to the semicarbazone, m. p. 198–200°. The pure 2,4-dimethylcyclohexanone had a b. p. 175–176°, $n^{25}D$ 1.4430. Sabatier[17] gives b. p. 176.5°.

*Anal.* Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.00; H, 11.37.

(15) Cornubert and Borrel, *Bull. soc. chim. France*, [4] **47**, 958 (1930).

(16) Baker and Schuetz, THIS JOURNAL, **69**, 1250 (1947), have developed this method of high pressure room temperature hydrogenation using platinum oxide.

(17) Sabatier, *Compt. rend.*, **142**, 554 (1901).

Determination of C-methyl gave a value of 1.28. A sample of the ketone was exposed to the known[18] racemizing action of 90% sulfuric acid, but it was recovered unchanged. The portion so treated gave a semicarbazone identical with the untreated material. Therefore, if any preferential *cis* hydrogenation occurred in the reduction step above, racemization must have taken place during the chromic acid oxidation to give an equilibrium mixture of racemates.

**2,5-Dimethylcyclohexanone.**—This isomeric ketone was prepared from 1-hydroxy-2,5-dimethylbenzene in a manner similar to that described above for 2,4-dimethylcyclohexanone except that the reduction was carried out in ethanol at 150–165° using Raney nickel catalyst. After purification through the semicarbazone (m. p. 155–157°) the 2,5-dimethylcyclohexanone was obtained as a colorless liquid, b. p. 175–176°, $n^{29}D$ 1.4406. Sabatier[19] gives b. p. 174–177°.

*Anal.* Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.07; H, 11.19.

**Methanetriacetic Acid and Derivatives.**—This acid (m. p. 119–121°) was prepared by the procedure of Kohler and Reid[20] using glutaconic ester prepared by the method of Lochte and Pickard.[21] The tri-*p*-bromophenacyl ester was made using the general directions of Shriner and Fuson.[22] It was recrystallized from dilute acetone, m. p. 115–116°.

*Anal.* Calcd. for $C_{31}H_{25}Br_3O_9$: C, 47.65; H, 3.23; Br, 30.69. Found: C, 47.36; H, 3.11; Br, 30.76.

The benzylisothiouronium salt was prepared by the method of Shriner and Fuson.[22] Dilute ethanol was the solvent used in the purification of this derivative, m. p. 139–140°.

*Anal.* Calcd. for $C_{31}H_{40}N_6O_6S_3$: N, 12.20; S, 13.96. Found: N, 11.38; S, 14.23.

**Glutarimide.**—Glutaric anhydride (20 g.) was heated to 130–140°, and ammonia gas was bubbled in rapidly for one-half hour. The mixture was then heated slowly to 250° (twenty-five minutes), and the imide was distilled at 275–280°. It was purified by recrystallization from acetone, m. p. 163–165°. Wolffenstein gives m. p. 154.5°.[23]

**α-Ethylglutarimide.**—α-Ethylglutaric acid was prepared by the following modification of the method of Auwers.[24] One mole of sodium was dissolved in 400 ml. of absolute ethanol, and one mole of ethyl diethylmalonate was added. To the hot solution was then added with stirring one mole of ethyl β-bromopropionate at such a rate as to maintain a gentle reflux (ten minutes). Stirring was continued twenty minutes longer, after which the sodium bromide was removed by filtration and the ethanol distilled *in vacuo*. Water and a little chloroform were added to the residue, and the organic layer was separated and fractionated *in vacuo*. A 61% yield of diethyl α-ethyl-α-carbethoxyglutarate was obtained, b. p. 177–182° at 13 mm. The ester was refluxed with a mixture of 600 ml. of concentrated hydrochloric acid and 500 ml. of water for seventeen hours. The solvents were removed completely *in vacuo*, and the residual α-ethylglutaric acid was refluxed with 450 g. of acetyl chloride for two hours. Excess reagent was distilled *in vacuo*, and the α-ethylglutaric anhydride was fractionated, b. p. 163–165° at 13 mm.; yield, 51% based on ethyl diethylmalonate.

The anhydride was converted to the cyclic imide by the procedure given above for glutarimide. It had a b. p. 265–280°; yield, 85%. Purification was effected by recrystallization from acetone–ether, m. p. 107–108°.

# Kinetics of Pyrrole Substitutions. The Iodination Reaction[1]

BY KENNETH W. DOAK[2] AND ALSOPH H. CORWIN

Wibaut[3] first showed that the presence of a methyl group in the benzene ring greatly increases its reactivity toward nitration. Ingold and Shaw[4] conclude that the rate of nitration by nitric acid in acetic anhydride is increased about 40–55-fold in each ortho and para position, while the reactivity in a meta position is increased threefold. McDuffie and Dougherty[5] have observed that toluene is acetylated about thirteen times as rapidly as benzene. The explanation for this increased reactivity is given in the general electronic theory of organic reactions, developed to a large extent by Lapworth, Robinson and Ingold,[6] which assumes that the attacking reagent seeks a pair of electrons from the aromatic nucleus. The methyl group facilitates the donation of an electron pair, by favoring polarization of the type $CH_3-\overset{+}{\langle\rangle}-$ and thus lowering the energy of the activated intermediate.[7]

Kinetic investigations of substitution reactions are entirely lacking in pyrrole chemistry. A fundamental difference between the benzene and pyrrole systems exists, since the major resonance in benzene is between two normal valence forms while the resonance in pyrrole[8] is mainly ionic, involving five principal structures.[6b] The ionic structures should have fairly low energy, since no octets are broken and no double bonds are lost. The large contribution of these structures to the normal state of the molecule makes the nitrogen positive, with the result that the N—H group is weakly acidic[9] instead of basic, as would be expected for a secondary amine. Activated structures involving them probably have much lower energy than the activated structures in benzene; this accounts for the well-known fact that pyrrole is more reactive than benzene to electron-seeking reagents. For example, when pyrrole is treated with bromine, chlorine or iodine, in dilute solution, the mono-alpha derivative is formed first. If excess halogen is used, the tetrahalogenated pyrrole is formed[10a] more readily than monohalogenated benzenes.

In order to obtain kinetic data upon the substitution of pyrroles, the velocity of iodination of four pyrrole derivatives has been measured.

I II III IV

In the presence of potassium iodide in a buffered solution, the iodinations proceed almost to completion with velocities which can be measured accurately. Pyrroles which have substituents in all α- and β-positions except one were chosen in order to eliminate competing reactions. The N-methylated compounds were studied in order to determine whether or not the N-methyl group has an effect similar to that of a methyl group in the benzene nucleus. A comparison of pyrroles II and IV, in which steric effects should be quite

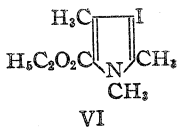
similar, should give an estimate of the relative reactivities of an $\alpha$- and $\beta$-position. These relative rates may be altered somewhat by the fact that the substituent methyl and carbethoxy groups are not quite equivalent in both pyrroles, due to the fact that one ring member is nitrogen. In each pyrrole, however, there are two methyl groups alpha to the reactive center, and a methyl and a carbethoxy group beta to it.



The reverse reaction, the reduction of an $\alpha$- or $\beta$-iodopyrrole to an $\alpha$- or $\beta$-free pyrrole, will occur

in a solution of hydriodic acid. Two experiments were carried out in order to obtain the approximate relative velocities of reduction of two iodopyrroles, V and VI.

V

VI

## Experimental

**Method for Measurement of Velocities of Iodination.**—These velocity measurements were carried out in aqueous dioxane (28% dioxane by weight) buffered by monosodium phosphate and disodium phosphate (0.035 *M* each) to a *p*H of 6.8–6.9. This was necessary to remove the hydriodic acid formed and drive the reaction to completion. The temperature was 26.5 ± 0.1°. Solutions of the pyrroles (0.020–0.035 *M*) were made up by dissolving them in dioxane freshly distilled from sodium amalgam. The reactions were started by adding to 40 cc. of pyrrole solution 100 cc. of aqueous iodine solution (0.0075–0.0120 *M*) containing 0.049 *M* phosphates and a large concentration of potassium iodide (0.560–1.200 *M*). The ionic strength was kept constant by the addition of sodium chloride. At intervals throughout the course of a reaction, 10.00-ml. samples of the reaction mixture were pipetted into 5.00 ml. excess standard sodium arsenite to destroy the iodine. This solution was buffered to a *p*H of 7.0 or slightly greater by addition of 1 ml. of monosodium phosphate (0.25 *M*) and 3 ml. of disodium phosphate (0.25 *M*), 2 g. of potassium iodide was added, and the excess arsenite ion was titrated with standard iodine solution.

If the *p*H is too low, some iodine is used during the back titration to iodinate the pyrroles, particularly the $\alpha$-free pyrroles. If the *p*H is too high, the titration of arsenite ion is inaccurate, as shown by Washburn.[11]

Second order velocity constants were determined by the equation

$$k_{obs.} = \frac{2.303}{(a - b)t} \log \frac{b(a - x)}{a(b - x)} \qquad (1)$$

in which $a$ and $b$ are the initial concentrations of pyrrole and titratable iodine, and $x$ is the concentration of iodopyrrole. Log $(a - x)/(b - x)$ was plotted against time, and $k_{obs.}$ was determined by the slope of the straight line, after converting the time to seconds.

$$k_{obs.} = 2.303/(a - b) \text{ (Slope)} \qquad (2)$$

Tables I and II give the data for two typical experiments. The apparent drift in velocity constant calculated from the data in Table I is due to the initial heating of mixing. This is shown by Fig. 1. Figures 1 and 2 are plots of log $(a - x)/(b - x)$ against time and show the straight lines required for a second order equation. Table IV summarizes the data for the iodination of the four pyrroles. Second order velocity constants were determined for different concentrations of iodide ion.

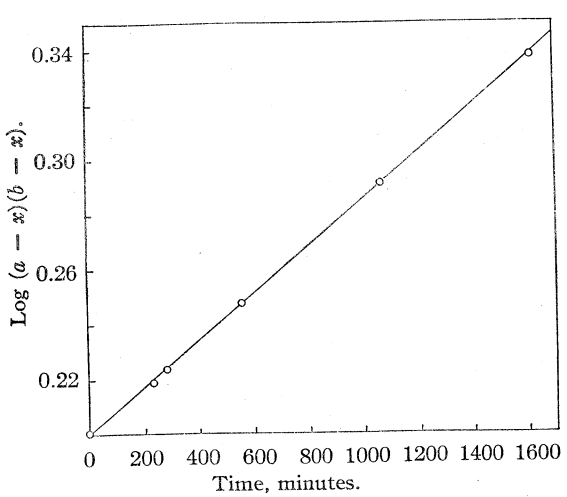

Fig. 2.—Iodination of Pyrrole III; data from Table II.

(11) Washburn, THIS JOURNAL, **30**, 31 (1908).

**Rates of Reduction of Iodopyrroles with Hydriodic Acid.**—A solution of the iodopyrrole to be examined (0.200 g. in 20.0 cc. of purified dioxane) was added to 10.0 cc. of water containing 1.5 g. of potassium iodide. The reaction was started by the addition of 1.00 cc. of 2.0 *N* hydrochloric acid. At intervals, 5.00-cc. samples were pipetted into 10 cc. of water saturated with potassium iodide and containing 1 g. of sodium acetate. The reaction is made extremely slow by the excess sodium acetate, while the iodination is checked by the large excess of iodide ion. If the iodine is titrated immediately by sodium thiosulfate, consistent results can be obtained. The data for two experiments are given in Table III.

TABLE III

REDUCTION OF PYRROLES

$[I^-] = a = 0.0645$, $[Py]_0 = b = 0.0210$, $[H\ Solv^+]_0 = c = 0.292$

| Pyrrole | Time, min. | $I_2^- = x$ |
|---|---|---|
| V | 0 | 0 |
| | 4 | 0.0036 |
| | 174 | .0192 |
| | 666 | .0211 |
| | | $k = 0.0140$ (l.²/mole² sec.) |
| VI | 0 | 0 |
| | 11 | 0.0003 |
| | 183 | .0042 |
| | 661 | .0101 |
| | 1573 | .0153 |
| | | $k = 6.87 \times 10^{-4}$ (l.²/mole² sec.) |

The reduction of pyrrole VI, for which more points are available, follows a third order rate equation closely and the plot extrapolates to zero time. The reduction of pyrrole V is assumed to obey the same law. Because of the speed of this reaction, there was a marked heating effect on mixing and the plot extrapolates to −212 seconds.

**Synthesis of α- and β-Free Pyrroles.**—These pyrroles were synthesized by the method of Corwin and Quattlebaum.[12] They were recrystallized from methanol at Dry Ice temperature and were dried under vacuum. Dioxane solutions were prepared, which were kept frozen until they were used.

**Synthesis of 2-Iodo-3,5-dimethyl-4-carbethoxypyrrole, and 3-Iodo-2,4-dimethyl-5-carbethoxypyrrole.**—These compounds were prepared by the method of Fischer.[10b]

**Synthesis of 2-Iodo-1,3,5-trimethyl-4-carbethoxypyrrole.**—Two grams of 1,3,5-trimethyl-4-carbethoxypyrrole was dissolved in 25 cc. of methanol, and water was added until precipitation began. The theoretical amount of iodine was dissolved in a minimum of alcohol and added over a period of several minutes to the pyrrole solution. Several grams of sodium bicarbonate was added. After twenty minutes, water was added to complete the precipitation of the iodopyrrole. The iodopyrrole was decolorized with bone black and recrystallized twice from methanol at Dry Ice temperature; yield, 78%, m. p. 103.0–103.5°.

*Anal.* Calcd. for $C_{10}H_{14}O_2NI$: C, 39.11; H, 4.59. Found: C, 39.28; H, 4.22.

**Synthesis of 3-Iodo-1,2,4-trimethyl-5-carbethoxypyrrole.**—This iodopyrrole was synthesized from 1,2,4-trimethyl-5-carbethoxypyrrole in a manner similar to that described above for its isomer; yield, 75%, m. p. 87°.

*Anal.* Calcd. for $C_{10}H_{14}O_2NI$: C, 39.11; H, 4.59. Found: C, 39.36; H, 4.53.

**Reduction of Iodopyrroles by Hydriodic Acid.**—The following experiment is typical of the reduction of an α-iodopyrrole to the corresponding α-free pyrrole. 2-Iodo-1,3,5-trimethyl-4-carbethoxypyrrole (1.8 g.), potassium iodide (1.0 g.), glacial acetic acid (5.0 cc.) and sodium bisulfite (1.5 g.) were added to 75 cc. methanol (80%) in an erlenmeyer flask, the flask was stoppered, and the mixture was allowed to stand overnight. The solution was evaporated under vacuum until the pyrrole began to precipitate. Water was added to complete the precipitation. The product was recrystallized from methanol at Dry Ice temperature; yield, 75%, m. p. 59–60°, mixed m. p. with 1,3,5-trimethyl-4-carbethoxypyrrole, 59–60°.

The β-iodopyrroles were less reactive and required hydrochloric acid instead of acetic acid. The sodium bisulfite is necessary to destroy free iodine as fast as it is formed and drive the reaction to completion. That the bisulfite ion (or sulfur dioxide) is not the reducing agent was demonstrated in an experiment in which the potassium iodide was omitted.

## Discussion

**The Mechanism of Iodination of Pyrroles.**—The fact that the velocity of iodination of pyrroles is greatly dependent upon the concentration of iodide ion leads to the following considerations which best explain the observed results. Iodide ion and free iodine are in equilibrium with triiodide ion.

$$K = (I_2)(I^-)/(I_3^-) \qquad (3)$$

This equilibrium constant in water can be calculated from the data of Jones and Kaplan.[13] For the temperature 26.5° we have used the value, $K = 0.00145$. This should be close to the correct value in dioxane–water because of the equivalence of charge in numerator and denominator. If the concentration of iodide ion is large compared with that of titratable iodine, then the liberation of iodide ion during the iodination reaction will change the concentration of iodide ion by a negligible amount, and it may be considered to be a constant. If the iodination is an electrophilic one, then triiodide ion will be repelled by negative centers in the pyrrole ring, and will not react, or will react at a specific rate much lower than that for the reaction with free iodine, the concentration of which is determined by the above equilibrium.

The appropriate kinetic equation is[14]:

$$\frac{dx}{dt} = \frac{k_2K}{K + (I^-)}(a - x)(n - x) \qquad (4)$$

If we substitute

$$k_{obs.} = k_2K/(K + I^-) \qquad (5)$$

this becomes the ordinary second order equation, which integrates to eqn. 1.

If $K$ is considered to be small compared to $(I^-)$ then

$$k_{obs.} = \frac{k_2K}{(I^-)} \text{ or } k_{obs.}(I^-) = k_2K = \text{constant} \qquad (6)$$

Equation 6 thus requires that the experimentally observed velocity constant multiplied by the iodide ion concentration be a constant for each pyrrole. Table IV shows that the relationship holds fairly well. There is, however, a drift

upwards as the concentration of iodide ion becomes small.

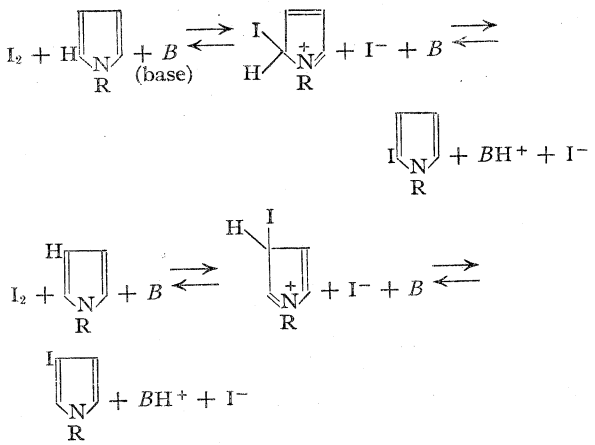
[a] Liters per mole sec.

This drift may be caused by some reaction of hypoiodous acid with the pyrrole. Li[15] showed that in the iodination of tyrosine by iodine solutions containing a low concentration of iodide ion (less than 0.10 molar) the observed second order constant obeys the following relationship

$$k_{obs.} = \frac{A}{(I^-)^2} + \frac{B}{(I^-)}$$



The first term is due to the reaction of hypoiodous acid, the second due to reaction by free iodine. At very low concentrations of iodide ion, the first term is very important. At higher concentrations of iodide ion, the second term increases in importance, and will eventually become much larger than the first term. Then, $k_{obs.} = B/I^-$, which is eqn. 4, in which $B = k_2K$. In the experiments reported here, the concentrations of iodide ion were much higher than in the experiments of Li (0.40–0.86 $M$, compared with 0.03–0.10 $M$), so that eqn. 4 is obeyed fairly well. Free iodine thus is shown to be the principal iodinating agent under the conditions of these experiments.

**Details of Mechanism.**—Sidgwick, Taylor and Baker[16] have expressed the belief that the great reactivity of pyrroles in both an $\alpha$ and a $\beta$-position may be due to their ability to assume pyrrolenine structures.

This view has been opposed by Brunings and Corwin.[17] The similar kinetics of iodination of both N-methyl and N—H pyrroles is consistent with that expected for typical electrophilic reactions. It is impossible for the N-methyl pyrroles to assume a pyrrolenine structure without the migration of a methyl group. Since they can be iodinated without a change in the carbon skeleton by a reaction which is reversible, it is extremely unlikely that a pyrrolenine intermediate is involved.

The facts of the forward and reverse reactions presented below are consistent with a mechanism involving an ionic intermediate, in which the first step is rate-determining:

**Relationship Between Structure and Reactivity. (a) The Effect of N-Methyl.**—The specific velocity constants for the iodination of the four pyrroles were estimated by the use of eqn. 6. The value of $K = 0.00145$ was used, although it may be somewhat in error. However, this does not affect the relative velocity constants. The averages of these constants (from Table IV, neglecting those for the experiments with the lowest concentration of iodide ion) are recorded in Table V.

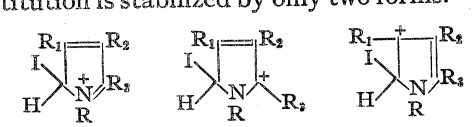


TABLE V

RELATIVE RATES OF IODINATION OF PYRROLES

| | Pyrrole | $k$ (l. per mole sec.) | Ratios | |
|---|---|---|---|---|
| I | N–H, $\alpha$–H | 15.7 | I/III | 26.2 |
| II | N–$CH_3$, $\alpha$–H | 16.9 | II/I | 1.08 |
| III | N–H, $\beta$–H | 0.60 | IV/III | 1.15 |
| IV | N–$CH_3$, $\beta$–H | 0.69 | II/IV | 24.5 |

The results in Table V show that in both cases N-methylation has slightly increased the reactivity, although the differences are small. The N-methyl group thus increases the reactivity of pyrroles to a much smaller extent than a methyl group increases the reactivity of the benzene ring.

**(b) The Effect of Position.**—Table V shows that the $\alpha$-free pyrroles are much more reactive than the $\beta$-free pyrroles. The ionic intermediate mechanism is consistent with this relationship, since the intermediate in $\alpha$-substitution is stabilized by three resonance forms while that in $\beta$-substitution is stabilized by only two forms.

$\alpha$-Substitution Intermediate

(17) Brunings and Corwin, THIS JOURNAL, **64**, 594 (1942).

β-Substitution Intermediate

**Iodopyrroles as "Positive Halogen" Compounds.**—The results in Table III on the reaction of two iodopyrroles with hydriodic acid are shown graphically in Fig. 3. The α-iodopyrrole is shown to be twenty times as reactive as the β-iodopyrrole. A difference of 24.5-fold was observed for the iodination of the corresponding unsubstituted pyrroles II and IV in Table V. This suggests a mechanism in which a proton attacks an electron pair, forming the same ionic intermediate present in the iodination, which then reacts with an iodide ion to form free iodine. The factors which determine the reactivity toward iodine also determine the reactivity toward a proton in the reverse reaction.

The iodopyrroles thus belong to class of "positive halogen" compounds, discussed by Bartlett and Tarbell and Altschul and Bartlett.[18] In compounds of this type, a halogen atom may be transferred as a positive group from one compound to another in a manner similar to that in which a proton is transferred. The iodine atom simultaneously loses an electron pair and shares another pair in both the forward and the reverse reaction, and probably does not exist as a positive atom.

**The Iodination Equilibrium.**—The estimation of the forward and reverse velocity constants permits an approximation to the magnitude of the equilibrium constant of the iodination reaction to be made. The constant

$$K = \frac{[RI][HSolv^+][I^-]}{[RH][Solv][I_2]}$$

is approximately 24 for the α iodination and 21 for the β, assuming the solvent to be 48.2 molar. The ratio of equilibrium constants is thus about 1.1 while the corresponding ratio of rate constants is 24.5. This is clearly a case in which rate constants and equilibrium constants are not parallel. A possible explanation is that the attacking reagents in both directions are sufficiently similar that a structural change which affects the rate of reaction of the unsubstituted pyrrole affects that of the iodopyrrole almost equally.

## Summary

1. The kinetics of iodination of four similar pyrrole derivatives have been studied.
2. The rates of these reactions are dependent upon the concentration of the pyrrole derivative and of the free iodine in the solution.
3. The kinetics indicate that still another species, perhaps hypoiodous acid, is active in iodination.
4. The α-position is found to be about 25 times as reactive as the β position in the pyrrole ring.
5. N-Methyl groups increase the reactivity of the pyrrole ring by 8–15%.
6. This effect is much smaller than the effect of methyl on the reactivity of benzene.
7. Iodopyrroles can be reduced to pyrroles with hydriodic acid.
8. The α position is approximately twenty times as reactive to hydrogen iodide reduction as the β position.
9. Rough values for the equilibrium constant of the iodination reaction have been obtained in two cases.
10. This equilibrium constant is little affected by a structural change in the pyrrole.
11. The significance of these findings with respect to the mechanism of the iodination reaction is discussed.

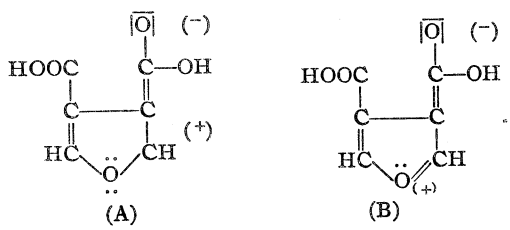
# Furan and Tetrahydrofuran Derivatives. IX. On *epi*-Oxybiotin and the Four Racemic 3,4-Diamino-2-tetrahydrofuran Valeric Acids[1]

BY KLAUS HOFMANN[2]

In recent communications[3,4] the first total synthesis of *dl*-oxybiotin has been described. The key to this synthesis was the catalytic hydrogenation of 3,4-dicarbethoxyamino-2-furanpentanol (II) to a *cis*-3,4-dicarbethoxyamino-2-tetrahydrofuranpentanol. Hydrogenation of a tri-substitution product of furan such as II creates three asymmetric carbon atoms in the molecule, and four racemic tetrahydrofurans, V, VI, VII, and VIII, may be expected. Two of these, V and VI, have a *trans*, and the others, VII and VIII, a *cis*-configuration of the carbethoxyamino groups. The isomers in each pair differ in the spatial configuration of the side chain R′. They may be designated as the *trans*, *cis* V, the *trans*, *trans* VI, the *cis*, *cis* VII and the *cis*, *trans* VIII isomers, respectively. All of the theoretically possible racemic 3,4-diamino-2-tetrahydrofuran valeric acids, XV, XVI, XVII and XVIII, have been prepared. Their synthesis and some of their properties will be described in this communication. In the last analysis, this work represents a study of the catalytic hydrogenation of 3,4-dicarbethoxy-2-furanpentanol (I) and of 3,4-dicarbethoxyamino-2-furanpentanol (II).



Attempts to reduce compound I or the corresponding free dicarboxylic acid in glacial acetic acid over a platinum oxide catalyst were unsuccessful. This observation is in agreement with the work of Archer and Pratt,[5] who also were unable to effect reduction of methyl-3,4-dicarboxy-2-furan acetate under similar conditions. Substitution of the furan nucleus with carboxyl groups endows this otherwise labile ring system with an unusual stability which reflects itself in resistance toward catalytic hydrogenation and stability toward strong mineral acids.[5,6]

These observations may be explained by the resonance concept. In addition to the obvious structures which contribute to the resonance hybrid of furan, additional structures such as A and B may be written for the furan dicarboxylic acids. They are the result of a conjugation between the unsaturation of the ring and the carboxyl groups. The electron-attracting carboxyl groups tend to remove electrons from the ring, thus lowering its affinity for electrophilic reagents and increasing its stability. The fact that resonance tends to bring the carboxyl groups into planarity with the ring may explain the finding that furan-3,4-dicarboxylic acids do not undergo intramolecular anhydride formation.[7,8] The failure of (I) to undergo hydrogenation under the above-mentioned conditions led us to investigate other reduction procedures. It was observed that the compound was smoothly reduced when subjected to high-pressure hydrogenation over a Raney nickel catalyst. A mixture of reduction products was obtained which on treatment with hydrazine hydrate yielded two crystalline isomeric hydrazides $C_{11}H_{22}O_4N_4$ of m. p. 208–210° and m. p. 177–180°.

Based on experimental evidence which will be presented later, we have assigned the *trans*, *cis*-structure III to the higher, and the *trans*, *trans*-configuration IV to the lower melting isomer.

Degradation of these hydrazides by the Curtius procedure with ethanol as the solvent for the decomposition of the corresponding azides yielded two isomeric urethans, V and VI, which on oxidation with chromic acid gave the corresponding 3,4-dicarbethoxyamino-2-tetrahydrofuran valeric acids XI and XII. These compounds were hydrolyzed with aqueous barium hydroxide and the resulting 3,4-diamino-2-tetrahydrofuran valeric acids, XV and XVI, were isolated as the crystalline sulfates and characterized as the dibenzoates and the dibenzoylmethyl esters. Treatment of these diaminocarboxylic acids with phosgene under a variety of experimental conditions did not result in the formation of the corresponding hexahydro-2-oxo-1-furo-(3,4)-imidazoles. Both compounds, therefore, must have a *trans* configuration of the amino groups.

Hydrolysis of the hydrazide (III) with aqueous barium hydroxide at 120° resulted in the formation of an acid. This material was esterified and the dimethyl ester reacted with hydrazine hydrate. Instead of the original hydrazide (III), the isomeric hydrazide (IV) was thus obtained. This was further substantiated by transformation of the isomerized hydrazide into the urethan (VI). The hydrazide (III) was then hydrolyzed with 2 *N* hydrochloric acid, and the hydrazide re-

generated from the resulting dicarboxylic acid. No rearrangement occurred under these conditions since III was obtained. Therefore, the barium hydroxide treatment must have racemized the molecule. In pairs of stereoisomers it is usually the *cis*-oid compound which has the higher energy content and the lower stability, and it seems logical to assume that the hydrazide (III) has the *trans, cis*- and the hydrazide (IV) the *trans, trans*-configuration. The rearrangement which occurs during the barium hydroxide treatment must involve positions 3 and 4, since the asymmet-

ric center at position 2 is stereochemically stable. These observations, in conjunction with the established *trans*-configuration of the substituents in positions 3 and 4 for both isomers, provide strong evidence for the correctness of the assigned stereo structures. The finding that two different diaminocarboxylic acids, XV and XVI, resulted from the degradation of the hydrazides, III and IV, indicated that no rearrangement had occurred during these transformations. Consequently, the configuration of the diaminocarboxylic acids also is established.

The 3,4-dicarbethoxyaminofurans are less "aromatic" than the 3,4-dicarboxyfurans, and undergo hydrogenation at room temperature and atmospheric pressure in the presence of a palladium-on-barium sulfate catalyst. Thus far, this has been demonstrated for 3,4-dicarbethoxyamino-2-furanpropanol,[9] -butanol,[10] and -pentanol.[3,4]

A careful study of the hydrogenation products of (II) revealed the presence of three isomeric 3,4-dicarbethoxyamino-2-tetrahydrofuranpentanols, VI, VII and VIII. During the development of the oxybiotin synthesis[3,4] these hydrogenation products were treated with barium hydroxide and no attempts were made to isolate the different isomeric urethans. It has now been possible to isolate the *trans*-isomer (VI) from this mixture. Its identity with the urethan obtained from the hydrazide (IV) was definitely established by degradation through the 3,4-dicarbethoxyamino-2-tetrahydrofuran valeric acid (XII) to the diaminocarboxylic acid (XVI). Therefore, hydrogenation of II under conditions which favor a *cis*-addition of hydrogen gave a mixture of hydrogenation products containing approximately 24% of the *trans,trans*-isomer (VI). Although the *cis*-3,4-dicarbethoxyaminotetrahydrofurans, VII and VIII, have not been isolated, their presence among the hydrogenation products was conclusively demonstrated by their transformation into cyclic urea derivatives. This has already been demonstrated[3,4] for the isomer which on treatment with barium hydroxide yielded a hexahydro-2-oxo-4-(5-hydroxypentyl)-1-furo-(3,4)-imidazole of melting point 153–154°. Because the spatial position of the side chain has not yet been established, this compound may have structure IX or X. It could be expected that the mother liquors from the above pentanol might contain its epimer with the opposite configuration of the side chain. These fractions have now been subjected to a chromatographic fractionation and it was possible to isolate a hexahydro-2-oxo-4-(5-hydroxypentyl)-1-furo-(3,4)-imidazole of melting point 104–106° which for reasons presented below must be the epimer of the derivative of m. p. 153–154° (structure IX or X). Oxidation of this material, followed by esterification, gave *epi*-oxybiotin methyl ester. *epi*-Oxybiotin was obtained upon hydrolysis of the ester, and on drastic hydrolysis was transformed into a *cis*-3,4-diamino-2-tetrahydrofuran valeric acid, XVII or XVIII. This substance also was characterized as its dibenzoate and its dibenzoyl methyl ester. Treatment of the above diaminocarboxylic acid with phosgene resulted in the regeneration of *dl-epi*-oxybiotin. This series of reactions establishes the constitution of *epi*-oxybiotin as XIII or XIV beyond any question.[11]

The experiments herein described have led to the isolation of three out of the four theoretically possible racemic 3,4-diamino-2-tetrahydrofuran valeric acids. The fourth isomer, namely, the one which stereochemically corresponds to oxybiotin has already been described.[4] This compound has now been transformed into its dibenzoate and the dibenzoylmethyl ester. It is of considerable interest to compare the reactions of these substances with those of the corresponding 3,4-diamino-2-tetrahydrothiophenevaleric acids which became known as a result of synthetic studies on biotin. In contrast to our tetrahydrofurans where only the isomers with a *cis*-configuration of the amino groups are capable of ring formation, the *trans*-3,4-diaminotetrahydrothiophenevaleric acids form bicyclic urea derivatives on treatment with phosgene.[12] This suggests fundamental differences between the two ring systems. One would conclude from this preliminary evidence that stereochemically the tetrahydrothiophene ring resembles the cyclohexane ring in contrast to the tetrahydrofuran ring which behaves more like cyclopentane. The suggested stereochemical differences between these two ring systems will be further investigated. Work is also in progress to establish the spatial arrangement of the side chain in oxybiotin and *epi*-oxybiotin.

## Experimental[13,14,15]

**Hydrogenation of 3,4-Dicarbethoxy-2-furanpentanol (I).**—3,4-Dicarbethoxy-2-furanpentanol[16] (20 g.) was dissolved in 120 cc. of grain alcohol and hydrogenated for three hours at an initial pressure of 1800 lb./sq. in. and a temperature of 180° over a Raney nickel catalyst prepared from 10 g. of the alloy. The catalyst was removed by filtration through Filter-Cel, the alcohol removed *in vacuo*, and the resulting oil dissolved in ether. The ethereal solution was washed with 2 *N* sodium carbonate and water and dried over sodium sulfate; the ether was removed on the steam-bath. The residue on distillation yielded 15.7 g. (78%) of hydrogenated esters which boiled at 175–180° at 0.02 mm.

*Anal.* Calcd. for $C_{15}H_{26}O_6$: C, 59.58; H, 8.66; $OC_2H_5$, 29.8. Found: C, 59.64; H, 8.42; $OC_2H_5$, 26.7.

**3,4-Dicarboxy-2-tetrahydrofurandihydrazide of m. p. 208–210° (III).**—A mixture of 15 g. of the above hydrogenated esters and 15 g. of hydrazine hydrate was refluxed for two hours and then placed in a refrigerator for twelve hours. The resulting crystals were collected, washed with absolute ethanol, and dried over concentrated sulfuric acid *in vacuo*. Recrystallization from dilute ethanol gave 3.2 g. of needles (24%) which melted at 208–210°.

*Anal.* Calcd. for $C_{11}H_{22}O_4N_4$: C, 48.16; H, 8.08; N, 20.41. Found: C, 48.15; H, 7.85; N, 20.18.

**3,4-Dicarboxy-2-tetrahydrofurandihydrazide of m. p. 177–180° (IV).**—The combined mother liquors from the preparation of III were concentrated *in vacuo* to a thick sirup which was kept over concentrated sulfuric acid for several days. The material was then dissolved in a small amount of absolute ethanol and the solution placed in a refrigerator for two days. The resulting crystals were collected, washed with a small amount of ice-cold ethanol, and purified by several recrystallizations from the same solvent; 1.5 g. (11%) of crystals melting at 177–180° was obtained.

*Anal.* Calcd. for $C_{11}H_{22}O_4N_4$: C, 48.16; H, 8.08; N, 20.41. Found: C, 48.01; H, 7.95; N, 20.27.

**Transformation of the Hydrazide (III) into the Isomer (IV).**—A solution of 6 g. of III, 15 g. of barium hydroxide octahydrate, and 80 cc. of water was heated to 120° for five hours in a sealed tube. A slow stream of carbon dioxide was passed into the hot solution and the resulting barium carbonate removed by filtration through Filter-Cel. The filtrate was concentrated to a small volume *in vacuo*, acidified to congo red with concentrated hydrochloric acid, and extracted with five 20-cc. portions of ethyl acetate. The combined ethyl acetate extracts were washed with a small amount of water, dried over sodium sulfate, and concentrated to dryness *in vacuo*. The resulting oily acid, 4.48 g. (83%), was esterified with diazomethane, and the methyl ester distilled *in vacuo*. Treatment of 656 mg. of this ester with 600 mg. of hydrazine hydrate gave 312 mg. (48%) of IV melting at 177–179°. Degradation of this hydrazide by the method given below yielded the urethan (VI) of melting point 128–130°.

**Hydrolysis of (III) with Hydrochloric Acid.**—A solution of 1.37 g. of III in 15 cc. of 2 *N* hydrochloric acid was refluxed overnight, and then evaporated to dryness *in vacuo*. The resulting acid was isolated and esterified as described above, and the methyl ester transformed into the hydrazide; 490 mg. of the ester gave 260 mg. (53%) of III melting at 207–209°. Degradation of this hydrazide by the method given below yielded the urethan (V) of melting point 108–110°.

**3,4-Dicarbethoxyamino-2-tetrahydrofuranpentanol of m. p. 108–110° (V).**—A solution of 1.1 g. of (III) in 10 cc. of 2 *N* hydrochloric acid was cooled in an ice-bath, and 6 cc. of a 10% solution of sodium nitrite was slowly added with vigorous stirring. Stirring was continued for an additional ten minutes and the resulting oily azide extracted with ice-cold ether. The ethereal solution was washed with ice-cold 2 *N* sodium carbonate and water, dried over sodium sulfate and filtered. Absolute alcohol (40 cc.) was then added and the solution slowly heated until the ether had evaporated. The resulting alcoholic solution was refluxed for one hour, and evaporated to dryness *in vacuo*. The residue was recrystallized from ethyl acetate; 523 mg. (40%) of V, melting at 108–110° was obtained.

*Anal.* Calcd. for $C_{15}H_{28}O_6N_2$: C, 54.21; H, 8.49; N, 8.42. Found: C, 53.92; H, 8.09; N, 8.57.

**3,4-Dicarbethoxyamino-2-tetrahydrofuran-pentanol of m. p. 128–130° (VI). a. From the Hydrazide (IV).**—The hydrazide (IV) (3.2 g.) was transformed into the corresponding urethan (VI) as described above. Crystallization from ethyl acetate gave 1.3 g. (34%) of needles melting at 128–130°.

*Anal.* Calcd. for $C_{15}H_{28}O_6N_2$: C, 54.21; H, 8.49; N, 8.42. Found: C, 53.84; H, 8.19; N, 8.64.

**b. From 3,4-Dicarbethoxyamino-2-furanpentanol (II).**—The hydrogenation products obtained from 61.2 g. of (II) as previously described[4] were seeded with a small amount of the above urethan and kept at room temperature overnight. The resulting crystals were collected, washed with ice-cold ethyl acetate, and recrystallized from the same solvent; 15 g. (24%) of needles was obtained which melted at 130–131°. No depression of the melting point was observed when this sample was mixed with a sample of the urethan prepared according to a above.

*Anal.* Calcd. for $C_{15}H_{28}O_6N_2$: C, 54.21; H, 8.49; N, 8.42. Found: C, 53.99; H, 8.20; N, 8.62.

**3,4-Dicarbethoxyamino-2-tetrahydrofuran Valeric Acid of m. p. 121–122° (XI).**—To a solution of the urethan (V) (3.2 g.) in 50 cc. of glacial acetic acid, 100 cc. of a 2% solution of chromium trioxide in glacial acetic acid was slowly added. The mixture was kept at room temperature for twelve hours; methanol (1 cc.) was then added and the solution heated on the steam-bath for thirty minutes. The solvents were removed *in vacuo*, the green residue dissolved in ethyl acetate, and the ethyl acetate solution washed with water. The acidic oxidation products were extracted from the ethyl acetate solution with 2 *N* sodium carbonate, and the acids liberated by acidification and re-extraction with ethyl acetate. The extracts containing the acidic material were dried over sodium sulfate, the ethyl acetate removed *in vacuo* and the crystalline residue purified by recrystallization from ethyl acetate at −20°; 1.3 g. (40%) of crystals was obtained which melted at 121–122°.

*Anal.* Calcd. for $C_{15}H_{26}O_7N_2$: C, 52.02; H, 7.56; N, 8.08. Found: C, 52.10; H, 7.34; N, 8.60.

**3,4-Dicarbethoxyamino-2-tetrahydrofuran Valeric Acid of m. p. 158–160° (XII).**—Compound (VI) (664 mg.) was oxidized as described above and the resulting crystals purified by crystallization from ethyl acetate; 280 mg. (40%) of needles melting at 158–160° was obtained.

*Anal.* Calcd. for $C_{15}H_{26}O_7N_2$: C, 52.02; H, 7.56; N, 8.08. Found: C, 52.05; H, 7.14; N, 8.21.

Oxidation by the same procedure of one gram of the urethan (VI) obtained from the hydrogenation of (II) yielded 600 mg. (58%) of needles, melting at 160–161.5°, which did not depress the melting point of the above material.

*Anal.* Calcd. for $C_{15}H_{26}O_7N_2$: C, 52.02; H, 7.56; N, 8.08. Found: C, 51.85; H, 7.32; N, 8.25.

***epi*-Hexahydro-2-oxo-4-(5-hydroxypentyl)-1-furo(3,4)-imidazole (IX or X).**—The combined mother liquors from several preparations of the hexahydro-2-oxo-4-(5-hydroxypentyl)-1-furo(3,4)imidazole of m. p. 153–154°[4] were concentrated to dryness *in vacuo*. The oily residue (15 g.) was dissolved in 500 cc. of acetone and the solution poured on a column prepared from 300 g. of aluminum oxide (Fisher adsorption alumina). The column was then eluted with 250-cc. portions of each of the following solvent mixtures which removed the amounts of material indicated in parentheses: acetone (3.1 g. of oil); acetone 90, methanol 10 (0.7 g. of oil); acetone 80, methanol 20 (1.7 g. of oil); acetone 70, methanol 30 (3.7 g. of crystals); acetone 60, methanol 40 (3 g. of crystals); acetone 50, methanol 50 (0.7 g. of oil). The fractions containing crystalline material were combined and recrystallized several times from 95% ethanol at −20°; 1.5 g. of the *epi*-pentanol was thus obtained which melted at 104–106°.

*Anal.* Calcd. for $C_{10}H_{18}O_3N_2$: C, 56.07; H, 8.47; N, 13.07. Found: C, 56.12; H, 8.30; N, 13.31.

***epi*-Oxybiotin Methyl Ester.**—To a solution of the above *epi*-pentanol (760 mg.) in 35 cc. of 0.1 *N* sodium hydroxide, 25 cc. of a 5% solution of potassium permanganate was added slowly and the mixture kept at room temperature for twelve hours. The manganese dioxide was removed by filtration through Filter-Cel. The filter cake

of manganese dioxide was washed repeatedly with hot water and the combined filtrate and washings were acidified to congo red with concentrated hydrochloric acid, and concentrated to dryness *in vacuo*.

The dry residue was extracted with two 25-cc. portions of methanol and an ethereal solution of diazomethane was added to the combined extracts until the yellow color remained. The mixture was kept for ten minutes and was then evaporated to dryness and the residue extracted with ethyl acetate. The combined ethyl acetate extracts were filtered and evaporated to dryness *in vacuo*, leaving a semicrystalline residue. This material was dissolved in 20 cc. of acetone and the solution chromatographed on 10 g. of Fisher alumina. The column was eluted with several 10-cc. portions of a mixture containing 90% acetone and 10% methanol. All of the eluates containing crystalline material were combined and the substance recrystallized from ethyl acetate; 190 mg. (22%) of needles was obtained which melted at 104–106°.

*Anal.* Calcd. for $C_{11}H_{18}O_4N_2$: C, 54.52; H, 7.45; N, 11.55. Found: C, 54.67; H, 7.35; N, 11.64.

**epi-Oxybiotin (XIII or XIV). a. From the Methyl Ester.**—A mixture of the above methyl ester (190 mg.), $Ba(OH)_2 \cdot 8H_2O$ (0.5 g.), and water (5 cc.) was heated to 100° for two hours in a sealed tube. Most of the barium was then precipitated with carbon dioxide and the resulting solution acidified to congo red with 2 *N* sulfuric acid. The barium sulfate was removed by filtration and the filtrate concentrated to a small volume *in vacuo*. The resulting *epi*-oxybiotin was collected and recrystallized from hot water; 150 mg. (83%) of prismatic crystals was obtained which melted at 185–186°.

*Anal.* Calcd. for $C_{10}H_{16}O_4N_2$: C, 52.63; H, 7.07; N, 12.27. Found: C, 52.91; H, 7.04; N, 12.23.

**b. From the Corresponding Diaminocarboxylic Acid and Phosgene.**—A solution of 50 mg. of the diaminocarboxylic acid prepared from *epi*-oxybiotin as described below, in 1 cc. of 10% sodium bicarbonate, was treated with phosgene in the usual manner.[4] The resulting *epi*-oxybiotin (25 mg.) (66%) melted at 183–184°. No depression of the melting point was observed when this material was mixed with a sample of *epi*-oxybiotin prepared according to a above.

***trans*-3,4-Diamino-2-tetrahydrofuran Valeric Acid (XV).**—A solution of 1.32 g. of (XI), 8 g. of $Ba(OH)_2 \cdot 8H_2O$ and 40 cc. of water was heated to 110° for three hours in a sealed tube. The crystalline sulfate of (XV) (870 mg.) (75%) was isolated in the usual manner.

**Dibenzoate of XV.**—A sample of the sulfate was benzoylated with benzoyl chloride and 5 *N* potassium hydroxide, and the dibenzoate recrystallized from dilute methanol. The substance melted at 215–217°.

*Anal.* Calcd. for $C_{23}H_{26}O_5N_2$: C, 67.30; H, 6.38; N, 6.82. Found: C, 67.15; H, 6.23; N, 6.96.

**Dibenzoyl Methyl Ester of XV.**—A sample of the dibenzoate was esterified with diazomethane and the resulting ester recrystallized from a mixture of methanol and ether. The substance melted at 183–185°.

*Anal.* Calcd. for $C_{24}H_{28}O_5N_2$: C, 67.89; H, 6.64; N, 6.60. Found: C, 67.87; H, 6.38; N, 6.62.

***trans*-3,4-Diamino-2-tetrahydrofuran Valeric Acid (XVI).**—Compound XII (720 mg.) was hydrolyzed with barium hydroxide as described above; 465 mg. (74%) of the sulfate of (XVI) was obtained.

**Dibenzoate of XVI.**—A sample of the sulfate was benzoylated and the dibenzoate recrystallized from dilute methanol. The substance melted at 194–195°.

*Anal.* Calcd. for $C_{23}H_{26}O_5N_2$: C, 67.30; H, 6.38; N, 6.82. Found: C, 67.57; H, 6.52; N, 6.76.

**Dibenzoyl Methyl Ester of (XVI).**—This derivative was prepared from the dibenzoate with diazomethane and was recrystallized from a mixture of ethanol and ether. The substance melted at 171–173°.

*Anal.* Calcd. for $C_{24}H_{28}O_5N_2$: C, 67.89; H, 6.64; N, 6.60. Found: C, 67.96; H, 6.31; N, 6.68.

***cis*-3,4-Diamino-2-tetrahydrofuranvaleric Acid from Oxybiotin.**—A sample of oxybiotin was hydrolyzed with barium hydroxide and the sulfate of the diamino carboxylic acid isolated as previously described.[4]

**Dibenzoate.**—A sample of the sulfate was benzoylated. The dibenzoate after recrystallization from a mixture of methanol and ethyl acetate melted at 230–231°.

*Anal.* Calcd. for $C_{23}H_{26}O_5N_2$: C, 67.30; H, 6.38; N, 6.82. Found: C, 67.17; H, 6.36; N, 6.83.

**Dibenzoyl Methyl Ester.**—This derivative was prepared from the dibenzoate with diazomethane. After recrystallization from methanol the material melted at 148–150°.

*Anal.* Calcd. for $C_{24}H_{28}O_5N_2$: C, 67.89; H, 6.64; N, 6.60. Found: C, 67.86; H, 6.35; N, 6.54.

***cis*-3,4-Diamino-2-tetrahydrofuranvaleric Acid from *epi*-Oxybiotin.**—A sample of *epi*-oxybiotin (100 mg.) was hydrolyzed with 1.5 g. of $Ba(OH)_2 \cdot 8H_2O$ in 7.5 cc. of water as described.[4] The resulting sulfate of the diaminocarboxylic acid (70 mg., 53%) melted at 233–234° with decomposition.

**Dibenzoate.**—This derivative was prepared in the usual manner and after recrystallization from dilute methanol melted at 188–189°.

*Anal.* Calcd. for $C_{23}H_{26}O_5N_2$: C, 67.30; H, 6.38; N, 6.82. Found: C, 67.52; H, 6.56; N, 6.67.

**Dibenzoyl Methyl Ester.**—This derivative, prepared from the dibenzoate with diazomethane, after recrystallization from methanol, melted at 162–165°.

*Anal.* Calcd. for $C_{24}H_{28}O_5N_2$: C, 67.89; H, 6.64; N, 6.60. Found: C, 67.49; H, 6.46; N, 6.98.

**Acknowledgments.**—The author wishes to express his thanks to Florence Baker and Anna Bridgwater for their valuable assistance.

## Summary

The four theoretically possible racemic 3,4-diamino-2-tetrahydrofuran valeric acids have been prepared and characterized. Only the two isomers with a *cis*-configuration of the amino groups were found to form bicyclic urea derivatives on treatment with phosgene. Definite stereo structures have been assigned to the two *trans*-isomers. *epi*-Oxybiotin has been prepared and its structure partially established. Differences between the 3,4-diamino-2-tetrahydrothiophenevaleric acids and the corresponding tetrahydrofurans have been discussed.

# Aromatization Studies. VIII. Catalytic Dehydrogenation of Di- and Trialkylcyclohexenones to Phenols

BY E. C. HORNING, M. G. HORNING AND G. N. WALKER[1]

An investigation[2] of the catalytic (palladium–carbon) dehydrogenation of 3-methyl-5-aryl-2-cyclohexen-1-ones indicated that aromatization of the alicyclic system to a phenolic system could be accomplished in good yield (*ca.* 70–85%) in a variety of boiling solvents. In contrast to most previous observations, it was found that the dehydrogenation process occurred rapidly under ordinary conditions of boiling, with the major part of the reaction taking place within the first fifteen minutes.

In order to study the effect of substituent groups on dehydrogenations leading to phenols, an investigation has now been carried out with several di- and trialkyl-2-cyclohexen-1-ones. 3-Methyl-5-alkyl-2-cyclohexene-1-ones, in which the alkyl group was methyl, ethyl, *n*-propyl, isopropyl and *n*-hexyl, were treated with a 5% palladium–carbon catalyst in a boiling solvent (usually trimethylbenzene) under the same general conditions employed previously.[2] The effects of variations in time and solvents on the yield of phenol are given in Table I. The effect of variations in the 5-alkyl group on the yield, for a two-hour reaction period at 168°, is shown in Table II. The 3-methyl-2,5-dialkyl-2-cyclohexen-1-ones listed in Table III were also aromatized, under the same conditions, to the corresponding phenols whose properties are in Table IV. The observed yields were generally in the range 40–50% (Tables I, II and IV) for a two-hour reaction period. This range is considerably below that found for 3-methyl-5-arylcyclohexenones, and the explanation is evidently to be found in a greater tendency of alkylcyclohexenones to undergo disproportionation. In the case of 3,5-dimethyl-2-cyclohexen-1-one, the expected 3,5-dimethylcyclohexanone was isolated as the semicarbazone (in about 25% of the total, or 50% of the expected yield) from the reaction mixture. The yields of phenols obtained here are not high, but the method described provides a convenient and useful means for obtaining alkyl phenols which are not available through ordinary aromatic reaction methods.

The 3-methyl-5-alkyl-2-cyclohexen-1-ones were obtained through the Knoevenagel condensation.[3] The fact that 3-methyl-5-alkyl-4-carbethoxy-2-cyclohexen-1-ones may be alkylated in the 2-position is well established, but when the reaction is carried out in ethanol with sodium ethoxide, the predominant reaction is loss of the 4-carbethoxy group by alcoholysis. Sodamide alkylation affords a better means of obtaining alkylated esters,[4] although the low degree of reactivity and the tendency of the sodium salts to form gums may make it difficult to carry out this reaction. After careful fractionation of the alkylated esters, the 4-carbethoxy group was removed by alkaline hydrolysis and decarboxylation. The resulting cyclohexenones are listed in Table III.

TABLE I

DEHYDROGENATION OF 3,5-DIMETHYL-2-CYCLOHEXEN-1-ONE

| Solvent | B. p., °C. | Time, hr. | Yield of phenol, % |
|---|---|---|---|

**Acknowledgment.**—This work was supported in part by a grant from the Research Corporation, for which we wish to express our appreciation. We are also indebted to Mrs. Sarah Miles Woods for the analytical data.

## Experimental

All melting points are corrected.

**Palladium Catalyst.**—A 5% palladium–carbon catalyst was prepared according to Hartung's method.[5]

**Solvents.**—All solvents were distilled before use. The trimethylbenzene solvent was the technical grade (mixed isomers) of the Eastman Kodak Co., b. p. 168–172°. This solvent was found to give particularly clean products.

**Dehydrogenation.**—The general procedure is illustrated by the following example. To 5.00 g. of 3,5-dimethyl-2-cyclohexen-1-one in 15 ml. of trimethylbenzene was added 1.50 g. of 5% palladium–carbon catalyst. The mixture was maintained under vigorous reflux for

[a] Recrystallized from pentane. [b] Recrystallized from cyclohexane.

two hours. After cooling to about 50°, the catalyst was removed by filtration, and washed with four 5-ml. portions of hot ethyl acetate. The solution was extracted with three 40-ml. portions of 10% sodium hydroxide solution. The combined alkaline extracts were washed with 40 ml. of pentane, and diluted with 100 ml. of water. Five milliliters of concentrated hydrochloric acid was added; the solution was chilled in an ice-bath and acidified with dilute hydrochloric acid. The phenol crystallized immediately. After chilling for several hours, the product was removed by filtration, washed well with water and air-dried. The yield was 1.89 g. (38%) of slightly discolored flakes, m. p. 62–63°.

Further extraction of the organic solution with Claisen solution and acidification of the alkaline extract did not yield additional 3,5-dimethylphenol.

The effect of variations in temperature of the boiling solvent and reaction time on the yield is shown in Table I. The yields given are for crude, dry product; all melting points were in the range 62–64°.

This general procedure, using trimethylbenzene as a solvent, with a two hour reaction time, was applied to 3-methyl-5-alkyl-2-cyclohexen-1-ones to provide the results shown in Table II. The dehydrogenation of the 3-methyl-2,5-dialkyl-2-cyclohexen-1-ones listed in Table III gave the corresponding phenols in the yield indicated in Table IV. In the case of trialkylphenols, the isolation procedure was modified in the following way. After removal of the catalyst, the organic solution was extracted with 5% sodium hydroxide solution; this alkaline wash was discarded. (In preliminary experiments, there were indications that small amounts of unchanged 4-carbethoxycyclohexenones were occasionally present in the alkylated products, and this in turn would perhaps result in small amounts of 3,5-dialkylphenols along with the desired 2,3,5-trialkylphenols. In later experiments, the alkylated esters and ketones were fractionated carefully, but at the same time this step was retained. 3,5-Dialkylphenols may be extracted from organic solvents with aqueous alkali, while 2,3,5-trialkylphenols require Claisen alkali for extraction.) The phenolic product was then extracted with Claisen solution, and the extract was washed with pentane. The alkaline solution was diluted and acidified with hydrochloric acid, with cooling. Liquid phenols were isolated by extraction with ether, and the crude products were distilled under reduced pressure through a small Vigreux column.

**Disproportionation to 3,5-Dimethylcyclohexanone.**—The dehydrogenation of 5.00 g. of 3,5-dimethyl-2-cyclohexen-1-one was carried out under the usual conditions in 15 ml. of phenyl ether. After extraction of the phenolic fraction with 10% sodium hydroxide solution, the organic solution was steam distilled to provide a distillate which included ethyl acetate, a ketonic fraction, and traces of phenyl ether. The organic layer was separated, and the aqueous layer extracted with 30 ml. of ether. The combined organic solutions were dried with magnesium sulfate, and the ether was evaporated by warming. The residue was added to 15 ml. of ethanol containing 2.7 g. of semicarbazide hydrochloride, and 5.0 ml. of pyridine. After a reflux period of four hours, 30 ml. of ethanol was added, and approximately 30 ml. of solvents (ethanol-ethyl acetate) was removed by distillation. The residue was poured into 100 ml. of ice-water, and the colorless crystalline product was removed by filtration, washed well with water, and air dried. The dry product was triturated with pentane to remove traces of phenyl ether; the residue was 1.58 g. of colorless material, m. p. 192–194° (dec.). A mixed m. p. with a sample of 3,5-dimethylcyclohexanone semicarbazone, prepared separately, was not depressed.

In a separate experiment, it was found that the semicarbazone of 3,5-dimethylcyclohexanone could be obtained in 88% yield, using the alcohol–pyridine method

with the quantities indicated above, with 2.50 g. of ketone. This indicated that the isolation methods used in the experiment described accounted for approximately 25% of the starting material as 3,5-dimethylcyclohexanone, and about 50% as 3,5-dimethylphenol.

**3,5-Dimethylcyclohexanone.**—3,5-Dimethyl-2-cyclohexen-1-one was hydrogenated in a low-pressure apparatus, using a 5% palladium–carbon catalyst without added solvent. The boiling point of the product was 62–66° (9 mm.). The semicarbazone, prepared by the alcohol–pyridine method, was a colorless solid, m. p. 194–195° (dec.) after crystallization from methanol (crude m. p. 194–196° (dec.)).

This ketone was described by Knoevenagel[6] as a mixture of *cis* and *trans* forms, giving a semicarbazone melting at 190–196°. The configuration of the methyl groups of the product obtained here is not known, but the materials obtained by catalytic reduction and by disproportionation were evidently identical.

**3-Methyl-2,5-dialkyl-2-cyclohexen-1-ones.**—These ketones were prepared through the sodamide alkylation of 3-methyl-5-alkyl-4-carbethoxy-2-cyclohexen-1-ones[3] with the appropriate alkyl iodide, as illustrated by the following example.

A. Alkylation: Sodamide was prepared in the usual way from 12.0 g. (0.52 mole) of sodium and about 500 ml. of liquid ammonia, using ferric nitrate nonohydrate as a catalyst. There was added 98.6 g. (0.50 mole) of 3,5-dimethyl-4-carbethoxy-2-cyclohexen-1-one over ten minutes; a yellow amorphous salt formed immediately. About 350 ml. of dry ether was added, and the ammonia was allowed to evaporate. The precipitated salt became increasingly viscous, but stirring was continued as much as possible. A total of 125 g. (0.8 mole) of ethyl iodide was added in small portions as the mixture was brought to reflux temperature, and finally 100 ml. of dry ether and 100 ml. of dry toluene was added. The mixture was heated under reflux with stirring in a nitrogen atmosphere for nine hours. After addition of water, the organic solution was separated, washed with 5% aqueous acetic acid and water, and dried over magnesium sulfate. The ether and toluene were removed by distillation at atmospheric pressure, and the residue was fractionated through a 12-inch Vigreux column. The yield was 78.7 g. (70%) of **2-ethyl-3,5-dimethyl-4-carbethoxy-2-cyclohexen-1-one** as a light yellow oil, b. p. 128–135° (4 mm.).

*Anal.* Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.98. Found: C, 69.80; H, 9.09.

The red-orange **2,4-dinitrophenylhydrazone** melted at 107.5–109°.

*Anal.* Calcd. for $C_{19}H_{24}O_6N_4$: C, 56.43; H, 5.98. Found: C, 56.53; H, 5.89.

Alkylation of the same ketoester with *n*-butyl iodide (with a thirty-six-hour reflux period) gave a 43% yield of **2-*n*-butyl-3,5-dimethyl-4-carbethoxy-2-cyclohexen-1-one**, b. p. 150–151° (4–5 mm.).

*Anal.* Calcd. for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59. Found: C, 71.37; H, 9.77.

An alkylation of 3-methyl-5-isopropyl-4-carbethoxy-2-cyclohexen-1-one with ethyl iodide gave a 61% yield of 2-ethyl-3-methyl-5-isopropyl-4-carbethoxy-2-cyclohexen-1-one, b. p. 137–150° (4 mm.). The boiling range indicated that this material was not homogeneous, and it was hydrolyzed directly to the desired ketone without additional fractionation.

These two alkylated esters gave 2,4-dinitrophenylhydrazones which could be obtained only as red, noncrystalline gums. In the course of alkylation it is necessary for the double bond to shift to the 3,4-position, and this unusual behavior of the dinitrophenylhydrazones may indicate that the esters are mixtures of 2,3- and 3,4-double bond isomers.

B. Hydrolysis and decarboxylation: A solution of 71.2 g. (0.32 mole) of 2-ethyl-3,5-dimethyl-4-carbethoxy-2-cyclohexen-1-one, 40 g. (1.0 mole) of sodium hydroxide, 160 ml. of water and 75 ml. of ethanol (95%) was heated under reflux for three and one-half hours. The warm solution was acidified by the slow addition of 150 ml. of 1:1 sulfuric acid; a vigorous evolution of carbon dioxide resulted. The acidified mixture was boiled under reflux one and one-half hours, cooled and extracted with ether. The ether solution was washed well with 5% sodium hydroxide solution, with 2% aqueous acetic acid, with water, and dried over magnesium sulfate. The ether was removed, and the residue distilled under reduced pressure through a 12-inch Vigreux column to yield 25.1 g. (52%) of 2-ethyl-3,5-dimethyl-2-cyclohexen-1-one.

The yields, boiling points and derivatives of these trialkylcyclohexenones are liste in Table III.

## Summary

A series of di- and trialkylcyclohexenones have been dehydrogenated with a palladium–carbon catalyst to the corresponding di- and trialkylphenols. The yields were usually 40–50%; in the case of arylcyclohexenones the yield is usually 70–85%, and the lowered yield observed here is apparently due to a greater tendency for the alkylcyclohexenones to undergo disproportionation.

The procedures described here provide a route to certain types of alkyl-substituted phenols which are not available by ordinary aromatic substitution methods.

# The Synthesis of Some Cyclopropane Hydrocarbons from Methyl Cyclopropyl Ketone[1]

BY ROSS VAN VOLKENBURGH, K. W. GREENLEE, J. M. DERFER AND C. E. BOORD

This paper describes the synthesis of three cyclopropane hydrocarbons from methyl cyclopropyl ketone obtained from a commercial source.[2]

Ethylcyclopropane was prepared by a Wolff–Kishner reduction of the ketone at atmospheric pressure, the method used being a modification of that of Herr, Whitmore and Schiessler[3] who first described a practical procedure for carrying out this reaction without the use of pressure equipment. These workers decomposed the hydrazone of methyl cyclopropyl ketone with sodium methylate in triethylene glycol by heating the mixture to a maximum temperature of 200°; the yield of ethylcyclopropane was about 60%. In the present work the reaction was carried out in diethylene glycol and the cheaper and more easily handled sodium hydroxide was used in place of sodium methylate; the yield of purified ethylcyclopropane was 72%, and the physical properties obtained were an improvement over the best previously reported (Table II).

Isopropenylcyclopropane was produced by dehydration of dimethylcyclopropylcarbinol, this product being obtained from the reaction of methyl cyclopropyl ketone and the Grignard reagent from methyl chloride. Four methods of dehydration were investigated: catalytically over (A) activated alumina, (B) oxalic acid, (C) sulfuric acid, and chemically (D) by the Tschugaeff xanthate method. Table I summarizes the products and yields (from the carbinol) obtained by fractional distillation (25 plates) of the organic material resulting by each method; headings, tailings and residues (largely polymerization products) are not shown in the table because of the inherent difficulty of calculating yields on these mixtures.

TABLE I

| | Method A | B | C | D |
|---|---|---|---|---|
| Isopropenylcyclopropane, % | 12 | 57 | 80 | 24 |
| Methylpentadiene, % | 20 | .. | .. | .. |
| 2,2-Dimethyltetrahydrofuran, % | 10 | 15 | .. | .. |

It will be noted that of the first three methods, the one employing the strongest acid (sulfuric) gave the highest yield of isopropenylcyclopropane. The formation of this hydrocarbon is best explained by a Whitmore-type[4] mechanism involving a carbonium ion, this ion (cyclopropyldimethylcarbonium) apparently being most easily stabilized without rearrangement by expulsion of a proton from one of the methyl groups, rather than by ring rupture or expansion. It is noteworthy that the tertiary hydrogen atom on the cyclopropane ring is not expelled to produce isopropylidenecyclopropane. An explanation of this behavior is possible if it is recalled that the cyclopropane group sometimes appears to have many of the attributes of a double bond and the structure of isopropenylcyclopropane may thus be considered as somewhat analogous to that of isoprene. This would account for the failure in the present case of hydrogen to be expelled according to Saytzeff's rule (since its nature would be somewhat vinylic) and for the consequent expulsion of a hydrogen atom from a methyl group normally low in reactivity, to form the pseudoconjugate isopropenylcyclopropane, stabilized to some extent by resonance. Further, the strain of a double bond attached to a three membered ring may also be a factor. Since more than one mechanism is apparently involved in methods (A) and (B), it appears that as the acid strength of the catalyst is increased, the reaction proceeds through the carbonium ion to a greater extent. Inasmuch as nothing except isopropenylcyclopropane was found when method C was used, the dehydration over sulfuric acid must have proceeded almost exclusively through the carbonium ion mechanism.

The structure of isopropenylcyclopropane was proved by an ozonolysis experiment (on a sample prepared by method C) from which methyl cyclopropyl ketone was isolated and identified through its semicarbazone; a mixed melting point with the corresponding derivative of an authentic sample of the ketone showed no depression. The physical properties of a sample of isopropenylcyclopropane of 99.4 mole per cent. purity are given in Table II. In order to verify the identity of the isopropenylcyclopropane prepared by the other three methods, a series of mixed melting points were determined with a portion of the hydrocarbon whose structure had been proved by ozonolysis; no significant depression occurred with any of the samples.

The preparation of isopropylcyclopropane by the hydrogenation of isopropenylcyclopropane under mild conditions was investigated. In the

TABLE II

| | B. p., °C. (760 mm.) | F. p., °C. | $d^{20}_4$ | $n^{20}D$ | Estimated purity[a] |
|---|---|---|---|---|---|
| Ethylcyclopropane (this work) | 35.94 | −149.41 | 0.6839 | 1.3786 | 99% |
| Ethylcyclopropane (Whitmore)[3] | 36.0 | ..... | .... | 1.3784 | .. |
| Isopropenylcyclopropane (this work) | 70.41 | −102.36 | .7514 | 1.4254 | 99.4 |
| Isopropenylcyclopropane (Van Keersbilck[7]) | 69.5 to 70.0/751 | ..... | .74999 | 1.42524 | .. |
| Isopropylcyclopropane (this work) | 58.7 | −118.3 | .6889 | 1.3833 | 85 |
| 2-Methylpentane[8] | 60.27 | −153.68 | .6532 | 1.3715 | .. |
| 2,3-Dimethylbutane[8] | 57.99 | −128.41 | .6616 | 1.3750 | .. |

[a] These values were calculated from cryoscopic data. For isopropenylcyclopropane the $\Delta t$/mole per cent. impurity was determined as 0.25°, and by use of this datum and analysis of the freezing curve the "100% pure" freezing point for this hydrocarbon was calculated to be −102.20°. Likewise for isopropylcyclopropane the $\Delta t$/mole per cent. impurity was 0.20° and the "100% pure" freezing point was −115.24°.

three trials, the best sample of isopropylcyclopropane[5] obtained (see Table II) was only 85 mole per cent. pure as calculated from cryoscopic data. The chief impurity appeared to be 2-methylpentane formed by rupture of the cyclopropane ring at the bond adjacent to the side chain; 2,3-dimethylbutane (the other possible product formed by ring rupture) was not detected.

While the completely preferential hydrogenation of a double bond in the presence of a cyclopropane ring would seem feasible in consideration of the severity of conditions required for rupturing the cyclopropane ring,[6] the present case appears to be an exception. This may be explained if, as before, isopropenylcyclopropane is considered to be pseudoconjugated. It may then be proposed that some addition of hydrogen proceeded "1,4-," as in the case of a truly conjugated diene, leading to rupture of a ring C–C bond adjacent to the side chain, with the intermediate formation of 2-methyl-2-pentene and finally 2-methylpentane.

When a sample of about 80% pure isopropylcyclopropane was hydrogenated under conditions vigorous enough to cause hydrogenolysis, 2,3-dimethylbutane was the major component of the resulting mixture.[5] 2-Methylpentane (the impurity in the isopropylcyclopropane hydrogenated) was detected as only a minor component, and an unidentified paraffin was also present in very small amount. No unchanged isopropylcyclopropane was found. This study seems to indicate that in the hydrogenation of isopropenylcyclopropane under mild conditions, the 2-methylpentane impurity was not formed by hydrogenolysis of the newly formed isopropylcyclopropane, but by some mechanism such as that proposed above.

Striking evidence for conjugation is found in the boiling point of isopropenylcyclopropane which is 11.7° higher than that of isopropylcyclopropane. This suggests that isopropenylcyclopropane is comparable to 2,3-dimethyl-1,3-butadiene which, due to conjugation, boils about 13.3° higher than 2,3-dimethyl-1-butene; the latter, by contrast, actually boils 2.4° lower than the saturated analog, 2,3-dimethylbutane. Similarly, the refractive index of isopropenylcyclopropane shows an exaltation of 0.0267 (at 20°) which approaches the exaltation of 0.0332 exhibited by 2,3-dimethyl-1,3-butadiene.

## Experimental

**Methyl Cyclopropyl Ketone.**—The commercial product[2] was distilled at about 25-plate efficiency, 78% of the charge being obtained as good product with the following physical properties: b. p. 111.2° (760 mm.), f. p. −68.3°, $d^{20}_4$ 0.8991, $n^{20}D$ 1.4250.

**Ethylcyclopropane.**—The apparatus and general procedure described by Whitmore and his co-workers[3] were used with the following exceptions: The hydrazone from 74 g. (0.879 mole) of methyl cyclopropyl ketone was prepared using 122 g. (2.06 moles) of hydrazine hydrate,[9] 200 ml. of diethylene glycol, and 5 ml. of acetic acid. The hydrazone was cooled and dropped slowly into a solution of 60 g. (1.5 moles) of sodium hydroxide in 200 ml. of diethylene glycol at a temperature of 180–200°. The hydrocarbon collected weighed 47.0 g. (76% yield from the ketone) and had a refractive index of 1.3786 at 20°. Distillation of this material at about 15-plate efficiency gave 44.2 g. of constant index material ($n^{20}D$ 1.3786), a 72% yield. The physical properties of ethylcyclopropane (Table II) were determined on a center cut from the redistillation of the constant index fractions. The product did not absorb bromine from a carbon tetrachloride solution in the cold.

**Dimethylcyclopropylcarbinol.**—Methyl chloride was added as a gas below the liquid surface to 267 g. (11.0 moles) of magnesium turnings in 4 liters of ether in a 5-gallon copper-lined reactor provided with a steel stirrer. Addition was continued until all of the magnesium turnings were used up, after which the mixture was refluxed about an hour before the slow addition of 841 g. (10.0 moles) of methyl cyclopropyl ketone in 2 liters of dry ether was begun. When the last of the ketone had been added and reflux had been maintained for a period of two days, the reaction mixture was hydrolyzed with 1 liter of saturated ammonium chloride solution. (A large excess of ammonium chloride is undesirable as it apparently converts significant quantities of the newly formed carbinol to a chloride which appears as "tailings" when the product is distilled.) The mixture was then washed, stripped of ether, and distilled at about 20-plate efficiency to obtain 679 g. (68% yield from ketone) of good dimethylcyclopropylcarbinol, 146 g. (15% yield) of material

(5) This sample was examined spectroscopically (infrared) by F. P. Hochgesang of the Socony-Vacuum Laboratories, Paulsboro, N. J.

worth redistillation and 50 g. of a high boiling residue. In a subsequent run of 5-mole proportions over twice as much of the high boiling material was obtained and had the following physical properties: b.p. *ca.* 73° (50 mm.), $n^{20}D$ 1.443 to 1.495; this material contained chloride (or chlorides), the probable genesis of which has been explained. The physical properties determined for the carbinol follow, the values in brackets are those of Bruylants[10] given for comparison: b.p. 123.4° (760 mm.) (123.4 to 123.6° (752 mm.)), $d^{20}_4$ 0.8842 (0.88063), $n^{20}D$ 1.4337 (1.43257), f. p. −43.0°.

**Isopropenylcyclopropane.**—Dimethylcyclopropylcarbinol was dehydrated in four different ways:

**A. Over Activated Alumina.**—A 2.4 (i.d.) × 120.0 cm. pyrex tube was placed in a vertical furnace and packed with 4–8 mesh, Grade F-1, Alorco alumina which was activated by heating to 300° and passing air through the tube overnight. The tube and its contents were cooled to 250° and the carbinol (154 g., 1.54 moles) was passed through at a rate of one drop per three seconds at this temperature. The conversion based on the water collected was 49%, and the yield of organic material was 95 g. This was distilled at about 30-plate efficiency with the results shown in Table I. No evidence was found for the presence of unchanged carbinol, and a subsequent run at 300° showed that the yield of isopropenylcyclopropane was decreased at the higher temperature, more of the other products being formed.

**B. Over Oxalic Acid.**—The carbinol (197 g., 1.97 moles) was dehydrated by boiling it with 10% its weight of oxalic acid and distilling off the low boiling products as they formed. After washing and drying, the product weighed 145 g. and was distilled at about 30-plate efficiency. The analysis of this distillation is shown in Table I.

**C. Over Sulfuric Acid.**—Twelve drops of concentrated sulfuric acid were added to 152 g. (1.52 moles) of the carbinol in a half-liter flask attached to a glass packed distilling column. The mixture was heated to a gentle boil, and the hydrocarbon was distilled through the column and collected as the carbinol was dehydrated. The crude product, washed and dried, weighed 104 g. and was distilled at about 20-plate efficiency (see Table I).

**D. By the Tschugaeff Xanthate Method.**[11]—Two liters of reagent grade "xylene" were dried by percolation through a column of silica gel and placed in a 5-liter flask equipped with a stirrer, dropping funnel and reflux condenser. Sixty-nine grams (1.76 moles) of metallic potassium, scraped free of oxide, were added, and the flask was heated until the potassium melted. The addition of 176 g. (1.76 moles) of dimethylcyclopropylcarbinol was begun dropwise and continued until complete (one and one-half hours). Carbon disulfide (151 g., 1.98 moles) was added slowly to the cooled mixture, after which 286 g. (2.02 moles) of methyl iodide was added over a period of one and one-half hours. After standing overnight, the mixture was refluxed at 65° for about ten hours and then was allowed to cool and stand for several days at room temperature. The solid potassium iodide was removed by filtration and the organic material adhering to it was leached with xylene. The bulked xylene solution of the xanthate was placed in a flask attached to a column packed with glass helices, and the xanthate was decomposed by heating at 130–135° for about eight hours, the hydrocarbon being distilled from the mixture as it formed. The distillate was washed with 25% sodium hydroxide, steam distilled, and fractionated at about 20-plate efficiency to obtain 80 g. of material (b.p. 53–80°) which smelled strongly of organic sulfur compounds. This product was washed again with 25% sodium hydroxide, then with water, and was dried over anhydrous sodium sulfate before being treated with sodium in liquid ammonia. The treated material still had a strong odor so it was shaken with saturated mercuric chloride solution and water, and, after steam distillation, was washed with dilute hydrochloric acid and dried over sodium sulfate. By distillation of this product at about 30-plate efficiency nothing except isopropenylcyclopropane was detected, but the yield was low (Table I).

**Proof of Structure of Isopropenylcyclopropane by Ozonolysis.**—A portion (11.79 g.) of the isopropenylcyclopropane obtained from the sulfuric acid dehydration of dimethylcyclopropylcarbinol was ozonized by the procedure and in the apparatus described by Henne and Perilstein,[12] acetic acid being used as the solvent. The solution of the ozonide was poured into 25 ml. of water, 5 g. of zinc dust was added, and, after standing overnight, the mixture was heated on a steam-bath for one-half hour. After decantation from the zinc, the organic material was distilled at about 20-plate efficiency, that portion boiling under 100° being collected. This water–ketone fraction was treated with 10 g. of semicarbazide hydrochloride, 15 g. of sodium acetate, and sufficient water to make a total volume of 100 ml. The mixture was heated on a steam-bath for a few minutes, and, on cooling, 6.3 g. (32% yield) of the crude semicarbazone crystallized. After 4 recrystallizations from absolute alcohol 3.2 g. (16% yield) of the semicarbazone remained and had a melting point of 121.4 to 122.5°. The semicarbazone prepared from an authentic sample of methyl cyclopropyl ketone in the same manner melted at 121.7 to 122.4°, and a mixed melting point showed no depression.

**Isopropylcyclopropane.**—A sample (56 g., 0.68 mole) of isopropenylcyclopropane was hydrogenated in a glass liner over Raney nickel at 40° and a pressure of 900 p.s.i. Fractionation of the hydrogenate indicated that the reduction was only about 40% complete, and that some 2-methylpentane (ring fission product) was present. A "best" fraction from this distillation had the following properties: b. p. 58.2 to 58.6° (uncor.), $n^{20}D$ 1.3850 to 1.3851.

A second hydrogenation was carried out as before using 70 g. (0.86 mole) of isopropenylcyclopropane (known purity 98.7 mole per cent.); the maximum temperature reached was 97°, and the maximum pressure 800 p.s.i. The product, separated from the nickel catalyst, was washed with 10% permanganate solution several times, but after steam distillation it still showed unsaturation. Instead of further permanganate treatment, the material was distilled at 20-plate efficiency. The main portion boiled at 58.5 to 58.8°, but the refractive index after rising to a maximum of 1.3842 for the second fraction dropped off gradually to 1.3774 toward the end of the distillation. It was evident that far more 2-methylpentane was present than that contained in the sample hydrogenated. The amount of impurity present in the hydrogenate, assuming the impurity to be 2-methylpentane, was calculated to be 12 to 13 g., or about 17 mole per cent. of the charge.

In a third attempt, 80 g. of isopropenylcyclopropane were hydrogenated over Raney nickel catalyst, at 35–40° and 1100 p.s.i., with 90% of the theoretical amount of hydrogen absorbed. The hydrocarbon recovered by washing the crude hydrogenate with water, steam distilling, and drying over anhydrous sodium sulfate was 82% of theory; it was distilled at about 30-plate efficiency. The first 6% of the distillate boiled from 57.9 to 58.6° and may have contained a little 2,3-dimethylbutane, but the refractive index, 1.3834 at 20°, was only slightly lower than the maximum which followed immediately on the curve. The next 45% boiled from 58.6 to 58.8° while the refractive index slowly dropped from 1.3836 to 1.3829; the physical properties listed in Table II were determined on this portion. Distillation was continued until a temperature of 59.0° was reached; meanwhile the refractive index dropped to 1.3811, presumably due to 2-methylpentane which would be expected to appear in the tailings. By a study of infrared absorption spectra,[5] 2-methylpentane was identified as an impurity in the portion of the distillate used in determining physical properties; 2,3-dimethylbutane was not detected and was judged to comprise less than 6% of the sample, if present at all.

**Hydrogenolysis of Isopropylcyclopropane.**—A sample of isopropylcyclopropane (b. p. 58.5 to 58.8°, $n^{20}D$ 1.3823–1.3841) was hydrogenated over 10% its weight of nickel-on-kieselguhr catalyst. Absorption of hydrogen began at 150° and 1250 p. s. i. When absorption had ceased, the temperature was raised to 200°, whereupon further absorption occurred (from 1220 p. s. i.). Further increase in temperature did not cause additional reaction. The hydrogenate was washed with water and dried over anhydrous sodium sulfate; this material (b. p. 53–61° (760 mm.), $n^{20}D$ 1.3740) was sent for infrared analysis.

**Acknowledgment.**—Sincere appreciation is expressed to Dr. F. P. Hochgesang for his determination and interpretation of the infrared absorption spectra of some of the hydrocarbon samples described herein.

## Summary

Ethylcyclopropane, isopropenylcyclopropane and isopropylcyclopropane have been synthesized from methyl cyclopropyl ketone. Evidence for the behavior of isopropenylcyclopropane as a pseudoconjugated system has been presented.

# A New Synthesis of Monoalkylcyclobutanes: Reduction of Neopentyl Type Tribromides[1]

BY JOHN M. DERFER, KENNETH W. GREENLEE AND CECIL E. BOORD

## Introduction

Hydrocarbons of the cyclopropane or cyclobutane series have been produced by the dehalogenation (or dehydrohalogenation) of mono-, di- and tetrahalo derivatives of neopentane.

Whitmore[2,3,4] and his co-workers have shown that the reaction of neopentyl chloride with an equivalent amount of metallic sodium gives a 25% yield of 1,1-dimethylcyclopropane; the overall yield of this hydrocarbon is increased to 51% when a four-fold excess of the chloride is employed. When propyl sodium is used instead of metallic sodium, the cyclopropane hydrocarbon is formed in 75% yield.

The debromation of *sym*-dibromoneopentane by either the Gustavson[5a] or the Hass–McBee[6] method gives good yields of 1,1-dimethylcyclopropane.[3,5b,7]

The products from the reduction of pentaerythrityl tetrabromide by the Gustavson method have been identified by Whitmore and Williams[8] as 2-methyl-1-butene and methylenecyclobutane in the ratio of about 1:11, respectively; Murray and Stevenson,[9] using Raman spectra, found traces of spiropentane also to be present. Slabey[10] found that when sodium iodide and sodium carbonate are added to the reaction mixture, the hydrocarbon product (obtained in 79–89% yield) consists of spiropentane (25%), methylenecyclobutane (56%), 2-methyl-1-butene (15%) and traces of 1,1-dimethylcyclopropane. When the Hass–McBee procedure is employed in the reduction of pentaerythrityl tetrabromide, a 38% yield of hydrocarbon material is obtained; this consists of 47–60% of spiropentane and smaller amounts of methylenecyclobutane and 2-methyl-1-butene.[10,11]

There is no indication in the literature that any investigation has ever been made concerning the debromination (or dehydrobromination) of tribromides containing the neopentyl structure, or even that such halides have ever been prepared. The present work not only closes this gap, but also appears to furnish a general and practical method for the preparation of monoalkylcyclobutanes with the possible exception of methylcyclobutane.

The general scheme employed in this work has been to prepare neopentyl type tribromides from the corresponding trihydric alcohols and to treat them with zinc by the Hass–McBee[6] procedure. Alkylidenecyclobutanes are formed in about 50% yield and can be hydrogenated to the corresponding alkylcyclobutanes. The method has been applied to three tribromides: 1,1,1-tris-(bromomethyl)-propane, 1,1,1-tris-(bromomethyl)-2-methylpropane and 1,1,1-tris-(bromomethyl)-ethane.

## Discussion

**Reduction of 1,1,1-tris-(Bromomethyl)-propane.**—The reaction of this tribromide with zinc by the Hass–McBee procedure[6] produced a mixture of hydrocarbons in yields of 90–93% of theory. Fractionation of this material at about

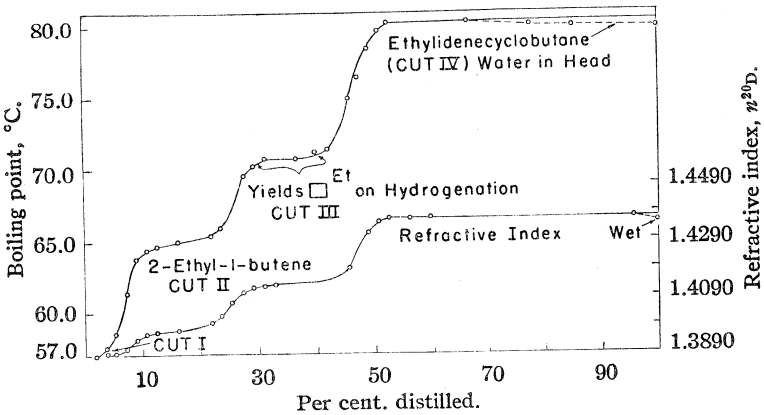

Fig. 1.—Curves describing the distillation of the crude product from the reduction of 1,1,1-tris-(bromomethyl)-propane.

40-plate efficiency[12] (Fig. 1) separated it into four cuts boiling at approximately 56, 64, 70 and 80°; these fractions constituted 3 (estm.) 12, 18, and 54% of the crude hydrocarbon mixture by weight, respectively and will be designated as Cut I, Cut II, Cut III and Cut IV.

The highest boiling and preponderant fraction (Cut IV) was shown to be a very pure individual compound by its time–temperature freezing curve and it was identified as ethylidenecyclobutane (not previously reported) by an ozonolysis experiment[13] from which both acetaldehyde and cyclobutanone were isolated and identified. Hydrogenation of ethylidenecyclobutane over Raney nickel at low pressures and temperatures gave ethylcyclobutane exclusively and quantitatively; the physical properties for this material were an improvement over those reported by Wibaut[14] for ethylcyclobutane prepared by another method.

Refractionation of Cut III at about 40-plate efficiency and determination of densities, refractive indices and standard boiling points on about every third fraction showed that this material was a mixture, and that it could not be separated by fractionation (Fig. 2) on the best column available (40-plates). The mixture gave ethylcyclobutane exclusively on hydrogenation, thus limiting the possible constituents to five substances: the two ethylcyclobutenes, ethylidenecyclobutane, vinylcyclobutane and ethylcyclobutane, itself. Oxidation of Cut III with chromic anhydride and glacial acetic acid failed to attack about 30% of it; the unoxidized material was identified as ethylcyclobutane on the basis of its physical properties and a mixed freezing point determination with an authentic sample of this hydrocarbon. By oxidation of Cut III with aqueous sodium dichromate–sulfuric acid solution, a small amount of material was isolated with physical properties in good agreement with those of cyclobutane carboxylic acid; esterification of this material with ethyl alcohol produced a substance which had approximately the same boiling point as the ethyl ester of cyclobutane carboxylic acid, and a carbon–hydrogen analysis gave values in fair agreement with the values calculated for this ester. Identification of this acid in the oxidation products indicated that a second component (about 70% of Cut III) was vinylcyclobutane; no evidence for the presence of either of the ethylcyclobutenes was found. The infrared absorption spectrogram of Cut III (Fig. 3) shows the characteristic absorption of an alpha olefin at 6.1 microns; vinylcyclobutane is the only olefin which would both exhibit this characteristic and hydrogenate to ethylcyclobutane.

Since both Cut III and Cut IV can be hydrogenated quantitatively to ethylcyclobutane, the over-all yield of ethylcyclobutane which can be produced by this reaction is about 65% of theory, based on the tribromide.

Cut II was identified as 2-ethyl-1-butene on the basis of its physical properties and by a mixed freezing point determination with an authentic sample of 2-ethyl-1-butene.

Cut I was shown conclusively to be 1-methyl-1-ethylcyclopropane (hitherto unreported) by subjecting it to hydrogenation at high pressures and temperatures and identifying the 2,2-dimethylbutane (neohexane) produced in this manner. (This type of hydrogenation is known to rupture the cyclopropane ring by splitting the bond opposite to the gem-substituted carbon atom.[7])

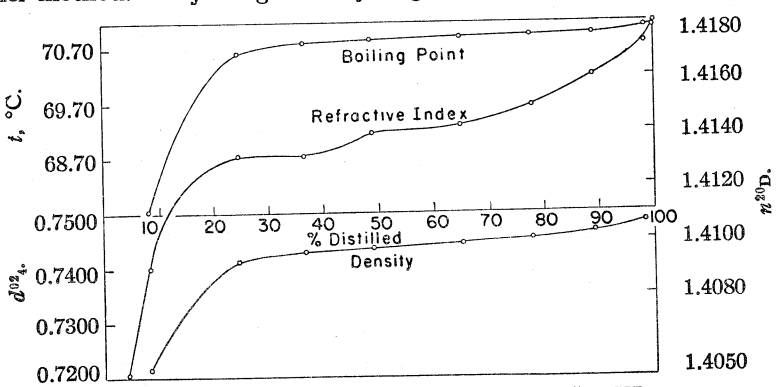

Fig. 2.—Curves describing the redistillation of Cut III.

Reduction of 1,1,1-tris-(bromomethyl)-propane by zinc in 45–80% *aqueous ethanol* produced chiefly an ether, tentatively identified as ethyl 1-ethylcyclopropylcarbinyl ether. No apparent reaction

(12) All plate ratings given in this paper represent estimates of column efficiency under actual operating conditions.

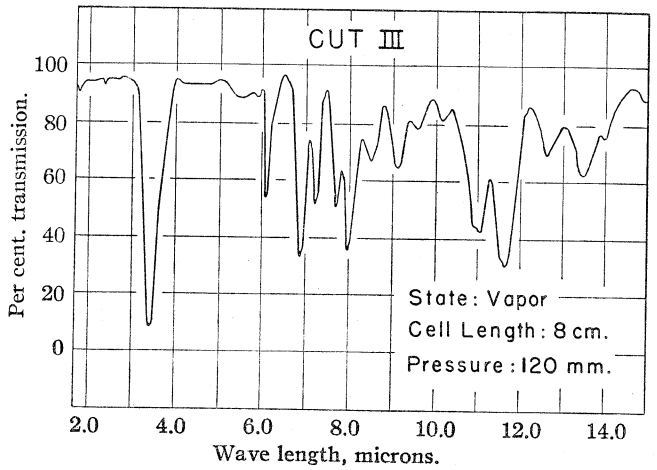

Fig. 3.—Infrared absorption spectrogram of Cut III.

took place between zinc and the tribromide in *anhydrous dioxane;* when a small amount of water was added to the mixture, reaction occurred, but no single product could be isolated.

**Reduction of 1,1,1-tris-(Bromomethyl)-2-methylpropane.**—The reaction of this tribromide with zinc by the Hass–McBee procedure produced a 97% yield of crude hydrocarbon material. Fractionation of this material at about 40-plate efficiency (Fig. 4) separated it into a forerun containing no constant refractive index or constant boiling fractions and a higher boiling cut (about 50% of the charge) which distilled at an essentially constant temperature (107°) and had a constant refractive index (1.4459).

The 107° material was shown to be a very pure individual compound by its time-temperature freezing curve, and was identified as isopropylidenecyclobutane (not previously reported) by an ozonolysis experiment from which both acetone and cyclobutanone were isolated and identified. Hydrogenation of isopropylidenecyclobutane over Raney nickel at low pressures and temperatures gave isopropylcyclobutane exclusively; physical properties determined on this material were an improvement over those reported for it by Kasansky.[15] The forerun was hydrogenated to saturation over Raney nickel at low pressures and temperatures; about 57% of the theoretical amount of hydrogen was absorbed, indicating that about this percentage of the forerun consisted of olefinic hydrocarbons. Fractionation of the hydrogenated material at about 40-plate efficiency separated it into two cuts boiling 81.7–83.2° and 88.8–92.1°. The lower boiling material was shown to be 1-methyl-1-isopropylcyclopropane (hitherto unreported) by a comparison of the infrared absorption spectrograms of its high pressure hydrogenation product (Fig. 5-A) with that of the expected product, 2,2,3-trimethylbutane (Fig. 5-B); these spectrograms are, for practical purposes, identical. The higher boiling material was found to be a mixture of 2,3-dimethylpentane and isopropylcyclobutane by a comparison of physical data (Table I), including infrared absorption spectrograms (Fig. 5-C-D-E). All characteristic bands of these two substances are present in the spectrogram of the mixture. By analogy with the corresponding study of the reaction producing ethylidenecyclobutane as the chief product, isopropylcyclobutane was undoubtedly a component of the unhydrogenated forerun; the 2,3-dimethylpentane identified in the hydrogenated material came from olefins with the same carbon skeleton, chief among which, by further analogy, was undoubtedly 3-methyl-2-ethyl-1-butene. Some isopropenylcyclobutane may also have been present, but the presence of one or both of the isopropylcyclobutenes seems improbable.

TABLE I

| | 2,3-Dimethylpentane | Isopropylcyclobutane | This material |
|---|---|---|---|
| B. p., °C. (760 mm.) | 89.8 | 92.70 | 88.8–92.1 |
| $d^{20}_4$ | 0.6951 | 0.7376 | 0.7213 |

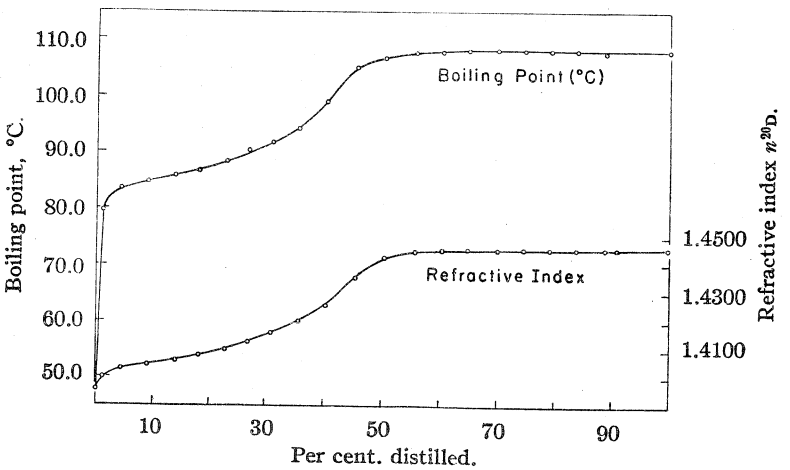

Fig. 4.—Curves describing the distillation of the crude product from the reduction of 1,1,1-tris-(bromomethyl)-2-methylpropane.

**Reduction of 1,1,1-tris-(Bromomethyl)-ethane.**—This tribromide was treated with zinc by the Hass–McBee procedure in the usual manner. The highest yield of hydrocarbon material obtained was 65%. Fractionation of this material at about 40-plate efficiency (Fig. 6) separated it into three cuts boiling at approximately 20, 31 and 37–43°; these fractions were

(15) Kasansky, *Ber.*, **69**, 950 (1936).

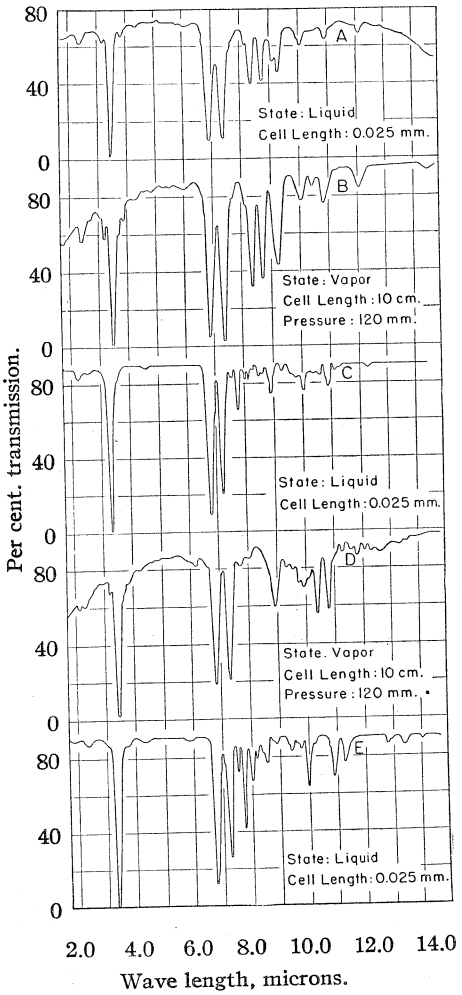

Fig. 5.—Infrared absorption spectrograms of: A, product formed by the hydrogenation of 1-methyl-1-isopropylcyclopropane; B, authentic sample of 2,2,3-trimethylbutane; C, 90° cut in the distillation of the hydrogenated forerun from the isopropylidenecyclobutane synthesis; D, authentic sample of 2,3-dimethylpentane; E, isopropylcyclobutane.

about 15, 38 and 47% of the crude hydrocarbon mixture by weight, respectively.

The 37–43° cut (expected to be relatively pure methylenecyclobutane) was a mixture ($n^{20}$D 1.3970–1.4203) which could not be separated into its components by redistillation at about 25-plate efficiency. About 78% of the theoretical amount of hydrogen was absorbed when this mixture was hydrogenated to saturation at low pressures and temperatures. Fractionation of the hydrogenate at about 20-plate efficiency produced no constant refractive index material (b. p. 34.6–36.6°, $n^{20}$D 1.3800–1.3880). An infrared absorption spectrogram of a cut soon after the obvious headings showed the material to be largely methylcyclobutane; no positive evidence as to the identity of the impurity could be obtained from the spectrogram. None of the fractions crystallized at liquid air temperature, but rather formed a viscous sirup. It is believed that methylcyclobutane of good purity could be obtained if the reaction were carried out on a large enough scale to permit the use of high-efficiency columns and other techniques not used in this work because of the small quantities of material involved. The original unhydrogenated material probably consisted of methylenecyclobutane (b. p. 42.2°, $n^{20}$D 1.4208), methylcyclobutane (b. p. 36.6°, $n^{20}$D 1.3875), and an unidentified impurity.

The 31 and 20° cuts were identified as 2-methyl-1-butene and 1,1-dimethylcyclopropane, respectively, as anticipated.

From the reaction residue were isolated two high-boiling by-products tentatively identified as 1-methylcyclopropylcarbinol and di-(1-methylcyclopropylmethyl) ether. Their formation was attributed to the reaction of 1-methyl-1-(bromomethyl)-cyclopropane with water produced by the interaction of protons with carbonate ions, carbonic acid thus being formed; evolution of carbon dioxide was noted during the reaction.

## Reaction Mechanisms

Logical mechanisms have been proposed for the formation of all products from these reactions. These mechanisms will be demonstrated for the reaction which produced ethylidenecyclobutane as the chief product, since this reaction has been described the most completely.

The products identified from this reaction were ethylidenecyclobutane (I), vinylcyclobutane (II), 1-methyl-1-ethylcyclopropane (III), ethylcyclobutane (IV), and 2-ethyl-1-butene (V). It will be noted that the products from this reaction fall into two categories on the basis of their carbon–hydrogen ratios; I and II contain both a cycle and a double bond, whereas the other products contain *either* a cycle *or* a double bond. This suggests that two different mechanisms are involved simultaneously.

We believe that the first reaction to occur is the closing of a cyclopropane ring, as shown in Equation 1. Isolation of ethyl 1-ethylcyclopropylcarbinyl ether from the reaction of this tribromide with zinc in ethanol supports this belief. The intermediate monobromide (1-ethyl-1-bromomethylcyclopropane) could not be isolated when the tribromide was reacted with a limited amount of zinc (in various solvents); this is as would be expected, since the monobromide is somewhat allylic in nature due to the cyclopropane ring embracing the beta and gamma carbon atoms. Additional zinc would be expected to react with this "allylic type" bromide in preference to reaction with a new molecule of tribromide when both were present in the reaction mixture.

The formation of I and II is best explained by a Whitmore-type[16] mechanism. Zinc bromide acts

(16) Whitmore, THIS JOURNAL, 54, 3274 (1932).

as the acid (electron seeking) reagent in much the same manner as it catalyzes the conversion of an alcohol to an alkyl halide in the presence of a hydrogen halide. The carbonium ion produced by Equation 2 undergoes rearrangement with ring expansion to form a new carbonium ion which stabilizes itself by expulsion of a proton to form I (Equation 3). In the formation of II, the same rearranged carbonium ion is formed, but migration of the alpha hydrogen atom with its bonding electrons (to the adjacent ring carbon atom) precedes the expulsion of a proton, as shown in Equation 4. It is possible that I rearranges to II in the presence of zinc bromide, but this seems less likely.

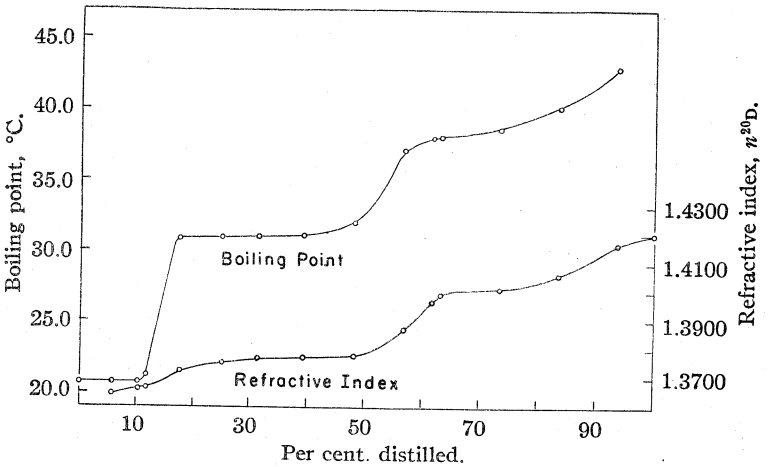

Fig. 6.—Curves describing the distillation of the crude product from the reduction of 1,1,1-tris-(bromomethyl)-ethane.

The formation of the other three products must involve an organozinc intermediate which can abstract an active hydrogen, probably by reaction with the enol form of the solvent, acetamide.

III is then formed without rearrangement, according to Equation 5 (HQ is acetamide or other molecule containing an active hydrogen).

IV results through a Whitmore-type rearrangement of the intermediate monobromide (as in the case of I), followed by the formation of an organozinc bromide which then reacts with an active hydrogen (Equation 6). It is not surprising that a bromide ion should combine with the rearranged carbonium ion as shown, since the concentration of bromide ions in the reaction mixture must be high, and since recombination with an original negative ion is one possibility suggested by Whitmore for rearrangements involving carbonium ions.

V is probably formed according to Equation 7. The initial electron shift is similar to that in Equation 3, except that the methylene group does not accompany the electron pair, but becomes positively charged. A methyl group is then formed by way of the organozinc intermediate, as shown. The similarity of this rearrangement to an allylic rearrangement will be noticed; other cases in which the cyclopropane ring appears to have some of the functions of a double bond have been noted.[17]

## Experimental

### Production of Trihydric Alcohols

**1,1,1-tris-(Hydroxymethyl)-propane.**—This triol was purchased from the Heyden Chemical Corporation, Garfield, New Jersey.

**1,1,1-tris-(Hydroxymethyl)-2-methylpropane.**

The procedure was developed by considerably modifying that of Von Marle and Tollens.[18] In a flask suitably equipped, were placed 172 g. (2 moles) of isovaleric aldehyde (Eastman Kodak Co.)and 650 g. (8 moles) of formalin (Merck, C.P.); stirring was started, and the slow addition of solid calcium hydroxide (1 mole) was begun from a side flask, the rate of addition being such that the temperature within the reaction flask remained at 55–65°. The reaction mixture was then heated (with stirring) for twelve hours at 32°, twenty-four hours at 50–60°, and six hours at 85°. The mixture was then filtered by suction, while hot, and evaporated to a volume of 600 ml. This residue was treated with about three times its volume of boiling 95% ethanol, and the solid calcium formate remaining was separated by filtration. The filtrate was stripped of alcohol and distilled at reduced pressure; 156 g. (53% yield, based on isovaleric aldehyde) of the desired triol boiling at 170–175° (6 mm.) was obtained. In subsequent runs, the reaction mixture was subjected to continuous ether extraction, and the triol concentrate obtained (after ether stripping) was treated, as such, with phosphorus tribromide, thus avoiding some decomposition during distillation.

The purified triol is hygroscopic, but a sample of the distilled triol, recrystallized five times from ether and dried for two days *in vacuo*, melted sharply at 82.0–82.1°.

*Anal.* Calcd. for $C_7H_{16}O_3$: C, 56.73; H, 10.88. Found: C, 56.74; H, 10.69.

**1,1,1-tris-(Hydroxymethyl)-ethane.**—This triol was prepared from propionaldehyde and formalin by the procedure of Brubaker and Jacobson[19] except that the solid sodium formate was removed by filtration of the acetone solution of the triol which was then purified by crystallization (yield from the aldehyde was 51%). After two recrystallizations from acetone solution this compound melted at 198.0–198.2°.

*Anal.* Calcd. for $C_5H_{12}O_3$: C, 49.98; H, 10.06. Found: C, 50.03; H, 10.21.

### Production of Tribromides

**1,1,1-tris-(Bromomethyl)-propane.**—This compound was prepared from the corresponding triol and phosphorus tribromide by the same procedure as that described by Schurink[20] for the preparation of pentaerythrityl tetrabromide, except that the heating period was at 140°. The orange-red impurity (13% by weight) was removed by filtration from the hot alcohol solution of the tribromide which was then purified by crystallization (59% yield from triol). After two recrystallizations from alcohol solution, the tribromide melted at 94.3°. Separation of the colored impurity was found unnecessary for the present purpose.

EQUATIONS DEMONSTRATING REACTION MECHANISMS

*Anal.* Calcd. for $C_6H_{11}Br_3$: C, 22.35; H, 3.42. Found: C, 22.38; H, 3.49.

**1,1,1-tris-(Bromomethyl)-2-methylpropane.**—This tribromide was prepared from the corresponding triol in the same way as the one above, except that the temperature was 145–150° during the heating period. This compound was a liquid and (after washing) was separated from the usual red impurity by suction filtration; after drying it was purified by vacuum distillation (yield 48%, based on triol). Physical properties were determined on a center fraction: f. p. +1.8°; b. p. 106° (3 mm.); $n^{20}D$ 1.5568; $d^{20}_4$ 1.9122.

*Anal.* Calcd. for $C_7H_{13}Br_3$: C, 24.99; H, 3.89. Found: C, 25.36; H, 3.93.

**1,1,1-tris-(Bromomethyl)-ethane.**—This tribromide (also a liquid) was prepared from the corresponding triol by the same procedure used in preparing 1,1,1-tris-(bromomethyl)-2-methylpropane; it was purified by vacuum distillation (68% yield, based on triol). Physical properties determined were: f. p. +9.2°; b. p. 108° (6 mm.); $n^{20}D$ 1.5593; $d^{20}_4$ 2.0917.

*Anal.* Calcd. for $C_5H_9Br_3$: Br, 77.67: Found: Br, 77.5.

**Production and Identification of Hydrocarbons**

**FROM 1,1,1-TRIS-(BROMOMETHYL)-PROPANE.**—In a flask, suitably equipped and surrounded by an oil-bath, were placed 1062 g. (18 moles) of acetamide (Merck C.P.), 636 g. (6 moles) of sodium carbonate, 27.0 g. (0.18 mole) of sodium iodide, and 392 g. (6 gram atoms) of powdered zinc. The mixture was heated to 110°, and stirring was started as soon as the contents of the flask had softened sufficiently. Crude red tribromide (1431 g., corresponding to 3.17 moles of pure tribromide) was added in small chunks through a side flask. As the hydrocarbon formed, it distilled from the reaction mixture through a 1 × 25 cm. Vigreux column into a series of two traps surrounded by a Dry Ice–acetone-bath. The yield was 244 g. or 93%, based on pure tribromide and the empirical formula $C_6H_{10}$; no significant difference in yield was noted when pure tribromide was used. The crude product was dried by passage through a column of silica gel and was fractionated at about 40-plate efficiency.

**Ethylidenecyclobutane (Cut IV, Fig. 1).**—The details of the ozonolysis of this substance are found elsewhere.[13] Acetaldehyde was identified through its 2,4-dinitrophenylhydrazone, m. p. 156–162° after five recrystallizations.

An authentic sample of this derivative also melted at 156–162°, and the mixed melting point was identical; a mixed melting point with the corresponding derivative of formaldehyde showed a 20° depression. A second ozonolysis product boiling at 100° was identified as cyclobutanone (b. p. 99°) and gave a 2,4-dinitrophenylhydrazone which melted (after two recrystallizations) at 140–142°; this derivative was not further purified, since it already melted higher than the literature value, which has since been shown to be erroneous (see under **Isopropylidenecyclobutane**). Physical properties: b. p. 80.26° (760 mm.), f. p. −105.37°; $d^{20}_4$ 0.7678; $n^{20}D$ 1.4370; $dt/dp$ 0.0505°/mm.

*Anal.* Calcd. for $C_8H_{10}$: C, 87.22; H, 12.27. Found: C, 87.25; H, 12.61.

**Ethylcyclobutane.**—This compound was produced by hydrogenation of ethylidenecyclobutane (1.0 mole) over Raney nickel (5 g.) at temperatures up to 90° on a Burgess–Parr low pressure hydrogenator (pressures up to 50 p. s. i.); the theoretical amount of hydrogen was absorbed. The hydrogenated material was distilled at about 25-plate efficiency to give ethylcyclobutane exclusively; physical properties determined on a center cut were (the values in brackets are those of Wibaut[14]): b. p. 70.64° (760 mm.) (70.7); f. p. −142.85°.[21] (−143.2); $d^{20}_4$ 0.7280 (0.7279); $n^{20}D$ 1.4020 (1.4021).

**Vinylcyclobutane–Ethylcyclobutane (Cut III, Fig. 1).**—Part of Cut III (335 g.) was hydrogenated to saturation over 15 g. of Raney nickel suspended in 20 cc. of ethylcyclohexane; an Aminco high pressure hydrogenation outfit was used, and the temperature was not allowed to exceed 100° (pressure, *ca.* 1000 p. s. i.). Fractionation of this material at about 40-plate efficiency produced (except for a very small amount of "heads") only ethylcyclobutane; physical properties of a center cut were: b. p. 70.64° (760 mm.); f. p. −143.16°; $d^{20}_4$ 0.7278, $n^{20}D$ 1.4021. This material was mixed with about 1/3 its weight of authentic ethylcyclobutane (f. p., −143.11°) and the mixed freezing point determined as −143.17° (no depression).

A portion of Cut III (20 g.) was subjected to oxidation by chromic anhydride in glacial acetic acid, according to the procedure of Chavanne and Becker.[22] About 30% (6.9 g.) of the hydrocarbon material remained unoxidized. Isolated by steam distillation, washed with 5% sodium bicarbonate and water, and dried over a chip of metallic sodium, this product (b. p. 71.8° (760 mm.), $n^{20}D$ 1.4058) exhibited a slight residual unsaturation to bromine. Therefore, the material (7 cc.) was treated exhaustively with permanganate, distilled, and dried over a chip of sodium ($n^{20}D$ 1.4021, the same as ethylcyclobutane). This sample (5 cc.) was mixed with 40 cc. of authentic ethylcyclobutane (f. p. −143.16°); the freezing point of the mixture was −143.17° (no depression). Distillation of the ether extract of the acidified (sulfuric acid) reaction residue produced acetic acid, largely; however, about 7 cc. of material thought to be cyclobutanecarboxylic acid was isolated: b. p. 190–192° (uncor.); $n^{20}D$ 1.4405; $n^{25}D$ 1.4394 (cyclobutanecarboxylic acid b. p. 195°; $n^{25}D$ 1.4403).[23]

Another oxidation of Cut III (90 g.) was carried out according to the procedure of Whitmore, *et al.*[24] Distillation of the lighter-than-water layer (50 g.) at about 10-plate efficiency gave 36.1 g. of ethylcyclobutane, 3.9 g. of intermediates, and 7.4 g. of cyclobutanecarboxylic acid which was then esterified in the usual manner.

*Anal.* Calcd. for ethyl ester ($C_7H_{12}O_2$): C, 65.7; H, 9.5. Found: C, 67.0; H, 10.4. (The material analyzed was distilled directly from the esterification mixture and was insufficient for further purification, hence the noticeable discrepancy between the C–H analysis and theory).

(21) This corresponds to a purity of 99.6 mole % as calculated from cryoscopic data.

TABLE II

| | This material | Cyclobutanecarboxylic acid: Perkin[25] | Cyclobutanecarboxylic acid: Other sources |
|---|---|---|---|
| B. p. | 190–192 (749 mm.) | 191 (720 mm.) | 189–191[26] |
| $n^{25}D$ | 1.4411 | ..... | 1.4403[23] |
| B. p. of Et ester | 152–154 (749 mm.) | 151 (720 mm.) | 159–162[27] |
| $n^{20}D$ of Et ester | 1.425 | ..... | ..... |

**2-Ethyl-1-butene (Cut II, Fig. 1).**—Cut II was redistilled at about 35-plate efficiency; physical properties determined on a center fraction were (values in parentheses are those listed by Rossini, *et al.*[28]): b. p. 64.69° (760 mm.) (64.95); f. p. −132.02° (−131.92); $d^{20}_4$ 0.6899 (0.6894); $n^{20}D$ 1.3969 (1.3969).

This material was mixed with an equal volume of authentic 2-ethyl-1-butene (f. p., −132.11°), and the mixed freezing point determined as −132.04° (no depression).

**1-Methyl-1-ethylcyclopropane (Cut I, Fig. 1).**—This material was treated exhaustively with permanganate, steam distilled, and refractionated at about 35-plate efficiency. Physical properties were determined on a center cut: b. p. 56.79° (760 mm.), f. p. −130.23°, $n^{20}D$ 1.3888, $d^{20}_4$ 0.7015.

Cut I was then hydrogenated at high temperature (250°) and pressure (2600 p. s. i.). Neohexane was the exclusive product; its physical properties were (values in brackets from Footnote 28 for comparison): b. p. 49.65° (760 mm.) (49.74); $n^{20}D$ 1.3688 (1.3688); $d^{20}_4$ 0.6491 (0.6491).

1,1,1-tris-(Bromomethyl)-propane also reacted with zinc in ethanol by the Gustavson[5a] procedure. The reaction mixture was distilled (1-plate) at atmospheric pressure, and the distillate (clear homogeneous liquid) boiling up to 90° was collected. Dilution of the distillate with about four times its volume of water caused it to separate into two layers. The organic layer (40% yield, based on tribromide and the empirical formula ($C_8H_{16}O$) was treated with sodium in liquid ammonia to remove any residual halide and was fractionated at about 35-plate efficiency. This material was probably ethyl 1-ethylcyclopropylcarbinyl ether (a new compound). Physical properties determined on a center cut were: b. p. 135° (760 mm.) $d^{20}_4$ 0.8352; $n^{20}D$ 1.4209. Mol. refraction: Calcd. for ethyl 1-ethylcyclopropylcarbinyl ether: 39.28; observed: 38.92. *Anal.* Calcd. for $C_8H_{16}O$: C, 74.95; H, 12.58. Found: C, 74.94; H, 12.66.

The infrared absorption spectrogram of this compound appeared to substantiate both the ether linkage (evidenced by a band at about 9 $\mu$) and the cyclopropane ring.[29] The material peroxidized extensively on standing.

**FROM 1,1,1-TRIS-(BROMOMETHYL)-2-METHYLPROPANE.**—This tribromide was treated with zinc in molten acetamide in the same manner as was 1,1,1-tris-(bromomethyl)-propane, the only difference being that a slightly higher reaction temperature (135–140°) was maintained; the yield of crude hydrocarbon material was 97% of theory, based on tribromide and the empirical formula $C_7H_{12}$. The crude hydrocarbon mixture was dried over metallic sodium and fractionated at about 40-plate efficiency (Fig. 4).

**Isopropylidenecyclobutane.**—A part of the 107° cut (Fig. 4) was ozonized and the ozonide decomposed by low pressure hydrogenation according to the procedure of Henne and Perilstein.[30] Acetone was identified by the

(29) A study of the infrared absorption spectra of a considerable number of cyclopropane and cyclobutane hydrocarbons has been carried out in this Laboratory and a paper on this subject is in preparation.

(30) Henne and Perilstein, THIS JOURNAL, **65**, 2183 (1943).

melting points of its 2,4-dinitrophenylhydrazone (125.7–125.8°) and semicarbazone (187.0–187.3°); mixed melting point determinations with authentic samples of these derivatives showed no depression. Cyclobutanone ($n^{16}D$ 1.4221, literature[23] $n^{16}D$ 1.4220) was identified through its semicarbazone (m. p. 202.6–203.0°, lit. 204°); the 2,4-dinitrophenylhydrazone of this material melted 146.3–146.7°; the literature gives a value of 132.3° for this derivative and must be considered in error.

Physical properties were determined on a center cut from the 40-plate refractionation of the 107° material: b. p. 107.26° (760 mm.); f. p. −58.33°, $d^{20}_4$ 0.7823, $n^{20}D$ 1.4459.

**Isopropylcyclobutane.**—Hydrogenation of isopropylidenecyclobutane over Raney nickel at 50–60 p. s. i. and 80–100° gave isopropylcyclobutane exclusively; the hydrogenation proceeded less readily than in the case of ethylidenecyclobutane. Physical properties were determined on a center cut from a 40-plate fractionation of the hydrogenated material (values in brackets are those of Kasansky[15]): b. p. 92.70° (760 mm.) (90.5–91.5 (750)); f. p. −106.43°; $d^{20}_4$ 0.7376 (0.7464 at 14.5°); $n^{20}D$ 1.4080 (1.4096 at 19°).

*Anal.* Calcd. for $C_7H_{14}$: C, 85.62; H, 14.38. Found: C, 85.44; H, 14.46.

**Purification and Identification of Forerun.**—The material boiling at 79.5–98.1° (Fig. 4) was refractionated at about 40-plate efficiency; no further separation was effected. All fractions were recombined and hydrogenated to saturation in the same way as was isopropylidenecyclobutane. The hydrogenated material was fractionated at about 40-plate efficiency.

The 82° cut (1-methyl-1-isopropylcyclopropane) made up about 15% of the distillate and had the following physical properties: b. p. 82.1° (760 mm.), $d^{20}_4$ 0.7227, $n^{20}D$ 1.3998; there was insufficient material for a freezing point determination. This material was hydrogenated under the same conditions as was 1-methyl-1-ethylcyclopropane.

The 88.8–92.1° cut had the following physical properties: $d^{20}_4$ 0.7213; $n^{20}D$ 1.4013–1.4087.

**FROM 1,1,1-TRIS-(BROMOMETHYL)-ETHANE.**—The reaction of this tribromide with zinc in molten acetamide was carried out in exactly the same manner as in the case of 1,1,1-tris-(bromomethyl)-propane. The major portion of the tribromide used was purified only to the extent of filtering out the solid red impurity; further purification seemed unnecessary, since a batch of crude, assayed by fractionation, was found to be about 97% pure. In three runs the yields of hydrocarbon material obtained ranged from 45–65%. The crude hydrocarbon mixture (214 g.) was dried and distilled at about 40-plate effiiciency (Fig. 6).

**Methylcyclobutane.**—Hydrogenation of the later fractions (66 g., b. p. 38.6–43.0°, $n^{20}D$ 1.4014–1.4203) from the redistillation of the 37–43° cut was carried out over Raney nickel at 50 p. s. i. and 55°.

**2-Methyl-1-butene.**—The 31° cut (Fig. 6) was refluxed over metallic sodium and redistilled at about 40-plate efficiency. Physical properties determined on a center fraction were (the values in parentheses are those listed by Rossini, *et al.*[28]): b p. 30.9° (760 mm.) (31.10); f. p. −138.06° (−137.58); $d^{20}_4$ 0.6508 (0.6504); $n^{20}D$ 1.3778 (1.3778).

**1,1-Dimethylcyclopropane.**—The best fraction from the 20° cut (Fig. 6) (b. p. 20.67° (760 mm.); $n^{20}D$ 1.3662) was essentially saturated; 3-methyl-1-butene (b. p. 20.06° (760 mm.) $n^{15}D$ 1.3675)[28] is the only other hydrocarbon having physical properties in this range, and it is unsaturated. Shortridge, *et al.*,[7] give the following properties for 1,1-dimethylcyclopropane: b. p. 20.63° (760 mm.); $n^{20}D$ 1.3668.

**High Boiling By-products.**—Steam distillation of the reaction residues produced a lighter than water layer; distillation at 25-plate efficiency separated the material into two fractions boiling at about120 and 174° in the ratio of 2:1.

**1-Methylcyclopropylcarbinol.**—Physical properties of the 120° cut were: b. p. 120–121° (760 mm.); f. p. (approx.) −15°, $d^{20}_4$ 0.9033, $n^{20}D$ 1.4333. Mol. ref.: Calcd. for 1-methylcyclopropylcarbinol, 25.3; obs., 24.8.

This substance reacted slowly with metallic sodium; its 3,5-dinitrobenzoate melted sharply at 133.3–133.4° after five crystallizations from a water–ethanol mixture.

*Anal.* Calcd. for $C_5H_{10}O$: C, 69.7; H, 11.7. Found: C, 69.4; H, 11.7.

**Di-(1-methylcyclopropylmethyl) Ether.**—The 174° material was refluxed two days over metallic sodium and redistilled at about 5-plate efficiency. Its physical properties were: b. p. 174° (760 mm.), $d^{20}_4$ 0.8892, $n^{20}D$ 1.4501. Mol. ref.: Calcd. for di-(1-methylcyclopropylmethyl) ether, 47.0; obs., 46.6.

*Anal.* Calcd. for $C_{10}H_{18}O$: C, 78.0; H, 11.7. Found: C, 78.05; H, 11.76.

Infrared absorption spectrograms of the two compounds above seem to substantiate the identities tentatively assigned to them.

**Acknowledgment.**—The authors are indebted to E. E. Pickett for aid in interpreting the infrared spectra, and to R. G. Kelso and W. L. Perilstein for technical assistance and advice. Sincere appreciation is expressed to M. S. Newman for his counsel concerning reaction mechanisms.

## Summary

Three neopentyl-type tribromides have been prepared for the first time, and their reactions with zinc in molten acetamide have been carefully studied. The hydrocarbon mixtures obtained were separated by distillation insofar as possible and the components were identified, four of them being new compounds. This reduction has been shown to constitute a general and practical method for synthesizing monoalkylidene and monalkyl cyclobutanes.

Reaction mechanisms, based on well recognized theories, have been proposed to account for all of the products identified.

# Studies of the Fischer–Tropsch Synthesis. V. Activities and Surface Areas of Reduced and Carburized Cobalt Catalysts[1]

BY ROBERT B. ANDERSON,[2] W. KEITH HALL,[2] ABRAHAM KRIEG[2a] AND BERNARD SELIGMAN[2]

## Introduction

Although the Fischer–Tropsch synthesis has been studied for more than twenty years, Craxford[3,4,5] was the first to attempt to relate activity and product distribution to the nature of the catalyst surface and the adsorbed layer of hydrocarbons upon it. Recently Hofer,[6,7] Weller,[8,9] Anderson[1,10–12] and Storch[13] have presented kinetic studies, X-ray diffraction data and surface area and pore volume studies of cobalt catalysts, and Pichler[14] has prepared a critical summary of the data of German research pertaining to the Fischer–Tropsch synthesis in which many of these factors are considered. The present paper relates surface area and surface accessibility to activity and product distribution. The data reported previously on the effect of bulk carbide on the activity of cobalt catalysts[9] have been extended to include the surface areas, activities and distribution of products in the synthesis with catalysts carburized with carbon monoxide under conditions which form carbide ($Co_2C$), "free" carbon or both.

## Experimental

The catalysts studied in this paper were Co:$ThO_2$:MgO:kieselguhr (100:6:12:200) catalysts characterized as number 89 and Co:$ThO_2$:kieselguhr (100:18:100) catalyst number 108 B. Descriptions have been published of the preparation and testing of these catalysts[10,11,13] as well as their surface areas,[1,11] mercury and helium densities[1,11] and activities at 185°.[12] In all tests described in this paper approximately two volumes of hydrogen to one volume of carbon monoxide synthesis gas was used. Surface areas were determined from adsorption isotherms of nitrogen at −195° by the simple equation of Brunauer, Emmett and Teller.[15] The method of determination of the volume of chemisorbed carbon monoxide at −195° has been described previously.[1]

Surface areas and mercury and helium densities were determined on a catalyst removed from a converter during the twelfth week of operation. The catalyst was dropped from the converter in an atmosphere of synthesis gas and at synthesis temperature into a tube through which pure argon was flowing. This tube was joined to the bottom of the converter by a rubber sleeve in which there was a small hole to allow the argon and synthesis gas to escape. When the catalyst had cooled to room temperature, it was transferred in a stream of carbon dioxide to suitable adsorption and density tubes. In this method of transfer, there was no possibility of exposure of the catalyst to air.

In the carburization studies reduced catalysts were treated with pure carbon monoxide prepared by dehydration of formic acid in the presence of phosphoric acid.[16] For surface area determinations, the catalyst was carburized in a glass adsorption tube[17] in a small automatically controlled electric furnace. For tests of carburized catalysts in the synthesis, the samples were treated with carbon monoxide in the converter. Before carburization, the catalyst that had been used in the synthesis was treated with hydrogen at 208° to remove most of the adsorbed hydrocarbons.

In many instances in this paper the results from cobalt–thoria–kieselguhr and cobalt–thoria–magnesia–kieselguhr catalysts have been compared as though the catalysts were the same. This is permissible since it has been found that the distribution of products, dependencies of rate upon temperature and pressure and the behavior of catalysts during and after carburization were very similar for these two types of catalysts.

### Surface Areas and Pore Volumes of Catalysts Used in the Synthesis

Pelleted catalyst 89FF (Co–$ThO_2$–MgO–kieselguhr) was removed from the converter during the twelfth week of operation at atmospheric pressure and transferred to suitable adsorption and density tubes in a manner that precluded exposure to air. The catalyst had been operated at an average temperature of 183° for eleven weekly periods of five days each with a two-hour reactivation in hydrogen at 195° followed by a forty-four-hour period in which a very slow stream of hydrogen was passed over the catalyst at about 150° between operating periods. Although the activity decreased somewhat during each period, the average activity of each period was the same for all eleven weeks. When removed from the converter, the catalyst had been operated for four days in the twelfth week. Since as indicated in Table I about 90% of the hydrocarbons on the catalyst should be removed by hydrogenation at 195°, most of the hydrocarbon on the catalyst was formed in the four days of operation prior to its transfer. Data of adsorption and mercury and helium densities are given in Tables I and II.

After use in the synthesis, the area of the catalyst was 4.36 square meters per gram compared with 80.0 square meters per gram after the initial reduction. The hydrogen reactivation at 200° for two hours decreased the weight of the sample by 23.5% and increased the surface area to 70.5 square meters per gram. Further reduction at 200° for twenty hours produced only a slight loss in weight and a small increase in area. Reduction at 400° under conditions of the original reduction f the catalyst caused only a slight loss in weight and increased the area to nearly that

TABLE II

DENSITY AND PORE VOLUME DATA ON REDUCED AND USED COBALT CATALYST 89FF[a]

| Treatment | Cumulative weight[b] loss, % | $d_{He}$ g./cc. | $d_{Hg}$, g./cc. | Pore volume, cc./g. |
|---|---|---|---|---|
| a. Reduced 2 hr. at $H_2$ at 400° SVH[c] = 6000 | .. | 3.031 | 1.138 | 0.549[d] |
| b. Used (a) plus 12 weeks of synthesis | 0.0 | 1.891 | 1.471 | 0.151[e] (0.201)[d] |
| c. (b) plus 2 hr. of $H_2$ at 200°, SVH = 200 | 23.8 | 2.881 | ... | ..... |
| d. (c) plus 2 hrs. of $H_2$ at 400°, SVH = 6000 | 25.5 | 3.007 | 1.112 | 0.566[d] |

[a] Cobalt:thoria:magnesia:kieselguhr = 100:6:12:200. [b] Weight was based on weight of used catalyst as removed from converter. [c] Space velocity per hour, volumes of gas (S.T.P.) per volume of catalyst per hour. [d] Pore volume in cc. per gram of reduced catalyst. [e] Pore volume in cc. per gram of catalyst as removed from converter.

of the original reduced catalyst. The ratio of volume of chemisorbed carbon monoxide to $V_m$[18] for nitrogen varied from 0.13 to 0.21, the ratio increasing with increasing surface area of the sample. It is interesting to note that even on the catalyst removed from the converter some cobalt was accessible to chemisorb carbon monoxide.

The helium density of the used catalyst was 1.891 and after reduction at 400°, 3.007, which is nearly equal to that of the original reduced catalyst. The mercury density of the used catalyst decreased on reduction at 400° from 1.471 to 1.112, while the pore volume (volume of pores with openings smaller than 5 microns in diameter[1,19]) increased from 0.201 to 0.566 cc. per gram of unreduced catalyst. Thus, the surface area, densities and pore volume of the used catalyst after reduction at 400° were very nearly identical to those of the original reduced catalyst.

The volumes of mercury displaced by the used catalyst before and after reduction per unit weight of cobalt were identical, indicating that the adsorbed hydrocarbons were located within the pellet in the space not penetrated by mercury and not on the external surface of the catalyst. At 30°, 65% of the pore volume of the used catalyst was filled with hydrocarbons. The hydrocarbons removed by hydrogenation had a density of 0.90 as calculated from change in weight and change in volume of helium displaced. This density compares well with the densities of soft and hard paraffins from atmospheric pressure synthesis, 0.90 and 0.93, respectively, as reported by Pichler.[14]

The data in Tables I and II establish definitely that the catalyst in its normal condition of operation at atmospheric pressure is heavily covered with hydrocarbons. In pressure operation, the catalyst is believed to be completely filled with hydrocarbon product at all times.[5] Experiments given in Table III indicate that the activities[20] of pelleted cobalt catalysts at one atmosphere are equal or slightly greater than at 7.8 atmospheres operating pressure. Pelleted catalysts produced greater percentages of methane and light hydrocarbons at 7.8 atmospheres than at one atmosphere, but granular catalysts produced nearly the same products under both conditions.

At atmospheric pressure, it was found that the percentage of methane and light hydrocarbons increased with increasing mercury density of the catalyst.[12] It was also found that granular and pelleted forms of the same catalyst had the same activity per gram of catalyst.[12] At 7.8 atmospheres a pelleted catalyst of higher density and greater pellet size had a lower activity and formed greater amounts of light hydrocarbons than a less dense and smaller size pelleted catalyst as shown in Table IV. Thus the larger pellets in test X-58 at a 4° higher temperature than in X-45 produced less oil than the smaller pellets, even though a greater weight of catalyst was used in X-58.

In Table V, data are presented for a test of a pelleted catalyst operated alternately at 1 and 7.8 atmospheres. After six weekly periods of operation at atmospheric pressure, the catalyst was operated at 7.8 atmospheres. No change in activity was observed. After a hydrogen reactivation, operation at one atmosphere required a 5° higher temperature to produce the same degree of conversion. After hydrogen reactivation, it was possible to operate at 7.8 atmospheres at 3° lower than in the previous period (h). In week j, operation at one atmosphere without a hydrogen reactivation required a temperature 10° higher than in the week i. Subsequent operation at 7.8 atmospheres after hydrogen reactivation was possible at the same temperature as in week j. Operation at one atmosphere in week 1 without reactivation required a 21° higher temperature than in week f.

Thus, operation at 7.8 atmospheres decreased the activity at atmospheric pressure. When hydrogen reactivation was omitted, the decrease in activity at atmospheric pressure operation after a period at 7.8 atmospheres was greater. In addition to changes in activity, alternation of operation at 1 and 7.8 atmospheres increased the percentage of methane and light hydrocarbons in the products compared with previous periods of operation at 1 and 7.8 atmospheres, respectively.

## Surface Areas and Activities of Carburized Cobalt Catalysts

Studies were made of the surface areas and activities (at atmospheric pressure) of pelleted Co–$ThO_2$–kieselguhr catalyst 108B after carburization at 208, 235 and 275°. Hofer[6,7] has shown that carburization at 208° formed chiefly cobalt carbide, $Co_2C$; at 235° cobalt carbide and "free" carbon were formed; and at 275° chiefly "free" carbon. After the surface area determination or activity test, the catalyst was hydrogenated under varying conditions, and the area or activity again determined. The data of surface area and activity studies are presented in Tables VI and VII.

The surface area data (Table VI) show that the surface area of the reduced catalyst (Period 1-R) does not decrease appreciably on carburization at 208° (1-C) and on subsequent reduction at 208° (2-R); however, the volume of chemisorbed carbon monoxide decreased on carburization

(18) $V_m$ is the volume of physically adsorbed gas, cc. (S. T. P.), required to form a monolayer on the surface.

(19) Pores not penetrated by mercury at atmospheric pressure. See Ritter and Drake, *Ind Eng. Chem., Anal. Ed.*, **17**, 782 (1945).

(20) In Tables III, IV and V, the space velocity of synthesis gas was constant with the temperature varied to maintain a 70% contraction. Thus the lower temperature of operation corresponds to the greater activity.

TABLE III

EFFECT OF OPERATING PRESSURE ON COBALT CATALYSTS

Tests at a space velocity per hour of 100

and increased on reduction to only about 50% of the chemisorption found on the freshly reduced catalyst.

Carburization at 235° (2-C) deposited carbon equivalent to 130% of carbide, and about the equivalent of carbon in $Co_2C$ was removable by reduction at 208° (3-R). In these steps, the surface area did not change greatly, but the chemisorbed carbon monoxide was less than for the carburization 1-C and reduction 2-R. The residual carbon may be termed "free carbon" as contrasted to the readily hydrogenated carbide carbon.[6,7] Carburization at 275° (3-C) increased the carbon content to the equivalent of 418% $Co_2C$ and increased the surface area and carbon monoxide chemisorption sizably. Reduction 4-R decreased the carbon content only slightly, and subsequent carburization at 208° (4-C) increased carbon by only the equivalent of 25% of $Co_2C$. Thus, after carburization at 275° the cobalt no longer contained sizable amounts of carbide, and carburization at 208° did not increase the carbide content appreciably. The surface area was increased to 50.6 square meters per gram in the carburization at 275° (3-C); the increase in area was probably that of the "free" carbon deposited in the catalyst. Hydrogenation (4-R) and carburization (4-C) at 208° did not significantly change the surface area. The volume of chemisorbed carbon monoxide after carburization at 275° was nearly equal to that after reduction 2-R.

Rereduction 5-R at 360° which was similar to 1-R removed carbon about equivalent to $Co_2C$, but did not increase the surface area or carbon monoxide chemisorption significantly over that of the catalyst after 3-C. Carburization 5-C at 208° increased the carbon content only by the equivalent of 30% $Co_2C$, indicating that carbide formation was still inhibited. In reduction 6-R at 360°, the carbon was slowly removed until after 296 hours only the equivalent of 7.9% $Co_2C$ remained. During the rereduction, the area decreased to only slightly greater than that of the original reduced catalyst, and the volume of chemisorbed carbon monoxide increased to two-thirds of that of the original reduced catalyst. The catalyst was still poisoned with respect to formation of carbide as indicated by carburization 6-C at 208°.

A similar carburization and reduction cycle was made on $Co-ThO_2-MgO$-kieselguhr catalyst 89K. The results were very similar to the data in Table VI. After several carburization and reduction cycles at 200°, catalyst 89K was carburized at 275° until 16 times the equivalent of the carbon in $Co_2C$ was deposited. In addition to an increase in total surface area from 62.0 sq. m. per gram for the original reduced catalyst to 149.4 sq. m. per gram the volume of chemisorbed carbon monoxide increased from 3.1 cc. (S.T.P.) per gram to 3.6 cc. (S.T.P.) per gram. (The adsorption data are given per gram of unreduced catalyst.) This indicates an increase in area of the cobalt possibly due to splitting of the metal lattice by carbon.

In Table VII are presented activity and product distribution data for another sample of catalyst 108B, tested at atmospheric pressure with two volumes of hydrogen to one volume of carbon monoxide gas. Reduction and carburization steps were arranged to be somewhat similar to those of Table VI. Before each carburization step, the catalyst was stripped of adsorbed hydrocarbons by hydrogenation for two hours at 208° to insure that the surface was accessible during the carburization. In these tests (weeks c–l) the temperature and flow of synthesis gas were held constant, and the activity was expressed as the fraction of the gas consumed, *i. e.*, the real contraction. Products are given as grams per cubic meter of synthesis gas consumed.

After carburization b at 208° the activity decreased and yields of methane and $C_1$–$C_4$ hydrocarbons were increased. Although hydrogenation at 208° (c) increased the activity and shifted the product distribution as compared with period b, the products contained a higher percentage of light hydrocarbons, and the activity was considerably lower than in operating period a. In the following carburization and reduction cycles (d to h), the hydrogenated catalyst was more active and had a more favorable product distribution than the corresponding carburized one, but the activity of the catalyst in the hydrogenated or carburized state decreased steadily, and greater fractions of methane and light hydrocarbons were formed. Thus, carbide formation has a marked effect on both activity and product distribution. Repeated cycles of carburization and reduction at 208° caused a gradual decrease in activity and a shift toward formation of lighter hydrocarbons that was super-imposed on the effect of carbide on activity and product distribution. After carburization at 275° in period i, the activity and methane formation were not significantly different from that of period h. Reduction at 208° in period j increased the activity sizably, but the product distribution was strongly shifted toward light hydrocarbons compared with period a. Reduction 1 at 400° increased the activity to that of period c, but distribution of products was less favorable than in the period c. Thus "free" carbon does not decrease the activity very much but has a marked effect on the product distribution.

## Discussion

The Fischer–Tropsch synthesis is a slow catalytic process compared with simple reaction such as the catalytic hydrogenation of ethylene, and in no case did the synthesis proceed to equilibrium. Although the catalyst was heavily covered with wax, the rate of synthesis does not appear dependent upon diffusion: First, the temperature coefficient was considerably higher than that expected for diffusional processes,[8,10] and second, the pressure coefficient was about zero. Thus, the rate must be dependent upon the rate of some surface process that is not pressure dependent, and the linear dependency of activity on surface area should be expected.

The study of the catalyst used in the synthesis at atmospheric pressure (Tables I and II) indicated the amount of the hydrocarbon on the catalyst. Hydrogen treatment at 200° for two hours removed 90% of the adsorbed wax. Further hydrogenation at this temperature caused only a very small loss in weight. However, reduction at 400° restored the catalyst to the same condition as after the initial reduction. The surface area and pore volume were unchanged after the eleven weeks of operation. This agrees with the fact that the activity remained constant during the operation of this catalyst and the observation that the X-ray diffraction patterns of the catalyst did not change during the synthesis.[9] The results indicate that little if any "free" carbon was deposited during the synthesis. The stability of the catalyst to sintering was not entirely unexpected since the temperature of the synthesis was more than 200° lower than the reduction temperature.

Thus, the surface of catalysts operated at atmospheric pressure was heavily covered with wax, and the pores of those operated at elevated pressures were probably almost entirely filled.[5] Although catalysts operated at elevated pressure produce a greater fraction of higher molecular weight hydrocarbons, it is probable that the average molecular weight of the product in the catalyst operated at elevated pressures is lower than that in catalysts used at atmospheric pressure. At elevated pressures hydrocarbons of lower molecular weight than at atmospheric pressure should condense in the catalyst bed and should flow over the catalyst as liquid. The liquid should continuously remove higher molecular weight hydrocarbons.[14] Catalysts operated entirely at elevated pressures or at elevated pressures after several weeks of operation at atmospheric pressure had the same activity as in atmospheric pressure operation. However, activities at atmospheric pressure after operation at the higher pressure were considerably less, this effect being more pronounced when the catalyst was not hydrogen treated between periods of operation. Alternate atmospheric and pressure operation decreased the activity compared with previous periods of atmospheric and pressure operation, respectively.

In operation at atmospheric pressure, the activity remains nearly constant for two or three weeks of continuous operation followed by a rapid decrease in activity. This loss in activity may be related to the time at which the pores of the catalyst are quite completely filled with adsorbed hydrocarbon; and reactivation involves removal of this hydrocarbon by hydrogenation or solvent extraction.[5,21] The pores of the catalyst operated at elevated pressures are assumed to be quite completely filled with hydrocarbons at all times, and the activity remains constant for periods of three or more months without any reactivation. Thus, in atmospheric pressure operation it appears that pores entirely filled with hydrocarbons are considerably less accessible than only partially filled pores, but in pressure operation, the rate of diffusion of reactants is sufficient to maintain constant activity even with completely filled pores.

Parallel to the decrease in activity (Table V), the product distribution was shifted toward the formation of larger fractions of methane and other light hydrocarbons. From these and other data (Tables III and IV and refs. 10 and 12), the following generalization may be made: Decrease of the accessibility of the surface either by deposition of excessive quantities of wax by operation at elevated pressure or by decreasing the average pore diameter by pelleting causes an increase in the fraction of methane and other light hydrocarbons and in some cases a decrease in activity. In pressure operation the greater proportion of light hydrocarbons may be due to the greater rate of diffusion of hydrogen compared with that of carbon monoxide through the hydrocarbon film covering the surface as postulated by Craxford,[5] so that the gas reaching the catalyst surface is richer in hydrogen than the synthesis gas.

The conversion of the cobalt in a catalyst to carbide did not appreciably change the total surface area (1-R and 1-C of Table VI); hence, the lower activity of the carbided catalyst (b of Table VI) must be related to the presence of the carbide. The volume of chemisorbed carbon monoxide at −195° on the carbided catalyst was only one-third of that chemisorbed on the original reduced catalyst. On reduction (2-R of Table VI) the volume of chemisorbed carbon monoxide was less than half that of the original reduced sample. This may be due to poisoning by the small amount of residual carbon. Repeated carbiding and reduction at 208° decreased the activity in the corresponding reduced and carbided states compared with the original reduced and carbided states.

Accompanying the decrease in activity of carbided catalysts, the fraction of light hydrocarbons in the products increased. "Free" carbon deposited from carbon monoxide at 235° and higher temperatures had a smaller effect on activity, but the product distribution was more strongly shifted

(21) Hall and Smith, *J. Soc. Chem. Ind.*, **65**, 128 (1946).

toward light hydrocarbons than in the presence of cobalt carbide.

It was found that "free" carbon or processes accompanying its formation inhibited carbide formation from carbon monoxide at 208°, some inhibition being observed even after the "free" carbon had been decreased to 2 mg./g. of catalyst by reduction at 360° (6-R of Table VI). The data indicate that the catalytic activity was not decreased by the "free" carbon even though the extent of carbide formation was decreased. This appears to be evidence against cobalt carbide as an intermediate in the synthesis.

At least part of the greater yield of methane and light hydrocarbons from the carbided catalyst may be formed by reduction of the carbide with hydrogen of the synthesis gas, and accompanying this process the activity of the carbided catalyst increased for the first several days.[9] The higher yields of light hydrocarbons with catalysts containing "free" carbon cannot be explained in this manner since "free" carbon does not hydrogenate at synthesis temperatures. It is possible that the presence of carbon atoms decreases the extent of polymerization at the surface by breaking the continuity of cobalt atoms in the cobalt crystallites. Although deposition of large amounts of "free" carbon slightly increased the area of the cobalt surface indicating some splitting of the cobalt lattice by carbon, this increase was small compared with the increase in the total area. Thus it appears that most of the "free" carbon was deposited at the surface and not within the crystallites of cobalt.

The results presented in this paper are in general agreement with those of Craxford.[3,4,5] The present paper and a previous one[9] show that the presence of bulk phase carbide decreased the catalytic activity and that bulk phase carbide was not formed in the synthesis. Thus, carbide if present at all in the catalyst in the synthesis must reside near the surface. In a recent paper[5] Craxford has postulated a surface carbide as an intermediate in the synthesis, because in his catalysts the cobalt atoms must be distributed into layers less than two atoms thick to account for the observed surface area. For purposes of reaction mechanisms the distinction between surface carbide and chemisorbed carbon monoxide is difficult.

**Acknowledgment.**—The authors are pleased to acknowledge the assistance of many persons in the experiments reported in this paper, especially the operating staff, Dr. R. A. Friedel and the mass spectrometry group for gas analyses, and our supervisors Drs. H. H. Storch and J. H. Crowell for helpful discussions and criticisms.

## Summary

1. The surface of a catalyst used in the synthesis was found to be heavily covered with hydrocarbon. Hydrogenation at 200° removed 90% of these adsorbed hydrocarbons, and reduction with hydrogen at 400° restored the catalyst to the same condition as after the initial reduction. There was no evidence of sintering of the catalyst or of carbon deposition.

2. Activity data for operation at 1 and 7.8 atmospheres are related to the adsorbed hydrocarbon film.

3. Decrease in the accessibility of the surface of these catalysts either by deposition of excessive quantities of wax or by reduction of average pore diameter by pelleting caused an increase in the fraction of methane and other light hydrocarbons and in some cases a decrease in activity.

4. The presence of bulk phase carbide in these catalysts caused a marked decrease in activity, but "free" carbon did not affect the activity very much. The presence of carbon in both forms shifted the product distribution toward light hydrocarbons. The surface area did not change appreciably when the cobalt in the catalysts was converted to cobalt carbide. Carburization at 275°, under conditions which form predominantly "free" carbon, increased the area sizably.

# The Modifications of the Carbide, $Fe_2C$; Their Properties and Identification

BY L. J. E. HOFER,[1] E. M. COHN,[1] AND W. C. PEEBLES[2]

In addition to the well-known carbides of iron, cementite and martensite, and the less-well-known iron acetylide, carbides of the formula $Fe_2C$ have been reported. Recent X-ray diffraction studies by Halle and Herbst[3] indicate the existence of a carbide in which the iron atoms are arranged in hexagonal structure. X-Ray diffraction studies also were made by Hägg[4] and later by Jack[5] on a more complex iron carbide whose structure has not yet been worked out. Pichler and Merkel[6] have recently made thermomagnetic studies of iron carbides, and they conclude that there are two ferromagnetic iron carbides with the formula $Fe_2C$ and with Curie points at 265° and 380°, respectively. Unfortunately, no X-ray diffraction experiments were made by Pichler and Merkel; and similarly Hägg, Jack, and Halle and Herbst made no thermomagnetic measurements. It is therefore impossible to interpret the thermomagnetic studies in terms of the X-ray diffraction studies and *vice versa*.

The chief purpose of this paper is to determine the relationship between the $Fe_2C$ carbides which were reported in thermomagnetic studies and those reported in X-ray diffraction studies. In addition, the results obtained with iron catalysts in this paper have made possible a general unification of data presented in the literature.

## Experimental

**Thermomagnetic Analysis.**—This method of analysis is based on the observation that every ferromagnetic phase loses its ferromagnetism at a temperature characteristic of the phase, known as the Curie point. The method has been described by many authors (see, for example, Lange and Mathieu[7]).

The magnetic balance used has been previously described.[8,9] The balance suspension assembly is shown in Fig. 1. A strong torsion wire (about 0.1° twist per gram-centimeter torque) was used. The sample holders used for the iron synthetic ammonia catalyst consisted of 6 mm. i. d. graded vitreous silica to Pyrex seals which were closed at the silica end and provided with a standard taper joint at the Pyrex end. (This sample holder is particularly useful for determining Curie points at high temperatures but was not essential to the experiments here described.) The sample holders used for the copper-promoted, precipitated iron catalysts were 7-mm. o. d. Pyrex tubes, closed at one end and also provided with a standard taper at the other. The samples were held in position at the bottom of the sample holders by means of Pyrex glass wool plugs. A coin-silver cap (i. d. 8.8 mm., o. d. 13.9 mm., length 38.4 mm., bottom thickness 2.5 mm.), provided with a groove on the inside for a thermocouple and its porcelain protective tube, was slipped over the end of the sample holders. This cap assured a uniform temperature distribution throughout the sample and also the identity of the temperature of the thermocouple with that of the sample. The junction of the thermocouple was placed as near the sample as possible. Two non-ferromagnetic thermocouples were used, platinum–platinum + 10% rhodium, or Chromel–constantan. To insure unrestricted motion of the suspension assembly, the ends of the thermocouple dipped into two mercury pools from which two wires, identical with those of the thermocouple, led to an ice-bath cold junction. The furnace consisted of an Alundum thimble about 0.9 cm. long and 1.5 cm. i. d., wound non-inductively with asbestos-covered 24-gage Nichrome wire, and insulated on the outside with a layer of asbestos paper. It was supported between the poles of the magnet by a brass holder and was adjusted so that it made no contact with the suspension assembly.

Normally, a thermomagnetic analysis is made by heating the unknown sample sufficiently slowly in the magnetic balance so that the magnetic moment can be measured at suitable intervals. The magnet is operated at a field strength of 2160 gauss. When a predetermined temperature has been reached, the heating is stopped, and the sample is allowed to cool slowly so that the magnetic moment can again be measured at suitable intervals. The whole process takes about one to two hours. Due to the excellent thermal characteristics of this system, the curves obtained on heating and cooling can be very nearly superimposed in every case where the sample has undergone no change during heating.

The thermocouples were calibrated in the following boiling baths, using proper pressure corrections: water, naphthalene, benzophenone and sulfur.

**X-Ray Diffraction Analysis.**—The X-ray diffraction studies were carried out with a simple Debye–Scherrer powder camera of 71.62 mm. inside diameter. Radiation, as obtained from a sealed-off iron target X-ray tube equipped with beryllium windows and manganese dioxide filters, was used. The tube was operated at 40 p.k.v. and 7.0 milliamperes. The samples were preserved under petroleum ether. They were ground to a fine paste while still wet with petroleum ether, mixed with collodion, and partly extruded from a short section of 19-gauge, 0.7-mm. i. d. stainless steel tubing. This procedure was effective in preventing oxidation of the samples, which otherwise were quite pyrophoric. The diameters of the diffracted rings on the films from which the $d/n$ values were obtained were determined by measuring to the outside of the ring and subtracting the sample diameter (0.7 mm.).

**Preparation of Carbide in Synthetic Ammonia Catalyst.**—The synthetic ammonia catalyst used was a commercial preparation obtained from the Hercules Powder Company. Its chemical analysis is as follows: Iron as $Fe_3O_4$, 92.6%; magnesium as MgO, 4.2%; silicon as $SiO_2$, 0.7%; and chromium as $Cr_2O_3$, 0.4%. This catalyst has been tried in the Fischer–Tropsch testing units previously described,[10] and yields of 70 g. of solid and liquid hydrocarbons were obtained per cubic meter of synthesis gas (one part carbon monoxide and one part hydrogen) per single pass over 50 cc. of catalyst at 255°.

The reduction and carburization of the catalyst were

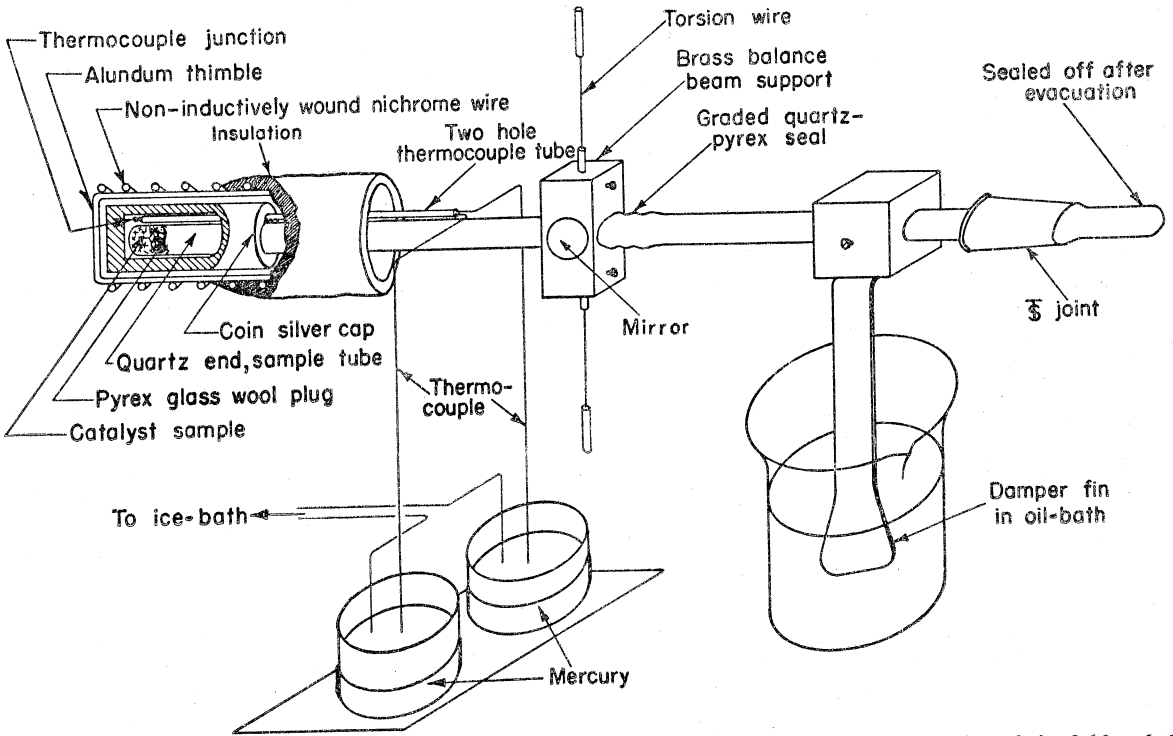

Fig. 1.—Schematic diagram of suspension assembly with quartz-Pyrex sample tube. The direction of the field and the field gradient is perpendicular to the plane of the paper.

carried out in an apparatus similar to that previously described.[11] Samples of about 5 g. each were weighed into four reaction vessels, which were placed side by side in the aluminum block furnace. A stream of electrolytic hydrogen (flowing at 0.75 liter per hour and purified by passage over palladized asbestos at 360°, soda lime, Ascarite and anhydrous magnesium perchlorate) was admitted to the reaction vessels. The temperature was maintained at 450°. During this time the reaction vessels were periodically disconnected and weighed. After eighty-two hours, the change in weight was less than 0.05 mg. per hour per sample.

At this point carburization was started. The carbon monoxide used in the carburization was made from formic acid and orthophosphoric acid at 150–200°. It was purified over sodium hydroxide, copper at red heat, soda lime and anhydrous magnesium perchlorate. The carburization was carried out at 240° for 539 hours. During this time the reaction vessels were periodically disconnected and weighed. (The samples were heated and cooled in an atmosphere of nitrogen to prevent carbonyl formation.) The weight increase observed is due almost entirely to the deposition of carbon rather than of oxygen. This was demonstrated by the fact that the products of hydrogenation of similar carburized catalysts are not absorbed in anhydrous magnesium perchlorate. The results of the carburization are summarized in Fig. 2. The final, average carbon:iron ratio (for 3 tubes) was 0.1164 (theoretical for $Fe_2C$ is 0.1076).

The reaction vessel was opened in a carbon dioxide atmosphere to prevent oxidation.

**Preparation of Carbide in Iron–Copper–Potassium Oxide (100:10:0.32) Catalyst.**—This catalyst is analogous to those used at the Kaiser Wilhelm Institut für Kohlenforschung.

Ferric nitrate nonahydrate (41.35 lb.) and copper nitrate trihydrate (2.17 lb.) were dissolved in 22.5 gallons of distilled water. A sodium carbonate solution (18.10 lb. in 20 gallons of distilled water) was made. Sixteen gallons of this solution were added to the nitrate solution at room temperature. The mixture was then heated to 70°, and the remaining carbonate solution (at room temperature) was added to form the precipitate. The mixture was then heated rapidly to boiling and held there for several minutes, after which it was filtered in a filter press and washed with 400 gallons of hot distilled water until the filtrate was free of nitrate ion. The filter cake was then dropped from the press and mixed into a smooth paste with a solution of 13 g. of potassium carbonate dissolved in 2 liters of distilled water. The catalyst was then dried at 105–110° for forty-eight hours.

The activity of this catalyst, when tried in the Fischer-Tropsch testing units, gave yields of 103 g. of liquid and solid hydrocarbons per cubic meter of synthesis gas (one part carbon monoxide and one part hydrogen) per pass over 50 cc. of catalyst at 236°.

The reduction and carburization were carried out with the same apparatus and using a procedure similar to that described above for the iron-synthetic ammonia catalyst. After reduction with hydrogen for 327 hours at 220°, the 7-g. samples did not vary more than 0.05 mg. per hour. The carburization (as shown in Fig. 2) was carried out at 188° for 211 hours when the carbon:iron ratio (average for 3 reaction tubes) had reached 0.1072. In a similar experiment a catalyst carburized at 205° for 239 hours to a carbon:iron ratio of 0.1068 lost all but 18% of the carbon as methane when heated with hydrogen at 250°. Thus the carbon in this catalyst was held largely as carbidic carbon.

The reaction vessel was opened in an atmosphere of carbon dioxide to prevent oxidation. The samples for the magnetic balance were transferred to sample holders in a carbon dioxide atmosphere, connected to a high-vacuum system, evacuated for two hours, and then sealed off.

## Results

**Carburized Iron Synthetic Ammonia Catalyst.**—The X-ray diffraction powder pattern of this

(11) L. J. E. Hofer and W. C. Peebles, THIS JOURNAL, 69, 893 (1947).

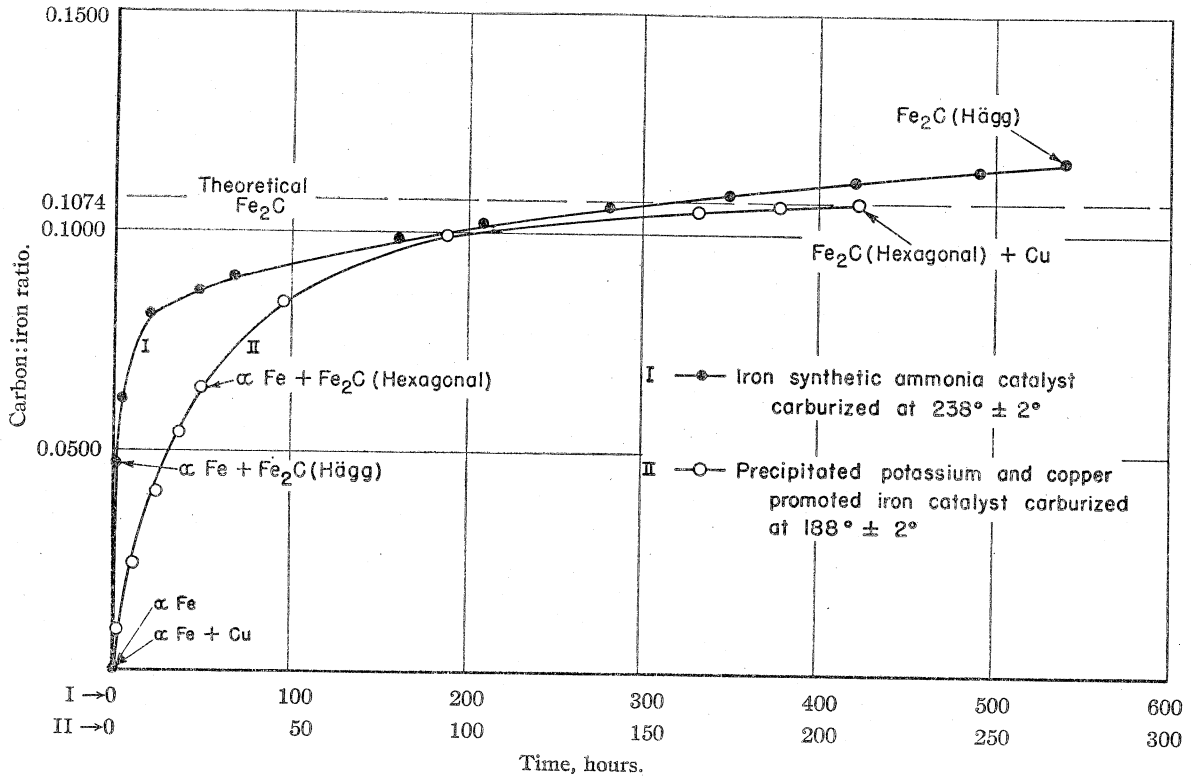

Fig. 2.—Carburization of two types of iron Fischer–Tropsch catalysts.

product was that of the Hägg[4] carbide. The $d/n$ values obtained are compared with those reported by Hägg in Table I, column 2. The diffraction pattern was diffuse, and some of the weaker lines reported by Hägg are missing; nevertheless, the match is good. Comparison of the pattern of Hägg carbide with that of cementite (column 1) reveals some similarities, but both patterns have enough characteristic lines to make identification positive.

vS = very Strong, S = Strong, M = Medium, w = weak, vw = very weak, + = slightly more intense, − = slightly less intense, br = broad.

The thermomagnetic curve for this product is given in Fig. 3, curve I. The temperature was not raised above 300° so as not to decompose the sample. The values obtained during the first heating (circles) correspond very closely to those obtained during the first cooling (X's), showing that the sample remained unchanged. Furthermore, a second heating and cooling (not shown) gave the same results. As an additional check on the thermal stability of the sample at temperatures up to 300°, another sample (with which a thermomagnetic curve similar to Fig. 3, curve I, had been obtained) was removed for X-ray diffraction analysis and found to consist of Hägg carbide. Thus the average Curie point at 247° is undoubtedly characteristic of the Hägg carbide. The uncertainty in this value as determined by thermomagnetic curves on different samples of this and similar products is ±3°. It will be noted that the magnetic moment at 300° is not zero. This is probably due either to some residual iron which was not converted to carbide, or to some magnetite formed during the carburization. The observed magnetic moment above the Curie point of the Hägg carbide can be accounted for by not more than 2% metallic iron or 6% magnetite.

The above-described sample was then heated at 580° for two hours and the thermomagnetic curve shown in Fig. 3, curve II, was obtained. This curve has a Curie point at 208°, considerably lower than that of curve I. After curve II was obtained, the sample was removed for X-ray diffraction analysis which proved that the sample contained cementite. The diffraction pattern was very sharp, and in Table I, column 1, the measured *d/n* values for the sample are compared with the

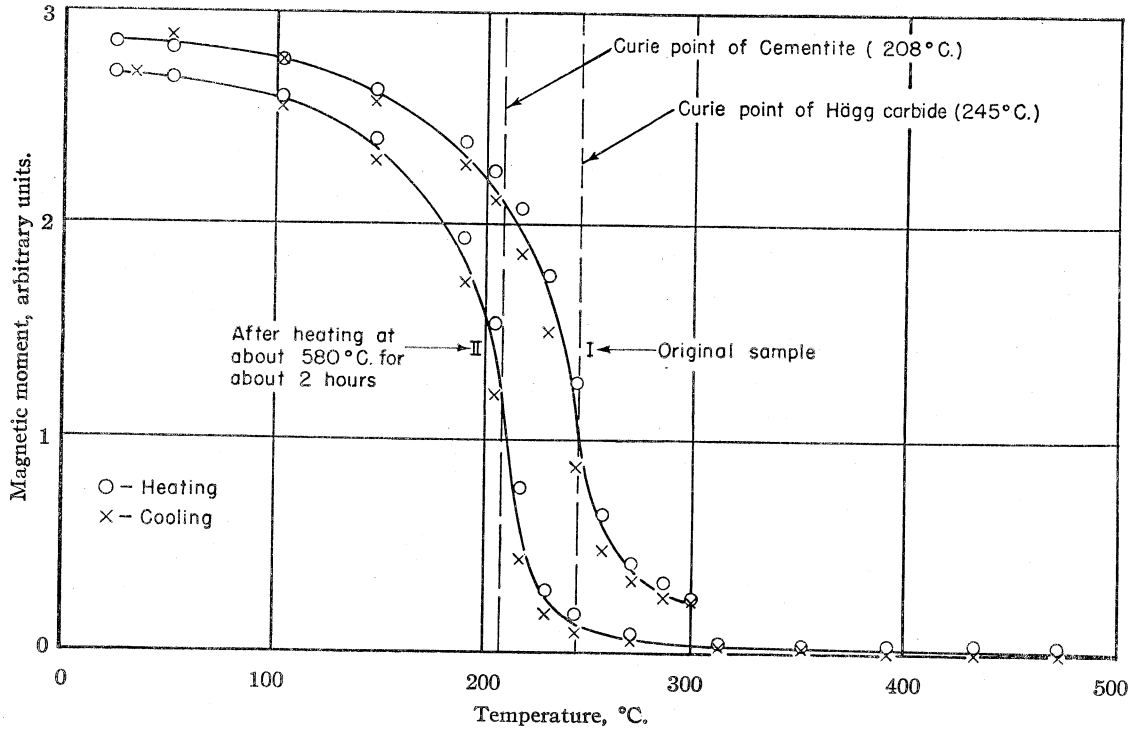

Fig. 3.—Thermomagnetic curves showing: I, presence of Hägg carbide in iron synthetic ammonia catalyst; II, same catalyst decomposed into cementite.

reported values for cementite as determined by Westgren.[12] (Only that part of Westgren's data is shown for which his calculated intensities are greater than 500 of his arbitrary units.) The agreement is very good. The Curie point, 208°, also checks the Curie points given for cementite in the literature, which range from 205° to 220°. (This wide range is due in part to experimental difficulties and in part to a certain arbitrariness in the definition of the term "Curie point." In the present paper, it has been defined as the point of inflection in the thermomagnetic curve.) Thus the Hägg carbide, with its characteristic diffraction pattern and its 247° Curie point, reacts at a sufficiently high temperature to form cementite with a different diffraction pattern and a different Curie point, according to the reaction

$$3Fe_2C \longrightarrow 2Fe_3C + C$$

Hägg Carbide Cementite Free Carbon

As can be seen from the curves in Fig. 3, the magnetic moment due to the Hägg carbide is roughly the same as that of an equivalent amount of cementite, since both curves were made on the same sample and with the balance at the same adjustment. Furthermore, the equivalent amounts of cementite and Hägg carbide are nearly equal in weight. As a result, the specific magnetizations of cementite and Hägg carbide must be about the same, or about 139 c. g. s. units per gram, according to Lange and Mathieu.[1]

(12) A. Westgren, *Jernkontorets Ann.*, **114**, 457 (1932).

**Carburized Iron–Copper–Potassium Oxide (100:10:0.32) Catalyst.**—The X-ray diffraction pattern contained faint lines due to the 200, 220, 311 and 222 reflections of face-centered copper metal. In addition, the relatively strong lines presented in Table I, column 3, were present. (One of the lines of the hexagonal iron carbide as observed in the diffraction pattern, the 2.08 Å., 101 line of the hexagonal carbide, coincides with the 111 line of copper. However, since this line is by far the strongest line of the pattern and since the copper lines are relatively weak due to the low percentage of copper, the high intensity of this line must be due to the hexagonal carbide.) No other lines were observed in the pattern.

Thermomagnetic analysis gave the curves shown in Fig. 4. During the first heating two Curie points were found, one at 247° and one at 380°, indicating the presence of two different ferromagnetic phases. As has been demonstrated, the first Curie point can be identified with the Hägg carbide. The occurrence of this phase is somewhat surprising because no lines from the X-ray diffraction pattern of the Hägg carbide could be detected. The other phase with the Curie point at 380° is unstable and decomposes below 435°, for upon cooling from 435° the curve (X's) does not coincide with the first heating curve (circles) but instead is the curve of a typical Hägg carbide. Similar experiments with other samples of this same preparation show that the 380° Curie point carbide decomposes appreciably in the range

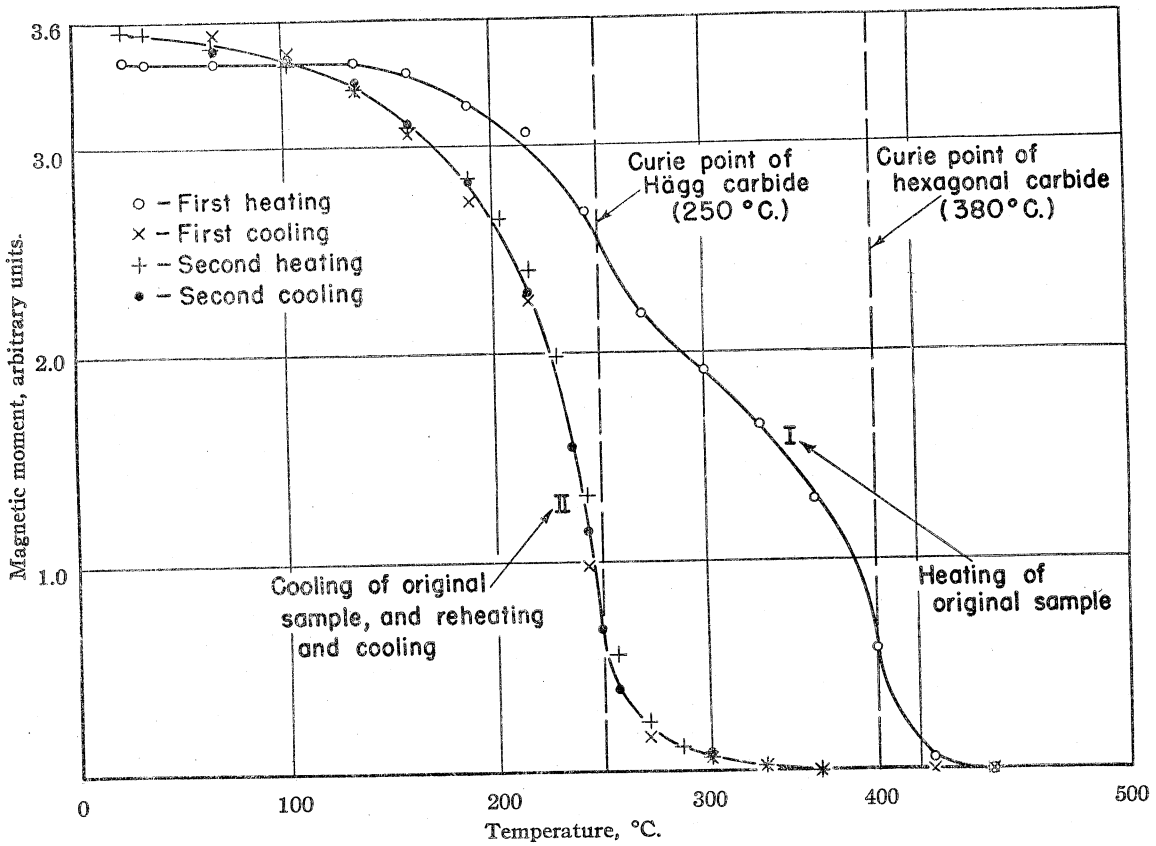

Fig. 4.—Thermomagnetic curves showing the presence of the Hägg and hexagonal iron carbides in copper-promoted Fischer–Tropsch catalyst, and the reversibility of the Hägg carbide curve.

300–380°. If the thermomagnetic measurements are made sufficiently rapidly, the point of inflection of the curve is invariant at 380° showing that it is a real transition temperature. The magnetic moment at 435° is very nearly zero, showing that no measurable amount of metallic iron or magnetite was present at that point. A second heating curve (crosses) and a second cooling curve( heavy dots) again coincided with the curve for Hägg carbide, showing the stability of the carbide under the conditions. This sample, when removed from the magnetic balance for X-ray diffraction analysis, was found to contain only Hägg carbide and copper. From these experiments one must conclude that the unstable carbide (Curie point 380°) is none other than the hexagonal close-packed iron carbide.

Since the formula of the Hägg carbide is nearly $Fe_2C$, as determined by both Hägg[4] and Jack,[5] and since the gross formula of this preparation is also $Fe_2C$, the formula of the hexagonal carbide must be $Fe_2C$. This formula can also be based on the similarity of structure between the hexagonal carbide and $Fe_2N$, which had been studied by Hägg.[13]

The over-all magnetic moment of the original sample is nearly the same as that of the Hägg carbide formed from it. Since the formulas of the two carbides are the same, one must conclude that the specific magnetization of the two carbides is the same, namely, about 140 c. g. s. units. Since the specific magnetization of both the Hägg carbide and the hexagonal carbide is known and since both carbides have the same formula, one can estimate the fraction of each carbide present from the shape of the thermomagnetic curve (Fig. 4, curve I). Calculated in this way, the Hägg carbide in the carburized catalyst is 10–30% of the total carbide.

Using the method previously described[14] and using the lattice parameter of face-centered cubic copper as 3.608kX, the lattice parameters of the hexagonal carbide were determined as $a_0$ = 2.749kX, $c_0$ = 4.340kX, and $a_0/c_0$ = 1.579.

In other experiments, the thermal stability of Hägg carbide was shown to be about the same in this catalyst as in the iron synthetic ammonia catalyst.

## Discussion

The 247° Curie point carbide or Hägg carbide is readily identified as the 265° Curie point carbide of Pichler and Merkel, since it was produced under similar conditions and behaved similarly. The

(13) G. Hägg, *Z. physik. Chem.*, **B8**, 455 (1930).

(14) L. J. E. Hofer and W. C. Peebles, THIS JOURNAL, **69**, 2497 (1947).

Curie points are sufficiently close together to support this identification. This carbide can also be identified with the so-called "cubic ferric sesquioxide saturated with potassium oxide" of Lefebvre and LeClerc.[15] This phase develops in iron Fischer–Tropsch catalysts during synthesis in the same way as the 265° Curie point carbide of Pichler and Merkel. Claims are made by both Lefebvre and LeClerc and by Pichler and Merkel that the phase improves the characteristics of the catalyst. Lefebvre and LeClerc place the Curie point at 250°, which is very close to that found in the present paper. On the other hand, Lefebvre and LeClerc present no positive evidence, such as X-ray diffraction data, that the phase with the 250° Curie point is really the cubic ferric sesquioxide ($\gamma$ $Fe_2O_3$) saturated with potassium oxide, which has been described in the literature. This *bona fide* cubic ferric sesquioxide saturated with potassium oxide does not have a Curie point at 250° but does have one at 630°.[16] From fragmentary data[17] it appears that the Hägg carbide (Curie point found about 250°) was also formed in Rheinpreussen (Moers, Ruhr Valley) catalysts during synthesis, although the distinctly different carbide was not recognized as such but was termed "unstable cementite."

The 380° Curie point carbide or hexagonal carbide is evidently the same as Pichler and Merkel's 380° Curie point carbide. Pichler and Merkel emphasized the importance of copper in promoting the formation of this carbide.

This carbide may possibly be identified with the carbides of Tutiya,[18] Hofmann and Groll,[19] and Brill and Mark.[20] For purposes of comparison the X-ray diffraction data of all three groups of investigators are compared with those for the hexagonal iron carbide in Table II. With the exception of a few extra lines contained in the data of Tutiya, and Hofmann and Groll, the data of these authors agree very well with those for the hexagonal carbide. The data of Brill and Mark, however, bear little resemblance to those for the hexagonal carbide.

The hexagonal carbide forms the carbon-rich extreme of the series of hexagonal close-packed $\epsilon$-phase carbonitrides studied by Jack.[3]

**Acknowledgment.**—The authors wish to thank Dr. H. H. Storch for his assistance and interest in this project, and Dr. H. P. Klug of Mellon Institute for helpful discussions. In addition they wish to thank Dr. R. B. Anderson and the personnel of the Catalyst Testing Unit for the activity data, H. Hewlett and K. Stein for the preparation of one of the catalysts, and W. E. Dieter for the ultimate chemical analysis.

## Summary

1. The existence of two carbides of iron with formula $Fe_2C$ and having Curie points at 247° and 380° has been confirmed. (Pichler and Merkel reported the Curie points at 265° and 380°, respectively.)

2. A hexagonal close-packed carbide of iron has been prepared; this carbide has properties similar to those of the carbide described by Halle and Herbst.

3. The identity of the 380° Curie point carbide of Pichler and Merkel with the hexagonal carbide has been established.

4. The identity of the 247° (265° according to Pichler and Merkel) Curie point carbide with the Hägg carbide has been established.

5. The carbides reported by Hofmann and Groll and by Tutiya seem to be the hexagonal carbide.

6. The hexagonal carbide decomposes above about 300° to Hägg carbide which in turn decomposes at about 550° in one hour to cementite and free carbon.

# Polarography of Selenium and Tellurium. II. The +4 States

BY JAMES J. LINGANE AND L. W. NIEDRACH[1]

The polarographic behavior of the −2 states of selenium and tellurium has been discussed in a preceding paper.[2] The present paper is concerned with the polarography of the +4 states of these elements.

The only previous study is that of Schwaer and Suchy,[3] who observed three waves for selenium (IV) and tellurium(IV) in 1 *N* hydrochloric acid which they attributed to reduction to the +2, elemental, and −2 oxidation states. In very dilute solutions the first and second waves merged into one, which Schwaer and Suchy concluded was due to reduction to the elemental states. We observed an additional wave to those reported by Schwaer and Suchy in acid medium, and have been unable to confirm their hypothesis that one of the waves results from reduction to the +2 state.

With ammoniacal buffers Schwaer and Suchy observed a single well-developed wave with both selenium(IV) and tellurium(IV), which they concluded was due to reduction to the elemental state in both cases. Our experiments confirm this conclusion only in the case of tellurium, and we have found that the reduction of selenium(IV) proceeds completely to the −2 state in ammoniacal media.

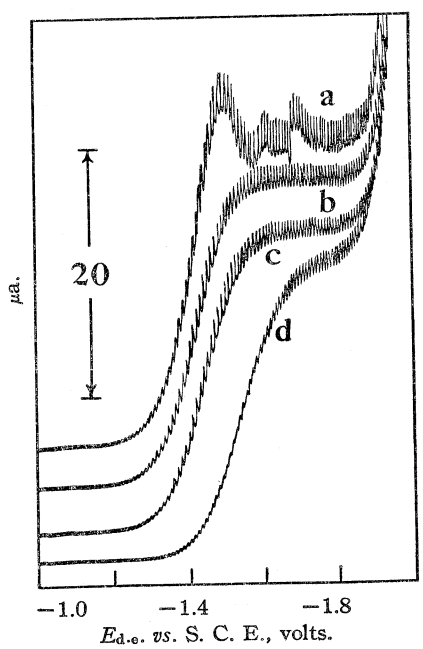

Fig. 1.—Polarograms of 1.5 millimolar selenium(IV) in 1 *M* ammonium chloride–ammonia at *p*H 8.0 with (a) 0, (b) 0.001, (c) 0.003 and (d) 0.01% gelatin.

Schwaer and Suchy found that tellurium(IV) is reduced from an approximately neutral tartrate solution, and they recommended this medium for the simultaneous determination of copper, bismuth and tellurium. They also observed that tellurium(IV) produces a wave in strongly alkaline solution, but selenium(IV) does not. The reduction product in alkaline medium was not identified.

In this investigation the polarographic characteristics of selenium(IV) and tellurium(IV) have been studied over a wide range of conditions, and the reduction states have been established conclusively by the coulometric analysis technique[4] based on controlled potential electrolysis with a large mercury cathode.

## Results and Discussion

The preparation of the pure selenium dioxide and tellurium dioxide used, and the technique of the coulometric and polarographic measurements, have been described in previous papers.[2,5]

**Selenium.**—The polarograms in Fig. 1 demonstrate the influence of gelatin on the selenium(IV) wave in ammoniacal medium. Decreasing the ammonium chloride concentration from 1 to 0.1 *M* at constant *p*H causes a slight negative shift of the half-wave potential, and the wave remains well developed when 0.001 to 0.003% gelatin is present. The *p*H of the solution may vary from 8.0 to 9.5, but at greater *p*H the wave shifts to a more negative potential and merges with the final current rise, and when the *p*H of the ammoniacal supporting electrolyte is smaller than about 8 additional ill-developed waves appear. The most satisfactory supporting electrolyte is 1 *M* ammonium chloride containing not more than 0.003% gelatin and ammonia to adjust the *p*H to 8.0 to 9.5. Under these conditions the diffusion current is directly proportional to the concentration of selenium(IV) as shown by the data in Table I. The half-wave potential is independent of the selenium(IV) concentration at a constant *p*H, but shifts to more negative values with increasing *p*H.

The reduction state in ammoniacal medium (1 *M* ammonium chloride and ammonia to *p*H 8.0) was established by electrolyzing a 1.59 millimolar solution of selenium(IV) with a large mercury cathode whose potential was maintained at −1.65 v. *vs.* S. C. E. by an automatic

potentiostat.[6] The quantity of electricity passed was determined by a hydrogen–oxygen coulometer, and was found to correspond to 6 electrons per mole of selenium(IV). Thus at *p*H 8.0 the reduction proceeds to the −2 state, according to

$$HSeO_3^- + 6H^+ + 6e^- = HSe^- + 3H_2O \quad (1)$$

The change in current with time during the controlled potential coulometric electrolysis is shown in Fig. 2. Soon after the start the solution showed a light pink coloration which gradually deepened to a bright red as the current decreased to the minimum. The current then increased rapidly and the color of the solution changed to orange. After passing through the maximum the current decreased continuously while the color became less intense and finally the solution became colorless. Although no solid phase was observed, the red color was undoubtedly due to colloidal selenium. Since in a controlled potential reduction the current at any instant is directly proportional to the momentary concentration of the electroreducible substance, the minimum and maximum in Fig. 2 are readily understandable. The −2 selenium formed in the primary electrode reaction 1 reacted with the remaining +4 compound and precipitated the element, $HSO_3^- + 2HSe^- + 3H^+ = 3Se + 3H_2O$. When all the +4 compound had been reduced in this manner, the current went through the minimum. The slow reduction of the element then produced −2 selenium which dissolved the element as polyselenide, $xSe + Se^{--} = Se_x^{--}$. The current increased until all the element had dissolved, and then decreased finally as the polyselenide was reduced.

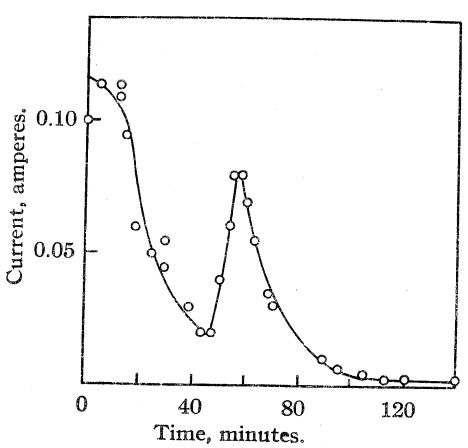

Fig. 2.—Current–time curve during coulometric reduction of 1.59 millimolar selenium(IV) in 1 *M* ammonium chloride–ammonia at *p*H 8.0 with potential of large mercury cathode at −1.65 v. *vs.* S. C. E.

(6) J. J. Lingane, *Ind. Eng. Chem., Anal. Ed.*, **17**, 332 (1945).

Polarograms recorded at various stages of the electrolysis confirmed the absence of −2 selenium when the +4 compound was present. A polarogram obtained with the final clear and colorless solution, agreed with those for −2 selenium.[2]

The effect of *p*H from 0 to 14 is illustrated by

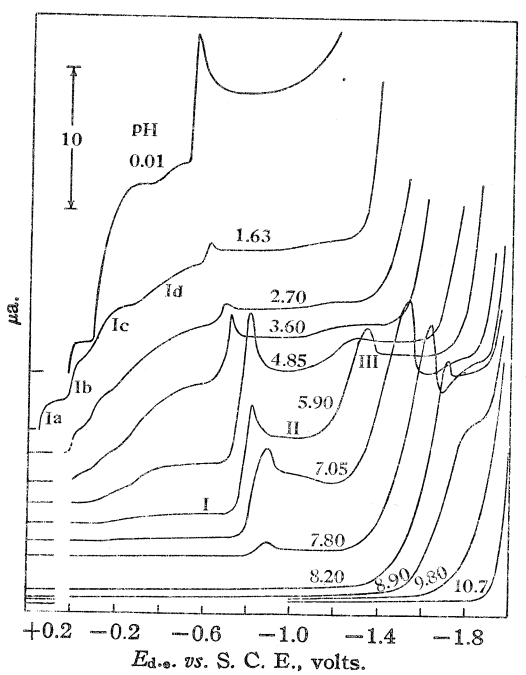

Fig. 3.—Tracings of polarograms of 1 millimolar +4 selenium at the various *p*H values indicated for each curve. The galvanometer zero for each curve is indicated by the short lines on the left ordinate. At low *p*H, hydrochloric acid and citrate buffers were used, at intermediate *p*H, phosphate buffers, and borate and carbonate buffers were used for the alkaline region. No gelatin or other maximum suppressor was present.

the tracings of automatically recorded polarograms in Fig. 3. The solutions used were 1 millimolar in +4 selenium and contained no maximum suppressor. No specific effects of the buffer constituents were found upon comparing polarograms obtained in the ranges where the buffers overlapped.

The presence of three major waves is illustrated by the polarograms at *p*H 4.85 and 5.90 in Fig. 3. The first of these is resolved into several additional waves in the lower *p*H range.

Moderate amounts of gelatin eliminated the maxima from all waves; however, at the higher *p*H as little as 0.001% suppressed the wave III quite markedly, while in hydrochloric acid (*p*H 0.01) wave II is sensitive to gelatin.

In 1 *N* hydrochloric acid the three waves mentioned by Schwaer and Suchy were found, and the effects of the selenium(IV) concentration on their form was confirmed. A fourth wave at the very start of the polarogram in 1 *N* hydrochloric is also observable, which indicates that the reduction potential of selenium(IV) is more positive than the dissolution potential of mercury in 1 *N* hydrochloric acid.

The effects of selenium(IV) concentration at *p*H 1.63 are illustrated in Fig. 4. Several additional steps develop as the concentration of selenium(IV) is increased. At higher values of *p*H the additional steps do not appear and the general form does not change with the selenium (IV) concentration.

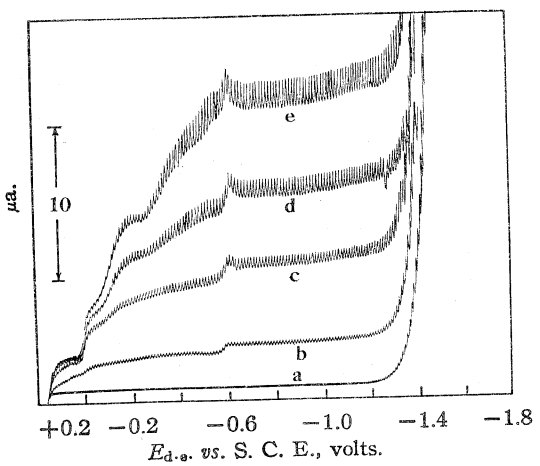

Fig. 4.—Polarograms of (a) 0, (b) 0.199, (c) 0.61, (d) 1.00 and (e) 1.50 millimolar selenium(IV) in 0.5 *M* citric acid at *p*H 1.63.

Figure 5 shows polarograms of selenium(IV) in unbuffered potassium chloride and ammonium chloride. In potassium chloride at *p*H 3.3 reduction begins but normal development of the waves is prevented by the increasing *p*H at the electrode surface as hydrogen ion is consumed. In neutral potassium chloride (curve b) the production of hydroxide ion at the surface of the mercury drops completely inhibits the reduction until the potential exceeds about −1.6 v. In the unbuffered ammonium chloride solutions (curves c and d) nearly normal waves are obtained because the hydrogen ion required for the reduction is furnished by ammonium ion, and the resultant production of ammonia buffers the solution at the electrode surface and prevents the *p*H from increasing.

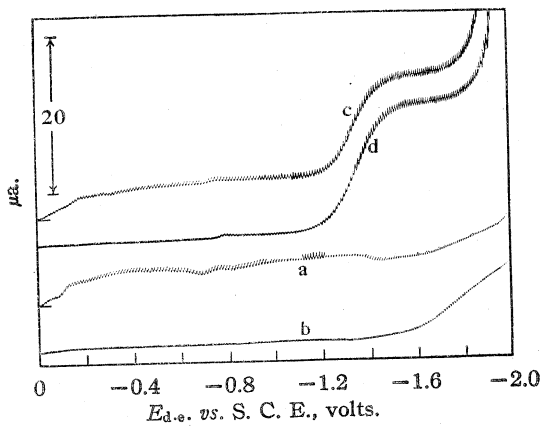

Fig. 5.—Polarograms of 1 millimolar selenium(IV) in (a) 1 *M* potassium chloride at *p*H 3.3, (b) 1 *M* potassium chloride at *p*H 7.2, (c) 1 *M* ammonium chloride at *p*H 3.2 and (d) 1 *M* ammonium chloride at *p*H 6.2. All solutions contained 0.003% gelatin.

The absence of anodic waves under all conditions shows that oxidation of +4 selenium to the +6 state does not occur at the dropping electrode. Furthermore, in agreement with Schwaer and Suchy, we found no reduction waves for either +6 selenium or +6 tellurium at any *p*H.

The complexity of the cathodic waves in Fig. 3 is due in part to stepwise reduction and it also suggests the reduction at different potentials of the different species formed by the dissociation of selenous acid. It is well known that the different ionization species of certain weak acids can produce separate reduction waves when the establishment of dissociation equilibrium is slow compared to the drop time.[7,8,9] Brdicka and his collaborators[10,11] have recently developed quantitative relations by means of which the several wave heights observed in such cases can be correlated with the rate constants involved in the establishment of the dissociation equilibria.

The upper graph in Fig. 6 shows the *total* diffusion current constant $i_d/(Cm^{2/3}t^{1/6})$ as a function of *p*H, and the solid curves in the lower graph show the observed *relative* heights of waves I, II and III as a function of *p*H. The dotted curves in the lower graph of Fig. 6 show the

relative proportions of the three species $H_2SO_3$, $HSeO_3^-$, and $SeO_3^=$ as a function of *p*H, and they were computed using the values $2.4 \times 10^{-3}$ and $4.8 \times 10^{-9}$ for the dissociation constants of selenous acid.[12]

There is seen to be approximate agreement of the shapes of the curves for the relative heights of the three waves and the relative equilibrium concentrations of the $H_2SeO_3$, $HSeO_3^-$, and $SeO_3^=$, which might be regarded as evidence that the three main waves result from reduction of the three different species. However, there are two facts which indicate that this is not a satisfactory interpretation. In the first place the change of the total diffusion current constant with *p*H shown by the upper curve in Fig. 6 is much too large to be attributed to different diffusion coefficients of the three species, and it points to a different reduction product, involving fewer electrons, at intermediate *p*H values. Since the coulometric analyses conclusively prove that reduction proceeds all the way to −2 selenium ($n = 6$) at *p*H 8.0 and above, and since the total diffusion current constant at small *p*H values is of the same order of magnitude as at high *p*H, the reduction at low *p*H must also involve 6 electrons. The diffusion current constants at intermediate *p*H are very nearly two-thirds of the extreme values, indicating a 4-electron reduction at *p*H values between about 3 and 7. Secondly, the cathodic half-wave potentials of wave II are the same (within 0.03 v.) at all *p*H values as the half-wave potentials of the *anodic* wave of −2 selenium discussed in a previous paper.[2] This anodic wave was shown[2] to result from the reaction

$$Hg + H_2Se = HgSe + 2H^+ + 2e \qquad (2)$$

at small *p*H values, and to the analogous reactions involving $HSe^-$ and $Se^=$ at intermediate and high *p*H, and the observed anodic half-wave potentials agreed very well with values computed from the standard potential of reaction 2 and the ionization constants of hydroselenic acid over the entire *p*H range. Wave II is thus the cathodic reflection of the anodic wave of −2 selenium.

It is evident, therefore, that wave I cannot be due to a net reduction to −2 selenium because at potentials more positive than wave II the −2 selenium depolarizes the dropping electrode anodically according to reaction 2. We believe that the *primary* electrode reaction at potentials more positive than wave II (*i. e.*, on wave I) is a 6-electron reduction producing −2 selenium according to

$$H_2SeO_3 + 6e + 6H^+ = H_2Se + 3H_2O \qquad (3)$$

and this is followed by the 2-electron anodic reaction 2. The *net* result is a 4-electron reduction in which mercuric selenide is the final product

$$H_2SeO_3 + 4e^- + 4H^+ + Hg = HgSe + 3H_2O \qquad (4)$$

(12) D. M. Yost and H. Russell, "Systematic Inorganic Chemistry," Prentice-Hall Inc., New York, N. Y., 1944.

This interpretation of wave I was confirmed by coulometric reduction of a 1 millimolar solution of selenium(IV) in a citrate buffer of *p*H 1.6. The potential of the large mercury cathode was maintained constant at −0.45 v. *vs.* S. C. E., a value corresponding to the top of wave I at this *p*H (see Fig. 3), and the coulometer reading corresponded to a 4-electron reduction. The reduction product was a black solid which qualitative tests showed to be a mercury compound (*i. e.*, mercuric selenide).

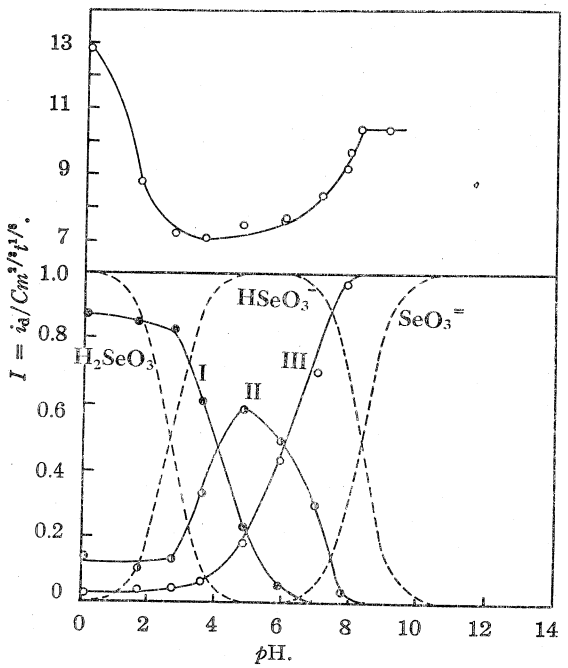

Fig. 6.—The upper curve shows the variation of the *total* diffusion current constant of 1 millimolar selenium(IV) with *p*H. The solid curves in the lower graph are the *relative* observed heights of the main waves I, II and III, and the dashed curves show the relative equilibrium concentrations of $H_2SeO_3$ (left), $HSeO_3^-$ (middle) and $SeO_3^=$ (right), calculated from the dissociation constants of selenous acid.

The fact that at potentials more negative than the half-wave potential of wave II the anodic reaction 2 is excluded, and yet at intermediate *p*H values the *total* diffusion current constant corresponds to only a 4-electron reduction, is, we believe, due to the formation of elemental selenium. The −2 selenium produced by the primary reaction 3 diffuses away from the electrode surface and reacts in the diffusion layer with the incoming hydrogen selenite ion to precipitate elemental selenium

$$HSeO_3^- + 2H_2Se + H^+ = 3Se + 3H_2O \qquad (5)$$

Since it is known from the coulometric electrolyses that elemental selenium is only slowly reduced (see Fig. 2), and since it is formed in the diffusion layer at some distance from the electrode surface,

the *net* reaction at intermediate *p*H is the 4-electron reduction

$$HSeO_3^- + 4e^- + 5H^+ = Se + 3H_2O \qquad (6)$$

At a *p*H of 8 or above, and at low *p*H values, reaction 5 (or the analogous reactions involving $H_2SeO_3$, $SeO_3^=$, $HSe^-$ and $Se^=$) proceeds so slowly that no appreciable formation of elemental selenium occurs during the drop life, and the final product is −2 selenium.

No evidence has been obtained at any *p*H for the reduction to +2 selenium postulated by Schwaer and Suchy.

At *p*H values below 8 the diffusion current quotients $i_d/C$ of the separate waves, as well as that of the total wave, were found to vary significantly with the concentration of +4 selenium. For example at *p*H = 5.0 the value of $i_d/(C\,m^{2/3}t^{1/6})$ for the total wave decreased from 10.5 and 8.5 when the concentration of selenium(IV) was increased from 0.2 to 2 millimolar. Hence supporting electrolytes of *p*H smaller than about 8 are not suitable for practical analytical purposes.

**Copper and Selenium.**—Since copper and selenium frequently occur together their simultaneous polarographic determination in ammoniacal medium was investigated. As shown in Fig. 7, polarograms of ammoniacal mixtures of +2 copper and +4 selenium display the familiar double wave which results from the stepwise reduction of the tetramminocupric ion, followed by the well-developed selenium wave.

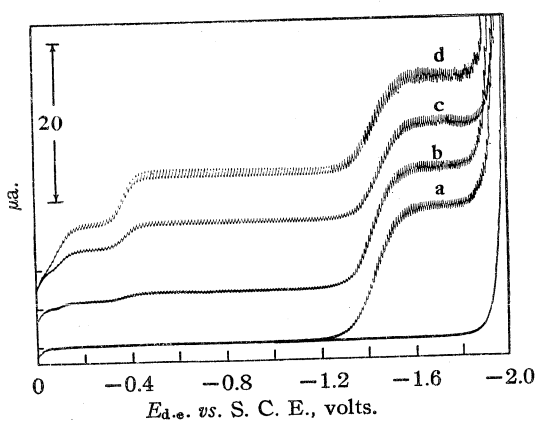

Fig. 7.—Polarograms of 1 millimolar selenium(IV) in 1 *M* ammonium chloride-ammonia at *p*H 8.4 with (a) 0, (b) 0.302, (c) 1.00 and (d) 2.00 millimolar copper(II). Gelatin (0.003%) was used as maximum suppressor. The galvanometer zero for each curve is indicated by the short marks on the left-hand ordinate.

Although the waves of both elements are well developed their analytical application is complicated by the fact that the height of the selenium wave decreases markedly with increasing concentration of copper. With 1.00 and 2.00 millimolar copper the height of the selenium wave in Fig. 7 is only 72 and 75% of its value in the absence of copper. This interesting effect is not due to a decreased diffusion current of the selenium, but rather to a smaller contribution of copper to the total diffusion current at potentials at which selenium(IV) is reduced. The −2 selenium formed at the electrode surface reacts with the incoming tetramminocupric ion in the diffusion layer, precipitating cupric selenide

$$Cu(NH_3)_4^{++} + Se^= = CuSe + 4NH_3 \qquad (7)$$

and the contribution of copper to the total diffusion current is correspondingly diminished. Since 6 electrons are involved in the formation of each selenide ion, but the reduction of the copper complex requires only 2 electrons, it is evident that if the diffusion coefficients of copper(II) and selenium(IV) were the same, then increasing the concentration of copper should decrease the apparent height of the selenium wave only until the molar concentrations of copper and selenium are equal. At this point the apparent height of the selenium wave alone should be two-thirds of its original value. The observed selenium wave height (72%) is slightly larger than two-thirds its original value because the diffusion coefficient of the tetramminocupric ion is somewhat larger than that of selenium(IV), and also because the precipitation of cupric selenide is not quite complete. With still larger concentrations of copper the apparent height of the selenium wave should remain constant, and this is the observed result. In other words, the *total* diffusion current at the potential of the selenium wave (−1.6 to −1.8 v.) remains practically constant until the quantity $CD^{1/2}$ for copper exceeds that for the tellurium, and then increases in direct proportion to the increased copper concentration.

Correction for this effect is complicated by the fact that the precipitation of cupric selenide is not quite complete, and hence in practical work the correction will have to be determined empirically. This same effect will doubtless also be observed with other metals that form insoluble selenides.

**Tellurium.**—The low solubility of tellurium dioxide in neutral and acid solutions limits the choice of supporting electrolytes for experiments at *p*H less than 7. It was found that the solubility in acid medium is greatly increased by the presence of citrate or tartrate, apparently because of the formation of telluryl citrate complexes, and in citrate media it is possible to work with concentrations of tellurium(IV) up to about 5 millimolar. Tellurium dioxide is freely soluble in ammoniacal and alkaline media.

Figure 8 shows tracings of polarograms of 1 millimolar tellurium(IV) in 0.5 *M* citrate buffers of *p*H between 0.4 and 6.88. Maximum suppressors such as methyl red, thymol blue, α-naphthol and thiourea are without effect, and even gelatin up to 0.01% does not eliminate the very large maximum.

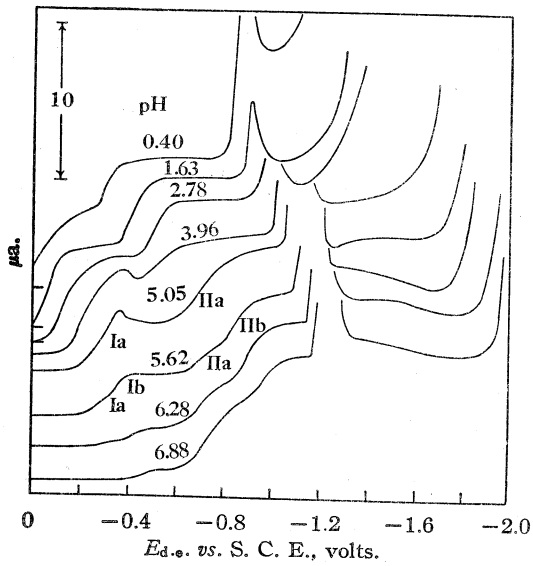

Fig. 8.—Polarograms of 1 millimolar +4 tellurium in 0.5 *M* citrate buffers at the *p*H values indicated for each curve. No maximum suppressor was present.

There are two main waves preceding the large maximum, and these are best developed at *p*H values between 0.4 and 3. The approximate equality of the heights of these two waves with 1 millimolar tellurium(IV) up to about *p*H 5 is purely fortuitous, and does not correspond to stepwise reduction, nor to the intermediate production of +2 tellurium. For example, with a citrate buffer of *p*H 1.63 only a single wave preceding the maximum is observed when the concentration of tellurium(IV) is smaller than about 0.4 millimolar. With increasing tellurium(IV) concentration the second wave at −0.4 v. develops, but the first wave retains a virtually constant height. With 3 millimolar tellurium(IV) the second wave height becomes nearly four times the height of the first wave. At *p*H 1.63, the *total* diffusion current measured at −0.6 to −0.8 v. was strictly proportional to the concentration of tellurium(IV) between 0.1 and 3 millimolar, with $i_d/(C\ m^{2/3}t^{1/6})$ equal to 5.72 ± 0.07. The diffusion current constant increases from 4.8 at at *p*H of 0.4 to a maximal value of 5.75 at about *p*H 2, and then gradually decreases to 4.8 as the *p*H is increased to 7.

The virtual constancy of the first wave height with increasing concentration of tellurium(IV) suggests the formation of a film of reduction product (elemental tellurium) on the electrode surface which inhibits further reduction until the potential exceeds about −0.4 v.

Coulometric analysis at −0.65 v. showed that the total double wave at *p*H 1.63 results from a 4-electron reduction to elemental tellurium

$$H_2TeO_3 + 4e^- + 4H^+ = Te + 3H_2O \qquad (8)$$

Since the change in the total diffusion current constant is not very great between *p*H 0.4 and 7, it is evident that the total wave over this *p*H range is due to reduction to the element.

At *p*H values between 5.5 and 7.0 additional poorly defined waves are observable before the maximum. These may be due in part to reduction to the +2 state, but film formation and reduction of the different ionization species of tellurous acid are probably more important factors.

In ammoniacal medium only one very well developed wave appears as shown in Fig. 9. In two coulometric reductions with the potential of the large mercury cathode at −0.90 v. *vs.* S.C.E. the coulometer reading corresponded to 4.07 and 3.95 electrons per mole of tellurium (IV) reduced, proving that the wave results from reduction to the element.

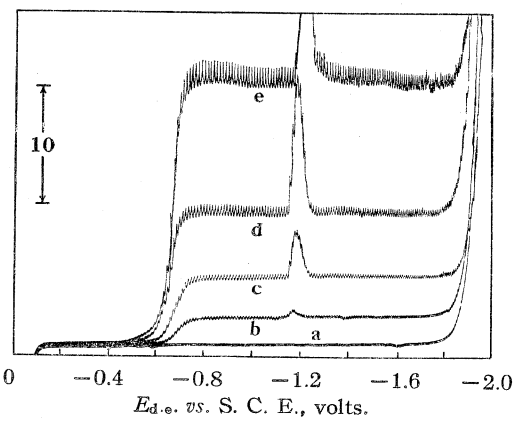

Fig. 9.—Polarograms of (a) 0, (b) 0.202, (c) 0.500, (d) 1.00 and (e) 2.00 millimolar tellurium(IV) in 1 *M* ammonium chloride–ammonia at *p*H 9.4 in the presence of 0.003% gelatin.

The polarographic characteristics in ammoniacal buffers are summarized in Table II. All the solutions contained 0.003% gelatin. The values of $i_d/(Cm^{2/3}t^{1/6})$ in the last column display a

TABLE II

+4 TELLURIUM IN AMMONIACAL BUFFERS AT 25°

| Buffer | *p*H | *C*, millimolar | $E_{1/2}$ *vs.* S.C.E. | $i_d$, microamp. | $\frac{i_d}{Cm^{2/3}t^{1/6}}$ |

| | | 2.000 | − .62 | 22.48 | 7.43 |
| | 9.4 | 0.202 | − .69 | 2.43 | 7.95 |
| | | 0.500 | − .67 | 6.04 | 7.99 |
| | | 1.000 | − .66 | 11.74 | 7.76 |
| | | 2.000 | − .66 | 22.44 | 7.75 |
| 1 *M* $NH_4$ Tartrate | 9.3 | 0.083 | − .72 | 0.85 | 6.7 |
| | | 1.67 | − .68 | 15.4 | 6.1 |
| | 10.0 | 0.083 | − .80 | 0.80 | 6.3 |
| | | 1.67 | − .77 | 15.8 | 6.3 |
| 0.1 *M* $NH_4$ Tartrate | 9.0 | 0.083 | − .76 | 0.98 | 7.8 |
| | | 1.67 | − .76 | 18.9 | 7.5 |
| | 10.0 | 0.083 | − .83 | 0.92 | 7.3 |
| | | 1.67 | − .79 | 18.1 | 7.2 |

small but significant decrease with increasing concentration of tellurium(IV) at any given *p*H, the trend being less pronounced the higher the *p*H. Thus the diffusion current is not strictly proportional to $C$ over a wide range of concentrations, but the discrepancy is small.

Single well developed waves were also obtained in borate and carbonate buffers between *p*H 7.8 and 11.1. The half-wave potentials at a given *p*H are somewhat more negative in borate and carbonate buffers than in ammoniacal medium. For example, at *p*H 9.4 the half-wave potentials in 0.5 *M* carbonate and borate buffers were −0.87 v. and −0.88 v., respectively, compared to −0.68 v. in 1 *M* ammonium chloride–ammonia at the same *p*H. The half-wave potential of the alkaline wave shifts markedly to more negative values with increasing *p*H; in 0.5 *M* borate buffers of *p*H 7.8, 8.8, 10.5 and 11.1 the values were *seriatim* −0.74, −0.84, −0.96 and −1.18 v. *vs.* S.C.E.

In 0.1 and 1 *M* sodium hydroxide in the presence of gelatin, a very well developed single wave is obtained as shown in Fig. 10. Without gelatin a small prewave precedes the main wave, but this is completely eliminated with 0.01% gelatin. The half-wave potentials in 0.1 and 1 *M* sodium hydroxide in the presence of 0.003% gelatin are −1.22 v. and −1.19 v., respectively. It is interesting to note that these values are very close to the standard potential (−1.21 v. with 1 millimolar tellurium) of the couple $Te + 2e = Te^{=}$ (see ref. 2). This indicates that the reduction proceeds all the way to −2 tellurium and that the $Te \rightarrow Te^{=}$ stage is the potential determining step.

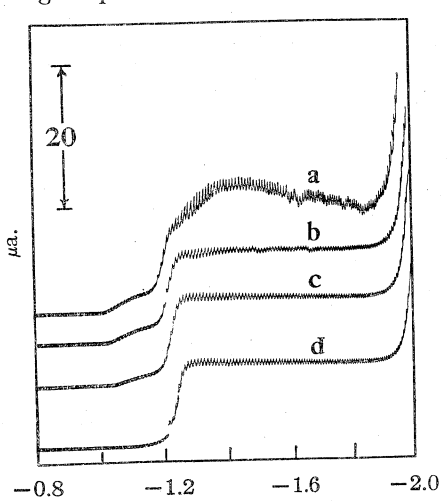

Fig. 10.—Polarograms of 0.837 millimolar tellurium(IV) in 1 *M* sodium hydroxide with (a) 0, (b) 0.001, (c) 0.003 and (d) 0.01% gelatin.

That reduction in sodium hydroxide medium proceeds to −2 tellurium, according to

$$TeO_3^{=} + 3H_2O + 6e^{-} = Te^{=} + 6OH^{-} \qquad (9)$$

was verified by the coulometric technique. A 1.37 millimolar solution of tellurium(IV) in 1 *M* sodium hydroxide was reduced with the potential of the large mercury cathode at −1-60 v. *vs.* S.C.E. The coulometer reading after the current decreased to zero corresponded to 5.97 electrons per mole of tellurium(IV) reduced. The current decreased from an initial value of 135 milliamp. to less than 1 milliamp., showing that reduction at this potential proceeds with 100% current efficiency. The current–time curve during this reduction had the same shape as that for the reduction of selenium(IV) shown in Fig. 2. During the first stage of the electrolysis elemental tellurium precipitated, then dissolved to form deep violet polytelluride ion, and the latter was finally completely reduced to colorless telluride ion.

The data in Table III show that $i_d/(C\,m^{2/3}t^{1/6})$ for tellurium(IV) in 1 *M* sodium hydroxide shows a significant variation with concentration. The trend is smaller with 0.003% gelatin than with either 0.001 or 0.01%. In the former case $i_d$ is a linear function of $C$ to ±1% over the concentration range 0.2 to about 2.8 millimolar.

| | | | 3.34 | 46.31 | 9.60 |

Since +4 selenium does not produce a wave in 1 *M* sodium hydroxide this is a most suitable supporting electrolyte for the determination of tellurium in the presence of selenium, especially when selenium predominates. As Schwaer and Suchy[3] pointed out, an ammoniacal supporting electrolyte is useful for the simultaneous determination of both elements, the wave of tellurium preceding that of selenium by about 0.8 v.

A most striking feature of the polarograms of +4 tellurium is the very large maximum which appears in the diffusion current plateau at all *p*H values in all the supporting electrolytes, except sodium hydroxide. This maximum is unusual in that it occurs after the diffusion current plateau has been reached, or in the middle of the plateau in ammoniacal media and in borate and

carbonate buffers, rather than as an extension of the rising part of the wave as in the case of ordinary maxima. The maximum is also exceptionally indifferent to the usual maximum suppressors. Significantly the potential at which the maximum develops coincides at all *p*H values with the half-wave potential of the *anodic* wave of the reaction $Te^{=} = Te + 2e^{-}$ discussed in a preceding paper.[2] It is also significant that the only medium in which the maximum is absent is 1 *M* sodium hydroxide, which is probably related to the fact that the cathodic tellurium(IV) wave occurs at almost exactly the same potential as the anodic $Te^{=}$ wave in this medium.[2] The occurrence of the maximum is thus intimately related to the $Te^{=}$–Te couple.

Apparently the rising part of the maximum reflects the beginning of reduction of the tellurium(IV) to the −2 state, but when this starts the normal diffusion layer at the surface of the mercury drops, is disrupted, and a vigorous stirring action ensues which causes the current to rise to a very large value. Observations under the microscope revealed the formation of a brown turbidity (elemental tellurium) as a succession of bands which expanded radially from the drop. At potentials before the maximum, as well as after it, the deposited tellurium formed an adherent coating on the drop and no streaming or turbidity near the drop was observed. The band pattern suggests a rhythmically recurrent process during the drop life. A likely mechanism is that the $Te^{=}$ which forms partially dissolves the adherent tellurium deposit, forming polytelluride ion in the diffusion layer and freeing part of the electrode surface. Part of the relatively large concentration of polytelluride ion formed near the electrode surface is rapidly reduced to $Te^{=}$, causing a large surge of current, and part of it diffuses outward from the electrode and reacts with tellurium(IV) to precipitate elemental tellurium and produce the observed bands. The combination of these processes and the resultant density gradients disturbs the diffusion layer and produces stirring which accelerates the transfer of tellurium(IV) to the electrode surface. The reduction of the enhanced concentration of tellurium(IV) to elemental tellurium proceeds at a faster rate than its reduction to $Te^{=}$, and than the reaction between the elemental tellurium and $Te^{=}$, so that the adherent tellurium coating tends to reform, the current surge decreases, and the diffusion layer begins to reestablish itself until the formation of polytelluride again catches up with the decreased rate of reduction of tellurium(IV). The cycle then repeats. The fact that at a slightly more negative potential these processes abruptly cease, so that the current falls to the original value corresponding to only a 4-electron reduction, remains to be explained.

**Tellurium in Presence of Other Metals.**—Metals which produce polarographic waves preceding that of tellurium(IV) and which form insoluble tellurides exert a pronounced suppressing effect on the apparent height of the tellurium wave in strongly alkaline medium. This effect, which is analogous to the suppressive action of copper on the selenium wave, is illustrated by the polarograms in Fig. 11 of mixtures of lead and tellurium in 1 *M* sodium hydroxide. The first wave at −0.76 v. is the normal wave due to reduction of the hydrogen plumbite ion, and the second is that for the reduction of tellurium(IV) to telluride ion.

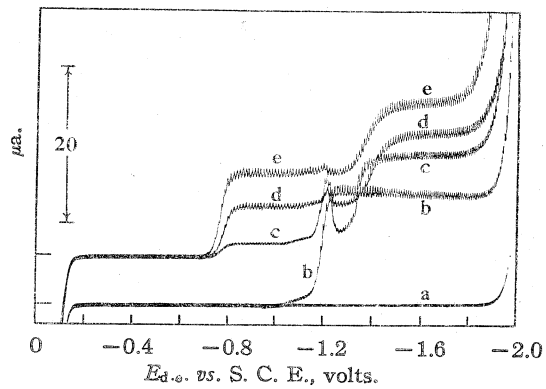

Fig. 11.—Polarograms of 1 millimolar tellurium(IV) in 1 *M* sodium hydroxide containing 0.003% gelatin with (a) 0, (b) 0.30, (c) 1.20 and (e) 2.00 millimolar lead ion added.

Amounts of lead up to the point where the product $CD^{1/2}$ for the plumbite ion becomes equal to this product for the tellurium(IV) produce no increase in the *total* diffusion current between −1.5 and −1.8 v., but the apparent height of the tellurium wave decreases. With larger amounts of lead the height of the tellurium wave remains constant and the *total* diffusion current increases in direct proportion to the excess lead added. These phenomena are due to the fact that the telluride ion produced at the electrode surface reacts in the diffusion layer with the incoming hydrogen plumbite ion to precipitate lead telluride

$$Te^{=} + HPbO_2^{-} + H_2O = PbTe + 3OH^{-} \quad (10)$$

Hence the hydrogen plumbite ion cannot contribute to the total diffusion current until its flux at the electrode (proportional to $CD^{1/2}$) exceeds the flux of +4 tellurium. Because the reduction of tellurium(IV) requires 6 electrons, and that of the plumbite ion only 2 electrons, it is to be expected that the apparent height of the tellurium wave will decrease only to $^2/_3$ of its original value, and this is precisely what we observed. With 1 millimolar tellurium the apparent height of the tellurium wave was 81, 69, 68 and 66% of its original value when the respective concentrations of lead were 0.30, 0.70, 1.20 and 2.00 millimolar. The same effect was produced by copper and mixtures of copper and lead.

From Fig. 11 it is seen that addition of lead

also shifts the half-wave potential of tellurium from its normal value of −1.20 v. to nearly −1.4 v. With relatively small amounts of lead a maximum appears at the normal half-wave potential of the tellurium, but this fades out as the relative concentration of lead is increased. This shift of the half-wave potential of the tellurium is probably connected with the production of hydroxyl ion both by reaction 10 and by the reduction of hydrogen plumbite ion, $HPbO_2^- + H_2O + 2e^- = Pb + 3OH^-$, which results in a much larger concentration of hydroxyl ion at the electrode surface than in the body of the solution.

## Summary

The polarographic characteristics of the +4 oxidation states of selenium and tellurium have been investigated over a wide range of *p*H and other conditions, and systematic data have been obtained for half-wave potentials and diffusion current constants. The reduction states of the various waves observed have been established conclusively by the coulometric analysis technique based on controlled potential electrolysis with a large mercury cathode.

In strongly acid medium and in buffered solutions above *p*H 8 the reduction of selenium(IV) proceeds all the way to the −2 state, but in buffered solutions of *p*H between 3 and 7 reduction stops at the elemental state.

In buffered solutions of *p*H between 0.4 and about 11 reduction of tellurium(IV) proceeds only to the element, but the wave observed in sodium hydroxide solutions does result from complete reduction to the −2 state.

The multiplicity of waves observed with both elements at low and intermediate *p*H values results from a combination of several factors, including reductions of the several ionization species of selenous and tellurous acids and the production of films of the elements on the surface of the dropping electrode. In the case of selenium one of the waves is a cathodic reflection of the anodic wave of selenide ion. No evidence of reduction to the +2 state has been obtained with either element.

The +6 states of selenium and tellurium are not reduced at the dropping electrode under any of the conditions investigated.

# The Electrolytic Oxidation of Arsenic(III) in Acid Solution[1]

BY WILLIAM MARSHALL MACNEVIN AND GEORGE LLOYD MARTIN[2,3]

This paper reports a study of the electrolytic oxidation of trivalent arsenic in acid solution. The purpose of the investigation was to determine whether conditions could be defined which would produce 100% efficient electrolytic conversion of trivalent to pentavalent arsenic.

Previous investigations of the electrolytic oxidation of As(III)[4,5,6,7,8] have dealt with the industrial preparation of arsenates. Alkaline media have been used almost entirely. One reason for this is that oxidation in excess of the current consumption occurs in alkaline solution if air is in contact with the cathode. Apparent current efficiencies of 150% have been obtained.[9,10] Metal impurities also increase the efficiency in alkaline solution in contact with air.[11]

Aleksyeev[4] reports that oxidation occurs in acid solution with lead dioxide anodes. Aleksyeev also states that a platinum electrode may be used for the oxidation in alkaline solution. The data are, however, insufficient to indicate the maximum efficiency obtainable and the absence of side reactions, or that a platinum electrode can be used in acid solution.

In the work described in the present paper, the effects of *p*H, current density and contact with air on the current efficiency have been determined. As will be seen, the current efficiency is low in the *p*H range 3–11, but quickly increases to 100% in strongly acid solutions.

## Experimental

**Current Measurement.**—The electrolyses were conducted with d. c. current held constant within 1%. The current was measured by balancing the drop in potential across a standard resistance with a potentiometer using a recording galvanometer as a null point indicator. Corrections for the small fluctuations of the current were calculated from the galvanometer record. The time intervals were measured with a stop watch.

**The Electrolysis Cell.**—The cell for electrolysis was assembled using two 400 ml. beakers sealed together with a 20 mm. tube which had two sintered glass disks sealed into it at the ends. Thus the cell was divided into cathode,

anode and bridge compartments. The bridge, in addition, had two 7 mm. tubes with stopcocks sealed into it. This provided a means of filling the bridge and of keeping it either under slight pressure during a run to prevent diffusion of the solutions from the electrode chambers, or under greater pressure when the anode chamber was being emptied. The bridge was kept filled with saturated potassium sulfate solution throughout the work. The cathode chamber was filled with potassium sulfate solution. A platinum cathode was used. The solution in the anode chamber was stirred steadily to reduce polarization effects. The temperature of the cell during electrolysis was not controlled. A thermometer was kept in the solution and the temperature was noted for each run.

**Electrodes.**—All oxidations were conducted with sand blasted platinum gauze electrodes of the type supplied for the Sargent–Slomin Electroanalyzer. The large electrode by geometric measurement had an apparent surface of 0.65 sq. dm. The small electrode had an apparent surface of 0.342 sq. dm. Due to the fact that the surfaces were sand blasted, the effective areas of both electrodes were probably larger than these values.

**Buffer Solutions and *p*H Adjustments.**—Standard buffer solutions were added to the arsenite solution to give the desired *p*H value. In most cases, the change of *p*H during electrolysis was 0.2–0.4 of a *p*H unit. This includes the change due to dilution as well as that due to electrolytic reaction.

All *p*H measurements were made with a Beckman Industrial Model M *p*H meter. The meter was calibrated regularly using standard buffer solutions. For measurement of *p*H values greater than 9.5, a Beckman High *p*H electrode was used.

**The Determination of Arsenic(III).**—The arsenic(III) was determined by titration with 0.1 *N* ceric sulfate using osmium tetroxide as catalyst and ferroin indicator according to the procedure developed by Gleu.[12] All solutions were made 1 *N* in sulfuric acid before titration. The buffers were shown to have no effect on the titration. The ceric sulfate solution was standardized against Primary Standard Arsenic Trioxide by the same procedure.

**The Determination of Arsenic(V).**—An adaptation of the method for arsenate given by Kolthoff and Furman[13] was used. This method uses the reduction of arsenate by iodide in acid solution followed by the determination of the iodine formed by thiosulfate titration. Kolthoff and Furman recommended a volume of 30 ml. of 4 *N* acid and 1 g. potassium iodide for 0.1 g. of arsenic pentoxide. The solution must be freed from air with bicarbonate.

The volume limitation could not be conveniently met in the solutions removed from the electrolytic cells. Thus it was necessary to establish the proper conditions for the determination of arsenate in these solutions. The volume used was 100 ml., and it was found that satisfactory results could be obtained by making the solution 6 *N* in sulfuric acid, using 2 g. of sodium carbonate for removing air, adding 6 g. of potassium iodide, and allowing it to stand at least thirty minutes before titrating with thiosulfate. The end-point was determined by adding carbon tetrachloride when the iodine was nearly gone and titrating until the organic layer was colorless.

**The Method of Calculating the Current Efficiency.**—On all the runs except those in which arsenic(V) was also determined, the current efficiency was based upon the difference between the amounts of arsenic(III) present before and after electrolysis. Stock solutions containing 0.020–0.025 g. arsenic trioxide/ml. were made up and the concentration determined by titration with standard ceric sulfate. Aliquots of these solutions were used for the electrolyses and the amount of arsenic trioxide present at the end was determined by ceric sulfate titration. The difference between the amount of arsenic trioxide present and the amount recovered was divided by the theoretical amount of arsenic trioxide oxidized as calculated from the number of coulombs passed. The arsenic (III) stock solutions were made up by dissolving the required amount of Primary Standard Arsenic Trioxide in dilute potassium hydroxide solution and making slightly acid with sulfuric acid. A small amount of reddish-brown precipitate appeared after the solution stood for some time and was filtered off before use. Reagent grade chemicals and distilled water were used throughout.

**Air Oxidation of Arsenic(III) Solutions.**—Runs to determine the effect of air oxidation were made by placing an electrode in a beaker containing an arsenic(III) solution prepared in exactly the same manner as the electrolysis solutions, and stirring the solution at the same rate and for the same length of time as the cell solutions. These solutions were then titrated to determine the change due to air oxidation.

Runs were also made under nitrogen in the electrolysis cell. A brass cap was constructed with sleeves for stirrer, electrode and gas inlet. The solution was outgassed with tank nitrogen for at least two hours before being placed in the cell, and the cell was swept for twenty minutes before electrolysis started.

## Results and Discussion

**The Effect of *p*H on the Current Efficiency.**—The results of a series of runs in which the *p*H of the arsenic(III) solution was varied are given in Table I.

TABLE I

THE EFFECT OF CHANGING *p*H ON THE CURRENT EFFICIENCY

(0.5 g. $As_2O_3$ in 200 ml., apparent current density 0.123 amp. per. sq. dm., 50% oxidized, sand-blasted platinum electrode)

| Temperature, °C. | *p*H | Current efficiency, % |
|---|---|---|
| 23 | (6 *N* $H_2SO_4$) | 100.08 |
| 24 | (1.25 *N* $H_2SO_4$) | 99.80 |
| 21 | (1.25 *N* $H_2SO_4$) | 100.20 |
| 24 | 1.8 | 100.07 |
| 24 | 3.4 | 94.83 |
| 23 | 5.4 | 54.06 |
| 21 | 5.4 | 51.52 |
| 22 | 5.5 | 66.80 |
| 24 | 6.6 | 48.13 |
| 21 | 6.6 | 22.43 |
| 24 | 8.3 | 58.65 |
| 21 | 9.3 | 30.50 |
| 23 | 9.4 | 32.50 |
| 25 | 11.0 | 99.20 |
| 25 | (1 *N* NaOH) | 109.20 |
| 21 | (1 *N* NaOH) | 118.00 |

Examination of the data in Table I shows that the oxidation proceeds smoothly with 100% current efficiency in strongly acid solution. The efficiency decreases through the neutral range, reaches a minimum, and then increases and becomes greater than 100% in strongly alkaline solution.

The exact position of the minimum cannot be located from these data, since it was found that the reaction is quite sensitive to temperature changes through this range. For this reason, no attempt has been made to correlate the location of the minimum with a possible reaction mechanism.

From the equation for the reaction $HAsO_2 + 2H_2O = H_3AsO_4 + 2H^+ + 2e^-$, one would

(12) L. Gleu, *Z. anal. Chem.*, **95**, 305 (1933).

(13) I. M. Kolthoff and N. H. Furman, "Volumetric Analysis," Volume II, John Wiley and Sons, Inc., New York, N. Y., 1929, p. 350.

expect the oxidation to go more smoothly in alkaline solution. Brown, Hatfield and Church[8] state that an alkaline bicarbonate solution just acid to phenolphthalein (probably *p*H 7–8) is the best for carbon and platinum anodes, but cite no data comparing results in solutions of different *p*H.

The existence of the minimum in the current efficiency values indicates that the reaction probably proceeds by different mechanisms in acid and alkaline solutions. The high current efficiencies in acid solution have not been previously observed and indicate the possibility of preparing alkali free arsenic(V) solutions.

Electrolyses in acid solution in the presence and absence of air showed no detectable difference in the amount of oxidation produced. Catalytic oxidation by air which occurs up to one-third of the total oxidation in alkaline solution therefore does not occur in acid solution. The electrolytic oxidation is free from appreciable side reactions.

**The Effect of Other Variables on the Oxidation Process.**—The results of a study of the effect of changing the current density on the current efficiency are given in Table II.

TABLE II

THE EFFECT OF CHANGING CURRENT DENSITY ON THE CURRENT EFFICIENCY

Temperature 24° and sand-blasted platinum electrode, 1.25 *N* $H_2SO_4$

| $As_2O_3$ per 200 ml., g. | Apparent current density, Amp./sq. dm. | Current efficiency, % |
|---|---|---|
| 0.5 | 0.123 | 100.2 |
| .5 | .185 | 100.3 |
| .5 | .230 | 99.2 |
| 1.0 | .230 | 100.4 |
| 0.5 | .269 | 99.6 |
| 0.5 | .307 | 99.1 |
| 1.0 | .307 | 98.8 |

It is seen that the current efficiency begins to decrease as the current density increases above about 0.2 amp./sq. dm. From the figures obtained, the best value of the current density to use for quantitative electrolysis is the lowest one given, 0.123 amp./sq. dm. Use of this value gives a considerable margin of safety before side reactions, usually the evolution of oxygen, begin.

Taking 0.123 amp./sq. dm. as the optimum current density, the effect of changing the per cent. oxidation was investigated. The results are given in Table III.

TABLE III

THE EFFECT OF CHANGING THE PER CENT. OXIDATION ON THE CURRENT EFFICIENCY

0.5 g. $As_2O_3$ in 200 ml. 1.23 *N* $H_2SO_4$ current density 0.123 amp./sq. dm., sand blasted platinum electrode

| Temperature, °C. | Oxidation, % | Current efficiency |
|---|---|---|
| 24 | 51.0 | 99.80 |
| 21 | 50.4 | 100.20 |
| 26 | 74.9 | 99.75 |
| 30 | 85.2 | 99.82 |
| 30 | 95.5 | 99.65 |
| 30 | 98.0 | 98.36 |

These results show that the current efficiency remains high even when 90% of the arsenic(III) has been oxidized.

On seven runs the arsenic(V) produced was determined as well as the arsenic(III) consumed. The average difference was less than 0.3%, which is within the limits of error of the determinations. This agreement indicates the absence of intermediate oxidation stages.

## Summary

1. The electrolytic oxidation of arsenic(III) at a platinum electrode has been shown to proceed at 100% current efficiency in strongly acidic solutions.

2. Air oxidation of arsenic(III) does not occur during electrolysis in acid solution.

3. The oxidation of arsenic(III) to arsenic(V) gives no indication of the presence of intermediate oxidation states.

# The Sodium Metaphosphate System. Two New Crystalline Phases of Sodium Metaphosphate Produced by Thermal Means[1]

BY ROBERT W. LIDDELL

The present contribution is primarily a study of two new forms of crystalline sodium metaphosphate obtained by a controlled crystallization from the melt. Previous investigators, with the exception of Huber and Klumpner,[2] have confined their work almost entirely to studying the more stable crystalline materials produced by molecular dehydration of monosodium orthophosphate or disodium pyrophosphate at various temperatures, ignoring the possibility of any intermediate forms.

In the study by Partridge, Hicks and Smith,[3] the following diagram showing the relationship between the various forms of sodium metaphosphate was presented.

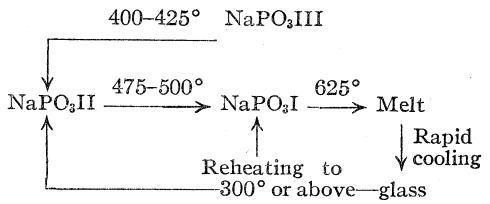

Fig. 1.—The sodium metaphosphate system according to Partridge, Hicks and Smith.

Since then the high-temperature fibrous sodium Kurrol salt has again been prepared and recharacterized by Huber and Klumpner,[2] and their results have been verified in this laboratory. Also a $NaPO_3$ (III) has been reported which has different X-ray spacings[4] than given by the above authors. The author has prepared two additional crystalline forms of sodium metaphosphate which in aqueous solutions exhibit the same properties as those of $NaPO_3$ (I), commonly referred to as trimetaphosphate. On crystallization from aqueous solution, each of these forms yields the hexahydrate of trimetaphosphate, $(NaPO_3)_3.6H_2O$, at 20°, or the monohydrate $(NaPO_3)_3.H_2O$, at approximately 40°, with mixtures of these two forms and perhaps others at intermediate temperatures.

## Experimental

**First New Form.**—Sufficient reagent grade monosodium orthophosphate monohydrate in a platinum dish was melted in an electric muffle furnace to produce a clear melt at 750–800° about 3 mm. deep. The dish was then transferred quickly into another furnace at 500° and the furnace set on automatic control at 525°. After about ten minutes, crystallization to characteristic brilliant plates took place. After a few more minutes incipient recrystallization into the ordinary $NaPO_3$ (I) was observed. When this was noted, the dish was removed from the furnace and cooled quickly by placing it on a heavy steel plate.

(4) A. S. T. M. Card Index of X-Ray Diffraction Data, First Supplementary Set, II-1725 (1945).

It was necessary to keep the melt shallow in order to prevent excessive temperature lag with resultant inversion into $NaPO_3$ (I). The products consisted mainly of a crystalline material having maximum and minimum refractive indices of 1.500 and 1.495, together with a small amount of $NaPO_3$ (I) at the surface with indices of 1.480 and 1.474 and a little residual glass. Table I shows the X-ray spacings determined by the Debye–Scherrer powder method with a General Electric Model XRD Type I unit using a camera of 143.2 mm. diameter and copper K$\alpha$ radiation filtered through a nickel foil.

This same new crystal form was also produced from an $NaPO_3$ melt dried by heating for two hours at 1000°, which had a water content of 0.03% as determined by mixing with three parts by weight of freshly ignited anhydrous tetrasodium pyrophosphate and igniting at 1000° to constant weight. By the use of a commercial glass with an $Na_2O:P_2O_5$ ratio of 1.15, the inversion to ordinary $NaPO_3$ (I) could be inhibited for a longer time although in this case $Na_5P_3O_{10}$ (II) was formed as an impurity.

**Second New Form.**—The second new crystal form was obtained by placing a clear sodium metaphosphate melt at about 650° in a furnace controlled at 375°. Secondary crystallization to trimetaphosphate was not as rapid as with the first form, perhaps due to the lower temperature, but a small amount of glass in parts of the material was frequently obtained. This second new form was also produced, with $Na_5P_3O_{10}$ (II) as an impurity, from a commercial glass with an $Na_2O:P_2O_5$ ratio of 1.15 by the same controlled crystallization from the melt, or by annealing at 375° for three hours the mixture of the first new form and $Na_5P_3O_{10}$ (II), prepared as described previously. The maximum and minimum refractive indices of this second new crystal form were found to be 1.520 and 1.475. The X-ray spacings are listed in Table I. Occasionally refractive indices of 1.501 and 1.515 were obtained, but this was thought due merely to a different orientation of the crystals and not to another crystal form, since the X-ray patterns were always identical.

The sodium metaphosphate system according to the data of the present study.

There was considerable overlapping in the temperature range of formation of these two forms. The first form has been produced at temperatures of from 375° to 525°; its proportion to the second form varied with the temperature. At temperatures much above 525° it was either not produced or was too transient to be retained readily; in the lower temperature ranges it may also have been formed during the cooling process and not after the material in the platinum dish had reached the recorded temperature. The second form has been found at temperatures as high as 525°, accompanying the first form, and at temperatures as low as 350°, along with considerable residual glass, but the conditions for producing the maximum amount of the relatively pure materials are given above. More than a dozen preparations of each form were made by the preferred method and practically all of these were of the composition described.

In aqueous solution the chemical properties of both of these new crystal forms were similar to those of ordinary $NaPO_3$ (I). They did not repress calcium ion against soap, and when free from glass gave no precipitate with dilute silver nitrate or barium chloride solution. The solubility in the water was approximately that of the trimetaphosphate. These facts together with the formation of hydrates identical with those of $NaPO_3$ (I) indicate that both the first and the second new form are merely different crystal forms of $NaPO_3$ (I), which may therefore be called $NaPO_3$ (I′) and $NaPO_3$ (I″), respectively.

**Sodium Kurrol Salt.**—On treating a sodium metaphosphate melt at 600–550° with seed crystals as described by Huber and Klumpner,[2] long fibrous crystals of Kurrol salt having essentially the properties given by these authors were obtained. The author was unable to obtain seed crystals from an acid melt in the 650–550° range given by Huber and Klumpner and a temperature slightly below 500° gave the best results. Several attempts to prepare the Kurrol salt from a sodium metaphosphate melt without seeding were unsuccessful.

## Discussion

In the present state of confusion in the nomenclature of inorganic chemistry and mineralogy and the still obscure relationships among all of the possible forms of metaphosphate, it seems unwise to attempt to change the accepted nomenclature of the known members of this series. Therefore, for this reason, the general scheme of nomenclature of Partridge, Hicks and Smith[3] will be used so far as possible, particularly since this system has been followed by Morey and Ingerson,[5] and Quimby.[6]

It has been found impossible to duplicate the $NaPO_3$ III of Partridge, Hicks and Smith,[3] and further study of their X-ray films and data by R. K. Scott of our Laboratories has led to the conclusion that their material was a mixture of $NaPO_3$ (I) and $NaPO_3$ (II). It should, therefore, be noted that the $NaPO_3$ (III) in the second diagram is not the $NaPO_3$ (III) of Partridge, Hicks and Smith.[3] The $NaPO_3$ (III) having the X-ray spacings given in the reference[4] was prepared by heating monosodium orthophosphate monohydrate to a temperature of 270 ± 5° for sixteen hours and then washing out the residual soluble material. Heating for the same period at 225 ± 5° and 245 ± 5° gave a product which was completely soluble in water. On heating, the insoluble $NaPO_3$ (III) was transformed wholly into the insoluble $NaPO_3$ (II) at a temperature of 425° and into $NaPO_3$ (I) at temperatures of 500° and above.

It is interesting to note that under apparently identical conditions of heating, varying amounts of $NaPO_3$ (I) and $NaPO_3$ (II) have been obtained from both monosodium orthophosphate and

(5) Morey and Ingerson, *Am. J. Sci.*, **242**, 1 (1944).

(6) Quimby, *Chem. Revs.*, **40**, 141 (1947).

disodium pyrophosphate. Thus Tammann,[7] and Karbe and Jander[8] reported that the results obtained at approximately 300° were inconsistent, but could offer no explanation. Boulle[9] found that when this heating was carried out in a stream of water vapor, his form B ($NaPO_3$ (II) was produced in a pure state. Such a condition may also be approximated by rapidly heating the monohydrate of monosodium orthophosphate in a fairly thick layer to 300°. The author has found that when the reverse is true, namely, when the vapor pressure of water was low, as when anhydrous disodium pyrophosphate was sprinkled in a very thin layer in a platinum dish and introduced into a furnace at 330°, $NaPO_3$ (III) was the principal product. Intermediate conditions, as for example slow heating to 300° using a moderately thick layer of material gave $NaPO_3$ (I) as the major product.

Quite a number of chemical compounds exhibit different polymorphic forms which, however, have the same chemical properties; the metaphosphate system appears to be unique in the fact that it comprises a number of crystalline phases, some of which in aqueous solution exhibit different chemical properties, while others behave identically when dissolved.

The diagram presents the current state of information concerning the sodium metaphosphate system.

**Acknowledgments.**—The author wishes to express his appreciation to Miss Catherine Hester who made most of the microscopical examinations and to Mrs. Jeanne Pfister and Mr. R. K. Scott who carried out the X-ray analysis.

## Summary

1. Two new crystalline sodium metaphosphates have been produced which in aqueous solution behave like $NaPO_3$ I.

2. The sodium metaphosphate diagram of Partridge, Hicks and Smith has been revised to show more recent developments including those of the present study.

# Cuprammonium–Glycoside Complexes. I. Conductometric Measurements

BY RICHARD E. REEVES AND JULIUS R. JUNG, JR.

In the continued investigation of cuprammonium–glycoside complexes, a means other than one dependent upon optical activity was required for the recognition of these complexes. Such a method was necessary for the study of complex formation between cuprammonium and inactive glycols, as well as for those substances which, though optically active, form complexes without exhibiting large rotatory changes.

Our earlier work,[2,3] dealing exclusively with the optical method of measurements, had shown that highly active complexes form between cuprammonium and properly oriented glycol groups. It was found that such complex formation was associated with a decrease in conductivity in the cuprammonium solution; hence it was decided to follow this phenomenon by the conductometric method of measurement.

By this method many degrees of affinity for cuprammonium could be detected in the various substances tested. It was possible to distinguish the D- and L-forms of 2,3-butanediol from the *meso* variety. Various methyl α-hexopyranosides could be sharply distinguished from each other, and a difference was encountered between the complex-forming tendency of a number of α- and β-glycoside pairs. Furthermore, it was shown that the substance D-glucosan<1,5>β<1,6> (levoglucosan) does react with cuprammonium, although on the basis of optical rotation measurements it was previously reported not to react.[4]

## Experimental Part

The physical properties of all the substances employed in this investigation were in excellent agreement with the properties listed in the literature.

A stock solution containing between 5 and 8 g. of copper per liter was prepared by passing a current of air through a concentrated A. C. S. standard ammonium hydroxide solution in the presence of copper turnings. The ammonia and turnings were contained in a tall glass cylinder which was cooled in an ice-bath during the reaction. This stock solution may be preserved in the refrigerator without added stabilizer for a long time. After analysis for copper and ammonia, portions of the stock solution were diluted to contain 0.01 mole of copper (0.635 g.), 3 moles of ammonia, and 10 ml. of ethanol per liter. This standard solution, "cupra A," was employed in most of the conductivity experiments; whenever a different solution was used a notation will be made regarding its composition.

To permit the use of small amounts of glycosides very dilute cuprammonium solutions were required. The specific conductance of various ammonium hydroxide solutions with and without 0.01 molar copper are shown in Fig. 1. Inspection of this figure shows that conductance is least sensitive to ammonia concentration in the region

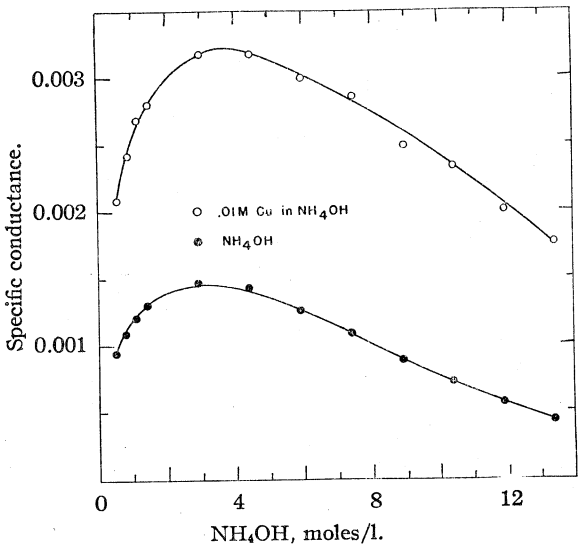

Fig. 1.—The specific conductance of ammonia solutions with and without copper.

of 3 molar ammonia (the region of maximum conductance) hence this concentration was chosen. The reason for the incorporation of ethanol is illustrated by the ethanol curve of Fig. 2. By its incorporation a "hydroxyl effect" is considerably levelled off, and only true complex-forming substances show a pronounced change in conductance.

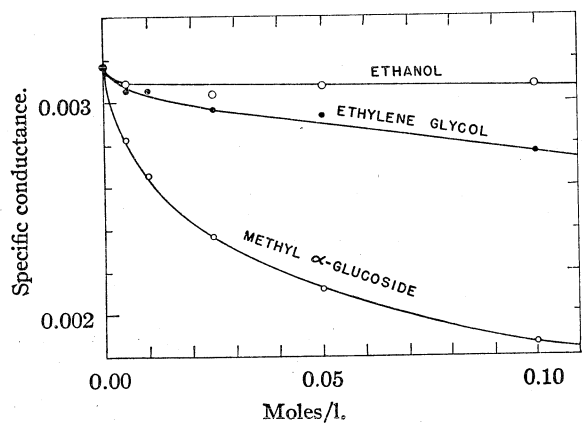

Fig. 2.—The change in specific conductance upon adding various substances to a solution containing 0.01 mole of copper and 3 moles of ammonia per liter.

Substances which ionize in solution, or esters which may decompose into ionizable substances, cannot be used in the conductometric method without obscuring the effect of the conductance change due to complex formation.

Conductivity measurements were made with a commercial 1000-cycle conductivity bridge using a dip-type cell capable of operating with 14 ml. of solution. The readings were made in terms of resistance (ohms, Ω), and specific conductance ($L$) was calculated by the formula $L = c/\Omega$. The cell constant, $c$, determined with 0.1 $M$ potassium chloride, was found to be 0.116. The temperature at the time of measurement was controlled by immersion of the tube containing the liquid in a water thermostat held at 25 ± 0.2°. Except while measurements were in progress the tubes were stoppered to prevent loss of ammonia and the attendant cooling of the cuprammonium solution. The small amounts of materia were added directly to the cupra and concentrations were calculated upon the original volume of solution.

## Results

**Aliphatic Glycols.**—In Fig. 3 are shown the resistance *versus* glycol concentration relationships for the three forms of 2,3-butanediol dissolved in the standard cuprammonium solution. The D- and L-forms are, of course, indistinguishable from each other, by this method, but they show a marked difference from the *meso* variety, the latter giving a smaller change in resistance. The behavior of ethylene glycol (not shown in the figure) was almost identical with that of the *meso* form of the butanediol. A type of behavior believed to be different is illustrated in Fig. 3 by trimethylene glycol. This substance has two hydroxyl groups separated by a methylene group and the data are regarded as indicating no significant change in conductivity. From this it is deduced that trimethylene glycol belongs in the group of substances which fail to form a copper complex.

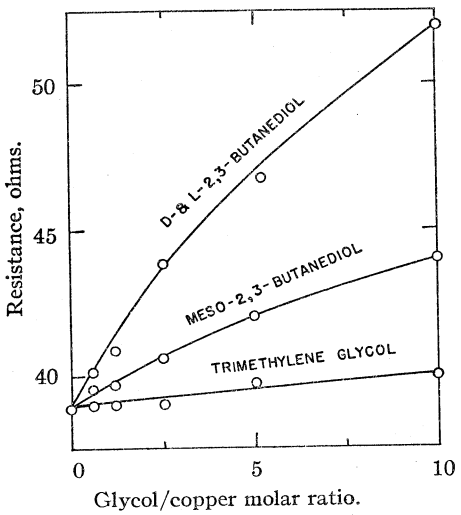

Fig. 3.—The resistance *versus* concentration relationships of various aliphatic glycols in cupra A.

**Glycopyranosides.**—In Fig. 4 are shown the resistance *versus* glycoside concentration relationships for a number of methyl α-hexosides. That these glycosides are much more actively complex-forming substances than the aliphatic glycols is indicated by the lower concentrations required to produce similar conductivity changes. The glycosides exhibited affinities for cuprammonium increasing in the order glucoside, galactoside, altroside, mannoside and guloside. In Fig. 5 comparison is made between a number of α- and β-pyranoside pairs. It will be noted, in each of these instances, that the curve for the β-glycoside lies above that of the corresponding α-glycoside.

**D-Glucosan <1,5>β<1,6>.**—The behavior of this substance in cuprammonium solution was first examined by Hess, Weltzien and Messmer,[4] who concluded that there was no reaction

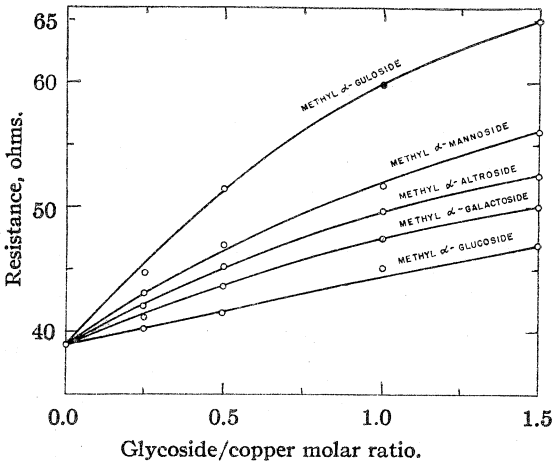

Fig. 4.—The resistance *versus* concentration relationships of various methyl α-D-hexopyranosides in cupra A.

between it and cuprammonium, since the optical rotation in this solvent was practically the same as in a copper-free solution. Their finding in regard to lack of rotatory shift was later confirmed,[3] but the conclusion that no complex formation occurred was shown to be incorrect by the data given in Fig. 6. The effect on conductivity of levoglucosan is at least equivalent to that of methyl α-glucoside, a substance known to be complex-forming because of its optical behavior, as well as because of the conductivity effect noted above.

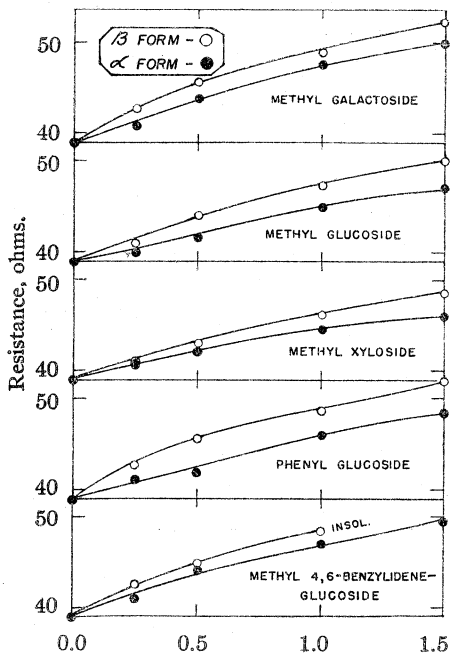

Fig. 5.—Comparison of resistance–concentration relationships of various α- and β-D-glycopyranoside pairs in cupra A.

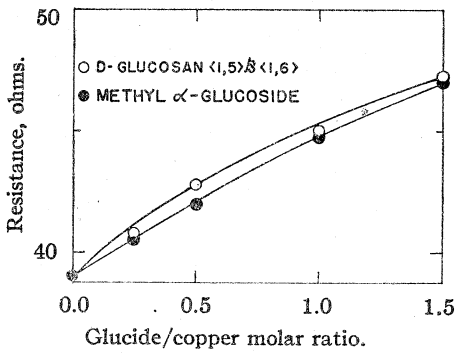

Fig. 6.—Comparison of the effect on resistance of D-glucosan<1,5>β<1,6>(levoglucosan) and methyl α-D-glucoside in cupra A.

Our studies to date indicate that complex formation is always accompanied by a marked decrease in the conductance of a dilute cuprammonium solution unless the effect is obscured by decomposition or ionization of the substance being examined. Complex formation may or may not be associated with a large shift in optical rotation. The conditions which determine the rotatory behavior will be considered more fully in subsequent communications.

**Acknowledgment.**—We are indebted to Dr. R. D. Coghill, Professor C. S. Hudson and Dr. H. S. Isbell for supplying some of the substances employed in this investigation.

## Summary

A conductometric method is described that is capable of measuring the relative affinities of various substances for cuprammonium. Differences in affinity were observed for the optically active and *meso* forms of 2,3-butanediol. Differences were noted in the behavior of various methyl α-hexosides, and between various α- and β-pyranoside pairs. The substance D-glucosan<1,5>β<1,6> was shown to react with cuprammonium solution.

# Cuprammonium–Glycoside Complexes. II.[2] The Angle Between Hydroxyl Groups on Adjacent Carbon Atoms

BY RICHARD E. REEVES

During the examination of a large number of cuprammonium–glycoside complexes some relationships were observed which appeared to cast light on the subject of the shape (conformation) of glycoside molecules in solution. However, before the problem of conformation could be attacked it was necessary to secure a better understanding of the meaning of complex formation. In the present communication a theory applicable to complex formation is proposed and selected examples involving hydroxyl groups on adjacent carbon atoms are cited in its support. In forthcoming reports the theory will be tested by examining its application to a large number of carbohydrate derivatives.

Let it be assumed that there is a particular distance between hydroxyl groups most favorable for complex formation with cuprammonium, and a range of distances over which complex formation may occur more or less readily depending on the variation from the optimum distance. Thus, affinity for cuprammonium would be inversely related to the deviation of rigidly fixed hydroxyl groups from a particular position, or, for hydroxyl groups not rigidly fixed, to the energy required to move the groups to a complex-forming position.

In dealing with adjacent hydroxyl groups located on pyranose and furanose rings the relative position of the groups is determined by the configuration of the carbon atoms and shape of the rings. Regarding the latter the following first approximations have been assumed: (1) the shape of a pyranoside ring in solution may be represented, adequately for the present purpose, by a regular skew hexagon having the tetrahedral angle between sides, arranged in one of the eight Sachse strainless ring conformations; (2) the furanoside ring may be adequately represented by a flat structure having coplanar, or essentially coplanar, ring carbon atoms. In such ideal structures the angle between any pair of adjacent carbon–oxygen bonds projected onto a plane perpendicular to the carbon–carbon axis must be one of the following angles[3] for pyranoside boat forms, 0°, ±60°, ±120°, 180°; for pyranoside chair forms, ±60°, 180°; for furanosides, 0°, ±120°. Note that the projection of the tetrahedral angle in this manner yields a projected angle of exactly 120°. The sign of the projected angle is defined with the aid of three dimensional molecular models in the following manner. Sighting along a line through the centers of the two hydroxyl-bearing carbon atoms, the reference plane is defined as that passing through the centers of these two atoms and the center of the hydroxyl oxygen atom nearer the observer. The divergent plane passes through the centers of the same two carbon atoms and the center of the far oxygen atom. When the divergent plane makes a clockwise angle with the reference plane the angle will be designated negative; when the angle is counterclockwise, positive.

## What Angle Is Capable of Complex Formation?

Having assumed that optimum conditions for complex formation occur when two hydroxyl groups are located at a particular distance from each other, it is apparent that for hydroxyl groups on adjacent carbon atoms this distance is a direct function of the projected angle between the carbon valences on which the hydroxyl groups are bound. There are cyclic substances in which this angle is fixed, for a particular conformation, more or less rigidly, by the spatial requirements of the whole molecule. A selected group of these substances will now be examined to see if there appears to be an optimum angle for complex formation.

**Cellulose** is the classical example of a complex-forming substance. In cellulose, the hydroxyl groups at positions 2 and 3 of each glucose unit react with cuprammonium to form a soluble complex.[4] Crystalline cellulose is composed of β-D-glucopyranoside units oriented in the particular chair form conformation in which the pyranoside oxygen and 6-carbon atom project on the same side of the plane of the 1,2,4,5-carbon atoms.[5,6,7] Cellulose is a very insoluble substance, and were it not for complex formation there is no reason to believe it would dissolve in cuprammonium. Furthermore, after regeneration from cuprammonium, cellulose exhibits the same unit cell length[8] and hence probably the same ring con-

(2) R. E. Reeves and J. R. Jung, Jr., THIS JOURNAL, **70**, 209 (1948).

(3) Admittedly in the actual molecules these angles are subject to small variations. In a rigorous determination of ring conformation exact knowledge of interatomic distances and valence angles would be required, and in studies dealing with the crystalline state these quantities would necessarily be emphasized. However, when the problem is one of conformation in solution, where shapes are undoubtedly more elastic than in the crystalline state, and where interchange of conformations is a possibility, it has not been attempted to interpret the results in terms of the exact angles and distances found for the crystalline state.

(7) F. T. Peirce, *ibid.*, **154**, 398 (1944); *Shirley Inst. Memoirs*, **20**, 81–97 (1946). Peirce's contention that the X-ray data better fit a slightly modified chair conformation need not concern us here for the proposal retains the recognizable conformation.

(8) W. A. Sisson in "High Polymers," Vol. V, Emil Ott, Ed., Interscience Publishers, Inc., New York, N. Y., 1943, p. 212.

formation as native cellulose. Since cuprammonium undoubtedly reacts with cellulose as it exists in the crystalline state, it may be concluded that the angle between the hydroxyl groups on positions 2 and 3 of the glucose units of cellulose is capable of complex formation. Inspection of a D-glucopyranoside model oriented in the cellulose conformation discloses this angle to be $-60°$.

***cis*-2,3-Dihydroxytetrahydrofuran** (erythritol anhydride) contains hydroxyl groups which according to assumption 2 must be situated at the true *cis* (0° projected angle) angle with respect to each other. That the groups are actually in the *cis* position has been confirmed by behavior of this substance toward cleavage by lead tetraacetate.[9] This substance, being optically inactive, can only show complex formation by the conductometric method, however, by this technique the evidence for complex formation was unmistakable.

A substance which must possess the true *cis* (0°) relationship for a pair of adjacent hydroxyl groups on a pyranoside ring is **methyl 2,6-anhydro-α-D-altroside** recently described by Rosenfeld, Richtmyer and Hudson (THIS JOURNAL, **70,** 2201 (1948)). The molecular model of this substance shows only one possible ring conformation, a boat form in which the hydroxyl groups at positions 3 and 4 are in the true *cis* position. A sample of this material was kindly furnished the writer by Dr. Richtmyer. The glycol group could be titrated directly with lead tetraacetate. An 0.01 molar concentration increased the specific resistance of cupra A from 324 to 564 ohm, cm. Its specific rotations (25°, 436 mμ) were +84° (*c*, 1.01, water) and +350° (*c*, 0.66, cupra B) corresponding to a rotational shift of +467°. The behavior with lead tetraacetate confirms the true *cis* relationship of the glycol and the behavior with cuprammonium indicates a strongly complex-forming group with an intermediate rotational shift.

**Non-Complex-Forming Substances.**—There are a number of substances which, though possessing hydroxyl groups on adjacent carbon atoms, fail to form cuprammonium complexes under the usual conditions. Among these is the newly discovered glucose anhydride, D-glucosan $<1,4>\beta<1,6>$. Examination of a molecular model representing this substance discloses that the groups are very rigidly held at the $-120°$ angle. Dimler, Davis and Hilbert[10] have commented on the resistance of this substance against oxidation by the glycol cleavage reagents, and have attributed this property to the widely spaced *trans* orientation of the hydroxyl pair. It seems probable that its failure to form a cuprammonium complex is also due to this condition.

A second non-complex-forming substance was 2,5-anhydrosorbitol. The *trans* (+120°) orientation for the hydroxyl groups has been confirmed by the low rate of reaction of this substance with the glycol cleavage reagents.[11]

The two preceding substances illustrate non-complex-formation in *trans* spaced hydroxyl groups located on a furan ring. A pyranoside derivative, methyl 4,6-benzylidene-α-D-altroside, also failed to form a complex, and consideration of molecular models of this substance shows that the benzylidene ring limits the possibilities to three of the eight conformations, one chair and two boat forms. Since the theoretical arguments of Gorin, Kauzmann and Walter[12] and Scattergood and Pacsu[13] tend to exclude the two boat forms, it is most probable that methyl 4,6-benzylidene-α-D-altroside exists in the chair form in which the angle between hydroxyl groups would be 180°.

These examples have included substances having hydroxyl pairs oriented at 0°, 60°, 120°, and (probably) 180°, and of the four angles only the 60° and 0° angles have shown a marked reaction with cuprammonium. Considered in relation to the theory, it may be said either that the latter two angles are sufficiently close to the optimum angle to allow complex formation to occur, or that the substances which possessed these angles had sufficient elasticity to allow the hydroxyl groups to move to a position capable of complex formation; while neither of these possibilities apply to the non-complex-forming substances.

## Experimental Results and Discussion

Conductivity measurements were made by the method described in the preceding communication.[2] The constant for the cell employed at the start of this work was 0.116. As the cell showed small changes with use all readings were recalculated to this value. Optical rotations were measured with the mercury blue line (436 mμ) or the sodium D line, as indicated. The cuprammonium solution used for optical rotations contained 15 g. of copper, 240 g. of ammonia and 1 g. of glycerol per liter. This solution is designated cupra B.

The results of conductivity measurements on the non-complex-forming substances in cuprammonium solution (cupra A)[2] are shown in Fig. 1, curve B. Observed resistances are plotted against molar glucide concentrations. Included for comparison is the curve representing methyl 4,6-benzylidene-α-D-glucoside, a typical complex-former. The results with this substance also show that the presence of a benzylidene ring does not inhibit complex formation provided the hydroxyl pair is properly oriented. In Table I are listed the specific rotations in water and

cuprammonium, and the rotational shifts ([α] cupra B [α] water) × Mol. wt./100 for the substances considered in Fig. 1.

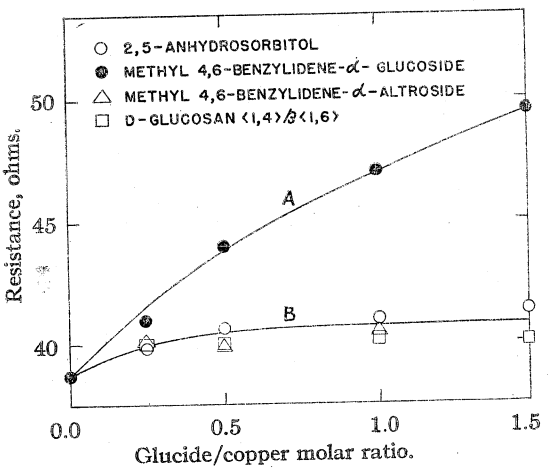

Fig. 1.—Resistance *vs.* concentration relationships for a complex-forming substance (curve A) and three non-complex-forming substances (curve B) in cupra A.

It is apparent that the non-complex-formers produced neither a marked change in conductance nor a pronounced shift in rotation (Table I) comparable with that caused by the complex-forming methyl 4,6-benzylidene-α-D-glucoside.

The complex-forming action of erythritol anhydride as measured conductometrically is shown in Fig. 2. For comparison the curve previously reported[2] for an active complex-forming substance, methyl α-D-gulopyranoside is reproduced in this figure.

The D-glucosan <1,4>β<1,6>, m. p. 110–11°, gave the following optical rotations: $[\alpha]^{25}_{436}$ +78° (*c*, 0.94 water), and +69° (*c*, 0.81 cupra B).

The sirupy 2,5-anhydrosorbitol was prepared by debenzoylation of the crystalline 1,6-dibenzoate[11] in methanol solution with barium methylate. It was purified by distillation at 0.002 mm. pressure at a bath temperature of 170°. The colorless

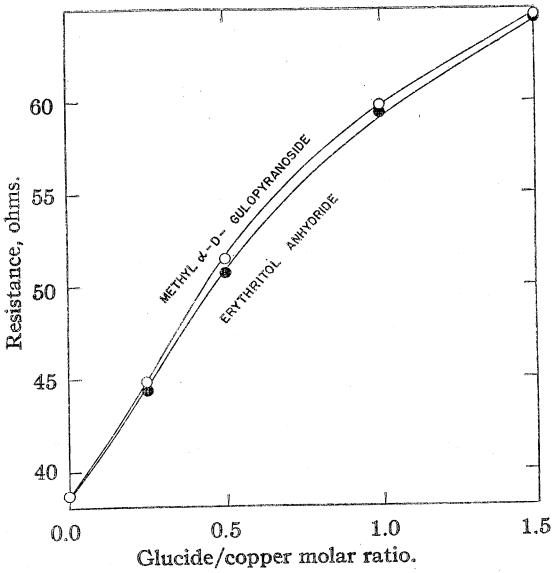

Fig. 2.—Resistance *versus* concentration relationships for erythritol anhydride and methyl α-D-glucoside in cupra A.

distillate gave the correct carbon–hydrogen analyses. Its optical rotations were [α] $D^{25}$ + 21° (*c*, 0.95 water); $[\alpha]^{25}_{436}$ + 48° (*c*, 0.95 water); −32° (*c*, 0.43 cupra B).

Methyl 4,6-benzylidene-α-D-altroside, m. p. 171–172°, was prepared from methyl benzylidene-α-D-glucoside by the method of Richtmyer and Hudson.[14] The optical rotations of the benzylidenealtroside were [α]$^{25}$D + 106° (*c*, 1 water), $[\alpha]^{25}_{436}$ + 204° (*c*, 1 water) and + 188° (*c*, 1.16 cupra B).

The writer wishes to thank Dr. R. J. Dimler of the Northern Regional Research Laboratory and Dr. Morris Zief of the Sugar Research Foundation, who kindly supplied some of the substances used in this investigation, and Mr. J. R. Jung, Jr., who made the conductometric measurements.

## Summary

The position is taken that complex formation between cuprammonium and two hydroxyl groups occurs most readily when the hydroxyl groups are located at a particular distance apart. Examination of a number of substances having hydroxyl groups on adjacent carbon atoms held more or less rigidly at a number of angles (hence distances) has shown complex formation to occur readily at the true *cis*-position (0° angle) and the 60° angle, but not at the 120° or the 180° angle.

# Cuprammonium–Glycoside Complexes. III. The Conformation of the D-Glucopyranoside Ring in Solution

BY RICHARD E. REEVES

In the preceding article of this series[2] a theory has been presented which defines some necessary conditions for complex formation between cuprammonium and two hydroxyl groups. According to this speculation the two complex-forming hydroxyl groups must be located at or near a particular optimum distance from each other. Distances capable of complex formation occur when hydroxyl groups on adjacent carbon atoms are oriented at the true *cis*-position (0° projected angle) or the ±60° projected angle positions. When the properties of numerous D-glucopyranoside derivatives were considered in the light of these findings it became possible to draw certain conclusions in regard to the ring conformation of glucopyranoside molecules in solution.

In an earlier communication[3] it was concluded on the basis of optical rotation measurements that glucopyranoside derivatives can form complexes at the 2–3 and 3–4 positions but the possibility of complex formation between other hydroxyl pairs was not rigorously excluded. Since that time it has been recognized that cuprammonium complexes can form without appreciable shift in optical rotation, hence the question of possible sites for complex formation has been reinvestigated by a conductometric technique. These results, given in the last column of Table II, indicate that only the above mentioned hydroxyl pairs are capable of complex formation, as far as the substituted ordinary D-glucopyranosides are concerned.

Proceeding on the assumption that the pyranoside ring can be adequately represented by a regular skew hexagon with tetrahedral angles between sides, oriented in one of the eight Sachse strainless ring conformations, it is possible by inspection of molecular models to evaluate, approximately, the angle between any pair of adjacent hydroxyl groups. These angles between the hydroxyl groups of positions 2–3 and 3–4 of D-glucopyranosides have been estimated and are shown in Table I. The conformations are those illustrated in Fig. 1 and the angles are those projected onto a plane perpendicular to the carbon–carbon bond as defined in the preceding article.[2] It is apparent by inspection of models that the hydroxyl pair at the 2–3 position can assume the complex-forming −60° angle, but not the 0° or the + 60° angles, while the hydroxyl pair at position 3–4 can form the + 60° angle but not the 0° or −60° angles. This situation is probably responsible for the strikingly different optical behavior of the first two groups of substances listed in Table II. Group I contains D-glucopyranosides substituted to allow complex formation only at position 2–3 while the second group is substituted to allow reaction only at posi-

TABLE I

THE ANGLE BETWEEN ADJACENT HYDROXYL GROUPS OF THE D-GLUCOPYRANOSE RING

| Conformation | 2–3 hydroxyls | 3–4 hydroxyls |
|---|---|---|
| C1 | − 60° | + 60° |
| 1C | 180° | 180° |
| B1 | −120° | + 60° |
| 1B | −120° | 180° |
| B2 | − 60° | +120° |
| 2B | 180° | +120° |
| B3 | 180° | 180° |
| 3B | − 60° | + 60° |

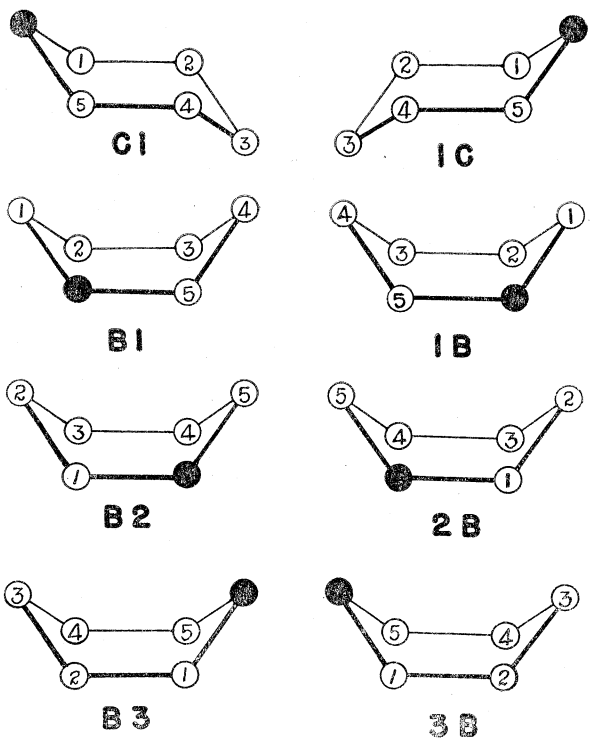

Fig. 1.—The eight pyranose strainless ring conformations and the corresponding symbols. By convention the heavy lines represent the sides of the three-dimensional figure nearer the observer. The dark circles represent ring oxygen atoms, and the numbered circles carbon atoms 1 to 5.

[a] Rotational shift equals ($[\alpha]_{436}$ Cupra B − $[\alpha]_{436}$ water) × mol. wt./100. For composition of Cupra B see Experimental part. [b] Increase in specific resistance of 0.01 molar glucoside or *s*-alcohol in Cupra A. For composition of Cupra A see Experimental part. [c] See footnote 3. [d] R. E. Reeves, *Science*, 99, 148–9 (1944). [e] R. E. Reeves, THIS JOURNAL, 70, 259–60 (1948). The rotational shift previously given did not include the mol. wt./100 factor.

The third group of substances listed in Table II have hydroxyl groups at positions 2, 3 and 4, unsubstituted (*i. e.*, with both the 2–3 and 3–4 glycol groups free). Complex formation in these substances produces a much smaller shift in optical rotation than it does in those compounds which can react at only one site. The affinities for cuprammonium of the substances in groups I–III (Table II) have been found to be approximately equal by the conductometric technique. Examples illustrating this similar affinity of the three complex-forming groups are given in Fig. 2. Since there is no reason to suspect a marked difference in the amount of cuprammonium complex formed by the three classes of substances under similar conditions, the reason for the relatively low shift in rotation for the third class may lie in simultaneous formation of dextro- and levorotatory complexes (compensating complexes). Table I shows that only the C1 and 3B conformations would allow the formation of compensating complexes in the glucopyranoside series.

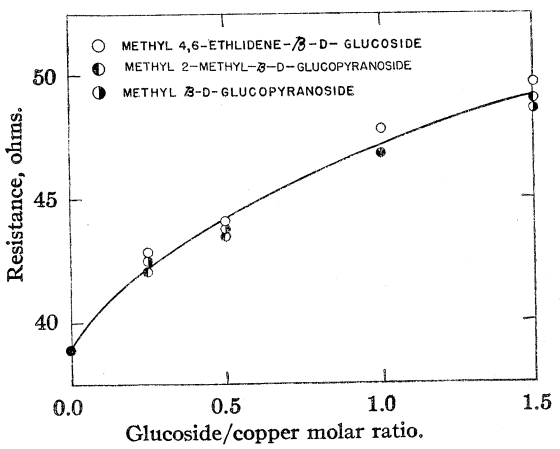

Fig. 2.—Resistance *versus* concentration relationships for some glucopyranosides in cupra A.

The group IV substances of Table II include simple alcohols and glucopyranoside derivatives regarded as non-complex forming because of their low rotatory shifts and the small changes in specific resistances. That these values are not zero is believed to be due to the formation of alcoholates between the basic cuprammonium and the secondary alcohol groups. Although they may be a particular form of bivalent alcoholate, complexes show a more pronounced increase in resistance and the effect increases more rapidly with increasing concentration than is the case in the reaction between cuprammonium and non-complex forming alcohols.

All the glucosides substituted to restrict complex formation to the 2–3 position showed marked evidence of reaction with cuprammonium. This behavior would be compatible with ring conformations C1, B2 and 3B. However, three of the sustances, the 4,6-ethylidene and 4,6-benzylidene compounds, could not exist in either the B2 or 3B conformations for steric reasons because of the spatial requirements of the second ring; hence, for these three substances a definite assignment of ring conformation can be made—they must exist in the C1 conformation.

Both of the glucosides substituted to allow complex formation only at the 3–4 position showed marked evidence of complex formation, behavior compatible with ring conformations C1, B1 or 3B.

It is noteworthy that a single conformation, C1, is compatible with the properties of all the complex forming D-glucopyranoside derivatives here examined. Furthermore this is the form which has been assigned to the D-glucopyranoside units of cellulose[4] and sucrose[5] which have been examined by physical methods in the crystalline state. Cox[6] has listed some reasons for believing

[a] A standard cuprammonium solution containing 15 g. copper, 240 g. ammonia and 1 g. glycerol per liter. [b] Bell and Synge give m. p. 50–52°. See ref. 9. [c] The rotations determined with the monohydrate were recalculated to the anhydrous basis. [d] In acetone.

that glycoside molecules do not readily change from one conformation to another in solution, or even in the change of state, crystalline⇄solution. While it does not seem that the arguments so far advanced against possible interchange of conformation can apply with equal validity to all glucosides and all permutations of conformation changes, nevertheless the data in the glucopyranoside series are consistent with a single conformation persisting in the crystalline state and, at ordinary temperatures, in solution.

## Experimental

Resistance measurements were made by the procedure previously described.[7] The readings were plotted against molar concentration of glucoside and the values at 0.01 molar concentration were taken from the smooth curve through the experimental points. The resistances were divided by the cell constant (0.116) to give specific resistance at 25°. The cuprammonium solution used for conductivity measurements, cupra A, contained 0.01 mole copper, 3 moles ammonia and 10 ml. ethanol per liter. It had a specific resistance of 336 ohm, cm. at 25°.

Melting points were measured between crossed polaroids in a Fisher–Johns melting point apparatus drilled to allow the passage of a 1 mm. beam of light.

Optical rotations were measured in a Gaertner polarimeter with the mercury blue line (436 mμ) or the sodium D line, as indicated. The cuprammonium solution used for optical measurements, cupra B, contained 15 g. copper, 240 ± 5 g. ammonia and 1 g. glycerol per liter. Copper to glucoside ratios of approximately 7:1 were employed to ensure essentially complete reaction between cuprammonium and the complex forming glucosides. The blue line specific rotations not previously recorded are given in Table III together with melting points and D line rotations which identify the substances and establish the purity of the preparations employed.

**Methyl 2,3-di-N-phenylcarbamyl-4,6-dimethyl-β-D-glucoside** was prepared from four grams of the methyl 2,3-di-N-phenylcarbamyl-β-glucoside[8] by methylation with methyl iodide and silver oxide in the presence of anhydrous calcium sulfate and dry acetone. After several recrystallizations from alcohol the product melted at 222–225°, $[\alpha]^{25}D$ −12° (*c* 2.5, acetone). It was dried at 78° in vacuum over phosphoric anhydride for analysis.

*Anal.* Calcd. for $C_{23}H_{28}O_8N_2$ (460.47): C, 59.99; H, 6.13. Found: C, 59.98; H, 6.16.

**Methyl 4,6-dimethyl-β-glucoside** was prepared by hydrolyzing 377 mg. of the above substance with barium hydroxide for four hours in boiling dilute ethanol. Carbon dioxide was passed through the solution which was then filtered and evaporated to dryness *in vacuo*. The residue was taken up in warm acetone which left 171 mg. residue on evaporation of the solvent. This material was distilled at 0.2 mm. pressure at 100° and the distillate crystallized on the condenser. At first the product melted at 52–55°, but on standing a higher melting form, m. p. 65–67°, appeared, and on recrystallization from a mixture of ether and petroleum ether the substance melted sharply at 67–68°. The high melting form was not hygroscopic. Its optical rotation in chloroform was $[\alpha]^{25}D$ −27° (*c* 0.92). Bell and Synge[9] give m. p. 50–52°, $[\alpha]D$ −28.8° (chloroform) for this substance.

**Acknowledgments.**—The writer is indebted to Lawrence E. Brown for micro carbon–hydrogen analyses and J. R. Jung, Jr., for conductometric measurements.

## Summary

Consideration of the properties of seventeen D-glucopyranoside derivatives has led to the conclusion that, in this series, complex formation between cuprammonium and two hydroxyl groups occurs only with the glycol on the second and third or third and fourth carbon atoms.

Consideration of the behavior of twelve complex-forming glucosides in the light of a previously presented theory reduces from eight to not more than three the number of conformations which need be considered to represent the shape of the pyranoside ring of each glucoside in solution; for three of the substances only one ring conformation appears to be possible. It is noted that a single ring conformation, the *trans* "chair form" in which the ring oxygen and 6-carbon atom project on the same side of the plane of the 1,2,4,5-carbon atoms, is sufficient to explain the behavior of all the complex forming glucosides in solution.

Methyl 2,3-di-N-phenylcarbamyl-4,6-dimethyl-β-D-glucoside has been prepared and a higher-melting form of methyl 4,6-dimethyl-β-D-glucoside has been described.

A symbol has been assigned to each of the eight pyranose strainless ring conformations.

# Electric Moments and Structure of Substituted Thiophenes. I. Certain Halogenated Derivatives[1]

BY RAM KESWANI AND HENRY FREISER

Interest in the structure of thiophene and in the influence of substituents upon that structure has prompted the initiation of a program for the determination of the dipole moments of substituted thiophenes. Aside from thiophene[2] itself and 2-nitrothiophene,[3] no measurements of dipole moments of members of this interesting heterocyclic family have been reported. The measurement of thiophene and 2-nitrothiophene have been repeated here for purposes of comparison. The work reported here on certain of the halogenated thiophenes represents the first phase of the program.

## Experimental

**Purification of Materials.**—Jones and Laughlin reagent-grade benzene was distilled in a three-foot glass helices-packed fractionating column and a central portion boiling within 0.03° was collected. It was found to have a density of 0.868231 g./ml. and a refractive index ($n_D$) of 1.49475, both measured at 30°.

Socony-Vacuum 99 mole per cent. thiophene was shaken with hydrochloric acid, washed, dried, and carefully distilled in the three-foot column. Fractions boiling at 82.5° at 747.1 mm. within a range of 0.02° were collected for use; $d^{30}_4$ 1.04760, $n^{30}D$ 1.5214.

The 2-chlorothiophene, 2-bromothiophene and 2,5-dichlorothiophene, which were obtained from the Michigan Chemical Corporation, were dried and fractionated prior to use. The boiling points obtained were 126.28–126.30° at 736.7 mm., 150.6–150.7° at 734.7 mm., and 160.0–160.1° at 734.0 mm. respectively, while the corresponding densities and refractive indices ($n_D$) measured at 30.0° were 1.27316 g./ml. and 1.5432, 1.69288 g./ml. and 1.5815, and 1.42901 g./ml. and 1.5575, respectively.

2-Nitrothiophene was prepared by the method of Babasinian[4] under the direction of Dr. M. F. Dull. It was recrystallized twice from petroleum ether without any change in freezing point which was found from melting curves to be 42.6°. This value differs from that reported by Steinkopf,[5] but is in good agreement with that obtained by Von Seemann and Lucas.[6]

2-Iodothiophene and tetrabromothiophene were also prepared under the direction of Dr. M. F. Dull from directions given by Steinkopf.[5] The 2-iodothiophene was purified by fractional crystallization followed by vacuum distillation; b. p. at 13 mm. 65.0°, $d^{30}_4$ 2.04926 g./ml.

The tetrabromothiophene was recrystallized until no further change in its melting point, 117°, was observed.

**Measurements and Calculations.**—The dielectric constants were measured at a frequency of 250 kilocycles with a heterodyne beat apparatus consisting of a Clough–Brengle Beat Frequency Audio Oscillator Model 179A whose variable frequency oscillator circuit was modified by the replacement of some of the original capacitance by a General Radio Precision Condenser 722 F and a dielectric cell in parallel. The measurement procedure has been reported elsewhere.[7] The cell, similar in design to that previously reported,[7] was constructed of stainless steel and Teflon. The densities of the liquids and solutions were measured in flask-type pycnometers of 20 ml. and 100 ml. capacities, respectively, in a manner similar to that previously reported,[8] with an estimated accuracy better than one part in 100,000. The dielectric constants, $\epsilon$, and the densities, $d$, of benzene solutions containing mole fraction, $f_2$, of the substance indicated are given in Table I.

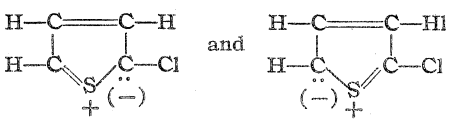
along with the molar polarization, $P_2$, in the fourth column. This table also lists in the fifth column the values of $MR_D$, the molar refraction for the sodium D line, obtained directly for thiophene, 2-chloro-, 2-bromo and 2,5-dichlorothiophene, from the solutions of 2-nitrothiophene and for the remaining substances the values were calculated from that of thiophene and the following atomic refraction values: hydrogen 1.1, iodine 13.9, and bromine 8.8[7].



The sixth column gives the polarization, $P_\infty$, obtained by extrapolation to $f_2 = 0$ of the values of $P_2$ in Table I, and the seventh column gives the dipole moments calculated in the usual manner. When the $P_2$ values showed no trend with concentration, the average value was taken as $P_\infty$. The precision of the electric moment determination is about 1%.

## Discussion of Results

The values of the moments of thiophene and 2-nitrothiophene are in good agreement with those previously reported.[2,3] In order to evaluate structural influences in the 2-halothiophenes the observed moment values were compared to those calculated on the basis of vector addition. The calculations were made in the following manner: The angles taken for the bonds in the thiophene nucleus were those obtained by Schomaker and Pauling[9] by electron diffraction studies on the thiophene itself. The halogen–carbon bond moment was assumed to act in the line bisecting the bond angle of the corresponding ring carbon atom while the sulfur bond moment, taken to be 0.53, was assumed to act in the line bisecting the CSC angle. Because the chemical properties of the halothiophenes resemble those of the corresponding halobenzenes, the values of the carbon–halogen bond moments were taken to be those in monohalogenbenzenes ($\mu_{C-Cl} = 1.58$, $\mu_{C-Br} = 1.48$, and $\mu_{C-I} = 1.25$). The values thus calculated for 2-halothiophenes are 1.76, 1.67, and 1.45 for 2-chloro, 2-bromo- and 2-iodothiophene, respectively. The over-all agreement between these calculated values and those experimentally determined is fair and confirms the belief that the carbon–halogen bonds in the thiophene series are very similar to those in the benzene series, making structures such as

as well as

of significance in the description of the ground state of 2-chlorothiophene.

The calculated values of the moments of the 2-halothiophenes while in general agreement with the observed values are somewhat higher than the latter, being about 0.16 $D$ higher for 2-chlorothiophene and twice that, about 0.31, in the case of the corresponding bromo- and iodine derivatives. These deviations may well be compared with similar deviations observed in ortho disubstituted benzene derivatives which are attributed to mutual inductive effects, since the 2-substituted thiophenes are structurally similar to the ortho disubstituted benzenes with the sulfur considered as one of the substituents. Mutual inductance of the two groups will cause a decrease in the moments of these compounds from the calculated values. It is possible that the smaller deviations encountered in the case of the chlorothiophene might be related to the greater importance of structures involving a double bond between carbon and halogen in the case of chlorine over that of the bromine or iodine. These structures as pictured above would tend to make the sulfur more negative in chlorothiophene than in thiophene itself.

The moment of 2,5-dichlorothiophene calculated in the manner mentioned above was found to be in exact agreement with the experimentally observed result. It must be observed, however, that because of the geometrical relationships in this compounds, the two C–Cl bonds meeting at an angle of 158°, the net moment is not at all sensitive to changes in the C–Cl bond moment. Also because of the importance of structures similar to that shown above for 2-chlorothiophene in which C–Cl has double bond character, the negative deviation expected in the 2,5-dichlorothiophene because of mutual inductive interaction is possibly counter-balanced by the resulting increase in negative character of the sulfur.

The value calculated for the moment of tetrabromothiophene in the manner explained above is 1.37 $D$ acting in the direction opposite to the thiophene moment. The large difference between this and the observed value of 0.73 $D$ may be accounted for on the basis of the mutual inductive effects of the four bromine atoms which are all close together. A similar negative deviation is encountered in the case of 1,2,3-trichlorobenzene whose observed moment, 2.31 $D$,[10] is 0.85 unit lower than that calculated by vector addition. Likewise, the observed moment of 1,2,3,4-tetrachlorobenzene, 1.90 $D$,[11] is 0.84 unit lower than that calculated by vector addition and 0.36 unit lower than the observed value of *o*-dichlorobenzene[12] with which, according to calculations based on vector addition, the value of tetrachlorobenzene should coincide. These cases lend weight to the above argument.

## Summary

1. Dielectric constants and densities at 30° are reported for benzene solutions of thiophene, 2-

(9) V. Schomaker and L. Pauling, THIS JOURNAL, **61**, 1769 (1939).

nitrothiophene, 2-chlorothiophene, 2-bromothiophene, 2-iodothiophene, 2,5-dichlorothiophene and tetrabromothiophene.

2. The dipole moments for these compounds, calculated by use of the Debye equation, have been found to be 0.53, 4.23, 1.60, 1.37, 1.14, 1.12 and 0.73, respectively.

3. The dipole moment values show the general resemblance of the structures of these substituted thiophenes to those of the corresponding benzene derivatives. Deviations between observed moment values and those calculated on the basis of vector additivity have been attributed largely to dipole-polarizability interactions. The possibility of decreased participation of the sulfur electrons in the thiophene ring resonance for the chloro-derivatives is also considered.

# Viscosity–Molecular Weight Relations for Various Synthetic Rubbers[1]

BY ROBERT L. SCOTT,[2] WALTER C. CARTER AND MICHAEL MAGAT[3]

## Introduction

Houwink[4] and Flory[5] have shown that the relation between the intrinsic viscosity of a high-polymer solution and the molecular weight of the polymer is of the form

$$[\eta] = KM^a \qquad (1)$$

where in the case of polyvinyl acetate compounds[4] and polymethacrylate[4] $a \sim 0.6$ and in the case of polyisobutylene[5] $a = 0.64$. More recently the authors[6] have shown that for natural rubber, the relation is

$$[\eta] = 5.02 \times 10^{-4} M^{0.667} \qquad (2)$$

In this paper, we are reporting viscosity–molecular weight relations for four more polymers: a butadiene–styrene copolymer (Buna S), sodium polymerized polybutadiene, a butadiene–acrylonitrile copolymer (Buna N), and neoprene. As will be shown, these measurements confirm the hypothesis that for these essentially linear polymers $a$ is very close, if not equal to, two-thirds.

## Experimental

**Materials.**—The rubber samples used in these experiments were kindly supplied by the Firestone Tire and Rubber Company of Akron, Ohio. The Buna S (GR-S) was of three kinds: one of low degree of conversion (100% soluble), one of medium degree of conversion (53.5% soluble) and one of high degree of conversion (32% soluble). The polybutadiene was polymerized with sodium according to methods similar to those used in the preparation of Russian SK.[7]

The toluene used was the commercial solvent dried with calcium chloride.

**Fractionation.**—Unlike natural rubber, the synthetic rubbers are not subject to rapid oxidative degradation in solution, so some of the precautions reported in the previous paper[6] are unnecessary. The rubbers were dissolved in toluene and fractionally precipitated[8] by methanol; in some cases fractions were refractionated into subfractions. Anti-oxidant ("Agerite," aldol - $\alpha$ - naphthylamine), although possibly unnecessary for these synthetics, was added to all solutions.

In certain polymers, a portion of the soluble fraction consists of "microgel," a material which is not easily removed by slow extraction with good solvents in the absence of agitation, but is more or less easily dissolved by energetic shaking, leaving only the insoluble cross-linked "macrogel." A second portion of the 100% soluble polymer was fractionated as follows: After extraction of the acetone-soluble fraction (9.0%) the rubber was dried under vacuum and then extracted with toluene in an atmosphere of carbon dioxide. Agitation of the mixture was avoided in order to minimize dispersion of the "microgel." At intervals of several days the supernatant liquid was carefully pipetted out and additional toluene added with as little disturbance to the swollen "microgel" at the bottom as possible. After much of the "sol" had been extracted in this way, fresh toluene was added and the mixture shaken. One or two shakes sufficed to bring the "microgel" into solution indicating that, for this sample at least, the bonds between the molecules of "microgel" are extremely weak. The resulting solution was completely stable, no material settling out after even a month's standing.[9] The "sol" and "microgel" portions were separately fractionated. A sample of the "macrogel" was degraded and solubilized by oxidation at high temperatures and subsequently fractionated.

**Measurements.**—The molecular weights of the fractions were calculated from osmotic pressures measured in a Flory-type osmometer, while solution viscosities were determined in an Ostwald viscosimeter. The details of these procedures were reported in the previous paper.[6]

For Buna N, the viscosity relation for various solvents was determined in the following manner: After measurements of the osmotic pressure and the viscosity in toluene, a sample of each fraction was dried in vacuum at room temperature and redissolved successively in acetone, chloroform and benzene[10] and its intrinsic viscosity in each of these solvents determined.

(7) For details of the preparation of SK see A. Talalay and M. Magat, "Synthetic Rubber from Alcohol," Interscience Publishers, New York, N. Y., 1945.

(8) In the fractionations of GR-S, the inhibitor, anti-oxidant and the lowest molecular weights were extracted with acetone before the remainder of the soluble material was extracted with toluene.

(9) No significance should be attached to the relative amounts of "sol," (23%) and "microgel" in view of the crude method of separation; the "microgel" portion undoubtedly contains some "sol."

(10) No significant oxidative degradation was observed in Buna N fractions, unlike natural rubber where the breakdown is rapid, or Buna S where the breakdown is slow but appreciable.

## Results

The viscosity–molecular weight measurements on the five series of fractions of GR-S (Buna S, 75% butadiene, 25% styrene) are shown in Fig. 1.

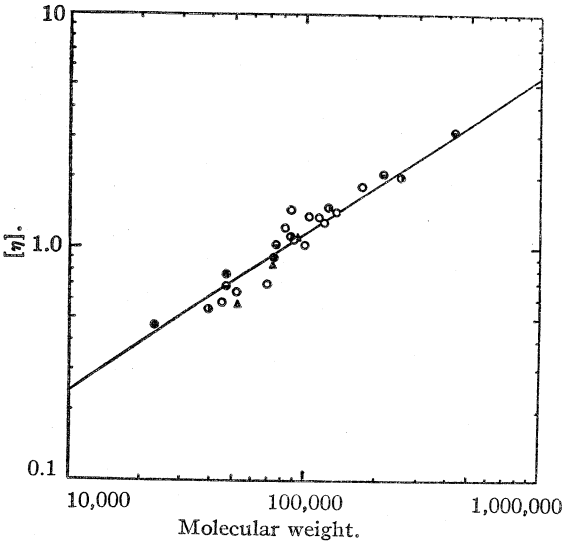

Fig. 1.—Viscosity of GR-S (Buna S) in toluene: ○, GR-S medium conversion-sol; ●, GR-S medium conversion-degraded macrogel; ◑, GR-S, low conversion-"sol"; ◒, GR-S low conversion, "microgel"; △, GR-S high conversion.

The same log–log straight line relation seems to hold approximately for all types of GR-S independent of the degree of conversion or the nature of the material: "sol," "microgel," or degraded "macrogel." Analytically the intrinsic viscosity of GR-S in toluene at 25° may be expressed as

$$[\eta] \text{ (toluene)} = 5.25 \times 10^{-4} M^{2/3} \qquad (3)$$

This relation is accurate to at least 10% for molecular weights between 25,000 and 500,000 and probably is valid for much higher molecular weights. Lower molecular weights could not be measured with our osmometer because of the permeability of the membrane.

The relations found for the other three polymers are shown in Table I and Figs. 2 and 3.

TABLE I

| Polymer | Solvent | $K \times 10^4$ | $a$ |
|---|---|---|---|
| Buna N | Toluene | 4.9 | 0.64 |
| | Acetone | 5.0 | .64 |
| | Chloroform | 5.4 | .68 |
| | Benzene | 1.3 | .55 |
| Neoprene | Toluene | 5.0 | .615 |
| Sodium polymerized polybutadiene | Toluene | 11.0 | .62 |

The reader may judge the accuracy of the determination of the exponent $a$ from the experimental data in Figs. 1–3. For GR-S $a$ is probably 0.67 ± 0.05. For the other polymers the accuracy is considerably better.

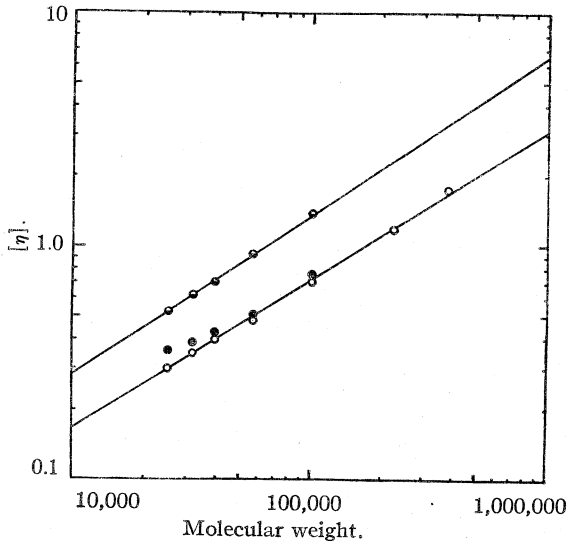

Fig. 2.—Viscosity of Buna N solutions: ○, toluene; ●, benzene; ◒, chloroform.

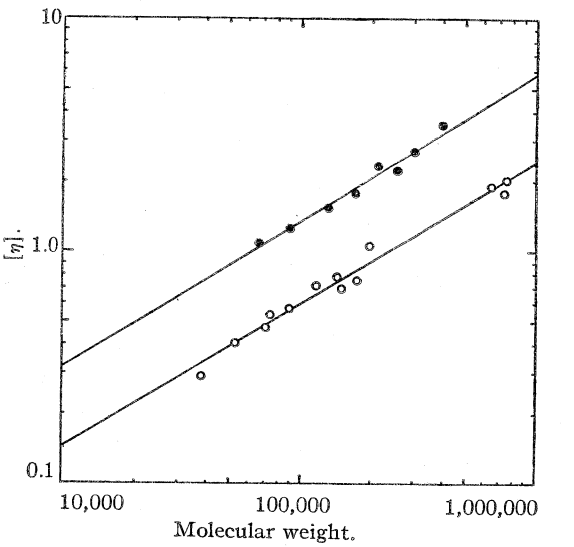

Fig. 3.—Viscosity of sodium polymerized polybutadiene (●) and neoprene (○) in toluene.

The data for Buna N in different solvents are further shown in Table II.

TABLE II

INTRINSIC VISCOSITY OF BUNA N SOLUTIONS

| Fraction | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|---|---|---|---|---|---|---|---|
| Mol. wt. × 1000 | 25.0 | 31.8 | 39.5 | 57.0 | 101 | 224 | 380 |
| Toluene | 0.30 | 0.35 | 0.40 | 0.48 | 0.71 | 1.16 | 1.76 |
| Acetone | .317 | .38 | .405 | .475 | 0.715 | | |
| Chloroform | .52 | .62 | .70 | .93 | 1.38 | | |
| Benzene | .36 | .39 | .43 | .51 | 0.76 | | |

No systematic work was done on polyisobutylene since this polymer has been studied exhaustively by Flory.[5] However, at the beginning of our work Dr. Flory kindly sent us three fractions of known molecular weight to check the

accuracy of our osmometer. As seen in Table III the agreement between the data of the two laboratories is quite satisfactory.

TABLE III

POLYISOBUTYLENE FRACTIONS

| No. | Osmotic molecular weight: Flory | Osmotic molecular weight: Scott and Magat | Intrinsic viscosity: In toluene (Scott and Magat) | Intrinsic viscosity: In diisobutylene (Flory) |
|---|---|---|---|---|
| 1 | 206,000 | 223,000 | 0.635 | 0.90 |
| 2 | 515,000 | 495,000 | 1.25 | 1.64 |
| 3 | 1,200,000 | 1,340,000 | 2.06 | 2.82 |

We have used these data to determine in a very rough way the dependence of the viscosity in toluene on the molecular weight. Figure 4 shows this relation (in broken line since based on but three points it is only very approximate) and the well-established relation for the viscosity in diisobutylene.[5] These relations expressed analytically are

$$[\eta] \text{ (toluene)} = 2.6 \times 10^{-4} M^{0.64} \quad (4)$$

$$[\eta] \text{ (diisobutylene)} = 3.60 \times 10^{-4} M^{0.64} \quad (5)$$

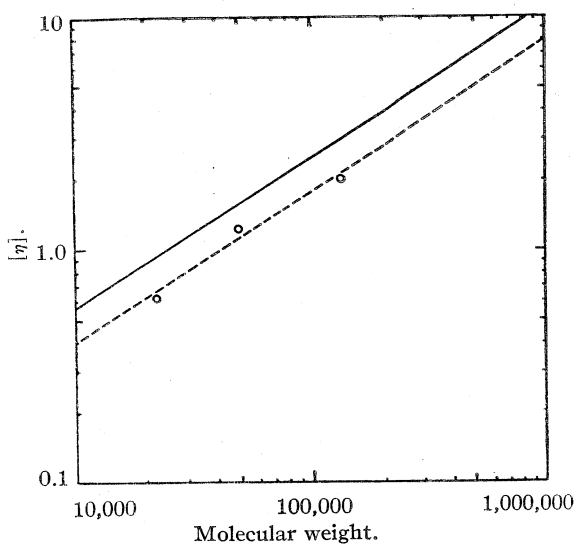

Fig. 4.—Viscosity of polyisobutylene: —, in diisobutylene (Flory); --O--, in toluene (this paper).

## Discussion

At about the same time as our research was carried out, Ewart and co-workers at the United States Rubber Company Laboratories measured solutions of fractionated GR-S in a glass osmometer using cellophane membranes.[11] While most, if not all, of their measurements were made upon benzene solutions, they fit our relation for toluene solutions remarkably well. Figure 5 shows the results of two different series of data by Ewart and French[12] and Tingey, Ewart and Hulse[13]; the line is our relation for toluene taken from Fig. 1. It should be emphasized that the U. S. Rubber measurements were made in an entirely different osmometer using a different kind of membrane, so that the possibility of systematic error is almost certainly excluded.

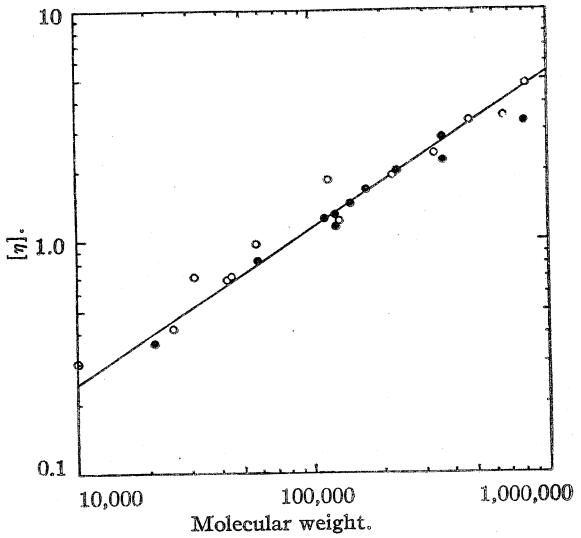

Fig. 5.—Viscosity of Buna S (GR-S) in benzene (U. S. Rubber Company measurements): O, Ewart and French; ●, Tingey, Ewart and Hulse.

In the previous paper on natural rubber,[6] the authors have discussed in some detail the various theories which attempt to explain the viscosity of high polymer solutions. Since those comments seem to be equally valid for these data, they need not be repeated here, but one additional point is worth consideration. The intrinsic viscosity should be a function of the chain length rather than the actual molecular weight.[14] Since the chain length is proportional to the molecular weight, the viscosity should be proportional to some inverse power of $w$, the weight per chain atom. That this seems to be true can be seen from Table IV.

TABLE IV

| Polymers | $w$ | $K \times 10^4$ |
|---|---|---|
| Polybutadiene | 13.5–27[15] | 6.34 |
| GR-S | 18–20 | 5.25 |
| Hevea | 18 | 5.02 |
| Buna NM | 15–26[15] | 3.35 |
| Neoprene GN | 22 | 2.73 |
| Polyisobutylene | 28 | 2.01 |

($w$ = molar weight per chain carbon atom)

The value of the empirical constant $K$ is given for a variety of rubbers (in toluene solutions); to secure uniformity, they are all recalculated for $a = 2/3$. We see that as $w$ increases, there is a systematic decrease in $K$, corresponding to lower solution viscosities for equal molecular

weights. This shift of the intrinsic viscosity–molecular weight curves is summarized graphically in Fig. 6. The theoretical expressions of Huggins[16] and of Hulburt, Harmon, Tobolsky and Eyring[17] represent the viscosity as proportional to inverse powers of the weight per chain atom so in this respect at least they are approximately valid.

It is interesting to note that of the various theories only that of Haller[18] predicts accurately the dependence of the viscosity on the two-thirds power of the molecular weight.[19]

**Acknowledgments.**—The authors wish to thank Dr. Paul J. Flory and the Esso Laboratories for furnishing the three fractions of polyisobutylene; the Firestone Tire and Rubber Company, in particular Dr. J. H. Dillon, for furnishing the rubber samples; Professor Arthur V. Tobolsky for several helpful discussions; and Professor Hugh S. Taylor for his generous interest and valuable advice.

(19) Since this paper was first submitted to the Editor of The Journal, two new theories of viscosity have appeared, one by P. Debye and A. M. Bueche (*J. Chem. Phys.*, **16**, 573, 1948) and one by J. G. Kirkwood and J. Riseman (*ibid.*, **16**, 565, 1948). On preliminary inspection, it seems that our data are entirely consistent with these new theories, but rather than further delay publication of these results, we postpone a detailed discussion to a subsequent paper.

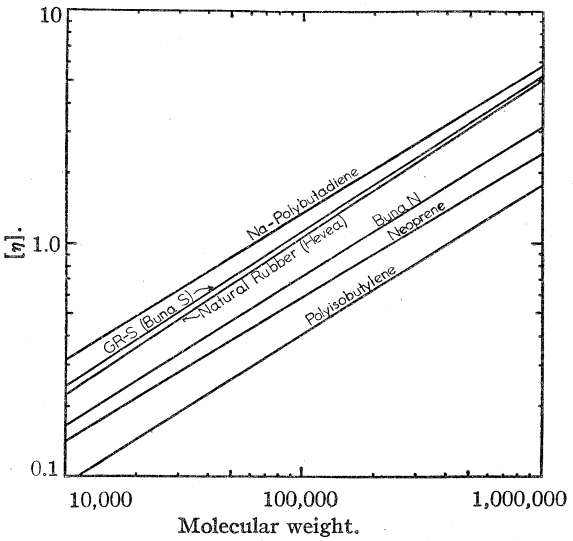

Fig. 6.—Viscosity–molecular weight relations for toluene solutions of various polymers.

## Summary

Measurements on six different high polymers have shown that the intrinsic viscosity of the solutions depends on approximately the two-thirds power of the molecular weight. Dependence of the viscosity on the weight per chain atom of the polymer is indicated.

# The Kinetics of Semicarbazone Formation with Para Substituted Acetophenones[1]

BY ROBERT P. CROSS AND PAUL FUGASSI

The kinetics of the reactions of *d*-carvone with semicarbazide and other carbonyl reagents have been investigated previously by Stempel and Schaffel[2] and Mariella[3] using a polarimetric method. It is the purpose of this investigation to examine the kinetics of semicarbazone formation with para substituted acetophenones by a competitive method in which *d*-carvone and acetophenone react simultaneously with semicarbazide, present in sufficiently low concentration that the carbonyl reagent distributes itself between the two ketones. The extent of reaction of the *d*-carvone is determined polarimetrically.

(1) Abstracted from the thesis submitted by Robert P. Cross on August 12, 1947, to the Committee on Graduate Degrees, Carnegie Institute of Technology, in partial fulfillment of the requirements for the degree of Doctor of Science. Presented before the Division of Physical and Inorganic Chemistry at the 113th meeting of the American Chemical Society at Chicago, April, 1948.

(2) Stempel and Schaffel, THIS JOURNAL, **66**, 1158 (1944).

(3) Mariella, Thesis, Carnegie Institute of Technology, October 4, 1945.

## Experimental Technique

**Preparation of Compounds.**—*d*-Carvone was obtained from Magnus, Mabee and Reynard. It was purified by preparing the solid hydrosulfide.[4,5] After several recrystallizations of the hydrogen sulfide compound, *d*-carvone was recovered by treating the compound with concentrated sodium hydroxide solution and steam distilling the mixture. Following extraction of the carvone with ether, the extract was vacuum distilled several times and a fraction collected boiling at 78° at 3 mm. The physical constants of our sample agreed with those found by Stempel and Schaffel.[2] Semicarbazide hydrochloride (an Eastman Kodak Co. product) was recrystallized from hydrochloric acid solution. Acetophenone was purified by the method of Flexser, Hammett and Dingwall.[6] The sample of acetophenone used boiled at 193° at 743 mm. *p*-methoxyacetophenone and *p*-chloroacetophenone were prepared by the method of Adams and Noller.[7] The

former compound melted at 38° and the latter boiled at 85° at 5 mm. *p*-Methyl and *p*-bromo acetophenone were Eastman chemicals. The *p*-bromoacetophenone was recrystallized several times from hot ethanol to give a sample with a melting point of 50.5°. *p*-Methylacetophenone was distilled several times at reduced pressure. The fraction used boiled at 94° at 10 mm.

**Physical Measurements.**—Rotations were measured with a Hilger M-8 polarimeter using the mercury green line at 5461 Å. Readings could be made to 0.01°. The polarimeter tube, 5 decimeters long, was provided with a water jacket, insulated with magnesia–asbestos, through which thermostatted water was pumped. Beckmann thermometers were placed at the inlet and outlet water connections and the thermostat adjusted so that the mean temperature of the polarimeter tube was 30, 40 or 50°.

Two general types of experiments were made. In the first type of experiment *d*-carvone reacted with semicarbazide, while in the other type *d*-carvone and an acetophenone reacted with semicarbazide. For the experiments with carvone alone the reactants were brought to the temperature of the experiment and mixed in a volumetric flask kept at the temperature of the experiment. Sufficient solvent (83% ethanol in water) was then added so that the starting concentrations of semicarbazide, semicarbazide hydrochloride and *d*-carvone were all equal to 0.015 mole/liter. After thorough mixing, the solution was transferred to the polarimeter tube and the rotations measured at definite time intervals taking zero time as the instant when the reactants were mixed. In the second type of experiment the reactants were mixed in a volumetric flask kept at the temperature of the experiment and sufficient 83% ethanol added so that the starting concentrations of carvone, substituted acetophenone, semicarbazide, and semicarbazide hydrochloride were all equal to 0.015 mole/liter. After mixing the solution was allowed to remain in the thermostat for a period of approximately twenty, ten or five hours depending on whether the temperature of the experiment was 30, 40 or 50°, respectively. These periods of time correspond to the time interval necessary for 99% of the reaction to take place when carvone alone is reacted with semicarbazide.

## Calculation of Velocity Constants

In the experiments with *d*-carvone a first order plot of $-\log(1-f)$ against time fits the experimental data for values of $f$ (fraction decomposed) up to 0.5. For the experiments at 30°, $f$ values of about 0.5 were the highest that could be obtained in reasonable reaction times. At 50°, however, $f$ values up to 0.93 were obtained. For the higher temperature experiments the experimental points corresponding to $f$ values greater than 0.5 were above the straight line first order plot. The experimental points at these higher values of $f$ diverged more and more from the first order line as $f$ increased in value. The direction of the drift indicates that in the later stages the reaction is approaching zero order. However, in view of the fact that we are dealing with a complex system and a reversible reaction in which the points obtained at low $f$ values should be stressed to minimize the effect of the reverse reaction, it does not seem desirable to stress fitting of the experimental points at high $f$ values. Consequently, the experimental data for the experiments with *d*-carvone alone were calculated on the basis of the first order equation, $kt = -2.3\log(1-f)$.

In the experiments where two ketones reacted simultaneously with semicarbazide, it appears possible to ignore the reverse reactions. Experimentally it is known that the semicarbazones of either carvone or acetophenone do not react appreciably, in the time intervals used here, with acetophenone or carvone, respectively. The equilibrium constant for the formation of carvone semicarbazone is known to be large. The equilibrium constant for the formation of acetophenone semicarbazone is also believed to be large. A value for the latter equilibrium constant is not cited because in the periods of time (weeks) necessary for equilibrium the solutions darken even if protective nitrogen atmospheres are employed. The darkening of the solution interferes somewhat with the measurement of the rotation and might be indicative of slow side reaction which would influence the equilibrium but would have little or no influence on the kinetics because of their slowness. In the kinetics measurements reported here all solutions were colorless at the end of the time intervals used. Until the origin of the darkening of the solutions is discovered it does not seem desirable to list numerical values for the equilibrium constant. With regard to substituted acetophenones it is fairly certain that the substitution of groups on acetophenone will change the numerical values of the equilibrium constant for semicarbazone formation but will not change its order of magnitude.

Accordingly we assume following Grazzi[8] that each ketone follows a rate equation of the form

$$dx_i/dt = k_i(a_i - x_i)f(x_i)$$

where $a_i$ is the starting concentration of the ketone, $x_i$ the concentration of ketone which has reacted at time $t$, and $f(x_i)$ a function of the concentrations of all the other reactants involved. Under the experimental conditions employed it is assumed that $f(x_i)$ has the same value for all ketones so that we may write

$$\frac{dx_1}{k_1(a_1 - x_1)} = \frac{dx_2}{k_2(a_2 - x_2)}$$

where the subscripts 1 and 2 refer to *d*-carvone and the other ketone, respectively. Integration of this equation together with the use of the boundary condition that at zero time the concentrations of *d*-carvone, other ketone, semicarbazide and semicarbazide hydrochloride are all equal gives the equation

$$k_2 = k_1\frac{\log f'}{\log(1-f')}$$

where $f'$ is the fraction of *d*-carvone which has reacted at the given time interval with the other ketone present, relative to the amount of reaction undergone by *d*-carvone at infinite time when the other ketone is absent.

## Experimental Data

For the experiments with *d*-carvone alone the following average values of $k$ representing the

(8) Grazzi, *Gazz. chim. ital.*, **38**, 32 (1908); **40**, 140 (1910).

mean of three determinations at each temperature were obtained: 30°, $3.74 \times 10^{-3}$ min.$^{-1}$; 40°, $7.68 \times 10^{-3}$ min.$^{-1}$; and 50°, $1.6 \times 10^{-3}$ min.$^{-1}$.

With experiments using two ketones a minimum of five experiments were made at each temperature for each ketone. The average values of the velocity constants were plotted on a typical Arrhenius plot and the constants in the Arrhenius equation, $\log k = A - \frac{E_A}{2.3RT}$, were evaluated. $E_A$ is the energy of activation. The values of the constants are collected in Table I.

TABLE I

ARRHENIUS EQUATION CONSTANTS

| Ketone | $A$, min.$^{-1}$ | $E_A$, cal. |
|---|---|---|
| *p*-Methoxyacetophenone | −0.57 | 4,000 |
| *p*-Methylacetophenone | 1.38 | 6,540 |
| Acetophenone | 2.33 | 7,800 |
| *p*-Chloroacetophenone | 4.44 | 10,330 |
| *p*-Bromoacetophenone | 5.00 | 11,040 |

## Discussion

Reference to Table I indicates that the activation energy of semicarbazone formation varies with the nature of the substituting group in the para position and that in order of decreasing activation energy the substituting groups would fall in the sequence Br > Cl > H > $CH_3$ > $CH_3O$. It is obvious that the above sequence is the same one that would be obtained if the substituting groups were arranged in the order of their ability to withdraw electrons from the ring. As semicarbazone formation only involves the carbonyl group, it is apparent that the charge density on the carbon atom is the determining factor and that the influence of the substituting group is due to its effect upon the charge density of the carbonyl carbon. A number of reactions are influenced by substitution in this manner and to these Hammett has applied the equation, $\log k - \log k^0 = \rho\sigma$. In this equation $k$ is the rate constant for the substituted compound, $k^0$ is the rate constant for the unsubstituted compound, $\sigma$ is a constant depending upon the nature of the substituting group, and $\rho$ is a constant characteristic of the reaction. If the values of $\sigma$ evaluated by Hammett are used, a plot of log $k$ *versus* $\sigma$ gives a straight line of slope $\rho$. The slope and value of $\rho$ for the semicarbazone formation turns out to be 0.91. Another method of illustrating the effect of the substituting groups is to plot log $K_{(\text{dissociation})}$ which is proportional to the free energy of dissociation of the corresponding substituted benzoic acid, against the energy of activation of the corresponding substituted ketone. Such a plot is illustrated in Fig. 1. Reference to Fig. 1 shows that the carbonyl carbon having the highest charge density as exemplified by the highest positive free energy of dissociation of the corresponding substituted benzoic acid also has the lowest activation energy. This behavior suggests that the rate-determining step in the semicarbazone reaction is a reaction involving the transfer of a proton to the reaction complex. However, the suggested mechanism for semicarbazone formation is quite complicated as will be seen by reference to Stempel and Schaffel.[2] Since for such a mechanism the experimental velocity constant is the product of the velocity constant of the rate determining step and a number of equilibrium constants, the activation energy obtained from the experimental velocity constant is a composite term in the sense that it includes heats of reactions for the various equilibrium reactions. Consequently the effect of a substituting group might be due in part to changes in heats of reactions caused by such groups.

**Acknowledgment.**—The authors wish to thank Dr. A. A. Orning, Dr. Gerson S. Schaffel and Dr. Guido H. Stempel for their comments and suggestions.

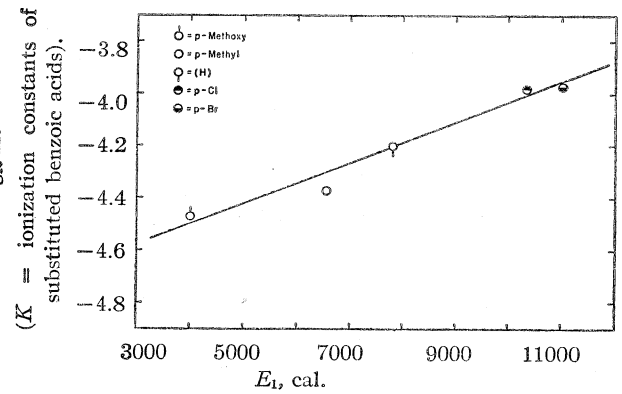

Fig. 1.—Energy of activation for semicarbazone formation of acetophenone series.

## Summary

1. The rate of semicarbazone formation of acetophenone and substituted acetophenones has been determined by a competitive method using *d*-carvone as the competing ketone.

2. The effect of para substitution upon the experimental activation energy of the semicarbazone reaction with acetophenone is given by the sequence, Br > Cl > H > $CH_3$ > $CH_3O$, with *p*-bromoacetophenone showing the highest activation energy.

3. It is suggested that the rate determining step is a reaction involving transfer of a proton to the reaction complex.

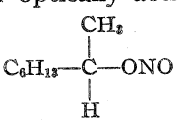
# The Mechanism of the Thermal Decomposition of Alkyl Nitrites in the Liquid Phase: the Pyrolysis of Optically Active 2-Octyl Nitrite

BY NATHAN KORNBLUM AND EUGENE P. OLIVETO[1,2]

The thermal decomposition of methyl, ethyl, *n*-propyl, isopropyl and *n*-butyl nitrites in the vapor phase at 170–240° has been investigated by Steacie and his co-workers.[3] They concluded that the major over-all reaction is the same in each case, *viz.*

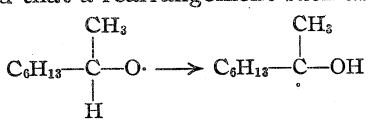


$$2RCH_2ONO \longrightarrow RCHO + RCH_2OH + 2NO \quad (1)$$

The vapor phase reaction has also been studied by F. O. Rice and Rodowskas,[4] who proposed the mechanism[5]

$$RCH_2ONO \longrightarrow RCH_2O\cdot + NO$$
$$RCH_2O\cdot + RCH_2ONO \longrightarrow RCH_2OH + R\dot{C}HONO$$
$$R\dot{C}HONO \longrightarrow RCHO + NO$$

$$2RCH_2ONO \longrightarrow RCH_2OH + RCHO + 2NO$$



The present investigation represents a test of Rice's hypothesis. According to the proposed mechanism pyrolysis of optically active 2-octyl nitrite

should give 2-octanol, 2-octanone and nitric oxide, and the 2-octanol should be optically active.

Upon treating *d*-2-octanol, $[\alpha]^{25}D$ +9.30°, with nitrosyl chloride in pyridine *d*-2-octyl nitrite, $[\alpha]^{25}D$ +6.44°, was obtained. This, when heated at 100° for eight days, underwent complete decomposition and the 2-octanol produced (80% yield) had $[\alpha]^{25}D$ +9.23°. Thus, in complete conformity with Rice's mechanism, no racemization had taken place.

If Rice's mechanism is accepted, then it follows that the secondary alkoxyl radical is optically stable and that a rearrangement such as

does not take place with facility, if at all, in the liquid phase at 100°. Clearly, more precise information concerning the optical stability of alkoxyl radicals will be of value not only because of its bearing on the mechanism of the thermal decomposition of alkyl nitrites, but also because of its own rather considerable intrinsic interest.

The present study was also concerned with the possibility that the pyrolysis of alkyl nitrites might not follow the same course in the liquid and vapor phases. Since all previous work on the thermal decomposition of alkyl nitrites had been conducted in the gas phase, at temperatures distinctly greater than 100°, it was of interest to establish whether or not the products of the liquid phase decomposition correspond to those previously obtained in the vapor phase.

In addition to *d*-2-octanol, the liquid phase thermal decomposition of *d*-2-octyl nitrite at 100° gave a number of other products. As one would anticipate from equation (1), 2-octanone was the other principal organic product. Just as with *d*-2-octanol, it was also formed in 80% yield so that these two, between them, account for four-fifths of the organic material. Nitric oxide, however, was produced in only 37% of the amount to be expected from equation (1). This led to a careful study of the other components of the reaction mixture whereupon eight additional compounds were found (Table I).

TABLE I

PRODUCTS FROM THE THERMAL DECOMPOSITION OF 1.02 MOLES OF *d*-2-OCTYL NITRITE

| Product | Amount, millimoles | Nitrogen, gram-atoms |
|---|---|---|
| *d*-2-Octanol | 380 | |
| 2-Octanone | 380 | |
| Nitric oxide | 380 | 0.38 |
| Nitrogen | 280 | .56 |
| Nitrous oxide | 24 | .05 |
| Acetic acid | 22.6 | |
| Heptanoic acid | 12.6 | |
| 2-Octyl acetate | 3 | |
| 2-Octyl heptanoate | 3 | |
| Capronitrile | 20 | .02 |
| Tarry residue | (11.2 g.) | .02 |
| Carbon dioxide[a] | | |
| | Total | 1.03 |

[a] This required a separate experiment since ordinarily the system was swept out with carbon dioxide.

Nitric oxide has recently been found to react with 2-octanone at 100°, in the dark, with the production of acetic acid, heptanoic acid and capronitrile, the nitric oxide being reduced to

(1) E. I. du Pont de Nemours and Co. Fellow, 1946–1947.

(2) Present address: Schering Corporation, Bloomfield, New Jersey.

(4) F. O. Rice and Rodowskas, THIS JOURNAL, **57**, 350 (1935).

(5) Rice and Rodowskas (ref. 4) studied the ethyl nitrite decomposition at 425°. They concluded that at pressures greater than about one third of an atmosphere, reaction (1) preponderates. However, at pressures of approximately 1 mm. they found that methyl radicals are formed in abundance and suggested that the predominant reaction is

$$CH_3CH_2ONO \longrightarrow CH_3CH_2\text{—}O\cdot + NO$$
$$CH_3CH_2\text{—}O\cdot \longrightarrow HCHO + CH_3\cdot$$
$$CH_3\cdot + CH_3CH_2ONO \longrightarrow CH_4 + CH_3\dot{C}H\text{—}ONO$$
$$CH_3\dot{C}HONO \longrightarrow CH_3CHO + NO$$

$$2CH_3CH_2ONO \longrightarrow HCHO + CH_4 + CH_3CHO + 2NO$$

nitrogen and nitrous oxide.[6] It appears probable, therefore, that the various minor products obtained upon heating 2-octyl nitrite at 100° arise from a set of secondary reactions, namely, cleavage of 2-octanone by nitric oxide and esterification of 2-octanol by the acids formed. The large amount of elementary nitrogen produced is especially noteworthy.

## Experimental[7,8]

*d*-2-Octanol.—Racemic 2-octanol was resolved according to Ingersoll.[9] The *d*-2-octanol obtained had $n^{20}D$ 1.4262; lit. value,[10] $n^{20}D$ 1.4264, $[\alpha]^{25}D$ + 9.30° ($c$ = 5, ethanol); lit. value,[9] $[\alpha]^{17}D$ + 9.8°.

*d*-2-Octyl Nitrite.—*d*-2-Octyl nitrite was prepared in 80% yield by the action of nitrosyl chloride on *d*-2-octanol; $n^{20}D$ 1.4080; $[\alpha]^{25}D$ + 6.44 ($c$ = 5, ethanol); lit. value,[11] $n^{20}D$ 1.4082.

**Thermal Decomposition of *d*-2-Octyl Nitrite.**—One hundred and sixty-two grams (1.02 moles) of *d*-2-octyl nitrite was decomposed by heating at 100 ± 2° for eight days in a three-neck flask fitted with a condenser, thermometer and a gas inlet tube. Prior to the reaction the system was swept out overnight with a stream of carbon dioxide which had previously passed through 96% sulfuric acid, Drierite and cotton. During the reaction a slow stream of carbon dioxide was maintained. The exit gases, upon leaving the condenser, were passed through two ice-traps, two wash bottles containing mixed acid (9 parts 96% sulfuric acid: 1 part 65% nitric acid) and finally collected over 50% aqueous potassium hydroxide. To eliminate photochemical effects, the reaction flask and condenser were painted black, and the reaction was carried out in a dark-room.[12] At the end of eight days there was no nitrite left, as evidenced by a negative Griess–Ilosvay test.[13] The liquid in the reaction flask now weighed 124 g. and was dark-brown in color. There was less than 0.1 ml. of liquid in the ice-traps. The organic liquid (124 g.) was extracted with three 50-ml. portions of water, giving a water extract (fractions $A_1$, $A_2$, $A_3$) and an organic residue (fraction B).

**Acetic Acid.**—Fraction $A_1$ required 14.9 meq. of sodium hydroxide for neutralization; fraction $A_2$ required 7.0 meq., and fraction $A_3$ 0.7 meq.

Fraction $A_1$ (which did not decolorize alkaline permanganate) was concentrated under reduced pressure at room temperature to *ca.* 25 ml. (fraction $A_4$). When the first 50-ml. portion of the distillate was rectified through an 18″ concentric tube column rated at 65 plates, no liquid boiling lower than 100° was obtained. (The column easily and cleanly separated a prepared solution of 3% acetonitrile in water into its components.) Thus, little or no acetonitrile was present.

A portion of fraction $A_4$ was converted to the S-benzyl thiuronium salt in 50% yield; m.p. 138–139°. This did not depress the m.p. of authentic S-benzyl thiuronium acetate[6]; m.p. 139–140°. *Anal.* Calcd. for $C_{10}H_{14}N_2O_2S$: N, 12.4. Found: N, 12.2. Another portion of fraction $A_4$ was converted to the *p*-phenylphenacyl ester in 65% yield. This melted at 107–108° and did not depress the m.p. of authentic *p*-phenylphenacyl ester of acetic acid; m. p. 108–109°. *Anal.* Calcd. for $C_{16}H_{14}O_3$: C, 75.6; H, 5.6. Found: C, 75.8; H, 5.4.

**Heptanoic Acid.**—Fraction B was extracted with three 35-ml. portions of 30% sodium carbonate solution, giving an aqueous alkaline extract (fraction C) and an organic residue (fraction D). Fraction C was acidified with 85% phosphoric acid and steam distilled. The distillate, which required 12.6 meq. of sodium hydroxide for neutralization, was then concentrated under reduced pressure at room temperature to a volume of *ca.* 15 ml. A portion was converted to the S-benzyl thiuronium salt in 70% yield; m.p. 147–148°; it did not depress the m.p. of an authentic sample[6] of S-benzyl thiuronium heptanoate, m.p. 148–149°. *Anal.* Calcd. for $C_{15}H_{24}N_2O_2S$: N, 9.4. Found: N, 9.6.

A *p*-phenylphenacyl ester was also prepared in 80% yield, m.p. 60–61°; this did not depress the m.p. of an authentic sample of the *p*-phenylphenacyl ester of heptanoic acid, m.p. 61–62°. *Anal.* Calcd. for $C_{21}H_{24}O_3$: C, 77.8; H, 7.5. Found: C, 77.7; H, 7.5.

**Fraction D.**—Extraction of fraction D with 0.1 *N* alkali did not remove any more acids. About 500 ml. of water was added and the mixture was distilled under reduced pressure at 30–35°. The non-distillable residue was extracted with petroleum ether, dried over Drierite, and the solvent was removed by ordinary distillation; there was left 11.2 g. of a black, viscous liquid. *Anal.* Found: C, 71.0; H, 12.0; N, 2.9.

The organic distillate (fraction $D_1$) was mechanically separated from the water layer and treated with Drierite. The dry, yellow liquid weighed 106 g., had $n^{20}D$ 1.4193, and analyzed 45% 2-octanone[14] and 44% 2-octanol.[15]

One hundred grams of the yellow liquid ($n^{20}D$ 1.4193) was rectified under reduced pressure. Twenty-two fractions were obtained and these, with the exception of fraction 3 (3.1 g.), were further studied.

**Identification of Capronitrile.**—Fractions 1 and 2, b.p. 63–68° at 27 mm. pressure, $n^{20}D$ 1.4100 to 1.4113, were combined (total 3.1 g.). Only these two fractions contained nitrogen. An unsuccessful attempt was made to isolate the nitrogen-containing component by rectification through a 65-plate column. A 0.5-ml. portion of the distillate, now about 20% richer in the nitrogen-containing component, was hydrolyzed to the amide.[16] The amide (50 mg.) had m.p. 98–99° (lit. m.p. 101°)[17] and did not depress the m.p. of authentic caproamide, m.p. 99–100°. *Anal.* Calcd. for $C_6H_{13}NO$: C, 62.6; H, 11.3; N, 12.1. Found: C, 62.4, 62.5; H, 11.3, 11.5; N, 12.1.

Another 0.5-ml. portion of the distillate was converted to the anilide[18] (150 mg.), m.p. 94–95° (lit. m.p. 96°),[17] which did not depress the m.p. of authentic caproanilide, m.p. 94–95°. *Anal.* Calcd. for $C_{12}H_{17}NO$: N, 7.4. Found: N, 7.5, 7.6.

**Isolation of 2-Octanone.**—Fractions 4–10; b.p. 69–70° (27 mm.); $n^{20}D$ 1.4148 to 1.4150; were combined (total, 39.6 g.) and an 8.4-g. sample was rectified through the 65 plate column. There was obtained 7.5 g. of analytically pure 2-octanone, b.p. 75–76° (20 mm.), $n^{20}D$ 1.4159; lit. value[19] $n^{20}D$ 1.41518. *Anal.* Calcd. for $C_8H_{16}O$: C, 74.9; H, 12.6. Found: C, 74.9; H, 12.5.

**Isolation of 2-Octyl Acetate.**—Fractions 11–16, b.p. 70° (27 mm.) to 68° (15 mm.); $n^{20}D$ 1.4150 to 1.4235; gave a positive hydroxamic acid test for esters[20] and were

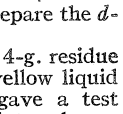
combined (total = 3.9 g.). Upon rectification through the 65-plate column there was obtained 0.6 g. of a colorless liquid, b.p. 81° (18 mm.), $n^{20}D$ 1.4180. *Anal.* Calcd. for $C_{10}H_{20}O_2$: C, 69.8; H, 11.7; sapon. equiv., 172. Found: C, 69.9; H, 11.9; sapon. equiv., 166. An S-benzylthiuronium salt was prepared from the neutral solution; m.p. 138–139° (40% yield). It did not depress the m.p. of an authentic sample of S-benzyl thiuronium acetate, m.p. 139–140°.

**Isolation of *d*-2-Octanol.**—Fractions 17–22, b.p. 68° (15 mm.), were combined (total = 40.1 g.); $n^{20}D$ 1.4249, lit. value,[10] $n^{20}D$ 1.4264; $[\alpha]^{25}D$ + 9.23° (*c* = 5, ethanol). A 5-g. portion, esterified with phthalic anhydride in the presence of pyridine,[10] gave a 95% yield of *d*-2-octyl hydrogen phthalate, m.p. 71–73°. This, after one recrystallization from petroleum ether (b.p. 60–70°), melted at 73–74° (lit. m.p.[9] 75°) and did not depress the m.p. of authentic *d*-2-octyl hydrogen phthalate, m.p. 74–75°. The purified ester had $[\alpha]^{25}D$ + 47.5° (*c* = 5, ethanol). (The *d*-2-octyl hydrogen phthalate obtained during the resolution of 2-octanol had $[\alpha]^{25}D$ + 47.7°). *Anal.* Calcd. for $C_{16}H_{22}O_4$: C, 69.0; H, 8.0. Found: C, 69.1; H, 8.2. The ester was hydrolyzed[9] to *d*-2-octanol; $n^{20}D$ 1.4262 (lit.[10] 1.4264), $[\alpha]^{25}D$ + 9.27° (*c* = 5, ethanol). The *d*-2-octanol used to prepare the *d*-2-octyl nitrite had $[\alpha]^{25}D$ + 9.30°.

**Isolation of 2-Octyl Heptanoate.**—A yellow 4-g. residue remained from the rectification of 100 g. of yellow liquid ($n^{20}D$ 1.4193). This had $n^{20}D$ 1.4285 and gave a test for esters.[20] It was rectified through the 65-plate column. There was obtained 0.7 g. of a colorless liquid; b.p. 112° at 10 mm., $n^{20}D$ 1.4320. *Anal.* Calcd. for $C_{15}H_{30}O_2$: C, 74.3; H, 12.4; sapon. equiv., 242. Found: C, 74.4; H, 12.2; sapon. equiv., 240. An S-benzylthiuronium salt was prepared from the neutral solution; m.p. 147–148° (65% yield). It did not depress the m.p. of authentic S-benzylthiuronium heptanoate, m.p. 148–149°.

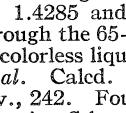
**Nitric Oxide.**—The two wash-bottles containing 96% sulfuric acid + 65% nitric acid had absorbed 11.4 g. of nitric oxide (titration with standard permanganate).[21]

**Nitrous Oxide and Nitrogen.**[22]—The gases collected over potassium hydroxide totaled 6750 ml. (S.T.P.). Upon analysis in a conventional Orsat apparatus, 8% of the gas was found to be nitrous oxide (determined by slow combustion with hydrogen) and the remaining 92% was inert (nitrogen). Carbon dioxide, carbon monoxide, olefins, saturated hydrocarbons, oxygen, nitric oxide and nitrogen dioxide were all absent.



**Demonstration of the Formation of Carbon Dioxide in the Thermal Decomposition of *dl*-2-Octyl Nitrite.**—Ten grams of *dl*-2-octyl nitrite was decomposed at 100 ± 2° over a period of eight days in a slow stream of dry oxygen-free nitrogen. The exit gases were passed through 96% sulfuric acid, glass wool and finally through two U-tubes containing Ascarite; the Ascarite tubes gained 177 mg. (4.0 meq. of carbon dioxide). The Ascarite which reacted did not give a test for cyanide.[23] The liquid remaining in the flask weighed 7.3 g., and contained 0.9 meq. of acetic acid and 0.7 meq. of heptanoic acid.

(21) Milligan, *J. Phys. Chem.*, **28**, 544 (1924).



(22) We are indebted to Professor P. J. Elving of this department for his kind assistance in connection with the gas analyses.

## Summary

The thermal decomposition of *d*-2-octyl nitrite in the liquid phase at 100° gives *optically pure* *d*-2-octanol in excellent yield. In addition to confirming F. O. Rice's mechanism for the pyrolysis of alkyl nitrites, this indicates that alkoxyl radicals of the type

do not rearrange to

in the liquid phase at 100°.

The other major organic product is 2-octanone. Small amounts of acetic acid, heptanoic acid, 2-octyl acetate, 2-octyl heptanoate and capronitrile are also produced. These probably arise from the cleavage of 2-octanone by nitric oxide followed by esterification of 2-octanol by the acids formed.

The gaseous products of the reaction are nitrogen, nitric oxide, nitrous oxide and carbon dioxide.

# The Optical Crystallographic Properties of Some Sulfonamides and their Derivatives

BY RAYMOND N. CASTLE,[1] NORMAN F. WITT AND C. F. POE

The optical crystallographic properties of organic compounds are useful for purposes of identification. This is particularly true of compounds containing aromatic or heterocyclic ring systems where examples of strong dispersion of several types and strong double refraction are frequently observed. Thus the optical crystallographic properties of the sulfonamides and their derivatives should prove useful in their characterization.

Optical crystallographic studies of some of the therapeutically important sulfonamides have received the attention of several investigators. Except for sulfanilamide these data are more or less incomplete. The optical properties of sulfanilamide and of a series of Schiff bases have been determined by White.[2] Grove and Keenan[3] reported the optical properties of two forms of sulfathiazole. Prien and Frondel[4] reported the application of the optical properties of sulfanilamide, sulfathiazole and sulfapyridine, and their

[a] The melting points of the Schiff bases and the parent sulfonamides were taken in the usual capillary tubing immersed in a mechanically stirred bath. A 76 mm. immersion thermometer calibrated against a Bureau of Standards thermometer was used. The melting points of the dilituarates were determined on the bloc-maquenne apparatus and are of little value due to excessive decomposition. [b] For data on the other four phases of sulfapyridine see ref. 8. [c] Sulfathiazole is dimorphic. See ref. 3. [d] Softens at 223. [e] Softens at 208°. [f] The yellow solid turns brick red at 80–90°. [g] Softens at 237. [h] Becomes opaque at 150°. Chars rapidly at 270°. [i] Melts with evolution of gas. [j] Decomposes rapidly at 255° but does not actually melt.

acetyl derivatives to the identification of these compounds in urine. Williams and Maresh[5] presented the optical properties for five phases of sulfanilamide, for sulfaguanidine, and for their acetyl derivatives. The optical properties of sulfadiazine have been reported by Wilkerson.[6] The refractive indices of sulfanilamide, sulfapyridine and sodium sulfapyridine have been reported by Keenan.[7] More recently the optical crystallographic properties of five phases of sulfapyridine have been reported by the authors.[8]

The present communication reports the optical crystallographic properties of the following sulfanilamide derivatives: sulfacetimide ($N^1$-acetylsulfanilamide), sulfadiazine (2-sulfanilamidopyrimidine), sulfaguanidine (sulfanilamidoguanidine), sulfamerazine (2-sulfanilamidothiazole) and sulfapyridine (2-sulfanilamidopyridine). In addition, the optical crystallographic properties of two series of Schiff bases and of a series of dilituric acid salts of the above amines are reported. The Schiff bases were prepared from the above amines with salicylaldehyde and 2-hydroxy-3-methoxybenzaldehyde.

The melting points, formulas, and analyses are recorded in Table I, and the optical crystallographic data are recorded in Table II.

## Experimental

**Material.**—The sulfapyridine and sulfathiazole were obtained from Merck and Company, the sulfamerazine from Sharp and Dohme, and the sulfanilamide from the Mallinckrodt Chemical Works. The sulfaguanidine was supplied by E. R. Squibb and Sons, the sulfadiazine by the Calco Chemical Division of the American Cyanamid Company, and the sulfacetimide from the Schering Corporation.[9] The salicylaldehyde was Eastman Kodak Co. no. 225 purified from the bisulfite addition compound. The 2-hydroxy-3-methoxybenzaldehyde available only as the practical product was purified by the bisulfite addition compound and thrice recrystallized from aqueous ethyl alcohol. The dilituric acid was prepared and purified by the method described in "Organic Syntheses."[10]

| Sulfathiazole, Phase II[j] | Lath shaped | | Monoclinic |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfacetimide | Deep red, acicular | Strong red-yellow Z>Y>X | Orthorhombic |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfadiazine | Brick red, tabular | Strong yellow-colorless Z>Y>X | Monoclinic |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfaguanidine | Orange, tabular | Z>Y>X | Monoclinic |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfamerazine | Brick red, columnar | Slight Z>Y>X | Triclinic (?) |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfapyridine | Brick red, tabular | Yes[1] | Monoclinic |
| $N^4$-(2-Hydroxy-3-methoxybenzylidene) sulfathiazole | Brick red, lamellar | Strong Z>Y>X | Orthorhombic |
| $N^4$-(2-Hydroxybenzylidene) sulfacetimide | Orange, acicular | Z>Y>X | Monoclinic |
| $N^4$-(2-Hydroxybenzylidene) sulfadiazine | Yellow, boat-shaped | Slight Z>Y>X | Monoclinic |
| $N^4$-(2-Hydroxybenzylidene) sulfaguanidine | Yellow, lamellar | None | Orthorhombic |
| $N^4$-(2-Hydroxybenzylidene) sulfamerazine | Yellow, tabular | Yellow, colorless Z>Y>X | Monoclinic |
| $N^4$-(2-Hydroxybenzylidene) sulfapyridine | Yellow, lamellar | None | Monoclinic |
| $N^4$-(2-Hydroxybenzylidene) sulfathiazole | Yellow, tabular | Z>Y>X | Monoclinic |
| Sulfanilamide dilituarate | Pinkish, tabular | None | Monoclinic |
| Sulfacetimide dilituarate | Lamellar | ... | (?) |
| Sulfadiazine dilituarate | Yellow, elongated | None | Monoclinic |
| Sulfaguanidine dilituarate | Buff, equant | None | Triclinic |
| Sulfamerazine dilituarate | Yellow, columnar | None | Orthorhombic |
| Sulfapyridine dilituarate | Yellow, lamellar | None | Monoclinic |
| Sulfathiazole dilituarate | Yellow, columnar | None | Monoclinic |

The sulfonamides were used without further purification for the preparation of derivatives. For determination of their optical properties sulfacetamide and sulfaguanidine were recrystallized from hot water. Sulfadiazine, sulfamerazine and sulfapyridine were recrystallized from 95% ethyl alcohol.

**Preparation of the Schiff Bases.**—The Schiff bases were prepared by adding the aldehyde (0.01 mole) to a hot, nearly saturated absolute alcohol solution of the sulfonamide (0.01 mole). The solutions were refluxed for varying periods of time up to three hours. In many instances crystals of the Schiff bases separated immediately. The Schiff bases from sulfacetimide, sulfaguanidine and sulfathiazole separated within five minutes. Sulfapyridine required refluxing up to one hour and sulfamerazine and sulfadiazine from one to three hours. In most instances crystals were filtered from the hot mother liquor and washed with several portions of cold alcohol. Yields were sacrificed, but by this procedure the Schiff bases were usually directly pure. When recrystallization was necessary, absolute ethyl alcohol was the solvent of choice. All Schiff bases were dried *in vacuo* at 100°.

**Preparation of the Dilituates.**—The dilituric acid (0.01 mole) dissolved in hot water or aqueous ethyl alcohol was poured into a hot solution of the sulfonamide (0.01 mole) dissolved in hot water, or hot aqueous alcohol depending upon the solubility of the particular sulfonamide. The mixture was refluxed a few minutes. The dilituates crystallize well on standing. Recrystallization was from hot water or hot aqueous ethyl alcohol. The dilituates were air-dried at room temperature.

### Optical and Crystallographic Properties

**Apparatus and Technique.**—A Leitz petrographic microscope Model No. 30 CM was used in the present investigation. The light source was a fluorescent lamp equipped with a 15-watt G. E. Mazda Fluorescent tube, 3500° white.

The principal refractive indices $\alpha$, $\beta$ and $\gamma$ at 25 ± 1°, were determined by the immersion method, using interference figures as a guide in selecting correctly oriented crystals. The immersion liquids used were those described by Winchell[11a] and Larsen and Berman.[11b] The optical axial angle $2V$ was calculated from the refractive indices $\alpha$, $\beta$ and $\gamma$, using the more exact formula suggested by Larsen and Berman.[12]

## Summary

1. The optical crystallographic properties of sulfacetimide, sulfaguanidine, sulfathiazole, Phase II, sulfadiazine, sulfamerazine and sulfapyridine have been determined. Certain corrections and additions have been made to existing optical crystallographic data.

2. Two series of Schiff bases of the above sulfanilamide derivatives have been prepared and their melting points, analyses and optical crystallographic properties have been determined.

3. A series of dilituric acid salts of the above sulfanilamide derivatives have been prepared and their melting points, analyses and optical crystallographic properties have been determined.

4. The optical crystallographic properties of the sulfonamides and their derivatives are useful in their identification.

[a] Calcd. from $\alpha$, $\beta$ and $\gamma$. [b] The values of the refractive indices are accurate to ±0.002 unless otherwise noted. [c] The crystals show only the pyramid faces. [d] The calculated value appears to be too high since the isogyres scarcely separate on rotation. [e] Wilkerson[6] has published the following data: $\alpha = 1.680$, $\beta = 1.695$, $\gamma = 1.788$, $2V = 45$–$46°$, $Z\wedge c = 20°$?. [f] Dispersion of the $\beta$ index of refraction. [g] Equant from hot water, skeleton crystals from butanol-1, and tabular from ethanol. [h] The interference figure shows characteristic purple color fringes. [i] For the details of the optical properties of sulfapyridine, Phase I–V see ref. 8. [j] Grove and Keenan[3] reported the following: $\alpha = 1.605$, $\beta = 1.733$, $\gamma > 1.733$, and parallel extinction. [k] Common orientation shows parallel extinction. [l] The absorption formula was not readily determinable. [m] The relationship of the ellipsoidal axes to the crystallographic axes was not readily determinable, thus a maximum extinction angle is reported. [n] $2V$ varies from 15 to 60° (estimated). The value for $\beta$ is constant regardless of $2V$. $\gamma$ varies greatly depending upon $2V$. The reason for this variation in optic axis is not understood. [o] Accuracy probably not greater than ±0.008.

# The Ultraviolet Absorption Spectra of Organic Sulfur Compounds. II. Compounds Containing the Sulfone Function[1]

BY EDWARD A. FEHNEL[2] AND MARVIN CARMACK

In a continuation of the work described in the preceding paper in this series,[3] we have determined the ultraviolet absorption spectra of a number of mono- and polysulfones, ketosulfones and carbalkoxysulfones in both neutral and alkaline solutions. As was anticipated on the basis of the limited spectroscopic data previously available for several simple aromatic sulfones,[4] no characteristic absorption bands attributable to the isolated sulfone function were observed in ethanol solutions in the near-ultraviolet region of the spectrum, and interaction between the sulfur-containing function and adjacent chromophores was found to be of a much lower order than in the corresponding sulfides. Strong conjugative effects were ap-

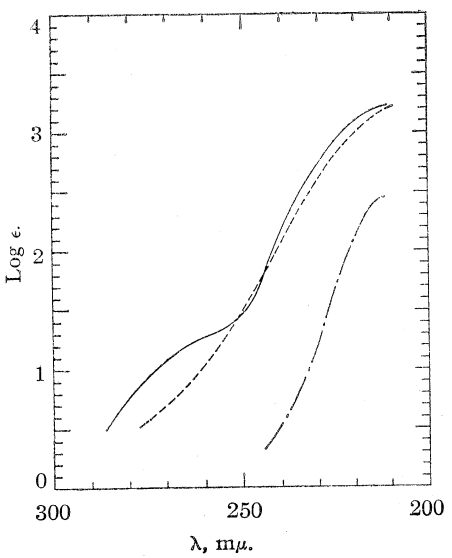
parent, however, in the spectra of the anions formed by the methylene disulfones, β-ketosulfones, and α-carbalkoxysulfones in alkaline solutions. These observations are of interest from the theoretical point of view because of their bearing on the question of the ability of the sulfonyl sulfur atom to accommodate more than eight electrons in its valence shell.

**Monosulfones.**—Solutions of the simple alkyl sulfones, such as ethyl sulfone, in ethanol and in ethanolic sodium ethoxide are completely transparent throughout the range of the Beckman quartz spectrophotometer (down to *ca.* 210 mμ). Ethanol solutions of the α,β-unsaturated sulfone, vinyl ethyl sulfone, however, begin to absorb strongly at about 240 mμ and appear to have a maximum in the neighborhood of 208–212 mμ[5] (Fig. 1). This represents a marked bathochromic displacement (*ca.* 15–20 mμ) of the absorption characteristic of the isolated vinyl group, as observed, for example, in the spectra of the simple alkenes, which exhibit maxima below 200 mμ.[6]



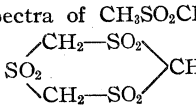


Fig. 1.—Absorption spectra of $CH_3SO_2CH_2SO_2CH_3$ in 0.01 *N* NaOEt, —;  in 0.01 *N* NaOEt, - - - -; $CH_2=CHSO_2C_2H_5$ in EtOH, –·–·–.

The aralkyl sulfones, benzyl ethyl sulfone (Fig. 2), benzyl sulfone (Fig. 3) and phenethyl sulfone (Fig. 3), give absorption curves which are essentially the same as those of the analogous benzenoid hydrocarbons.[7] When the sulfone function is attached directly to a benzene ring, as in phenyl sulfone (Fig. 3) and the phenyl alkyl sulfones (Fig. 2), bathochromic and hyperchromic displacements of the benzenoid absorption are observed which are very similar to the effects produced by the carboxyl group in benzoic acid. The absorp-

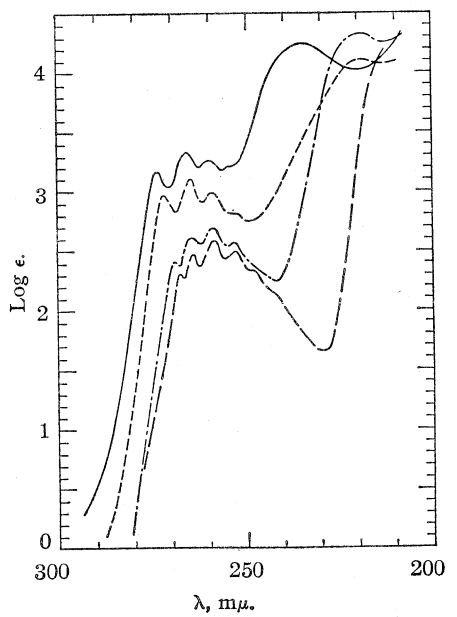

Fig. 3.—Absorption spectra of $(C_6H_5)_2SO_2$, —; $C_6H_5SO_2CH_2C_6H_5$, - - - -; $(C_6H_5CH_2)_2SO_2$, –·–·–; $(C_6H_5CH_2CH_2)_2SO_2$, — — —; (in EtOH).

(5) The uncertainties involved in making readings close to the lower limit of observation (below *ca.* 215 mμ with the ethanol used in the present work) do not permit an accurate description of this portion of the curve.

(6) Absorption spectra of most of the comparison compounds mentioned in this paper may be found in the "International Critical Tables," Vol. V, McGraw-Hill Book Co., New York, N. Y., 1929, p. 359 ff.

(7) Compare, for example, benzyl ethyl sulfone with the alkylbenzenes (*e. g.*, toluene) and the symmetrical aralkyl sulfones with the diphenylalkanes (*e. g.*, diphenylmethane).

tion spectra of these aromatic monosulfones remain unchanged in ethanolic sodium ethoxide.

**Polysulfones.**—Like the corresponding monosulfones, the simple aliphatic methylene disulfones, *e. g.*, bis-(methylsulfonyl)-methane, are transparent in ethanol solution throughout the range of the Beckman spectrophotometer, and aromatic methylene disulfones, *e. g.*, bis-(phenylsulfonyl)-methane (Fig. 4), exhibit spectra characteristic of the phenylsulfonyl portions of the molecule. On formation of the sulfone anions by solution of these compounds in ethanolic sodium ethoxide, the optical properties are greatly modified. Under these conditions bis-(methylsulfonyl)-methane and trimethylene trisulfone begin to absorb strongly in the near-ultraviolet region of the spectrum and appear to have an intense absorption band with a maximum somewhat below 210 mμ (Fig. 1).[8] In alkaline solutions of bis-(phenylsulfonyl)-methane the benzenoid fine structure is replaced by a single broad absorption band of much higher intensity (Fig. 4). When the central carbon atom of a methylene disulfone is completely alkylated so that no anion can be formed in alkaline solution, the spectra in neutral and alkaline media are identical (Table I).

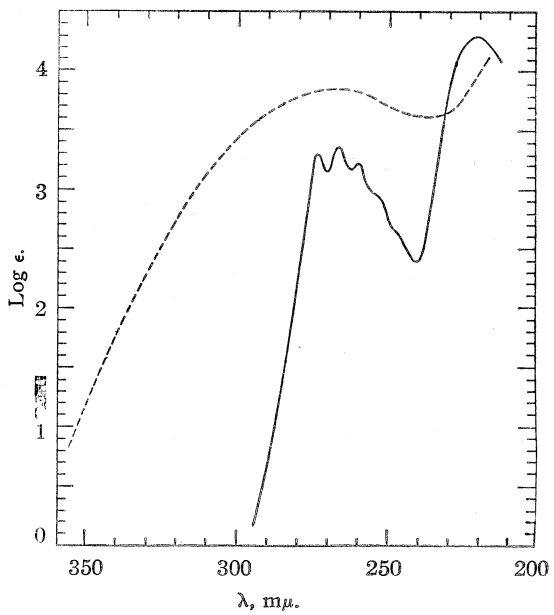

Fig. 4.—Absorption spectra of $C_6H_5SO_2CH_2SO_2C_6H_5$ in EtOH, —; in 0.01 *N* NaOEt, - - - -.

**Ketosulfones and Carbalkoxysulfones.**—As in the case of the methylene disulfones described above, the spectra of the β-ketosulfones, $RSO_2CH_2COR$, and α-carbalkoxysulfones, $RSO_2CH_2CO_2R$, are greatly modified in the presence of strong alkali. The effect is illustrated by the absorption curves for *n*-butylsulfonylacetone (Fig. 5), phenylsulfonylacetone (Fig. 6), and ethyl phenylsulfonylacetate (Fig. 7). In ethanol the spectra of these compounds are approximately summations of the spectra of the component chromophores, while in ethanolic sodium ethoxide marked changes in the form, intensity and location of the absorption bands are observed. The spectrum of α-phenylsulfonylisopropyl methyl

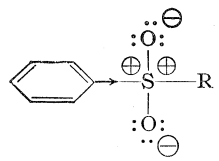
ketone (Table I), which is incapable of forming a stable anion in ethanolic alkali, shows no change in alkaline solution.

## Discussion



Although the question of the ability of the sulfur atom in the sulfone function to undergo an expansion of the valence shell has stimulated many interesting investigations, no general agreement seems to have been reached on the interpretation of the results.[9] A large body of chemical evidence[10] has accumulated which reveals an extensive similarity in the activating influence of the sulfonyl, carbonyl and nitro functions on adjacent methylene groups and olefinic bonds. These observations seem to favor the interpretation that the sulfonyl group, like the carbonyl and nitro groups, promotes an electromeric withdrawal of electrons from the adjacent carbon atoms. The application of such a resonance mechanism to the sulfones, however, requires that the sulfonyl sulfur atom be capable of accommodating, at least temporarily, more than eight electrons in its valence shell. Several investigators[11] have concluded on the basis of the chemical evidence that this is quite probably the case.

Others[9c,12] have preferred to attribute the activating influence of the sulfone function to the inductive effect produced by the net positive charge on the sulfur atom in the static system  ; the assumption of an expanded valence shell is rejected on the grounds that it violates the classical "octet rule" and that there is no evidence for sulfur–oxygen double bonds in the sulfone group. As G. N. Lewis has clearly pointed out, however, it is entirely possible that under certain conditions the sulfur atom (and other atoms beyond the first period of the periodic table) may exceed a covalence of four.[13] In support of this view, recent physical evidence based on X-ray[14] and electron-diffraction[15] studies, dipole moment measurements,[16] and thermochemical data[16] has indicated that the sulfur–oxygen link in sulfones possesses considerable double-bond character. In addition, evidence for the conjugative interaction of the sulfone function with an attached benzene ring has been obtained in studies of the dipole moments of aryl sulfones[17] and sulfonamides[18] and in a study of the ultraviolet absorption spectra of several benzenesulfonamides.[19]

An expansion of the sulfur valence shell also appears to provide the only satisfactory basis on which to account for the spectroscopic data obtained in the present investigation. Like the spectrum of the anilinium cation[20] (I), the spectrum of a phenyl alkyl sulfone would be expected to be very nearly identical with that of benzene, if the sulfonyl sulfur atom bears a fixed positive charge and exerts only a coulombic displacement effect on the electrons of the benzene ring (structure II).[19,21] The observed shift of the absorption

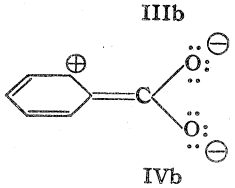
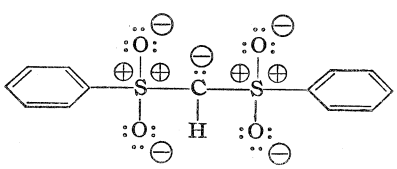
curves of the phenyl alkyl sulfones toward longer wave lengths and higher intensities, as compared with benzene, can be readily accounted for, however, if structures such as IIIa and IIIb may be considered to make significant contributions to the resonance in these molecules. The close resemblance between the spectra of the phenyl alkyl sulfones and the spectrum of the benzoate anion[19,22] is consistent with this interpretation, since the displacement of the benzenoid absorption by the substituent carboxylate function is attributed to resonance involving structures IVa and IVb.



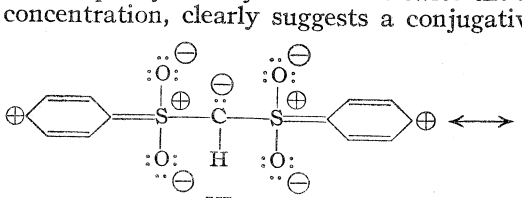
IIIa

IIIb



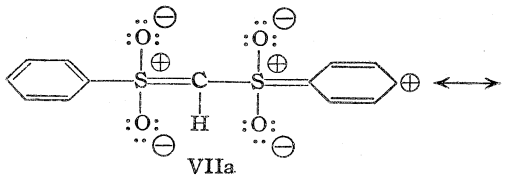
IVa

IVb



Similar considerations lead to the conclusion that the observed bathochromic displacement of the ethylenic absorption in vinyl ethyl sulfone must result from the conjugative interaction between the sulfone function and the attached vinyl group.

Resonance interactions between the sulfone functions in the methylene disulfone anions appear to provide the only satisfactory basis on which to account for the profound differences in the optical properties of neutral and alkaline solutions of these polysulfones. Thus, for example, a static charge distribution such as that represented in structure V should have little or no effect on the



V

absorption by the benzenoid portions of the carbanion derived from bis-(phenylsulfonyl-methane). The fact that the anion exhibits greatly increased absorption at longer wave lengths, while the spectrum of the undissociated molecule is essentially that of phenyl methyl sulfone at twice the molar concentration, clearly suggests a conjugative re-

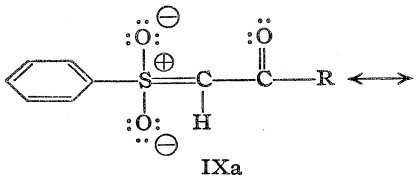
VIIa

VIIb

distribution of charge involving the unshared pair of electrons on the central carbon atom, as in structures VI, VIIa and VIIb. In the case of the bis-(alkylsulfonyl)-methane anions, similar considerations lead to structures VIIIa and VIIIb,

VIIIa VIIIb



which are identical with those previously proposed by Rothstein[11c] to account for the chemical properties of these compounds.

The application of these concepts to the interpretation of the spectra of the analogous keto- and carbalkoxysulfones might, of course, be questioned on the ground that enolization in the —CH—C=O system could, by itself, give rise to the observed effects.[23] It seems reasonable to assume, however, that if the sulfonyl sulfur atom is capable of expanding its valence shell in the bis-sulfonylmethane anions, it is capable of doing so in the anions of the $\beta$-ketosulfones and $\alpha$-carbalkoxysulfones. Our observations on the spectra of these compounds are consistent with this interpretation. It does not seem possible, for example, to account for the intense absorption of the anions of phenylsulfonylacetone or ethyl phenylsulfonylacetate in terms of isolated enolic and benzenoid chromophores. Displacement of the benzenoid absorption toward longer wave lengths and higher intensities and loss of fine structure are features which are characteristic of benzene derivatives having unsaturated substituents conjugated with the aromatic nucleus.[24] The striking similarity of the absorption spectra of the $\beta$-keto- and $\alpha$-carbalkoxysulfone anions and the spectra of benzalacetone ($\lambda_{max.}$ 286, 220.5 m$\mu$; log $\epsilon$ 4.37, 4.08, resp.[24a]) and cinnamic acid ($\lambda_{max.}$ 282, 222 m$\mu$; log $\epsilon$ 4.30, 4.16, resp.[24b]) clearly suggests a conjugative interaction, *through the sulfone function*, of

**Preparation of Compounds.**—Most of the previously known compounds were prepared by procedures described in the literature, and were purified by two or more recrystallizations[27] immediately before determination of the spectra. Source references are given in Table I.

**Vinyl ethyl sulfone**[28] was obtained by treating a solution of 52.8 g. (0.26 mole) of ethyl β-bromoethyl sulfone in 600 ml. of benzene with 55.5 g. (0.55 mole) of triethylamine and allowing the mixture to stand for thirty minutes. The precipitate of triethylamine hydrobromide was filtered off, the solvent and excess amine were removed on the steam-bath, and the residual oil was distilled under diminished pressure to yield 24.8 g. (79%) of almost colorless oil, b. p. 103–107° at 8 mm. Redistillation of this product offered a colorless oil, b. p. 105–106° at 8 mm.

*Anal.* Calcd. for $C_4H_8O_2S$: C, 39.94; H, 6.71. Found: C, 39.85; H, 6.63.

***n*-Butylsulfonylacetone** was prepared by refluxing a mixture of 13.9 g. (0.15 mole) of chloroacetone, 21.6 g. (0.15 mole) of sodium butanesulfinate, and 100 ml. of ethanol for one hour. At the end of this time, most of the solvent was removed by distillation and the residue was diluted with several times its volume of water. The layers were separated and the aqueous layer was extracted several times with ether. The combined oil layer and ether extracts were dried over anhydrous magnesium sulfate and distilled under diminished pressure to yield 16.5 g. (62%) of a yellow oil, b. p. 147–150° at 7 mm. Redistillation of this material gave the pure product as a viscous, colorless oil, b. p. 136–137° at 4 mm.

*Anal.* Calcd. for $C_7H_{14}O_3S$: C, 47.18; H, 7.92. Found: C, 47.32; H, 7.73.

**α-Phenylsulfonylisopropyl methyl ketone** was prepared in a similar manner by treating 16.5 g. (0.10 mole) of α-bromoisopropyl methyl ketone with 20.0 g. (0.10 mole) of sodium benzenesulfinate dihydrate in refluxing ethanol. The oily product slowly crystallized on standing; yield, 10.8 g. (48%) of colorless crystals, m. p. (cor.) 42–46°. Recrystallization from aqueous ethanol afforded colorless leaflets melting at 47–48° (cor.).

*Anal.* Calcd. for $C_{11}H_{14}O_3S$: C, 58.38; H, 6.24. Found: C, 58.24, 58.47; H, 6.13, 6.10.

## Summary

The ultraviolet absorption spectra of a number of mono- and polysulfones, ketosulfones and carbalkoxysulfones have been determined in both neutral and alkaline solutions. The preparation of vinyl ethyl sulfone and two new ketosulfones is described.

No characteristic absorption bands attributable to the isolated sulfone function are observed in ethanol solutions in the near-ultraviolet region of the spectrum, although the attachment of a sulfonyl group to benzene shifts and intensifies the benzenoid peaks in a manner similar to the carboxyl group in benzoic acid. Strong conjugative effects are observed in the anions formed by the methylene disulfones, β-ketosulfones and α-carbalkoxysulfones in alkaline solutions. When the central carbon atom in the latter compounds is completely alkylated so that no anion can be formed, the spectra in neutral and alkaline solutions are identical.

These effects are interpreted as evidence for the conjugative interaction of the sulfone function with attached aromatic nuclei in aryl sulfones and with the unshared pair of electrons on the central carbon atom in sulfone anions. Resonance forms involving pentacovalent sulfur are discussed.

# Absorption Spectra of Heterocyclic Compounds. V. Some Substituted 4-Quinolones[1]

BY EDGAR A. STECK, GALEN W. EWING[1a] AND FREDERICK C. NACHOD

## Introduction

A discussion of the influence of the position of hydroxyl groups upon the absorption spectra of quinolinols and isoquinolinols has been presented in the first paper of this series.[2] The behavior of the 4-substituted compound, which was indicated to have the quinoline structure, was sufficiently interesting to warrant an extension of the study. A considerable number of 4-quinolone derivatives were available from other work in these Laboratories.[3-5] All compounds were prepared through use of the synthetic method of Conrad and Limpach,[6] with some recent improvements.[7]

## Discussion

A bifurcation in the 320–360 mμ region of the spectra of 4-quinolone and its 2- and 3-methyl homologs was observed when the studies were made in alcoholic solution.[2] This unique character of the 4-quinolones was much less noticeable or absent in the absorption spectra in acidic or basic media. It was of interest to examine the influence of substituents upon the pattern of 4-quinolone spectra. The 3-substituted types were employed not solely because of ready accessibility, but also because certain features in the molecule result in an amplification of fine structure in the spectra.

A comparison of the patterns exhibited by 4-quinolone and the 3-methyl derivative in alcoholic solution[2] shows a definite batho- and hypochromic shifting which is greater than when the alkyl group is in position 2. The bifurcation in the 320–360 mμ region is affected to a varying extent by the steric and electron-repelling effects of the alkyl rest. In the case of the parent compound and the 3-substituted one in alcohol, the second peak of the twin maxima is the greater, while the 2-methyl-4-quinolone spectrum shows a higher maximum around 320 mμ. While 4-quinolone shows a bifurcation in alcohol and *p*H 7 buffer, the spectra in acid and base fail to present this feature. This twinning is absent only with the spectrum in acid for 2-methyl-4-quinolone; however, the related 3-methyl compound exhibits it in alcohol, acid and base. The principal underlying causes of these effects, and also the shoulder around 280–300 mμ presumably resides in the influence of the substituents upon the tautomerism of the quinolinol–quinolone type. It should not be forgotten that the 2-methyl group may also complicate the pattern due to its lability and concomitant effects (Fig. 1). These are also to be observed in chemical behavior of the several types.

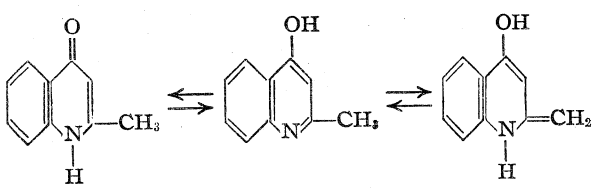

Fig. 1.

The introduction of substituents into the benzene moiety of quinolinone types and the concomitant alterations in spectral characteristics is closely akin in form to our earlier studies on aminoquinolines[8] and certain 4-aminoquinoline derivatives.[9] The comparison of the spectra of the 4-quinolone types was carried out using alcoholic solutions because the greatest amount of structural resolution was found in that solvent. The characteristic bifurcations in the short wave range (below 260 mμ) are approximately the same for the bz-methyl- and bz-chloro-3-methyl-4-quinolones (Figs. 2 and 3). The chloro-3-methyl types show a constant bathochromic shift of 6 mμ when compared with the corresponding dimethyl compounds. It should be noted that the resolution of spectral characteristics is more pronounced with the more electrophilic chloro group. This is not only true for the doublet peaks in the 320–360 mμ region, but also for the inflection which occurred around 280–300 mμ in the case of the parent 4-quinolone. While the inflection does become a true secondary maximum with the introduction of a 3-methyl group, substitution of the benzenoid ring results in marked alterations in form. The positions being considered *in toto*, we notice that the most profound change occurs when the methyl or the chloro group is introduced into position 7. The character of the alkyl substituent would be expected to result in less influence upon the tautomerism than the more electron-attracting halogen. This is indeed the case, as has been shown in Figs. 2 and 3. In all instances, the resolution of the dimethyl compounds is less marked than of the 3-methyl-bz-chloro compounds. There is not only a greater

retention of the secondary maximum in the 280–300 mμ region throughout, but also the 7-chloro-3-methyl-4-quinolone exhibits an additional feature of structure in the twinning of the peak in the 240–260 mμ region. The importance of the position of a nucleophilic grouping is apparently less marked than an electrophilic rest. The substituent in the benzene ring influences the state in a molecule through resonance effects, and also the dipoles which are associated with its location (Fig. 4). It is in position 7 of the 4-quinolones that the grouping might well prove to be of greater importance than in positions 5, 6 or 8. An analogous effect has been indicated for derivatives of 4-aminoquinoline.[9,10] The combination of these influences appear to be responsible factors in the poorly developed character in the 3,8-dimethyl-4-quinolone spectrum.

The extent of the influence of a halo substituent is brought into focus when a comparison is made of the spectra of 3-methyl, 3,5-dimethyl, and 3,5-dichloro-4-quinolones, all in alcoholic solution (Fig. 5). While the additional alkyl group in position 5 does cause a slight batho- and hyperchromic shifting, the 3,5-dimethyl compound shows a decrease in the second peak of the bifurcation in the 320–360 mμ region. This may well be due to steric effects. The 3,5-dichloro-4-quinolone exhibits the expected characteristics

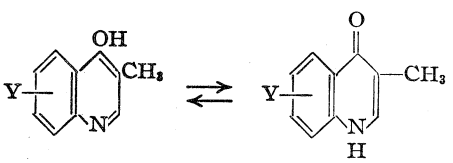

Fig. 4.

resulting from the electrophilic halogen substituents. The entire spectrum is bathochromically shifted, and, for the most part, also a displacement is noted. Of particular interest is the batho- and hyperchromic shifting of the secondary maxima in the 290 mμ region with increase in nucleophilic substitution.

In Fig. 6, the spectra of five bz-alkoxy-3-methyl-4-quinolones are compared. The differences in effect of the methoxy and ethoxy groupings are but slight, as is to be seen in the figure. The 7-ethoxy-3-methyl-4-quinolone is unique in the lack of a secondary maximum in the 260–320 mμ region. Actually there are two secondary maxima in the case of both the 6-methoxy and 6-ethoxy compounds, whereas the 8-methoxy shows an inflection and the 8-ethoxy-

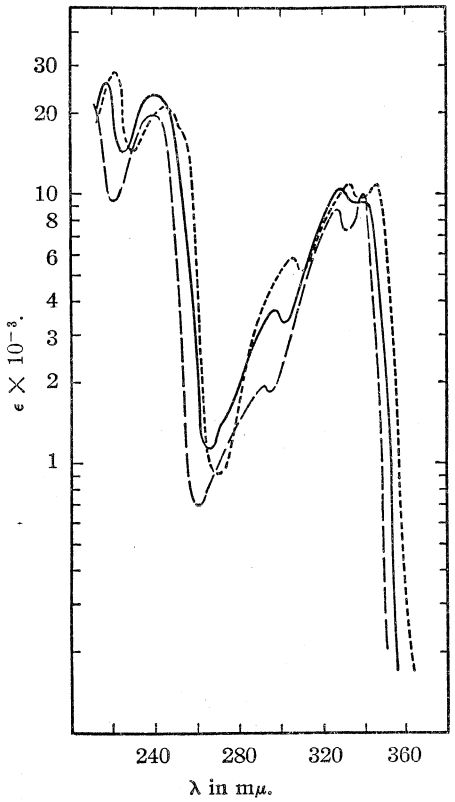

Fig. 5.—Absorption spectra of: — —, 3-methyl-4-quinolone; —, 3,5-dimethyl-4-quinolone; . . . . ., 3,5-dichloro-4-quinolone; in 95% ethanol.

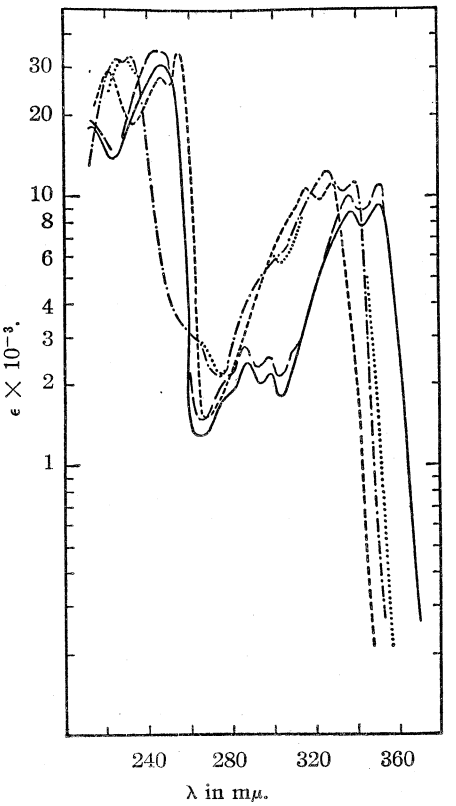

Fig. 6.—Absorption spectra of: —, 6-methoxy-3-methyl-4-quinolone; — —, 6-ethoxy-3-methyl-4-quinolone; – – –, 7-ethoxy-3-methyl-4-quinolone; —·—, 8-methoxy-3-methyl-4-quinolone; . . . . ., 8-ethoxy-3-methyl-4-quinolone; in 95% ethanol.

3-methyl-4-quinolone a slight singular inflection apart from the related methoxy analog. All of the alkoxy compounds show the characteristic bifurcations in the 300–360 mμ region. The 6- and 8-alkoxy-substituted 3-methyl-quinolones are bathochromically shifted with respect to the 7-ethoxy derivative. While there is little difference in the patterns presented by the methoxy and ethoxy compounds when the substituent is in position 8, the influence of the additional methylene group in the alkoxy substituent is made apparent when that rest is in position 6. The passage from 6-methoxy-3-methyl-4-quinolone to the 6-ethoxy analog results in a definite hyperchromic intensification of all maxima.

The evidence presented concerning the spectra of the disubstituted 4-quinolones indicates that the 7-position of the molecule is exceptional in its influences. This is in agreement with our earlier observations.[9]

## Experimental

**I. 4-Quinolones.**—The preparation of the requisite compounds has been described in detail in contributions relating to 4-substituted quinoline types.[3–5]

**II. Absorption Spectra.**—All spectra were determined with a Beckman Quartz Spectrophotometer, Model DU, Serial No. D-377. The method has been indicated in the first paper of this series.[2]

**Acknowledgments.**—The authors wish to express their appreciation to Mrs. E. R. Falkner and Mrs. M. Becker for technical assistance, and to Mrs. B. Beecher for her aid in tracing the curves required.

## Summary

The absorption spectra of fourteen disubstituted 4-quinolones have been determined and the effects of substitution discussed critically.

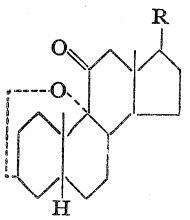
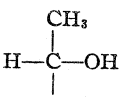
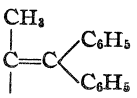
# Studies in Steroid Metabolism. VI. The Characterization of 11- and 12-Oxygenated Steroids by Infrared Spectrometry

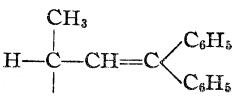
BY R. NORMAN JONES, P. HUMPHRIES AND KONRAD DOBRINER

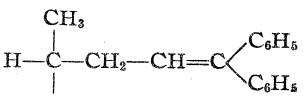


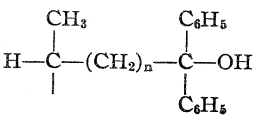
The use of infrared spectrometry for the detection and identification of steroid metabolites in human urine has been reported in a previous publication in this series.[2] It has also been demonstrated that the presence of certain functional groups in the steroid molecule can be recognized by infrared spectrometry,[3] and a distinction between ketosteroids in which the carbonyl group is at the 3, 17 or 20 positions can be made from a determination of the location of the carbon–oxygen stretching vibration in the region between 1660 and 1780 cm.$^{-1}$.

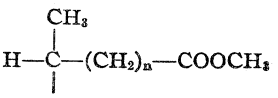




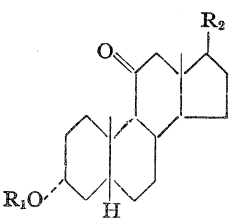




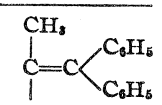


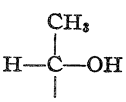


It seemed reasonable to anticipate that a carbonyl group at positions 11 and 12 might also absorb at characteristic frequencies and a systematic investigation of the infrared spectra of a number of steroids containing ketonic and hydroxyl groups at these positions has been carried out.



The recognition of steroids oxygenated at position 11 is of special importance in connection with steroid metabolism, since carbonyl or hydroxyl groups at this position are indicative of steroids originating in the cortex of the adrenal gland. Among the twenty-eight steroids isolated from the adrenal gland[4] fifteen contain a ketone or hydroxyl group at this position.





It has already been demonstrated[5,6] that metabolites of 11-oxygenated adrenocortical hormones are present in human urine. Androstanediol-3$\alpha$,-11$\beta$-one-17, etiocholanol-3$\alpha$-dione-11,17, and androstanol-3$\alpha$-dione-11,17 occur in the urine of both normal and diseased persons,[5,6,7] while etiocholanediol-3$\alpha$,11$\beta$-one-17, its transformation product $\Delta^{9,11}$-etiocholenol-3$\alpha$-one-17 and pregnanol-3$\alpha$-dione-11, 20 have been observed frequently in the urine of diseased persons and rarely in the urine of healthy individuals.[6]

In addition to these completely characterized compounds, a variety of additional steroids containing a hydroxyl or a carbonyl group at position 11 may be found in human urine, and some of

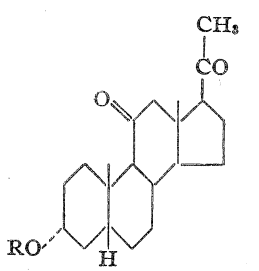
these may be included among compounds which have already been isolated, but which have not, as yet, been fully characterized.[8]

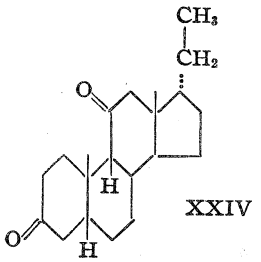
**11-Ketosteroids.**—The recognition of an absorption band associated with the 11-ketone group could be achieved unequivocally from measurements on 11-monocarbonyl compounds in which there could be no interference from carbonyl groups located elsewhere in the molecule. Unfortunately, the number of such compounds is limited, but through the kind coöperation of Dr. R. Turner and Dr. L. H. Sarett we have obtained

(8) Lieberman, Dobriner, Hill, Fieser and Rhoads, *J. Biol. Chem.*, **172**, 263 (1948).



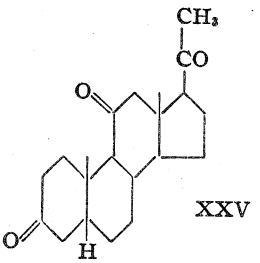
nine 11-ketosteroids which satisfy this criterion.

The infrared absorption spectra of carbon disulfide solutions of eight of these substances (I–VI, X–XI) exhibit one maximum only in the carbonyl region at 1710–1713 cm.$^{-1}$. The ninth compound (XII) gave a maximum at 1716 cm.$^{-1}$ in solution in tetrachlorethane (Table IA). Similar data are also listed in Table IB for twelve 11-ketosteroid esters (VII–IX, XIII–XXI), all of which possess two maxima in the carbonyl region at 1710–1713 and 1739–1742 cm.$^{-1}$, respectively.



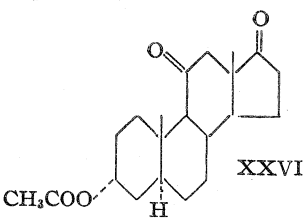
It has been shown previously[3] that both the 3- and 17-acyl esters of steroid alcohols as well as the methyl esters of cholanic acid derivatives possess a maximum at 1739–1742 cm.$^{-1}$. Consequently in these compounds it may be inferred that the absorption band at 1710–1713 cm.$^{-1}$ is associated with the carbonyl group at position 11, and that no interactions occur between the vibrations associated with the ketone group at this position and ester groups at positions 3, 17 or on the side chain.

**11,20-Diketones.**—In the non-conjugated 20-ketosteroids the carbonyl absorption maximum is at 1706–1710 cm.$^{-1}$ and because of the proximity of the 11-ketone and 20-ketone band maxima a simple spectrometric differentiation of these two important structures is uncertain (*vide* p. 246). Two compounds containing 11,20-diketone grouping have been examined. In XXII only a single band at 1713 cm.$^{-1}$ occurs, while XXIII has two bands at 1710 and 1739 cm.$^{-1}$, the latter due to the ester group at position 3.

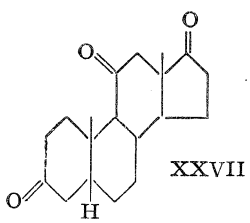


XXII (R = —H)
XXIII (R = —CO—CH3)

**3,11-Diketones.**—A similar situation arises in the identification of 11-ketosteroids which contain a second (unconjugated) ketone group at position 3, as the non-conjugated 3-ketone group absorbs at 1715–1719 cm.$^{-1}$ which is also very close to the frequency of the 11-ketone band. The only compound of this kind so far examined is uranedione-3,11 (XXIV) which gives a single maximum at 1713 cm.$^{-1}$. Measurements on compounds XXV and XXVII support the evidence from XXIV in indicating that no anomalous displacements of the band positions are associated with the 3,11-diketone structure.

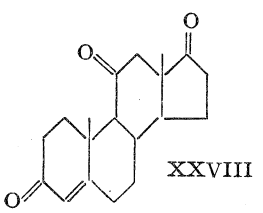


XXIV



XXV

In 11-ketosteroids containing a conjugated ketone group at position 3, the band at 1674–1677 cm.$^{-1}$ characteristic of this conjugated group occurs at the expected position.



**11,17-Diketones.**—In 17-ketosteroids in which ring D is saturated, an absorption maximum occurs at 1742–1745 cm.$^{-1}$, but in 11,17-diketones this band is displaced to 1748–1754; the band normal to the 11-ketone at 1710–1716 cm.$^{-1}$ is present also.[9]

XXVI

XXVII

XXVIII

**Interaction Effects.**—These measurements indicate that interaction occurs between carbonyl groups at positions 11 and 17 which displace the bands from their normal positions. A similar interaction effect has been noted previously between a ketone group at position 20 and an acetoxy group at position 21 in the acetylated derivatives of steroids containing the ketol side chain.[3] Compounds XXIX–XXXI contain both the 11-ketone and the 20-keto-21-acetoxy groupings and are of particular interest as they are derivatives of adrenocortical steroid hormones. The bands at 1732 and at 1756–1758 cm.$^{-1}$,

(9) In compound XXVI which contains an acetate group at position 3 in addition to the 11,17-diketone group, the band maxima are at 1745 and 1713 cm.$^{-1}$. It is presumed that the former band is an unresolved doublet, due to the acetate band at 1739–1742 and a band at 1748–1754 cm.$^{-1}$. In the corresponding compound in the etiocholane stereochemical series this band is resolved (see Table ID).

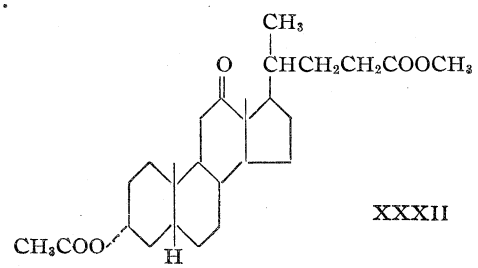
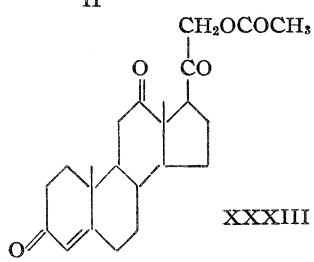
characteristic of the 20-keto-21-acetoxy group in addition to the 11-ketosteroid maximum at 1710–1713 cm.$^{-1}$ occur in all three compounds.[10]

XXIX

XXX

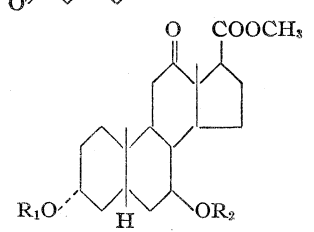


XXXI



It may be concluded that a band at 1754–1760 cm.$^{-1}$ is suggestive of the presence of either the 11,17-diketone or the 20-keto-21-acetoxy grouping. The former structure also produces a second maximum at 1710–1716 cm.$^{-1}$ whereas in the latter case the second band is near 1730 cm.$^{-1}$. The distinction between these two groupings can be confirmed from measurements in the 1200–1250 cm.$^{-1}$ region since a strong band characteristic of the acetoxy group and lacking in the carbonyl group occurs near 1230 cm.$^{-1}$.

(10) In XXX the non-conjugated 3-ketone group no doubt contributes also to the maximum at 1713 cm.$^{-1}$.



**12-Ketosteroids.**—Eleven compounds containing a carbonyl group at position 12 have been examined (see Table II). In pregnanone-12 and XXXII the band at 1710 cm.$^{-1}$ can be assigned to the unconjugated 12-ketone grouping. The spectrum of XXXIII, which contains the acetylated ketol side chain and the conjugated ketone group at position 3 exhibits the maxima characteristic of all four carbonyl groups (*cf.* Fig. 1). In compounds XXXIV–XXXVI which contain the 12-keto-17-carbomethoxy grouping, the 12-ketone band is displaced to 1723 cm.$^{-1}$ (*vide p.* 246).

XXXII

XXXIII

XXXIV ($R_1 = R_2 = H$)
XXXV ($R_1 = R_2 = —CO—CH_3$)
XXXVI ($R_1 = —CO—CH_2—CH_2—COOH$; $R_2 = —CO—CH_3$)

In the Δ$^9$–12 ketones the maximum is at 1680–1684 cm.$^{-1}$. This is significantly higher than the

frequency observed for $\Delta^4$-3-ketosteroids (1674–1677 cm.$^{-1}$) and for $\Delta^{16}$-20-ketosteroids (1666–1669 cm.$^{-1}$). The two 11,12-diketones listed in Table II possess a maximum at 1726 cm.$^{-1}$. The displacement of this band from 1706–1716 to 1726 cm.$^{-1}$ is indicative of interaction in the $\alpha$-diketone structure.

**Other Ketosteroids.**—As these investigations were initiated with the primary object of improving techniques for the identification of steroid hormones and hormone metabolites, attention has been chiefly directed to steroids containing functional groups at the positions which are of major importance in relation to the hormonal activity. Up to the present time only a few steroids containing carbonyl groups at other positions have been examined; the results, summarized in Table III, suggest that the non-conjugated 7-ketone group absorbs near 1719 cm.$^{-1}$, the non-conjugated 16-ketone near 1754 cm.$^{-1}$, the 3,6-diketosteroid group at 1723 cm.$^{-1}$ and the $\Delta^{3,5}$-diene-one-7 group at 1663 cm.$^{-1}$. One monoketosteroid of uncertain structure kindly supplied by Dr. Heard[11] and believed to contain a ketone group at position 15 had an absorption maximum at 1751 cm.$^{-1}$. The location of this band is in general agreement with the observation that a carbonyl group in a cyclopentanone ring system absorbs at a high frequency, and would seem to be consistent with the postulated structure of this compound.

**11-Hydroxy Compounds.**—The position of the hydrogen–oxygen stretching vibration of the hydroxyl group in a steroid molecule cannot be related to the position of substitution in the molecule in a manner similar to that for the carbon–oxygen bond of the carbonyl group.[3] Nevertheless, the presence of an absorption band near 3600 cm.$^{-1}$ in the spectrum of a solution of a steroid is associated with the presence of a hydroxyl group in the molecule.

TABLE III

CARBON–OXYGEN STRETCHING VIBRATION OF KETOSTEROIDS WITH CARBONYL GROUPS AT POSITIONS OTHER THAN 3, 11, 12, 17 AND 20

| Compound | Position of max. (cm.$^{-1}$) solvent $CS_2$ | Sources[a] |
|---|---|---|
| Sitostanedione-3,6 | 1723 | 5 |
| $\Delta^{22}$-Sitostenedione-3,6 | 1723 | 5 |

[a] See footnote to Table I.

(11) Heard and McKay, *J. Biol. Chem.*, **131**, 371 (1939); **165**, 677 (1946).

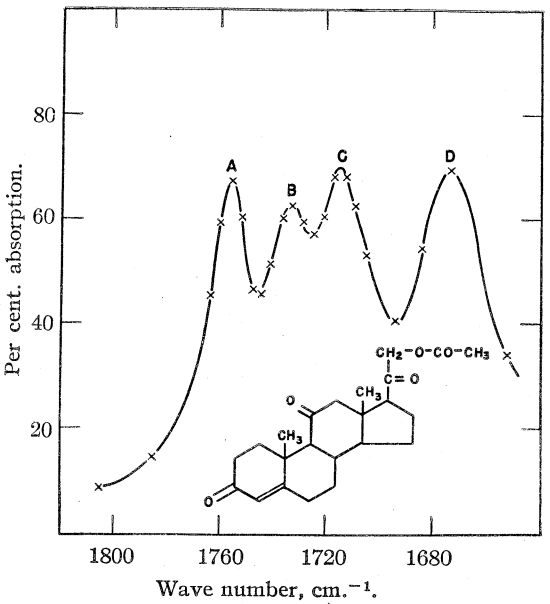

Fig. 1.—Infrared absorption spectrum of 11-dehydrocorticosterone acetate between 1640 and 1800 cm.$^{-1}$. Maxima A and B are associated with the acetylated ketol side chain, maximum C with the ketone group at position 11, and maximum D with the $\alpha\beta$-unsaturated ketone group at position 3 (solvent carbon disulfide).

No simple 11-monohydroxy steroids have been available for measurement, but several dihydroxy steroids in which one of the hydroxyl groups is at position 11 have been examined. In these spectra the normal hydroxyl absorption band near 3600 cm.$^{-1}$ is observed and no behavior specifically relatable to the 11 position is to be noted. In a compound such as androstanediol-3$\alpha$,11$\beta$-one-17-acetate-3, where the hydroxyl group at position 3 is esterified, the absorption band at 3616 cm.$^{-1}$ can be attributed to the 11-hydroxyl group.

## Discussion

The relationships which have been observed between the frequencies of the carbonyl band maxima, and the structure for all types of steroids are summarized in Table IV. In evaluating these data, it must be noted that they apply to solutions in carbon disulfide only. The significance which is to be attached to them is dependent on the number of compounds of each type examined, and this is indicated in the third column of the table.

The recognition of the 11-ketone group in a steroid by infrared spectrometry is only partially successful. Such identification is possible provided certain other ketone groupings are known to be absent, but non-conjugated ketone groups at other positions on the hexacyclic rings or in the side chain may absorb quite close to the same frequency. This is certainly true of 3-ketones and 20-ketones, and probably also of ketone groups at positions 6, 7 and 12. With the spec-

TABLE IV

SUMMARY OF POSITIONS OF CARBONYL BAND MAXIMA

[a] These structures give rise to two maxima both of which are listed in the table. [b] Second maximum at 1739 cm.$^{-1}$.

trometers at present available and using a sodium chloride prism, an accuracy of ± 3 cm.$^{-1}$ in the determination of the maximum is about the best which can be achieved. If this could be increased to better than ± 1 cm.$^{-1}$ a distinction between 3-, 11- and 20-ketones could be made more certainly. In the case of 3-, 11- and 11,20-diketones an increase in the resolving power of the spectrometer might separate the bands. A careful analysis of the widths and absolute intensities of the absorption bands may also yield further information; such measurements are being made, and will be reported in a subsequent communication.

Certain dicarbonyl groupings, notably the 11,17-diketones and 11,12-diketones, appear to exhibit characteristic absorption. The band at 1726 cm.$^{-1}$ associated with the 11,12-diketone may be common to other $\alpha$-diketosteroids, none of which has yet been studied. The absorption specific to the 20-keto-21-acetoxy group is significant in connection with the identification of adrenocortical hormones and their metabolites, as also is the observation that the introduction of the 11-ketone group does not disturb the position of these bands. An example is provided by the spectrum of dehydrocorticosterone acetate (XXXI) in which all of the four carbonyl maxima can be related to distinct carbonyl groups as indicated in Fig. 1.

The interaction effects which occur when two or more carbonyl groups are present are of theoretical interest. Such effects have only been encountered when the two carbonyl groups are in the 1:2, 1:3 or 1:4 positions relative to one another. In the 12-keto-17-carbomethoxy compounds (XXXIV–XXXVI), where the carbonyl groups are 1:4, the 12-ketone maximum is displaced from 1706–1710 cm.$^{-1}$ to 1723 cm.$^{-1}$, but in XIV, which contains the 11-keto-17-carbomethoxy 1:5-grouping, there is a maximum at 1713 cm.$^{-1}$ the location normal to the 11-ketone. In a similar manner, the 1:4 diketone group of 11,17-diketones exhibits an interaction effect while the 1:5-diketone group of 11,20-diketones does not.

The most effective application of infrared spectrometry to the characterization of 11-oxygenated ketosteroids will result from a combination with chemical methods. Advantage might be taken of the inertness of the 11-ketone group to reaction with the common carbonyl reagents, whereby the carbonyl absorption bands of the more reactive 3, 12, 17 and 20 ketone groups could be removed, and the 11-ketone band observed in the spectrum of the derivative. The inertness of the 11-ketone group to reaction with the Girard reagent has already been utilized in this manner. The appearance of an intense band near 1713 cm.$^{-1}$ in the spectrum of a "non-ketonic" urinary steroid fraction led to the isolation and identification of pregnanediol-3$\alpha$,20-*epi*[b]-one-11.[12]

A similar method might be applied to characterize the unreactive 11$\beta$-hydroxyl group, which fails to acetylate under conditions which bring about acetylation of hydroxyl groups at 3, 12, 20, 21, and also at 17 in the androstane and etiocholane series. In the pregnane and allopregnane series the tertiary 17-hydroxyl group is also resistive to acetylation but can be made to react under mildly forcing conditions which still leave the 11$\beta$-hydroxyl group unattacked.[13]

The characterization of the readily acetylated 11$\alpha$-hydroxyl group will be more difficult, but this is of less consequence since it appears that in the naturally occurring steroid hormones and hormone metabolites the 11-hydroxyl group commonly occurs in the $\beta$ configuration.

## Experimental

The spectra were determined in carbon disulfide solution using a Perkin–Elmer model 12a spectrometer with sodium chloride prism and recording galvanometer. Full details of the

experimental techniques have been given in earlier publications.[2,3]

**Acknowledgments.**—The authors wish to acknowledge their indebtedness to the several investigators, listed individually in a footnote to Table I, whose collaboration in supplying many of the compounds made these studies possible. The technical assistance of Miss E. Packard of the Sloan–Kettering Institute is also gratefully acknowledged.

This investigation was aided by grants from the American Cancer Society (on recommendation of the Committee of Growth of the National Research Council), Ayerst, McKenna and Harrison, Ltd., the Jane Coffin Childs Memorial Fund for Medical Research, the Commonwealth Fund, the Anna Fuller Fund, the Lillia Babbitt Hyde Foundation, International Cellucotton Products Company, the Albert and Mary Lasker Foundation, the Adele R. Levy Fund, the National Cancer Institute of the National Institute of Health, U. S. Public Health Service, the New York Foundation and the Sidney Rheinstein Fund.

## Summary

A comparative study has been made of the infrared absorption spectra between 1660 and 1780 cm.$^{-1}$ of ketosteroids containing a carbonyl group at positions 11 and 12.

A non-conjugated ketone group at position 11 gives rise to a maximum at 1710–1713 cm.$^{-1}$ in carbon disulfide solution. In 3,11- and 11,20-diketosteroids the maxima associated with the two carbonyl groups are too close to be separated, but there is no evidence of interaction effects causing displacements of the bands. In the 11,17-diketosteroids the band attributed to the 11-ketone group occurs at the normal position (1710–1713 cm.$^{-1}$) but the band attributed to the 17-ketone group is displaced from 1742–1745 to 1748–1754 cm.$^{-1}$.

Similar data are given also for 12-ketosteroids and the significance of these observations in the elucidation of steroid structure is discussed.

# The Dehydration of 22-Phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene

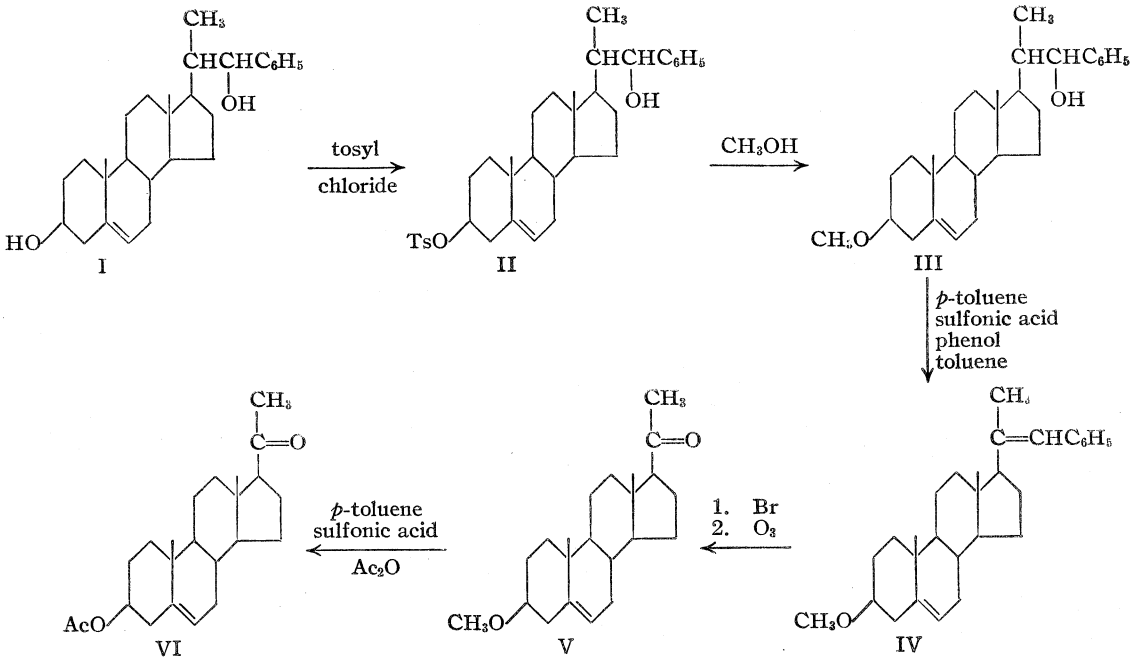
BY F. W. HEYL, M. E. HERR AND A. P. CENTOLELLA

The reaction of 3-acetoxy-bisnor-5-cholenaldehyde with phenylmagnesium bromide, yielding 22-phenyl-3,22-dihydroxy-bisnor-5-cholene (I) as well as the preparation of several analogous 22-phenyl-3-alkoxy-22-hydroxy-bisnor-5-cholenes from stigmasteryl ethers have been reported.[1,2] The problem of introducing a double bond into the C-20,22 position of the side chain involves the difficulties usually encountered in the dehydration of a secondary alcohol.

For the purpose of studying this dehydration reaction, it was decided to use 22-phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene (III) which was prepared from stigmasteryl methyl ether as previously reported,[2] and also by refluxing the monotosylate (II) prepared from 22-phenyl-3,22-dihydroxy-bisnor-5-cholene (I), with methanol, whereby the same methoxy compound (III) is obtained and the position of this tosyl group is established.

The dehydration of this 3-methoxy-22-ol (III) was accomplished by using a variation of the method of Wuyts[3] in which the alcohol was refluxed in toluene in the presence of a catalytic amount of *p*-toluenesulfonic acid and a trace of phenol. The desired 22-phenyl-3-methoxy-bisnor-5,20-choladiene (IV) was obtained in good yields.

The 5,6 dibromo compound of the diene (IV) was ozonized directly to pregnene-3$\beta$-ol-20-one methyl ether (V) which was isolated as the semicarbazone in 62% yields. Acid hydrolysis of the semicarbazone resulted in a 92% yield of pregnenolone methyl ether (V). This compound was converted to pregnene-3$\beta$-ol-20-one acetate (VI), the immediate precursor of progesterone, according to the recently described method of Huffman and Lott.[4]



## Experimental[5]

**22-Phenyl-3,22-dihydroxy-bisnor-5-cholene-3-tosylate (II).** —To 3.14 g. of diol (I) dissolved in 25 ml. of dry pyridine was added 2.2 g. (1$^1/_2$ moles) of *p*-toluene-sulfonyl chloride. After standing twenty-four hours at 37° it was poured into ice and sodium bicarbonate (1 g.) and the tosyl ester extracted with benzene. The solution was dried over sodium sulfate and upon removing the benzene and remaining pyridine *in vacuo* there was obtained a quantitative yield of crystalline residue. Recrystallization from benzene–hexane gave 2.85 g. of silky needles, m. p. 157–159° (dec.). Working up the mother liquor gave a second crop of slightly lower melting tosyl ester.

*Anal.* Calcd. for $C_{35}H_{46}O_4S$: C, 74.69; H, 8.24; S, 5.7. Found: C, 74.82; H, 7.98; S, 5.7. $[\alpha]^{25}D$ −38.9 (79.1 mg. made up to 10 ml. in chloroform, $\alpha^{25}D$ −0.308, *l*, 1 dm.).

When the above esterification was carried out at room temperature most of the diol was recovered. When the

reaction was allowed to proceed twenty-four hours at 55–58° little of the desired tosyl ester could be obtained. Considerable material resulted which was insoluble in ether. When recrystallized from large volumes of acetone high melting fractions separated. One melting at 272–275° contained no sulfur and was not investigated further.

**22-Phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene (III).**—The above tosyl ester was refluxed for three hours with an amount of methanol sufficient to dissolve it and upon cooling an almost quantitative yield of crystals separated out. Recrystallized from methanol-chloroform, it melted at 205–206°, and, when mixed with the 3-methoxy-ol (III) previously reported,[2] there was no m. p. depression.

*Anal.* Calcd. for $C_{29}H_{42}O_2$: C, 82.43; H, 10.02. Found: C, 81.93; H, 9.9. $[\alpha]^{25}D$ −45.7 (0.09623 g. made up to 10 ml. with chloroform, $\alpha^{25}D$ −0.44, *l*, 1 dm.).

**22-Phenyl-3-methoxy-22-chloro-bisnor-5-cholene.**—0.42 g. of 22-phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene was dissolved in 15 ml. of hot benzene and to this was added a slight excess of thionyl chloride and the mixture was refluxed for one hour. After removal of most of the solvent the chloro compound crystallized out. Recrystallized from hexane, it melted at 189–190°.

*Anal.* Calcd. for $C_{29}H_{41}OCl$: Cl, 8.04. Found: 8.20.

**22-Phenyl-3-methoxy-22-acetoxy-bisnor-5-cholene.**—250 mg. of 22-phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene was dissolved in 20 ml. of dry pyridine and 5 ml. of acetic anhydride added. The mixture was refluxed one-half hour, cooled, and poured, with stirring, into a mixture of 15 ml. of concentrated hydrochloric acid and ice. This was extracted with ether, washed with saturated sodium bicarbonate solution and water, and dried over magnesium sulfate. Upon evaporating the solvent and recrystallizing the residue from chloroform–methanol the compound melted at 216–217°.

*Anal.* Calcd. for $C_{31}H_{44}O_3$: C, 80.12; H, 9.54. Found: C, 80.24; H, 9.59.

**22-Phenyl-3-methoxy-bisnor-5,20-choladiene (IV).**—500 mg. of 22-phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene was dissolved in 200 ml. of toluene by heating and 20 mg. of phenol was added. The mixture was heated until the phenol was in solution and 50 mg. of *p*-toluene sulfonic acid monohydrate was added. The solution was refluxed eighteen hours, using a water trap. After cooling the solution was washed with five per cent sodium hydroxide and with water until neutral and the toluene was removed *in vacuo*. The crystalline residue was dissolved in 50 ml. of boiling benzene and, after cooling, the clear solution was passed over a column of 15 g. of activated alumina (Fisher adsorption), and the product eluted with benzene in 40 ml. fractions. The first four fractions in several runs weighed 305–370 mg. (60–75%) and were nicely crystalline. Recrystallized from methanol–chloroform the melting point was 166–169°.

*Anal.* Calcd. for $C_{29}H_{20}O$: C, 86.11; H, 9.97. Found: C, 86.45; H, 10.47.

**Pregnene-3β-ol-20-one Methyl Ether Semicarbazone.**—400 mg. of the diene (IV) was dissolved in 25 ml. of chloroform and, while cooling in an ice-bath, 0.158 g. of bromine in 5 ml. of chloroform was added dropwise with mechanical stirring. The ice cooled solution was ozonized for thirty minutes (*ca.* 7.2 mg. of ozone per minute). The solvent was removed *in vacuo* below 30° and the residue taken up in 20 ml. of glacial acetic acid and debrominated by careful addition of 0.5 g. of zinc dust. The product was extracted with ether, washed with 5% sodium hydroxide and then water till neutral. After drying the ether solution over sodium sulfate the solvent was removed to yield 0.34 g. of oily crystalline material having a strong odor of benzaldehyde. Upon refluxing this residue with 30 ml. of methanol, 3 ml. of water, 0.4 g. of semicarbazide hydrochloride and 0.4 g. of sodium acetate for one hour, the semicarbazone of V precipitated. After cooling, filtering and washing with water and a little methanol, 240 mg. of the semicarbazone was obtained, m. p. 224–228°. Recrystallized from methanol–chloroform it melted at 235–237°. A mixed m. p. with a sample of semicarbazone made from an authentic sample of pregnene-3β-ol-20-one methyl ether prepared according to the method of Butenandt and Gross[6] showed no depression.

*Anal.* Calcd. for $C_{23}H_{37}O_2N_3$: N, 10.84. Found: N, 10.76.

**Pregnene-3β-ol-20-one Methyl Ether (V).**—240 mg. of the semicarbazone was taken up in 50 ml. of methanol and 25 ml. of 5 *N* sulfuric acid was added. After refluxing one-half hour and diluting with 125 ml. of water the prod-

(6) Butenandt and Gross, *Ber.*, **70**, 1448 (1937).

uct was extracted with ether. The ether solution was washed with water till neutral and dried over sodium sulfate. Upon removing the ether 192 mg. of nicely crystalline product was recovered, m. p. 118–121°. When recrystallized from a small volume of dilute acetone it melted at 124–125° and did not depress the m. p. of an authentic sample of V.

*Anal.* Calcd. for $C_{22}H_{34}O_2$: C, 79.94; H, 10.37. Found: C, 79.68; H, 10.45.

**Pregnene-3β-ol-20-one Acetate (VI).**—80 mg. of pregnene-3β-ol-20-one methyl ether and 40 mg. of *p*-toluene sulfonic acid monohydrate was covered with 4 ml. of redistilled acetic anhydride and heated on a steam cone with stirring for one-half hour. The mixture was cooled and poured into ice-water with stirring, and allowed to stand two hours. The product was extracted with ether, washed with sodium bicarbonate solution and water and dried over sodium sulfate. Upon removing the solvent and recrystallizing the residue three times from dilute methanol the product melted at 143–144° and did not depress the melting point of an authentic sample of VI.

## Summary

1. The secondary carbinol, 22-phenyl-3-methoxy-22-hydroxy-bisnor-5-cholene (III), has been dehydrated in yields of 60–75% and the resulting diene (IV) has been degraded to give pregnene-3β-ol-20-one methyl ether (V).

2. The mono tosylate mentioned previously[1] has been shown to be 22-phenyl-3,22-dihydroxy-bisnor-5-cholene-3-tosylate (II).

# A Method for the Determination of Organic Compounds in the Form of Isotopic Derivatives.[1,2] I. Estimation of Amino Acids by the Carrier Technique

BY ALBERT S. KESTON, SIDNEY UDENFRIEND[3] AND R. KEITH CANNAN

In a preliminary communication[4] we have outlined a general method for the estimation of organic compounds in the form of isotopically labelled derivatives. The method is of particular value for the estimation of the components of mixtures of related compounds for which individual chemical methods of analysis are not available. We have applied it to the estimation of certain of the amino acids which are present in hydrolysates of proteins.

The mixture is treated with a reagent containing a stable or a radioactive isotope under such conditions that the components which are to be estimated are quantitatively converted into derivatives of the reagent. If any one of these derivatives can be separated quantitatively from the others, it can then be directly estimated[5] with the precision and sensitivity characteristic of isotopic measurements. In the analysis of mixtures of amino acids, however—and, indeed, of most biological materials—the quantitative separation of a single component is not always attainable. In this situation, the isotopic method may be applied with the aid of carrier or indicator techniques.[4,5]

In the carrier method, an overwhelming excess, $W$ moles, of the unlabelled derivative of the desired constituent is added to the mixture and is then separated and purified to constant molal isotope concentration, $Cc$. If $Cr$ be the molal isotope concentration of a pure isotopic derivative which has been prepared with the same sample of the reagent, then the amount of the isotopic derivative ($w$) which was present in the mixture is

$$w = Cc(w + W)/Cr$$

When relatively large amounts of the carrier are added, this equation reduces to

$$w = WCc/Cr$$

The carrier principle gives the method wide scope and flexibility. It makes it possible to carry out estimations of very minute amounts of the compound of interest and yet to operate with milligram quantities of material. It is, moreover unnecessary to seek a quantitative recovery of the compound in pure form. What is essential is the rigorous purification of the carrier from significant amounts of isotopic impurities. To accomplish this large losses of the product may be accepted. Finally, in the analysis of optically active compounds, the use of a large excess of a racemic carrier ensures the estimation of the total of both of the active forms. This is a significant advantage in the analysis of proteins in which indeterminate degrees of racemization may have occurred during hydrolysis. If, on the other hand, one wishes to estimate only one of the isomers the corresponding carrier may be used.

The validity and precision of the method which has been outlined depend primarily on, (a) the completeness of the reaction between the isotopic reagent and the compound which is to be estimated, (b) the rigorous purification from radioactive contaminants of the carrier after addition to and isolation from the reaction mixture and (c) the precision of the measurements of $Cc$ and $Cr$.

(5) A. S. Keston, S. Udenfriend and M. Levy, *ibid.*, **69**, 3151 (1947).

In this communication, we describe in detail the application of the carrier technique to the estimation of glycine, alanine and proline in hydrolysates of proteins. The reagent which we have used is *p*-iodophenylsulfonyl chloride (pipsyl chloride) containing $I^{131}$. The evidence that the above analytical criteria are met in the estimation of these amino acids in mixtures will first be reviewed.

**The Reaction of Pipsyl Chloride with Amino Acids.**—In preliminary investigations[4] the amino acid was dissolved in a solution of carbonate and treated with a substantial excess of pipsyl chloride. The progress of the reaction was followed by the rate of disappearance of amino nitrogen as indicated by Folin's naphthoquinone reaction.[6] When all of the amino nitrogen had disappeared it was assumed that the sole product was the monosubstituted sulfonamide. In some later experiments, however, the presence of a small amount of a second radioactive product was observed. These products, which were obtained from alanine and isoleucine but not from glycine or proline, were well-defined crystalline substances, highly insoluble in water both as free acids and as potassium salts. They have not been rigorously identified but, since they have been found to contain two atoms of labelled iodine per atom of nitrogen, we may assume that they are the disubstituted sulfonamides (dipipsyl derivatives).

The attempt was made to drive the secondary reaction to completion with the object of using the dipipsyl derivatives as carriers. Good yields were obtained when a solution of aniline or of isoleucine in saturated potassium carbonate was shaken with a large excess of pipsyl chloride dissolved in acetone.[7] Under the best conditions, however, the secondary reaction attained only about 90% completion. The attempt to use the dipipsyl derivatives as carriers was, therefore, abandoned.

Re-investigation of the over-all reaction indicated that the second stage occurs to a significant extent only after substantial completion of the first. When a series of successive partial reactions is carried out with intermittent removal of the monopipsyl compound formed it has been possible, consistently, to recover 98–100% of the amino acid as the monopipsyl derivative. This manner of carrying out the reaction has been adopted as the standard analytical procedure. Mono- and dipipsyl carriers have been used to estimate the amounts of these two types of derivative which are formed under the standard conditions (Table I). In our experience, so little dipipsyl material is formed in a protein hydrolysate that the use only of a monopipsyl carrier gives results of sufficient accuracy. If desired, of course, a second estimation may be made using the dipipsyl carrier and correcting the monopipsyl estimation for any dipipsyl compound which may be found. Since proline and hydroxyproline are secondary amines, they cannot form dipipsyl compounds. Apparently glycine does not readily do so.

(6) O. Folin, *J. Biol. Chem.*, **51**, 377 (1922).

(7) The aqueous and acetone phases were immiscible in the presence of the high concentration of carbonate.

**The Purification of the Carriers.**—The radioactive impurities which may be expected to be present in a protein hydrolysate which has been treated with pipsyl chloride are the monopipsyl derivatives of the amino acids together with traces of the dipipsyl compounds of some of them, pipsyl amide arising from reaction with ammonia and *p*-iodophenyl sulfonic acid which is formed by the hydrolysis of the excess of pipsyl chloride. The pipsyl amino acids are readily extracted by ether from acid solutions and return to the aqueous phase when shaken with dilute ammonia. The iodophenyl sulfonic acid is not readily extracted by ether from dilute acid, whereas the pipsyl amide remains in the ether when shaken with ammonia. Thus the removal of the major radioactive contaminants from the pipsyl amino acids presents no great difficulty.

TABLE I

RECOVERY OF AMINO ACIDS AS THE MONOPIPSYL AND DIPIPSYL DERIVATIVES[a]

| Amino acid | Amount added, mg. | % recovered as monopipsyl | % recovered as dipipsyl | Total, % |
|---|---|---|---|---|
| Glycine | 1.000 | 100.2 | ...[b] | 100.2 |
| | 1.000 | 99.8 | ...[b] | 99.8 |
| D,L-Alanine | 1.000 | 98.7 | 1.3 | 100.0 |
| | 1.000 | 99.1 | 1.2 | 100.3 |
| D,L-Isoleucine | 2.000 | 98.0 | 1.5 | 99.5 |
| L-Proline | 3.232 | 98.6 | ...[c] | 98.6 |

[a] These recoveries are from analyses of the individual pure amino acids, using the standard procedure. [b] No dipipsyl derivative of glycine could be isolated for use as carrier. [c] Proline is a secondary amine and can form only the monosubstituted derivative.

A more difficult problem has been the separation of the carrier from traces of other pipsyl amino acids. We have found alternate repeated crystallization and treatment with charcoal to be effective though sometimes tedious. The free pipsyl amino acids are poorly soluble. Consequently, crystallization is readily carried out by acidification of an ammoniacal solution. The crystals may then be dissolved again in ammonia, treated with charcoal and recrystallized. This cycle must be repeated very many times before constant isotopic concentration is attained. The pipsyl derivatives of leucine and isoleucine, for example, are very difficult to separate from one another by crystallization. The purification of pipsylalanine in the presence of pipsylglycine or pipsylproline has also proved to be very tedious if crystallization alone is relied on.

The pipsyl amino acids, like the amino acids themselves (unpublished data), evidently have a strong tendency to co-precipitate. We have found that the phenomenon results in a distribution between the solid and the dissolved carrier as though the impurities were distributing between

two immiscible solvents. The distribution co-precipitation constant $k$ equals

$$\frac{\left(\frac{\text{Amount of impurity}}{\text{Amount of carrier}}\right)_{\text{Supernatant}}}{\left(\frac{\text{Amount of impurity}}{\text{Amount of carrier}}\right)_{\text{Crystals}}} = k$$

The absolute amount of the impurity has little effect on the magnitude of the distribution constant. Dilution of the isotopic impurity with its nonisotopic analog is thus of little value. The value of $k$ and the amount sacrificed determine the degree of purification in a crystallization. The various pipsyl amino acids have individual characteristic distribution coefficients in the presence of a particular carrier. The coefficients can be determined in simple experiments and are helpful in determining which particular pipsyl amino acid impurities will be difficult to remove from a given carrier.

When this type of distribution obtains, the efficiency of purification in relation to the amount of material lost increases as the number of crystallizations over which the loss is spread is increased. If the distribution coefficient is unfavorable, the asymptotic approach to isotopic purity is very slow. We accept a carrier as pure only when its isotope concentration has remained constant, within the error of measurement, through several recrystallizations and treatments with charcoal so conducted that there have been large losses of carrier.

The tedium of crystallization in some cases made it desirable to find other methods of purification. The work of Martin and Synge[8,9,10] on the distribution of the N-acetyl amino acids between solvent pairs was suggestive. Accordingly, we determined approximate distribution coefficients of the pipsyl amino acids between selected pairs of solvents. Representative results are given in Table II where the coefficient is expressed as the concentration in the organic phase divided by that in the aqueous phase.

The coefficients in Table II show wide characteristic differences. It is interesting to note from columns 4 and 5 that the relative coefficients of the pipsyl amino acids in a chloroform–water system closely parallel those of the acetyl amino acids. The range of distribution coefficients is so wide that some groups of pipsyl amino acids can be effectively separated from others by simple extraction. The leucine derivatives, for example, can be separated from those of the dicarboxylic acids by extracting an acid solution of the mixture with carbon tetrachloride.

Advantage may be taken of smaller differences in distribution by the use of an appropriate form of counter-current separation. For the separations with which this paper is concerned, we have found that a ten-plate discontinuous counter-current process of the type exploited by Craig[11] is adequate. The conduct of such a separation is described in a later section. From the crude fractions which are obtained, pure samples of the pipsyl derivatives of glycine, alanine and proline are readily obtained by crystallization. The adoption of this process of preliminary purification has made it possible to carry out several estimations on a single aliquot of a protein hydrolysate by adding several carriers to it prior to counter-current separation. Glycine, alanine and proline can be conveniently estimated in this way. We have also used the counter-current technique to ascertain the isotopic homogeneity of supposedly purified carriers.

The traces of dipipsyl derivatives which are formed in the reaction with pipsyl chloride tend to accumulate in the proline fraction of the counter-current process. They are difficult to remove by crystallization. The dipipsyl derivatives show a notable tendency to co-precipitate. We have been able to expedite the purification of pipsylproline by taking advantage of this characteristic. A small amount of sodium dipipsylalanine is added to an ammoniacal solution of the pipsylproline fraction and is then precipitated by addition of potassium chloride. This removes much of the radioactivity impurity in the fraction and facilitates final purification of the pipsylproline by crystallization.

TABLE II

DISTRIBUTION COEFFICIENTS OF SEVERAL PIPSYL AMINO ACIDS

PROPERTIES OF PIPSYL DERIVATIVES OF SEVERAL AMINO ACIDS

| Pipsyl amino acid | Melting point (cor., °C.) | Mol. extinct. coeff. at 250 mμ × $10^{-3}$ | Neutralization equivalent Found | Neutralization equivalent Theoretical |
|---|---|---|---|---|
| Glycine | 205–205.5 | 15.9 | 339.6 | 341.0 |
| DL-Alanine | 194.5 | 15.8 | 355.3 | 355.0 |
| D-Alanine | ... | 15.8 | 356.2 | 355.0 |
| Aminoisobutyric acid | 183.0 | .. | 372.0 | 369.1 |
| DL-Valine | 181.5 | .. | ... | ... |
| DL-Leucine | 125.5–126.5 | .. | ... | ... |
| DL-Isoleucine | 149.0 | 15.8 | 397.6 | 397.0 |
| DL-Serine | 209.5 (dec.) | 15.7 | ... | ... |
| DL-Methionine | 127.0 | .. | 416.7 | 416.0 |
| DL-Proline | ... | 16.5 | ... | ... |
| L-Proline | 126.0 | 16.5 | 384.0 | 382.0 |
| DL-Aspartic acid | 182.0–184.0 | .. | ... | ... |

attained. The first is a measurement of the amount of carrier which remains. This may be done conveniently on a very small sample by measuring the absorption at 250 mμ (Table III). The second is a measurement of radioactivity. We use a double-walled thin glass cylinder[12] which is slipped over a Geiger–Müller counter filled with tetramethyllead vapor[13] together with a Technical Associates model GS-4 scaling unit.

sis. This corrects for radioactive decay. The standard is purified by extraction into ether and re-extraction into dilute alkali followed by recrystallization. A solution of the purified material is prepared, standardized photometrically and used in all assays.

The spectrophotometric measurements may be made with an accuracy better than 0.5%. The measurement of radioactivity, when carried out as described, is capable of a high degree of accuracy. The probable error due to randomness of counting is equal to $1.67\sqrt{A + 2B}$, where $A$ is the number of counts of the sample and $B$ is the background count. We have routinely relied on observations involving 5,000–10,000 counts in a two-minute period. With a background count of 20 the error due to randomness is about 1%. Several two-minute counts have been averaged to reduce this error.

The procedure which is described in the section headed "Analytical Procedure" has been applied to the estimation of glycine, alanine and proline in a mixture of pure synthetic amino acids (Table IV) and to the acid hydrolysates of four crystalline proteins for which some comparative analytical data are available (Tables V–VIII). Control estimations have also been carried out on amino acid mixtures from which the particular amino acid to be estimated was omitted.

In the absence of the amino acid, it has in all

[a] The amino acid mixture contained 150 μg of leucine and of lysine, 110 μg of glutamic acid, 100 μg of isoleucine and of phenylalanine, 99.5 μg of alanine, 80.8 μg of proline, 50 μg of threonine, of glycine and of valine and 25 μg each of methionine and aspartic acid. In all cases (except glycine) the synthetic racemic forms were used. In the control analyses the glycine, alanine and proline were omitted from the mixture. [b] The value for alanine is corrected for 1.3% dipipsylalanine.

With each set of determinations of the unknown counts are also made of a standard solution of an isotopic monopipsyl derivative prepared from the same radioactive reagent as is used in the analy-

cases been possible to purify the carrier to an isotopic concentration corresponding to a negligible content of the amino acid in the mixture analyzed. In the presence of the amino acid, very satisfactory recoveries have been recorded on mixtures of known composition.

The four proteins were hydrolyzed in 6 *M* hydrochloric acid for about twenty hours in sealed tubes at 110–120°. The amount of protein was based on the weight of an air-dried sample and corrected for the moisture which was determined by drying to constant weight at 110°. The hydrolysates were partially neutralized and diluted to contain about 5–10 mg. protein per ml. For analysis, an aliquot was measured with a constriction micro pipet,[14] transferred to a Folin sugar tube, neutralized and analyzed by the procedure described below.

The alanine and proline carriers were prepared from the DL amino acids except in two cases noted in the tables. The isoleucine carrier used in the hemoglobin analysis was prepared from a sample of the synthetic product which was stated to be free from leucine (The Winthrop Chemical Co.). The analyses recorded in the tables for alanine include a correction of 1.3% for the amount of dipipsylalanine presumed to have been formed (Table I). No corrections have been applied to the glycine and proline results.

The samples of β-lactoglobulin[15] and of crystalline human hemoglobin[16] were prepared in this Laboratory. The crystalline preparations of aldolase and phosphoglyceric aldehyde dehydrogenase of rabbit skeletal muscle were supplied by Dr. S. F. Velick of Washington University, St. Louis.

In the analysis of β-lactoglobulin, the estima-

[a] S. F. Velick and F. Ronzoni, *J. Biol. Chem.*, 173, 627 (1948). Attention is drawn to an error in the text of this paper (p. 637). The glycine content of the dehydrogenase given as 6.88 per cent. by the isotopic derivative method should be corrected to 6.04 and the value for microbiological assay given as 6.98 per cent. should be corrected to 6.15. The correct values are those in the tables in the same article.

tion of total proline and of L-proline are in excellent agreement. The D-alanine estimation is a maximum one because constant isotope concentration was not attained. It is evident, however, that no significant amount was present in the hydrolysate. The same comment applies to the isoleucine estimation of human hemoglobin. This protein contains a large amount of leucine which, at the present stage of development of the method, is not easily separated from isoleucine.

## Analytical Procedure

The procedure described below for the determination of glycine, alanine and proline in a single sample is given in detail to illustrate the use of more than one carrier.

To a Folin sugar tube, containing an amount of hydrolysate corresponding to 0.3–2 mg. protein, are added 15 mg. of sodium bicarbonate, 9 mg. of radioactive pipsyl chloride and water to a volume of 0.6 ml. The tube is placed in a boiling water-bath. When the pipsyl chloride has melted, the tube is agitated with an efficient vibrator for a few minutes. We have used an electrical massaging unit so attached to the ring stand holding the reaction tube as to produce high frequency-short amplitude vibrations sufficient to emulsify the pipsyl chloride and water.

After ten minutes the tube is cooled and acidified with 0.2 ml. of *M* hydrochloric acid. A glass bead and 2 ml. of ether are added and the pipsyl derivatives are extracted into the organic solvent. The ether is transferred by a rubber-bulb pipet to a vessel containing measured amounts (about 200 mg. each) of the appropriate carriers in ammoniacal solution. Three more extractions with ether are made and the extracts are transferred without loss to the carrier mixture. The contents of the sugar tube are reduced to dryness by heat and suction, 9 mg. of pipsyl chloride, 15 mg. of sodium bicarbonate and 0.6 ml. of water are added and the reaction is repeated as before. The mixture is acidified and extracted with ether and then is submitted to a third reaction with 12 mg. of pipsyl chloride.

The vessel containing the carriers and the combined ether extracts is warmed to remove the ether. Water and hydrochloric acid are added to make a final volume of 150 ml. of approximately 0.2 *M* hydrochloric acid and the solution is transferred to the first of ten numbered 500-ml. separating funnels. The succeeding funnels each contain 150 ml. of 0.2 *M* hydrochloric acid. To the first funnel is added 150 ml. of chloroform and the mixture is shaken to establish equilibrium. The chloroform layer is then passed on to the succeeding funnel. This procedure is continued until chloroform reaches the tenth funnel. The distribution of the components at this point may be calculated from their distribution coefficients with the aid

TABLE IX

THE CALCULATED DISTRIBUTIONS OF THE PIPSYL DERIVATIVES OF GLYCINE, ALANINE AND PROLINE BETWEEN CHLOROFORM AND DILUTE HYDROCHLORIC ACID, IN A TEN-PLATE COUNTER-CURRENT DISTRIBUTION

| Compound | Phase | Per cent. of compound in each separatory funnel (funnel number) 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|---|

| | Solvent | .40 | 2.4 | 6.4 | 9.9 | 9.9 | 6.7 | 3.0 | 0.86 | .14 | .01 |
| Alanine | Aqueous | .00 | 0.00 | 0.00 | 0.06 | 0.34 | 1.4 | 3.6 | 5.9 | 6.0 | 2.7 |
| | Solvent | .00 | .00 | .02 | .22 | 1.4 | 5.6 | 14.3 | 23.7 | 24.1 | 10.7 |
| Proline | Aqueous | .00 | .00 | .00 | .00 | 0.00 | 0.00 | 0.00 | 0.1 | 0.7 | 2.4 |
| | Solvent | .00 | .00 | .00 | .00 | .00 | .00 | .2 | 2.7 | 21.3 | 72.6 |

of the binomial expansion (Table IX). The experimental distributions have agreed well with those calculated.

By pooling the fractions as indicated below, one obtains pipsylglycine substantially free from the pipsyl derivatives of proline and alanine. The latter are combined in a single fraction from which pipsylproline may be removed by extraction with a mixture of chloroform and carbon tetrachloride.

**Glycine Carrier.**—The chloroform phase of funnels 2, 3 and 4 and the aqueous phase of funnels 3, 4 and 5 are combined and made alkaline (Table IX). The aqueous phase, which now contains the pipsylglycine is acidified and extracted with about 100 ml. of normal butanol. The butanol is washed with several volumes of water and then mixed with about 200 ml. of petroleum ether. The mixture is extracted twice with 10 ml. of 0.2 *M* NaOH and the alkaline extract is treated with charcoal and filtered into a centrifuge tube. Upon acidification with hydrochloric acid, pipsylglycine crystallizes out. The product is submitted to repeated alternate recrystallizations and charcoal treatments to constant specific activity.

**Alanine Carrier.**—The chloroform phase of funnel 8 and both phases of funnels 9 and 10 are combined, made alkaline and shaken. The aqueous layer is acidified with hydrochloric acid and extracted five times with a 60:40 mixture by volume of chloroform and carbon tetrachloride. The first three extracts are pooled for the proline estimation and the last two are discarded. The aqueous phase, which contains the pipsylalanine is extracted with butanol and further purified in the manner described for pipsylglycine.

**Proline Carrier.**—The three pipsylproline extracts referred to above are pooled and extracted twice with 10 ml. of 0.2 *M* NaOH. The alkaline solution is treated with dipipsylalanine and potassium chloride as described in an earlier section and is then further purified in the same way as the pipsylglycine.

**The Preparation of Non-Isotopic Pipsyl Chloride.**—This has been prepared in kilogram quantities for use in the preparation of carriers. *p*-Diazobenzene sulfonic acid is prepared[17] in quantities of about 100 g. at a time and treated with potassium iodide, while still wet, to yield *p*-iodophenyl sulfonic acid.[18]

The sodium salt of the latter is salted out with sodium chloride and dried. The acid chloride is prepared from this by addition of phosphorus pentachloride in phosphorus oxychloride. After reaction, the mixture is dissolved in benzene, washed with ice-water to remove phosphorus halides and dried over anhydrous sodium sulfate. Further purification by vacuum distillation below 150° is desirable. The acid chloride crystallizes on addition of excess of petroleum ether to the benzene solution in colorless crystals melting at 86° (literature, 86–87°).[19]

**The Synthesis of Isotopic Pipsyl Chloride.**—Quantities of a few hundred milligrams have been made at one time. For reasons of economy and sensitivity, the method of synthesis has been so modified as to incorporate as much as possible of the $I^{131}$ into the product. The progress of the synthesis is controlled by radioactive counts on the intermediate products.

**Isotopic Synthesis.**—To the radioactive iodine,[20] in solution, in the form of iodide ion, is added sufficient potassium iodide to make a total of 25 mg. The solution is adjusted to a *p*H above 7 and evaporated to a volume of less than 0.5 ml. The sample is transferred quantitatively, with the aid of several small portions of water, to a Pyrex test-tube and the volume is reduced to about 0.2 ml. A few small crystals of sodium sulfite are added. After cooling, an equal volume of concentrated hydrochloric acid is added followed by 25 mg. of diazobenzenesulfonic acid. After the initial evolution of nitrogen the sample is warmed to complete the reaction. The tube is cooled again and another 15 mg. each of diazobenzenesulfonic acid and potassium iodide are added and allowed to react as before. The reaction mixture is then saturated with sodium chloride and cooled, whereupon the sodium salt of *p*-iodophenylsulfonic acid crystallizes out. The crystals are centrifuged down and washed with brine. The combined mother liquor and washings are warmed and about 40 mg. of non-isotopic sodium iodophenylsulfonate, in solution in a small volume of water, is added. Upon cooling, the added sodium salt crystallizes out carrying down residual isotopic analog. This is also centrifuged down and washed with brine and the procedure repeated. The separate batches of sodium salt are dried and then each is dissolved in about one ml. of phosphorus oxychloride containing a substantial excess of phosphorus pentachloride. The batches are pooled and the mixture is heated gently to ensure reaction. The reaction mixture is transferred to a separatory funnel containing ice-water and about 50 ml. of benzene. Small portions of benzene are used to facilitate the transfer from the test tubes to the funnel. At this point, approximately 200 mg. of pure non-isotopic pipsyl chloride is added. The benzene layer is washed several times with cold water to remove excess phosphorus halides. The rate of hydrolysis of pipsyl chloride is negligible, under these conditions, as is indicated by the absence of any appreciable amounts of radioactivity in the wash water. The benzene solution is dried over anhydrous sodium sulfate and the drying agent is washed with benzene until it is substantially free of radioactivity.

The combined benzene solution is evaporated to a small volume and transferred to a cold finger micro-distillation apparatus. The benzene is evaporated in a stream of air and the pipsyl chloride is distilled onto the cold finger at 150° at a few mm. of mercury pressure. The distilled material is washed into a vessel with a minimum of benzene. At this point more non-isotopic pipsyl chloride

(20) The radioactive iodine used in the early part of the work was obtained through the kindness of Dr. Robley D. Evans of the Department of Physics at the Massachusetts Institute of Technology. The $I^{131}$ used more recently in this investigation was supplied by the Clinton Laboratories on allocation from the U. S. Atomic Energy Commission. An irradiation unit containing approximately 100 millicuries of $I^{131}$ was used for each isotopic synthesis. The $I^{131}$ was separated from the tellurium by a procedure developed in this Laboratory (M. Levy, A. S. Keston and S. Udenfriend, THIS JOURNAL, **70**, 2289 (1948)). Isotopic pipsyl chloride was prepared at approximately six-week intervals.

may be added to make a desired specific activity. The pipsyl chloride must be completely dissolved and thoroughly mixed to ensure isotopic homogeneity. Recrystallization may be achieved by adding petroleum ether to the benzene and concentrating the solution. The small amount of residual solvent is then drawn off with a capillary pipet and the crystals are dried at 70° for about one hour. The reagent has been successfully used even when the last recrystallization was omitted.

**The Synthesis of Pipsyl Amino Acids for Use as Carriers.**—In the case of the monobasic amino acids, an excess of amino acid, in aqueous solution, is heated with pipsyl chloride in the presence of enough sodium bicarbonate to neutralize the acids formed during the reaction. Efficient stirring must be provided and the temperature maintained near boiling until the pipsyl chloride has all reacted. Potassium chloride is then added to precipitate some dipipsyl impurities which have very insoluble potassium salts and the reaction mixture is treated with activated charcoal and filtered. Crystals of the derivative generally appear after acidification and cooling of the filtrate. If they do not, the compound may be extracted into ether or ethyl acetate and then returned to a small volume of alkali. Upon acidification, the crystalline derivative will then appear. The derivatives may be recrystallized either from hot water or from a mixture of acetone and water. The crystals are dried at 105°. The properties of a number of derivatives are given in Table III.

## Discussion

Hevesy and Hobbie[21] in 1932 were the first to use isotopes to overcome the difficulties of analytical methods which required the quantitative isolation of a pure sample from a mixture. They developed a microanalytical method for the analysis of lead in ores which involved adding a measured trace amount of radium D, which is isotopic with lead, to the dissolved ore and then separating a pure sample of lead from the mixture by standard chemical procedures. The total amount of lead present in the sample at the start of the analysis was then found by dividing the amount of lead isolated by the fraction of radioactivity recovered. The use of isotopically prepared organic compounds, in a manner similar to radium D in the analysis of lead, has come to be known as the isotope dilution method.[22,23,24]

The analysis of radioactive constituents in a mixture by carrier techniques has been a commonplace for a long time in the fields of radioactivity and its biological applications. The simplest statement of the new method described here is that the compounds of interest are converted into radioactive substances by direct chemical binding with a radioactive reagent.

The isotopic derivative method, presented here, has much higher sensitivity than the isotope dilution technique, being operable below the microgram level, and has the inherent specificity and accuracy characteristics of isotopic methods. One isotopic reagent suffices for the determination of many compounds. It is also possible to check analytical values with many reagents of different types. The use of large amounts of carrier makes possible rigorous isotopic purification. The use of large amounts of racemic carrier, moreover, enables one to estimate simultaneously both forms of an optically active compound, eliminating any errors that might arise due to racemization during preparation. The method may be made optically specific by using the appropriate enantiomorph as the carrier. Furthermore, the estimation of naturally occurring compounds whose syntheses present difficulties may be accomplished, since it is usually easier to prepare a derivative as a carrier than to synthesize the compound itself in isotopic form.

The significance of co-precipitation to the problem of the purification of isotopic compounds has been emphasized above. Co-precipitation is a phenomenon familiar to inorganic chemists.[25] It is evidently common in mixtures of related organic compounds also. We suggest that more attention should be paid to it in all tracer studies in which the tracer is isolated from a complex mixture and then purified.

The isotopic derivative method may also be applied where quantitative conversion to a derivative is not achieved. The addition of a trace amount of the compound to be determined, labelled with a second isotope which can be distinguished from that used in the reagent, enables one to calculate and correct for the extent of conversion to the derivative.

Pipsyl chloride has been applied to the determination of peptides in partial hydrolysates of proteins[26] and pipsyl chloride containing $S^{35}$ as the isotopic label has been made and used as an indicator in the application of the procedure to paper chromatography.[5] The application of the procedure to the systematic analysis of proteins, using both the carrier technique and paper chromatography, is now in progress.

## Summary

A new principle for the application of isotopes to the determination of organic compounds is introduced and its application to the determination of amino acids is presented.

A mixture is treated with an isotopic reagent to form quantitatively an isotopic derivative of the desired amino acid. A large excess of the unlabelled derivative is added as carrier and purified to constant isotope concentration. Knowing the specific radioactivity of the purified carrier and of a suitably prepared standard and also the fraction of carrier remaining after purification, one can calculate the quantity of amino acid present in the original mixture.

As reagent *p*-iodophenyl sulfonyl chloride (pipsyl chloride) containing $I^{131}$ was used.

(26) M. Levy and E. Slobodiansky, *Federation Proc.*, **7**, 168 (1948).

The method has extremely high sensitivity, being operable below the microgram level, and has the inherent specificity and accuracy characteristic of isotope techniques.

Recoveries of added amounts of glycine, alanine and proline from a mixture of twelve synthetic amino acids are reported to demonstrate the accuracy and specificity of the analytical procedure.

Values are reported for the glycine, alanine and proline contents of the crystalline proteins β-lactoglobulin, human hemoglobin, aldolase and phosphoglyceraldehyde dehydrogenase.

# Preparation and Reactions of Several Chlorine Substituted Phenoxyacetyl Chlorides

BY CARL M. HILL, MYRON B. TOWNS AND GILBERT SENTER

Chemical investigation involving study of the several phenoxy acetic acids and their derivatives has been chiefly concerned with their insecticidal and herbicidal activity. Of the six phenoxy substituted acetic acids (phenoxy, 2-chlorophenoxy, 4-chlorophenoxy, 2,4-dichlorophenoxy, 2,4,5-trichlorophenoxy and 2,4,6-trichlorophenoxy) the derivatives of the two trichloro acids described in this paper are not reported in the literature. It was of interest, therefore, to investigate the preparation and properties of these derivatives and to establish their identification.

Inasmuch as the phenyl esters (except phenyl phenoxyacetate) of the six acids mentioned above are not described in the literature, these were prepared and identified.

## Experimental

**Acids.**—The 2,4,5- and 2,4,6-trichlorophenoxyacetic acids were obtained from Dow Chemical Company and were purified by recrystallization from chloroform; 2,4,5-trichlorophenoxyacetic acid, m. p. 152–153° (uncor.) (lit.,[1] m. p. 154–55°), neut. equiv. calcd. for $C_8H_5O_3Cl_3$ 255.5, found, 257.7; 2,4,6-trichlorophenoxyacetic acid, m. p. 177–178° (uncor.), (lit.,[1,2] m. p., 190°, 177°), neut. equiv. found 256.0.

**2,4,5-Trichlorophenoxyacetyl Chloride.**—Into a round-bottomed flask equipped with a condenser set for reflux was placed 64 g. of 2,4,5-trichlorophenoxyacetic acid. One hundred and nineteen grams of purified thionyl chloride were added dropwise to the acid over a period of twenty-four hours. At the end of this time, the reaction mixture was refluxed on a steam-bath for two hours. The excess thionyl chloride was removed by distillation at atmospheric pressure. Distillation of the residue from a modified Claisen flask, under reduced pressure, gave 54.8 g. (80.0%) of 2,4,5-trichlorophenoxyacetyl chloride; b. p. 165–167° (6 mm.). This product was a waxy, white solid with a cocoanut-oil odor; m. p., 78–79° (uncor.).

*Anal.* Calcd. for $C_8H_4O_2Cl_4$: ionizable Cl, 12.94. Found: Cl, 12.46.

**2,4,6-Trichlorophenoxyacetyl Chloride.**—This compound was prepared by the method described for 2,4,5-trichlorophenoxyacetyl chloride using 64 g. of 2,4,6-trichlorophenoxyacetic acid; yield 61.6 g. (90.0%). This product was a waxy, white solid; b. p. 147–150° (5 mm.), m. p., 55–56° (uncor.).

*Anal.* Calcd. for $C_8H_4O_2Cl_4$: ionizable Cl, 12.94. Found: Cl, 13.03.

(1) Synerholm and Zimmerman, *Contrib. Boyce Thompson Institute*, **14**, 91 (1945); *Chem. Abst.*, **39**, 1474 (1946).

(2) Haskelberg, *J. Org. Chem.*, **12**, 426 (1947).

Both chlorides were analyzed for ionizable chlorine according to the following procedure: Fifty ml. of ethanol, 15 ml. of 2 *M* potassium hydroxide and 0.5 g. of the acid chloride were refluxed for twenty minutes in an erlenmeyer flask attached to a water-cooled condenser. The solution was allowed to cool, after which 50 ml. of distilled water was added through the head of the condenser. The solution was transferred to a 400-ml. beaker and the washings from the flask were added. After acidifying the solution with 1:1 nitric acid, the chlorine was precipitated with 0.5 *M* silver nitrate. The solution was then heated, with stirring, and the precipitated silver chloride filtered. The precipitate was washed on filter with 1:1 nitric acid followed by ethanol, dried and weighed as silver chloride.

### Amides

**2,4,5-Trichlorophenoxyacetamide.**—To 0.5 g. of 2,4,5-trichlorophenoxyacetyl chloride was added a slight excess of concentrated ammonia and the mixture heated over a water-bath until precipitation of the amide was complete. The crude amide was filtered and recrystallized from dilute ethanol. The pure product was a white solid; m. p. 173–174° (uncor.), yield 0.50 g. (97.5%).

*Anal.* Calcd. for $C_8H_6O_2Cl_3N$: N, 5.50. Found: N, 5.81.

**2,4,6-Trichlorophenoxyacetamide.**—This amide was prepared in the manner described for the 2,4,5-trichlorophenoxyacetamide, starting with 0.5 g. of 2,4,6-trichlorophenoxyacetyl chloride. This product was a white crystalline solid; m. p. 195–196° (uncor.), yield 0.50 g. (98.0%).

*Anal.* Calcd. for $C_8H_6O_2Cl_3N$: N, 5.50. Found: N, 5.59.

### Ethyl Esters

**Ethyl 2,4,5-Trichlorophenoxyacetate.**—To 5 g. of 2,4,5-trichlorophenoxyacetyl chloride was added a slight excess of 95% ethanol. The mixture was heated under reflux for two hours, allowed to cool, and washed with a saturated solution of sodium bicarbonate and then with water. The crude ester was extracted with diethyl ether and the ethereal solution dried over anhydrous calcium chloride. After removal of the ether, the crude ester was recrystallized from dilute ethanol. This product was a white crystalline solid; m. p. 63–64° (uncor.), yield 5.1 g. (89%), sap. equiv. calcd. for $C_{10}H_9O_3Cl_3$ 283.6, found 281.0.

**Ethyl-2,4,6-Trichlorophenoxyacetate.**—Five grams of 2,4,6-trichlorophenoxyacetyl chloride was used; yield 2.8 g. (85%). This ester was a white crystalline solid; m. p. 33–34° (uncor.), sapn. equiv. found, 280.0.

### Anilides

**2,4,5-Trichlorophenoxyacetanilide.**—A solution of 5 g. of 2,4,5-trichlorophenoxyacetyl chloride and 15 ml. of chloroform was placed in an erlenmeyer flask. To this was added a slight excess of pure aniline. The reaction mixture was heated under reflux for thirty minutes and then allowed to cool. The crude anilide was filtered off

and recrystallized from dilute ethanol. This pure anilide was a white crystalline compound; m. p. 176–177° (uncor.), yield 4.4 g. (67%).

*Anal.* Calcd. for $C_{14}H_{10}O_2Cl_3N$: N, 4.25. Found: N, 4.52.

**2,4,6-Trichlorophenoxyacetanilide.**—This compound was prepared according to the procedure described for 2,4,5-trichlorophenoxyacetanilide using 5 g. of the corresponding acyl chloride. This anilide was a white crystalline solid; m. p. 107–108° (uncor.), yield 4.1 g. (63%).

*Anal.* Calcd. for $C_{14}H_{10}O_2Cl_3N$: N, 4.25. Found: N, 4.20.

### Phenyl Esters

**Phenyl Phenoxyacetate.**[3]—To 5 g. of phenoxyacetyl chloride in an erlenmeyer flask was added dropwise an alkaline solution containing an equivalent amount of phenol dissolved in 10% sodium hydroxide. The reaction mixture was heated over a steam-bath for thirty minutes and then cooled. The ester crystallized out and was purified by recrystallization from dilute ethanol. The white crystalline product melted at 56–57° (uncor.); yield 5.0 g. (73%), sapn. equiv. calcd. for $C_{14}H_{12}O_2$ 228.0, found 224.0.

**Phenyl 2-Chlorophenoxyacetate.**—This phenyl ester was prepared from the corresponding acyl chloride according to the procedure described for phenyl phenoxyacetate. Five grams of the acyl chloride gave 4.9 g. (80%) of phenyl 2-chlorophenoxyacetate, a white crystalline solid; m. p., 58–59° (uncor.); sapn. equiv. calcd. for $C_{14}H_{11}O_3Cl$, 262.7, found, 262.2.

**Phenyl 4-Chlorophenoxyacetate.**—Used 5 g. of 4-chlorophenoxyacetyl chloride. This phenyl ester melted at 73–74° (uncor.); yield, 4 g. (63.5%); sapn. equiv. calcd. for $C_{14}H_{11}O_3Cl$, 262.7, found, 276.0.

**Phenyl 2,4-Dichlorophenoxyacetate.**—This compound was prepared from 5 g. of 2,4-dichlorophenoxyacetyl chloride by the method described for phenyl phenoxyacetate. Recrystallization of the ester from dilute ethanol gave 5.1 g. (82%) of product; m. p., 100–101° (uncor.); sapn. equiv. calcd. for $C_{14}H_{10}O_3Cl_2$ 297.2, found 301.5.

**Phenyl 2,4,5-Trichlorophenoxyacetate.**—A solution of 5 g. of the acyl chloride and an equivalent amount of phenol dissolved in 10% sodium hydroxide was treated as described for the preparation of phenyl phenoxyacetate. Recrystallization from dilute ethanol gave 4 g. (70%) of white crystalline product; m. p., 116–117° (uncor.), sapn. equiv. calcd. for $C_{14}H_9O_3Cl_3$ 331.6, found 336.0.

**Phenyl 2,4,6-Trichlorophenoxyacetate.**—Five grams of 2,4,6-trichlorophenoxyacetyl chloride and an equivalent amount of phenol were used in alkaline solution. The resulting phenyl ester was recrystallized from dilute ethanol. The yield of ester was 4.5 g. (75%); m. p. 84.5–85° (uncor.), sapn. equiv. found 332.0.

Determination of the saponification equivalents of the six phenyl esters presented several experimental difficulties. Because of the formation of phenol upon acidification of the hydrolytic mixture, certain experimental errors were introduced which rendered the usual procedure employed for determination of saponification equivalents inaccurate and unreliable.

Therefore, the following procedure was employed. An accurately weighed sample (0.2 to 0.5 g.) of the phenyl ester was introduced into an erlenmeyer flask and a measured excess of 0.25 *N* sodium hydroxide solution added. The flask was then attached to a water cooled condenser and the mixture refluxed for six to eight hours or until the ester disappeared. At the end of this time, the mixture was allowed to cool and a calculated excess of 0.25 *N* hydrochloric acid was added from a buret. At this point the total volume of the mixture was noted. The excess acid was then backtitrated with standard alkali to the end point of phenolphthalein as indicator.

The titration error due to the production of phenol was corrected by weighing out the theoretical amount of pure phenol as was present in the weighed sample of phenyl ester, and preparing an aqueous solution of the same molar concentration and volume as that of the saponification mixture after addition of the excess standard acid. The aqueous phenolic solution was then titrated with 0.25 *N* sodium hydroxide solution to the end point of phenolphthalein. The number of milliequivalents thus obtained was subtracted from the total number of milliequivalents of standard alkali used in saponification of the phenyl ester.

## Summary

The preparation of 2,4,5- and 2,4,6-trichlorophenoxyacetyl chlorides from the corresponding acids has been reported. The reaction of these acyl chlorides with ammonia, aniline, ethanol and phenol has been investigated.

The phenyl esters chlorophenoxy-, 2-chlorophenoxy-, 4-chlorophenoxy-, 2,4-dichlorophenoxy-, 2,4,5-trichlorophenoxy- and 2,4,6-trichlorophenoxy acetate were prepared.

Several new compounds were prepared and identified.

# The Preparation and Properties of Some Branched-Chain Alkyl Bromomethyl Ethers

BY HAROLD W. LUCIEN[1] AND CLARENCE T. MASON[2]

The importance of the halomethyl ethers as intermediates in synthesis, and the greater reactivity of the bromomethyl ethers[3] make necessary the present investigation to extend the knowledge of the branched-chain bromomethyl ethers.

The Henry synthesis and its modifications[4–7] are carried out by saturating equimolar quantities of an alcohol–aldehyde mixture with a hydrogen halide. In the present work branched-chain bromoethers were prepared by the Henry synthesis,[4] Wedekind's adaptation,[7] and two new modifications of Henry's method. When pre-

[a] By Henry's synthesis. [c] By Wedekind's method modified by using calcium chloride during the preparation. [d] From molar quantities of bromomethanol and an alcohol with hydrogen bromide.

pared by known methods the yields reported for straight-chain ethers were not achieved, due, in part, to the easier formation of alkyl halides. A mixture composed of the bromomethyl ether, formals and alkyl halides was isolated from Henry's synthesis. Unless the amount of water was reduced during these preparations, an excess of hydrogen bromide was necessary to complete the reaction.

The use of molar quantities of calcium chloride in conjunction with the Wedekind modification of Henry's synthesis boosted yields by about 15%. From the reaction of the alcohol with bromoethanol, yields of the order of 97% were obtained. Contaminated bromomethyl tertiary alkyl ethers were isolated in small amounts by all of the methods employed, but their preparation in high yields does not appear imminent.

The ease of preparation, yield, boiling point, refractive index and stability of the bromoethers prepared increase with molecular weight; the density and heat of vaporization[8] vary in an inverse manner. The exaltation increases with carbon content, being about 0.2 times the number of carbon atoms. These properties are summarized in Table I.

The formation of bromoethers from the reaction between an alcohol and bromomethanol appeared to take place by way of a hemiformal as an intermediate. It was not possible to isolate nor identify the compound suspected to be a hemiformal, due to the ease of formal formation. It was possible to obtain a bromoether from the reaction between a formal, paraformaldehyde, and hydrogen bromide.[9] The reactions encountered suggest the mechanism

(8) Calculated by substituting $p$ and $T$ data in the Clapeyron-Clausius equation.

(9) $ROCH_2OR + 2HBr + HCHO \rightarrow 2ROCH_2Br + H_2O$.

## Experimental

All alcohols and paraformaldehyde were obtained from Fisher Scientific Co. and were of the highest grade of purity. Bromomethanol was prepared according to Henry[10] and di-isobutyl formal was prepared by the method of Favre.[11]

**Bromomethyl Alkyl Ethers. A. By the Henry Synthesis.**[4]—Into a three-neck flask fitted with thermometer, stirrer and an inlet and outlet tube for hydrogen bromide, were placed one mole of the alcohol and 80 ml. of 37–38% formaldehyde solution. The flask was cooled to −5° and hydrogen bromide bubbled through the mixture until an excess of 1 mole accumulated in the flask. During the addition, the temperature was not allowed to rise above 25°. The crude bromoether was separated from the aqueous layer and dried for two hours over anhydrous calcium chloride. The products which resulted were amber in color, fumed on contact with air, and were lachrymatory. After drying, the crude bromoether was placed in an apparatus arranged for reduced pressure distillation, and the excess hydrogen bromide removed at 20 mm. pressure by bubbling nitrogen through the mixture. The product was distilled under reduced pressure.

**B. By Wedekind's Modification**[7] **of the Henry Synthesis.**—Procedure A was modified by substituting 30.0 g. of paraformaldehyde for 80 ml. of a 37–38% formaldehyde solution.

**C. By a Modification of the Wedekind Procedure.**—Procedure B was modified by using molar quantities of calcium chloride to remove the water as it was formed, and using only 1 mole of hydrogen bromide to 1 mole of alchohol and 30 g. of paraformaldehyde. The resulting product was decanted from the solid material and the latter extracted three times with 25-ml. portions of isopropyl ether. After the removal of ether by distillation, the bromoether was combined with the extract and purified as in procedure A.

**D. By the Reaction between Bromomethanol and an Alcohol.**—Into a 500-ml. erlenmeyer flask containing 74.1 g. (1 mole) of isobutyl alcohol was placed 111.1 g. (1 mole) of bromomethanol. The temperature rose to 50° and after an hour the mixture had cooled and two water-insoluble layers remained. The bottom layer was more dense than water, the top layer was less dense than water, and constantly decomposed to the more dense product and an aqueous solution. The total water-insoluble portion was dried and purified as before and yielded 153.1 g. (91.6%) 1-bromomethoxy-2-methylpropane, b. p. 51–53° at 30 mm., $n^{25}D$ 1.4402, $d^{25}_4$ 1.2352.

*Anal.* Calcd. for $C_5H_{11}BrO$: Br, 47.83; *MR*, 34.698. Found: Br, 47.94; *MR*, 34.889.

Experiment D was repeated to find some indication of hemiformal formation in the top layer which was constantly changing to bromomethyl isobutyl ether, but all attempts to isolate a hemiformal from this layer resulted in the isolation of di-isobutyl formal, b. p. 164–166°,

(10) Henry, *Rec. trav. chim.*, **23**, 16 (1904).

(11) Favre, *Compt. rend.*, **119**, 285 (1894).

$n^{25}D$ 1.4003, $d^{25}_4$ 0.8389. The product obtained also had a mixed boiling point with di-isobutyl formal (Favre,[11] b. p. 164.5°) of 164–166°.

The general procedure developed for the preparation of the bromoethers was similar to method **D**. Equimolar quantities of bromomethanol and an alcohol were intimately mixed and reduced pressure was applied to the flask containing the mixture. At the first indication of the formation of water, the use of reduced pressure was discontinued and the reaction was allowed to proceed of its own accord.

**E. By the Reaction between a Formal, Paraformaldehyde and Hydrogen Bromide.**—Into a 250-ml. round-bottom flask, cooled by running tap water and containing 50.6 g. (0.5 mole) of di-isobutyl formal, was placed 15 g. of paraformaldehyde. Hydrogen bromide was bubbled through the mixture until two layers separated, and thereafter for five minutes. The product of the reaction was isolated as in procedure **A** and yielded 76.8 g. (91.5%) of bromomethyl isobutyl ether, b. p. 40–42° at 23 mm., $n^{25}D$ 1.4401, $d^{25}_4$ 1.2350.

*Anal.* Calcd. for $C_5H_{11}BrO$: Br, 47.83; *MR*, 34.698. Found: Br, 47.91; *MR*, 35.887.

**The Identification of the Alkyl Portions of the Bromomethyl Alkyl Ethers.**—A 10-g. sample of the purified bromoether was hydrolyzed by refluxing with 20 ml. of a 10% solution of sodium hydroxide for thirty minutes. The alcohol obtained was isolated and the 3,5-dinitrobenzoate prepared. The ester obtained was compared with that obtained from the known alcohol by melting point and mixed melting point determinations.

**Acknowledgment.**—The authors wish to express gratitude to the Research Corporation for a Frederick Gardner Cottrell grant which helped to support this investigation.

## Summary

The bromomethyl ethers of seven branched-chain alcohols in the $C_3$ to $C_1$ range have been prepared. The physical constants determined include the boiling point, density, refractive index and the heat of vaporization. Evidence suggests the possibility that these bromomethyl alkyl ethers are formed in the Henry synthesis by way of a hemiformal as an intermediate.

# The Two-Step Reduction–Oxidation of Thiaxanthone-5-dioxide and Thiaxanthenol-5-dioxide[1]

BY HANS HEYMANN

In connection with another investigation the synthesis of the acetate of thiaxanthenol-5-dioxide was required. The interesting color phenomena exhibited by this ester, by the related alcohol and by the corresponding ketone prompted the study reported here. Carl Graebe[1a] had noted that thiaxanthone-5-dioxide gives blue solutions when heated with zinc and alkali or on heating with alcoholic potassium hydroxide; he observed that the color disappeared on continued heating with zinc and base. Ullmann and Glenck[2] found that the compound can be vatted with alkaline dithionite to give colored solutions. Recently Amstutz and his collaborators have again noted color phenomena akin to those seen by the earlier workers, and have voiced the suggestion that the colors appearing during the reduction of thiaxanthone-5-dioxides are due to semiquinone intermediates.[3] The same thought had occurred to us and we wish to present substantiation of the hypothesis in the present paper.[4]

(1) A preliminary report of this work was presented to a meeting of the Oregon Academy of Science on Jan. 17, 1948, in Salem, Oregon.

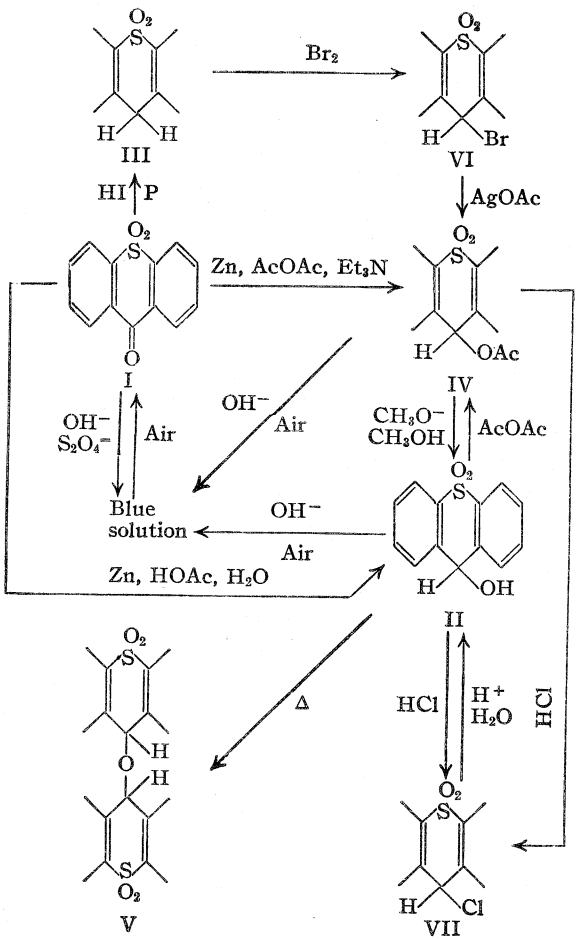
(4) Our work had been in progress for over a year when Dr. Amstutz's publication appeared. In his friendly reply to our inquiry Dr. Amstutz informed us that he does not intend to investigate, at the present time, the oxidation–reduction properties of the thiaxanthone dioxides.



## A. Preparative Part

The synthetic reactions are summarized in the accompanying flow sheet. The ketone I was obtained according to well-known procedures.[1,2] Reduction to thiaxanthenol-5-dioxide was achieved smoothly by means of zinc dust in 80% acetic acid, conditions under which substituted sulfone-ketones like I may be reduced to the corresponding thiaxanthene-5-dioxides.[3] The alcohol II melts sharply when heated relatively rapidly (*ca.* 0.5° per minute), but the behavior of a sample that is permitted to resolidify after melting indicates that a change accompanies protracted heating: the alcohol is transformed into the ether V, much as benzhydrol upon distillation goes to benzhydryl ether.

The carbinol II may be acetylated smoothly with acetic anhydride in pyridine to yield the acetate IV, and the same compound is conveniently prepared by reductive acetylation of I in the presence of little triethylamine. Larger amounts of base lead to the formation of small quantities of a yellow by-product of unknown nature. The acetate IV was also obtained by displacement with silver acetate of the bromine atom in 10-bromothiaxanthene-5-dioxide (VI), which was the sole product of the action of bromine in carbon tetrachloride on III. The correlation described confirms the assignment of the bromine atom to position 10.

The conditions of hydrolysis or displacement of

FLOW SHEET

the acetate group in IV were investigated briefly because (see below) IV and the alcohol II appeared to be indistinguishable as far as their oxidation behavior in alkaline medium is concerned. When a warm solution of IV in acetic acid was treated with concentrated hydrochloric acid the insoluble 10-chlorothiaxanthene-5-dioxide (VII) crystallized instantaneously; when the mixture was boiled for two hours, during which much hydrogen chloride escaped, the alcohol II was formed in a not clean-cut reaction. Thus the bond from position 10 to the oxygen atom must be rather tenuous, as one would expect, and it is natural that the alcohol II yields the chloride as easily as does the acetate when subjected to the same conditions. The formation of the alcohol II from the chloride presumably involves a slow solvolysis, as encountered in the benzhydryl halide series. Sulfuric acid in aqueous acetic acid or in aqueous alcohol hydrolyzes IV rapidly but the reaction is not smooth, the yield is poor, and the product is generally contaminated with the ether V; presumably the insolubility of VII and the greater apparent affinity of the chlorine atom for position 10 prevent side reactions from occurring with hydrogen chloride.

Next the acetate IV was exposed to prolonged action of sodium benzoate in alcoholic solution in order to learn whether a weakly nucleophilic agent would attack at position 10, although the observations cited argue against this possibility and, indeed, only the unchanged acetate (63%) was isolated after boiling for forty-eight hours. However, sodium methoxide in practically oxygen-free absolute methanol and under rigid exclusion of oxygen from the air rapidly produced II in 87% yield. Had position 10 been attacked by the base the methyl ether of II should have been the product. Thus one may conclude that under basic and acidic conditions IV is rapidly hydrolyzed to II.

### B. Study of the Reduction–Oxidation Equilibrium

The alcohol II and the acetate IV both develop an intense blue color when their solutions in alcohol are treated with alkali. In the case of the acetate hydrolysis no doubt precedes color formation. The blue tint is decolorized on shaking with air, returns after a short time, may be discharged again, etc., until finally the solution remains colorless and contains the ketone I. In an experiment of this sort, using aqueous pyridine as the solvent, the ketone was isolated in 93% yield; the mother liquor had a pale orange color owing to the occurrence of a non-identified and apparently negligible side-reaction. Color formation is virtually suppressed by thorough expulsion of oxygen from both the solution of the alcohol II and from the alcoholic alkali before mixing. When, however, oxygen-free alcoholic potash is added to an oxygen-free solution of equimolar amounts of I and II the intense blue color appears immediately. The blue species described here is no doubt identical with the coloration seen by Graebe.[1] Since alcoholic potash alone is capable of producing the color from I upon heating, and since this must involve a reducing action exerted by ethoxide ion, we tried to isolate acetaldehyde from such a blue solution, but without success. Probably the small amounts of aldehyde present are rapidly aldolized in the strongly basic medium. However, even in neutral solutions and at room temperature I oxidizes alcohol at a measurable rate: an alcoholic solution of I had acquired a strong odor of acetaldehyde after having stood for about a month; the aldehyde was flushed from the solution by nitrogen and identified by means of a solid derivative.

By scanning the adsorption spectrum of the blue material as it exists in aqueous pyridine solutions of varying alkalinity (0.025, 0.14, 0.9 $M$ in hydroxide ion) we found absorption bands at 370 and 570 m$\mu$, separated by an absorption minimum at 475 m$\mu$. The spectral curves have approximately the same shape; for the least alkaline sample the ratio $D_{570}:D_{475}$ is somewhat smaller than for the more alkaline solutions ($D$ refers to log $I_0/I$). However, in view of the

rather crude experimental technique employed the difference of the ratios described may not be significant.

The color intensity of the oxidation–reduction system increases markedly with rising *p*H, at constant concentration. This intensification was demonstrated objectively by colorimetry with the aid of a suitably modified Thunberg tube in which equimolar amounts of I and II were brought together with aqueous alkaline pyridine in the absence of oxygen. The relative optical density of a system containing, before contact with alkali, $8.4 \times 10^{-3}$ mole/l. of each I and II varied as 1:2.5:8.0 as the hydroxide concentration changed from 0.027 to 0.14 to 0.91 *M*.

There is evidence that besides the blue species a red entity exists in the oxidation–reduction system. Samples at low alkalinity appear purplish rather than blue, particularly in aqueous dioxane solution, and the smaller ratio $D_{570}:D_{475}$ mentioned above conceivably indicates an increased absorption at 475 mμ. Furthermore, when samples of the blue system are subjected, in an inert atmosphere, to controlled oxidation by means of ferricyanide solution or simply by means of air-saturated buffer, the color changes from blue to purple to pure pink before it is discharged completely. Spectroscopic examination of the red body was not very satisfactory because of the low concentration and high air-sensitivity of the compound; none the less, an absorption maximum between 470 and 480 mμ was recognized.

In sealed-glass vessels the blue solutions appear to be unchanged over long periods of time, but on heating at 110° for two days the color is discharged and in the resulting solution sulfite and xanthone (10–15%) were found, besides a small amount of unchanged I. The course of this interesting cleavage is not known at present.

Rapid neutralization with acid of the blue solution led to a mixture from which pure I and pure II were isolated, but there was no evidence of the presence of any other compound, in contradistinction to Bachmann's findings regarding the colored solutions of metal ketyls in aprotic solvents[5] from which high yields of the corresponding pinacols were obtained by acid decomposition.

The observations related so far strongly indicate that the colored body is an intermediate between I and II differing in oxidation level from these substances by one additional or one lacking electron, respectively, that the relative amount of the intermediate increases with rising *p*H, and that the intermediate comprises a blue and a red species. The intermediate may be considered to be a new type of semiquinone, derived from a simple ketone, to be added to the list of well-known one-step intermediates in two-electron oxidation–reduction reactions. However, more definite and more conclusive information was desirable, and we considered that an apparently mobile system like that of I and II might be susceptible to electrochemical investigation.

The fundamental studies of Michaelis[6] and of Elema[7] have shown how to interpret potentiometric titration curves obtainable from mobile, reversible oxidation–reduction systems with particular reference to the detection of one-electron steps in multi-electron reactions. We found that the system under discussion did, indeed, give rise to stable potentials on oxidative titration with ferricyanide in a medium containing 30% by volume of pyridine or dioxane; inclusion of such a large proportion of organic solvent was required by the low solubility of I. The potentials are established with practicable rapidity only at alkali concentrations greater than about 0.01 *M*. Tables I and II summarize the results obtained by potentiometric titrations; the symbols used are those introduced by Michaelis.[6] $E_m$ is the mean normal potential, referred to the normal hydrogen electrode, for the over-all reaction $I \leftrightarrows II$; $E_{i25}$ and $E_{i75}$ are the index potentials, *i. e.*, the numerical differences between $E_m$ and the e. m. f. of the galvanic chain at 25 and 75% completion of the oxidation. The index potential serves as a convenient measure of the degree to which the theoretical mid-point slope $RT/2F$ of a titration curve for a two-electron change is modified by the participation of two one-electron reactions. Knowledge of $E_i$ permits computing the amount of semiquinone in equilibrium with the reduced and the oxidized forms, and therewith $E_1$ and $E_2$, the normal potentials of the first and the second one-electron steps.

Table I shows the results obtained in a series of oxidative titrations in pyridine-containing media covering a *p*H-range from the most alkaline phosphate buffer capable of existence through various concentrations of sodium hydroxide to about 1 *N* tetramethylammonium hydroxide. The last-named base was employed because pyridine is not miscible with sodium hydroxide more concentrated than about 0.4 *M*. $E_i$ is seen to increase with rising alkalinity indicating that the two-step change becomes more and more prevalent at higher basicity.

Species intermediate in oxidation level between alcohols and ketones must have an odd electron and they may also bear an ionic charge, *i. e.*, they are neutral or ion-radicals and such radicals may exist in equilibrium with their dimers. If they do, the shape of the titration curve should depend on the total concentration of the oxidation-reduction system.[6] As experiments 6 and 7, 10 and 11, and 15 and 16 in Table I show, dimerization does not appear to take place to a degree detectable within the limits of the experimental accuracy.

In the experiments referred to by Table I the ionic strength underwent a more than ten-fold change; the alkaline agent employed was not the same for all runs, and the reproducibility of the measurements was not satisfactory. Therefore, another series of titrations was carried out, so designed as to employ the same alkaline agent throughout, and by incorporation in the medium of suitable amounts of potassium chloride the ionic strength was held constant at 1.4 for all runs. Furthermore, the temperature and the alkalinity were controlled more carefully. Dioxane was substituted for pyridine as the organic solvent, because dioxane permitted the use of higher concentrations of alkali hydroxide. Runs 1a to 6a, and 1b to 6b in Table II, represent two independent series of determinations, carried out with separate sets of reagents, and the results are seen to be reasonably well reproducible. Runs 7a are duplicate determinations of the a-series, and runs 8a and 9a, agreeing with one another, again show the absence of measurable dimerization of the semiquinone. Runs 2c to 5c were carried out in the absence of potassium chloride, thus involving a variation of the ionic strength from 0.03 to 0.3. It is of interest to note that with increasing alkalinity the hydrogen ion activity as well as $E_m$ diverge more and more from the values observed in series a and b, but that the values for $E_i$ are very nearly alike for solutions of the same molarity of alkali hydroxide, irrespective of the ionic strength. In another case[8] $E_i$ varied appreciably with the ionic strength of the medium.

The dependence of $E_m$ upon alkalinity is a consequence of the fact that I and II differ by two protons in addition to their disparate state of oxidation. Clark and Cohen have formulated the relation[9] between bends in an $E_m$ *versus* $p$H curve and the $pKa$ values of the protolytic dissociations pertaining to the species involved in the oxidation–reduction equilibrium. It is of great interest to construct a potential-$p$H diagram for the three potentials $E_1$, $E_2$ and $E_m$ of the system under discussion. The quantity referred to as $p$H in this article was calculated in the usual way from the e. m. f. of a cell consisting of the saturated calomel electrode and of the system hydrogen, colloidal palladium, platinum immersed in the fully reduced oxidation–reduction system, as recommended by Michaelis. The question of the significance of $p$H values of this nature is involved; all of the values are considerably higher than those to be expected from purely aqueous solutions of equal molarity. However, it seems not inconceivable to us that $p$H values calculated from potentials measured in such solvents as we have used might, up to a certain point, constitute a self-consistent $p$H scale which has a consistent relation to the normal potentials of a oxidation–reduction system involving protolytic equilibria. In the hope of detecting the presence of such dissociations and of gaining qualitative information about the nature of the colored intermediate we have plotted the experimental results in Fig. 1.

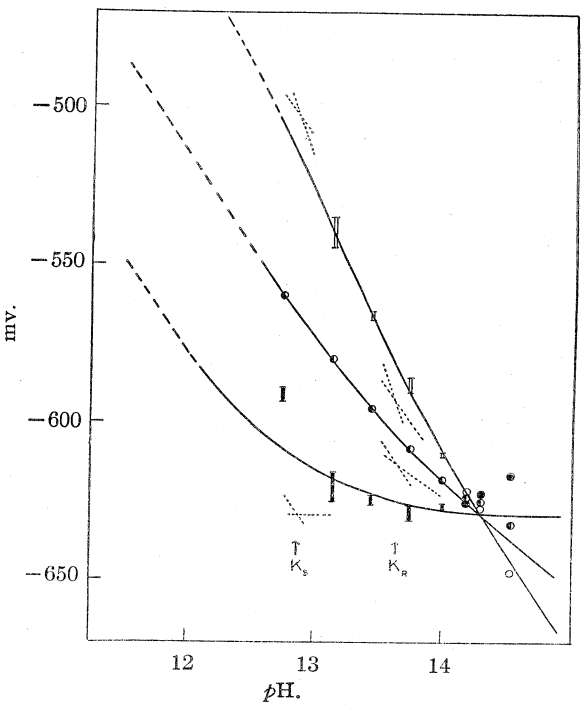

Fig. 1.—The three normal potentials of the oxidation–reduction system from oxidative titrations in aqueous dioxane. The lines drawn are theoretical curves: ○, $E_1$; ◐, $E_m$; ●, $E_2$.

Figure 1 contains the more reliable data, those obtained in the experiments with aqueous dioxane as the solvent. On this graph we have drawn an $E_m$-curve that begins with a slope of 59 mv. per $p$H unit at the low-alkalinity end of the plot and and gradually bends over to a slope of 29 mv. as one passes to higher values of $p$H. Continuations of the straight-line portions of the curve intersect at a point labelled $K_R$. The curve drawn is a *theoretical* curve of the type characteristic of oxidation–reduction systems, in which the reduced form differs from the oxidized form by two protons and two electrons; a bend like the one drawn occurs when $p$H approaches and passes through $pK_a$ of the first dissociable proton.[10] However, inspection of the experimental points shows that the steepest slope realized by measurement is only 55 mv. Since in well-studied cases of the dependence of oxidation–reduction potentials upon $p$H the non-linear portion of the curves extends over one to two $p$H units, a range comparable to that covered by all of the measurements in Table II, we consider it plausible that owing to the im-

(8) Michaelis and Fetcher, THIS JOURNAL, **59**, 2460 (1937).

(9) W. M. Clark and Cohen, U. S. Pub. Health Repts., **38**, 933 (1923).

(10) In view of the unknown relation between the normal $p$H scale and our "$p$H" values the usual interpretation that the $p$H at the intersection equals $pK_a$ is, of course, inadmissible.

mobility of the equilibrium at low alkalinities our measurements could not be extended to reach the region where the slope becomes equal to the theoretical value of 59 mv. Even at the lowest $p$H used, we feel, the over-all reaction is to be represented by both of the following equilibria,[11] with the second equilibrium becoming more and more prevalent as the alkalinity increases. Since $RH_2$ (II) dissolves readily to give a colorless solution in 30% aqueous dioxane containing

$$RH_2 \rightleftharpoons T + 2H^+ + 2e^-$$
$$RH^- \rightleftharpoons T + H^+ + 2e^-$$

potassium hydroxide in 1.4 $M$ concentration, when air is excluded and the system is kept in the reduced state by means of dithionite, whereas in the absence of potassium hydroxide the solubility of II in the same solvent is small, we do not doubt the reality of the acidic function of $RH_2$ implied in the $E_m$ curve.

At the flatter end of the $E_m$ curve the experimental points seem to deviate from the theoretical curve in a minor way. However, as the alkali concentration is increased with concomitant reduction of the potassium chloride concentration, the potential at the liquid junction $KCl_{satd.}$ KOH, KCl no doubt changes by greater and greater increments, and introduces a larger and larger error into the potential measurements. We hope to show presently that the values of $E_m$ and $p$H may be trusted up to a $p$H of 14 to 14.2 (0.2 to 0.3 $M$ potassium hydroxide); there is reason to think that beyond that point the seemingly fair agreement of the data with the theoretical curve is spurious.

The *index potentials* should be reliable regardless of any error caused by the liquid junction potential, because they are relative values that depend only on the shape of the titration curves and not on the absolute values of the mid-point potentials. Consequently the values of the semiquinone formation constant $k = (S)^2/(R)\times(T)$ are significant, and so are the values for $E_2 - E_1$ computable from $k$. Unfortunately most of our values for $E_2 - E_1$ had to be calculated in that region where small variations of $E_i$ cause a large uncertainty in the value of this potential difference; nonetheless we feel that to the left of $p$H 14 the data for $E_2$ and $E_1$ conform at least qualitatively to the theoretical curves which we have drawn for these two potentials in Fig. 1. From this agreement we draw the conclusion that the values for $E_m$ and $p$H may also be fairly reliable within the same region.

The slope of the $E_2$-curve changes from 59 mv. to zero at a region labelled $K_S$, which corresponds to a transition from the first to the second of the following equilibria. In the region of

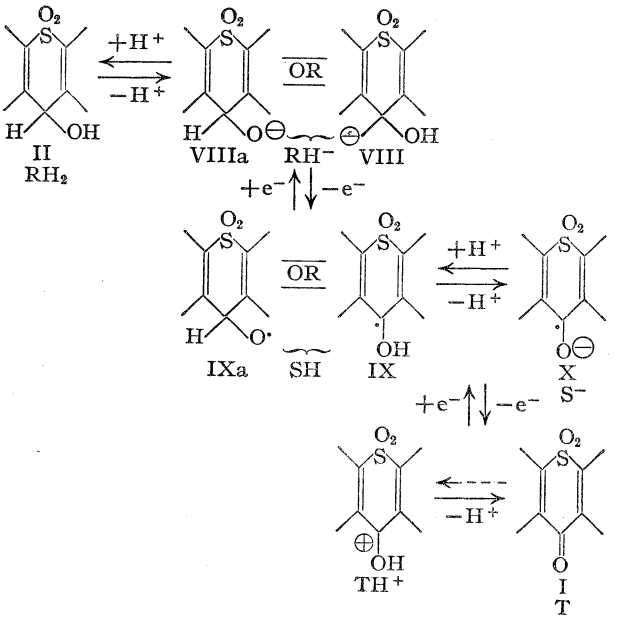
$$SH \rightleftharpoons T + H^+ + e^-$$
$$S^- \rightleftharpoons T + e^-$$

zero slope the semiquinone differs from the ketone I merely by one additional electron. Because of the proximity of $K_S$ and $K_R$ as drawn in Fig. 1 the bends in the theoretical $E_1$-curve are not clearly visible; we have tried to indicate changes from slope 59 to 118 and back to 59, corresponding to the equilibria

$$RH_2 \rightleftharpoons SH + H^+ + e^-$$
$$RH_2 \rightleftharpoons S^- + 2H^+ + e^-$$
$$RH \rightleftharpoons S^- + H^+ e^-$$

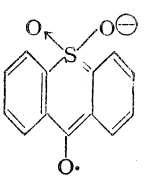
The theoretical $E_2$-curve continues beyond $p$H 14 with a slope of zero, and the other two curves are drawn accordingly. The experimental values of $E_2$ and $E_1$, calculated by adding $\pm(E_2-E_1)/2$ to the measured value of $E_m$ diverge markedly from the lines; indeed, $E_2$ seems to rise again. We have considered the possibility that this might indicate a second acidic dissociation of the semiquinone, involving a species $SOH^{--}$. This idea is not acceptable on electrochemical grounds and on the basis of other considerations; *e. g.*, it is inconceivable that $S^-$, a negative ion, should act as a Lewis acid to accept a hydroxyl ion when T (I), which does not bear any charge, shows no signs whatever of such a dissociation. Furthermore, in the light of the great stability of the S-form relative to $R$ and $T$ in the region under discussion ($k$ for runs 8a and 9a equals 3.2–3.5) existence of the semiquinone as $SOH^{--}$ is excluded because any structural expression of such an entity implies that it would be of very high energy. Thus we believe that the theoretical system of curves approximates the true situation; the experimental points deviate because beyond $p$H 14.2 both $E_m$ and $p$H are falsified by increasingly larger errors. For instance, in runs 8a and 9a $E_2 - E_1$ equals 31 mv.; the curves drawn differ by this amount at "$p$H" 14.80, where the $E_m$-curve has a value of $-647$ mv. This is taken to mean that the potential measurements upon which $p$H and $E_m$ are based must have been in error by $+15$ to $+16$ mv.[12]

The data of Table I give rise to a plot of similar pattern (not included in this article). Although the experimental points show considerable scatter, which is to be expected in view of the variable conditions in this series of experiments, we believe that the plot corroborates the conclusions we have drawn from Fig. 1.



We do not intend to attach quantitative significance to the values of $K_R$ and $K_S$ which, in any

(11) It is convenient, in slight modification of existing usage,[6,9] to use the letters T, S and R for general reference to the oxidized, semiquinone and reduced forms in an oxidation-reduction equilibrium, and to indicate charges and dissociable protons by means of the usual symbols and by the letter H, respectively, attached to these letters in discussions of protolytic equilibria. Thus a reduced form with two dissociable protons can give rise to the species $RH_2$, $RH^-$ and $R^{--}$.



(12) We are indebted to Dr. L. Michaelis for the suggestion that the possibility of measuring index potentials in highly alkaline media may be used to extend the $p$H scale toward the alkaline side similarly to its extension to strongly acid media by Michaelis and Granick, THIS JOURNAL, 64, 1861 (1942).

case, would be hard to interpret, nor do we believe that the relative positions of these bends on the graph should be taken as precise. We do feel, however, that the data and the interpretation attempted make probable in a qualitative way the actual existence of the several protolytic and oxidation–reduction equilibria discussed. The colorimetric measurements agree with the view that $S^-$ is the blue entity, the relative amount of which increases rapidly as one approaches the region where most of the reduction–oxidation system exists, at half-oxidation, as the semiquinone form. The purplish appearance of the solution at lower alkalinity is quite possibly due to SH, the conjugate acid of the semiquinone, which may perhaps be identified with the red species described before. If one ascribes greater tinctorial power to $S^-$ than to SH, which appears to be a reasonable assumption (*cf.* formulas IX and X), the preponderance of the blue color even at low alkalinity becomes understandable, although in this region SH must be present in concentrations comparable to, or greater than, those of $S^-$. A region where the solution was of a pure pink at the midpoint of the titration was not realized experimentally, and the appearance of the pink color only at the extreme ends of the oxidation process is puzzling. Since no reversion of the pink to purple was visible within thirty minutes, we do not believe that sluggish establishment of the equilibrium near the end-point is the cause; on the other hand, the ratio $(S^-)/(SH)$ should be independent of the total concentration of the S-form for any given *p*H. At this time we cannot offer an adequate explanation for the phenomenon.

We have formulated the species involved in the equilibria considered in this discussion in the accompanying set of structures, which are so arranged that horizontal displacements correspond to protolytic equilibria, vertical ones to oxidation–reduction changes. The species $TH^+$ is included for the sake of clarity; there is no reason to believe that it is present and therefore the appropriate equilibrium arrow is shown as a broken line. Both VIII and VIIIa must be considered as expressions for $RH^-$ and the present work does not furnish conclusive evidence in favor of either one. The known mobility of the hydrogen atom in benzohydryl ethyl ether[13] as well as such phenomena as the ready isomerization oxanthrone–anthrahydroquinone might be cited as precedent supporting the carbanion structure VIII. Such an ion would be expected to be stabilized by resonance to a considerable degree, but it might also be expected to show some color, which was not observed in the alkaline solution of $RH_2$. The intrinsic greater mobility of a proton bound to oxygen argues in favor of structure VIIIa, but when one considers the formulations IXa and IX for SH, which results from $RH^-$ by loss of one electron, formula IX alone seems capable of accounting for the small but definite stability of this free radical. Since the formation of IX is best understood if VIII is

assumed to be its precursor, we consider the carbanion formula VIII preferable to the alkoxide structure VIIIa. The stable form of the semiquinone, $S^-$, is formulated as the ion-radical structure X. Species $S^-$ should be represented by two structures showing the usual resonance of a metal ketyl grouping; furthermore, both the charge and the lone electron must be thought of as distributed over the lateral rings so that for X one has to consider at least 13 additional structures (excluding Kekule resonance) of comparable energy. In most of the known cases of stable semiquinones one can write limiting structures in which the charge and the lone electron are distributed to both of two atoms other than carbon, such as nitrogen or oxygen, so that a state of more or less equivalent resonance exists. We should like to raise the question whether in a formulation of $S^-$ structures involving distribution of the charge and of the lone electron to the sulfone oxygens ought to be considered, *e. g.*, structures like XI.

XI

This consideration touches upon the problem whether sulfur is capable of expanding its valence shell with utilization of a 4s or 3d orbital without a great increase in the energy of the system. Although this problem has recently been discussed in

[a] When only one value for $E_i$ is listed this was obtained from the straight line of a plot of the e. m. f. *versus* the logarithm of the ratio % oxidized/(100 − % oxidized). The important section of such plots deviated only negligibly from linearity. [b] No potassium chloride was added in these runs. [c] Owing to the slowness of the equilibrium this run required six hours for completion and $E_{i\ left}$ differed by three to four mv. from $E_{i\ right}$. The value listed pertains to the left-hand side; it is not considered reliable.

TABLE II

OXIDATIVE TITRATIONS OF II IN AQUEOUS DIOXANE AT 24.5 ± 0.5°

In all experiments except no. 9a the concentration of II was $10^{-3}$ *M*; in run 9a it was $3 \times 10^{-3}$ *M*. The buffer consisted of 16 cc. of dioxane and 35 cc. of an alkali solution of the composition listed.

| Expt. | Composition of alkali solution KOH *M* | KCl *M* | *p*H | $E_i$ 25%, mv. | $E_i$ 75%, mv. | $E_m$, mv. |
|---|---|---|---|---|---|---|

[a] Run 3bb was carried out by retitrating the sample used in run 3b after the reduction for the final measurement of *p*H. The same amount of ferricyanide was consumed; possibly the slight change in the medium is responsible for the rise of 3 mv. of $E_m$.

several places[14] the question remains open. The remarkable stability of the ion-radical X may have some bearing on this point.

Finally we should like to consider the slow step in the oxidation–reduction equilibrium manifest during air oxidations and visible during titrations in the lower *p*H region. Here each addition of a portion of oxidizing agent discharges the blue color immediately; the tint returns after a short period of time and reaches a maximum density. Simultaneously the e. m. f. becomes constant with time. Apparently the conversion of S to T is fast and the regeneration of S is slow. The process most likely to be time-consuming is the dissociation of $RH_2$ to $RH^-$, because a number of carbon–hydrogen dissociations on record are known to be slow, and it is reasonable to assume that $RH^-$ rather than $RH_2$ is the species that is being oxidized by ferricyanide or by T to give SH and then $S^-$. The observation that at low *p*H the potentials are established very slowly agrees with this interpretation.

## Experimental[15]

### A. Preparative Part

**Thiaxanthenol-5-dioxide (II). (a) By Reduction of I.**—A solution of 8.9 g. of I in 150 cc. of glacial acetic acid and 30 cc. of water was boiled for five minutes with 10 g. of zinc dust, filtered, and diluted with much water when

(14) (a) Bordwell and Albisetti, THIS JOURNAL, **70**, 1558 (1948); (b) Doering and Levy, Acidity of a Bicyclic Trisulfone, presented at the 112th meeting of the American Chemical Society, New York, N. Y., September, 1947; (c) Woodward and Eastman, THIS JOURNAL, **68**, 2229 (1946). There earlier references may be found.

(15) All melting points are corrected.

7.48 g. of a hydrate of II separated. Recrystallization from 400 cc. of benzene yielded 6.6 g. (73.5%) of large prisms of II, m. p. 184.2–186.2°, and another 0.5 g. (6%) was obtained from the mother liquors. The pure alcohol melts at 186–187.5°; the melting point is somewhat uncertain because on slow melting the alcohol partly changes to the ether V.

**(b) By Alkaline Hydrolysis of IV in Methyl Alcohol.**—Into a glass-stoppered flask equipped with gas-inlet and outlet tubes fitted with stopcocks was placed a small test-tube containing 1 g. of IV, 50 cc. of absolute methanol (commercial) and 1.15 g. of sodium. Contact between the contents of the test tube and the solvent was avoided. After the metal had dissolved oxygen-free nitrogen was passed through the liquid for twenty-five minutes; then the system was closed and the acetate was caused to fall into the methoxide solution. The solid dissolved and a very faint lavender color developed. After the mixture had stood at room temperature for one hour 10 cc. of 6 *N* hydrochloric acid was added quickly, followed by 200 cc. of water. The excess acid was neutralized with bicarbonate and 800 mg. (87.3%) of II was collected, m. p. 186.5–187°.

**(c) By Acid Hydrolysis of IV.**—This reaction proceeds rapidly in hot solutions, but the product is contaminated with the chloride VII when hydrochloric in acetic acid is used, and with the ether V in the case of sulfuric acid.

*Anal.* Calcd. for $C_{13}H_{10}O_3S$: C, 63.40; H, 4.09. Found: C, 63.29, 63.55; H, 4.11, 4.23.

**10-Bromothiaxanthene-5-dioxide (VI).**—To a solution of 10.4 g. of III in 1 l. of carbon tetrachloride was added 7.6 g. of bromine dissolved in the same solvent, and the mixture was boiled for one and three-quarters of an hour. The bromide began to crystallize during this period; it was obtained in the form of a tan powder. The yield was 12.25 g. (87.6%). The material may be recrystallized from hot dioxane; it darkens at 260° but does not melt.

*Anal.* Calcd. for $C_{13}H_9O_2SBr$: C, 50.50; H, 2.93; Br, 25.85. Found: C, 50.85; H, 3.19; Br, 25.83, 26.83.

**10-Chlorothiaxanthene-5-dioxide (VII).**—To the solution of 0.4 g. of IV in 7.5 cc. of hot glacial acetic acid was added 2.5 cc. of concentrated hydrochloric acid. After a few seconds VII began to separate; heating was continued for one and one-half minutes, then the mixture was cooled and filtered. Water precipitated a small additional amount of VII from the filtrate. The yield was 0.35 g. (95%); recrystallization from benzene yielded shiny prisms that melt with discoloration at 253–258°. The compound gives a strong Beilstein test.

The alcohol II is converted to the same substance when treated as described.

*Anal.* Calcd. for $C_{13}H_9O_2SCl$: C, 58.98; H, 3.43. Found: C, 59.49, 58.95; H, 3.67, 3.51.

**10-Acetoxythiaxanthene-5-dioxide (IV).—(a) By reductive acetylation.**—To a mixture of 0.5 g. of I and 0.5 g. of zinc dust was added 5 cc. of acetic anhydride and one drop of triethylamine. The mixture became warm during five minutes and then cooled off again. It was heated for five minutes on the steam-bath, filtered, and decomposed with water at 100°. The product separated as a colorless solid weighing 0.52 g. (88%), m. p. 154–156°. Recrystallization from benzene or from alcohol yields the pure acetate, m. p. 155.6–157°. The substance may appear in the form of needles or leaflets, and of hexagonal plates; occasionally a sample resolidifies after melting as described and remelts at 158–158.5° or 159–160°. The use of larger amounts of base during the acetylation leads to contamination of the product by a small quantity of an unidentified yellow substance.

**(b) From the Bromide VI.**—A mixture of 12.25 g. of VI, 7 g. of silver acetate, and 100 cc. of glacial acetic acid was stirred on the steam-bath for one-quarter of an hour. After filtration water was added and the whitish product was collected. Recrystallization from alcohol afforded 8.4 g. (73.5%) of pure IV, m. p. 154.8–156.8°.

Acetylation of II in the usual manner with pyridine and acetic anhydride gave IV in 99% yield.

*Anal.* Calcd. for $C_{15}H_{12}O_4S$: C, 62.48; H, 4.19. Found: C, 62.46, 62.53; H, 4.33, 4.45.

**Ether of Thiaxanthenol-5-dioxide (V).**—The alcohol II (0.2 g.) was heated in an oil-bath at 197 ± 5° for one-half hour when the melt solidified to a compound melting at 262–272° with discoloration. The solid was recrystallized from glacial acetic acid (15 cc.) which deposited 0.14 g. (72%) of a colorless crystal powder having the composition of V and melting at 280–283° with darkening.

*Anal.* Calcd. for $C_{26}H_{18}O_5S_2$: C, 65.80; H, 3.82. Found: C, 65.95, 65.66; H, 4.00, 3.93.

**Solubility of II in Alkali.**—To 20 mg. of II contained in a small ampoule was added 1 cc. of a mixture of 1.5 cc. of dioxane, 3.5 cc. of potassium hydroxide and 66 mg. of sodium dithionite. The vessel was sealed, and the blue color that had developed disappeared soon. The solid dissolved within a few minutes of agitation at room temperature. When the vessel was opened the blue color reappeared rapidly.

When 20 mg. of II was treated similarly with 1 cc. of 30% aqueous dioxane, partial solution occurred only on heating, and most of the material crystallized again on cooling to room temperature.

### B. Study of the Oxidation Reduction Equilibrium

**Alkaline Cleavage of the Oxidation Reduction System.**—A mixture of 100 mg. of each ketone I and alcohol II, 5 cc. of pyridine and 10 cc. of 0.6 *N* sodium hydroxide was sealed into a pyrex glass ampoule, without any special precautions to keep out oxygen from the air. The deep blue liquid was heated at 110° for two days at the end of which the color had faded to a very pale yellow. The originally homogeneous solution had separated into two phases, one of which had a volume of about 2 cc. and appeared to be a concentrated alkaline solution of sodium silicate. On dilution with water a white solid separated, which was collected, dried, and extracted with benzene. A residue of silica was left undissolved; the filtrate contained 22 mg. of a white compound melting at 174–176°, which after recrystallization melted at 175.4–176° and did not depress the melting point of authentic xanthone.

The alkaline pyridine–water filtrate was freed of pyridine under reduced pressure and a small amount of solid separated, identified as I by its color reaction with zinc and alcoholic potash. On acidification of the filtrate a strong odor of sulfur dioxide was observed, but no other identifiable fission products were isolated.

**Acid Decomposition of the Blue Solution.**—To 40 cc. of ethanol in an erlenmeyer flask equipped with a ground-glass stopper was added 1.9 g. of sodium, while the flask was cooled with ice. After dissolution of the metal 0.5 g. each of I and II was added rapidly and the flask was stoppered. After agitation with slight warming for fifteen minutes most of the material had dissolved and the liquid was a dark inky blue. The material was poured rapidly into 6 cc. of acetic acid and the flask was rinsed with a few additional cc. of the same acid. By filtration of the solution, dissolution of the precipitated sodium acetate with water, collection of the organic material precipitated by more water, and finally removal of the organic solvents under reduced pressure and recrystallization from ethanol of the deposited organic material, four crops of I totalling 242 mg., m. p. 187.2–188.6°, were obtained.

The ethanolic mother liquor was diluted with water and the precipitated solid was collected and dried. Owing to mechanical loss the weight of this fraction is not known precisely but estimated at 200 to 250 mg. On recrystallization from benzene 50 mg. of II was obtained, m. p. 186–187° alone or when mixed with authentic II.

Although only a fraction of the total material was accounted for, the conclusion is justified that no significant amounts of the pinacol could have been present because this substance should have appeared among the least

soluble, high-melting fractions, yet no trace of such a compound was detected at any point during the separation.

**Air Oxidation of II.**—To a solution of 500 mg. of II in 4 cc. of pyridine and 3 cc. of water was added 7 cc. of 1 *N* tetramethylammonium hydroxide. An inky blue coloration resulted at once and white crystals were being deposited. The solution was agitated for seven minutes when the blue color had disappeared permanently. The pale orange liquid was filtered from the solid which weighed 460 mg. (93%), m. p. 186–187.8°.

**Colorimetry.**—A Thunberg tube was equipped with gas inlet tubes fitted with stopcocks and extending to the bottom of the main compartment and of the side-arm. Into the side-arm was placed 0.5 cc. of a solution containing $8.4 \times 10^{-3}$ mole/l. of each I and II in pyridine; the main compartment contained 4.5 cc. of a pyridine-buffer mixture. Hydrogen was passed through for ten minutes, admitted through an all-glass train; then the vessel was closed, inserted into a Klett colorimeter (red filter, no. 66) and the galvanometer was zeroed. The liquids were mixed, the tube was replaced in the same position and the optical density was read as usual. The results are as follows:

| Alkali *M* | Optical density |
|---|---|
| 0.027 | 0.106 |
| .11 | .265 |
| .91 | .850 |

**Spectrophotometry.**—Flat-bottomed ampoules drawn from a piece of 16-mm. pyrex tubing were filled with pyridine-alkali mixtures as used in runs 4, 8 and 17 in Table I and pure nitrogen was bubbled through the liquid for ten minutes. The ampoule was closed with a rubber cap and a small amount of a strong solution (about 0.01 *M*) of II in pyridine was added by means of a syringe and hypodermic needle. The oxygen contained in the pyridine solution as well as oxygen remaining in the buffer mixture caused the immediate appearance of the blue color of the semiquinone. When the intensity appeared suitable the ampoule was sealed; some heat decomposition near the neck of the ampoule could not be avoided. After several attempts samples suitable for spectrophotometry were obtained; the degree of oxidation or the concentration of the oxidation–reduction system are, of course, not known. The ampoules were placed into the cell holder of a Beckman spectrophotometer and the place for the blank solvent was occupied by an ampoule filled with pyridine-alkali. In spite of the optically most unsatisfactory shape of the ampoules the optical densities appeared to be reproducible within about ±1% of their numerical values on successive measurements when the cell holder was shifted from and restored to its rest position in the instrument. The results are listed.

| Alkali *M* | λmax. (mμ) | *D* max. | λmin. (mμ) | *D* min. | λmax. (mμ) | *D* max. | $\frac{D_{370}}{D_{475}}$ |
|---|---|---|---|---|---|---|---|
| 0.027 | 370 | 1.76 | 475 | 0.258 | 570 | 0.79 | 2.54 |
| .14 | 370 | 2.9 | 475 | .431 | 570 | 1.46 | 3.39 |
| .91 | 370 | 2.9 | 475 | .509 | 570 | 1.29 | 3.06 |

The columns labelled *D* refer to the optical density registered; the densities at 370 mμ are so high that their quantitative significance is very small.

The red form in aqueous dioxane was studied in the presence of 0.11 mole/liter potassium hydroxide in a square Corex glass cell equipped with a ground-in glass-stopper, into which the liquid was forced by nitrogen pressure from a titration cell where it had been obtained by careful oxidation of a blue solution with air-saturated buffer. No change in color was visible after such a pink solution had stood in the titration cell under nitrogen for one-half hour. Because of the low concentration and the sensitivity of the system, some air oxidation could not be avoided during the transfer, and the optical density of the solution finally secured in the cell was very low: at the absorption maximum at 470 and 480 mμ the sample had an optical density of only 0.051. The red form could also be seen during the potentiometric titrations, although, as shown by a separate experiment, the palladium colloid tends to obscure the color.

Existence of the red form could be demonstrated not only at the *p*H mentioned but also at lower and higher alkalinity. On the basis of visual inspection the red form seems to make a greater contribution to the total color at low alkalinity, but apart from the somewhat debatable spectroscopic data there is no objective evidence for this subjective estimation of color.

**Potentiometry.**—The procedure was based on Michaelis' recommendations.[16] The nitrogen was purified by passage through Fieser solution followed by lead acetate solution and a 25-cm. section of copper filings heated to 450°. The gas was conducted to the titration cell through all-glass connections made flexible by means of a ball-and-socket joint, and proved to be inert toward moist white phosphorus. The cell was equipped with two electrodes of shiny platinum (*ca.* 1 sq. cm.), gas outlet, buret, etc., and an externally operated electromagnetic stirrer was found to be a convenient means of agitation. A sleeve-type saturated calomel half-cell was used to complete the galvanic chain. Potentials were measured with a type K-2 potentiometer and a Leeds and Northrup box-type galvanometer having a sensitivity of $1.7 \times 10^{-8}$ amp. per mm.

The pyridine used as a solvent was purchased from the Barrett Company, New York ("Barrett refined") and purified by distillation through a Widmer column. The dioxane was purified by the customary treatment with hydrochloric acid and then sodium metal.

Stock solutions of II appeared to be stable for a week or two when pyridine was the solvent. After this length of time they were generally discarded because of the appearance of a faint yellow tinge. No discoloration was noticeable with dioxane solutions, but some change did take place within a month of standing. As a rule, only fresh solutions were used.

The composition of the reaction media is listed in Tables I and II. At the beginning of a run the added II was partly or wholly oxidized to I by the oxygen contained in the solvents. Colloidal palladium was added and hydrogen was passed in until the blue color had been discharged and the potential of the chain had become constant and equal to within 0.1 mv. for the two electrodes; the *p*H was computed from the e. m. f. thus observed. Some difficulty was experienced in the most alkaline media because of premature coagulation and deactivation of the colloid. The e. m. f. would reach a maximum value, keep this value for a few minutes, and then, while hydrogen was still being admitted, the potential would begin to drift away from its steady position. An additional amount of palladium would generally restore the e. m. f. close to its previous steady value, and there is no reason to doubt that this potential does correspond to equilibrium conditions. At the highest alkalinities it was sometimes found difficult to expel the hydrogen from the system prior to the beginning of the oxidative titration, presumably owing to retention of the gas by the coagulated palladium. If in such cases a reasonable rise of the potential could not be achieved within about one-half hour after the addition of the first few per cent. of oxidizing agent the run was discarded. Three kinds of palladium colloid were investigated; a commercial product ("Baker Colloid 46"), a colloid stabilized with gum arabic[17] and one containing sodium protalbinate.[18] The last-named preparation, obtained according to Paal's original recommendation by reduction of palladous chloride with hydrazine, proved to be the most satisfactory for our purposes. The sodium protalbinate had been made from a sample of commercial egg albumin.

(18) Paal and Amberger, *ibid.*, **37**, 134 (1904).

The oxidizing agent was potassium ferricyanide, used in aqueous buffer solutions for the pyridine runs; the concentrations were chosen so that from 3 to 5 cc. of oxidizing solution was added to the 50-cc. volume containing the oxidation–reduction system in the titration cell. In the dioxane runs the ferricyanide was dissolved freshly for each experiment in the same solvent mixture that was used as buffer in the titration cell; the volumes added were between 3 and 4 cc. for 50 cc. of buffer containing the oxidation–reduction system.

In most runs the potentials were established about as rapidly as the potentiometer could be adjusted, and the potentials registered by the two electrodes agreed with one another within ±0.1 mv. or better, except in the regions of 0 to 5% and 95 to 100% completion. The potentials were stable with time and in general showed no noticeable drift. At the lower alkalinities potentials were established more and more sluggishly and, particularly toward the end-point, long periods of waiting became necessary. In such cases it was advantageous to use the return of the blue color as a guide rather than to wait for the potential to fall to a constant value.

Finally the *p*H was measured again after addition of more palladium colloid, and the tables give the average of the initial and final *p*H value together with the deviation of these figures from the average. In all cases the higher *p*H is the initial one.

**Acknowledgments.**—We are grateful to Professor L. Michaelis for his advice and his interest.

We take pleasure to thank the Graduate Council of the University of Oregon for a grant which helped to further the investigation reported.

## Summary

1. Thiaxanthenol-5-dioxide and several of its derivatives have been prepared and characterized.

2. The existence of a mobile, two-step oxidation–reduction equilibrium between thiaxanthenol-5-dioxide and thiaxanthone-5-dioxide in alkaline solution has been established. By optical, chemical and electrochemical means it was shown that the colored entity in this equilibrium is a semiquinone.

3. The structure of the semiquinone is discussed with particular reference to potential *vs.* *p*H diagrams.

# The Relative Reactivities of Chloromethyltrimethylsilane and Chloromethylpentamethyldisiloxane

BY GEORGE F. ROEDEL

When chloromethyl siloxanes are treated with alkaline reagents, Si–C cleavage of the $-SiCH_2Cl$ group occurs to form methyl chloride.[1] It has been claimed that the cleavage is accompanied by a competitive hydrolysis of the C–Cl bond.[1] On the other hand no Si–C cleavage of the $-SiCH_2Cl$ group was reported when chloromethyltrimethylsilane was treated with basic reagents.[2] Since methyl chloride, the cleavage product, reacts with the alkaline reagents used in the previous work cited, it was not clearly established that hydrolysis of the C–Cl bond in chloromethyl siloxanes occurs to any significant degree nor that Si–C cleavage is absent with chloromethyltrimethylsilane. In an effort to establish these points and to further elaborate the effect of silicon-bonded oxygen on the behavior of the functional group attached to the silicon, the reactivities of $(CH_3)_3SiCH_2Cl$ (I) and $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ (II) have been compared in this paper.

The activating effect of oxygen bound to silicon has previously been shown by Sommer, Bailey, Strong and Whitmore.[3] They found markedly greater reactivity of the C–Cl bond in α-chloroethyldiethylsilanol as compared with α-chloroethylmethyldiethylsilane toward such reagents as sodium ethoxide in ethanol and potassium acetate in glacial acetic acid.

Whitmore and Sommer[2] found that chloromethyltrimethylsilane (I) with sodium iodide in dry acetone gave a good yield of the corresponding iodide. In this study chloromethylpentamethyldisiloxane (II) was found to behave similarly with this reagent to also give the iodide in good yield.

$$(CH_3)_3SiOSi(CH_3)_2CH_2Cl + NaI \longrightarrow (CH_3)_3SiOSi(CH_3)_2CH_2I + NaCl$$

III

Neither α-chloroethyldiethylsilanol,[3] nor I, nor II reacts with aqueous or ethanolic silver nitrate. Iodomethyltrimethylsilane is also unreactive with silver nitrate reagents,[2] but iodomethylpentamethyldisiloxane (III) reacts readily with ethanolic silver nitrate to precipitate silver iodide.

Both chloro-(II) and iodomethylpentamethyldisiloxane (III) readily form Grignard reagents in a similar manner to chloro-(I) and iodomethyltrimethylsilane.[2]

The Si–C bond of the chloromethylsilyl group, $-SiCH_2Cl$, is not split by sulfuric acid at room temperature. This was shown by adding small amounts of I and II to methyl siloxane systems of known functionality and equilibrating with sulfuric acid.[4] The viscosities of the oils obtained

(2) Whitmore and Sommer, *ibid.*, 68, 481 (1946).
(3) Sommer, Bailey, Strong and Whitmore, *ibid.*, 68, 1881 (1946).
(4) Roedel, *Anal. Chem.*, 20, 705 (1948).

showed that the change in functionality which would have accompanied cleavage of the Si–C bond did not occur.

The greater reactivity of the $-SiCH_2Cl$ group when oxygen is also bonded to the silicon is shown by the results tabulated in Table I. The reactivity of chloromethylpentamethyldisiloxane (II) was significantly greater than that of chloromethyltrimethylsilane (I) with sodium ethoxide in absolute ethanol and potassium acetate in glacial acetic acid. This behavior parallels closely the greater reactivity of α-chloroethyldiethylsilanol as compared to α-chloroethylmethyldiethylsilane with the same reagents.[3] With potassium hydroxide in *n*-butanol the difference in reactivity between I and II was slight.

TABLE I

RELATIVE REACTIVITIES OF CHLOROMETHYLTRIMETHYLSILANE AND CHLOROMETHYLPENTAMETHYLDISILOXANE

| Reagent[a] | Reaction, % $(CH_3)_3SiCH_2Cl$ (I) | Reaction, % $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ (II) |
|---|---|---|
| 2.0 *M*-$C_2H_5ONa$/abs. $C_2H_5OH$ | 36 | 91 |
| ($1^2/_3$ hours reflux) | (35-1-0)[b] | (59-29-3) |
| 1.0 *M*-$CH_3CO_2K$/glacial $CH_3CO_2H$ | 2 | 76 |
| ($1^3/_4$ hours reflux) | (2-0-0) | (76-0-0) |
| 1.0 *M*-KOH/moist $C_4H_9OH$ | 77 | 90 |
| ($1^3/_4$ hours reflux) | (67-10-trace) | (47-43) |
| 1.0 *M*-KOH/moist $C_4H_9OH$ | 77 | 80 |
| (1 hour reflux) | (71-6-0) | (62-17-1) |

[a] Molar ratio of $C_2H_5ONa$, $CH_3CO_2K$ and KOH to $(CH_3)_3SiCH_2Cl$ or $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ was 2:1. [b] Figures in parentheses give % reaction determined for the reaction flask, trap 1 and trap 2, respectively.

Since it had previously been shown that alkaline reagents react with chloromethyl siloxanes to form methyl chloride,[1] provision was made for determining any methyl chloride which formed and escaped from the reaction mixtures. This was effected by using bubbler traps filled with sodium ethoxide in absolute ethanol. The reaction between methyl chloride and sodium ethoxide in absolute ethanol is rapid and complete when the reagent is warm. The decrease in concentration of the sodium ethoxide in the traps is a measure of that methyl chloride which formed and escaped from the reaction mixture.

Since methyl chloride does not react with 1.0 *M* potassium acetate in glacial acetic acid, the fact that all of the sodium ethoxide remained unreacted in the traps is good evidence that no –Si–C cleavage of the $-SiCH_2Cl$ group in I or II occurs with this reagent. This evidence indicates the reaction to be entirely bimolecular nucleophilic substitution on the methylene carbon as suggested by Whitmore and Sommer.[2]

With sodium ethoxide in absolute ethanol and potassium hydroxide in *n*-butanol, however, formation of methyl chloride shows that Si–C cleavage of the $-SiCH_2Cl$ group occurs with both I and II. The trap figures are minimum figures for the Si–C splitting, since methyl chloride can react with both reagents.

It is not shown in this work whether hydrolysis of the C–Cl bond accompanies cleavage of the Si–C bond in chloromethyl siloxanes. However, the inadequacy of a chloride ion determination in the reaction vessel as sole measure of a C–Cl hydrolysis reaction is established. The cleavage product methyl chloride reacts readily with alkaline reagents, and the amount which escapes from the reaction zone varies with the experimental conditions.[5] Actually determining the presence or absence of a hydrolytic reaction is not readily accomplished. Isolation of ethoxymethylpentamethyldisiloxane, the expected product of the hydrolytic reaction of II with sodium ethoxide in absolute ethanol, was attempted but was unsuccessful. Rearrangement of siloxane bonds during the reaction produces a series of methyl siloxanes[1] that make isolation by fractional distillation difficult. Even were it proved that no ethoxymethylpentamethyldisiloxane were present in the reaction product, the possibility would still exist that it formed but was in turn subjected to Si–C cleavage of the $Si-CH_2OC_2H_5$ group by the reagent. Such a cleavage would presumably produce methyl ethyl ether, but this is also the product of the methyl chloride–sodium ethoxide reaction.

However, the reaction of sodium ethoxide in absolute ethanol with chloromethyltrimethylsilane (I) has been elaborated. The chief attack is at the methylene carbon (1). Of the total reaction, however, 5–10% is attack at the silicon

$$(CH_3)_3SiCH_2Cl + C_2H_5ONa \xrightarrow{C_2H_5OH} \underset{\text{IV}}{(CH_3)_3SiCH_2OC_2H_5} + NaCl \quad (1)$$

with resultant Si–C bond cleavage. This cleavage reaction is primarily reaction (2) but some Si–C cleavage of the $-SiCH_2OC_2H_5$ group of

$$(CH_3)_3SiCH_2Cl + C_2H_5OH \xrightarrow{C_2H_5ONa} (CH_3)_3SiOC_2H_5 + CH_3Cl \quad (2)$$

(5) When 1.95 g. of chloromethylpentamethyldisiloxane and 9.9 cc. of 2.0 *M* sodium ethoxide in absolute ethanol were allowed to react in a 25-cc. test-tube, the methyl chloride detected in the trap system varied with the rate of reflux. Vigorous reflux for one hour and forty minutes gave a total reaction of 91%. The methyl chloride escaping to the trap system represented 32% of the reaction. Gentle reflux for a similar period produced 90% total reaction with methyl chloride caught in the traps representing but 21%. In these reactions a hot bath was raised around the reaction tube. In another experiment 150 g. of chloromethylpentamethyldisiloxane and 755 cc. of 2.0 *M* sodium ethoxide in absolute ethanol were allowed to react in a one liter round-bottomed flask, the mixture being heated to reflux by means of a heating mantle over a forty-five minute period and continued at reflux for four hours. Methyl chloride which escaped from the reaction mixture was not determined but an extent of reaction of 86% in the reaction flask indicates that under such conditions much less methyl chloride escapes. It is, however, possible that when the temperature is raised slowly the course of the reaction is changed and less Si–C cleavage occurs.

ethoxymethyltrimethylsilane (IV) may also occur. The evidence for these conclusions consists of (a) the isolation and characterization of ethoxymethyltrimethylsilane (IV), (b) the determination of the amount of monofunctional methyl siloxane, $(CH_3)_3SiO_{1/2}$, in the product, (c) the measurement of methyl chloride evolved, and (d) the identification of hexamethyldisiloxane and IV in the product by means of the mass spectrometer.

## Experimental

**Preparation of Chloromethylpentamethyldisiloxane (II) and Chloromethyltrimethylsilane (I).**—The method described by Krieble and Elliott[6] was employed in preparing chloromethylpentamethyldisiloxane, $n^{20}D$ 1.4102, b.p. 151–152°.

Chloromethyltrimethylsilane[2] was made by treating a mixture of chloromethylmethyldichlorosilane[1] and chloromethyldimethylchlorosilane[1] with methylmagnesium bromide.[7] Dibutyl ether was used as the solvent. The chloromethyltrimethylsilane used for the comparative reactivity experiments had these properties: b.p. 98.2–98.7° (747 mm.), $n^{20}D$ 1.4169, Cl, 28.4, 28.5 (calcd. for $C_4H_{11}SiCl$, 28.9 Cl).

**Iodomethylpentamethyldisiloxane (III).**—The technique employed for the preparation of III followed in detail that used by Whitmore and Sommer in the preparation of iodomethyltrimethylsilane.[2] From the reaction of 65.5 g. (0.44 mole) of dry sodium iodide and 49.5 g. (0.25 mole) of chloromethylpentamethyldisiloxane (II) and 500 cc. of dry acetone was obtained upon fractionation 54.5 g. (0.19 mole) of iodomethylpentamethyldisiloxane, b.p. 77° (20 mm.), 187° (757 mm.), $n^{20}D$ 1.4575. The yield was 76%.

*Anal.* Calcd. for $C_6H_{17}Si_2OI$: I, 44.0. Found: I, 43.6, 43.6.

**Reactions with Silver Nitrate.**—One gram of chloromethylpentamethyldisiloxane was added to 25 cc. of 20% aqueous silver nitrate. No precipitate formed even after five minutes of boiling. The result was the same when a saturated ethanol solution of silver nitrate was used. Treating chloromethyltrimethylsilane with the same reagents likewise produced no reaction.

One gram of iodomethylpentamethyldisiloxane with 25 cc. of 20% aqueous silver nitrate showed only faint opalescence after five minutes of boiling. In ethanolic silver nitrate at room temperature a faint turbidity developed in a few seconds and after five minutes a curdy precipitate of silver iodide had settled.

**Grignard Reagents from Chloro- and Iodomethylpentamethyldisiloxane: $(CH_3)_3SiOSi(CH_3)_2CH_2MgCl$ and $(CH_3)_3SiOSi(CH_3)_2CH_2MgI$.**—A mixture of 3.9 g. (0.02 mole) of chloromethylpentamethyldisiloxane, 0.5 g. (0.02 mole) of magnesium turnings and 10 cc. of dry ethyl ether was placed in a 125-cc. flask topped by a reflux condenser and a Drierite–Ascarite tube. Reaction began upon adding a crystal of iodine and heating at gentle reflux for fifteen minutes. After twenty hours the customary titration indicated an 80% yield of $(CH_3)_3SiOSi(CH_3)_2CH_2MgCl$.

A mixture of 2.9 g. (0.01 mole) of iodomethylpentamethyldisiloxane, 0.24 g. (0.01 mole) of magnesium turnings and 5 cc. of dry ethyl ether was allowed to react as above. The reaction began readily without the application of heat. After twenty hours, titration showed a 93% yield of $(CH_3)_3SiOSi(CH_3)_2CH_2MgI$.

**Chloromethyltrimethylsilane and Chloromethylpentamethyldisiloxane with Sulfuric Acid.**—The general technique of equilibrating methyl silicone oils with sulfuric acid has been described by Patnode and Wilcock.[8] It has also been shown that the relationship existing between the viscosity of equilibrated methyl silicone oils and their functionality can be used as a sensitive analytical tool for the determination of mono- and trifunctional methyl siloxane units in an otherwise difunctional methyl siloxane system.[4]

To 18.0 g. of an equilibrated methyl silicone oil (A) composed of mono- and difunctional units was added 0.042 g. of chloromethyltrimethylsilane. The mixture was then equilibrated as has been described[4] by shaking for forty-eight hours with 0.7 cc. of concentrated sulfuric acid to yield oil B. Oil C was prepared by merely dissolving 0.030 g. of chloromethyltrimethylsilane in 12.0 g. of A. The viscosities obtained lie within the experimental range of accuracy. Had the $-CH_2Cl$ groups been completely split from the Si, the mono-functional groups, $(CH_3)_3SiO_{1/2}$, resulting would have lowered the viscosity of oil B to 200 centistokes.[9] It was also found that chloromethyltrimethylsilane could be purified of –SiOSi– containing compounds by shaking with concentrated sulfuric acid. Compounds containing the siloxane linkage dissolved in the acid; the chloromethyltrimethylsilane separated as a second phase. No pressure buildup was noted during such operations to indicate volatile decomposition products.

| Oil | Viscosity, centistokes-100°F. |
|---|---|
| A | 242 |
| B | 239 |
| C | 241 |

A similar technique was used to check chloromethylpentamethyldisiloxane. Hexamethyldisiloxane and chloromethylpentamethyldisiloxane were equilibrated with octamethylcyclotetrasiloxane, contact with 1.2 cc. of concentrated sulfuric acid being effected for forty-eight hours. The amount of each disiloxane added was equivalent to 1.10 mole per cent monofunctional units. The greater viscosity of the oils prepared with chloromethylpentamethyldisiloxane is believed due to the greater polarity of the C—Cl bond. If no viscosity increase is attributed to the presence of C—Cl bonds, the cleavage of the Si—C bond of the —Si—$CH_2Cl$ group in chloromethylpentamethyldisiloxane was at most 2%. This derives from the fact that a methyl silicone oil composed of mono- and difunctional units has a viscosity of 258 centistokes at 100 °F. when the monofunctional unit content is 1.08 mole per cent.[9] The drop in monofunctionality of from 1.10 to 1.08 mole per cent would require but 2% cleavage to a difunctional unit.

| Wt. $[(CH_3)_2SiO]_4$, g. | Wt. chain stopper, g. | Viscosity (centistokes-100°F.) |
|---|---|---|
| 30.0 | 0.363 $(CH_3)_3SiOSi(CH_3)_3$ | 242 |
| 30.0 | .443 $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ | 257 |
| 30.0 | .441 $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ | 259 |

**Measurement of Evolved Methyl Chloride.**—Isolation and identification of methyl chloride as the volatile cleavage product of chloromethyl siloxanes has been reported by Elliott and Krieble.[1,6] A readily effected quantitative method of determining methyl chloride evolved is bubbling the gases through sodium ethoxide in absolute ethanol. To the 25-cc. erlenmeyer flask in which the reactions of Table I were run was attached a 45-cm., water-cooled, Liebig reflux condenser. The condenser outlet was in turn connected to a pair of traps (25 cm., 1 cm. diameter) arranged in series with an Ascarite–Drierite tube at the trap outlet. All connections were glass tubing and ground glass joints since rubber absorbs methyl chloride. Into each trap was pipeted 9.9 cc. of 2.0 *M* sodium ethoxide in absolute ethanol. The first trap was heated by the vapors of refluxing acetone to increase the speed of reaction. The final trap was allowed to stand overnight before titration.

(6) Krieble and Elliott, THIS JOURNAL, **67**, 1810 (1945).
(7) Whitmore, Sommer and Gold, *ibid.*, **69**, 1976 (1947).
(8) Patnode and Wilcock, *ibid.*, **68**, 358 (1946).
(9) D. F. Wilcock, private communication.

When 54.9 cc. (0°, 760 mm.) of methyl chloride was bubbled into the trap system from a gas buret over a one and a half hour period, 94% of the methyl chloride reacted in trap 1. A negligible amount of methyl chloride was indicated in trap 2. In this experiment trap 2 was not allowed to stand before titration. The extent of reaction ($CH_3Cl + NaOC_2H_5 \rightarrow CH_3OC_2H_5 + NaCl$) was determined by diluting with water and titrating with standard sulfuric acid using phenol red as an indicator. Turbidity due to sodium chloride separation was marked after only 5 cc. of methyl chloride had been added.

**Reaction of Chloromethyltrimethylsilane and Chloromethylpentamethyldisiloxane with Reagents of Table I.**—The experimental setup was that described above. The reagent (9.9 cc.) and I or II were charged to the 25 cc. erlenmeyer flask, the molar ratio of sodium ethoxide, potassium hydroxide or potassium acetate to I or II being two. Heat was supplied by raising a hot silicone oil-bath around the reaction flask. The temperature of each reaction was the reflux temperature of the reaction mixture. At the conclusion of reaction the system was swept with a slow stream of nitrogen. For sodium ethoxide in absolute ethanol and potassium hydroxide in moist butanol the extent of reaction in the erlenmeyer flask and the methyl chloride evolved were then determined by dilution with water and titration with 0.990 *N* sulfuric acid employing a phenol red indicator. Twenty-five per cent. of the titrations were checked against Volhard chloride determinations with excellent agreement. For potassium acetate in glacial acetic acid the extent of reaction was determined by Volhard chloride analysis; no methyl chloride entered the traps. Blanks were titrated for the volume of alkaline reagents pipeted into the reaction flask and traps.

To check on the efficiency of the water condenser, 1.2 g. of chloromethyltrimethylsilane (I) was refluxed in the system with 10 cc. of moist butanol for one hour. Nitrogen was then swept through the system for one hour as the mixture cooled (nitrogen inlet just above neck of erlenmeyer flask). Only a very faint opalescence developed when the diluted trap I contents were tested with silver nitrate.

**Reaction of Chloromethyltrimethylsilane (I) with Sodium Ethoxide in Absolute Ethanol.**—To a 250-cc. round-bottomed flask were charged 210 cc. of 1.91 *M* sodium ethoxide (0.40 mole) in absolute ethanol and 24.5 g. (0.20 mole) of I ($n^{20}D$ 1.4179, Cl, 29.0%).[10] The condenser and trap system described above were attached. The reaction was continued for four hours at reflux. Titration showed 0.10 mole sodium ethoxide had reacted in the flask, an extent of reaction of 50%. The amount of sodium ethoxide reacted with in traps 1 and 2 was 0.0041 and 0.0004 mole, respectively. This increases the extent of reaction 2% and shows that a minimum of 4% of the total reaction was the cleavage reaction forming methyl chloride. Upon dilution of the reaction product with 1 l. of water, 18.5 g. of a water immiscible phase was separated. This reaction product contained 2.4% by weight of monofunctional methyl siloxane units [0.0054 mole $(CH_3)_3SiO_{1/2}$]. Thus 5% of the chloromethyltrimethylsilane which reacted was subjected to Si—C bond cleavage. Analysis of the reaction product in the mass spectrometer showed the typical main peak for hexamethyldisiloxane (mass number 147). Also the presence of ethoxymethyltrimethylsilane was indicated by significant peaks at mass numbers 103 and 117, corresponding to the fragments $(CH_3)_3SiCH_2O$ and $(CH_3)_2SiCH_2OC_2H_5$, respectively.

A similar experiment was performed on a larger scale. To a 1-liter round bottomed flask were charged 750 cc. of 2.01 *M* sodium ethoxide (1.51 moles) in absolute ethanol and 94.3 g. of I ($n^{20}D$ 1.4176, Cl, 28.2 %). After four hours at reflux, 0.50 mole of sodium ethoxide had reacted in the reaction flask, an extent of reaction of 67%. The amount of reaction in traps 1 and 2 was 0.0042 and 0.0010 mole of sodium ethoxide, respectively. The cleavage reaction resulting in methyl chloride formation is at least 1% of the total reaction. The reaction product was diluted with 2 l. of water and 85 g. of a water immiscible phase (A) separated. Upon washing free of alkali and drying with anhydrous sodium sulfate, A was analyzed by the gel test method[4] and found to have a monofunctional methyl siloxane unit concentration of 3–5% by weight. This represents 0.042 mole $(CH_3)_3SiO_{1/2}$ and shows that Si–C cleavage constituted 8% of the total reaction. Seventy-two grams of the water immiscible phase (A) was then shaken with concentrated sulfuric acid for one-half hour and 25 g. of a sulfuric acid insoluble layer (B) separated. B upon washing and drying was found to have a $n^{20}D$ of 1.4174 and represented unreacted chloromethyltrimethylsilane. The sulfuric acid solution was run slowly into 2 l. of water with cooling and 30 g. of an immiscible phase (C) separated. After drying with anhydrous sodium sulfate, a gel test analysis[4] showed the presence of 21% by weight of monofunctional methyl siloxane units. Degradation of some ethoxymethyltrimethylsilane to $(CH_3)_3SiO_{1/2}$ apparently occurred during solution in sulfuric acid. To rid C of most of these methyl siloxane units (presumably present as hexamethyldisiloxane boiling at 100°) a methyl silicone oil incorporating the $(CH_3)_3SiO_{1/2}$ units in a polymeric system was prepared.[11] Twenty-five grams of C was added to 475 g. of octamethylcyclotetrasiloxane and the solution equilibrated.[3,6]. Before fractional distillation 75 cc. of xylene was added to reduce the viscosity. Three fractions boiling from 102.3–102.9° had the same refractive index ($n^{20}D$ 1.3940) and were combined (5.4 g.). Analysis showed this material to be ethoxymethyltrimethylsilane (IV).

*Anal.* Calcd. for $C_6H_{16}OSi$: C, 54.5; H, 12.2; mol. wt., 132.2. Found: C, 54.5; H, 12.0; mol. wt., 130 and 134.

**Acknowledgment.**—The author is indebted to Dr. Paul Zemany for the mass spectrometer analyses, Mr. Lester Bronk for the Volhard chloride determinations, Miss Mary Caldwell for the micro combustion analysis and the Schenectady Works Laboratory for Parr chlorine and viscosity determinations.

## Summary

The reactivities of chloromethyltrimethylsilane and chloromethylpentamethyldisiloxane have been compared.

The replacement of an alkyl group attached to the Si holding the chloromethyl group by a trimethylsiloxy group greatly enhances the reactivity to such reagents as potassium acetate in glacial acetic acid and sodium ethoxide in absolute ethanol.

The reaction of sodium ethoxide with chloromethyltrimethylsilane results primarily in attack on the chloromethyl carbon and formation of ethoxymethyltrimethylsilane, a silicon containing ether. A small amount of Si–C cleavage of the $-SiCH_2Cl$ group also occurs. With chloromethylpentamethyldisiloxane the same reagent causes considerable attack at the Si resulting in Si–C cleavage of $-SiCH_2Cl$ group to form methyl chloride. This may be the sole reaction in this system.

RECEIVED AUGUST 18, 1948

(10) The chloromethyltrimethylsilane was in addition checked both in the General Electric Nier Type (60 degree) mass spectrometer and by the gel test method.[4] In the mass spectrometer the main peak for hexamethyldisiloxane is the fragment of mass number 147, corresponding to $(CH_3)_2SiOSi(CH_3)_3$. No 147 hump appeared when I was run. Also the gel test showed no monofunctional, $(CH_3)_3SiO_{1/2}$ units, present.

# Chloromethylmethylpolysiloxanes

BY JOHN L. SPEIER

The availability of chlorochloromethylmethylsilanes[1] has prompted the preparation of the linear polymers derived from these and their linear copolymers containing dimethyl or trimethylsiloxy units. The compounds prepared may be regarded as the chlorinated derivatives of the open chain dimethylsiloxanes with trimethylsiloxy end-groups described by Hunter[2] and others.[3,4,5] Data concerning these compounds are to be found in Table I.

## Experimental Part and Discussion

The polymers of series I were prepared by refluxing for two hours in aqueous alcoholic solution, chlorochloromethyldimethylsilane (178 g., 1.24 moles) and hexamethylcyclotrisiloxane (46 g., 0.62 mole). The products of the reaction were washed with water, dried over calcium chloride and distilled.

The polymers of series II were prepared by refluxing for three and one-half hours an aqueous alcoholic solution of hexamethyldisiloxane (162 g., 1 mole), and dichlorochloromethylmethylsilane (163.5 g., 1 mole) followed by washing with water, drying over calcium chloride and distilling.

The polymers of series III were prepared by copolymerizing chlorochloromethyldimethylsilane (2 moles) and dichlorochloromethylmethylsilane (1 mole). The mixture of chlorosilanes was added to aqueous alcohol and shaken. The products were then given the same treatment afforded series I and II.

Despite the fact that three different methods were used to form the three series of polymers the molar distribution of products was the same in each case as nearly as can be determined by distillation analysis.

Also of interest is the fact that only in the case of series I was the slightest trace of cyclic polymers detected in the mixtures. This is surprising in view of the findings of Scott[7] and Wilcock[8] who found that cyclic compounds form when methylpolysiloxane systems were "equilibrated." Perhaps this difference is due to the differences in methods of "equilibrating" or it may be due to an influence of the chloromethyl group which hinders the formation of cyclic polymers. In series I, an indication of the presence of about 2 ml. of hexamethylcyclotrisiloxane, b. p. about 133°, was detected.

A curious fact is that each of the members of series I possesses very nearly the same specific refraction and energy of activation for viscous flow.

The chlorine contents of the compounds of series I and II were determined by heating the chloride with a known excess of potassium hy-

droxide in diethylene glycol in a closed bottle at about 150–175°, followed by titrations of the excess alkali with standard acid. Series III formed gels when treated in this way. Titration of the excess alkali in the gel was difficult and led to variable results. Therefore, the molecular weights of the members of series III were determined ebulliometrically. The values given are those obtained by extrapolation to zero concentration.

The viscosities were obtained in a carefully calibrated Fenske pipet.

## Summary

Three series of open chain chloromethylmethylpolysiloxanes were prepared and characterized. The boiling points, index of refraction, density, viscosity and freezing point of the polymers were determined.

# Some Aminodibenzothiophenes

BY HENRY GILMAN AND JOHN F. NOBIS

In connection with studies concerned with antimalarial and antituberculous compounds, some substituted dibenzothiophenes[1] were prepared.

2-Acetyldibenzothiophene[2] is an important starting material for the preparation of 2-amino- and 2-acetaminodibenzothiophenes. 2-Aminodibenzothiophene can be prepared in excellent yields by a Beckmann rearrangement of the oxime of 2-acetyldibenzothiophene followed by hydrolysis of the resulting acetamino compound. This amine can also be prepared by the nitration and reduction of the parent heterocycle, but the over-all yields are lower, although catalytic reduction of the 2-nitro compound gives high yields of the amine.

2,8-Diacetyldibenzothiophene[3] was prepared and was found to be a suitable intermediate in the preparation of 2,8-diaminodibenzothiophene. Formation of the dioxime of the diacetyl compound, treatment of the dioxime with phosphorus pentachloride, and hydrolysis of the resulting diacetamino compound (m. p. 304–305°) gave a good yield of the 2,8-diamino compound (m. p. 199.5–200°). These same melting points were recently reported.[4] The older literature reported the melting point of the diamino compound to be 178°[5] and 194°,[3] and the melting point of the diacetamino derivative as 237°[5] and 254°.[3]

In order to confirm the structure of the 2,8-diaminodibenzothiophene, an authentic specimen was prepared by nitration of 2-nitrodibenzothiophene followed by catalytic reduction of the resulting 2,8-dinitrodibenzothiophene. Acetylation of this diamino compound gave 2,8-diacetaminodibenzothiophene. The melting points of the latter two compounds were in agreement with the melting points of the compounds obtained from 2,8-diacetyldibenzothiophene, and mixed melting points were not depressed.

The oxidation of 2,8-diacetaminodibenzothiophene to the 5-dioxide was accomplished with either hydrogen peroxide or hypochlorous acid where it had been previously reported[4] that hydrogen peroxide oxidation was not possible.

The authors are grateful to Parke, Davis and Company for arranging for pharmacological tests, the results of which will be reported elsewhere.

## Experimental

**2-Nitrodibenzothiophene.**—Since the previous directions[6] could not be duplicated to give the reported 40% yield, the following procedure was developed. To 10 g. (0.054 mole) of dibenzothiophene dissolved in 80 cc. of glacial acetic acid at 30° was added 10 cc. of fuming nitric acid (d., 1.51) over a period of thirty minutes. When the addition was complete the reaction mixture was stirred at room temperature for one hour and filtered. The yellow solid was refluxed for several hours with 100 cc. of 95% ethanol and the insoluble 2-nitrodibenzothiophene removed by filtration. The yield of product was 3.5 g. (28%) melting at 186–187°.

**2,8-Dinitrodibenzothiophene.**—The following procedure was worked out from the brief directions reported previously.[5] To 18 cc. of fuming nitric acid (d., 1.51) in 25 cc. of glacial acetic acid was added 7.2 g. (0.031 mole) of 2-nitrodibenzothiophene in small portions. When the addition was complete an additional 10 cc. of fuming nitric acid was added dropwise. The reaction mixture was stirred for one hour and poured into water; the resulting yellow product was recrystallized from glacial acetic acid to give 4 g. (47%) of product melting at 320–330°. Recrystallization from dioxane gave 3.2 g. (38%) of the dinitro compound melting at 339–340° (previously reported, 324–325°[5]).

One attempt to prepare this compound by direct nitration of dibenzothiophene gave only 12% of the 2-nitrodibenzothiophene.

**2-Aminodibenzothiophene-5-dioxide.**—2-Nitrodibenzothiophene-5-dioxide was prepared in 88% yield by refluxing the 2-nitro compound with an excess of hydrogen peroxide.[6] The crude product was recrystallized from dioxane and from acetone to give pure material melting at 255–256°. A mixture of 9 g. (0.034 mole) of this nitro compound, 23 g. of granular tin metal, 115 cc. of hydrochloric acid, and 100 cc. of ethanol was refluxed for one hour, cooled, and the amine hydrochloride removed by filtration. An 87% yield of the amine (m. p. 274–276°) was obtained by treatment of the salt with ammonium

hydroxide. Recrystallization from methanol gave 4.7 g. (59%) of product melting at 278–280°.

*Anal.* Calcd. for $C_{12}H_9O_2NS$: S, 13.84. Found: S, 13.50.

**2-Acetyldibenzothiophene.**—Conflicting reports[2] exist concerning the preparation and yield of this compound. The following procedure was developed.

One hundred and twenty grams (0.64 mole) of dibenzothiophene in 900 cc. of dry carbon disulfide was treated with 52 g. (0.64 mole) of acetyl chloride.[2a] The reaction product was distilled at reduced pressure (b. p. 183–185° (1 mm.)) to give 112.5 g. (78%) of crude compound. This material was refluxed for two hours with two successive 500-cc. portions of ether to give the desired 2-acetyldibenzothiophene melting at 109–110°. Recrystallization from methanol gave 60 g. (41%) of material melting at 111–111.5°.

**2-Aminodibenzothiophene. A. From 2-Nitrodibenzothiophene.**—A suspension of 13.5 g. (0.059 mole) of 2-nitrodibenzothiophene and one and one-half teaspoonfuls of Raney nickel catalyst in 150 cc. of absolute ethanol was hydrogenated at 50 p. s. i. The reaction was complete in eighteen hours; there was obtained 3.7 g. of amine melting at 133°. Dilution of the filtrate gave 7 g. of product melting at 129–131°, making a total yield of 91%. Reduction of the 2-nitro compound with tin and hydrochloric acid gave only a 66% yield of 2-aminodibenzothiophene melting at 125–126°.

B. **From 2-Acetyldibenzothiophene.**—Eighteen grams (0.075 mole) of the oxime of 2-acetyldibenzothiophene was treated with phosphorus pentachloride,[2a] yielding 2-acetaminodibenzothiophene quantitatively. This crude product was refluxed with 500 cc. of 1:1 hydrochloric acid for four hours and filtered hot. The residue was extracted with two liters of boiling water and the combined extracts were treated with ammonium hydroxide to give 10.7 g. (72%) of product melting at 129–131°.

**2,8-Diacetyldibenzothiophene Dioxime.**—2,8-Diacetyldibenzothiophene was prepared by an adaptation of the method of Burger, Wartman and Lutz.[3] To a mixture of 22.6 g. (0.1 mole) of 2-acetyldibenzothiophene and 53 g. (0.4 mole) of aluminum chloride in 500 cc. of dry carbon disulfide was added 7.8 g. (0.1 mole) of acetyl chloride over a period of ten minutes. The reaction mixture was refluxed for six hours, poured into an ice–hydrochloric acid mixture, and filtered; the crude yield was quantitative. The white solid was washed with 50 cc. of benzene and recrystallized from 95% ethanol to give 20.5 g. (76%) of pure product melting at 206–208°.

A mixture of 26.8 g. (0.1 mole) of 2,8-diacetyldibenzothiophene, 27.2 g. (0.4 mole) of hydroxylamine hydrochloride, 60 cc. of pyridine, and 250 cc. of absolute ethanol was refluxed for three hours. The solution was evaporated to one-half the volume and the remaining liquid poured into 1600 cc. of water. There was obtained, subsequent to filtration and washing with water, 28.5 g. (95%) of 2,8-diacetyldibenzothiophene dioxime melting at 266–267°.

**2,8-Diacetaminodibenzothiophene. A. From 2,8-Diacetyldibenzothiophene Dioxime.**—To 26.7 g. (0.09 mole) of the dioxime in 500 cc. of benzene was added 60 g. (0.287 mole) of phosphorus pentachloride at such a rate as to cause gentle refluxing. When the reaction had subsided, the mixture was poured onto ice and the suspension made alkaline with sodium carbonate. There was obtained 25 g. (93.5%) of crude diacetamino compound melting at 240–280°. (When this rearrangement was effected with hydrogen chloride[3] a 30% yield of crude product was obtained melting at 220–280°.) The crude diacetamino compound was hydrolyzed in the usual manner. The yield was 13.7 g. (76%) of 2,8-diaminodibenzothiophene melting at 197–198°. Two recrystallizations from 95% ethanol raised the melting point to 199.5–200°. A mixed melting point with 2,8-diaminodibenzothiophene obtained by reduction of 2,8-dinitrodibenzothiophene was not depressed.

*Anal.* Calcd. for $C_{12}H_{10}N_2S$: S, 14.95. Found: S, 14.90.

One-tenth gram (0.0004 mole) of 2,8-diaminodibenzothiophene in 25 cc. of benzene was refluxed for one hour with a few drops of acetic anhydride. There was obtained 0.11 g. (92%) of the diacetamino compound melting at 299–301°. Recrystallization from dilute ethanol gave a melting point of 303°.

*Anal.* Calcd. for $C_{16}H_{14}O_2N_2S$: N, 9.39. Found: N, 9.44.

B. **From 2,8-Diaminodibenzothiophene.**—2,8-Diaminodibenzothiophene (m. p. 194–196°) was prepared in 46% yield by catalytic reduction of 2,8-dinitrodibenzothiophene in the manner previously described for the preparation of 2-aminodibenzothiophene. (Reduction of the 2,8-dinitro compound with tin and hydrochloric acid gave a 35% yield of impure material.) A mixed melting point with the material obtained from the Beckmann rearrangement was not depressed.

One-tenth gram (0.0004 mole) of this diamine was treated with acetic anhydride to give 0.1 g. of 2,8-diacetaminodibenzothiophene (m. p., 301–302°) after recrystallization from dilute methanol. A mixed melting point with the material prepared from 2,8-diacetyldibenzothiophene dioxime was not depressed.

**2,8-Diacetaminodibenzothiophene-5-dioxide.**—One gram (0.003 mole) of 2,8-diacetaminodibenzothiophene was dissolved in 20 cc. of glacial acetic acid by warming to 70°. To this solution was added 2 cc. of 30% hydrogen peroxide; the temperature was slowly raised to 93°. At the end of three hours, during which time an additional 2 cc. of hydrogen peroxide was added, the reaction mixture was poured onto ice. There was obtained 1 g. (95%) of dioxide melting at 330–331°. This material was refluxed first with 75 cc. of 95% ethanol and then with 100 cc. of dioxane to give a melting point of 356–357°. This oxidation method had been previously reported[4] to give no isolable product.

*Anal.* Calcd. for $C_{16}H_{14}O_4N_2S$: S, 9.70. Found: S, 9.65.

**2,8-Diaminodibenzothiophene-5-dioxide.**—A mixture of 0.8 g. (0.002 mole) of 2,8-diacetaminodibenzothiophene-5-dioxide and 100 cc. of 18% hydrochloric acid was refluxed for thirty minutes. The clear solution was diluted with an equal volume of water and filtered hot. Treatment of the filtrate with ammonium hydroxide gave 0.6 g. of material melting at 306–308°. Recrystallization from 95% ethanol gave 0.3 g. (51%) of the 2,8-diamino compound melting at 327–328°.

In another preparation, 10 g. (0.034 mole) of crude 2,8-diacetaminodibenzothiophene was suspended in 300 cc. of glacial acetic acid at 80° and 100 cc. of freshly prepared sodium hypochlorite solution[7] was added over a period of fifteen minutes. The reaction mixture was poured into one liter of water and a quantitative yield of crude dioxide was obtained by filtration. This crude product was refluxed for two hours with 300 cc. of 18% hydrochloric acid and allowed to stand overnight. The insoluble material was extracted with two one-liter portions of water and the combined extracts were treated with decolorizing carbon. Neutralization of the filtrate with ammonium hydroxide precipitated 4 g. (48% based on the 2,8-diacetaminodibenzothiophene) of 2,8-diaminodibenzothiophene-5-dioxide melting at 325–326°.

*Anal.* Calcd. for $C_{12}H_{10}O_2N_2S$: S, 13.0. Found: S, 13.4.

**4-Methoxydibenzothiophene-5-dioxide.**—An 85% yield of this dioxide was obtained by refluxing 4-methoxydibenzothiophene[2a] with an excess of hydrogen peroxide. After recrystallization from 95% ethanol the melting point was 191–192°.

*Anal.* Calcd. for $C_{13}H_{12}O_3S$: S, 13.00. Found: S, 13.33.

**Reaction of Dibenzothiophene with Aluminum Halides.**—In attempts to obtain a dibenzothiophenecarboxylic acid, dibenzothiophene was heated with various aluminum halides in sealed tubes under a variety of conditions. No

(7) Weijlard, THIS JOURNAL, 67, 1031 (1945).

acid was obtained by carbonation of the reaction mixtures, although 2-dibenzofurancarboxylic acid was isolated in similar reactions with dibenzofuran.[8]

## Summary

New procedures are given for the preparation of some aminodibenzothiophenes and aminodibenzothiophene-5-dioxides. Additional proof is presented for the structure of 2,8-diacetyldibenzothiophene.

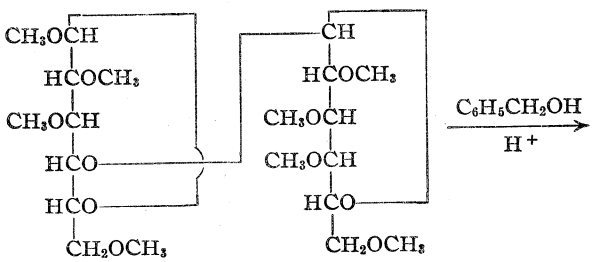
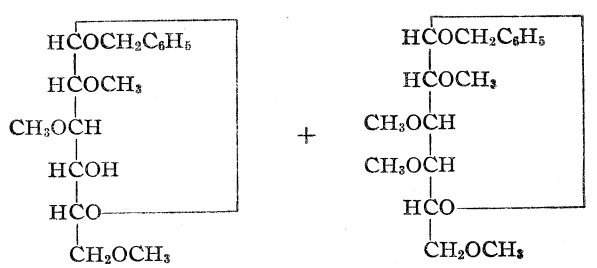
# The Alcoholysis of Sugar Derivatives



BY ELMER E. COMBS,[1] CHESTER M. MCCLOSKEY, ROBERT L. SUNDBERG AND GEORGE H. COLEMAN[2]

The study of the alcoholysis reaction was undertaken in this Laboratory with the object of developing a method for the preparation of 2,3,6-trimethylglucose. The method was found to be satisfactory enough to warrant investigation of a larger field than originally planned with the object of obtaining a practical method of separation of the alcoholysis products of methylated disaccharides.



Berner[3] investigated the methyl alcoholysis of sucrose and other carbohydrates. From sucrose he obtained glucose and methyl fructofuranoside. Voss and Wachs[4] investigated the reaction rates of alcoholysis, acetolysis and hydrolysis of phenyl glucosides and found that the length of time required for completion of the reaction increased in the order mentioned with the reaction constant for methyl alcoholysis being over one-hundred times as great as that for hydrolysis. Methyl alcohol was used by the above workers and by others[5]; however, the use of methyl alcohol had the disadvantage that the hydrolysis rate of the methyl glycoside approximated that of the original compound. Considerable decomposition of the free sugars sometimes resulted during hydrolysis making it difficult to obtain crystalline compounds.

Richtmyer[6] studied the conditions under which benzyl glycosides are cleaved by catalytic hydrogenation. He found that palladium catalysts in glacial acetic acid, at room temperature and atmospheric pressure were capable of cleaving benzyl glycosides giving a quantitative yield of the free sugar. Methylated benzyl glycosides have been shown to be capable of distillation under high vacuum.[7,8] Studies of the benzyl alcoholysis of methyl α-fructofuranoside and of fructose have been described.[9] In view of these findings benzyl alcohol was selected for use in this investigation of the alcoholysis reaction.

The general procedure of benzyl alcoholysis is illustrated using methyl heptamethyl-β-lactoside.

Methyl heptamethyl-β-lactoside

Benzyl 2,3,6-trimethyl-D-glucoside

Benzyl 2,3,4,6-tetramethyl-D-galactoside

The benzyl glycosides obtained were distilled under vacuum and the separate fractions redistilled. In eleven runs the yield of the benzyl tetramethylglycoside averaged 87.7% and the yield of the benzyl trimethylglycoside averaged 46.1%. The lower yield of the trimethyl fraction was probably due to its higher boiling point and to the fact that it was subjected to high temperatures of distillation for a longer period of time. For this reason smaller runs generally gave better percentage yields than did larger runs. After separation the benzyl glycosides were catalytically reduced to the free sugar using palladium–charcoal catalyst in glacial acetic acid. In every case a nearly quantitative yield of the free sugar was obtained.

The methylated disaccharides used in this in-

TABLE I

PHYSICAL CONSTANTS OF BENZYL GLYCOSIDES

| | | Boiling point, °C. | Mm. | $n^{25}D$ | $[\alpha]^{25}D$ in $CHCl_3$ ($c$, 2) | Analyses, % Calculated C | Calculated H | Found C | Found H |
|---|---|---|---|---|---|---|---|---|---|
| 1 | Benzyl 2,3,4,6-tetramethyl-D-galactoside | 114–116 | 0.020 | 1.4980 | 80.3 | 62.6 | 8.0 | 62.79 | 8.23 |
| 2 | Benzyl 2,3,4,6-tetramethyl-D-glucoside | 110–111 | .014 | 1.4936 | 76.1 | 62.6 | 8.0 | 63.05 | 8.01 |
| 3 | Benzyl 2,3,4-trimethyl-D-glucoside | 133–134 | .025 | 1.5080 | 173 | 61.5 | 7.7 | 61.31 | 8.07 |
| 4 | Benzyl 2,3,6-trimethyl-D-glucoside | 127–128 | .020 | 1.5110 | 74.9 | 61.5 | 7.7 | 63.30 | 7.89 |
| 5 | Benzyl 2,4,6-trimethyl-D-glucoside | 132–133 | .014 | 1.5110 | 92.5 | 61.5 | 7.7 | 62.13 | 8.31 |

vestigation and the benzyl glycosides obtained therefrom were as follows: methyl heptamethyl-$\beta$-lactoside → benzyl 2,3,6-trimethylglucoside + benzyl 2,3,4,6-tetramethylgalactoside. Methyl heptamethylmaltoside → benzyl 2,3,6-trimethylglucoside + benzyl 2,3,4,6-tetramethylglucoside. Methylheptamethyl-$\beta$-cellobioside→benzyl 2,3,6-trimethylglucoside + benzyl 2,3,4,6-tetramethylglucoside. Methyl heptamethyl-$\beta$-melibioside→benzyl 2,3,4-trimethylglucoside + benzyl 2,3,4,6-tetramethylgalactoside.

Of these four benzyl glycosides none has been previously reported.[10] The physical constants of the four glycosides were determined. The effect of temperature on the rate of the reaction was investigated over the range of 25 to 150°. The higher temperatures were found to cause decomposition and side reactions; 100° was selected as the optimum temperature. It was found that the reaction would not occur in the absence of an acid catalyst and that the rate of the reaction was dependent on the acid concentration. However, high acid concentrations (5% and greater) were to be avoided as causing decomposition and side reactions. The optimum concentration was found to be 2.5%.

*p*-Toluenesulfonic acid monohydrate was the catalyzing acid used in this investigation. It was sufficiently strong for the purpose and was easily removed by extraction with aqueous ammonia. It was found to cause no harmful side reaction. Dibenzyl ether was usually formed under the reaction conditions, but this did no harm. Hydrochloric acid was first used as the catalyst, but was discontinued as it reacted quickly with the benzyl alcohol to give benzyl chloride, making it difficult to determine the length of effective reaction. The benzyl alcoholysis of methyl heptamethyl-$\beta$-lactoside was completed in two hours as compared to twenty-two hours for the hydrolysis.

The benzyl alcoholysis procedure was applied to several monosaccharides for reference purposes, these being trimethyllevoglucosan, 2,3,4,6-tetramethylglucose and 2,4,6-trimethylglucose. In general the reaction conditions and the reaction rates were the same as for the dissacharides.

(10) The benzyl glycoside which had been reported by Hess and Gramberg (ref. 8) was a benzyl 2,3,6-trimethyl-$\beta$-D-glucoside; it was quite impure, with a methoxyl content 3.5% too high due to the presence of some trimethylglucose. Its rotation of $[\alpha]^{20}D$ +8.3° is quite different from the value +74.9° reported by the present authors.

## Experimental

**Alcoholysis of Methyl Heptamethyl-$\beta$-lactoside.**—A mixture of 30 g. of methyl heptamethyl-$\beta$-lactoside and 9 g. of *p*-toluenesulfonic acid monohydrate was dissolved in 300 ml. of benzyl alcohol contained in a 500-ml. round-bottomed flask. The flask was heated in an oil-bath at 100° for two hours at atmospheric pressure followed by two hours at aspirator pressure. The solution was cooled and 1 l. of chloroform added. The resulting solution was extracted with 250 ml. of water containing 30 ml. of concd. ammonium hydroxide followed by two extractions with 250 ml. of water. The chloroform layer was dried over potassium carbonate and the solvent distilled off at 0.5 to 1.0 mm. pressure. The amber colored oil was fractionated under reduced pressure through a 10-inch externally heated column packed with platinum gauze, giving two principal fractions. Each fraction was then redistilled separately. The physical constants given are for the redistilled fractions.

Fraction 1: Benzyl 2,3,4,6-tetramethyl-D-galactoside, yield 26 g. (80%), b. p. 114–116° at 0.02 mm., $n^{25}D$ 1.4980, $[\alpha]^{25}D$ 80.3 in chloroform ($c$, 2). *Anal.* Calcd. for $C_{17}H_{26}O_6$; C, 62.6; H, 8.0. Found: C, 62.7; H, 8.23. Catalytic hydrogenation, using palladium-charcoal as the catalyst, gave a quantitative yield of sirupy 2,3,4,6-tetramethyl-D-galactose. On standing at 0° for several days, about 25% of the material crystallized out; m. p. 70.2° (cor.)

Fraction 2: Benzyl 2,3,6-trimethyl-D-glucoside, yield 17.5 g. (51%), b. p. 127–128° at 0.02 mm., $n^{25}D$ 1.5110, $[\alpha]^{25}D$ 74.9 in chloroform ($c$, 2). *Anal.* Calcd. for $C_{16}H_{24}O_6$: C, 61.5; H, 7.7. Found: C, 63.30; H, 7.89. Catalytic hydrogenation of 12.9 g. of this compound in glacial acetic acid gave 6.7 g. of crystalline 2,3,6-trimethyl-D-glucose (73%).

**Alcoholysis of Other Methylated Sugars.**—All other methylated disaccharides and monosaccharides mentioned above were subjected to the same benzyl alcoholysis procedure as described for octamethyl lactose. The properties of the benzyl glycosides obtained are summarized in Table I.

Compounds 3 and 5 in Table I were obtained in crystalline form from their respective sirupy distillates in approximately 75% yield. Compound 3, m. p. 79–80.2 cor.; compound 5, m. p. 90.6–91.1° cor. Compounds 1, 2, and 4, being sirups, are probably mixtures of the $\alpha$- and $\beta$-forms, with considerable $\alpha$ as evidenced by the positive rotation. Compound 3, being crystalline, seems to be definitely an $\alpha$-form. Compound 5 should also be an $\alpha$-form, the $\beta$-form having been described by Richtmyer.[11]

**Catalytic Reduction of Benzyl Glycosides.**—The general procedure used in reduction of the glycosides is illustrated by the following example. A solution of 12.9 g. of benzyl 2,3,6-trimethyl-D-glucoside in 50 ml. of glacial acetic acid with palladium–charcoal catalyst (0.5 g. of palladium chloride and 3 g. of charcoal) absorbed the theoretical amount of hydrogen overnight (hydrogen pressure 3–4 atm.). The catalyst was filtered off and the reaction flask and catalyst washed with water. The combined filtrate and washings were evaporated under reduced pressure to a sirup. Toluene (250 ml.) was added and removed under reduced pressure. Ether was added to

(11) Richtmyer, THIS JOURNAL, 61, 1831 (1939).

the residue which crystallized. Crystallization was completed on standing for several days at 0°; yield 6.7 g. (73%).

In addition to reduction of benzyl glycosides this method was successfully applied to the reduction of the benzyl group from 3-benzyl 2,4,6-trimethyl-D-glucose without reduction of the aldehydic group. The 2,4,6-trimethyl-D-glucose was crystallized from carbon tetrachloride, m. p. 126°. When mixed with an authentic sample of 2,4,6-trimethyl-D-glucose, the melting point was not depressed.

## Summary

1. A new method of separation of the cleavage products of methylated disaccharides has been developed. This involves conversion of the methylated disaccharide to two benzyl glycosides, treatment with benzyl alcohol in the presence of an acid, separation of the glycosides by fractionation under high vacuum, and reduction of the benzyl glycosides to give the methylated monosaccharides.

2. This method gives good yields (85%) of the tetramethyl monosaccharides and fair yields (50%) of the trimethyl monosaccharides.

3. Two new crystalline benzyl glycosides, (presumably α-forms) have been prepared; benzyl 2,3,4-trimethyl-D-glucoside, and benzyl 2,4,6-trimethyl-D-glucoside. Three new sirupy benzyl glycosides (presumably mixtures of the α- and β-forms) have been prepared: benzyl 2,3,4,6-tetramethyl-D-galactoside, benzyl 2,3,4,6-tetramethyl-D-glucoside, and benzyl 2,3,6-trimethyl-D-glucoside.

# Aluminum Monolaurate and Proposed Structures for Aluminum Soaps[1]

BY CHARLES G. McGEE[2]

The chemistry of aluminum soaps has long been in confusion. It has been stated: that only mono soaps exist,[3,4] that only a basic compound intermediate between mono- and di-soaps exists together with various sorption products,[5] and that the mono- as well as the di- and tri-soaps all exist.[6] Di-soaps have been prepared by several authors,[7,8,9] while efforts to prepare tri-soaps[10,11] failed.

It is the purpose of this paper to present evidence concerning the existence of aluminum mono-soaps. In the course of this work, no compounds were prepared having a ratio of exactly one molecule of fatty acid per atom of aluminum, but the preparations obtained had approximately one to one ratios and were stable under a wide variety of conditions. It is believed that these are true compounds, of the nature of co-polymers, and that as a result exact stoichiometric composition is not necessarily to be expected. Products containing from 1.2–0.8 molecules of fatty acid per aluminum atom will be referred to as aluminum mono-soaps.

The materials used in this study are those used in the previously reported work.[8] Analysis was carried out by ashing or by a split analysis in which the aluminum was determined by a standard procedure using 8-hydroxyquinoline and the fatty acid determined by precipitation and weighing.

## Aluminum Mono-Soaps

**Preparation from Aluminum Di-soaps, Accompanied by Alcoholysis.**—In the course of an investigation on the free acid content of commercial aluminum soaps, it was noted that the use of hot methanol for extraction gave much higher results than when acetone was employed. Analysis of these residues indicated that they approximated the composition then expected for a compound of the formula $Al(OH)_2$-fatty acid.

However, this reaction was repeated on samples of aluminum dilaurate prepared by Smith, *et al.*[9] Exhaustive treatment with hot methanol gave products containing 1.2–1.0 molecules of fatty acid per aluminum atom. The initial reaction is always accompanied by a marked physical change in the soap from a powder to a plastic mass. The reaction required several minutes at the boiling point of the methanol, and many days at room temperature. The plastic product contained large amounts of methanol and much free fatty acid. It gradually hardened over a period of several days, after which it was ground up and retreated with the methanol. During later treatments, it frequently reconsolidated.

To examine this assumed reaction, a weighed sample of aluminum dilaurate was treated with methanol, and the weight of fatty acid liberated and the loss in weight of the soap were determined. It was found that after drying *in vacuo*

over phosphorus pentoxide, the aluminum soap retained one molecule of methanol per molecule of soap initially present and lost one molecule of fatty acid. This indicates that methanolysis, analogous to hydrolysis, takes place. Similar reactions were observed with ethanol and higher alcohols, and with a solution of 10% water in acetone.

**Direct Preparation of Aluminum Mono-soaps.**—Aluminum mono-soaps were prepared directly in methanol by adding aqueous ammonium hydroxide to a solution of aluminum nitrate and lauric acid in hot methanol. If an excess of ammonia was added quickly, a finely divided product, which often consolidated on further treatment with hot methanol, was obtained. Most of these products contained distinctly more than one molecule of lauric acid per aluminum atom, even after they had been washed free of salts with methanol. Continued treatment with hot methanol, or methanol plus water, was necessary to bring the acid content down. Extraction with acetone did not alter the acid content. The material began to decompose at 250° without melting; at 270° it softened to a brown transparent mass.

Aluminum mono-soaps were prepared from aluminum hydroxide by precipitating the hydroxide in aqueous solution, washing it with water and then methanol, and finally adding a solution of lauric acid in methanol and heating. A slow reaction took place, leading to the formation of a gummy mass similar to that obtained in the other reactions.

An attempted direct precipitation in water yielded a mixture of at least two products, one containing 1.5 molecules of lauric acid per aluminum atom and soluble in a benzene–acetone mixture, the other containing about 0.6 molecule of lauric acid per aluminum atom, insoluble in benzene–acetone and unaffected chemically by it.

**Direct Conversion of Monolaurate to Dilaurate by Reaction with Lauric Acid.**—Shreve, Pomeroy and Mysels[12] had found that no water was formed in the benzene distillation of a mixture of aluminum monolaurate and lauric acid. They concluded that no reaction forming dilaurate had taken place. Later evidence showed that the monolaurate may have contained methoxyl groups. Reaction with lauric acid would have produced methanol, which would not have been detected in the benzene distillation. Hence, the reaction was reinvestigated, using acetone as a solvent. A large excess of lauric acid was employed, the mixture was refluxed, the acetone evaporated and the mixture dried over phosphorus pentoxide. It was then extracted repeatedly with cold acetone until the acetone was substantially free of fatty acid. Analysis of the residue showed that it contained 1.9 molecules of lauric acid per aluminum atom, indicating that substantial conversion to dilaurate had taken place.

**Behavior of Aluminum Monolaurate toward Organic Solvents.**—Aluminum laurates containing less than 1.2 molecule of lauric acid per aluminum atom are not noticeably soluble in the common organic solvents at room temperature. At its boiling point (171°), butyl cellosolve dissolved a fair amount, the solution gelling upon cooling. The residue from this treatment retained the composition of the original material.

Certain mixed solvents were effective in dissolving certain aluminum mono-soaps, methanol–benzene in particular. The solubility varied greatly with the composition of the soap. No solvents were found for products containing less than one molecule of lauric acid per aluminum atom. Treatment with solvents for fatty acids did not reduce the acid content of these materials.

**The Nature of Aluminum Mono-soaps.**—The question immediately arises as to whether these materials are true compounds or merely sorption products of lauric acid on hydrous alumina. The evidence seems strongly in favor of true compounds. Treatment of di-soaps with methanol always yields products having about one molecule of lauric acid per aluminum atom. Extended treatment with organic solvents does not significantly lower the acid content further. Treatment of aluminum hydroxide with lauric acid gives a product similar in every way to that from the degradation of dilaurate. With some products, solution can be effected in methanol–benzene mixtures from which the dissolved material can be precipitated by the addition of excess of methanol or acetone. The precipitated material is similar to the original material. Mono-soap was converted by reaction with lauric acid into di-soap which is a well-defined compound.[9]

**The Structure of Aluminum Mono-soaps.**—A rational structure for the aluminum mono-soaps can be built up on the basis of the known preference of aluminum for octahedral coördination. Each fatty acid ion will occupy two adjacent corners of the octahedron with hydroxyl (or methoxyl) groups in the other four. In order to maintain electrical neutrality, each of the hydroxyl groups must be shared. If neighboring aluminum ions share edges of the octahedra, long chains of the type shown in Fig. 1 will be formed. Structures based on corner and face sharing seem much less probable. The suggested structure would be expected to produce a non-crystalline material, as is observed. Powder X-ray diffraction photographs yield only diffuse halos, even after prolonged heating of the solid in methanol.

Low solubility is conferred by the high molecular weight and by a mechanism analogous to vulcanization. An aluminum hydroxide octa-

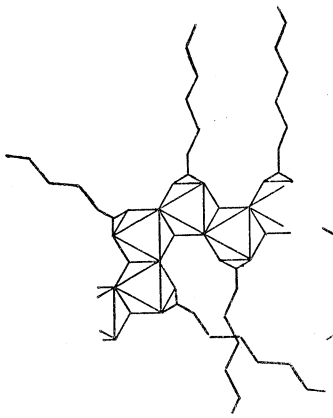
Fig. 1.



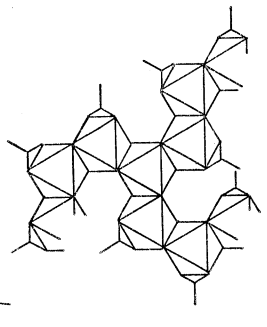


Fig. 2.

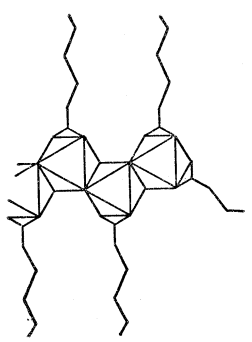

Fig. 3.

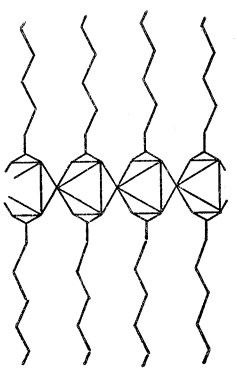

Fig. 4.

hedron can join three chains by sharing its edges with three molecules of mono-soaps as in Fig. 2.

If the chains terminate in di-soap molecules as in Fig. 3, it will be seen that the composition of the material may vary from that of a di-soap to aluminum hydroxide, depending upon the chain length and degree of cross linking. Since products containing close to one molecule of fatty acid per aluminum atom were obtained under a fairly wide variety of conditions, it seems probable that chains of mono-soap molecules predominate and that the term mono-soap is justified when referring to these materials. The high ratio of fatty acid to aluminum found in many cases may be due to incomplete conversion and/or failure to extract completely the free acid.

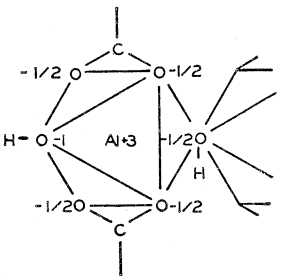
The physical behavior of these substances is similar in many respects to certain high polymers. They are much more soluble in mixed than in single solvents (although this is true of ordinary sodium soaps also), they are soluble in butyl cellosolve, they lack a definite melting point, they are frequently elastic and sometimes sticky when not free from solvent. They give gels in solvents and their solutions show very high viscosity.

## Structure of Aluminum Di-soaps

Some of the physical properties of aluminum di-soaps are also polymer-like, but they have not been reported with a fibrous X-ray structure. Ross and McBain[13] found by X-ray diffraction that they are crystalline and suggested a structure in analogy with that of sodium soaps.

An alternative suggestion is shown in Fig. 4. Here the two carboxyl groups occupy four of the coördinating positions while the two remaining positions contain hydroxyl ions which are shared to form a chain. This structure has been proposed by Grey[14] who, however, did not note that these chains would have to end in charged groups. It will be seen from Fig. 5a that a chain ending as shown will possess a net charge of minus one-half on the terminal group, while a chain ending as in Fig. 5b or 5c will possess a charge of plus one-half. This is an important feature of this structure, for it provides a reasonable mechanism for the observed association of aluminum di-soaps in dilute solutions.[14,15]

Fig. 5a.



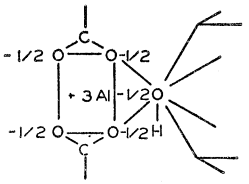


Fig. 5b.

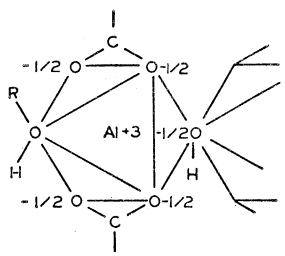

Fig. 5c.

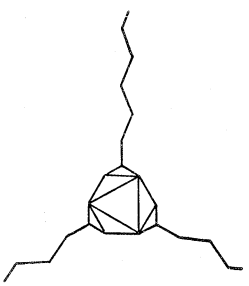

Fig. 6.

The suggested structure for aluminum di-soaps permits a much more regular arrangement of the molecules than did the structure for mono-soaps. Adjacent di-soap chains would be held together by both van der Waals forces between the hydrocarbon chains and hydrogen bonds between the hydrogen of the shared hydroxyl ions and the oxygen atoms of the carboxyl groups. The observed melting points may correspond to the breaking of these two forces, leaving the individual aluminum soap chains intact, since the molten soap possesses extremely high viscosity. In aluminum di-soap–hydrocarbon systems, the forces holding the hydrocarbon chains together

(13) Ross and McBain, *Oil and Soap*, **23**, 214 (1946).

(14) Grey, *Trans. Faraday Soc.*, **42B**, 197 (1946).

(15) McBain and Working, *J. Phys. and Colloid Chem.*, **51**, 947 (1947).

would be largely eliminated, leaving only the hydrogen bonds holding the aluminum soap chains to one another. Hence, the gel–jelly transition, which was found[16] to be largely independent of temperature for different aluminum di-soaps in a given solvent, may be a melting process taking place with only the hydrogen bonds left.

The effects of various substances upon aluminum di-soap in hydrocarbon systems can be interpreted on the assumption of the above model. Compounds which can coördinate with the aluminum ion will reduce the chain length and hence the viscosity, and usually increase the rate of solution or gelation of soap. Alcohols, water, amines and higher fatty acids all show this behavior.[17] Lower fatty acids increase the time required for gelation. This might be due to metathesis and resultant precipitation of less-soluble aluminum di-soaps on the surface of the particles, or simply to the possibility that although the rate of solution was increased, the dissolving chains were broken down by the acid so that some time had to elapse before the concentration of long chains was sufficient to gel the system.

McBain and Working[15] found that in benzene, the viscosity of aluminum di-soap solutions often increases with increasing temperature. This might be due to unfolding of chains, thus increasing the asymmetry of the particles. There were long time aging effects present, however, and what the situation would be at equilibrium is not clear. Mysels[18] reported no increase in viscosity with increase in temperature in cyclohexane, but observed very long time effects in the aging of the systems which sometimes led to anomalous results. His observations fit in well with the picture of reorganizing long chains.

McBain and Working[15] also found by osmometry that aluminum dilaurate was associated in benzene solutions as dilute as 0.001% by weight. The degree of association was found to increase very rapidly with increased concentration, but the effect of moisture was not examined. The jellies of aluminum dilaurate are very sensitive to moisture,[19] and it is possible that residual moisture in the soap and benzene gave rise to the apparent decreased association in the dilute solutions.

The dilaurate is characterized by a modest degree of crystallinity, solubility in hydrocarbons, reversible association, formation of jellies from gels at well-defined temperatures, and instability in the presence of water and alcohols. On the other hand, the monolaurates had low crystallinity, very low solubility in hydrocarbons, formation only of gels, no jellies, and stability in the presence of alcohols. These properties are reasonably in accord with the proposed structures based upon identical principles for both compounds.

### Aluminum Tri-soaps

Attempts to prepare tri-soaps by treating an aluminum alcoholate with a fatty acid have failed.[10,11] A structure analogous to those suggested for mono- and di-soaps, Fig. 6, in which the oxygen atoms of three carboxyl groups occupy the six coördination positions, would appear stable. It gives a reasonable explanation of the failure of attempts to prepare tri-soaps, since the molecule would be expected to possess a solubility very similar to that of the fatty acid; in fact, because of the shape of the molecule and the resultant difficulty of fitting into a compact crystal lattice, the tri-soap might be a liquid, miscible with the solvents used to extract the free acid. Hence, if produced, it would be found with the free acid and not in the residue, as assumed by previous workers.

### Detailed Preparation of Aluminum Monolaurates

**From Aluminum Dilaurate and Methanol.**—Four grams of aluminum dilaurate was boiled with 100 ml. of methanol for ten minutes. The methanol was removed by filtration and the solid was then washed with a 20-ml. portion of methanol and three 15-ml. portions of acetone. Evaporation of the methanol yielded a considerable quantity of lauric acid. The solid was dried in a vacuum desiccator. On ashing it was found to contain 8.4% aluminum; theoretical of $Al(OH)_2L$ is 10.4%; theoretical for $Al(OH)L_2$ is 6.1%. On repeating the treatment with methanol the aluminum content rose to 9.2%.

**From Aluminum Dilaurate in Benzene Solution and Methanol.**—A 2-g. portion of a monolaurate prepared from dilaurate and methanol was dissolved in 30 ml. of benzene by wetting it with methanol, adding the benzene and heating. An excess of methanol was added to the solution, reprecipitating the aluminum soap as an elastic material containing a large amount of solvent. This material was dried and analyzed. It contained 8.8% aluminum and had a ratio of 1.1 laurate to 1 aluminum.

**From Aluminum Dilaurate and Methanol with a Material Balance.**—1.677 g. of aluminum dilaurate (6.28% aluminum; theory 6.10%) was placed in a weighed 50-ml. centrifuge tube; 20 ml. of dried methanol was added and the tube was stoppered. It was allowed to stand overnight at room temperature; 10 ml. more of methanol was added, the solid was separated by centrifuging and 20 ml. of the supernatant liquid was pipetted out, transferred to another weighed tube and evaporated. An additional 20 ml. of dried methanol was added to the solid and the process repeated. After the third treatment the alcohol was raised to its boiling point to hasten the removal of the acid.

It was found that 0.669 g. (3.34 mmoles.) of lauric acid had been removed from the dilaurate. The dilaurate had lost only 0.538 g. The differ-

ence, 0.131 g. (3.8 mmoles.) represents the amount of methanol retained by the aluminum soap after drying in a vacuum over phosphorus pentoxide. It is slightly above the 3.34 mmoles. of acid extracted, but in good agreement with the 3.79 mmoles. of dilaurate originally present. It is probable that the extracted acid is low, due to the clumping of the particles during the experiment, and subsequent failure to extract completely the freed acid.

**By Precipitation in Methanol.**—37.5 g. (0.1 mole) of $Al(NO_3)_5 \cdot 9H_2O$ and 20 g. (0.1 mole) of lauric acid was dissolved in 200 ml. of boiling methanol; 20 ml. of concentrated ammonium hydroxide was added as quickly as possible. A very voluminous precipitate formed and 600 ml. of methanol were added to disperse the product. It was washed repeatedly with hot methanol and finally with acetone. After drying it contained 10.0% aluminum. It was treated with two portions of boiling methanol, after which it contained 10.6% aluminum. A small portion of this material was sealed in an evacuated capillary and heated. It began to decompose at 250° without melting. At 270° it softened to a brown transparent mass.

**From Aluminum Hydroxide and Lauric Acid.**—2.41 g. (0.01 mole) of $AlCl_3 \cdot 6H_2O$ was dissolved in 30 ml. of distilled water and a slight excess of ammonia was added. The aluminum hydroxide was centrifuged off and washed four times with methanol; 6.0 g. (0.03 mole) of lauric acid was then added and the mixture was heated to 70°. A gelatinous white precipitate formed which began to clump together after a few minutes. Within fifteen minutes it had formed a soft plastic mass, similar to that formed by treating dilaurate with methanol. This was dried, ground under methanol, and washed twice with hot methanol. During the second wash it again clumped together. It was washed with acetone and dried. It contained 7.8% aluminum and had almost 1.4 molecules of laurate per atom of aluminum.

**Acknowledgment.**—The author wishes to acknowledge the stimulating direction of Professor J. W. McBain, the many thought-provoking discussions with Drs. K. J. Mysels and G. H. Smith, and the financial assistance of the Colgate–Palmolive–Peet Company during the latter portion of this work.

## Summary

The preparation and properties of aluminum mono-soaps have been described. It has been suggested that aluminum mono-soaps are polymers in which the repeating units are alumina octahedra joined by sharing edges, with the carboxyl groups occupying the remaining positions.

The structure of aluminum di-soaps has also been discussed. A polymer structure has been suggested in which alumina octahedra are joined by sharing two opposite corners, which carboxyl groups occupying the remaining four. An attempt has been made to correlate such a structure with the known properties of the di-soaps.

Aluminum tri-soaps have likewise been discussed. Possible structures have been suggested and reasons for failure hitherto to prepare them have been considered.

# The Autoxidation of Methyl Oleate

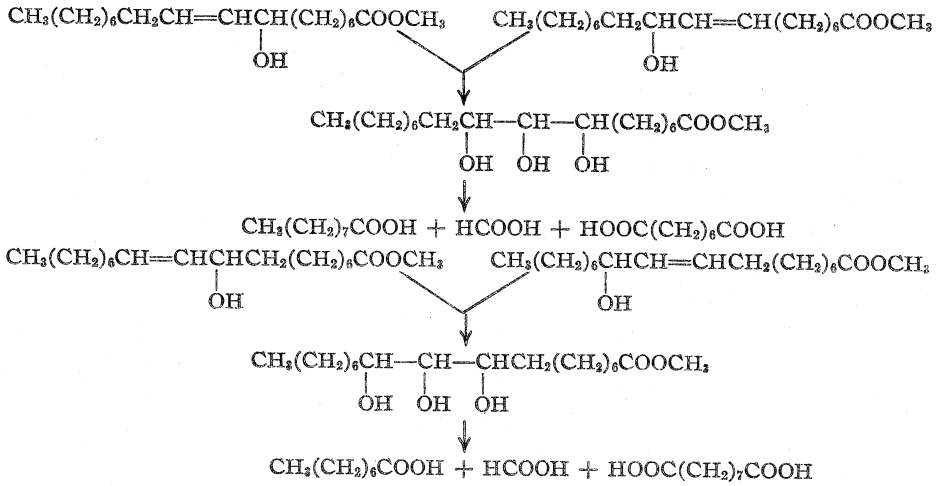
BY JOHN ROSS, ARTHUR I. GEBHART AND J. FRED GERECHT

It has been shown that autoxidation of olefinic compounds involves, in effect, addition of a molecule of oxygen with formation of a hydroperoxide group on a carbon atom adjacent to an olefinic group. Farmer, *et al.*, further developed this view and suggested a free radical chain reaction mechanism.[1]

Autoxidation, of the various resonance forms of methyl oleate, *via* such mechanism, should give rise to the structures:

$CH_3(CH_2)_6CH_2CH{=}CHCH(OOH)(CH_2)_6COOCH_3$,
$CH_3(CH_2)_6CH{=}CHCH(OOH)CH_2(CH_2)_6COOCH_3$
$CH_3(CH_2)_6CH_2CH(OOH)CH{=}CH(CH_2)_6COOCH_3$,
$CH_3(CH_2)_6CH(OOH)CH{=}CHCH_2(CH_2)_6COOCH_3$

We have examined autoxidation of methyl oleate with oxygen in the presence of ultraviolet light at 35° and found evidence that such is the case.[2]



The position of the hydroperoxide group was determined as follows: The mixture of hydroperoxides of methyl oleate was reduced to methyl hydroxyoleates, hydrogenated to methyl hydroxystearates, and oxidized to methyl ketostearates. After saponification, 9- and 10-ketostearic acids were isolated pure by fractional crystallization. The 8- and 11-ketostearic acids were not isolated pure, but their presence was demonstrated by conversion to suberic and nonane dicarboxylic acids, respectively, by hydrolysis of the amides obtained by Beckmann transformation of the oxime.

Evidence for the position of the ethylenic

(1) W. A. Waters, *Ann. Repts. on Progress Chem. (Chem. Soc. London)*, 130, **42**, 1945 (1946).

(2) Farmer, *et al.*, *J. Chem. Soc.*, 545 (1943), in a study of autoxidation of methyl oleate did not identify structurally any of the products of oxidation but later felt that all four hydroperoxides were probably present. In his examination of substituted cyclohexenes the structural evidence presented for the existence of four position isomers appears doubtful.

double bond was sought as follows: Dihydroxylation of the mixed hydroxy methyl oleates by performic acid gave two trihydroxy stearates, namely, 8,9,10- and 9,10,11-trihydroxystearic esters. Periodic oxidation of the mixed trihydroxystearic acids gave suberic and azelaic acids.

However, performic acid treatment of the mixed hydroxy oleates yields only 50% of trihydroxystearates. The remainder of the material suffered oxidative fission giving among other products, suberic, azelaic and sebacic acids. The appearance of appreciable amounts of acidic material is quite unusual under these conditions. Performic acid has been used with great success upon simple olefinic compounds to give almost theoretical yields of the monoformate of the dihydroxy derivative. Furthermore, ricinoleic ester under these conditions gives a 96% yield of 9,10,-12-trihydroxystearic ester[3] so that it appears that a non-adjacent hydroxy olefinic compound behaves normally according to the literature. The behavior of performic acid with olefinic compounds having a hydroxy group on a carbon atom directly adjacent to the olefinic group does not seem to have been examined previously. Compounds of this structure have been found to give abnormal products with other reagents. The explanation of the formation of suberic, azelaic and particularly sebacic acid must await further examination of this reaction of performic acid upon hydroxy olefins.

The relative proportion in which the isomeric hydroperoxides are formed in the case of oleic ester is of great interest. Our examination yielded the different substitution products in the order $C_{10} > C_{11} > C_8 > C_9$. However the preparation of the pure concentrated hydroperoxide and hydroxy olefinic ester undoubtedly involved selective crystallization.

Recently[4] we had occasion to examine the addition of olefinic esters to maleic anhydride and found that the main products were those in which addition occurred to the carbon atoms originally carrying the olefinic linkage, the latter in the final product taking up a position at the adjacent carbon atoms. There is insufficient evidence at present for regarding this addition reaction as proceeding by free radical chain mechanism.[5]

Writers in this field have introduced the term "methylenic reactivity" to describe substitution or reaction at or involving a methylene group adjacent to an olefinic linkage. We would suggest that the older term "allylic reactivity" is more inclusive and descriptive of the dynamic implications.

## Experimental

**Purification of Methyl Oleate.**—Commercial red oil or crude oleic acid (5600 g.) was heated at 200° with maleic anhydride (950 g.) for three hours in a carbon dioxide atmosphere.[6] After cooling, 4 liters of methanol containing 40 ml. of concentrated sulfuric acid was added and the solution refluxed for two hours. After standing overnight, 4 liters of water was added and the mixture was extracted with petroleum ether. The extract was washed with potassium carbonate solution to remove acidic material, dried, and the solvent removed. The esters were distilled at 2 mm. pressure, collecting up to 170° in order to leave the maleic anhydride condensation product of polyolefinic esters in the still residue. This crude methyl oleate was then fractionated through a modified Fenske column, 100 cm. long, and a total of 2550 g. of a fraction boiling 161.2–161.8° at 1.1 mm. pressure collected. Analysis showed this to be approximately 93% methyl oleate and 5% methyl linoleate. Using the procedure of Swern, Knight and Findley,[7] this crude ester was fractionally crystallized at low temperature in acetone solution, yielding a total of 1835 g. of methyl oleate having the analysis: *Anal.* Calcd. for $C_{19}H_{38}O_2$: I. V., 85.6; T. V., 85.0 (*cf.*[8]). Found: I. V., 85.7; T. V., 85.5. By spectrophotometric analysis it was

(5) W. G. Bickford, G. S. Fisher, Lillian Kyame and C. E. Swift, *J. Am. Oil Chem. Soc.*, 24, 7, 254 (1948), since this present paper was written have shown that addition occurs at carbon atom 8, 9, 10 and 11.

(6) We felt that maleic anhydride treatment offered a rapid method for eliminating polyunsaturates when present in large amounts. As a result of further work we cannot say that there are necessarily any advantages in this treatment provided a good sample of oleic acid is available.

(7) D. Swern, H. B. Knight and T. W. Findley, *Oil and Soap*, 21, 133 (1944).

(8) Mehlenbacher, *Chem. Eng. News*, 22, 606 (1944).

estimated that this sample of ester contained 0.09% linoleic and 0.04% linolenic esters.

**Structure of Methyl Oleate Used.**—In order to be certain that no isomerization of the methyl oleate had occurred as a result of the maleic anhydride or any prior treatment, a sample (14.8 g.) was converted to methyl dihydroxystearate by performic acid.[3] A yield of 15.3 g. of solid dihydroxystearic acid, m. p. 93–93.5°, was obtained. The theoretical yield was 15.8 g. Swern, *et al.*, report m. p. 94°. Periodic oxidation of the above dihydroxystearic acid[9] gave only azelaic acid in the dicarboxylic acid fraction.

**Autoxidation of Methyl Oleate.**—In a liter thin-wall pyrex erlenmeyer flask connected to an oxygen reservoir, 300 g. of methyl oleate was shaken for twenty-four hours at 35° while being irradiated with ultraviolet light from a 500-watt Hanovia lamp with a type L burner. The oxygen pressure during this time averaged about 9 cm. of mercury above atmospheric. In this manner a peroxide value[10] of 250 milliequivalents per kg. was obtained which corresponded to about 4% of total methyl oleate oxidized. A total of 4570 g. of methyl oleate was oxidized in this manner.

Methyl oleate was separated from the mixture containing methyl hydroperoxido-oleate by crystallizing twice at −72° from a 10% solution in acetone,[11] whereby 158 g. of oil was obtained analyzing 70.1% methyl hydroperoxido-oleate.

**Methyl Hydroxyoleate.**—To a solution of 157 g. of the above 70% methyl hydroperoxido-oleate in a mixture of 1600 ml. of chloroform and 2400 ml. of acetic acid there was added a saturated solution of potassium iodide (200 g. in 150 ml. water) and the mixture was vigorously stirred for five minutes. Saturated aqueous sodium sulfite solution was then added and stirring continued until the liberated iodine had been destroyed, when the mixture was transferred to a separatory funnel and allowed to separate. The chloroform layer was drawn off, washed with 2% aqueous potassium carbonate until neutral, dried, and the solvent removed *in vacuo*. There was obtained 154 g. of a light brown oily liquid which according to hydroxyl determination[12] contained 70.3% methyl hydroxyoleate. By crystallization twice from 1500 ml. of petroleum ether at −60° and −40°, respectively, there was obtained 63 g. of ester containing 98.3% methyl hydroxyoleate according to hydroxyl value and 91.4% as calculated from iodine value. The ester showed an epoxide content of 1.2% by the method of Nicolet and Poulter.[13] By periodic acid oxidation, this ester also showed the presence of 2.5% of methyl dihydroxystearate. These amounts of epoxide and dihydroxystearate are of such low an order that they can be ignored. Making corrections for these it appears that the product contained 91.2% methyl hydroxyoleate.

**A. Methyl Hydroxystearate.**—Sixteen grams of the above methyl hydroxyoleate was hydrogenated at 50° and 600 p. s. i. of hydrogen with Raney nickel catalyst. After filtering off catalyst and removing solvent 16.0 g. of hydroxystearic esters was obtained.

**Methyl Ketostearates.**—The above hydroxystearic esters were dissolved in 50 ml. of glacial acetic acid and a solution of 3.98 g. of chromic oxide ($CrO_3$) in 24 ml. of 90% acetic acid was added over a period of one hour at 30–35° with stirring. Two hours later the mixture was poured into water and extracted with petroleum ether. After washing and drying, the solvent was removed and 16.0 g. of mixed ketostearic esters was obtained.

**Separation and Identification of Ketostearic Acids.**—The above mixed esters were saponified and the acids obtained fractionally crystallized using 20% acetone in petroleum ether (b. p. 35–50°) as solvent.

**9-Ketostearic acid** was obtained as fine needles, m. p. 82°, and separated first as the least soluble isomer, yield 0.5 g. This was identified by mixed melting point with a known sample of 9-ketostearic acid (see B below). It also gave a semicarbazone, m. p. 118–120°, which was identical with the semicarbazone of 9-ketostearic acid.

**10-Ketostearic acid** was obtained as thick needles or large rhombic prisms, m. p. 72–73°, yield about 5.0 g. This was identified by mixed melting point with a known sample of 10-ketostearic acid by preparation and comparison of the semicarbazone, m. p. 101–103°, as well as by isolation of sebacic acid, m. p. 133°, from the products of Beckmann transformation of the oxime.

**11-Ketostearic acid** was not isolated in the pure state. The next series of crystal crops (5.0 g.) consisted of fine short needles mixed with rhombs of 10-ketostearic acid. A quantity of the rhombs was separated manually with the aid of a microscope and by preferential solubility of the fine needles in cold solvent, but the concentrated material still contained some rhombic (and probably needle form) 10-ketostearic acid. Therefore 3 g. of this product was converted to the oxime and submitted to the Beckmann transformation and from the products of hydrolysis there was isolated sebacic acid (0.4 g.) and nonanedicarboxylic acid (0.2 g.), m. p. 109–110° when recrystallized from water at 65°.

*Anal.* Calcd. for $C_{11}H_{20}O_4$: neut. equiv., 108. Found: neut. equiv., 108. The above nonanedicarboxylic acid was identified by mixed melting point with a sample, m. p. 110–111°, prepared by the method of V. Braun and Danziger,[14] from nonane-1,9-diol prepared from diethyl azelate by the method of Chuit.[15]

**8-Ketostearic acid** was likewise not isolated in the pure state. The fourth series of crystal crops and final mother liquors were combined and 3.5 g. converted to the oxime and submitted to the Beckmann transformation. From the hydrolysis products of the amides there was isolated some nonane dicarboxylic acid (0.1 g.) sebacic acid (0.1 g.) and 0.1 g. of suberic acid, m. p. 139–140°, when recrystallized from acetone.

*Anal.* Calcd. for $C_8H_{14}O_4$: neut. equiv., 87. Found: neut. equiv., 87.7.

The suberic acid was identified by mixed melting point with a known sample.

**B. Preparation of 9- and 10-Ketostearic Acids.**—Ten grams of methyl 9,10-epoxystearate[16] was dissolved in 700 ml. of ethanol and the solution carefully neutralized to phenolphthalein with caustic soda; 3.5 g. of Raney nickel was added and hydrogenation carried out on a shaking machine at 25°; 600 ml. of hydrogen at S. T. P. was absorbed. After filtering, the solvent was removed and 10 g. of hydroxy ester was recovered. This ester was oxidized with 14 ml. of a solution of chromic acid in acetic acid containing 0.16 g. of chromic oxide per ml., stirring for one hour at 30–35° and two hours at room temperature. The oxidation mixture was then poured into 300 ml. of water and the product extracted with petroleum ether. About 10 g. of methyl ketostearate was obtained as a pale yellow liquid. This was saponified and the keto acids recovered.

The keto acids were fractionally crystallized from acetone–petroleum ether mixture (1:2).

9-Ketostearic acid was obtained as lustrous plates, m. p. 81.5°, yield 0.21 g. Behrend[17] obtained this acid, m. p. 83°, and proved the structure by obtaining azelaic acid, decanoic acid, ω-aminoöctanoic acid and nonylamine through the Beckmann transformation of the oxime.

The semicarbazone of 9-ketostearic acid, which was prepared and crystallized from alcohol, melted at 118–120°.

*Anal.* Calcd. for $C_{19}H_{37}O_3N_3$: N, 11.83. Found: N, 11.7.

10-Ketostearic acid was obtained as needles or rhombic prisms, m. p. 71°, yield 8.5 g. This acid gave a semicarbazone, m. p. 101–103°, crystallized from alcohol.

*Anal.* Calcd. for $C_{19}H_{37}O_3N_3$: N, 11.83. Found: N, 11.9.

Baruch[18] obtained this acid, m. p. 75°, and proved its structure. A sample of our keto acid, m. p. 71°, was converted to the oxime and by Beckmann transformation yielded sebacic acid, m. p. 133°.

**C. Beckmann Transformation on Oxime of 12-Ketostearic Ester.**—In order to ascertain the conditions for the Beckmann transformation upon long chain ketoximes the following examination was carried out. This is described in detail since to our knowledge it has not been previously reported for this readily available compound.

**Methyl 12-Hydroxystearate.**—Methyl ricinoleate, b. p. 189–191° at 1 mm. pressure, was prepared by fractional distillation of methyl esters of castor oil acids. The ester (227 g.) was hydrogenated directly using Raney nickel catalyst in a shaking bomb at 100° and 600 p. s. i. initial hydrogen pressure. The product was dissolved in 250 ml. of methanol, filtered and crystallized at 0°. After recrystallization from methanol 194 g. of pure methyl 12-hydroxystearate was obtained, m. p. 57–58°.

**Methyl 12-Ketostearate.**—The above ester (60 g.) was dissolved in 160 ml. of glacial acetic acid at 30° and 11.1 g. of chromic anhydride dissolved in 50 ml. of 80% acetic acid was gradually added with stirring. The reaction mixture was stirred for an additional two hours and then poured into water and the solid ester extracted with Skellysolve F, washed, dried and recovered. After recrystallization from methanol 52 g. of methyl 12-ketostearate, m. p. 45–46°, was obtained.[19]

**Oxime of Methyl 12-Ketostearate.**—The above ester (12 g.) was dissolved in 90 ml. of 80% alcohol, and solutions of 6.7 g. of hydroxylamine hydrochloride in 30 ml. of 80% alcohol and 10 g. of sodium acetate in 30 ml. of 80% alcohol were added, when the mixture was refluxed for two and one-half hours and then stood at 30° overnight. The alcohol was then distilled off and the residual oil taken up in ether, washed and dried. The oxime was obtained as 12 g. of oil and was not further purified.

**Beckmann Rearrangement of Oxime.**—The above crude oxime was added to 60 ml. of concentrated sulfuric acid and heated on steam-bath one hour. After cooling, the reaction mixture was poured into water. The solid amides which were filtered and washed weighed 12 g.

**Hydrolysis of Amides.**—This was carried out by heating the above amides with 60 ml. of 20% caustic potash in a bomb at 175–200° for three hours. The hydrolysis products were isolated in the order: (a) Monocarboxylic acid, by steam distillation of acidified hydrolysis mixture. Recovered 1.5 g. of *n*-heptanoic acid. *Anal.* Calcd. for $C_7H_{14}O_2$: neutral equivalent, 130. Found: neutral equivalent, 131. The *p*-toluidide had m. p. 80°. Reported *n*-heptanoic-*p*-toluidide, m. p. 81°. (b) Dicarboxylic acid, by ether extraction of acidified hydrolysis mixture after removal of (a). Recovered 6 g. of decane dicarboxylic acid. This was recrystallized from ethylene dichloride and had m. p. 127–128°. Reported m. p. was 127–128°. *Anal.* Calcd. for $C_{12}H_{22}O_4$: neutral equivalent, 115. Found: neutral equivalent, 116.5. (c) Amine, by making alkaline aqueous liquor from (b) and extraction with ether. Recovered 1 g. hexylamine, b. p. 127–128°. Reported b. p. 129–130°. (d) Amino acid, by acidifying the alkaline solution from above with acetic acid, adding ammonia until just alkaline and filtering the amino acid which precipitated as a solid (1.5 g.). This ω-aminoundecanoic acid recrystallized from water and had m. p. 183–184°.

*Anal.* Calcd. for $C_{11}H_{23}O_2N$: N, 6.96. Found by Kjeldahl: N, 6.80.

It was found that for the Beckmann rearrangement of the oximes of these keto acids concentrated sulfuric acid was more reliable than phosphorus pentachloride in ether and good yields of amides were obtained without any reversion to the keto acid, which sometimes occurred with the phosphorus pentachloride.

**D. Action of Performic Acid on Methyl Hydroxyoleates.**—Performic acid was prepared using the method of Swern, *et al.*[3] To 20 g. of 98% methyl hydroxyoleates dissolved in 320 ml. of 98% formic acid, 40.2 ml. of hydrogen peroxide (32%) was added. The reaction temperature was not allowed to exceed 40°. When the temperature began to drop the reaction mixture was left overnight at room temperature. The product was poured into water, saturated with sodium chloride and the separated oil extracted with ether. The ether solution was washed with water, then with acidified ferrous sulfate solution to remove peroxide and finally with 2% potassium carbonate to remove acidic material.

The neutral ether-soluble portion was recovered as an oil which was deformylated by refluxing in 150 ml. of methanol containing 1% sulfuric acid. This reaction mixture was poured into water and the solid which precipitated was taken up in ether, washed free of acid and dried. Evaporation of the ether yielded 10.6 g. of white solid which was crude methyl trihydroxystearates. This was purified by extraction with one liter of petroleum ether for forty-five minutes, cooling and filtering. There was obtained 5.6 g. of insoluble solid which by periodate analysis was 96% pure methyl trihydroxystearates. A portion was saponified and converted to the acid which melted at 115–120°.

*Anal.* Calcd. for $C_{18}H_{36}O_5$: neutral equivalent, 332. Found: neutral equivalent, 338.

Calcd. for $C_{18}H_{33}O_2(OH)_3$: hydroxy equivalent, 110.7. Found: 112.5.

The acidic fraction of this reaction was recovered as 10 g. of thick liquid material upon acidification and extraction of the potassium carbonate washings above. These acid esters were saponified with alcoholic caustic potash and the acids were recovered. The monocarboxylic acids were separated by steam distillation. A total of 5.0 g. of volatile acids was collected which after fractional redistillation in vacuum were found to boil from 87–100° at 0.7 mm. and these fractions had neutral equivalents varying from 153–167.

The material non-volatile with steam was taken up in 500 ml. of boiling water and filtered. A small amount (0.7 g.) of solid insoluble in water proved to be trihydroxystearic acid. The filtrate was fractionally crystallized and the following acids were separated and identified.

**Sebacic Acid.**—This separated at 60° from the water solution. A yield of 1.0 g. was obtained which upon recrystallizing from a 50% mixture of dioxane and water had m. p. 131–132.5°. *Anal.* Calcd. for $C_{10}H_{18}O_4$: neutral equivalent, 101. Found: neutral equivalent, 101. It gave a diphenacyl ester m. p. 81°.[20] The identity was proved by mixed melting point of the acid and the diphenacyl ester with pure specimens, respectively.

**Azelaic Acid.**—This separated at 25° from the water solution. A yield of 2.6 g. of acid was obtained which melted at 105–106° after recrystallization from benzene and then methyl acetate. *Anal.* Calcd. for $C_9H_{16}O_4$: neutral equivalent, 94. Found: neutral equivalent, 93. Identity was confirmed by mixed melting points of acid and diphenacyl ester (m. p. 70–71°) with pure specimens, respectively.

**Suberic Acid.**—This was obtained upon concentration of the aqueous mother liquor. Yield was approximately 1.1 g. after recrystallization from acetone, m. p. 140–141°. *Anal.* Calcd. $C_8H_{14}O_4$: neutral equivalent, 87. Found: neutral equivalent, 86. Its identity was confirmed by mixed melting points of acid and diphenacyl ester (m. p. 107.5°) with pure specimens of these.

**Periodate Oxidation of Above Mixed Trihydroxystearic Acids.**—Six grams of the above acid was dissolved in 60 ml.

of ethanol and treated with 8.5 g. of periodic acid in 60 ml. of ethanol with cooling and then kept at room temperature for thirty minutes.

The reaction mixture was poured into water and extracted with ether. The acid half-aldehydes were separated from the normal aldehydes by aqueous carbonate washing of the ether extract, and were subsequently separately oxidized to the carboxylic acid by treatment with peracetic acid.[9] There was thus recovered 2.47 g. of liquid monocarboxylic acids which were not further examined.

From the carbonate extract there was obtained 2.81 g. of mixed dicarboxylic acids after oxidation of the half aldehydes. These acids were separated by maceration with anhydrous ether. The portion insoluble in ether (0.6 g.) was washed with benzene and then crystallized from acetone to give a pure acid which was identified as suberic acid, m. p. 140–141° by mixed melting point with an authentic sample. *Anal.* Calcd. for $C_8H_{14}O_4$: neut. equiv., 87.0. Found: neut. equiv., 88.0.

The ether soluble fraction was crystallized from water and then from methyl acetate. 0.58 g. of pure acid was obtained which was identified by analysis and mixed melting point with a known sample as azelaic acid, m. p. 105–106°. *Anal.* Calcd. for $C_9H_{16}O_4$: neut. equiv., 94. Found: neut. equiv., 95.

## Summary

1. The products of autoxidation of methyl oleate at 35° in the presence of ultraviolet light have been examined.

2. The position of substitution of the hydroperoxido groups has been determined by conversion to the corresponding ketostearic acids. Substitution has been shown to occur at carbon atoms $C_8$, $C_9$, $C_{10}$ and $C_{11}$.

3. Evidence has been obtained that a double bond shift occurs in the formation of two of the above hydroperoxido substitutions so that in all four compounds the olefinic group is adjacent to the hydroperoxido group. In the peroxidation and double bond shift only the carbon atoms $C_8$, $C_9$, $C_{10}$ and $C_{11}$ are involved.

4. The products identified strongly support a chain reaction mechanism sequence involving allylic resonance of the two free radicals initially possible.

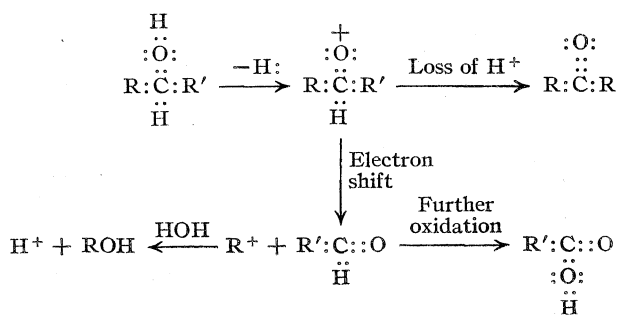
# Oxidation of Some Aliphatic Alcohols with Chromic Acid



BY WILLIAM A. MOSHER AND ESLEY O. LANGERAK[1]

Mosher and Whitmore[2] recently reported the isolation of *t*-amyl alcohol from the chromic acid oxidation of methyl-*t*-amylcarbinol and isopropyl-*t*-amylcarbinol and *t*-butyl alcohol from the oxidation of methyl-*t*-butylcarbinol. A tentative mechanism involving the new concept of an intermediate containing an electronically-deficient oxygen atom was proposed. Work has been continued on this general problem by a careful search for anomalous oxidation products from other secondary aliphatic alcohols.

The secondary alcohols referred to above all have a neopentyl carbon in the alpha position to the hydroxyl-bearing carbon atom. It is probably due to the weak electron-attracting power of this type of group[3] and to the "steric strain"[4] that the splitting occurs to any appreciable extent. The first extension of the above work was to study the oxidation of secondary alcohols which had carbon atoms of lower substitution in the alpha position. The oxidation of ethyl-*s*-butylcarbinol with chromic anhydride in 80% aqueous acetic acid gave 63% of the corresponding ketone, 1% *s*-butyl alcohol, and about 1% methyl ethyl ketone probably formed by the oxidation of some of the *s*-butyl alcohol. The similar oxidation of methyl-*n*-amylcarbinol gave 83% of the corresponding ketone and a trace of *n*-amyl acetate presumably formed from the esterification of the corresponding alcohol or carbonium ion.

The question of the second part of the molecule formed by the split has been clearly answered in the case of *n*-propyl-*t*-butylcarbinol. The oxidation of this alcohol gave 41% of the corresponding ketone, 4% *n*-butyraldehyde and a corresponding amount of *t*-butyl alcohol. Traces of aldehyde have been isolated in other aliphatic alcohol oxidation but further oxidation to acid appears to be the usual course.

In the case of secondary aliphatic alcohols it would appear that some cleavage at the carbon alpha to the hydroxyl-bearing carbon is a general phenomenon. The amount of cleavage observed decreases as the electron attracting power of the group increases and the steric strain decreases. The proposed mechanism is written below in generalized form for any secondary alcohol.

(1) F. G. Cottrell Research Fellow in chemistry.

(2) Mosher and Whitmore, THIS JOURNAL, **70**, 2544 (1948).

(3) Whitmore and Bernstein, *ibid.*, **60**, 2626 (1938).

(4) H. C. Brown, *et al.*, *ibid.*, **66**, 435 (1944).

From the above mechanism it will be seen that the split of the molecule to yield carbonium ion and aldehyde occurs at the position beta to the position of electron deficiency. The electrons in this particular position are the most accessible to the oxygen atom. The position of the split, as well as the extent of splitting, is in complete harmony with the findings of Whitmore and Stahly[5] and Whitmore and Mosher.[6] This "beta-effect," discussed by Dean Whitmore[7] in 1944, has its physical basis in the fact that the beta electrons are the closest electrons to the deficient atom in which the deficient atom does not already have a part interest.

This work was possible through a Frederick G. Cottrell Grant from the Research Corporation, which we gratefully acknowledge.

## Experimental

**Preparation of Alcohols.**—Methyl-*n*-amylcarbinol was obtained from Carbide and Carbon Chemical Corporation. Ethyl-*s*-butylcarbinol and *n*-propyl-*t*-butylcarbinol were prepared by the Grignard reaction from the appropriate starting materials. Materials were purified by fractionation through a Whitmore–Lux[8] total condensation, partial take-off type column packed with single turn glass helices,[9] and equivalent to 20 theoretical plates.

**Oxidation.**—(a) All secondary alcohols were oxidized in the following manner exemplified with ethyl-*s*-butylcarbinol: a solution of 80 g. (0.8 mole) of chromic anhydride in 50 ml. of water and 125 ml. of glacial acetic acid was added dropwise to a stirred solution of 168 g. (1.4 mole) of the carbinol in 100 ml. of glacial acetic acid over a period of 5.75 hours. The temperature was kept below 30° at all times. The oil layer formed on dilution of the reaction mixture was separated, washed with bicarbonate solution, and then with water. The aqueous layer was steam distilled and the oil layer, after washing as before, was combined with the main portion. The dried oil layers were fractionated through a column of 20 theoretical plates. From the distillation charge of 133 g. the following cuts were obtained: I (1.5 g., 0.9%), 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. with an authentic derivative of methyl ethyl ketone 116–117°; II (1.4 g., 0.8%), phenylurethan, m. p. and mixed m. p. with a derivative of *s*-butyl alcohol 64–65°; III (100.1 g., 63%), ethyl *s*-butyl ketone, 2,4-dinitrophenylhydrazone m. p. 78°. Unchanged carbinol (11.0 g., 7%) was recovered. Still residue, 8.1 g., was a dark viscous liquid.

(b) Methyl-*n*-amylcarbinol distillation charge 220 g. The corresponding ketone and *n*-amyl acetate boil very close together. The acetate was isolated from the proper fractions by removing the ketone as the bisulfite addition compound and the final traces as the semicarbazone. After drying over anhydrous sodium sulfate a trace (0.08 g., 0.03%) of *n*-amyl acetate, $n^{20}D$ 1.4039, characteristic odor, was isolated; 192 g. (83.2%) of methyl *n*-amyl ketone, 2,4-dinitrophenylhydrazone m. p. and mixed m. p. 74°, was obtained; 7.6 g. (3.4%) unoxidized carbinol was recovered. Still residue was 14.3 g.

(c) *n*-Propyl-*t*-butylcarbinol: No glacial acetic acid was used in order to facilitate isolation of any aldehydes or acids. The carbinol was added dropwise to a vigorously stirred aqueous solution of chromic anhydride. Distillation charge 180 g.; 6.8 g. (4%) of *n*-butyraldehyde, 2,4-dinitrophenylhydrazone m. p. and mixed 122–123°, and a corresponding amount of *t*-butyl alcohol, isolated as the chloride, were obtained. The main fraction (67.3 g., 40.8%), 2,4-dinitrophenylhydrazone m. p. 123–124°, consisted of the corresponding ketone; 50 g. (30.3%) of unoxidized carbinol, phenylurethan m. p. 70–71°, was recovered. Still residue amounted to 21.6 g.

(5) Whitmore and Stahly, THIS JOURNAL, **55**, 4153 (1933); **67**, 2158 (1945).

(6) Whitmore and Mosher, *ibid.*, **68**, 281 (1946).

## Summary

1. The chromic acid oxidation of ethyl-*s*-butylcarbinol yields the expected ketone, but also small amounts of *s*-butyl alcohol and methyl ethyl ketone.

2. Methyl-*n*-amylcarbinol in acetic acid solution gives a trace of *n*-amyl acetate.

3. Oxidation of *n*-propyl-*t*-butylcarbinol gives small amounts of *t*-butyl alcohol and *n*-butyraldehyde in addition to the expected ketone.

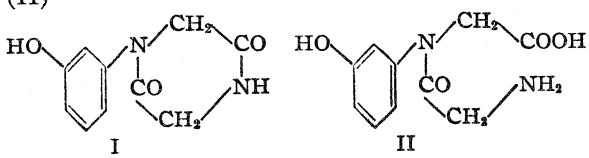
# A Reaction between Resorcinol and Glycine

BY N. LICHTENSTEIN, J. DOBKIN AND EVA HEIMANN-HOLLAENDER

Glycine dissolves with the evolution of carbon dioxide when heated in melted resorcinol at 175–185°. A colorless, crystalline substance can be isolated from the product which remains after the excess resorcinol is removed with ether. The elementary composition and chemical properties of this substance correspond to those to be expected of N-(*m*-hydroxyphenyl)-glycine anhydride (I).

The substance is insoluble in sodium bicarbonate solution, but dissolves readily in dilute sodium hydroxide. It gives positive color reactions with Millon reagent, with 2,6-dichloroquinonechlorimide,[1] and with diazotized sulfanilic acid. The picric acid reaction for diketopiperazines[2] is positive, whereas the fluorescein reaction for resorcinol and the ninhydrin color reaction give negative results. Van Slyke amino determination and titration in acetone according to Linderstrøm–Lang failed to reveal the presence of a free amino group.

Benzoylation of our substance converted it into a corresponding monobenzoyl derivative which was insoluble in dilute sodium hydroxide and gave no color reaction with Millon reagent.

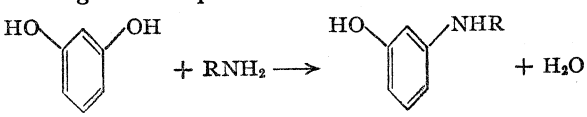


The substance was hydrolyzed with hydrochlo-

(1) H. D. Gibbs, *J. Biol. Chem.*, **72**, 649 (1927).

(2) E. Abderhalden and E. Komm, *Z. physiol. Chem.*, **139**, 181 (1924).

ric acid. When the hydrolysate was evaporated to dryness, dissolved in absolute alcohol and saturated with hydrogen chloride, glycine ethyl ester hydrochloride crystallized out.



It is known that the glycine anhydride ring can easily be opened by treatment with sodium hydroxide to form glycylglycine. In a similar manner, we succeeded in opening the substituted diketopiperazine ring of our substance by treating it with sodium hydroxide and we were able to isolate in good yield a product whose C, H, N and amino N content correspond to the values theoretically expected of glycyl-N-(*m*-hydroxyphenyl)-glycine (II)

Finally, the same substance as that obtained from glycine was isolated after treating glycylglycine with hot resorcinol under similar conditions.

On heating with resorcinol at 175–185°, glycine anhydride could be recovered unchanged.

The formation of N-(*m*-hydroxyphenyl)-glycine anhydride from glycine and resorcinol may be explained as follows. It is known[3] that resorcinol reacts on heating with ammonia or with amines according to the equation

In a similar manner glycine may be assumed to react with resorcinol, yielding N-(*m*-hydroxyphenyl)-glycine. Heating would lead to the decomposition of a considerable part of this substance into carbon dioxide and *m*-methylaminophenol and the latter is thereafter removed with ether. An analogous decarboxylation of N-phenylglycine "on rapid distillation" is described by Bischoff and Hausdörfer.[4] A portion of the N-(*m*-hydroxyphenyl)-glycine, however, reacts with a second molecule of glycine to yield our substance (I). Similarly, glycylglycine would react primarily with resorcinol to give N-(*m*-hydroxyphenyl)-glycylglycine, which then forms the corresponding substituted diketopiperazine (I) by losing one molecule of water. However, we have not yet succeeded in isolating any of the hypothetical intermediary products mentioned above.

## Experimental

**Preparation of N-(*m*-Hydroxyphenyl)-glycine Anhydride (I).**—One hundred grams of resorcinol was heated in an oil-bath at a bath temperature of 175°. Twenty grams of glycine was added to the melted resorcinol, and the mixture was heated for an hour at 175–185° (bath temperature) with occasional stirring. The glycine soon dissolved with the evolution of gas bubbles. When the evolved gas was introduced into an aqueous solution of barium hydroxide, a precipitate was formed which was free of organic matter and which dissolved in diluted acids with the formation of gas bubbles. The clear hot solution was poured into a porcelain mortar. The solidified mass was treated with dry ether, the ether drawn off by suction and the residue washed with ether and dried; yield, 16 g. This material was repeatedly boiled with several portions of absolute alcohol, using the total volume of 1600 cc. of alcohol. The pooled filtered alcoholic extracts were concentrated to about 100 cc. and allowed to stand overnight. The brownish precipitate was filtered by suction, washed with a little absolute alcohol and dried; yield, 9 g. This substance was boiled with about 40 parts of water and filtered through a hot water funnel. The filtrate was boiled with *carbo animalis* and refiltered. On cooling, a precipitate in the form of yellowish needles appeared. It was filtered by suction, washed with water and dried. On recrystallization of the substance from 100 parts of 70% alcohol 3 g. of a colorless, crystalline substance was obtained in the form of glittering needles. The substance gives a red color reaction when boiled with Millon reagent. A deep orange color appears when diazotized sulfanilic acid and soda are added to its aqueous solution. With dichloroquinone chlorimide[1] and borate buffer (*p*H 9.2) a blue color is formed. The diketopiperazine reaction of Abderhalden and Komm[2] is positive. The ninhydrin color reaction and the fluorescein test for resorcinol are negative. The Linderstrøm-Lang titration value and the amino value according to Van Slyke are 0. The substance is insoluble in cold aqueous sodium bicarbonate but dissolves readily in dilute sodium hydroxide.

For analysis, the substance was twice recrystallized from 70% alcohol and dried *in vacuo* over phosphorus pentoxide at 100°.

*Anal.* Calcd. for $C_{10}H_{10}N_2O_3$: C, 58.2; H, 4.9; N, 13.6. Found: C, 58.5; H, 4.7; N, 13.5.

The substance has no definite melting point. It decomposes at 265–270° after previous darkening.

**N-(*m*-Benzoyloxyphenyl)-glycine Anhydride.**—One gram of N-(*m*-hydroxyphenyl)-glycine anhydride was treated with 45 cc. of 0.1 *N* sodium hydroxide (about 0.9 mole) and filtered. The filtrate was cooled in a mixture of ice and water and 0.6 g. of benzoyl chloride was added drop by drop with constant stirring. The colorless precipitate was filtered by suction, repeatedly washed with cold water and dried; yield, 900 mg. For analysis, the substance was recrystallized twice from a small amount of absolute alcohol, m. p. 171° (uncor.). *Anal.* Calcd. for $C_{17}H_{14}N_2O_4$: N, 9.03. Found: N, 9.08. The substance is insoluble in dilute sodium hydroxide and gives no color reaction with Millon reagent.

**Acid Hydrolysis of N-(*m*-Hydroxyphenyl)-glycine Anhydride.**—One gram of N-(*m*-hydroxyphenyl)-glycine anhydride was boiled with 15 cc. of hydrochloric acid (1:1) for fifteen to twenty hours. The hydrolyzate was evaporated to dryness in a vacuum desiccator over sulfuric acid and soda lime. α-Amino carboxyl determination (Van Slyke's ninhydrin method) showed that at least the greatest part of the substance was completely hydrolyzed. The evaporated hydrolyzate was dissolved in a small amount of absolute alcohol and saturated with dry hydrogen chloride. On standing, about 200 mg. of glycine ethyl ester hydrochloride crystallized out. *Anal.* Calcd.: N, 10.0; Cl, 25.4. Found: N, 10.1; Cl, 25.5.

**Glycyl-N-(*m*-hydroxyphenyl)-glycine (II).**—Two grams of N-(*m*-hydroxyphenyl)-glycine anhydride was dissolved in 40 cc. of *N* sodium hydroxide and allowed to stand for three days at 30°. Forty cc. of *N* hydrogen chloride was added, and the solution was evaporated to dryness *in vacuo*. The substance obtained was treated with 100 cc. of absolute alcohol and filtered the next day. The remaining product was dissolved in 4 parts of hot water, and the precipitate which formed on cooling was again recrystallized from water. Eight hundred and fifty mg. of a

(3) Beilstein's "Handbuch der organ. Chemie," **6**, 799, 806, 807 (1923).

(4) C. A. Bischoff and A. Hausdörfer, *Ber.*, **25**, 2270 (1892).

reddish, crystalline substance free of chlorine were obtained in this manner. The substance was dried *in vacuo* at 100° over phosphorus pentoxide. It gives positive color reactions with ninhydrin, with diazotized sulfanilic acid and with dichloroquinone chlorimide.

*Anal.* Calcd. for $C_{10}H_{12}N_2O_4$: C, 53.6; H, 5.6; N, 12.5; amino-N, 6.3. Found: C, 53.4; H, 5.6; N, 12.6; amino-N, 6.3 (Linderstrøm-Lang titration).

The substance has no definite melting point.

**Formation of N-(*m*-Hydroxyphenyl)-glycine Anhydride from Glycylglycine and Resorcinol.**—To 25 g. of melted resorcinol was added 5 g. of glycylglycine. The mixture was heated for three hours in an oil-bath at a bath temperature of 175–185°. The limpid, hot solution was poured into a porcelain mortar and the solidified material was treated with ether. (No gas formation was observed on heating the dipeptide with resorcinol). After removing the ether by suction the remaining substance was washed with ether and dried; yield, 7.4 g. Five grams of this product was extracted with ethyl acetate for twenty-four hours in a Soxhlet apparatus. The yellowish product which appeared in the extract was filtered by suction, washed with ethyl acetate and dried. The substance (1.1 g.) was recrystallized from 30 cc. of water to which *carbo animalis* was added. On cooling, 250 mg. of a colorless substance was obtained in the form of glittering needles. The Millon reaction was positive. *Anal.* Found: N, 13.2. On benzoylation of 200 mg. under the conditions previously described and on recrystallization from alcohol 170 mg. of a product was obtained whose melting point (171°) was identical with the melting point of the product obtained by benzoylation of N-(*m*-hydroxyphenyl)-glycine anhydride. The m. p. of a mixture of the two substances was also 171°.

*Anal.* Calcd. N, 9.0. Found: N, 9.2.

**Treatment of Glycine Anhydride with Hot Resorcinol.**—Glycine anhydride was heated for three hours with 5 parts of resorcinol at 175–185° in a similar manner to the treatment of glycine or glycylglycine. It dissolved in a short time. After solidification, the reaction mixture was treated with ether. The material obtained after drawing off the ether was boiled with 96% alcohol, filtered, washed with alcohol and dried. The product so obtained (80% of the original material) gave no color reaction with Millon reagent. It was recrystallized from water. *Anal.* Calcd. for glycine anhydride: N, 24.6. Found: N, 24.5.

## Summary

N-(*m*-Hydroxyphenyl)-glycine anhydride was isolated after treating glycine with hot resorcinol at 175–185°. The same product is formed when glycylglycine is heated with resorcinol.

Treating with sodium hydroxide converts N-(*m*-hydroxyphenyl)-glycine anhydride into glycyl-N-(*m*-hydroxyphenyl)-glycine.

# The Preparation of 3,3′-Dibromobiphenyl and its Conversion to Organometallic Compounds

BY H. R. SNYDER, CLAY WEAVER[1,2] AND CLIFFORD D. MARSHALL

Although the reactions of various dibromobiphenyls with magnesium[3,4] and with an alkyllithium[5] have been reported, 3,3′-dibromobiphenyl appears to have escaped such investigation. Since symmetrical difunctional organometallic compounds related to biphenyl have been of interest to us as possible intermediates[6] in the synthesis of biphenyldiboronic acids,[7,8,9] the behavior of 3,3′-dibromobiphenyl toward magnesium, lithium and *n*-butyllithium has been examined.

3,3′-Dibromobiphenyl was prepared from *o*-nitrobromobenzene by reduction to the hydrazo compound, rearrangement to the benzidine, and deamination of the tetrazonium salt with hypophosphorous acid.[10] The hydrazo compound and the benzidine thus prepared were found to have melting points quite different from those observed on samples, obtained by processes involving the bromination of azobenzene[11] and of N,N′-diacetylbenzidine,[12] which have been considered[13] to have the structures of 2,2′-dibromohydrazobenzene and 3,3′-dibromobenzidine, respectively. The bromination of N,N′-diacetylbenzene was repeated, and a dibromobenzidine identical with our sample was the only product isolated in a pure state from the reaction mixture. In a Sandmeyer reaction with cuprous bromide the tetrazonium salt from our dibromobenzidine gave a product possessing the same melting point as the tetrabromobiphenyl[14] prepared by van Roosmalen from a dibromobenzidine obtained by the direct bromination method. Furthermore, our compounds had the expected compositions and yielded 3,3′-dibromobiphenyl of the correct properties.[15]

3,3′-Dibromobiphenyl did not react with magnesium under the usual conditions of Grignard preparations, but it did react in the presence of ethylmagnesium bromide. The difunctional Gri-

gnard reagent so formed separated from the ether as a heavy oil. Because of the separation, and because of the presence of ethylmagnesium bromide in the solutions, it was not convenient to determine the extent of reaction of the dibromobiphenyl by titration. Carbonation of such solutions produced the known 3,3′-biphenyldicarboxylic acid which was further characterized as the methyl ester.[16,17] Since the yield of once-recrystallized dicarboxylic acid was moderately good (40%), the conversion of the dibromo compound to the Grignard reagent must have been high. When the Grignard preparation was carried out with only one equivalent of magnesium, both the mono- and difunctional organometallic compounds were formed, as shown by the conversion to 3′-bromo-3-biphenylcarboxylic acid and 3,3′-biphenyldicarboxylic acid. 3,3′-Dibromobiphenyl could not be induced to react with metallic lithium; however, it did react with *n*-butyllithium to produce the difunctional organometallic compound, the presence of which was demonstrated by carbonation.

## Experimental[18]

**2,2′-Dibromohydrazobenzene.**—The method of preparation was patterned after that used by Lukashevich[19] for the synthesis of the chloro analog. A mixture of 20 g. of *o*-nitrobromobenzene and 5 ml. of 50% aqueous sodium hydroxide was stirred at 60°, and zinc dust was added intermittently in small portions such that the temperature remained at 70–80°. After 15 g. of zinc had been added, the sludge was diluted with 50 ml. of water and 30 ml. of 20% aqueous sodium hydroxide. Then 20 g. of zinc was added rapidly, and the mixture was stirred at 70–80° until it was nearly colorless. The cooled mixture was poured slowly into 200 ml. of 25% sulfuric acid at 10°; the mixture was stirred for a few minutes and then filtered. The dry solid was extracted with three 30-ml. portions of ether, and the residue from the evaporation of the ether was recrystallized from petroleum ether (b. p. 40–60°), diluted with a little benzene, to give 10.8 g. (57%) of the hydrazo compound melting at 97–98°.

*Anal.* Calcd. for $C_{12}H_{10}Br_2N_2$: C, 42.1; H, 2.95. Found: C, 42.4; H, 3.30.

**3,3′-Dibromobenzidine.**—Method A: A solution of 4 g. of 2,2′-dibromohydrazobenzene in 50 ml. of ether was added slowly with shaking to 25 ml. of cold concentrated hydrochloric acid. Shaking was continued for one hour, and the dihydrochloride was separated by filtration and washed with ether. A suspension of the white product (wt., 4 g.) in excess 10% aqueous sodium hydroxide was heated on the steam-bath for one hour. The free base was extracted from the cooled mixture with ether, and the extracts were dried over calcium sulfate. The benzidine, recovered from the ether extracts, was recrystallized from ethanol to give 3 g. (75%) of a nearly white solid melting at 127–129°.

*Anal.* Calcd. for $C_{12}H_{10}Br_2N_2$: C, 42.1; H, 2.95. Found: C, 42.3; H, 3.27.

For the preparation of larger quantities of the dihydrochloride, essentially the same procedures were used but the intermediate hydrazo compound was not isolated. The yield of 3,3′-dibromobenzidine dihydrochloride from 61 g. of *o*-nitrobromobenzene was 35–40 g. (57–65%).

Method B: To a well-stirred suspension of 2.68 g. of N,N′-diacetylbenzidine in 100 ml. of water containing a trace of ferric bromide, 3 ml. of bromine was added over a two-hour period. The mixture was stirred for fifteen hours more and then permitted to stand for three days, at the end of which time a brown solid was removed by filtration, washed with water, and added to 40 ml. of 42% sulfuric acid. This mixture was gently refluxed for eighteen hours, cooled, diluted with water, and made alkaline with solid sodium carbonate. A dark solid was collected and extracted with ether. After treatment of the combined extracts with Darco, the ether was removed under reduced pressure. The dark solid so obtained was dissolved in a small amount of alcohol; careful addition of concentrated ammonia to the alcoholic solution produced, first, a very dark precipitate which was removed and discarded, and second, a light brown precipitate, which after separation and washing was dissolved in dilute sulfuric acid. This acidic solution, after decolorization with Darco, was made alkaline with ammonia and gently heated on a steam-bath for several minutes. A cream-colored precipitate was collected and washed with water; it was dissolved in alcohol and to the hot, filtered solution water was added to incipient cloudiness. From the cooled solution a finely crystalline precipitate was collected and washed with cold alcohol–water solution. The solid melted at 128–130° either alone or when mixed with a sample made by Method A, while admixture with benzidine caused a large depression in melting point.

**3,3′,4,4′-Tetrabromobiphenyl.**—The procedure employed was essentially that of van Roosmalen[14]; a portion of 3,3′-dibromobenzidine prepared by Method A was used in the reaction. The product, recrystallized from benzene, melted at 166.5–168.5° (lit.[14] 169°).

**3,3′-Dibromobiphenyl.**—A mixture of 42 g. of 3,3′-dibromobenzidine dihydrochloride and 50 ml. of concentrated hydrochloric acid was diluted with 25 g. of ice and 25 ml. of water and tetrazotized by the addition of a solution of 14 g. of sodium nitrite in 50 ml. of water. The mixture was stirred for one hour after the addition of the nitrite and was then allowed to settle. The clear supernatant solution was added to 330 g. of 30% hypophosphorous acid at 10°; the small amount of residual solid was treated with 10 ml. of concentrated hydrochloric acid and sufficient sodium nitrite to cause complete solution, and this solution was also added to the hypophosphorous acid. The mixture was allowed to stand in the refrigerator for thirty hours and then in the room, with occasional shaking, for twenty hours. The mixture was then extracted with five 50-ml. portions of ether. The combined ether extracts were washed with two 50-ml. portions of 5% sodium hydroxide, followed by 50 ml. of water. The extracts were dried over potassium carbonate and the oil remaining after evaporation of the ether was distilled from a short-necked flask with a very wide side tube.[20] The yield of nearly colorless oil (b. p. 130–140° (2 mm.)), which soon solidified, was 22.0–25.2 g. (71–81%). A sample recrystallized from ethanol melted at 52–52.5° (lit.,[15] 53°).

**3,3′-Biphenyldicarboxylic Acid.**—From the difunctional Grignard reagent: To 3.12 g. of 3,3′-dibromobiphenyl, 0.58 g. of magnesium, and 12 ml. of anhydrous ether, contained under a nitrogen atmosphere in a 3-necked 50-ml. flask equipped with a mercury sealed stirrer and a condenser, there was added an ethylmagnesium bromide solution prepared from 0.76 ml. of ethyl bromide, 0.28 g. of magnesium and 4 ml. of dry ether. After the mixture had been gently refluxed for eight hours, a heavy dark red oil had formed. The content of the flask was poured, portionwise with stirring, onto an excess of powdered Dry Ice contained in a flask toward whose mouth a vigorous stream of nitrogen was directed. After the carbonated mixture had been hydrolyzed with 20 ml. of 6 *N* sulfuric acid, a light yellow solid was removed by filtration and washed with several small portions of ether and

(18) All melting points uncorrected.

(19) Lukashevich, *Anilinokrasochnaya Prom.*, **4**, 605 (1934) [(*C. A.*, **29**, 2527 (1935)].

(20) The flask was of the type recommended by Koelsch, "Organic Syntheses," **20**, 20 (1940).

then with water (wt. of solid 1.60 g.). The ether layer of the filtrate was extracted with two 20-ml. portions of 5% sodium bicarbonate; acidification (congo red) of the combined bicarbonate washes with sulfuric acid gave a small amount of light yellow precipitate, which was collected and washed with water.

The solution of the two above precipitates in dilute sodium carbonate was decolorized with Darco. Acidification (congo red) of the solution with sulfuric acid produced a flocculent white solid, which was collected and washed with water. Recrystallization from dioxane gave a white powdery solid (wt. 0.97 g., 40%) melting at 330–332° (lit. 339–341°,[17] 356–357°[16]) and containing no halogen.

From 3,3′-biphenyldilithium: To an ice-cold *n*-butyllithium solution in 24 ml. of dry ether, prepared from 0.56 g. of lithium and 3.4 g. of *n*-butyl chloride, contained in the apparatus described above and under an atmosphere of nitrogen, 2.34 g. of 3,3′-dibromobiphenyl in 12 ml. of dry ether was added by means of a dropping funnel over a thirty-minute period. The mixture was cooled and stirred for four hours and was then gently refluxed for one hour. After carbonation of the mixture, the acid was isolated and purified as above, m. p. 330.5–332° (wt. 0.83 g., 46%).

**Dimethyl Ester of 3,3′-Biphenyldicarboxylic Acid.**—The procedure of Bulow and von Reden[17] was employed. The dimethyl ester so obtained melted at 97.5–99 (lit.[17] 100–101).

**3′-Bromo-3-biphenylcarboxylic Acid.**—To 3.20 g. of 3,3′-dibromobiphenyl, 0.24 g. of magnesium and 20 ml. of dry ether, contained in the apparatus previously described and under an atmosphere of nitrogen, approximately 0.005 mole of ethylmagnesium bromide in 5 ml. of dry ether was added; the mixture was stirred and gently heated for seven hours. The reaction mixture was carbonated and hydrolyzed as before.

From the hydrolysis mixture, 0.31 g. of light yellow solid (m. p. above 300°) was removed by filtration and washed with several small portions of ether. The separated ether layer was extracted with two 20-ml. portions of 5% sodium bicarbonate, then with two 20-ml. portions of 5% sodium hydroxide.

The combined sodium bicarbonate washes were decolorized with Darco, and acetic acid was added until the solution was almost neutral to litmus. A precipitate (A, wt. 0.59 g.) was collected and washed with water. Acidification (congo red) of the filtrate from A with sulfuric acid gave a second precipitate (B, wt. 0.13 g.). Similar treatment of the sodium hydroxide extracts with acetic acid gave a precipitate (C, wt. 0.37 g.); on further acidification of the filtrate no appreciable precipitate was obtained.

A portion of C was dissolved in dilute sodium carbonate and decolorized with Darco. Acidification of the filtered solution gave a white solid which was removed by filtration, washed with water and dried. The solid, which contained bromine, was recrystallized twice from benzene to give 3′-bromo-3-biphenylcarboxylic acid, melting at 190–191°.

*Anal.* Calcd. for $C_{13}H_9O_2Br$: C, 56.34; H, 3.27. Found: C, 56.76; H, 3.54.

Precipitate A consisted primarily of the monobasic acid as shown by its almost complete liquefaction at a temperature of 190° and by its separation into the mono- and dibasic acids by stepwise acidification of its solution in dilute sodium carbonate. Precipitate B was primarily the dibasic acid as shown by the melting point, roughly determined as above 300°.

## Summary

3,3′-Dibromobiphenyl has been synthesized from *o*-nitrobromobenzene by zinc–alkali reduction to 2,2′-dibromohydrazobenzene, rearrangement of the hydrazo compound to 3,3′-dibromobenzidine, and deamination of the benzidine by reaction of the tetrazonium salt with hypophosphorous acid. A dilithium compound and a difunctional Grignard reagent were prepared from 3,3′-dibromobiphenyl. From the monofunctional Grignard reagent the new 3′-bromo-3-biphenylcarboxylic acid was obtained.

The melting points of the 2,2′-dibromohydrazobenzene and 3,3′-dibromobenzidine prepared in this work do not agree with those of substances previously considered to have these structures.

# The Stereochemical Course of Amine Replacement Reactions. Some Reactions of *d*-(+)-N,N,N-Trimethyl-α-phenylethylammonium Iodide

BY H. R. SNYDER AND JAMES H. BREWSTER[1]

Quaternary ammonium compounds containing benzyl groups can be used in the benzylation of the anions of such salts as sodiomalonic ester,[2] sodium cyanide,[3] sodium phenolate,[3,4] and the sodium salts of carboxylic acids[3] or of sulfur containing acids.[3,5] These reactions appear to be completely analogous to the formation of benzyl alcohol[6] and benzyl chloride[7] by thermal decomposition of quaternary benzylammonium hydroxides and chlorides, and it would be expected that all of these processes occur by similar mechanisms.

Evidence has been presented to show that both methanol and benzyl alcohol are formed from benzyltrimethylammonium hydroxide by reactions having $S_N2$ mechanisms.[8,9] Reactions proceeding by such mechanisms occur with complete inversion of configuration when they take place at an asymmetric carbon atom; other mechanisms result in partial or complete racemization or in retention of configuration.[10] Read and

Walker[11] concluded that Walden inversion occurred in the formation of *d*-neopiperitol from *l*-piperityltrimethylammonium hydroxide. Accordingly it would be anticipated that an optically active quaternary salt containing an α-substituted benzyl group would alkylate the various reagents mentioned above to give products of configuration opposite to that of the original salt. The present work was undertaken to test this assumption. Optically active forms of α-phenylethyltrimethylammonium salts were chosen for the experiments because the configurational relationships of a large number of compounds containing the α-phenylethyl group have been established.[12] These relationships may be summarized in the statement that in the α-phenylethyl series optically active halo, hydroxy, amino, dimethylamino and acetoxy compounds which have the same sign of rotation have the same configuration.

α-Phenylethylamine (I) was resolved by means of malic and tartaric acids.[13] The optical purity of the *d*-(+)-form ($[\alpha]^{25}D$ +36.24°, $[\alpha]^{22}D$ +36.60°) was estimated to be no more than 97.5%, on the basis of the rotation observed by Marckwald and Meth[14] ($[\alpha]^{22}D$ 37.70°), and to be no less than 94.5%, on the basis of the rotation found by Holmberg[15] ($[\alpha]^{19}D$ 38.73°). The optically active primary amine was methylated by means of formaldehyde and formic acid. N,N-Dimethyl-α-phenylethylamine (II) has a high rotation ($[\alpha]^{26}D$ +61.76°) and might be a useful resolving agent; it forms a methiodide (III) which is dextrorotatory in water.

A water solution of the methiodide (III) was treated with silver oxide and then with acetic acid; the solution of the quaternary acetate was distilled to dryness. From the distillate there was obtained 1-(−)-α-phenylethyl acetate (IV) (26.3%) ($[M]^{28}D$ −185.1 in benzene) having an estimated optical purity of 95.4%, based on the value of Levene and Marker[16] ($[M]^{25}D$ −194 in benzene). Thus, inversion of configuration occurred to the extent of 98–100%, strongly indicating an $S_N2$ mechanism for the reaction. Styrene (33.1%) and *d*-(+)-II (12.1%) were also obtained from this degradation.

Sodiomalonic ester can be alkylated by the racemic salt (III) in diethyl carbitol solution. When the optically active methiodide was employed, the α-methylbenzylmalonic ester (V) formed was optically inactive. A small amount of weakly dextrorotatory II was also obtained, suggesting that the quaternary salt was largely racemized before it could participate in the alkylation reaction.

When an aqueous solution of III and sodium cyanide was distilled to dryness none of the desired hydratroponitrile could be isolated from the distillate, which appeared to consist mainly of styrene.

## Experimental

***d*-(+)-α-Phenylethylamine (I).**—*dl*-α-Phenylethylamine (60 g., 0.50 mole) was resolved by the successive use of *l*-malic acid and *d*-tartaric acid[13] to give 16.1 g. (53.7%) of *d*-(+)-α-phenylethylamine, $n^{20}D$ 1.5264; $d^{20}_4$ 0.951; $[\alpha]^{25}D$ +36.24°, $[\alpha]^{22}D$ +36.60° (*l* = 1 dcm.).

***dl*- and *d*-(+)-N,N-Dimethyl-α-phenylethylamine[17] (II).**—The general method of "Organic Syntheses"[18] for the methylation of amines was found to be applicable to α-phenylethylamine. *dl*-N,N-Dimethyl-α-phenylethylamine, b.p. 92–94° (30 mm.), $n^{20}D$ 1.5023, $d^{20}_4$ 0.908 (lit.[12c] $n^{14}D$ 1.5025, $d^{16}_4$ 0.8986), was obtained in 75% yield, and *d*-(+)-N,N-dimethyl-α-phenylethylamine, $n^{20}D$ 1.5025, $d^{20}_4$ 0.908, $[\alpha]^{26}D$ +61.76° (*l* = 1 dcm.), in 64.5% yield.

***dl*- and *d*-(+)-N,N,N-Trimethyl-α-phenylethylammonium Iodide (III).**—To a solution of N,N-dimethyl-α-phenylethylamine (60.0 g., 0.40 mole) in ether (100 ml.) was added slowly a solution of methyl iodide (64.0 g., 0.45 mole) in ether (100 ml.). After fifteen minutes the mixture had solidified. The flask was cooled under the tap several times during the succeeding two hours and then let stand at room temperature for fourteen hours. The white solid was collected by filtration and washed with two 100-ml. portions of ether. After it had been dried in the air and finally in a vacuum desiccator (continuous pumping for twenty-four hours) the solid weighed 111 g. (95%).

In a similar manner, *d*-(+)-α-phenylethylamine (9.5 g., 0.064 mole) was converted to its methiodide, 17.0 g. (92%), m. p. 157° $[\alpha]^{26}D$ + 11.88 (in water) (*c* = 1.-2627) [lit.[19] m. p. 157.0–157.5°, $[\alpha]^{26}D$ + 19.60° (in alcohol) (*c* = 2.5)].

**Degradation of *d*-(+)-N,N,N-Trimethyl-α-phenylethylammonium Acetate.**—The still moist, thoroughly washed silver oxide prepared from 11.0 g. of silver nitrate

was added slowly, and with good stirring, to a warm (50°) solution of *d*-(+)N,N,N-trimethyl-α-phenylethylammonium iodide (11.64 g., 0.04 mole) in water (100 ml.). The precipitate of silver iodide was broken up continuously to expose fresh silver oxide until the precipitate as a whole was light brown in color. The silver oxide–silver iodide precipitate was removed by filtration and washed with four 50-ml. portions of water. The combined filtrate and wash water was treated with glacial acetic acid (30 g., 0.50 mole), and concentrated to a thick sirup on a steam cone at the water pump.

This oil was transferred, while still warm, to a 50-ml. distilling flask with a wide low-set side arm. Two 1-ml. portions of water and two 1-ml. portions of glacial acetic acid were used in this transfer. The solution in the distilling flask was then distilled at 34 mm. pressure with a Woods metal-bath to heat the bulb of the flask. Most of the excess water and[5] acetic acid distilled below 80° (bath temperature 130° or less). When the bath temperature reached 170–175°, vigorous ebullition occurred and the entire contents of the flask distilled smoothly and rapidly (vapor temperature, 80–110°). The distillate had a strong odor of acetic acid, and weighed 9.5 g.

The distillate was dissolved in ether (50 ml.) and extracted with three 50-ml. portions of water and then with two 25-ml. portions of 5% aqueous sodium bicarbonate. The five aqueous washings were combined (A).

The ether solution was distilled at atmospheric pressure and then at water pump pressure. Fractions which distilled at 69–71° (30 mm.) and at 118–119° (30 mm.) were collected.

The lower-boiling fraction, identified as styrene, weighed 1.38 g. (33.1%); $n^{20}D$ 1.5455, dibromide, m. p. 73–74° (lit., b. p. 145–145.8°[20] ($n^{20}D$ 1.5463,[20] dibromide m. p. 74–75°).[21]

The higher-boiling fraction was 1-(−)-α-phenylethyl acetate; it weighed 1.72 g. (26.3%); $n^{20}D$ 1.4953 (after two further distillations); $[\alpha]^{28}D$ −112.9° (in benzene) ($c$ = 0.1196); $[\alpha]^{28}D$ −112° (homogeneous) ($l$ = 1 dcm.) (capillary); $[M]^{28}D$ −185.1° (lit., b. p. 104° (23 mm.),[12d] $n^{20}D$ 1.49432,[22] ($[M]^{25}D$ −194°).[16]

To the combined aqueous extracts (A) was added 15 ml. of 37% hydrochloric acid. The solution was then evaporated to dryness on a steam cone at the water pump. The white solid was taken up in four 3-ml. portions of water, and these solutions were combined and treated with a solution of sodium hydroxide (10 g.) in water (15 ml.). A vigorous evolution of a basic gas, probably trimethylamine, occurred and an organic liquid separated. The aqueous mixture was extracted three times with 10-ml. portions of ether. The ether was distilled at atmospheric pressure, and the residue was distilled at 31 mm. to yield *d*-(+)-N,N-dimethyl-α-phenylethylamine, b. p. 95–96° (31 mm.), 0.72 g. (12.1%), $n^{20}D$ 1.5021, $[\alpha]^{27}D$ + 59.04 (homog.) ($l$ = 1 dcm.).

**Alkylation of Malonic Ester with *d*-(+)-N,N,N-Trimethyl-α-phenylethylammonium Iodide.**—It was found that absolute diethyl carbitol[23] is a superior solvent for the alkylation of sodiomalonic ester with quaternary salts containing the α-phenylethyl group, for styrene formation was much lower in non-protonic solvents than in the more acidic solvents, such as alcohol. Diethyl carbitol is a polyfunctional ether, and as such has greater solvent powers than dibutyl ether.

Sodium (0.51 g., 0.022 mole) was converted to sodium sand in dry xylene. This operation was carried out in a 50-ml. round-bottomed flask with a ground joint and a gas-inlet side-arm. The xylene was decanted from the sodium sand, and was immediately replaced by about 15 ml. of absolute diethyl carbitol. This was in turn decanted from the sodium, and fresh absolute diethyl carbitol (25 ml.) was added at once. The flask was then fitted with a two-necked adapter bearing a reflux condenser and a small Hershberg stirrer. Diethyl malonate (8.0 g., 0.05 mole) was added slowly to the well-cooled, stirred suspension of sodium sand. After the initial vigorous reaction had subsided and most of the sodium had gone into solution, the cooling-bath was removed, and the reaction allowed to proceed at room temperature. Sodiomalonic ester is quite soluble in diethyl carbitol and the reaction was complete within an hour. Powdered dry *d*-(+)-N,N,N-trimethyl-α-phenylethylammonium iodide (8.73 g., 0.03 mole) was added rapidly. A source of nitrogen was attached to the gas-inlet side-arm of the flask, and the system was flushed out with nitrogen.

The flask was heated by means of an oil-bath. While the contents of the flask were vigorously stirred the oil-bath was maintained at a temperature of 130–140° for twenty-four hours. The temperature of the bath was raised to 150° and held there for one-half hour. During all of this heating only a slow evolution of trimethylamine was noted.

To the cooled mixture in the flask was added 10% hydrochloric acid (20 ml.) and benzene (25 ml.). The organic layer was separated from the acidic aqueous layer.

The benzene solution was extracted with two 50-ml. portions of 5% sodium bicarbonate solution and then with three 25-ml. portions of 37% hydrochloric acid. Diethyl carbitol is wholly extracted from the benzene by this procedure. The benzene solution was distilled, finally under reduced pressure. The fraction boiling at 118–120° (1 mm.) was collected; it consisted of α-methylbenzylmalonic ester (V) 0.93 g. (17.5%), $n^{20}$ 1.4752. This material was optically inactive.

The substituted malonic ester was saponified by the use of 50% potassium hydroxide. The malonic acid so formed melted at 144–145°.[24]

The aqueous solution obtained when hydrochloric acid was added to the reaction mixture was made strongly basic by the addition of 10% sodium hydroxide. The liquid which separated was taken up in ether. The ether solution was evaporated and the residue was distilled. The fraction boiling at 95–96° (30 mm.) was collected; weight 0.72 g. (24.2%), $n^{20}D$ 1.5003, $[\alpha]^{27}D$ + 19.06 (homog.) ($l$ = 1 dcm.). The material was largely racemized N,N-dimethyl-α-phenylethylamine.

## Summary

1(−)-α-Phenylethyl acetate has been prepared from *d*-(+)-N,N,N-trimethyl-α-phenylethylammonium iodide by amine replacement. Essentially complete Walden inversion occurred, indicating an $S_N2$ mechanism for the replacement reaction.

Although the quaternary salt can be used in the alkylation of malonic ester, extensive racemization occurs during the long heating period required.

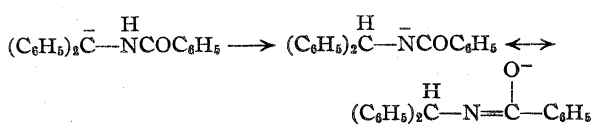
# Metalation and Carbonation of Benzohydrylamine and Derivatives Using Potassium Amide[1]



BY CHARLES R. HAUSER, INA C. FLUR AND SIMON W. KANTOR

Because nitrogen is more negative than carbon, the amino hydrogens of methylamine are more acidic than the methyl hydrogens and, with a sufficiently strong base, the amino hydrogens would presumably be ionized preferentially. However, because of the well-known activating effect of the phenyl group, the methylene hydrogens of benzylamine and especially the methinyl hydrogen of benzohydrylamine might be expected to approach or even surpass the amino hydrogens in acidity. Actually, both of these amines produce red colored solutions with potassium amide in liquid ammonia indicating the formation of the corresponding carbanions. Confirmation of the presence of the carbanion (II) from benzohydrylamine (I) has been obtained by carbonation of the potassium salt to form the amino acid (III). However, similar carbonation of the salt from benzylamine has yielded no carboxylic acid. Even with the potassium salt of benzohydrylamine, carbonation has produced the amino acid (III) only under special conditions; frequently the corresponding carbamic acid (V) is obtained. The formation of (V) indicates that the anion of the potassium salt is partly the amide ion (IV), although (V) may also be formed from the free amine. The interconversion of anions (II) and (IV) is considered to involve reaction with the solvent and amide ion, although it might conceivably occur intramolecularly involving the shift of a proton.

The conditions required for the formation of the amino acid (III) are somewhat difficult to define. This product has been obtained twice in yields of 33% and 42% by evaporating the liquid ammonia in the presence of ether and treating the resulting ether suspension with Dry Ice; these are the conditions employed previously in the carbonation of potassium diphenylmethide.[2] However, attempts to duplicate these results have failed; instead of the amino acid, the carbamic acid (V) was obtained. A more certain way of obtaining the amino acid is to evaporate the liquid ammonia rapidly and then to carbonate an ether suspension of the residue. Apparently, as the liquid ammonia is evaporated, salt (II) is converted to salt (IV): this conversion appears to be minimized by the rapid evaporation of the solvent. However, even with some liquid ammonia present, carbonation has given only the carbamic acid. Similarly, carbethoxylation with diethyl carbonate in liquid ammonia has given only the carbamic acid ethyl ester. With these reactions in liquid ammonia solution, especially with the relatively slow carbethoxylation, a steric factor may be important in that the less-hindered amide ion (IV) may react faster than the carbanion (II), the equilibrium shifting in favor of the former.

The two derivatives of benzohydrylamine, N-isopropylbenzohydrylamine[3] and N-phenylbenzohydrylamine,[4] produce red colored solutions with potassium amide in liquid ammonia but, rather surprisingly carbonation of the ether suspension of the residue, obtained on the evaporation of the ammonia, yielded neither the amino acid nor the carbamic acid, most of the amine being recovered. N - Benzoylbenzohydrylamine[5] reacts with potassium amide in liquid ammonia to produce a red colored solution which gradually lightens to pink and finally becomes colorless after four to five minutes. Apparently some of the carbanion is formed but it is soon converted to the amide ion, thus

It is obvious that derivatives of benzohydrylamine in which both of the hydrogens are substituted can produce only the carbanion. An interesting derivative of this type is benzalbenzohydrylamine (VI) the carbanion of which reacts on carbonation as if it had resonance form (VIIB) rather than (VIIA) since (VIII) is produced apparently exclusively. The acid corresponding to (VIII)

(1) Part of the work reported in this paper was carried out in connection with a contract with the Office of Naval Research.

(3) This compound (b. p. 170–171° at 19 mm.) was prepared in 72% yield from benzohydrylamine and isopropyl iodide by the method of Leeuw, *Rec. trav. chim.*, **30**, 250 (1911).

(4) This compound was obtained as its hydrochloride as described by Busch and Rinck, *Ber.*, **38** [2], 1767 (1905).

(5) This compound was prepared in 97% yield by the Schotten–Baumann method; see Shriner and Fuson, "The Systematic Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1948, p. 88.

was not isolated but its hydrolysis products, benzophenone and *dl*-α-aminophenylacetic acid, were obtained in good yields on acidification of the reaction mixture.

Benzohydrylidenebenzohydrylamine[6] produces a red colored solution with potassium amide in liquid ammonia but the color disappears on replacing the ammonia with ether and the carbonation fails.[7]

It should be pointed out that also certain important syntheses involve metalations of the system, CHNH. One of these consists in the metalation of benzoyl[8] or acetyl[9] aminomalonic ester, followed by alkylation and hydrolysis to form α-amino acids. Application of certain of the ideas discussed above to such syntheses is contemplated.

## Experimental[10]

**Benzohydrylamine.**—This amine has been prepared on a half mole scale from benzophenoneoxime both by reduction with sodium in ethanol and by hydrogenation over Raney nickel. The former method in which the very small scale procedure of Jones and Hurd[11] was adapted gave a satisfactory yield (85%) but the process was somewhat difficult to carry out on the large scale. The hydrogenation in which the general procedure of Adkins[12] was adapted gave equally good yields (85–92%) and it was more convenient.

The oxime (109 g., 0.55 mole) in 600 ml. of 95% ethanol was hydrogenated over Raney nickel at 1000–1300 pounds pressure at 75°. After removal of the catalyst and alcohol, the residue was dissolved in ether. The ether solution was washed with dilute sodium hydroxide, then with water and dried over solid sodium hydroxide. The amine, after removal of the solvent, distilled at 134–135° at 3.5 mm. and at 125–127° at 1 mm.

**Carbonation of Benzohydrylamine.**—To a stirred solution of 0.075 mole of potassium amide in about 200 ml. of liquid ammonia[13] was added 9.15 g. (0.05 mole) of benzohydrylamine. The solution became red immediately. The ammonia was evaporated rapidly using a steam-bath. When all the liquid ammonia was gone, the black residue was heated on the steam-bath for fifteen minutes. The bath was removed and 200 ml. of anhydrous ether was added with constant stirring. An excess of powdered Dry Ice was then added and the mixture stirred for two hours. When the excess Dry Ice was gone, 200 ml. of water was added and after shaking, the aqueous layer was filtered. Carbon dioxide was then bubbled into the aqueous alkaline solution until neutral to *p*H paper. The precipitate was filtered off and washed with methanol or ethanol to dissolve carbamic acid leaving the amino acid, α,α-diphenylglycine, m. p. 238°, in 31% yield. After several washings with ether and alcohol the melting point was raised to 243–245° dec. (reported m. p. 245–246° dec.).[14] The amino acid was further identified by conversion to benzilic acid, m. p. 150°.[15] In two other runs the pure amino acid, m. p. 243–245°, was obtained in 10% yield. Evaporation of the original ether extract of the mixture generally yielded a considerable amount of recovered benzohydrylamine. The recovered amine plus the carbonated product usually accounted for 80–90% of the starting material.

When the residue obtained on the evaporation of the liquid ammonia was suspended in anhydrous dioxane, a red color was produced but, on carbonation, only a 5% yield of the amino acid (m. p. 238°) was obtained. There was obtained a 50% yield of the carbamic acid, m. p. 89–91° (reported m. p. 91°).[16]

When the liquid ammonia solution was evaporated on a steam-bath as anhydrous ether was added at such a rate as to maintain a constant volume, the amino acid (m. p. 238°) was obtained in 42% yield on immediate carbonation and in 34% yield when the ether suspension was refluxed for two hours before carbonation. However, two attempts to duplicate the first result and one attempt to duplicate the latter have failed; instead of the amino acid the carbamic acid was obtained in yields up to 40%.

When the liquid ammonia solution of the potassium salt of benzohydrylamine was allowed to evaporate to a volume of 50 ml. and the contents of the flask then poured on an excess of powdered Dry Ice, only the carbamic acid (26%) was obtained.

When a mixture of 0.05 mole each of benzohydrylamine and diethylaminomagnesium bromide in ether[17] was refluxed for six hours and powdered Dry Ice then added, no carbonation product could be isolated. Most of the amine was recovered. The amine was similarly recovered when equivalent amounts of methylmagnesium iodide and benzohydrylamine were refluxed for one hour and then carbonated.

**Carbonation of Benzalbenzohydrylamine.**—To a stirred solution of 0.2 mole of potassium amide in 200 ml. of liquid ammonia was added 27.1 g. (0.1 mole) of benzalbenzohydrylamine (m. p. 100°).[18] The solution became red immediately. The liquid ammonia was evaporated as sufficient ether was added to maintain constant volume and the resulting red suspension was carbonated in the usual manner. After stirring with water, the aqueous layer was acidified with dilute acetic acid. The solid was filtered off and washed with water; it weighed 22.7 g. and melted over a considerable range. This solid was stirred thoroughly with 50 ml. of ether and the mixture filtered. The precipitate was identified as *dl*-α-aminophenylacetic

(6) This compound was prepared by the method of Ingold and Wilson, *J. Chem. Soc.*, 1502 (1933).

(7) The destruction of the red colored carbanion presumably involves reversion to benzohydrylidenebenzohydrylamine and potassium amide. Similar reversions on replacement of the liquid ammonia by an inert solvent have been observed with sodium triphenylmethide (Kraus and Rosen, THIS JOURNAL, **47**, 2739 (1925)) and with sodium diphenylmethide (see ref. 2) but not with potassium triphenylmethide or potassium diphenylmethide. We have observed the reversion with potassium sym-tetraphenylethide. The tendency for the reversion appears to be dependent both on the metallic cation and on the carbanion. The tendency is greater with sodium ion than with potassium ion and apparently with carbanions which have a greater capacity for resonance.

acid, m. p. 255–257° (after sublimation *in vacuo*) (reported m. p. 255–256°, subl.);[19] the yield was 10.7 g. (71%). The acetyl derivative melted at 197.5–198.5° (reported 198.5).[20] The ether filtrate was evaporated yielding 12 g. (66%) of benzophenone. The semicarbazone melted at 163–164° (reported m. p. 164°).[21]

## Summary

1. Benzohydrylamine and certain of its derivatives react with potassium amide in liquid ammonia to form red colored solutions indicating the formation of the corresponding carbanions.

2. Carbonation of the potassium salt of benzohydrylamine has given the corresponding α-amino acid.

3. Carbonation of the carbanion of benzalbenzohydrylamine gives the N-benzohydrylidene α-phenylglycine instead of N-benzal α,α-diphenylglycine.

# Allylic Rearrangements. XXV. Reaction of the Sodium Derivative of Allylbenzene with α-Haloacetic Acids

BY TOD W. CAMPBELL AND WILLIAM G. YOUNG

The sodium derivative of allylbenzene, which has been the subject of recent investigations[1] undergoes reactions which can best be expressed[1c] as nucleophilic attacks by the resonating anion

$$\left[C_6H_5\overset{\curvearrowleft}{C}H{=}CH{-}\overset{\curvearrowright}{CH_2} \longleftrightarrow C_6H_5\overset{\curvearrowright}{CH}{-}CH{=}\overset{\curvearrowright}{CH_2}\right]^- Na^+$$

I II

Since most reactions studied in which steric effects are not serious lead to mixtures of products derived from both of the principal resonance forms of the allylbenzene anion, it seemed odd that the reaction with simple halides[1a] gave, at least principally, products derived from form II above.

In an attempt to clarify the issue, the reaction of sodium allylbenzene with a series of α-haloacetate ions was examined. This particular series was chosen since it should be possible to determine the effect of (a) steric hindrance, (b) polarization and (c) the nature of the ion being displaced, on the manner in which the resonating allylbenzene carbanion reacts in displacement reactions. When the chosen reactants were mixed, a rapid reaction ensued. From the reaction product was isolated a mixture of carboxylic acids, whose formation can be represented by the equation

$$\left[\begin{matrix}\text{I}\\ \updownarrow \\ \text{II}\end{matrix}\right] + XCR_2CO_2^- \xrightarrow{\begin{matrix}X = Cl, Br\\ R = H, CH_3\end{matrix}}$$

$$C_6H_5CH{-}CH{=}CH_2 + C_6H_5{-}CH{=}CH{-}CH_2CR_2CO_2^-$$

$$\quad\quad |$$

$$\quad\quad CR_2CO_2^-$$

All possible combinations of X and R were examined. The individual acids produced were separated and carefully characterized, principally as benzylamine salts.[2] The composition of the original mixtures was estimated to about ± 2% from the characteristic absorption spectrum[3] for the conjugated system.

From the results listed in Table IV, it will be seen that the polarizing effect of the carboxylate ion adjacent to the carbon atom being attacked is probably more important than simple steric hindrance, since the unsubstituted α-haloacetate ions are certainly less hindered than a compound such as α-methallyl chloride.[1a] It will be noted that the addition of methyl groups on the α-haloacetate ions leads to an increasing amount of the product arising from the primary form of the carbanion, as might be predicted from steric effects.[1c] It is also interesting to note that in this series the nature of the halogen being displaced definitely affects the composition of the mixture obtained from the resonating carbanion, the effect becoming more apparent as the number of methyl groups is increased. This effect of the halogen being displaced on the products has not been noted before in any of the reactions of sodium allylbenzene.

## Experimental Part

All melting points are uncorrected.

**Reaction of the Sodium Derivatives of Allylbenzene with α-Haloacetic Acids—General Method.**—The sodium derivative was prepared in 300 ml. of liquid ammonia in the usual manner[1] from 0.1 *M* of allylbenzene. The solution was forced over as rapidly as possible (by the vapor pressure of the liquid ammonia solvent) into a two-liter three-necked flask containing 0.05 mole of the appropriate α-haloacetic acid dissolved in 20 ml. of ether (anhydrous). The flask was equipped with a stirring device and a wide outlet tube to provide for escape of the ammonia vapors. The characteristic red color of the sodium derivative was discharged rapidly. After evaporation of the solvent, water was added, and the carboxylic acids were separated from the non-acidic material. Table I is a résumé of results obtained by this method. Data are averages of several experiments.

TABLE I

PRODUCTION OF ACIDS BY COUPLING OF AN α-HALOACETIC ACID WITH SODIUM ALLYLBENZENE

| α-Haloacetic acid | Equivalent weight of mixture Theory | Observed | Yield,[a] % of mixed acids | Abs. spectrum of mixture[b] $\epsilon_{284}^{Max.}$ | $\epsilon_{294}^{Max.}$ |
|---|---|---|---|---|---|
| $ClCH_2CO_2H$ | 176 | 177 | 43 | 647 | 440 |
| $ClCH(CH_3)CO_2H$ | 190 | 189 | 54 | 784 | 545 |
| $ClC(CH_3)_2CO_2H$ | 204 | 203 | 40 | 1100 | 742 |
| $BrCH_2CO_2H$ | 176 | 176 | 74 | 650 | 450 |
| $BrCH(CH_3)CO_2H$ | 190 | 188 | 67 | 927 | 663 |
| $BrC(CH_3)_2CO_2H$ | 204 | 204 | 72 | 1270 | 919 |

[a] Yield based on α-haloacetic acid. [b] Maximum deviation in values of maximum averaged was 5%, mean deviation about 2%.

**Identification of Acidic Components of the Reaction Mixture from Bromoacetic Acid and Sodium Allylbenzene.**—The mixture of acids, obtained in 74% yield, was partially separated by filtration of the chilled product. The solid separated in this manner from the residual oil was recrystallized several times from ligroin. It formed shining white scales, m. p. 90°, which was identified as 4-phenyl-3-pentenoic acid by its melting point and the melting point (162°) of its dibromide.[4] Its equivalent weight was 176 (calculated for $C_{11}H_{12}O_2$, 176), and it yielded benzoic and succinic acids on ozonization. The benzylamine salt[2] of 4-phenyl-3-pentenoic acid melted at 108°.

*Anal.* Calcd. for $C_{18}H_{21}NO_2$: C, 76.29; H, 7.47. Found: C, 76.40; H, 7.61.

The oily mixture of acids remaining after filtration was dissolved in four times its volume of benzene, and an equivalent amount of potassium hydroxide was added as a 25% solution in methanol. The solid which precipitated was filtered off and found to be nearly pure potassium 4-phenyl-3-butenoate. This separation was purely fortuitous and was not expected. The residual solution was treated with dilute sulfuric acid, dried, and the solvent removed. The oily acid remaining gave a benzylamine salt melting at 97–98°.

*Anal.* Calcd. for $C_{18}H_{21}NO_2$; C, 76.29; H, 7.47. Found: C, 76.26; H, 7.55.

The oily acid was converted by hydrogenation to a solid acid, m. p. 58°. The benzylamine salt of the latter melted at 96–97°.

*Anal.* Calcd. for $C_{18}H_{23}NO_2$: C, 75.75; H, 8.12. Found: C, 75.94; H, 8.21. The hydrogenated acid was shown to be β-phenylvaleric acid (see below), thus the liquid acid was β-vinylhydrocinnamic acid. It could not be 2-phenyl-2-pentenoic acid, since the absorption spectrum of the liquid acid indicated that the double bond was out of conjugation with the benzene ring.[3]

**Synthesis of β-Phenylvaleric Acid.**—β-Ethylcinnamic acid, m. p. 94°, was synthesized through the Reformatsky reaction from propiophenone and ethyl bromoacetate.[5] Its benzylamine salt melted at 139–140°. *Anal.* Calcd. for $C_{18}H_{21}NO_2$: C, 76.29; H, 7.47. Found: C, 76.34; H, 7.43. This acid (19.70 g.) absorbed 2740 ml. of hydrogen at 750 mm. and 23° (theory 2750) over platinum oxide in ethyl acetate. The acid melted at 58° after recrystallization from warm (35°) methanol, to which water had been added to the cloud point. Its benzylamine salt melted at 96.5°. Neither the melting point of the acid, nor the melting point of the benzylamine salt, was depressed by addition of the corresponding product obtained by hydrogenation of β-vinylhydrocinnamic acid described above.

**Separation of the Reaction Products from α-Bromopropionic Acid and Sodium Allylbenzene.**—The methods described above could not be used to separate this mixture of acids. Benzylamine was added to the mixture, and the mixture of solid benzylamine salts was fractionally crystallized. It was possible to isolate the spectroscopically pure benzylamine salt of the *secondary* acid, α-methyl-β-vinylhydrocinnamic acid, m. p. 145.5°, by fractional crystallization from ethyl acetate. *Anal.* Calcd. for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80. Found: C, 76.35; H, 7.87. The benzylamine salt of the primary acid could not be obtained optically pure, by direct recrystallization.

The residual impure benzylamine salt, which was rich in the primary acid, was dissolved in glacial acetic acid. An equivalent amount of bromine in acetic acid was added, followed by dilution with water, to give an oily dibromo-acid and a solid dibromo-acid. The solid was isolated and purified by recrystallization from aqueous ethanol; long, lustrous needles, m. p. 133°. This solid dibromo-acid was refluxed with zinc dust in isopropyl alcohol. The resulting oily acid was isolated and converted to a benzylamine salt, which was recrystallized from Skellysolve C, giving long needles, m. p. 119°. *Anal.* Calcd. for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80. Found: C, 76.58; H, 7.92. The absorption spectrum[3] of the salt indicated that it was derived from the primary acid.

**Separation of Acids Derived from the Sodium Derivative of Allylbenzene and α-Bromoisobutyric Acid.**—The primary acid was obtained by filtration of the partially solidified mixture. It was obtained optically pure on recrystallizing from methanol–water. It formed massive prisms, m. p. 104°. Its benzylamine salt melted at 145.5°. *Anal.* Calcd. for $C_{20}H_{25}NO_2$: C, 77.13; H, 8.09. Found: C, 77.23; H. 8.28. The secondary form of the acid could not be obtained spectroscopically pure.

**Absorption Spectra of the Pure Acids Derived from the Primary Form of the Allylbenzene Carbanion.**—The absorption spectra of these acids and their benzylamine salts were taken on the Beckmann ultraviolet spectrophotometer and are tabulated in Table II.

TABLE II

| Acid | Absorption spectra of acid 293 Max. | 284 Max. | 250 Max. | Absorption spectra of benzylamine salt 293 Max. | 284 Max. | 250 Max. |
|---|---|---|---|---|---|---|
| $C_6H_5CH{=}CHCH_2CH_2CO_2H$ | 791 | 1120 | 18,470 | 820 | 1260 | 17,020 |
| $C_6H_5CH{=}CH{-}CH_2CH(CH_3)CO_2H$ | (850)[a] | (1250)[a] | (18,800)[a] | 850 | 1385 | 18,500 |
| $C_6H_5CH{=}CHCH_2C(CH_3)_2CO_2H$ | 978 | 1380 | 19,030 | 971 | 1498 | 19,980 |

[a] Estimated values from benzylamine salt.

**Composition of Original Reaction Mixture by Spectral Analysis.**—From the extinction coefficients quoted above, the percentage composition was calculated from the formula

$$(\%\text{ of Compound I}) = \frac{\epsilon_{molar}^{mixture}}{\epsilon_{molar}^{Pure\ I}} \times 100$$

TABLE III

| α-Haloacetic acid | Composition of mixture $x$ = Cl, per cent from anion primary | secondary | Composition of mixture $x$ = Br, per cent from anion primary | secondary |
|---|---|---|---|---|
| $XCH_2CO_2H$ | 57.2 | 42.8 | 57.6 | 42.4 |

where (I) is derived from the primary form of the allylbenzene carbanion. It was assumed that the acid derived from the secondary form of the allylbenzene carbanion would have extinction coefficients of approximately zero at 294 mμ, 20 at 283 mμ and $\epsilon_{molar}^{mixture}$ was accordingly corrected. The results are tabulated in Table III.

## Summary

1. Sodium allylbenzene has been prepared and allowed to react with a series of α-haloacetic acids to give mixtures of substituted γ-benzalbutyric and hydrocinnamic acids.

2. The observed results have been discussed with regard to the possible influences which may alter the course of the reaction.

# Perfluoro-2-butyne and its Hydrogenation Products

BY ALBERT L. HENNE AND WILLIAM G. FINNEGAN

Preceding articles have reported fluorinated compounds with a $CF_3$ group adjacent to another function, double bond, acid, alcohol or halide. A compound, $CF_3C{\equiv}CCF_3$, with a triple bond flanked by two $CF_3$ groups has now been prepared[1] and examined. In line with our expectations, the triple bond is so sluggish that it does not appreciably accept halogens at room temperature; it is however very sensitive to alkaline oxidation, and breaks quantitatively to give two moles of trifluoroacetic acid. In addition, it easily accepts one mole of hydrogen on Raney nickel to yield $CF_3CH{=}CHCF_3$, presumed to be the *cis*-isomer; it takes up two molecules of hydrogen with equal facility to form $CF_3CH_2$-$CH_2CF_3$.

**Preparation of $CF_3C{\equiv}CCF_3$.**—A three-liter flask heated on an electric nest is equipped with a sealed stirrer and a reflux condenser of the "down draft and overflow return" type the outlet of which leads to a Dry Ice-cooled receiver. This type of condenser permits high rates of reflux without flooding; it receives vapors at its top and syphons the condensate from its bottom back to the boiler. The flask is loaded with six moles (420 g.) of zinc dust, six moles (1380 g.) of dried and distilled $CF_3CCl{=}CClCF_3$[2] and 900 ml. of absolute alcohol. Constant stirring and refluxing is maintained for ten days, with a liquid temperature of about 40°. At the end of this period, distillation is performed until the liquid in the flask reaches 78°; the distillate is combined with the reaction product which had been collected in the chilled receiver during the ten-day period. Rectification of this combined material yields 477 g. (49.1% conversion, 54.4% net yield) of $CF_3C{\equiv}CCF_3$, b. p. −24.7° to −24.5°; 5 g. of an intermediate fraction, b. p. −20° to +24°; 14 g. of impure $CF_3CH_2CH_2CF_3$, b. p. 25° to 27°; 322 g. of impure $CF_3CCl{=}CH$-$CF_3$ (mixed *cis* and *trans*), b. p. 31 to 37°; 31.5 g. of an intermediate cut; and 140 g. of recovered $CF_3CCl{=}CClCF_3$, b. p. 65 to 67°. The material balance is thus 90%. Refractionation of the (−20 to +24°) intermediate yielded 4 g. of a compound boiling within one degree of 6°; this will be referred to as "the 6° cut." Wojcik[1] mentions a (0 to +5°) cut, and states that it is "a $C_4F_6$ isomer."

The main reaction product was quantitatively oxidized in a sealed vessel by the procedure previously reported[3] to give 1.74 moles of trifluoroacetic acid per mole of $CF_3C{\equiv}CCF_3$, identified as its amide. The next most important product, $CF_3CCl{=}CHCF_3$, was found identical with a by-product obtained in the preparation of $CF_3$-$CCl{=}CClCF_3$ and previously reported[2] as "presumably $CF_3CCl{=}CFCF_3$" on account of its ability to yield two moles of trifluoroacetic acid when oxidized. Recalculation of the atomic refraction $AR_F$ for fluorine on this new basis gave the excellent value of 1.07.

**Hydrogenation of $CF_3C{\equiv}CCF_3$.**—In a one-liter pressure vessel, 3.43 moles (556 g.) of $CF_3C{\equiv}CCF_3$ was hydrogenated by means of 3.5 moles of hydrogen at an initial pressure of 100 atm. and with 5 g. of Raney nickel and 10 ml. of absolute alcohol as catalyst. Reduction started at room temperature and proceeded rapidly with a large evolution of heat. A leak caused some material loss. The reduced material was distilled from the pressure vessel (heated to 50°) directly into a receiver cooled with Dry Ice. Rectification of this distillate gave 100 g. of recovered $CF_3C{\equiv}CCF_3$, and 368 g. of material boiling from 0 to +33°. The latter material was refractionated to give 119 g. of $CF_3CH_2CH_2CF_3$ and 191 g. of $CF_3CH{=}CHCF_3$. The material balance in the reduction step was only 83% on account of the leakage; the distillation steps had a material balance of 90%.

**Identification.**—The saturated derivative $CF_3CH_2CH_2CF_3$ was analyzed for fluorine: 68.6% calcd., 68.2% found. The identity of the olefin and that of the alkyne are derived from the facts that both yielded two molecules of $CF_3CO_2H$ on oxidation, and were transformed into the analyzed

(1) Others have also obtained this derivative recently: W. T. Miller, Cornell, and E. T. McBee, Purdue, private communications; Wojcik, American Chemical Society fall meeting, New York, N. Y., 1947.

(2) Henne and Trott, THIS JOURNAL, **69**, 1820 (1947).

(3) Henne and Zimmerschied, *ibid.*, **69**, 281 (1947).

paraffin by acceptancy of one mole and two moles of hydrogen, respectively; this was done quantitatively in independent, conventional experiments, using Raney nickel, and differing only by the amount of hydrogen supplied. The Bayer (potassium permanganate) test was positive while the bromine in carbon tetrachloride negative for both the alkyne and the alkene.

**Physical Tests.**—All three compounds are soluble in light paraffins, toluene, carbon tetrachloride, acetone, alcohol and ether as far down as −25°; they are also soluble in acetic acid above its freezing point. At −78° the alkyne was insoluble in all those solvents which were still liquid, while the olefin and the paraffin were not observed. In concentrated sulfuric acid, all three were insoluble at room temperature.

A dielectric constant measurement on the alkyne at −30°, by the heterodyne beat procedure showed a value comparable to that of a saturated straight-chain paraffin, indicative of a substantially zero dipole moment. The olefin, however, had a dielectric constant of approximately 20.8 at +20°, as compared to 4.3 for ether and 80.0 for water. This indicates a substantial dipole moment and the *cis*-configuration was therefore assigned to this compound.

The alkyne boils remarkably low; a contrast between hydrocarbons and their perfluorinated derivatives emphasizes the fact that the fluorinated derivatives are less associated, probably not at all.

Contrasting boiling points.

| | | | |
|---|---|---|---|
| $CH_3CH_2CH_2CH_3$ | − 0.4° | − 1.4° | $CF_3CF_2CF_2CF_3$ |
| $CH_3CH{=}CHCH_3$ | + 1.0° | + 0.4° | $CF_3CF{=}CFCF_3$ |
| $CH_3C{\equiv}CCH_3$ | +27.2° | −24.6° | $CF_3C{\equiv}CCF_3$ |

Addition of hydrogen to the triple bond affects the molecular weight negligibly but permits hydrogen bonding[4] in the resulting product, and the boiling point rises consequently by nearly 50°.

| | | | |
|---|---|---|---|
| $CF_3C{\equiv}C{-}CF_3$ | −24.6° | +24.6° | $CF_3CH_2CH_2CF_3$ |

The importance of hydrogen bonding is also shown by the fact that both $CF_3CH{=}CHCF_3$ and $CF_3CH{=}CClCF_3$ boil at nearly the same temperature (33° and 34°, respectively) in spite of their different masses, a case similar to that of $CHF_3$ and $CClF_3$ (−82° and −81°). An additional example is the contrast between $CF_3CH{=}CClCF_3$ and $CF_3CF{=}CFCF_3$, boiling about +35° and 0°, respectively, in spite of their almost identical molecular masses.

**Physical Properties.**—Conventional physical measurements[5] were made after repurification, with the accuracy claimed by the decimals shown in the table:

| Compound | $CF_3C{\equiv}CCF_3$ | $CF_3CH{=}CHCF_3$ | $CF_3CH_2CH_2CF_3$ | $CF_3CH{=}CClCF_3$ |
|---|---|---|---|---|
| B. p., °C., 760 mm. | − 24.6 | +33.2 | +24.6 | + 34.4 |
| F. p., °C. | −117.4 | −90.5 | −53.7 | −106.1 |
| $d_4$ | | 1.4128 at 0° | 1.3702 at 0° | 1.4909 at 20.0° |
| $n_D$ | | 1.2825 at 2.2° | 1.2732 at 3.0° | 1.2996 at 20.0° |
| $AR_F$ | | 1.16 | 1.12 | 1.07 |

The atomic refraction for fluorine, $AR_F$, was computed in the conventional way by subtracting from the experimental molecular refraction the customary increments for C, H, Cl and double bond.

**Infrared Spectrum.**—Infrared adsorption spectra were taken on the alkyne, *cis*-alkene and the 6° by-product in order to obtain information as to the structure of the 6° by-product. Inasmuch as the alkyne is symmetrical, it would show only C–F bond absorption in the infrared, and any other absorption would be attributable to the 6° material present as an impurity. The alkyne and 6° cut absorption curves are indeed essentially the same.

Strong C–F bond absorption was noted from 7 to 10 microns with the C—F bond overtone at 4.2 microns for all three compounds. A major C—H bond stretching band was obtained at 3.35 microns with the alkene and a smaller one at the same place with the 6° cut. This latter is probably due to $CF_3{-}CH{=}CH{-}CF_3$ (*trans*) or $CF_3{-}CH_2{-}CH_2{-}CF_3$ as impurities in the 6° cut, as this absorption is not present in the alkyne absorption curve. A strong absorption from 6.4 to 7.1 microns in the alkene, absent in the alkyne and 6° cut curves, could be attributed to hydrogen bonding. A very strong absorption at 5.95 microns in the alkene curve is attributed to C=C; this absorption is absent in the alkyne curve and is present to a smaller degree in the 6° cut curve. Thus the 6° by-product is contaminated with olefinic material similar in nature to the *cis*-alkene; this is probably the *trans*-alkene.

The alkyne and 6° cut curves show five bands from 6 to 7 microns with the strongest at 6.4 microns; these bands are absent in the alkene curve and could thus be attributed to components of an allenic type of structure. Two absorption peaks at 4.7 and 4.85 microns, respectively, appear in the alkyne and 6° cut curves, but only the 4.7 micron peak appears in the olefin. The 4.7 micron peak is attributed to partial allenic character of the following types: $CF_3{\cdots}C{\cdots}C{\cdots}CF_3$, $CF_3{\cdots}CF{\cdots}C{=}CF_2$, and $CF_3{\cdots}CH{\cdots}CH{\cdots}CF_3$.

(4) The term "hydrogen bonding" is used in extension of the conventional cases, on the basis that fluorinated compounds containing hydrogen invariably boil higher than the perfluoro compounds: $CH_2F_2 > CF_4$; $CHF_2CO_2H > CF_3CO_2H$; $CHF_2COCl > CFCOCl$; etc. . . . The hydrogen is attached to an electronegative group ($CF_2$) instead of electronegative atom (O).

(5) Weissberger, "Techniques of Organic Chemistry," Interscience Publishers, New York, N. Y., Vol. I, New York, N. Y., 1945. For freezing point, Mair, Glasgow and Rossini, *J. Research Natl. Bur. Standards*, **26**, 591 (1941).

The peak at 4.85 microns could be attributed to absorption of the C=C=C structure.

Because of the symmetry of the alkyne and similarities between the absorption curves of the alkyne and 6° by-product curves, and because of the almost complete dissimilarity between these and the alkene absorption curves, the following conclusions are drawn.

(1) The impurity of the alkyne is essentially the 6° by-product material.

(2) The 6° by-product material is probably the perfluorinated methylallene, $CF_3—CF=C=CF_2$, obtained by rearrangement of the alkyne by zinc chloride during its synthesis.

## Summary

The preparation and physical properties of $CF_3C\equiv CCF_3$, $CF_3CH=CHCF_3$, $CF_3CH_2CH_2CF_3$ and $CF_3CH=CHClCF_3$ are reported.

# Preparation and Reactions of α,β-Dichlorovinyltrichlorosilane

BY C. L. AGRE

Recently several publications[1] have disclosed the addition of trichlorosilane and related silanes to ethylenic and acetylenic hydrocarbons under the activation of peroxide, ultraviolet light, or elevated temperature below the decomposition point of the reactants. The results, in general, are illustrated by the addition of trichlorosilane to propylene and to acetylene to yield, respectively, *n*-propyltrichlorosilane and 1,2-bis-(trichlorosilyl)-ethane. The yields of the products varied appreciably and were dependent both on the experimental conditions and on the nature of the reactants. Silicon tetrahalides were reported not to add to the unsaturated materials.

The present investigation, based in part on work done several years ago, is somewhat parallel to the above efforts but differs primarily in that the reaction was carried out at a temperature appreciably above the decomposition temperature of the unsaturated compound charged to the apparatus. Preliminary experiments showed that trichloroethylene and trichlorosilane, in the presence of a peroxide catalyst, gave very little addition product under the experimental conditions employed. It was thought worthwhile, however, to pass the mixture through a hot tube at atmospheric pressure to determine the effect of the greatly elevated temperature. The reaction thus would be run under conditions amenable to commercial practice should interesting products be obtained. It was observed that at a temperature of about 500° a mixture of trichloroethylene and trichlorosilane evolved hydrogen chloride and gave a good yield of a product identified as α,β-dichlorovinyltrichlorosilane. The reaction can be explained simply according to the equations

$$Cl_2C=CHCl + HSiCl_3 \longrightarrow Cl_2HCCHClSiCl_3 \quad (1)$$
$$Cl_2HCCHClSiCl_3 \longrightarrow HCl + ClHC=CClSiCl_3\ I \quad (2)$$

It is more likely, however, that hydrogen chloride first is eliminated from the trichloroethylene to give dichloroacetylene. In the absence of trichlorosilane, and to a very limited extent in its presence, the dichloroacetylene almost instantaneously polymerizes to give hexachlorobenzene in a manner parallel to the formation of benzene from acetylene. However, the dichloroacetylene preferentially adds to trichlorosilane to give the observed product I.

$$Cl_2C=CHCl \longrightarrow HCl + ClC\equiv CCl \quad (3)$$
$$ClC\equiv CCl + HSiCl_3 \longrightarrow ClHC=CClSiCl_3\ I \quad (4)$$

In similar manner, I is obtained in low yield from *s*-tetrachloroethane and trichlorosilane. The first step apparently is the elimination of hydrogen chloride[2] to form trichloroethylene, which then reacts as indicated above.

It is reported[3] that a halogen atom in a position beta (as contrasted to alpha and gamma) to $-SiCl_3$ has unusual activity and upon titration reacts as illustrated in the example

$$ClCH_2CH_2SiCl_3 + 4NaOH \longrightarrow CH_2=CH_2 + Si(OH)_4 + 4NaCl \quad (5)$$

It was obviously of interest to determine if the beta-chlorine atom in I would have similar activity. Titration of I with standard base showed the presence of three active chlorine atoms, which are the three chlorine atoms attached to silicon. The presence of the ethylenic bond in the side chain has, in the customary manner, deactivated the adjoining chlorine atoms to the extent that the beta-chlorine atom does not have the unusual activity observed in the saturated analog, β-chloroethyltrichlorosilane.

The silane I reacts with ethylmagnesium bromide in the expected manner to give α,β-dichlorovinyltriethylsilane (II)

$$ClHC=CClSiCl_3 + 3C_2H_5MgBr \longrightarrow ClHC=CClSi(C_2H_5)_3\ II \quad (6)$$

(2) British Patent 575,530; *Chem. Abst.*, **41**, 6891 (1947).

(3) (a) Sommer and Whitmore, THIS JOURNAL, **68**, 485 (1946); (b) Sommer, Dorfman, Goldberg and Whitmore, *ibid.*, **68**, 488 (1946).

The inactivity of the β-chlorine atom is apparent in this reaction also. This is in contrast to the saturated analogs for it is reported[4] that a saturated side chain having a beta-halogen atom is separated from the silicon atom as follows

$$ClCH_2CH_2SiCl_3 + 4CH_3MgX \longrightarrow CH_2{=}CH_2 + (CH_3)_4Si \quad (7)$$

Alcohols react with I to give the anticipated esters without any effect on the beta-chlorine atom as follows

$$ClHC{=}CClSiCl_3 + 3ROH \longrightarrow ClHC{=}CClSi(OR)_3 \quad (8)$$

In this manner the esters in which R was methyl and *n*-butyl were prepared.

Trichlorosilane adds to I in a sealed tube in the presence of a peroxide catalyst to give a product believed to be 1,2-bis-(trichlorosilyl)-1,2-dichloroethane (III) according to the equation

$$HSiCl_3 + ClHC{=}CClSiCl_3 \longrightarrow Cl_3SiCHClCHClSiCl_3 \text{ III} \quad (9)$$

This structure is assigned to the product because the addition should be similar to the addition of two molecules of trichlorosilane to acetylene[1b] with the formation of 1,2-bis-(trichlorosilyl)-ethane. Product III is interesting in that it has two chlorine atoms in positions beta, respectively, to the two $-SiCl_3$ units and thus should be very reactive. Titration with standard base shows the presence of seven active chlorine atoms. Hydrolysis and fission probably occur

$$Cl_3SiCHClCHClSiCl_3 + 7NaOH \longrightarrow Si(OH)_4 + CHCl{=}CHSi(OH)_3 + 7NaCl \quad (10)$$

Direct reaction of III with methanol gives rise to a vigorous evolution of hydrogen chloride and a product which boils over a wide range and has less than the anticipated chlorine content. The reaction proceeds satisfactorily by reaction of III and methanol in the presence of pyridine as an acid acceptor. Under these conditions, the two beta-chlorine atoms are not affected and the product obtained is the expected 1,2-bis-(trimethoxysilyl)-1,2-dichloroethane.

$$Cl_3SiCHClCHClSiCl_3 + 6CH_3OH \longrightarrow (OCH_3)_3SiCHClCHClSi(OCH_3)_3 \quad (11)$$

Hydrolysis of III in ether by the addition of water gave a completely water-soluble product since no residue remained on evaporation of the ether layer. Titration of a portion of the aqueous solution showed that slightly over seven of the total of eight chlorine atoms in III had been removed as hydrogen chloride. Evaporation of the water left a powdery, white resin which gradually lost chlorine on prolonged heating. The analytical data do not fit well any proposed product obtained by the hydrolysis of III, but they show that the reaction is deep-seated and probably involves more than the mere hydrolysis of the six chlorine atoms attached to silicon.

The various reactions enumerated above leave very little question relative to the structure of product I. However, to prove more definitely its structure, I was made by the addition of trichlorosilane to dichloroacetylene in a sealed tube in the presence of peroxide catalyst. Extreme precautions must be observed in the handling of dichloroacetylene for, as reported,[5] it explodes violently in the presence of oxygen. Furthermore, it appears to be unstable even in the absence of oxygen because a severe explosion was encountered while approximately fifteen grams of dichloroacetylene in a well stoppered Carius tube was standing in a bath at about −10°. No difficulty was encountered in its preparation even at temperatures much higher than reported[5] as being safe. The relatively pure dichloroacetylene does not react with trichlorosilane at room temperature in the absence of a catalyst but does add essentially completely under the influence of a peroxide at moderate temperature. In view of the observation that the product thus obtained is identical with I prepared pyrolytically from trichloroethylene and trichlorosilane, the structure of I as given previously is correct.

In agreement with observations previously mentioned in the attempted addition of silicon tetrahalides to unsaturated hydrocarbons, no appreciable (if any) addition occurred when attempts were made to add silicon tetrachloride and silicon tetrabromide to trichloroethylene in a heated tube.

Hydrolysis of I gives rise to a resinous product, probably initially according to the following steps

$$ClHC{=}CClSiCl_3 \longrightarrow ClHC{=}CClSi(OH)_3 \longrightarrow ClHC{=}CClSiO_{1.5} \text{ IV} \quad (12)$$

The initial resin was obtained in nearly the theoretical quantity for IV and was clear and tough. However, prolonged heating at 110° caused a gradual loss in weight, probably in part due to the loss of hydrogen chloride, until finally the resinous product became colored and brittle. Analysis of this final resinous product showed the presence of more silicon and less chlorine than required by the formula IV.

Both to aid in the proof of the structure of I and also to observe the possible activity[3] of the beta-chlorine atom in the saturated chain, I was chlorinated and the product was studied.

$$ClCH{=}CClSiCl_3 + Cl_2 \longrightarrow Cl_2HCCCl_2SiCl_3 \text{ V} \quad (13)$$

Titration of V, α,α,β,β-tetrachloroethyltrichlorosilane, gave results which showed that four chlorine atoms had reacted quantitatively and, therefore, proved that one chlorine atom attached to a carbon atom had been removed as well as the three chlorine atoms on the silicon.

(4) Sommer, Goldberg, Dorfman and Whitmore, THIS JOURNAL, **68**, 1083 (1946).

(5) (a) Ott, Ottmeyer and Packendorff, *Ber.*, **63B**, 1941 (1930); (b) Ott, *ibid.*, **75B**, 1517 (1942); (c) Ott and Packendorff, *ibid.*, **64B**, 1324 (1931).

$$Cl_2HCCCl_2SiCl_3 + 4NaOH \longrightarrow HClC{=}CCl_2 + Si(OH)_4 + 4NaCl \quad (14)$$

In this experiment the trichloroethylene was recovered by steam distillation of a sample of V treated with excess alkali. The fission of the side chain is therefore directly parallel to that mentioned previously.

Similarly, the bromination of silane I proceeded as follows to give $\alpha,\beta$-dibromo-$\alpha,\beta$-dichloroethyltrichlorosilane, VI

$$ClHC{=}CClSiCl_3 + Br_2 \longrightarrow ClBrHCCClBrSiCl_3 \text{ VI} \quad (15)$$

Titration of VI gave 36.5% active halogen, calculated as chlorine, which agrees closely with the removal of the three chlorine atoms attached to silicon plus one additional halogen atom. This had been anticipated because here too the presence of the beta-halogen atoms would cause a C–Si fission on treatment of the silane with alkali. Since both a bromine atom and a chlorine atom are beta to the silicon atom, the beta-elimination could proceed by the removal of either of the halogen atoms along with the silicon. Consideration of the C–Cl and C–Br bond energies[6] would lead one to predict the preferential fission of the C–Br linkage. This actually was observed because titration of VI with base proceeded as

$$ClBrHCCClBrSiCl_3 + 4NaOH \longrightarrow ClHC{=}CClBr + Si(OH)_4 + 3NaCl + NaBr \quad (16)$$

The aqueous phase, after the titration, was tested for the bromide ion in the customary manner and a positive test was observed. The 1,2-dichlorobromoethylene obtained in this experiment was identified on the basis of the properties reported in the literature[7] and the appreciable difference between these data and those recorded for the alternate possibility, 1,2-dibromochloroethylene.

Hydrolysis of V and VI, respectively, in ether by the addition of water resulted in the formation of clear, tough resins after heating at about 55° for twenty-four hours or more. These appeared to be formed (by comparing the actual weight with the calculated weight) as follows

$$ClHCXCXClSiCl_3 \longrightarrow ClXHCCXClSiO_{1.5} \text{ (X is Cl or Br)} \quad (17)$$

Prolonged heating of the resins at 110° in the presence of air caused a gradual loss of weight, development of a yellow color, and change from tough to rather brittle residues. Analyses indicate that some loss of halogen occurred when the resins were heated.

## Experimental

**Trichloroethylene and Trichlorosilane in Heated Tube.**—The furnace employed was a commercially available combustion unit with a heated portion about seven inches in length. This was used to heat a Pyrex tube, 9 mm. internal diameter, fitted with a separatory funnel to feed the charge and with a condenser attached to a receiver set in a salt–ice mixture. The tube ordinarily was unpacked but was indented to provide more intimate contact of the charge for better heat transfer. The temperature recorded was that observed on the inbuilt thermocouple in the furnace near the surface of the tube and represents approximately the temperature in the middle portion of the tube.

During three hours a mixture of trichloroethylene (35 g.) and of trichlorosilane (25 g.), both freshly distilled, was passed through the tube at about 490°. The liquid product was amber in color and weighed 50.3 g. Distillation through an 8 inch packed column gave the following cuts:

| Cut | B. p., °C. | Weight | Si, % | Titrable chlorine, % | Calcd. weight product I |
|---|---|---|---|---|---|
| 1 | 35–78 | 6.6 g. | .. | 62.9 | 0.0 g. |
| 2 | 78–155 | 26.5 | .. | 28.1 | 16.2 |
| 3 | 155–169 | 11.3 | 12.2 | 48.1 | 11.3 |
| 4 | 169–190 | 1.8 | 11.8 | 46.1 | 1.9 |
| 5 | Residue | 2.5 | .. | .. | .. |
| | | | | | 29.4 g. |

Analysis of Cut 1 indicated that 5.3 g. of trichlorosilane was recovered, so 19.7 g. was used. Analyses of the various cuts indicated a total yield of adduct I of 29.4 g., or 87.5% yield of $\alpha,\beta$-dichlorovinyltrichlorosilane I based on unrecovered charge. The hydrogen chloride evolved was determined by titration to weigh 7.0 g., compared with a theoretical yield of 6.5 g. Redistillation of the above product combined with similar cuts from other runs gave a colorless liquid, b. p. 159° (729 mm.), with slight decomposition, 52° (8 mm.), $n^{20}D$ 1.4942. Active chlorine was determined by direct titration with standard base, total chlorine[8] by fusion with sodium peroxide followed by potentiometric titration, and the silicon by acid digestion of the sample followed by ignition to constant weight.

*Anal.* Calcd. for $C_2HSiCl_5$: active Cl, 46.2; total Cl, 77.6; Si, 12.15. Found: active Cl, 46.5; total Cl, 77.1; Si, 12.21.

**Trichloroethylene and Trichlorosilane in Sealed Tube.**—A mixture of freshly distilled trichlorosilane (7.0 g.) and trichloroethylene (12.0 g.), together with 1.5 g. of a 30% solution of diacetyl peroxide in dimethyl phthalate, was sealed into a tube and was heated at 65–85° for six hours. Distillation of the product gave 14.5 g. of recovered charge, b. p. 36–88°, and 3.5 g. of a fuming liquid which boiled at 89–240°. This product, together with similar material (8.5 g.) from parallel runs using benzoyl peroxide as the catalyst, was distilled to give the following fractions.

| Cut | B. p., °C. | Weight, g. | Si, % | Active Cl, % |
|---|---|---|---|---|
| 1 | 83–100 | 4.0 | 1.2 | 5.5 |
| 2 | 100–155 | 4.1 | 2.9 | 12.1 |
| 3 | 155–195 | 2.2 | 7.1 | 24.2 |
| 4 | 195–245 | 1.0 | 4.0 | 13.9 |

Since the anticipated adduct, $C_2H_2Cl_6Si$, should have 10.4% silicon and 39.7% active chlorine, it is evident that the product obtained in low yield was only partly organosilicon compounds.

**Reaction of I with Alcohols.**—Anhydrous methanol (15 g.) was added dropwise to silane I (21.0 g.) contained in a 50-cc. Claisen flask. Reaction was vigorous and hydrogen chloride was evolved. The mixture was refluxed gently for fifteen minutes after addition was completed. Distillation gave 14.5 g. of liquid which boiled at 181–188°. Two redistillations through a 6-inch packed column gave 8.0 g. (40%) of $\alpha,\beta$-dichlorovinyltrimethoxysilane, b. p. 104–106° (50 mm.), $n^{20}D$ 1.4421.

*Anal.* Calcd. for $C_5H_{10}O_3SiCl_2$: total Cl, 32.7; Si, 12.92. Found: total Cl, 33.2; Si, 12.95.

(6) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1940, p. 53.

(7) Swarts, *Chem. Zentr.*, I, 588 (1899). The following properties are recorded: b. p. 112–113°, $n^{16}$ 1.5190.

(8) All total chlorine analyses were made by Mr. R. W. Perlich and his co-workers at the Minnesota Mining and Manufacturing Co.

A portion of this product (0.4760 g.) was placed in a porcelain crucible, water (2 cc.) and 1 drop of concd. hydrochloric acid were added, and the mixture was evaporated to dryness and the residue was heated at 175° for one hour. The resin thus formed was glassy and was moderately tough. Its weight of 0.318 g. amounted to 67% of the original charge, whereas the expected resin, $CHCl{=}CClSiO_{1.5}$, should weigh 67.8% of the charge.

Parallel reaction of I (20.0 g.) with *n*-butanol (25.0 g.) gave on redistillation 15.5 g. (53%) of α,β-dichlorovinyltributoxysilane, $CHCl{=}CClSi(OC_4H_9)_3$, boiling at 163–165° (10 mm.), $n^{20}D$ 1.4434.

*Anal.* Calcd. for $C_{14}H_{28}O_3SiCl_2$: total Cl, 20.7; Si, 8.17. Found: total Cl, 21.2; Si, 8.27.

The resin obtained by hydrolysis of this ester initially was a tough glass but gradually became colored and brittle upon prolonged heating in an oven at 110°.

**Reaction of I with Ethylmagnesium Bromide.**—Ethyl magnesium bromide in ether was prepared from ethyl bromide (47 g.) and magnesium (11 g.). The slow addition of I (20.0 g.) in ether to the cooled Grignard reagent resulted in the formation of a precipitate. After refluxing for two hours, the mixture was cooled and was hydrolyzed in the customary manner. Distillation of the dried ether solution gave 13.2 g. (73%) of α,β-dichlorovinyltriethylsilane, $ClHC{=}CClSi(C_2H_5)_3$, b. p. 97–99° (14 mm.), $n^{20}D$ 1.4780.

*Anal.* Calcd. for $C_8H_{16}SiCl_2$: total Cl, 33.6. Found: total Cl, 33.1.

**Reaction of I with Trichlorosilane.**—Trichlorosilane (13 g.), silane I (6.3 g.), and benzoyl peroxide (0.2 g.) were placed in a sealed tube and heated at 70–80° for sixty-five hours. Distillation gave 3.9 g. (40%) of product, 1,2-bis-(trichlorosilyl)-1,2-dichloroethane III, boiling at 98–103° (4 mm.), $n^{20}D$ 1.5158, plus some foreshot and tailings of approximately the same boiling point. Titration of active chlorine gave 67.35% chlorine, while seven active chlorine atoms would indicate 67.7% chlorine.

*Anal.* Calcd. for $C_2H_2Si_2Cl_8$: total Cl, 77.7; 7 active Cl, 67.7; Si, 15.3. Found: total Cl, 77.4; 7 active Cl, 67.4; Si, 15.6.

**Reaction of III with Methanol.**—In a 250-cc. Erlenmeyer flask were placed dry ether (50 cc.), anhydrous methanol (5.5 g.), and anhydrous pyridine (12.2 g.). Silane III (7.03 g.) in about 50 cc. of dry ether was slowly added. Reaction was instantaneous, heat was evolved, and there separated a lower liquid layer which soon became a dough-like mass. The mixture was warmed at 35° for one hour, was cooled, and the ether solution was decanted. The residue in the flask was washed twice with ether, and the combined ether layers were distilled to remove the ether. The distilled ether was shaken with slightly acidic (HCl) distilled water to decompose any methyl orthosilicate possibly formed and the ether was then evaporated to leave no residue of silica. The liquid residue left after distillation of the ether was distilled twice to give 3.7 g. (56%) of 1,2-bis-(trimethoxysilyl)-1,2-dichloroethane, b. p. 140–146° (10 mm.), 121° ( 1 mm.), $n^{22}D$ 1.4406.

*Anal.* Calcd. for $C_8H_{20}Si_2Cl_2O_6$: total Cl, 21.2; Si, 16.7. Found: Total Cl, 20.9; Si, 16.9.

**Resin Formation from III.**—Silane III (1.7745 g.) in about 50 cc. of dry ether was extracted carefully with four 15-cc. portions of water. Evaporation of the residual ether solution left only 0.0573 g. of residue, so practically all of the resin was water-soluble. Titration of an aliquot portion of the combined aqueous layers indicated 1.231 g. of chlorine, or 69.3% of the weight of the charged silane III, whereas seven active chlorine atoms require 67.7% chlorine. Evaporation of the water left 0.756 g. of a white powder of resinous nature. Analyses showed the presence of 32.7% silicon and 15.2% chlorine.

Silane III (1.6105 g.) in 25 cc. ether was treated carefully in a beaker with about 2 cc. of distilled water. After the vigorous reaction had subsided, the ether was evaporated at a maximum temperature of 70° and the residue was maintained at this temperature for three hours. The resin amounted to 54.5% of the original III and contained 24.1% chlorine. The resin was heated at 110° for an additional forty-nine hours. The product, corrected for removed samples, amounted to 47.8% of the original III and contained 17.3% chlorine.

**Reaction of Dichloroacetylene with Trichlorosilane.**—A 250-cc. distillation flask was filled to the neck with sodium hydroxide pellets, analytical grade, and was immersed in an oil-bath maintained at about 260°. Air was removed by passage of a slow stream of dry natural gas. During ninety minutes, trichloroethylene (20 cc.) was added dropwise from a separatory funnel through an open tube extending to the bottom of the reaction flask. The dichloroacetylene, unconverted trichloroethylene, and some water distilled from the flask and were caught in a 50-cc. Claisen flask in an ice–salt mixture. Trichlorosilane (3 cc.) was added to this flask to remove the small amount of water. The dichloroacetylene was then slowly distilled into the bottom of a Carius tube with constricted neck placed in a salt–ice mixture. The water-bath employed for heating the flask can advantageously be raised to about 75° toward the end of the distillation because the dichloroacetylene does not readily distill completely. The receiver was then clamped to prevent entrance of air and was separated from the long delivery tube leading from the intermediate Claisen flask. Only slight hazard is ordinarily encountered in dismantling the apparatus, although it is best to continue the flow of gas (preferably nitrogen) until all residual dichloroacetylene has escaped. The dichloroacetylene plus any small amount of contaminant in the Carius tube weighed 7 g. To this was added trichlorosilane (10 cc.) containing 0.7 cc. of a 30% solution of diacetyl peroxide in dimethyl phthalate. The tube was sealed and then was heated at 70° for sixty-five hours. On several occasions tubes exploded at this stage, so extreme precautions are necessary. Distillation gave 4.7 g. (28%) of a liquid, b. p. 87–92° (55 mm.), $n^{20}D$ 1.4988, identified as α,β-dichlorovinyltrichlorosilane, I.

*Anal.* Calcd. for $C_2HSiCl_5$: active Cl, 46.2; Si, 12.15. Found: active Cl, 45.7; Si, 11.9.

In addition to more material approximating the above product, there was 3.4 g. of liquid boiling at 76–126° (10 mm.) with only 32.8% active chlorine.

**Resin Formation from I.**—Silane I, 4.7 g., was placed in about 20 cc. of ether and was shaken carefully twice with 25 cc. of water. The ether was evaporated at a maximum temperature of 50° to leave an oil which soon changed to a clear glass. The residue gradually decreased in weight during prolonged heating at 110° as follows with the recorded percentages being the ratios of residue to the original charge of I.

| Hours at 110° | Residue, % | Nature |
|---|---|---|
| 0 | 63.8 | Liquid |
| 1 | 56.0 | Clear glass, tough |
| 22 | 45.8 | |
| 75 | 37.0 | |
| 215 | 35.2 | Yellow, brittle |

Analyses of the final sample indicated 32.3% silicon and 17.6% chlorine. In view of the fact that the inital resin, $ClHC{=}CClSiO_{1.5}$, should amount to 64.2% of the charge and contain 19.0% silicon and 40.8% chlorine, it is evident that the resin lost a large portion of its chlorine.

***s*-Tetrachloroethane and Trichlorosilane in Hot Tube.**—A mixture of *s*-tetrachloroethane (26.5 g.) and trichlorosilane (26.0 g.) was passed through a tube at 500° during ninety-five minutes. The product was a dark, mobile liquid which weighed 35.5 g. Distillation through a Claisen flask gave mainly recovered charge plus 3.3 g. of a liquid, b. p. 157–167°, $n^{19}D$ 1.4928. The yield of α,β-dichlorovinyltrichlorosilane amounted to a maximum of 15% under these experimental conditions.

**Addition of Chlorine to α,β-Dichlorovinyltrichlorosilane.**—The silane I (8.5 g.) and chloroform (10.0 g.) were placed in a Pyrex test-tube. The tube was immersed in ice and dry chlorine (1.2 g.) was absorbed to give a yellow

solution. Immediate and vigorous reaction occurred when the tube was removed from the ice and was exposed to full sunlight. The solution was recooled, additional chlorine (1.4 g.) was added, and the reaction again was effected by exposure to sunlight. The tube again was cooled and chlorine (0.5 g.) was added. As expected, the yellow color remained after this third brief exposure to the sun since an excess amount of chlorine (theory was 2.6 g.) had been added. The tube was allowed to stand stoppered at room temperature for three days. After this period the yellow color was gone so addition was complete and possibly some substitution of hydrogen by chlorine had occurred. The chloroform was removed by distillation and the colorless residual liquid was distilled through a modified Claisen flask. The main fraction (7.9 g., 71%) boiled at 104–106° (17 mm.) and is $\alpha,\alpha,\beta,\beta$-tetrachloroethyltrichlorosilane, V, $n^{27}D$ 1.5149.

*Anal.* Calcd. for $C_2HSiCl_7$: total Cl, 82.6; titrable Cl, 47.0 (4 Cl); Si, 9.1. Found: total Cl, 84.3; titrable Cl, 46.5; Si, 9.3.

**Removal of Side Chain from V.**—Silane V (6.0 g.) was placed in a distillation flask, distilled water was added, and then sufficient sodium hydroxide pellets were added to make the mixture definitely basic. Steam distillation gave a lower organic layer of about 1.2 cc. of colorless liquid. The dried liquid was distilled to give 1.45 g. of trichloroethylene, b. p. 85–88° (739 mm.), $n^{27}D$ 1.4740, which properties coincide well with the accepted values.

*Anal.* Calcd. for $C_2HCl_3$: total Cl, 81.0; Found: total Cl, 81.6.

**Addition of Bromine to I.**—Bromine (7.0 g., calcd. 6.95 g.) was added to I (10.0 g.) in a chloroform (15 g.) and the solution was allowed to stand in the laboratory for twenty-four hours. Since the red color still persisted, the tube was placed in direct sunlight for one day. Analysis of the reaction mixture showed that about 0.15 g. of bromine still remained. Distillation gave 3.8 g. of foreshot, boiling at 59–119° (10 mm.), and 11.0 g. (65%) of product, $\alpha,\beta$-dichloro-$\alpha,\beta$-dibromoethyltrichlorosilane, VI, b. p. 118–120° (10 mm.), $n^{25}D$ 1.5595.

*Anal.* Calcd. for $C_2HSiCl_5Br_2$: active halogen as Cl, 36.3; total halogen as Cl, 63.7; Si, 7.15. Found: active halogen as Cl, 36.5; total halogen as Cl, 63.7; Si, 6.9.

The aqueous solution after titration was acidified with nitric acid, boiled to about half its volume, cooled, and filtered. Fresh chlorine water was added to the solution which then was shaken with carbon tetrachloride. A definite brown color showed the presence of bromide ions in the water and indicated that, in part at least, the beta-bromine had been removed.

**Side Chain Removal from VI.**—Silane VI (6.0 g.) was placed in a 250-cc. Claisen flask and was steam distilled from sodium hydroxide solution. The lower organic layer of about 2 cc. was distilled from a small modified Claisen flask to give about 2 g. of 1,2-dichlorobromoethylene,[7] b. p. 109–112°, $n^{16}D$ 1.5198.

*Anal.* Calcd. for $C_2HCl_2Br$: total halogen as Cl, 60.4. Found: total halogen as Cl, 60.1.

**Resin Formation from V.**—Silane V (0.954 g.) was placed in a 50-cc. beaker and 1 cc. of distilled water suspended in ether was added. Vigorous reaction occurred, hydrogen chloride was evolved, and a lower liquid layer separated. The ether was evaporated and the residue was heated overnight at 55°. The resin was clear and tough, and weighed 0.678 g. (theory is 0.693 g.). Continued heating at 55° for twenty-four hours reduced the weight to 0.65 g. The total chlorine content was 57.0% in comparison with the required 64.9% for $C_2HSiCl_4O_{1.5}$.

**Resin Formation from VI.**—Silane VI (1.7433 g.) in dry ether as above was treated slowly with about 2 cc. of water to give a vigorous reaction and separation of a lower liquid layer. The ether was evaporated and the residue was heated for seventy hours at 55°. The resin weighed 1.315 g. (theoretical is 1.375 g.), and was tough and colorless. The residue was heated at 110° for twenty-four hours to leave a yellow, fairly tough resin which weighed 1.2489 g. Additional heating for twenty-four hours at 110° left 1.1618 g. of resin. After a total heating at 110° for one hundred hours there remained a yellow, brittle resin weighing 1.1279 g. The total halogen amounted to 45.1% as compared to a value of 46.1% for $ClBrHCCBrClSiO_{1.5}$.

**Acknowledgment.**—Appreciation is expressed to the Minnesota Mining and Manufacturing Company for the interest in this work and to Mr. R. W. Perlich for the analyses he so kindly had performed.

## Summary

1. Trichlorosilane and trichloroethylene react in a hot tube at about 500° to give $\alpha,\beta$-dichlorovinyltrichlorosilane and hydrogen chloride.

2. Trichlorosilane adds to dichloroacetylene in the presence of a peroxide catalyst to give $\alpha,\beta$-dichlorovinyltrichlorosilane.

3. $\alpha,\beta$-Dichlorovinyltrichlorosilane reacts with alcohols and with ethylmagnesium bromide to replace the chlorine atoms attached to the silicon atom.

4. $\alpha,\beta$-Dichlorovinyltrichlorosilane adds trichlorosilane to give 1,2-bis-(trichlorosilyl)-1,2-dichloroethane, which by alkaline titration is shown to have seven active chlorine atoms.

5. $\alpha,\beta$-Dichlorovinyltrichlorosilane adds chlorine and bromine, respectively, to give $\alpha,\alpha,\beta,\beta$-tetrachloroethyltrichlorosilane and $\alpha,\beta$-dichloro-$\alpha,\beta$-dibromoethyltrichlorosilane. Titration in each instance showed the presence of four active halogen atoms.

6. Alkaline hydrolysis of $\alpha,\alpha,\beta,\beta$-tetrachloroethyltrichlorosilane gives trichloroethylene. Alkaline hydrolysis of $\alpha,\beta$-dibromo-$\alpha,\beta$-dichloroethyltrichlorosilane gives 1,2-dichlorobromoethylene.

7. Resins formed by the hydrolysis of the above polyhalogenated silanes lose halogen on prolonged heating in air at 110°.

# Quantitative Studies on Lithium Aluminum Hydride Reactions[1]

BY F. A. HOCHSTEIN[2]

The reactions of lithium aluminum hydride closely resemble those of Grignard reagents.[3,4,5,6,7] These agents appear to differ principally in the more aggressive behavior of the hydride, resulting in a lessening of side-reactions and of steric influences. An analytical procedure employing lithium aluminum hydride may, therefore, be more generally useful than the Zerewitinoff procedure which was so elegantly refined on a macro scale by Kohler and co-workers.[8,9]

Results obtained in the determination of active hydrogen in alcohols, glycols, phenols and amines are satisfactory. Benzyl alcohol, *n*-amyl alcohol,

TABLE I

COMPARISON OF HYDRIDE METHOD AND ZEREWITINOFF METHOD FOR ENOLIZABLE COMPOUNDS

| Compound | Solvent | Active hydrogen, found By $LiAlH_4$ | By $CH_3MgI$ |

[g] No active hydrogen calcd. [h] Nature of reaction not known. [i] 4.0 active hydrogen calcd. Very small sample used, so percentage error was large. [k] Red color at end of reaction, which disappears on hydrolysis. [m] 3.0 active hydrogen calcd. [n] Reaction time ten to twenty minutes. [y] A = dibutyl ethers; B = N-ethylmorpholine.

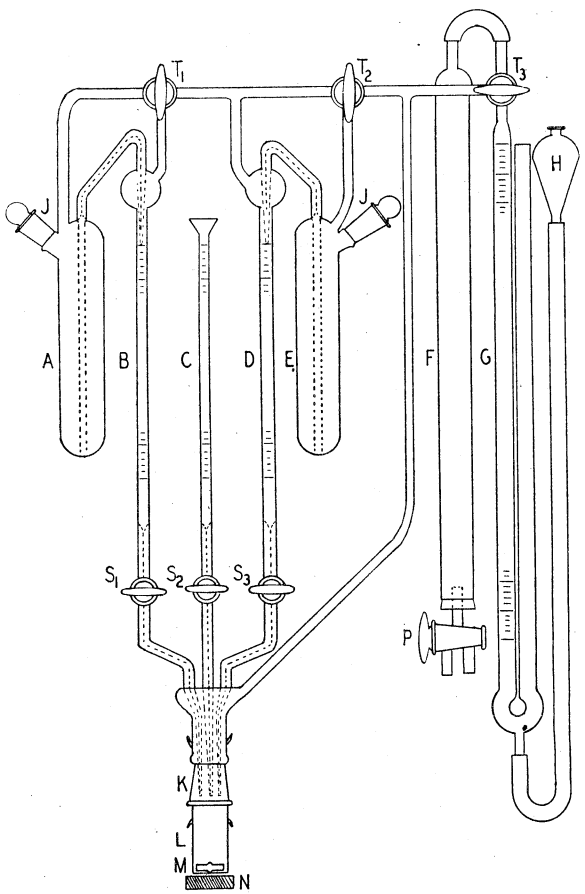

Fig. 1.—Apparatus for measurement of active hydrogen and of $LiAlH_4$ consumption: A, E, 125 ml. reservoirs; B, 2 ml. reagent buret; C, 2 ml. hydrolyzing agent buret; D, 5 ml. solvent buret; F, nitrogen drying tube, packed with phosphorus pentoxide on pumice; G, 25 ml. gas measuring buret; H, mercury reservoir; J, 14/30 ⅀ filling ports; K, 24/40 ⅀ female joint; L, 12 ml. reaction flash, with 24/40 ⅀ male joint; M, glass covered iron stirrer; N, rotating magnet; P, three-way stopcock, for nitrogen; $S_1$, $S_2$, $S_3$, 1 mm. capillary bore stopcocks; $T_1$, $T_2$, $T_3$, three-way 6 mm. stopcocks.

β-naphthol, thio-β-naphthol, 2,4,6-tribenzylphenol, benzylaniline, diphenylamine and dibenzylamine gave values indicating 1.00 active hydrogen, with an average deviation of ±0.015. Phenylethylene glycol, 1,6-hexanediol, hydroquinone, aniline and *n*-butylamine gave values indicating 2.00 active hydrogen, with an average deviation of ±0.010. Water, in N-ethylmorpholine solution, gave values indicating 1.7 to 1.9 active hydrogen.

TABLE III

REACTIONS OF $LiAlH_4$ WITH UNSATURATED COMPOUNDS[a]

| Compound | Active hydrogen found | Moles $LiAlH_4$ consumed Found | Calcd.[b] | Temp. °C. |
|---|---|---|---|---|
| Allyl alcohol[c] | 1.01 | 0.41 | 0.25 | 95 |

| 1-Tyrosine ethyl ester[b] | 2 | 60 | 2-Amino-3-(*p*-hydroxyphenyl)-propanol[e] |
| Benzophenone oxime[b] | 7 | 60 | Benzhydrylamine[f] |

[a] Reductions carried out in ether at 35° unless otherwise specified. [b] Reductions carried out in tetrahydrofuran at 65°. [c] Isolated as diacetate, $d^{20}_{20}$ 1.028, $n^{20}D$ 1.4294. [d] New compound. Colorless needles from benzene, m. p. 110.5–111.5°. *Anal.* Calcd. for $C_9H_{10}O_2$: C, 72.0; H, 6.71; act. $H_2$ 1.33%; Br. No., 108. Found: C, 72.0; H, 6.52; act. $H_2$, 1.37%; Br. No., 118. Dibenzoate (act. $H_2$ 0.0%), rectangular plates from methanol, m. p. 92.5–93.5°. [e] New compound: isolated as triacetyl derivative; white needles from alcohol m. p. 118–119°. *Anal.* Calcd. for $C_{15}H_{19}O_5N$: N, 4.78. Found: N, 4.76, 4.89. $[\alpha]^{25}D$, + 1.95° (in ethanol). 2-Amino-3-(*p*-hydroxyphenyl) propanol sulfate, m. p. 272–7° (decomp.). *Anal.* Calc. for $(C_9H_{13}NO_2)_2H_2SO_4$: $SO_4$, 22.2. Found: $SO_4$, 22.3. [f] 20% of oxime recovered unchanged.

Further data, with reference to types of compounds which undergo reduction as well as replacement of active hydrogen, are presented in Tables I–III. The agreement with the theory is in general within the limits of experimental error.

It was occasionally desirable to run larger scale reactions in order that reaction products might be investigated. Some of these are described in Table IV, the procedures having been described previously.[4]

## Experimental

Early experiments were carried out with the usual type of micro-scale Grignard machine,[10] the reactions being performed in air. Erratic results, due to a slow reaction of the hydride with oxygen and the consequent liberation of hydrogen, were remedied by carrying out the operations in an atmosphere of nitrogen. Difficulties encountered because of the leaking and fouling of the three-way stopcock were overcome by a modification of the apparatus. Dioxane, anethole and N-methylmorpholine are less satisfactory than dibutyl ether as a solvent, while N-ethylmorpholine is the most satisfactory solvent used to date. Pyridine cannot be used since it is reduced by the reagent.

The design of the apparatus is shown in Fig. 1. It may be noted that if an accuracy of better than one per cent. is desired, the design should be altered to minimize the free space in the head of the reaction vessel and in the connections to the gas buret, and also that the latter should be maintained at constant temperature.

The operation of the apparatus is similar in principle to that described by Soltys.[10] A weighed sample is placed in the reaction vessel, L, the apparatus is flushed with dry nitrogen, and the desired quantity of solvent is added from the buret, D. The gas buret is levelled at zero, and with stirring by the magnetic bar, M, the desired quantity of lithium aluminum hydride solution (taken in 20–30% excess) is added from buret, B. The evolution of hydrogen from compounds containing active hydrogen is usually complete in one to ten minutes at room temperature; reduction reactions may require a longer time, or may require heating. After measurement of the hydrogen gas volume, the excess hydride is decomposed by the addition, from buret, C, of 1.0 ml. of a mixture of amyl alcohol in two volumes of dibutyl ether. Complete decomposition of the reagent may require some time; usually fifteen minutes at room temperature is adequate.

**Reagents.**—Stock solutions of lithium aluminum hydride were prepared by shaking 2 g. of the compound[11] with 200 ml. of dibutyl ether for fifteen minutes or longer, allowing the mixture to settle and filtering the supernatant liquid through sintered glass, all operations being conducted under nitrogen. This yields a clear solution, 0.20–0.25 molar in $LiAlH_4$, which slowly deposits a white precipitate and deteriorates at a rate of less than 1% per month when stored under dry nitrogen.

The solvents, N-ethylmorpholine and dibutyl ether, were first dried over calcium hydride, then treated with lithium aluminum hydride (2 g. per l.) at 90–100° for two hours, and were then distilled at 20 mm. pressure. After placing the solvent in the reservoir, control runs were made on the basis of which the calculated quantity of lithium aluminum hydride solution was added to the solvent contained in the reservoir and the mixture heated to 70° for one hour. With this procedure the quantity of hydrogen liberated from 1 ml. of solvent by the addition of hydride solution could be made smaller than 0.05 ml.

Cylinder nitrogen was used without purification, other than drying over phosphorus pentoxide.

The test compounds were purified by conventional procedures but with special care to exclude moisture. In the recrystallization of solids it was necessary to avoid the use of hydroxylic solvents. Liquids were dried over calcium hydride where possible, otherwise over Drierite.

**Acknowledgments.**—Dr. Weldon G. Brown offered much helpful advice in the development of this method; he supplied many of the compounds tested in the apparatus.

## Summary

The quantitative aspect of the reaction of lithium aluminum hydride with several types of organic compounds has been investigated. It is shown that lithium aluminum hydride may be used as a reagent for the determination of active hydrogen, and reducible groups.

# An Empirical Expression for the Melting Points of the Straight-Chain Dicarboxylic Acids

BY JOHN G. ERICKSON

It was pointed out by Baeyer[1] in 1877 that the melting points of the unsubstituted aliphatic dibasic acids are of an oscillatory nature, that is, the melting points of successive members of the series are alternately high and low. The melting points converge to an asymptotic value, the melting points of the acids with an even number of carbon atoms decreasing and the melting points of the acids with an odd number of carbon atoms increasing with the length of the carbon chain. The convergence value for the dibasic acids is 123°.

(1) Baeyer, *Ber.*, **10**, 1286 (1877).

This oscillation is not peculiar to the melting points of the dicarboxylic acids; other homologous series, including aliphatic monobasic acids and their α-hydroxy derivatives, α,α′-dibromodicarboxylic acids, dinitriles, glycols, diamines, dialdehydes, alcohols and paraffins, show similar oscillatory effects and other physical properties, including solubilities, molecular volumes, optical rotatory powers and dissociation constants are affected. However, the oscillatory or "alternating" effect is much the most pronounced with the dicarboxylic acids and has attracted the most atten-

tion with these compounds. The effect has been discussed by a number of persons[2] and explanations have been offered. A good summary of the conclusions reached is given by Ralston.[3]

King and Garner[4] have fitted a mathematical expression to the melting points of the ethyl esters of the saturated straight-chain monocarboxylic acids. This is a series which shows a slight alternating effect in the sense that, while the melting points for both even and odd numbered esters increase with the length of the carbon chain, the differences between successive members of the series are alternately relatively large and small. These differences become small as the chain becomes long so that, plotted as melting point *vs.* length of chain, the even and odd numbered esters give two curves which rise and tend to converge as the carbon chain increases in length. King and Garner found that the melting points could be represented by the following equation: for esters of even acids

$$T_m = \frac{0.7630n + 0.63}{0.00179n + 0.01475}, \text{ up to } n = 20$$

and

$$T_m = \frac{0.7081n - 3.28}{0.001796n - 0.0012} \text{ above } n = 20$$

for esters of odd acids

$$T_m = \frac{0.8389n - 5.58}{0.00224n - 0.00904}$$

$T_m$ represents the melting points and $n$, the number of carbon atoms in the acid.

This paper reports an expression which shows the alternating effect and convergence for the dicarboxylic acids and reproduces their melting points, from glutaric acid on, with a fair degree of accuracy. It is of a type quite different from that of King and Garner and takes the form of a single sequence, applicable over the entire range of values. It may be expressed:

$$(T_m)_n = ab^{cd_{n-1}} + e = ad_n + e$$
$$(T_m)_{n+1} = ab^{cd_n} + e = ad_{n+1} + e$$
$$(T_m)_{n+2} = ab^{cd_{n+1}} + e = ad_{n+2} + e, \text{ etc.}$$

where $(T_m)_n$ represents the melting point of a dibasic acid, $(CH_2)_n(COOH)_2$, where $n$ is greater than two, and $a$, $b$, $c$ and $e$ are constants whose values are: $a = 100.00$, $b = 0.09500$, $c = 0.85000$, $e = 80.000$. Each term in the $d_n$ sequence, $d_n = b^{cd_{n-1}}$, $d_{n+1} = b^{cd_n}$, $d_{n+2} = b^{cd_{n+1}}$, etc., is calculated from the preceding one. The initial term for this sequence is $d_2 = 0.87300$.

the highest melting points would correspond to compounds of the greatest purity. In view of this, it is not surprising that most of the values which agree most closely with the calculated values are also the highest reported values. It will be seen that, in general, the difference between the calculated and observed values for an acid is considerably less than the range of values reported for the acid. The large difference, 6.3°, between calculated and observed melting points for the $C_{23}$ acid may be attributed to the fact that this acid was isolated from a naturally occurring wax and the difficulties of purifying long-chain compounds when contaminated with compounds of nearly the same properties are rather great. The melting points for the $C_{26}$, $C_{39}$ and $C_{34}$ acids were taken from the very careful work of Fairweather[2h] and definitely fix the convergence value of the series as 123°.

## Summary

An empirical expression, which takes the form of a mathematical sequence is proposed for the melting points of the unsubstituted dicarboxylic acids. It is shown that this expression reproduces the melting points of these acids satisfactorily.

# Properties of Electrolytic Solutions. XXXVII. The Conductance of Some Long Chain Salts in Acetone–Water Mixtures[1]

BY HOWARD S. YOUNG,[2] PHILIP F. GRIEGER[3] AND CHARLES A. KRAUS

## I. Introduction

The effect of added methanol on the conductance of several long chain electrolytes (principally *n*-octadecyltrimethylammonium salts) in aqueous solution has been described in preceding numbers of this series.[4,5,6]

Based on the form of their conductance curves in water and mixtures of water with other solvents, long chain salts may be divided into three classes: I, the conductance curve exhibits a breakpoint in water as well as in mixtures of water with other solvents; II, the curve exhibits a maximum in water as well as in its mixtures; and III (an intermediate case), the curve exhibits a breakpoint in water and a maximum in mixtures containing sufficient additive.

Solutions of the octadecyltrimethylammonium ion have been measured in combination with seven different gegenions in methanol–water mixtures. Of these, the bromide, nitrate and oxalate fall into Class I; the chloride, bromate, iodate and formate fall into Class III. Of the octadecylpyridonium salts measured, the bromide and nitrate fall into Class I, the chloride falls into Class III and the iodate into Class II.

In the present investigation, the conductance of three octadecyltrimethylammonium salts (oxalate, formate and bromate) was measured in acetone–water mixtures (0 to 30% acetone by weight) in order to compare the effects of added acetone with those observed with methanol. Although the measurements with acetone are less extensive than those with methanol,[3,4] they permit of an adequate comparison in the case of several salts.

Among other things, it was of interest to determine whether salts in acetone–water mixtures fall into the methanol–water classification groups. It was also of much interest to determine whether or not the critical phenomenon (breakpoint or maximum) may be correlated with the physical constants of the solvent mixtures, such as dielectric constant.

## II. Experimental

**Apparatus and Procedure.**—The details appertaining to these have been fully described in earlier numbers of this series.[4] All measurements were made at 25 ± 0.01°.

**Salts.**—The salts were identically the same as those used in a previous investigation.[5]

**Solvents.**—Water was prepared according to the technique already described[4]; its specific conductance was in the neighborhood of $1 \times 10^{-6}$.

**Acetone.**—Commercial acetone was treated by the silver hydroxide method described by Werner.[7] The water introduced in this treatment was removed by refluxing over anhydrous potassium carbonate. The carbonate was removed by filtration, and the acetone was fractionally distilled from activated alumina. It was freshly distilled from activated alumina immediately before use. The lowest specific conductance obtained in this manner was $6 \times 10^{-9}$.

## III. Results

In Tables I, II and III are recorded selected values of the equivalent conductance, Λ, as a func-

tion of the square root of equivalent concentration, $C$, for *n*-octadecyltrimethylammonium oxalate, formate and bromate, respectively. The numbers in parentheses in the tables are the percentage solvent correction; they are included to indicate the magnitude of this correction. The solvent composition is given in weight per cent. The following data are included for the solvents: specific conductance, $\kappa$; density, $d$[8]; and dielectric constant, $D$.[9] In computing the equivalent concentration, the densities of the solutions were assumed equal to those of the pure solvents[3]; no buoyancy corrections were applied.

In Figure 1, $\Lambda$ is plotted against $\sqrt{C}$ for *n*-octadecyltrimethylammonium oxalate in acetone–water mixtures. Earlier results[4] with water as solvent are included in the figure for comparison. In Figs. 2 and 3 are shown similar plots for the formate and the bromate. Previous results[4,10] with water and water–methanol mixtures as solvents are also plotted for purposes of comparison.

## IV. Discussion

As may be seen from an inspection of Figs. 1, 2 and 3, the effect of added acetone on the conductance of octadecyltrimethylammonium salts in water is similar to that of methanol. In methanol–water mixtures, the oxalate shows the simple breakpoint phenomenon (Class I); an analogous situation prevails in acetone–water mixtures. Similarly, the bromate and formate, which exhibit a maximum in $\Lambda$ in methanol–water mixtures (Class III), likewise exhibit a maximum in acetone–water mixtures.

The low value of the breakpoint concentration of octadecyltrimethylammonium oxalate in water and the wide range of concentration over which it is displaced on addition of added solvents render this salt particularly useful in any attempt to correlate the breakpoint concentration with the

physical properties of the solvent mixtures. For smaller additions of acetone or methanol, the breakpoint remains quite sharp, but, for larger additions, for example, 28.8% acetone, the breakpoint concentration can only be approximated.

Breakpoint concentrations for octadecyltrimethylammonium oxalate in acetone–water and methanol–water mixtures are given in Table IV.[11]

The composition of the solvent is given in terms of both weight per cent. and mole per cent. of additive. The reciprocal of the dielectric constant of the solvent (column 3) and the logarithm of the breakpoint concentration (column 5) are also given.

TABLE IV

BREAKPOINT CONCENTRATION, $C_b$, OF *n*-OCTADECYLTRIMETHYLAMMONIUM OXALATE IN ACETONE–WATER AND METHANOL–WATER MIXTURES

| Wt. % org. comp. | Mole % org. comp. | $10^2/D$ | $10^2\sqrt{C_b}$ | $4 + \log C_b$ |
|---|---|---|---|---|
| | | Acetone | | |
| 0 | 0 | 1.274 | 0.8 | −0.19 |
| 9.91 | 3.30 | 1.366 | 1.2 | +0.158 |
| 13.9 | 4.76 | 1.408 | 1.6 | .408 |
| 20.7 | 7.48 | 1.488 | 2.3 | .724 |
| 28.8 | 11.1 | 1.597 | 3.6 | 1.123 |
| | | Methanol | | |
| 20.7 | 12.7 | 1.435 | 1.64 | 0.428 |
| 30.2 | 19.5 | 1.529 | 2.6 | .828 |
| 40.1 | 27.3 | 1.642 | 4.2 | 1.246 |

Inspection of Table IV will show that on a weight per cent. basis, acetone increases the breakpoint concentration more than does methanol. The relationship is shown clearly in Fig. 4

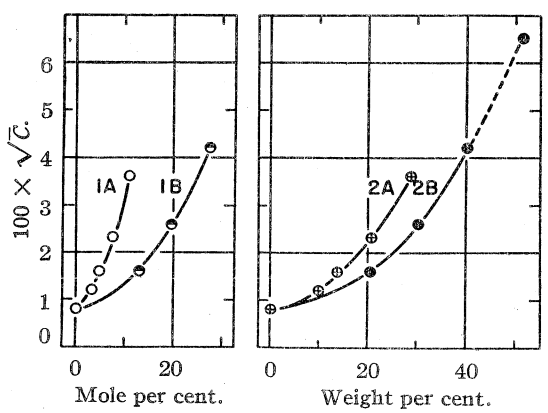

Fig. 4.—Square root of breakpoint concentration for octadecyltrimethylammonium oxalate as function of composition for: water–acetone mixtures (A); water–methanol mixtures (B); Composition: mole per cent, curves 1; weight per cent, curves 2.

(11) The breakpoint concentration of the oxalate in water has not been evaluated experimentally. However, according to Dakin, THIS JOURNAL, **63**, 1007 (1941), the conductance of the oxalate ion is known to be 74.1 and that of the octadecyltrimethylammonium ion[4] 18.3, yielding a value of approximately 92 for the equivalent conductance of the oxalate. If a line be drawn from the Λ axis from the point corresponding to this value and according to the theoretical slope, its intersection with the extension of the experimental curve at higher concentration should give an approximate value of the breakpoint. This procedure leads to the value $\sqrt{C} = 0.8 \times 10^{-2}$.

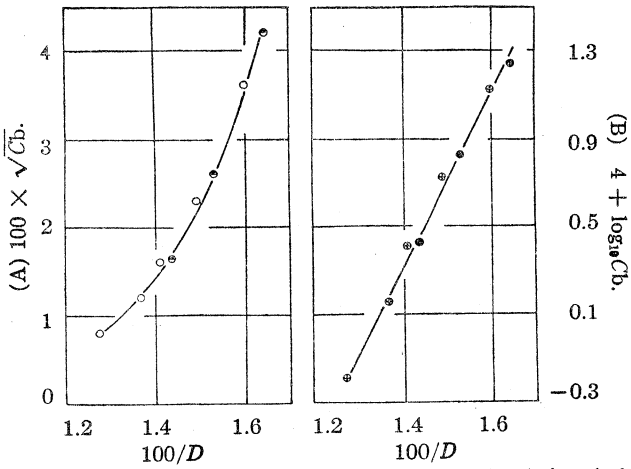

Fig. 5.—Breakpoint concentration of octadecyltrimethylammonium oxalate as a function of reciprocal of dielectric constant $1/D$; (A) $100\sqrt{Cb}$, ○ acetone, ◒ methanol; (B) $\log_{10}Cb$, ⊕ acetone, ● methanol.

where the square root of the breakpoint concentration is plotted as a function of solvent composition (1, mole per cent., and 2, weight per cent. of additive). Curves A relate to acetone and Curves B to methanol. The divergence of the curves is greater on a mole than on a weight per cent. basis. It will be noted that the change in the breakpoint concentration, for a given amount of additive, increases with increasing additive content of the solvent.

The results for acetone and methanol can be brought to substantial coincidence by plotting the breakpoint concentration as a function of the reciprocal of the dielectric constant. In Fig. 5A, the square root of the breakpoint concentration is plotted as a function of the reciprocal of the dielectric constant of the mixtures. It will be noted that the points for the two solvents lie on the same curve within the limit of experimental error. In Fig. 5B, the logarithm of breakpoint concentration is plotted as a function of the reciprocal of dielectric constant. Here the points lie on the same straight line within the experimental error.

The coincidence of the values for the two solvents, when plotted as a function of $1/D$, would seem to indicate a possible connection between the breakpoint phenomenon and the dielectric constant of the solvent medium. However, such a coincidence in the present instance may be purely fortuitous. Thus, Brown[6] has shown that, with dodecylammonium chloride, methanol increases the breakpoint concentration while isopropyl alcohol and *t*-butanol decrease it.

Specific differences between acetone and methanol are more apparent in the cases of the bromate and formate than in that of the oxalate. In 10.1% methanol, the bromate does not show a maximum, while in 15.1% methanol, a maximum occurs: Λ starts to rise at about $C = 3.2 \times 10^{-4}$ and reaches its largest value at $C = 6.2 \times 10^{-4}$; the peak in Λ is about two units high.[4] The highest peak for the bromate comes at about 20% methanol (Curve 3, Fig. 3) and is about 2.5 Λ-units high. In contrast, the bromate in 10.0% acetone shows a maximum starting at $C = 2.4 \times 10^{-4}$, the largest value of Λ comes at $C = 7.3 \times 10^{-4}$, and the peak is 7 Λ-units high.

Similarly, in the case of the formate, the maximum phenomenon is more pronounced in acetone–water mixtures than it is in methanol–water mixtures. Thus, in 19.4% and 23.5% methanol, the peak for the formate is about 3.5 and 2.5 Λ-units high,[5] respectively, while for the same salt in 10.0 and 13.9% acetone the maximum is 10.7 and 7.5 Λ-units high, respectively.

In 10% acetone, the formate exhibits a higher peak than the bromate; similarly, in a given methanol–water mixture, the formate gives rise to a more pronounced maximum than does the bromate.

As far as the present investigation goes to show, it appears that a salt which exhibits a maximum in Λ in a methanol–water mixture will also show a maximum in an acetone–water mixture, but in the latter case, the start of the rise in Λ comes at a somewhat lower concentration and the height of the peak is markedly greater (perhaps by a factor of two or three). However, the salt concentration corresponding to the maximum value of Λ is about the same in the two solvent mixtures.

## V. Summary

1. Measurements have been made on the conductance of octadecyltrimethylammonium oxalate in water–acetone mixtures (0 to 28.8% acetone by wt.), *n*-octadecyltrimethylammonium formate in 10.0 and 13.9% acetone and *n*-octadecyltrimethylammonium bromate in 10.0% acetone, all at 25°.

2. In water–acetone mixtures, the oxalate shows the breakpoint phenomenon; the critical concentration increases with increasing acetone content of the solvent. The results in water–acetone mixtures are similar to those previously obtained with water–methanol mixtures.

3. The curves obtained by plotting the square root of the breakpoint concentration of octadecyltrimethylammonium oxalate against the reciprocal of the dielectric constant of the solvent for water–acetone and water–methanol mixtures nearly coincide.

4. The logarithm of the critical concentration is a linear function of the reciprocal of the dielectric constant for the oxalate in water–acetone and water–methanol mixtures.

5. *n*-Octadecyltrimethylammonium formate and bromate show maxima in conductance curves for water–acetone as well as for water–methanol mixtures. The peaks for acetone are higher than for methanol.

PROVIDENCE, R. I. RECEIVED AUGUST 31, 1948

# Unit Cell Dimension of Face-centered Cubic Chromium Hydride and Space Groups of Two Chromium Hydrides

BY CLOYD A. SNAVELY[1] AND DALE A. VAUGHAN[1]

Chromium metal normally assumes the body-centered cubic crystalline arrangement. However other crystalline arrangements have been reported for electrodeposited chromium. A hexagonal close-packed structure was first reported in 1926,[2] and an $\alpha$-manganese type structure was reported in 1931.[3] Several workers have identified the hexagonal structure since 1926, but there has been no corroboration of the $\alpha$-manganese type structure. Recently one of the present authors presented additional data[4] which show that the hexagonal structure in electrodeposited chromium is actually a chromium hydride, with the hydrogen in interstitial positions in the hexagonal close-packed lattice. In addition, the existence of a face-centered cubic hydride of chromium was reported. It is desired to present here additional recent work which provides a more precise value for the lattice parameter of the face-centered cubic hydride, and to suggest structures for the chromium hydrides.

The initial studies of the F.C.C. hydride of chromium were made with an X-ray spectrometer, with which it was possible to determine the lattice of a given sample in the form of an electroplate, and to follow any structural changes occurring over a period of time. The data gave definite proof of the existence of the new phase. However, to avoid the well-known pitfalls of the spectrometer method as to errors in intensity of the diffraction maxima resulting from grain size or orientation, and to obtain a complete pattern of the new compound, samples were prepared for study by the powder X-ray diffraction method.

The F.C.C. hydride was deposited from an aqueous plating bath originally made up to contain 1021 g./l. of $CrO_3$, 3.4 g./l. of $SO_4$ and 20 g./l. of cane sugar. The sugar was added to the bath last as a sirup, and had the effect of reducing to the trivalent state from 7 to 10% of the contained chromium. The bath was refrigerated to $5 \pm 4°$ during plating operations. The current density was approximately 0.8 amp./sq. in. Disks of brass $\frac{1}{2}$ in. in diameter and 0.020 in. thick were used as cathodes. The anode was cut from antimonial lead sheet. Plating was continued for periods of from six to twelve hours to provide thick deposits which could be handled easily. After plating, the samples were dropped into dilute nitric acid to dissolve the brass backing disk. Care was necessary in this step, as the heat generated was sufficient to decompose the hydride if the acid was too concentrated. The chromium hydride, which was not attacked by the acid, was then rinsed, dried and crushed into fine particles. It was so brittle that the crushing was easily carried out in a glass beaker, using a glass rod as a pestle. This provided a satisfactory sample for powder X-ray diffraction studies.

The powder photograms were taken with unfiltered chromium radiation ($\lambda$Ka = 2.29090 Å.) in a 114.6 mm. camera of the Buerger design. The data obtained from the diffraction pattern of the new "structure compound," corrected for systematic errors by extrapolation, gave 3.8605 ± 0.0005 Å. for the unit cell dimension. A more precise value could not be obtained owing to the fact that the diffraction maxima were broader than those usually obtained from a material as friable as is this compound. This broadening is believed to be the result of either or both of two factors, namely, small particle size and variations in lattice spacing resulting from variations in the number of interstitially placed hydrogen atoms. The intensities of the diffraction maxima are the same as those of a face-centered cubic metal.

Westgren[5] compiled much of the available data on the metal hydrides, which show that the hydrides are interstitial solid solutions of variable hydrogen content within certain definite composition limits. Westgren concluded that the hydrogen atoms occupy the second largest interstices in the metal lattice, since spatial considerations show that the largest interstice would provide too much space for the accepted value of the hydrogen radius. With few exceptions, hydrides of compositions ranging between $M_2H$ and MH tend to adopt the H.C.P. crystal arrangement. Those of formula MH to $MH_2$ tend to adopt the F.C.C. arrangement. Thus, a complete composition range between the limits $M_2H$ and $MH_2$ is possible, and the crystalline arrangement is governed by the composition.

In the case of $Cr_2H$–CrH, the metal atoms fall in a hexagonal close-packed arrangement with the hydrogen occupying the second largest interstitial positions.[4] However, the metal atoms are not in actual contact with each other, but bond through the hydrogen atoms. Two space groups are possible. If the chromium atoms have true holohedral symmetry, the space group is $D_{6h}^4$-$C6/mmc$. However, if the chromium atoms assume hemihedral symmetry, the space group is $C_{6v}^4$-$C6mc$. These two space groups are indistinguishable by X-ray diffraction methods, and it is only necessary for our purposes to consider one, *e. g.*, the latter. The chromium atoms assume hexagonal positions as H atoms enter the allowed interstitial point positions specified below, until these are filled, whereupon the addition of another hydrogen atom will cause an unstable structure due to the proximity of two hydrogen atoms. If more hydrogen atoms are present than will be included in the H.C.P. structure, the metal atoms assume a face-centered cubic structure which will accept two hydrogen atoms for each chromium atom. The space group becomes $T_d^2$-$F43m$ (or $O_h^5$-$Fm3m$ if all of

H at 8(c) $1/4\ 1/4\ 1/4$; $1/4\ 3/4\ 3/4$; $3/4\ 1/4\ 3/4$; $3/4\ 3/4\ 1/4$
$3/4\ 3/4\ 3/4$; $3/4\ \overline{1/4}\ \overline{1/4}$; $\overline{1/4}\ 3/4\ \overline{1/4}$; $\overline{1/4}\ \overline{1/4}\ 3/4$

The important result of the discovery of these hydrides of chromium is that the radius of the chromium atom no longer constitutes an anomaly within the family of metals. Recent discussions of the chromium atom radius[7,8] have treated the hexagonal hydride as a normal H.C.P. allotropic form of the metal. A somewhat complicated postulate regarding behavior of the electrons in the outer rings was advanced to explain the very large apparent radius (1.35 Å.) of the atom in the H.C.P. arrangement. With the introduction of the hydride concept, the chromium atoms may be considered to undergo only the normal radius change of 3% in passing from the F.C.C or H.C.P. hydride phases to the B.C.C. metallic phase ($r = 1.25$ Å.). The interstitially placed hydrogen atoms expand the metal lattice in both hydride phases and the Goldschmidt correction[9] of 3% provides a radius value of 1.28 Å. which appears to satisfy the X-ray data for these phases.

## Summary

1. A determination of the lattice parameter of F.C.C. chromium hydride is reported. The new value is $a = 3.8605 \pm 0.0005$ Å.

2. Structures are postulated for the F.C.C. and H.C.P. chromium hydrides.

3. Argument is presented to refute the concept that chromium is allotropic.

# Heat Capacities at Low Temperatures and Entropies of Vanadium Carbide and Vanadium Nitride

BY C. H. SHOMATE[1] AND K. K. KELLEY[2]

In previous papers from this laboratory, Anderson[3] has reported low-temperature heat-capacity measurements of vanadium and three of its oxides and Shomate[4] has reported similar data for vanadium di- and trichlorides. The present paper reports heat capacity measurements throughout the temperature range 50.4 to 298.16°K. and entropies at 298.16°K. of vanadium carbide and vanadium nitride. No similar data for either of these substances are in the literature.

**Materials.**[5]—The starting material for the preparation of vanadium carbide was vanadium containing 8% carbon and only a trace of other impurities. An intimate mixture of this material was made with Norblack sufficient to comply with the formula VC. The mixture was heated in vacuum at 1300 to 1350° for a total of twenty-six hours. After twelve and twenty-two hours heating, the product was analyzed and reground, and minor adjustment was made in the composition. The final product was uniform and showed no signs of incomplete reaction, which also was confirmed by the X-ray diffraction pattern.[6] No free carbon was evident on solution in 1:3 nitric acid. The product was analyzed for vanadium by permanganate titration, after fusion in a mixture of sodium bisulfate and potassium nitrate, and for carbon by absorbing and weighing the carbon dioxide evolved on combustion in pure oxygen in the presence of red lead oxide. The results were 80.90% vanadium and 19.04% carbon, as compared with the theoretical 80.92% and 19.08%, respectively.

Vanadium containing carbon, as mentioned above, also was the source material for the preparation of vanadium nitride. A 5:1, by volume, mixture of purified nitrogen and hydrogen was passed over the finely ground carburized vanadium at 1200° for twenty-eight hours. This gas mixture slowly replaced carbon by nitrogen, the carbon being carried out of the hot zone evidently by free radical formation with hydrogen. At seven-hour intervals, the reaction mixture was cooled, removed from the furnace, and reground. After twenty-eight hours of treatment, the product contained 0.76% carbon and an excess of nitrogen. It then was heated for eight hours at 1100° in a stream of pure hydrogen. The final product was analyzed for vanadium by permanganate titration, after burning to oxide and fusing in sodium bisulfate. The average result was 78.24% vanadium, as compared with the theoretical 78.43%. Combustion analysis for residual carbon gave only 0.05%. The X-ray diffraction pattern showed no evidence of materials other than vanadium nitride.

**Heat Capacities.**—The heat capacities were measured with apparatus previously described.[7] The results, expressed in defined calories (1 cal. = 4.1833 int. joules) per mole, are listed in Table I and are plotted against temperature in Fig. 1.

(5) The preparations and analyses of these substances were conducted by A. E. Salo, formerly chemist, Pacific Experiment Station, Bureau of Mines.

(6) X-Ray diffraction examinations of both substances were made by E. V. Potter, formerly physicist, Salt Lake City Station, Bureau of Mines.

(7) Kelley, Naylor and Shomate, Bureau of Mines Technical Paper 686, 1946, 34 pp.

The molecular weights accord with the 1947 International Atomic Weights. The samples of carbide and nitride weighed 284.19 g. and 351.29 g., respectively, corrected to vacuum.

The heat capacity curves follow a normal course, the nitride curve being higher at all temperatures. The difference in heat capacity ranges from 0.6 cal./deg./mole at 50°K. to 1.1 cal./deg./mole at 298.16°K. At the lowest points measured the heat capacity of the carbide is just on the verge of following the $T^3$-law, while an additional 20° lower temperature would be required to bring the nitride heat capacity to this region. Values of the heat capacities at 298.16°K., as read from smooth curves, also are included in Table I.

TABLE I

MOLAL HEAT CAPACITY OF VC (MOL. WT., 62.96)

| T, °K. | $C_p$, cal./deg. | T, °K. | $C_p$, cal./deg. | T, °K. | $C_p$, cal./deg. |
|---|---|---|---|---|---|
| 52.5 | 0.5895 | 115.1 | 3.132 | 216.2 | 6.326 |
| 56.5 | .7180 | 125.2 | 3.525 | 226.0 | 6.555 |

MOLAL HEAT CAPACITY OF VN (MOL. WT., 64.96)

| | | | | | |
|---|---|---|---|---|---|
| 52.6 | 1.272 | 115.1 | 4.255 | 216.1 | 7.483 |
| 56.7 | 1.484 | 125.1 | 4.649 | 226.1 | 7.727 |
| 60.9 | 1.702 | 135.0 | 5.036 | 235.8 | 7.925 |
| 65.1 | 1.925 | 145.6 | 5.413 | 246.1 | 8.159 |
| 69.4 | 2.150 | 155.5 | 5.759 | 256.1 | 8.379 |
| 73.5 | 2.365 | 165.4 | 6.085 | 266.0 | 8.546 |
| 80.0 | 2.688 | 175.3 | 6.415 | 276.0 | 8.727 |
| 84.8 | 2.917 | 185.6 | 6.700 | 286.1 | 8.899 |
| 94.7 | 3.376 | 195.9 | 6.980 | 296.3 | 9.053 |
| 104.5 | 3.809 | 205.8 | 7.244 | 298.16 | (9.080) |

**Entropies.**—The entropies were calculated in the usual manner, the portion between 52.00 and 298.16°K. being obtained by numerical integration of a plot of $C_p$ against log $T$ and the portion below 52.00°K. being obtained by extrapolation. The latter was accomplished by the empirical use of Debye functions, $D(476/T)$ and $D(351/T)$, respectively, for the carbide and nitride. These functions fit the measured data to within 0.02 cal./deg./mole, or better, at temperatures below 70 and 80°K., respectively. The results of the entropy calculations are in Table II. It is noteworthy that the extrapolated portions of the entropies are only 3.0 and 5.3% of the totals at 298.16°K.

TABLE II

ENTROPIES AT 298.16°K. (E. U./MOLE)

| | VC | VN |
|---|---|---|
| 0–52.00°K. (extrapolated) | 0.20 | 0.47 |
| 52.00–298.16°K. (measured) | 6.57 | 8.44 |
| $S^\circ_{298.16}$ | 6.77 ± 0.03 | 8.91 ± 0.04 |

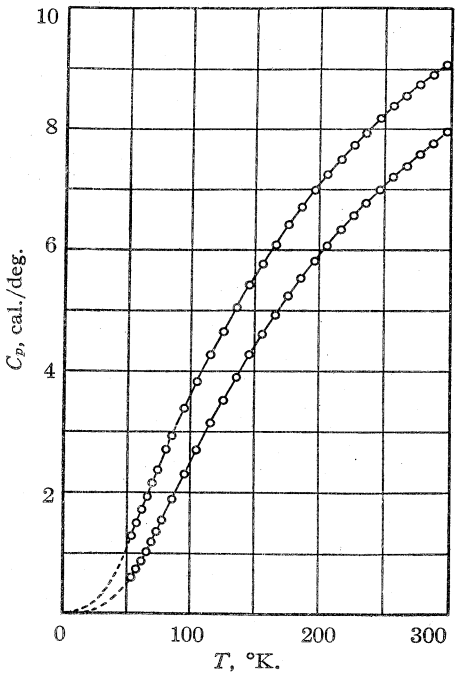

Fig. 1.—Molal heat capacities: upper curve, VN; lower curve, VC.

The results in Table II and the entropies of the elements[8] ($S^\circ_{298.16}$ = 7.0 ± 0.1 for V, $S^\circ_{298.16}$ = 1.36 ± 0.03 for C, and $S^\circ_{298.16}$ = 45.79 ± 0.01 for $N_2$) yield $\Delta S^\circ_{298.16}$ = −1.6 ± 0.1 for the entropy of formation of vanadium carbide from the elements and $\Delta S^\circ_{298.16}$ = −21.0 ± 0.1 for the entropy of formation of vanadium nitride from the elements.

## Summary

The heat capacities of vanadium carbide and vanadium nitride were measured throughout the temperature range 50.4 to 298.16°K.

The entropies of vanadium carbide and nitride are, respectively, $S^\circ_{298.16}$ = 6.77 ± 0.03 and $S^\circ_{298.16}$ = 8.91 ± 0.04. The corresponding entropies of formation from the elements are $\Delta S^\circ_{298.16}$ = −1.6 ± 0.1 and $\Delta S_{298.16}$ = −21.0 ± 0.1.

# High Temperature Heat Contents of Vanadium Carbide and Vanadium Nitride

BY E. G. KING[1]

In a recent paper, Shomate and Kelley[2] reported low temperature heat capacity data for vanadium carbide and vanadium nitride, but with the exception of three measurements of vanadium nitride between 273 and 732°K. by Sato,[3] no high temperature heat content values have been available for these substances. This paper reports the results of high temperature heat content measurements covering the temperature range from 298 to 1611°K.

## Materials and Method

The materials used in the present work were identical with those employed by Shomate and Kelley.[2] Reference is made to their paper for the description of methods of preparation, chemical analyses and X-ray examinations.

The heat content measurements were made by the "drop" method, for which apparatus and experimental procedure have been described[4] previously. The calorimeter was calibrated electrically in terms of international joules and conversion to calories was made by the relation, 1 cal. = 4.1833 int. joules.

During the measurements the samples were contained in platinum–rhodium alloy capsules, the heat contents of which were determined by separate experiments. The capsules, after being filled with sample, were evacuated of air, filled with helium, and then quickly sealed gas-tight by platinum welding.

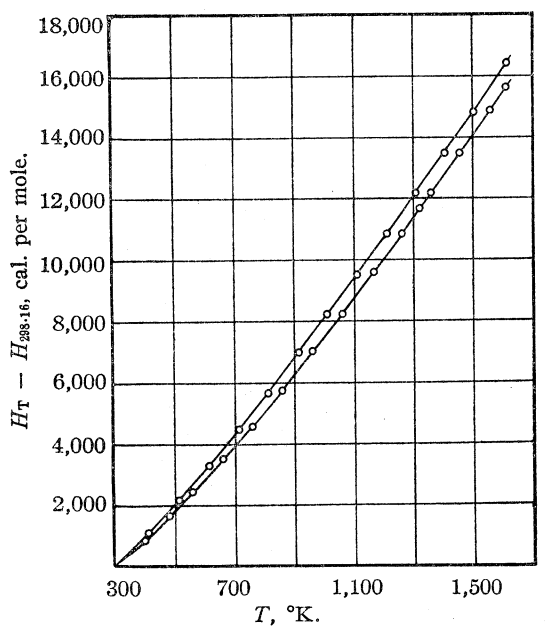

Fig. 1.—High temperature heat contents: upper curve, VN; lower curve, VC.

The weights of materials used in the measurements were 17.1426 g. of vanadium carbide and 19.3105 g. of vanadium nitride, corrected to vacuum by means of the densities, 5.93 g./cc. and 6.21 g./cc., respectively. The heat content of the empty capsule averaged about 12% of the total heat content in each instance.

## Results

The experimental results, covering the temperature range 298° to 1611°K., are listed in Table I and shown plotted against temperature in Fig. 1. In Table I, $T$, °K., is the temperature of the sample immediately before dropping into the calorimeter, and $H_T - H_{298.16}$ is the heat liberated per gram mole in cooling from this temperature to 298.16°K. The molecular weights are in accord with the 1947 International Atomic Weights.

TABLE I

HEAT CONTENTS ABOVE 298.16°K. (EXPERIMENTAL VALUES)

| VC (mol. wt. = 62.96) | | VN (mol. wt. = 64.96) | |
|---|---|---|---|
| $T$, °K. | $H_T - H_{298.16}$, cal./mole | $T$, °K. | $H_T - H_{298.16}$, cal./mole |
| 397.2 | 855 | 408.1 | 1,105 |
| 476.9 | 1,660 | 511.0 | 2,195 |
| 557.2 | 2,435 | 609.6 | 3,310 |
| 657.4 | 3,500 | 709.8 | 4,475 |
| 756.4 | 4,570 | 807.7 | 5,685 |
| 858.1 | 5,765 | 910.0 | 6,970 |
| 958.1 | 7,000 | 1006.8 | 8,220 |
| 1057.0 | 8,220 | 1106.6 | 9,520 |
| 1162.9 | 9,580 | 1206.6 | 10,840 |
| 1258.1 | 10,810 | 1306 | 12,170 |
| 1319 | 11,620 | 1406 | 13,490 |
| 1359 | 12,150 | 1503 | 14,830 |
| 1458 | 13,470 | 1611 | 16,400 |
| 1558 | 14,870 | | |
| 1611 | 15,620 | | |

Measurements at temperatures above 1611°K. were invalidated by the progressive development of embrittlement, which finally produced leaks in the platinum–rhodium alloy capsules. The occurrence of a leak was readily detectable by weighing the capsule and contents after each of the higher temperature determinations, because of resulting oxidation of the sample. The capsules remained gas-tight for all determinations listed in Table I.

It is evident from Fig. 1 that the behavior of these substances is normal in all respects. The heat content of vanadium nitride is the higher throughout the measured temperature range, thus extending the similar observation of Shomate and Kelley[2] for low temperatures. The three previous determinations of Sato[3] for vanadium nitride deviate from the present work and merit no weight in comparison. The deviations are, respectively,

−1.4% at 373°K., +2.2% at 578°K., and +4.9% at 732°K., the temperatures being those reported by Sato.

Table II gives heat content values read from smooth curves at 100° intervals, together with the corresponding entropy increments above 298.16°K. The latter were computed from and exactly match the former.

TABLE II

HEAT CONTENTS AND ENTROPIES ABOVE 298.16°K. (SMOOTH VALUES)

| | VC | | VN | |
|---|---|---|---|---|
| $T$, °K. | $H_T - H_{298.16}$, cal./mole | $S_T - S_{298.16}$, cal./deg./mole | $H_T - H_{298.16}$, cal./mole | $S_T - S_{298.16}$, cal./deg./mole |
| 400 | 890 | 2.55 | 1,010 | 2.91 |
| 500 | 1,850 | 4.70 | 2,080 | 5.30 |
| 600 | 2,870 | 6.55 | 3,200 | 7.34 |
| 700 | 3,950 | 8.22 | 4,370 | 9.14 |
| 800 | 5,090 | 9.74 | 5,590 | 10.76 |
| 900 | 6,280 | 11.14 | 6,850 | 12.25 |
| 1000 | 7,510 | 12.43 | 8,130 | 13.60 |
| 1100 | 8,770 | 13.64 | 9,430 | 14.84 |
| 1200 | 10,060 | 14.76 | 10,750 | 15.99 |
| 1300 | 11,380 | 15.81 | 12,090 | 17.06 |
| 1400 | 12,720 | 16.80 | 13,450 | 18.07 |
| 1500 | 14,080 | 17.74 | 14,820 | 19.01 |
| 1600 | 15,450 | 18.63 | 16,200 | 19.90 |

High temperature heat content equations were derived by the method of Shomate[5]; using all the data of Table I and the molal heat capacities[2] at 298.16°K., $C_{p,\ 298.16} = 7.970$ for vanadium carbide and $C_{p,298.16} = 9.080$ for vanadium nitride. The resulting equations, which follow, fit the measured data to within an average deviation of 0.3% in each instance.

$$\text{VC: } H_T - H_{298.16} = 9.18T + 1.65 \times 10^{-3}T^2 + 1.95 \times 10^5T^{-1} - 3538$$

$$\text{VN: } H_T - H_{298.16} = 10.94T + 1.05 \times 10^{-3}T^2 + 2.21 \times 10^5T^{-1} - 4096$$

The corresponding molar heat capacity equations are:

$$\text{VC: } C_p = 9.18 + 3.30 \times 10^{-3}T - 1.95 \times 10^5T^{-2}$$

$$\text{VN: } C_p = 10.94 + 2.10 \times 10^{-3}T - 2.21 \times 10^5T^{-2}$$

## Summary

High temperature heat contents above 298.16°K. of vanadium carbide and vanadium nitride were measured from about 400° to 1611°K. A table of heat content and entropy increments above 298.16°K. is reported, and heat content and heat capacity equations are derived.

# Low-Temperature Heat Capacity and High-Temperature Heat Content of Ammonium Vanadate

BY S. S. TODD[1] AND J. P. COUGHLIN[1]

Ammonium vanadate is the commercially most readily obtainable, substantially pure, vanadium-containing substance and frequently is the source material in the preparation of other vanadium compounds. Consequently, considerable interest attaches to its properties. This paper reports the results of low temperature heat capacity measurements in the temperature range 51.4 to 298.16°K. and of high temperature heat content measurements in the temperature range 298.16 to 550°K. No previous similar data are available for this substance.

**Material.**—Ammonium vanadate of 96.7% purity was dissolved in hot concentrated hydrochloric acid until saturation, diluted by two volumes of distilled water, and filtered. The filtrate was heated to boiling, oxidized with ammonium persulfate in the presence of a small amount of nitric acid, and again filtered. The oxidized solution was neutralized with ammonium hydroxide in the presence of an excess of ammonium chloride. The precipitated ammonium vanadate was filtered off, washed several times with 1:40 ammonium hydroxide and once with distilled water, and finally dried for twenty-four hours at 75 to 80°. The product was analyzed by dissolving in 10% sulfuric acid, reducing the vanadium with sulfur dioxide, expelling excess sulfur dioxide by bubbling with a stream of carbon dioxide, and titrating with 0.1 $N$ potassium permanganate. The analysis gave 43.55% vanadium content, which is the theoretical value for ammonium vanadate.

(1) Chemist, Pacific Experiment Station, Bureau of Mines.

## Measurements and Results

Both the low temperature heat capacity and high temperature heat content measurements were made by means of previously described[2] apparatus and methods. The defined calorie (1 cal. = 4.1833 int. joules) is used throughout. All weighings were corrected to vacuum and the molecular weight of ammonium vanadate is taken as 116.99 in accordance with the 1947 International Atomic Weights. The ice point is taken as 273.16°K.

A 41.810 g. sample was employed in the low temperature heat capacity measurements. The measured results are given in Table I and are plotted against temperature in Fig. 1. The heat capacity curve is normal, there being no indication whatever of the transition encountered in similar measurements of the ammonium halides[3,4,5] and

ammonium sulfate.[6] In this respect the substance behaves similarly to both hydrated and anhydrous ammonium–aluminum sulfate.[6] (The heat capacity value at 298.16°K., included in Table I, was read from a smooth curve.)

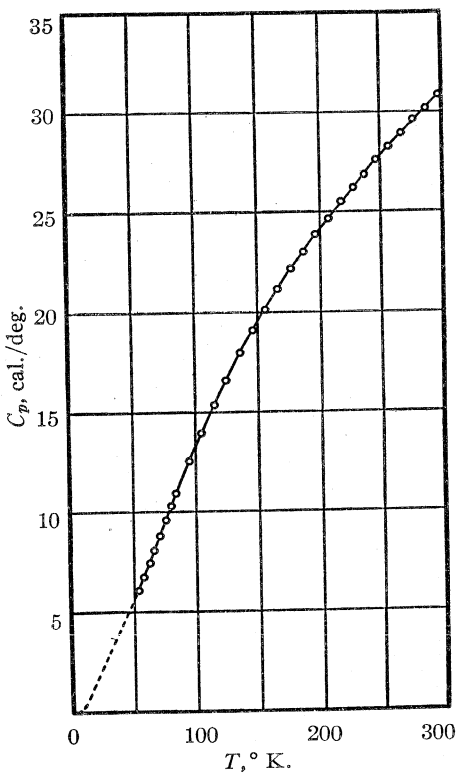

Fig. 1.—Molal heat capacity at low temperatures of ammonium vanadate.

The entropy of ammonium vanadate, obtained from these heat capacity measurements, is $S^\circ_{298.16} = 33.6 \pm 0.3$ cal./deg./mole. Of this amount, 30.00 is the measured portion between 51.00 and 298.16°K., and 3.61 is the extrapolated portion between 0 and 51.00°K. The former was obtained by numerical integration of a plot of the measured heat capacity against log $T$. The latter was obtained from the following empirical sum of Debye and Einstein functions, which represent the measured heat capacity over the entire experimental range to within 1%

$$D\left(\frac{125}{T}\right) + 3E\left(\frac{331}{T}\right) + 3E\left(\frac{919}{T}\right).$$

Combination of this entropy value and the entropies of the elements[7] leads to $\Delta S^\circ_{298.16} = -132.3$ as the entropy of formation of ammonium vanadate. Bichowsky and Rossini[8] give $\Delta H_{293.16} = -283{,}500$ cal. per mole as the heat of formation. (The correction of the latter value to 298.16°K. is negligible.) The free energy of formation from the elements is, therefore, $\Delta F^\circ_{298.16} = -244{,}050$ cal. per mole.

TABLE II

HIGH TEMPERATURE HEAT CONTENTS OF $NH_4VO_3$

| T, °K. | $H_T - H_{298.16}$, cal./mole | T, °K. | $H_T - H_{298.16}$, cal./mole | T, °K. | $H_T - H_{298.16}$, cal./mole |
|---|---|---|---|---|---|
| 351.7 | 1785 | 525.7 | 8,460 | 569.3 | (10,730) |
| 401.5 | 3625 | 554.7 | (9,795) | 576.8 | (10,920) |
| 452.8 | 5575 | 564.1 | (10,320) | 597.4 | (12,290) |
| 502.7 | 7510 | | | | |

A 4.3485-g. sample of ammonium vanadate was used in the high temperature heat content measurements. During measurement the substance

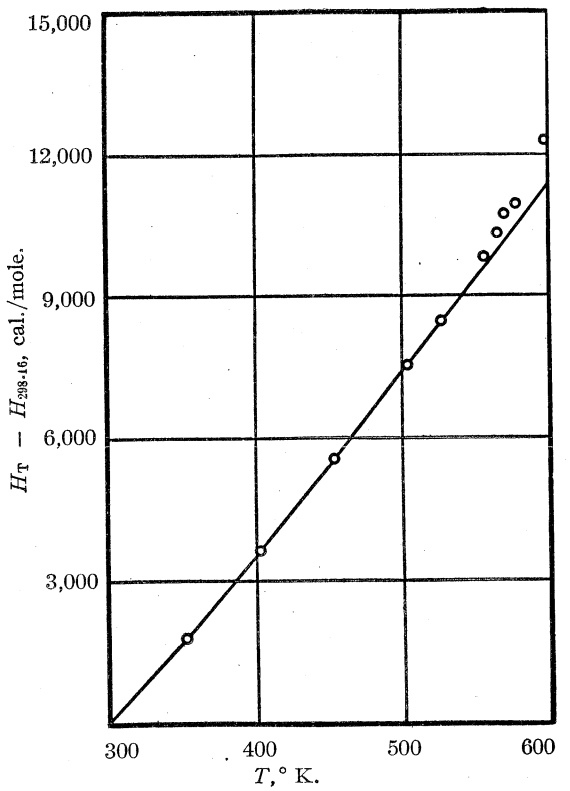

Fig. 2.—High temperature heat content of ammonium vanadate.

(7) Kelley, U. S. Bureau of Mines, Bull. 434, 1941, 115 pp.

(8) Bichowsky and Rossini, "Thermochemistry of Chemical Substances," Reinhold Publishing Corp., New York, N. Y., 1936.

was contained in a platinum–rhodium capsule which was sealed gas tight by gold soldering. The heat content of the capsule was determined by separate measurements. The experimental results are listed in Table II and are plotted in Fig. 2.

The substance behaved satisfactorily up to about 550°K. Above that temperature the results are somewhat discordant and become progressively too high. This is attributed to beginning of thermal decomposition of the substance, which is confirmed by the fact that the gas pressure within the platinum–rhodium capsule became large enough to cause rupture at 610°K. All values in parentheses in Table II show decomposition effects. Between 298.16 and 550°K., the results are represented to within an average deviation of 0.8% by the equation

$$H_T - H_{298.16} = 45.42T + 12.90 \times 10^5 T^{-1} - 17{,}869$$

The corresponding molal heat-capacity equation is

$$C_p = 45.42 - 12.90 \times 10^5 T^{-2}$$

These equations, however, should not not be employed for extrapolation to higher temperatures.

Table III gives smooth values of the high-temperature heat content and corresponding entropy increments above 298.16°K.

TABLE III

HEAT CONTENT AND ENTROPY INCREMENTS FOR AMMONIUM VANADATE ABOVE 298.16°K.

| $T$, °K. | $H^\circ_T - H^\circ_{298.16}$, cal./mole | $S^\circ_T - S^\circ_{298.16}$, cal./deg./mole |
|---|---|---|
| 350 | 1730 | 5.35 |
| 400 | 3580 | 10.29 |
| 450 | 5480 | 14.76 |
| 500 | 7420 | 18.85 |
| 550 | 9390 | 22.61 |

## Summary

The low temperature heat capacity of ammonium vanadate was measured throughout the temperature range 51.4 to 298.16°K. The entropy is $S^\circ_{298.16} = 33.6 \pm 0.3$ cal./deg./mole.

The high temperature heat content of ammonium vanadate was measured throughout the temperature range 298.16 to 550°K. Thermal decomposition precluded obtaining satisfactory results at higher temperatures. Heat content and entropy increments above 298.16°K. are tabulated.

# Thermodynamic Data on the Cadmium Chloride Complexes Determined from the Solubility of Cadmium Ferricyanide

BY EDWARD L. KING[1]

In this paper data on the solubility of cadmium ferricyanide in solutions containing chloride ion will be presented. It is possible to interpret these data in terms of the formation of the cadmium chloride complexes: $CdCl^+$, $CdCl_2$ and $CdCl_3^-$. These complexes have been studied previously by I. Leden[2] and others.[3] The solubility measurements have been carried out at several temperatures making it possible to calculate heats of formation and entropies of the several complex species as well as the several equilibrium constants.

## Experimental Work

**Preparation of Solutions Used in These Experiments.**—All solutions were prepared using doubly distilled water, the second distillation being from an alkaline permanganate solution. Analytical reagent grade chemicals were used in all cases without further purification. In the preparation of the sodium perchlorate solution, equivalent amounts of perchloric acid and sodium carbonate were mixed.

**Preparation of the Cadmium Ferricyanide.**—The solid used in the solubility measurements was prepared by precipitating cadmium ferricyanide at room temperature from a freshly prepared dilute solution of potassium ferricyanide by the addition of cadmium nitrate solution. The solid separates as a very finely divided yellow material. Analyses of the material used in the solubility measurements as well as several other samples of solid precipitated in the presence of a low (less than 0.1 *M*) excess of potassium ferricyanide or in the presence of an excess of cadmium nitrate were performed. The solid was decomposed by heating with concentrated sulfuric acid. The iron and cadmium were then separated by isopropyl ether extraction of iron as described by Swift.[4] The iron was analyzed iodometrically[5] and cadmium was determined gravimetically by conversion to the sulfate. The ratio of cadmium to iron in the five different samples analyzed ranged from 1.47 to 1.52 with an average of 1.49. Thus the finely divided yellow solid is $Cd_3\{Fe(CN)_6\}_2 \cdot xH_2O$. The degree of hydration of the solid was not determined as in no case was the solid dried and weighed; only the ratio of cadmium to iron was determined.

**Solubility Measurements.**—Before using the $Cd_3\{Fe(CN)_6\}_2 \cdot xH_2O$ in a solubility determination, it was washed several times with a dilute solution of sodium perchlorate. Then each portion was washed with a solution of the composition to be used in the solubility experiment. The solubility equilibrium is established very rapidly; in no experiment was a slowness detected even though in the experiments at 47.5° samples were removed after two minutes stirring. In several experiments equilibrium was approached from the supersaturated side as well as from the other side. Because of the high rate of solution, it was possible to carry out the measurements in open vessels; no errors due to evaporation would be expected. The

solid was stirred with the solution in 40 ml. test-tubes with a mechanical stirrer in a thermostat. At two or three different times, aliquots of solution and suspended solid were removed, delivered into a centrifuge cone and centrifuged to remove the suspended solid, which otherwise settled exceedingly slowly upon standing. By using 15 ml. centrifuge cones which were centered in the cups for 50-ml. cones by use of a rubber stopper with the appropriate sized hole, it was possible to jacket the cone with the thermostat media. Only in the case of the experiments at 47.5° was real trouble experienced during centrifugation in keeping the solution at the approximate temperature of the experiment. In these experiments at 47.5°, hot air was blown into the centrifuge (International Clinical model) through the small hole in the lid. Even with this device, the solution temperature would drop several degrees during the centrifugation. Because the saturated solution at 47.5° will be supersaturated at room temperature, a measured aliquot of the solution from the centrifugation was diluted for analysis.

The concentration of dissolved cadmium ferricyanide was determined by measurement of the ferricyanide concentration by means of light absorption. The absorption at several wave lengths in the region 4200 to 4600 Å. was determined with a Beckman Quartz Spectrophotometer. This proved to be a convenient method of analysis at the concentrations under consideration.

## Experimental Results and Discussion

In practically all experiments two or three portions of saturated solution were removed at various times. The average variation in the concentrations in the successive aliquots in a given experiment was 1.7% for the experiments at 0.0° and 25.0°, while in the experiments at 47.5° it was 3%. The greater variation in the experiments at 47.5° is due no doubt to the temperature variations during centrifuging. The results of the solubility experiments are presented in Table I and also in Fig. 1.

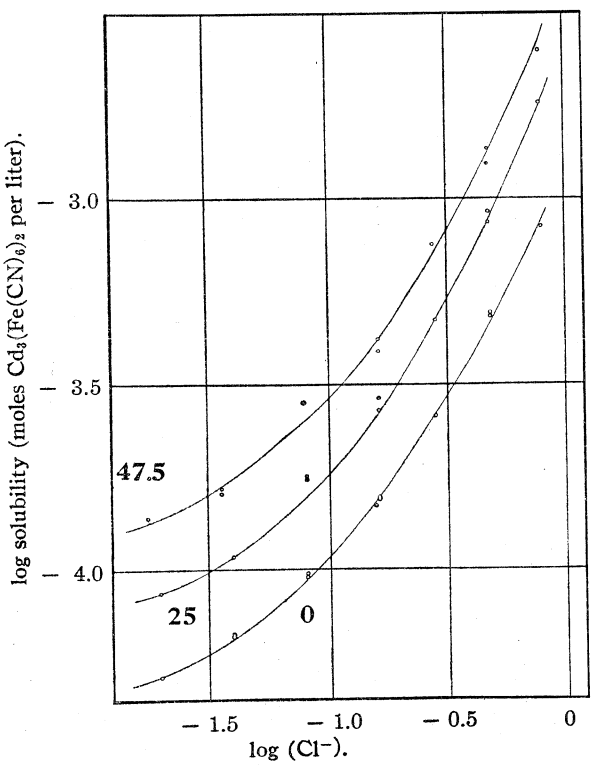

Fig. 1.—Solubility of $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$ in solutions containing chloride ion at 0, 25 and 47.5°.

**The Equilibria which are Consistent with Solubility Data.**—The equations for the net reactions occurring when $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$ dissolves in a solution containing chloride ion are

$$1/3Cd_3(Fe(CN)_6)_2 \cdot xH_2O + nCl^- = CdCl_n^{+2-n} + 2/3Fe(CN)_6^{=} + x/3H_2O \quad (1)$$

$n = 0, 1, 2, 3$

The equilibrium constants for these reactions are

$$K_n = (CdCl_n^{+2-n})(Fe(CN)_6^{=})^{2/3}/(Cl^-)^n$$

The equilibrium constants for the reactions of cadmium ion to form the several complex species

$$Cd^{++} + nCl^- = CdCl_n^{+2-n} \quad (2)$$

[a] In this experiment $(H^+) = 0.15$ $M$, $(Na^+) = 2.85$ $M$. [b] In all experiments at 47.5° $(H^+) = 0.02$ $M$, $(Na^+) = 2.98$ $M$. [c] When two figures are given they are the results of two independent experiments.

are related to the $K$'s for the solubility reactions in the following manner

$$\beta_n = \frac{(CdCl_n^{+2-n})}{(Cd^{++})(Cl^-)^n} = \frac{K_n}{K_0}$$

It is seen that $K_0$ is the cube root of the solubility product constant for $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$.

The solubility experiments were all carried out at constant ionic strength made up of sodium ion, hydrogen ion, perchlorate ion and chloride ion. In the solutions in which the solid is most soluble, the increased ionic strength due to the ferricyanide ion and the various complexes is of the order of one per cent. of the total. The approximation has been made that the activity coefficients of the various species are not affected at constant ionic strength when the medium is varied from 3.0 $M$ $ClO_4^-$ to 2.20 $M$ $ClO_4^-$, 0.80 $M$ $Cl^-$. Thus the equilibrium constants presented will all be concentration equilibrium constants for a solution of ionic strength of 3.00.

**The Value of $K_0$, the Cube Root of the Solubility Product Constant for $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$.**—The values of $K_0$ at the several tempera-

tures can be determined from the results of single experiments at each temperature. This is the measurement of the solubility in the absence of chloride ion. It is seen that $K_0 = S^{5/3} \times 3 \times (2)^{2/3} = 4.76\ S^{5/3}$ where $S$ is the solubility of $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$. Using the values of the solubility of $3.85 \times 10^{-5}$, $6.65 \times 10^{-5}$ and $9.7 \times 10^{-5}$ mole per liter, values of $K_0$ calculated are $2.1 \times 10^{-7}$, $5.2 \times 10^{-7}$ and $9.7 \times 10^{-7}$ at 0°, 25° and 47.5°, respectively.

In the interpretation of the data on the solubility in the presence of chloride ion it is necessary to know that at the concentration of ferricyanide present, no soluble cadmium ferricyanide complexes exist. This was checked in a simple experiment. A solution of $9.1 \times 10^{-4}$ *M* cadmium nitrate in 2.69 *M* sodium perchlorate–0.04 *M* perchloric acid was added with rapid stirring to a solution of the composition: $3.8 \times 10^{-3}$ *M* potassium ferricyanide, 2.96 *M* sodium perchlorate and 0.04 *M* perchloric acid. At a point in the addition of the cadmium solution when the concentration of cadmium was less than $6 \times 10^{-5}$ *M*, precipitation had already occurred. This leads to an upper limit of $K_0$ of $1.4 \times 10^{-6}$ at 25°. This is 2.7-fold higher than calculated from the solubility of the pure salt but would still lead to the result that no more than one per cent. of the cadmium (II) dissolved in a solution of 0.80 *M* chloride ion is present as a ferricyanide complex.

From the values of the equilibrium constants at the three temperatures, it is possible to calculate the heat of solution of $Cd_3\{Fe(CN)_6\}_2 \cdot xH_2O$ in a solution of ionic strength 3.0. When log $K_0$ is plotted *vs.* $1/T$, an approximately straight line results with a slope which corresponds to a $\Delta H$ of solution of 17.2 ± 0.7 kcal. per formula weight of $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$.

**The Dependence of the Solubility upon Hydrogen Ion Concentration.**—In eq. (1) for the net reaction which occurs when cadmium ferricyanide dissolves in a solution containing chloride ion, neither the cadmium chloride complex ion nor ferricyanide ion are shown with attached hydrogen ion. One would expect $CdCl_nH^{+3-n}$ to be a strong acid since hydrochloric acid is strong and the presence of the metal ion would cause an acid strengthening. Kolthoff and Tomsicek[6] have presented data which indicate that ferricyanide ion exists as such at hydrogen ion concentrations as high as $6 \times 10^{-3}$ *M*. In one of the solubility measurements run at 0°, the hydrogen ion concentration was 0.15 *M* instead of 0.04 *M* (see Table I and Fig. 1). It is seen that this experimental point is on the same smooth curve as are the other data. If the species of ferricyanide present in a solution of this hydrogen ion concentration range were $HFe(CN)_6^{=}$, a 3.7-fold change in hydrogen ion concentration would give rise to a change in solubility by a factor of 1.7. Therefore, these data indicate that at a hydrogen ion concentration as high as 0.15 *M*, ferricyanide exists as $Fe(CN)_6^{=}$.

**The Values of the Several Equilibrium Constants.**—It is possible to calculate the various equilibrium constants by a variety of methods. The method which best uses all of the data in the chloride ion concentration range in which the appropriate constant is most relevant is the method of Leden[2] and Connick.[7] A few obvious modifications of the method of Leden make it suitable for the treatment of these solubility data.

It was found necessary to assume the presence in solution of the species $Cd^{++}$, $CdCl^+$, $CdCl_2$ and $CdCl_3^-$ in order to explain the solubility data. It was not necessary to assume the presence of $CdCl_4^{=}$. The values of $K_n$, the equilibrium constants for reactions (1), are given in Table II. The curves in Fig. 1 are calculated using these equilibrium constants and the solubility product constants discussed earlier. Included in Table II are the values of $K_n$ at 25° calculated from Leden's values[2] of $\beta_n$ and the value of $K_0 = 5.2 \times 10^{-7}$.

TABLE II

EQUILIBRIUM CONSTANTS FOR REACTIONS

$$1/3\ Cd_3\{Fe(CN)_6\}_2 \cdot x\ H_2O + n\ Cl^- = CdCl_n^{+2-n} + 2/3\ Fe(CN)_6^{=} + x/3\ H_2O$$

| Temperature, °C. | $K_1 \times 10^5$ | $K_2 \times 10^5$ | $K_3 \times 10^5$ |
|---|---|---|---|
| 0.0 | 0.57 ± 0.04 | 3.7 ± 0.3 | 1.6 ± 0.3 |
| 25.0 (this work) | 1.3 ± 0.15 | 8.0 ± 1 | 13 ± 3.0 |
| (Leden) | 2.0 | 8.8 | 13.5 |
| 47.5 | 3.5 ± 0.5 | 13.0 ± 3.0 | 28 ± 4 |

It should be noted that in the case of the bromide and iodide complexes of cadmium, complexes which involve four halide ions are observed.[2] The chloride complexes appear to be less stable to an extent such that at 0.8 *M* $Cl^-$, the species $CdCl_4^{=}$ is not present at appreciable concentrations.

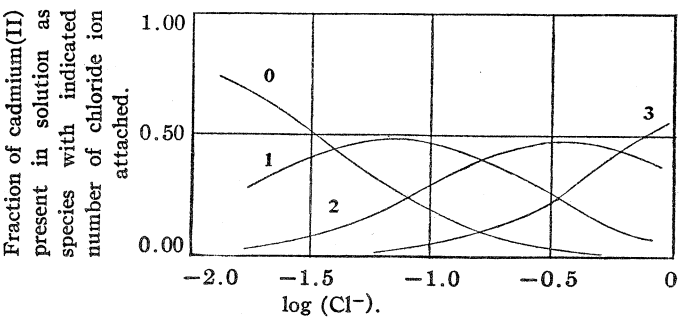

Fig. 2.—Distribution of cadmium (II) among the various complex species at 25°.

The overlapping of the chloride ion concentration ranges in which the various complexes are most important is clearly shown in Fig. 2. In systems where such an overlapping occurs, it is possible to fit the experimental data, unless they

(6) Kolthoff and Tomsicek, *J. Phys. Chem.*, **39**, 955 (1935).

(7) R. E. Connick, private communication.

are exceedingly accurate, with an appreciable range of values for each equilibrium constant. This accounts for the rather large uncertainty shown in values in Table II.

**The Heats of Formation and Entropies of the Several Complexes.**—It is possible to obtain heats of formation of the complex species $CdCl^+$, $CdCl_2$ and $CdCl_3^-$ from the ions $Cd^{++}$ and $Cl^-$ by considering the values of $\beta_n$ as a function of temperature. These data are plotted in Fig. 3. The vertical lines in this figure indicate the ranges of values of $\beta_1$, $\beta_2$ and $\beta_3$ which are consistent with the experimental inaccuracies. Heats of reaction (2) at 25° have been calculated from the slope of these curves. These values are given in the first column of Table III. It is seen that all of the complexes except $CdCl_2$ are formed endothermically. Their stability is due to the entropy increase which occurs upon their formation. Unlike association reactions in the gas phase which are associated with a decrease in entropy, these association reactions of ions in solution are accompanied by an increase in entropy. This is due to the greater freedom of motion of the solvent molecules in the field of the complex compared to their freedom in the field of the several reacting ionic species.

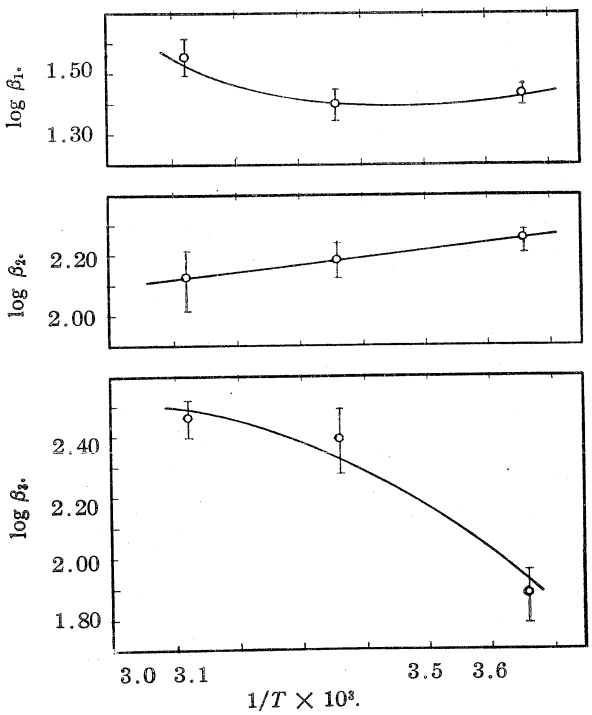

Fig. 3.—Values of $\beta_n$ at various temperatures.

The entropies of the several complex species can be calculated from the $\Delta S$ of the reactions for their formation and the known entropies of cadmium and chloride ions. The entropies of these two ions are given by Latimer, Pitzer and Smith[8] as $-16.4$ for $Cd^{++}$ and $+13.5$ for $Cl^-$. The results of these calculations are given in the last column of Table III. In these calculations the entropies used are for the hypothetical one molal solution while the entropy change is for a hypothetical one molal solution in which the ionic strength is 3.0. The use of the two sets of quantities without correction to the same standard state is the best one can do in view of lack of data regarding the effect of ionic strength changes on the entropy.

TABLE III

VALUES OF HEAT, FREE ENERGY AND ENTROPY CHANGES FOR THE REACTIONS: $Cd^{++} + nCl^- = CdCl_n^{+2-n}$

| Reaction for the formation of | $\Delta H/T$, cal./mole deg. | $-\Delta F/T$, cal./mole deg. | $\Delta S$ cal./mole deg. | $S$ complex |
|---|---|---|---|---|
| $CdCl^+$ | 2.1 | 6.4 | 8.5 | 5.6 |
| $CdCl_2$ | −3.7 | 10.1 | 6.4 | 17.0 |
| $CdCl_3^-$ | 15.5 | 11.0 | 26.5 | 50.7 |

The entropy of the species $CdCl_3^-$ is quite large. That it is probably larger than one would expect is realized if the entropy change for the reaction

$$CdCl_2 + Cl^- = CdCl_3^-$$

is considered. This entropy change is +20.2 entropy units. If the entropy change arises largely from the change in the polarization of water by ionic charges, it might be expected to be small. However Frank and Evans[9] have pointed out that other factors play an important role in determining entropies of dissolved species.

It is very desirable to have more data on the entropies of complex ions in solution such that correlations could be made.

## Summary

The solubility of $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$ has been determined in aqueous solution containing various concentrations of chloride ion at 0.0°, 25.0° and 47.5°. These data have been interpreted on the basis of there being present in solution the species: $Cd^{++}$, $CdCl^+$, $CdCl_2$ and $CdCl_3^-$. The complex species $CdCl_4^{=}$ is not appreciably stable in solutions in which the chloride ion concentration is 0.8 $M$.

The $\Delta H$ of solution of $Cd_3(Fe(CN)_6)_2 \cdot xH_2O$ has been found to be 17.2 ± 0.7 kcal. per formula weight.

The heats and entropies of formation of the several complex species have been calculated by considering the variation of the various equilibrium constants with temperature.

# The Hydrogenation of Sodium Bicarbonate to Sodium Formate

BY LESTER G. LUNDSTED

The hydrogenation of an aqueous solution of potassium bicarbonate to potassium formate in 70% yield over a palladium-black catalyst by Bredig and Carter[1] suggested the probability that a similar reaction could be carried out with the cheaper sodium bicarbonate over some of the more recently developed hydrogenation catalysts.

In order to select a suitable catalyst for this study, thirteen catalysts were tested in a preliminary way by attempting to hydrogenate a 5% aqueous solution of sodium bicarbonate. Under the conditions chosen, ten catalysts showed some activity for the reaction while three, copper chromium oxide and manganese and iron chromites, displayed no activity. In Table I will be found a list of the catalysts tested, the conditions used and the percentage of sodium formate found in the products based on the starting sodium bicarbonate. The percentages of sodium formate given are not necessarily the maximum obtainable over individual catalysts since optimum conditions were not determined. This was shown by two experiments with the Universal Oil Products Hydrogenation Catalyst in which the sodium formate in the products was increased from 24 to 75% by an increase in reaction time from two and one-half to eight and one-half hours.

TABLE I

PRELIMINARY TESTS OF CATALYSTS FOR THE HYDROGENATION OF SODIUM BICARBONATE[a]

| Catalyst | Time, hr. | Sodium formate, % |
|---|---|---|
| U. O. P. hydrogenation catalyst | 2.5 | 24.2 |
| Nickel chromite | 1.0 | 45.5 |
| Copper and nickel | 5.0 | 63.5 |
| Zinc chromite | 6.0 | 14.0 |
| Nickel on kieselguhr | 4.0 | 16.0 |
| Copper chromium oxide | 5.0 | 0.0 |
| Raney nickel | 6.0 | 49.0 |
| Ruffert nickel pellets | 5.0 | 64.6 |
| Ruffert nickel | 6.0 | 77.0 |
| Nickel (from $Ni(OOCH)_2$) | 1.0 | 16.0 |
| Boron phosphate on charcoal | 3.0 | 9.1 |
| Iron chromite | 6.0 | 0.0 |
| Manganese chromite | 1.3 | 0.0 |

[a] The tests were carried out under 1800 p. s. i. g. initial hydrogen pressure at a temperature of 200° using 4 g. of catalyst and 600 ml. of a 5% aqueous sodium bicarbonate solution.

The effect of variations in the reaction conditions on the percentage of sodium formate found in the products is shown in Table II for a series of studies with the Ruffert nickel catalyst in a wax support. Over the ranges studied an increase in either the quantity of catalyst or the hydrogen pressure increased the rate of hydrogenation as shown by the higher percentages of sodium formate in the products at the end of one hour. Longer reaction times increased the percentage of sodium formate found in the products when other conditions were such as to favor a low rate of reaction since under such conditions side reactions appeared to be at a minimum. Increasing the concentration of the sodium bicarbonate solution lowered the percentage of sodium formate in the products, although the actual quantity of sodium bicarbonate hydrogenated was greater. In such cases, an increased period of reaction served to raise the percentage of sodium formate in the products. An increase in the reaction temperature increased the rate of the reaction, but when the temperature became too high, side reactions increased to an extent which left little sodium formate in the product.

TABLE II

EFFECT OF VARIABLES ON THE HYDROGENATION OF SODIUM BICARBONATE OVER RUFFERT NICKEL CATALYST

| Expt. | Variable | Catalyst, g. | Conc. of solution.,[1] % | Temp., °C. | Pressure | Time, hr. | Sodium formate, % |
|---|---|---|---|---|---|---|---|
| 58 | Catalyst | 2 | 5 | 200 | 2000 | 1 | 52 |
| 42 | concn. | 4 | 5 | 200 | 2200 | 1 | 67 |
| 44 | | 6 | 5 | 200 | 1700 | 1 | 72 |
| 58 | Time | 2 | 5 | 200 | 2000 | 1 | 52 |
| 55 | | 2 | 5 | 200 | 2000 | 2 | 69 |
| 61 | | 2 | 5 | 200 | 2000 | 3 | 70 |
| 63 | Pres. | 2 | 5 | 200 | 850 | 1 | 42 |
| 58 | | 2 | 5 | 200 | 2000 | 1 | 52 |
| 56 | | 2 | 5 | 200 | 3000 | 1 | 74 |
| 57 | | 4 | 5 | 200 | 1000 | 1 | 47 |
| 42 | | 4 | 5 | 200 | 2200 | 1 | 67 |
| 54 | | 4 | 5 | 200 | 2800 | 1 | 78 |
| 59 | Temp. | 4 | 5 | 150 | 2000 | 1 | 14 |
| 42 | | 4 | 5 | 200 | 2000 | 1 | 67 |
| 43 | | 6 | 5 | 200 | 2000 | 1 | 71 |
| | | 6 | 5 | 250 | 2000 | 1 | 10 |
| 67 | | 8 | 5 | 150 | 2000 | 1 | 16 |
| 64 | | 8 | 5 | 200 | 2000 | 1 | 58 |
| 42 | Soln. | 4 | 5 | 200 | 2000 | 1 | 67 |
| 62 | concn. | 4 | 16⅔ | 200 | 2000 | 1 | 54 |
| 66 | | 4 | 16⅔ | 200 | 2000 | 2 | 62 |

Similar results can also be expected over other catalysts although the allowable variation in reaction conditions and the magnitude of the effect on the percentage of sodium formate in the product will differ from one catalyst to another.

## Experimental

**Materials Used.**—The sodium bicarbonate used was a U. S. P. grade manufactured by Wyandotte Chemicals Corporation.

(1) Bredig and Carter, *Ber.*, **47**, 541 (1914).

**Catalysts Preparation.**—The U. O. P. hydrogenation catalyst was obtained from Universal Oil Products Company, Riverside, Illinois. Raney nickel was purchased as an aqueous suspension from the Gilman Paint and Varnish Company, Chattanooga, Tennessee. The Ruffert nickel pellets and nickel catalyst supported in wax were obtained from The Ruffert Chemical Division of the Seymour Manufacturing Company.

Copper chromium oxide,[2] nickel on kieselguhr,[3] nickel chromite[4] and zinc chromite[5] were prepared and used according to standard methods. Iron chromite and manganese chromite were prepared according to the method used for zinc chromite.

The boron phosphate on charcoal catalyst was prepared by mixing 58 g. of phosphoric acid (85%) and 30.9 g. of boric acid in 100 ml. of distilled water with vigorous stirring and heating at 85° for one hour. The mixture was evaporated to dryness with constant stirring on a hot-plate, the residue taken up in 200 ml. of distilled water and heated to boiling until a homogeneous suspension was obtained.

Fifteen grams of Darco activated charcoal were added with vigorous stirring and the suspension evaporated to dryness. The resulting cake was dried at 120° for twelve hours and then ground up for use.

The nickel–copper catalyst was prepared by dissolving 145.3 g. of nickel nitrate hexahydrate and 120.8 g. of cupric nitrate trihydrate in 1500 ml. of distilled water at 85°. One hundred seventy ml. of ammonium hydroxide, diluted with two parts of water, were added with vigorous mechanical stirring over a period of ten minutes while the temperature was maintained at 80–85°. Stirring and heating were continued fifteen minutes after which the suspension was filtered on a Büchner funnel. The residue was washed three times by alternate suspension in hot water and filtration. After the last filtration the residue was sucked as dry as possible on the filter and then dried in an oven at 110° for three days. Before use the catalyst was reduced in a slow hydrogen stream at 450° for forty-five minutes.

Nickel formate was obtained from the Harshaw Chemical Company, Cleveland, Ohio. Before use, it was reduced at 350° in a slow hydrogen stream for one hour and then transferred directly to the reactor.

**Method of Reaction.**—The hydrogenations were carried out in a rocking bomb of 1200 ml. void according to the method of Adkins.[6] The reaction product was washed from the bomb with distilled water, made up to a known volume and aliquots analyzed for sodium formate by the method of Blackadder.[7] Additional aliquots were acidified and used for the determination of Duclaux constants to demonstrate the presence of formic acid in the acidified product.

## Summary

Sodium bicarbonate, in aqueous solution, has been converted to sodium formate by hydrogenation over ten different catalyst. Nickel-containing catalysts appear to be the most effective type among those tested. Catalyst concentration, hydrogen pressure, reaction temperature, reaction time and solution concentration have been shown to effect the conversion of sodium carbonate to sodium formate over a nickel catalyst.

# The Thermal Dimerization of Acrylonitrile[1]

BY EUGENE C. COYNER[2a] AND WILLIAM S. HILLMAN[2b]

Various carbonylenic compounds, such as acrolein and methyl vinyl ketone, have been found by Alder and co-workers[3] to undergo thermal dimerization to give up to 55 per cent. yields of dihydropyran derivatives of the type represented by structure I.

R = H or $CH_3$ I

The present work was initiated with a view to carrying out this type of reaction with a nitrogen-containing analog, acrylonitrile, which it was thought, might correspondingly give a dihydropyridine derivative. However, under the optimum conditions found for the thermal dimerization of acrylonitrile, the only dimeric products isolated were not heterocyclic in nature, but were found to be *cis*- and *trans*-1,2-dicyanocyclobutane. Both products, upon hydrolysis, gave *trans*-1,2-cyclobutanedicarboxylic acid, whose structure was established by conversion to the known dihydrazide and by its resolution into the *d* and *l* forms.

(1) Abstracted from a thesis by William S. Hillman submitted in partial fulfillment of the requirements for the M.S. degree.

(2) (a) Present address: Mallinckrodt Chemical Works, St. Louis, Mo. (b) Present address: Organic Chemicals Department, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

(3) Alder, Offermanns and Rueden, *Ber.*, **74B**, 905 (1941); Alder and Rueden, *ibid.*, 920.

## Experimental

**1,2-Dicyanocyclobutane.**—All runs were carried out in an externally heated steel bomb of 250 cc. capacity under autogenous pressures (20–130 atmospheres). About 0.1 g. of hydroquinone was added to inhibit chain polymerization. Representative reaction conditions and the yields of acrylonitrile dimer obtained are given in Table I.

TABLE I

DIMERIZATION OF ACRYLONITRILE

| | | | | | | |
|---|---|---|---|---|---|---|
| Acrylonitrile | 53[a] g. | 53 g. | 53 g. | 100 cc. | 100 cc. | 100 cc. |
| Benzene, cc. | 100 | 100 | 100 | | | |
| Temp., °C. | 245–250 | 275–280 | 295–304 | 195–200 | 200–210 | 245–265 |
| Time, hours | 7.5 | 2.0 | 0.5 | 24 | 3.5 | 0.8 |
| Dimer, g. | 1.5 | 2.6 | 2.4 | 5.5 | 1.2 | 2.8 |

[a] A glass liner was used.

No significant differences in results were observed whether or not benzene was added or a glass liner was used. The dimerization reaction became excessively slow below 190°, and decomposition which produced carbonaceous residues occurred extensively above 300°.

After the heating cycle was completed, the reaction mixtures, which usually possessed a strong ammoniacal odor, were fractionally distilled. Unreacted acrylonitrile and the solvent, if any, were distilled at atmospheric pressure, and the residue was then distilled *in vacuo* through a 16 in. Vigreux-type column. The product was obtained in three colorless fractions of approximately the same weight.

TABLE II

FRACTIONS OF 1,2-DICYANOCYCLOBUTANE

[a] Determined ebullioscopically in benzene. [b] By difference.

It is probable that fractions 1 and 3 are the relatively pure *cis* and *trans* forms and that fraction 2 is a mixture of the two. All three fractions failed to react with bromine in carbon tetrachloride.

***trans*-1,2-Cyclobutanedicarboxylic Acid.**—Fractions 1,2 and 3 (see Table II) gave nearly identical yields (*ca.* 70–80%) of *trans*-1,2-cyclobutanedicarboxylic acid, m.p. 129–130°,[4] upon hydrolysis in excess alcoholic potassium hydroxide or in 10% hydrochloric acid.

A typical alkaline hydrolysis was carried out as follows: To a solution of 10 g. of potassium hydroxide dissolved in 80 cc. of 70% ethyl alcohol was added 6 g. of fraction 1 of the dinitrile, m.p. < 0°. A bright blue color developed immediately which turned dark green in a few seconds and after a few minutes disappeared, leaving a colorless solution which was heated under reflux for twenty-four hours under a slow stream of nitrogen. The alcohol was then removed by distillation. The residue was made acidic with hydrochloric acid and was extracted with three 100 cc. portions of ether. Upon evaporation of the ether, a viscous liquid was obtained which solidified on cooling to give 5 g. (73%) of crude acid, m.p. 120–125°. After one recrystallization from concentrated hydrochloric acid it melted at 129–130°.

A typical hydrolysis with hydrochloric acid was carried out as follows: Five grams of dinitrile, fraction 2, m.p. 27°, was boiled under reflux with 100 cc. of 10% hydrochloric acid. The reaction mixture was extracted with ether and the ether was removed by evaporation. The yield of acid, m.p. 123–127°, was 5.6 g. (82%). After one recrystallization from concentrated hydrochloric acid it melted at 129–130°.

The isolation of only the *trans* isomer is not to be unexpected, since this acid is the more stable. Thus, if *cis*-1,2-cyclobutanedicarboxylic acid is heated in concentrated hydrochloric acid it is converted into the *trans* isomer.[4] The *cis* dinitrile should be even more susceptible to isomerization.

*Anal.* Calcd. for $C_6H_8O_4$: C, 49.99; H, 5.60; neutral equivalent, 72. Found: C, 49.88; H, 5.55; neutral equivalent, 74.

The corresponding dihydrazide, *trans*-1,2-cyclobutanedicarboxdihydrazide, m.p. 219–220°, was prepared by the method of Buchman, *et al.*[5]

*Anal.* Calcd. for $C_6H_{12}O_2N_4$: C, 41.85; H, 7.02; N, 32.53. Found: C, 41.90; H, 7.07; N, 32.19.

**Resolution of *trans*-1,2-Cyclobutanedicarboxylic Acid.**—The resolution was carried out by the procedure of Goldsworthy,[6] but, by employing a simple modification, a purer sample of the *l* isomer was obtained. To a solution of 7 g. of quinine in 25 cc. of ethyl alcohol was added a solution of 3 g. of *d,l-trans*-1,2-cyclobutanedicarboxylic acid in 200 cc. of water. The alcohol was then evaporated by boiling the mixture for forty-five minutes and the total volume was made up to 650 cc. with boiling water. The solution was cooled to 35° and the precipitated impure *l*-salt was removed by filtration. It was redissolved in hot water and allowed to crystallize at room temperature. The purified *l*-salt was removed by filtration and dried in air; it weighed 4 g. It was dissolved in 200 cc. of water and made alkaline with ammonium hydroxide. The solution was cooled to 0° and the quinine was removed by filtration. The filtrate was made acid with hydrochloric acid and extracted with ether. The ether extract was evaporated to dryness, leaving 0.5 g. of impure *l-trans*-cyclobutane-1,2-dicarboxylic acid which, after one recrystallization from benzene, melted at 114–117°. The specific rotation was −150° at 28° in water. This is a higher specific rotation than that reported by Goldsworthy[6] (−124.3° at 30°), and thus represents a more complete resolution.

The mother liquor from the initial crystallization was concentrated to one-third of the original volume and the *d*-acid, in less pure condition, was separated as outlined above for the *l*-form. The melting point was 115–117° and the specific rotation at 28° was found to be +104°.

## Discussion of Mechanism

Although the type of product obtained upon the thermal dimerization of acrylonitrile is quite different from the heterocyclic compounds obtained by Alder, *et al.*,[3] from oxygen analogs, such as acrolein, it is probable that the mechanisms of the reactions involved are quite similar, as illustrated below:

According to Hurd,[7] the primary effect of heat

(6) Goldsworthy, *J. Chem. Soc.*, **125**, 2012–2013 (1924).

(7) Hurd, *Ind. Eng. Chem.*, **26**, 54 (1934).

upon the C=C of an olefin is the rupture of one bond giving rise to a divalent radical C—C. In the examples given above this process is represented by step 1. The splitting of one electron pair of the double bond is doubtless facilitated in the compounds illustrated by resonance involving one of the unpaired electrons (process 2).

The establishment of a covalent bond between β-carbon atoms, as represented in step 3, is to be expected for two reasons. First, the most reactive center in the activated molecule (the di-radical) is the β-carbon atom, since the resonance involving the odd electron associated with the α-carbon atom and the oxygen atom in acrolein or the nitrogen atom in acrylonitrile (process 2) should make any reaction involving that electron less likely. Second, the new di-radicals thus formed can exist in four resonating forms, as partially illustrated by process 4, and hence are stabilized to some extent, whereas, if the initial union were between α-carbon atoms, no such resonance could occur. Similar considerations have been advanced by Koelsch and Boekelheide[8] to account for the orientations observed in the coupling of aryl radicals with α,β-unsaturated compounds.

The final phase of the reaction (step 5) is a cyclization process. In the case of acrolein a relatively stable six-membered heterocyclic ring is formed. With acrylonitrile, however, the distribution of the odd electrons which would be required for the formation of a six-membered ring produces the linear configuration C=C=N, and the resulting distance between the atoms bearing the odd electrons is too great for electron pairing bond formation. The final electron pairing reaction therefore takes place between the two α-carbon atoms.

(8) Koelsch and Boekelheide, This Journal, **66**, 413 (1944).

## Summary

1. Acrylonitrile has been thermally dimerized to give low yields of 1,2-dicyanocyclobutane.

2. It is proposed that this reaction occurs by an electron pairing mechanism.

3. A similar mechanism is advanced for the thermal dimerization of acrolein and related carbonylenic compounds.

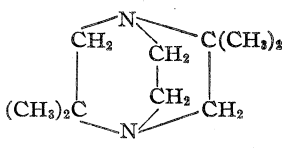
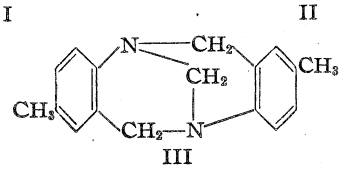
[Contribution from the Laboratory of Organic Chemistry of the University of Wisconsin]



# 2,2,5,5-Tetramethylpiperazine and Derivatives

By S. M. McElvain and Everett H. Pryde[1]



The preparation of 2,2,5,5-tetramethylpiperazine (I) was undertaken in the hope that by bridging its nitrogens with an ethylene radical the bicyclic structure (II), which contains asymmetric nitrogen atoms comparable in structure to those of Troeger's base (III), might be obtained and resolved into its optical antipodes. The resolution of III[2] is the only recorded successful separation of a *dl*-mixture into its component optical isomers, the asymmetry of which is due to trivalent nitrogen atoms. Although the synthesis of II has not been achieved and further work in this direction is in progress in this Laboratory, the preparation of I and the properties of certain of its derivatives seem of sufficient interest to report at this time.

I

II

III

The preparation of the dihydrochloride[3] and the N,N'-dinitroso derivative[4] of I in low yields have been reported, but none of these procedures appeared adaptable to the production of substantial quantities of I. For this reason it seemed that 2,2,5,5 - tetramethyl - 3,6 - diketopiperazine (IV), if it could be obtained readily, offered a better approach to I.

The preparation of the diketopiperazine (IV) in 34% yield by heating methyl α-aminoisobutyrate[5] and in 23% yield from the ethyl ester[6] have been reported; however the requisite methyl ester was obtained in yields that left much to be desired.[5] The preparation of IV from N-(α-aminoisobutyryl)-α-aminoisobutyric acid also has been reported.[7] The ester approach[5] to IV was investigated in the present work and, although a method of preparation of methyl α-aminoisobutyrate in good yield was developed, the product resulting from heating this ester contained only about 3% of

IV; the major reaction product was α-aminoisobutyric acid.

Recently Sannié[8] reported the preparation of certain diketopiperazines in 60–70% yields by heating α-amino acids in ethylene glycol; however, he found that such amino acids as α-aminoisobutyric acid, in which the amino group is on a tertiary carbon, gave negative results. In the present work it was found that the latter amino acid could be made to undergo this cyclization in the higher boiling diethylene glycol, and a procedure has been developed for the preparation of IV in 40% yield.

The reduction of certain diketopiperazines to the corresponding piperazines in low yields (15–17%) by sodium in amyl alcohol has been effected[9]; however, much higher yields (57–86%) of pyridines and pyrrolidines have been obtained from the reduction of 2-piperidones and 2-pyrrolidones with sodium in butyl alcohol, using a 10:1 ratio of sodium to reductant.[10] Following the latter procedure yields of 24% of I and 40% of half reduced product V were obtained from IV in the present work. The yield of I was improved somewhat by the use of higher ratios of sodium to IV, but with such ratios the manipulation of the reaction mixtures became more difficult. The hydrogenation of IV to I over a copper–chromium oxide catalyst was much more successful. In spite of the insolubility of IV in all of the ordinary solvents, it could be hydrogenated in a dioxane suspension to I in 87% yield.

Attempts to prepare the bicyclic structure II by the catalytic intramolecular alkylation[11] of the 4-nitrogen of VI—obtained together with some of the 1,4-di-(β-hydroxylethyl) derivative, VIa, from the reaction of I with ethylene oxide—with the 1-hydroxyethyl substituent were unsuccessful. At temperatures up to 200°, VI was recovered unchanged; at 250° some of VI was recovered, but the major portion of it lost the 1-substituent and reverted to the original piperazine I.

The bicyclic compound, 1,4-diazobicyclo-(2,2,-2)-octane, the unmethylated homolog of II, has been prepared in low yields by heating (a) diethanolamine hydrochloride (2%)[12] and (b) 1-(β-chloro- (or-bromo)-ethyl)-piperazine dihydrohalides (20–25%)[13]; and by treatment of 1-(β-chloroethyl)-piperazine with aqueous alkali.[13] However, an attempt to effect a similar cyclization of 1-(β-bromoethyl)-piperazine by the latter procedure was unsuccessful.[14]

When the corresponding 1-(β-bromoethyl) derivative of I (VIIa) was added to an aqueous sodium hydroxide solution, it dissolved immediately, but within a few seconds a precipitate began to separate. The amount of this precipitate was dependent upon the dilution of the solution with respect to VIIa, *i. e.*, the more dilute the solution the less the amount of precipitate. This insoluble material was separated into the dimer (IX, *n* is 1), m. p. 123–125, the trimer (IX, *n* is 2), m. p. 160–167°, and a higher melting (above 260°), insoluble material, which is, presumably, a more complex polymer (IX, $n > 2$). From the aqueous alkaline solution only VI was isolated; the yields of this compound increased, as those of the insoluble products (IX) decreased, with the dilution of the solutions of VIIa.

The chloro derivative (VII) showed an interesting and significant variation in behavior. When an aqueous alkali solution was added to an aqueous solution of VII, there was an immediate precipitation of the free base, due to the neutralization of the hydrochloride functions. This precipitate, however, rapidly returned to solution and from the resulting clear solution the polymers IX began to separate. All of these changes occurred within approximately one minute after the salt VII was added to the alkaline solution.

This behavior indicates that the free bases of VII and VIIa are preferentially converted into the ethyleneimmonium ion[15] (VIII) rather than the bicyclic structure II; VIII then reacts with water to produce VI (if the solution is sufficiently dilute) or intermolecularly to produce the polymer IX. In the case of the bromo derivative (VIIa), the formation of VIII is so rapid that there is no evidence of the intermediate free base; but with the less reactive chloro compound, the free base of VII is momentarily precipitated before it cyclizes to the soluble ion (VIII) that undergoes the subsequent reactions.

When the salts VII and VIIa were heated alone or in suspension in Stanolind oil, 77–88% of one equivalent of hydrogen halide was evolved at 220–240°. However, investigation of the remaining salt in a search for the bicyclic compound II yielded only the piperazine I. Whether or not the formation of this product involved the quaternary ion VIII could not be determined; it is possible that a salt of I could form from VII by dehydrohalogenation followed by the loss of acetylene.

## Experimental

**Methyl α-Aminoisobutyrate.**—A mixture of 51.5 g. (0.5 mole) of α-aminoisobutyric acid, prepared by the hydrolysis of 5,5-dimethylhydantoin,[16] and 600 ml. (15.3 mole) of methanol was treated with hydrogen chloride until 30 g. (0.82 mole) had been absorbed. The resulting solution was refluxed on a steam-bath for sixteen hours, after which time 150 g. of Drierite was added. Throughout this experiment, the solutions were protected from atmospheric moisture with calcium chloride drying tubes.

After filtering off the Drierite, the methanol and excess hydrogen chloride were removed under vacuum until the residue was solid; it then was placed in a vacuum desiccator over potassium hydroxide until completely dry. A quantitative yield of methyl α-aminoisobutyrate hydrochloride, m. p. 179–182° dec., and which contained 23.2% chlorine (calcd. 23.1%), was obtained. The ester hydrochloride after recrystallization from absolute alcohol and ether melts at 182–183° dec.[5]

The free ester was liberated from its salt by adding a solution of sodium methoxide in dry methanol (from 14 g. of sodium and 200 ml. methanol) to a sirup of the ester hydrochloride in methanol until the solution was alkaline to phenolphthalein. After filtering off the sodium chloride, the methanol solution was distilled in a modified Claisen flask at atmospheric pressure. A 64% yield of methyl α-aminoisobutyrate, b. p. 133–134°, was obtained.

**2,2,5,5-Tetramethyl-3,6-diketopiperazine (IV).**—To 200 ml. of diethylene glycol contained in an open 500-ml. long-neck, round-bottom flask was added 100 g. of crystalline α-aminoisobutyric acid, which had been ground and passed through a 20-mesh screen (a larger crystal size caused prolongation of the heating time). The glycol was refluxed at such a rate that the water formed in the reaction was driven out as steam. During four hours of heating, the temperature at reflux gradually increased from 210 to 234°, and all the acid had gone into solution. The diketopiperazine crystals which formed when the solution was allowed to cool to room temperature were collected on a filter and washed with methanol until free from glycol; the yield was 16 g.

To the filtrate was added another 100 g. of α-aminoisobutyric acid and the mixture heated as above. After five hours, the temperature of the vapors above the refluxing glycol had increased to 249°, and only a small amount of insoluble material remained. After the solution had cooled, 47.5 g. of IV was collected. Two repetitions of this procedure, using 75 g. and 50 g. of acid in the same glycol filtrate, yielded 31.5 g. and 16.5 g. of diketopiperazine, respectively. Smaller quantities of acid were employed in these latter runs to insure complete solution of the acid in the glycol. After these four runs, the diethylene glycol solution was dark brown and viscous, and not suitable for further use. The total yield of the diketopiperazine (IV) from 325 g. of α-aminoisobutyric acid was 111.5 g. (41.6%).

Undoubtedly, some acid and diketopiperazine are lost through sublimation from the diethylene glycol. In an effort to determine the fate of the remainder of the acid not recovered as IV, the diethylene glycol solution from the above runs was diluted with methanol and benzene. No precipitate separated; any acid or diketopiperazine that was in solution would have been precipitated by this change in solvent. When the diethylene glycol solution was distilled, 7% of its weight was recovered as methyl α-aminoisobutyrate; 42% as diethylene glycol, b. p. 75–120° (0.4 mm.), $n^{25}D$ 1.4483; 27% as material, b. p. 160–198° (0.3 mm.), $n^{25}D$ 1.4630–1.4760; and 16% remained as residual tar. The latter two materials were not investigated further. The methyl ester was formed from the methanol used to wash the diketopiperazine crystals and which was added to the diethylene glycol filtrate. That portion of the acid not recovered probably was in the form of glycol esters.

The diketopiperazine (IV) does not melt, even in a sealed capillary tube, below 400°, but sublimes in the temperature range 360–370° (cor.) in an open capillary and at about 390° in a sealed capillary. Many sublimation tem-

peratures have been reported,[6] varying from 210 to 260°, all of which are much lower than those found for IV in the present work. The diketopiperazine is much less volatile than α-aminoisobutyric acid (sublimation temperature 300–320°). The sublimation temperatures now reported for these compounds are those ranges in which the rate of sublimation suddenly increases as the compounds are heated. The diketopiperazine (IV) is insoluble in water, and relatively insoluble in most organic solvents. It dissolves to the extent of about 0.2% in hot 95% ethyl alcohol, 0.4% in hot butanol, 3% in hot glacial acetic acid, 10% in diethylene glycol at 250°, but less than 0.5% at room temperature. Recrystallization from this latter solvent, followed by leaching with hot water, gives a very pure product.

*Anal.* Calcd. for $C_8H_{14}N_2O_2$: C, 56.47; H, 8.23; N, 16.47; mol. wt., 170. Found: C, 56.66; H, 8.33; N, 15.96; mol. wt. (in acetic acid), 170, 177.

When α-aminoisobutyric acid was heated in diphenyl ether or diphenyl amine, the acid sublimed from the liquid and no diketopiperazine was found. Apparently, a polar solvent such as diethylene glycol, is necessary to keep the acid from volatilizing at the temperature required for its condensation to IV.

When methyl α-aminoisobutyrate hydrochloride was heated in a distilling flask, only a small amount of a semi-solid distillate, from which was recovered some of the original acid, was obtained. No trace of diketopiperazine was found. When methyl α-aminoisobutyrate was heated in a glass lined bomb at 200° it was converted to a solid, only 3% of which (IV) was insoluble in water. Evaporation of the aqueous solution yielded only α-aminoisobutyric acid.

**2,2,5,5-Tetramethylpiperazine (I) and 2,2,5,5-Tetramethyl-3-ketopiperazine (V) (a).**—A mixture of 34 g. (0.2 mole) of IV, 15 g. of copper–chromium oxide catalyst[17] and 50 ml. of dioxane were placed in a steel bomb, which then was filled with hydrogen to 3500 p. s. i. The hydrogenation was carried out at 250° for sixteen hours. The dioxane solution, after separation from the catalyst by centrifuging, was distilled and two fractions, b. p. 85–168° (a liquid) and 168–173° (a crystalline solid), collected. Hydrogen chloride was added to the first fraction, and the dioxane evaporated. The free base (I) was liberated from the remaining salt with 50% sodium hydroxide and extracted with benzene; the benzene solution then was distilled and yielded 10.5 g. of crystalline I, which, when combined with the second fraction, gave a total yield of 22 g. (77%) of I.

After recrystallization from absolute ether, **2,2,5,5-tetramethylpiperazine** (I) is obtained as a white, crystalline, fairly volatile solid, m. p. 85–87° with previous softening at 83°. It boils at 168–171° and has a pleasant ammoniacal odor. It is very soluble in water and all organic solvents. In contrast to the unsubstituted piperazine, the tetramethylpiperazine is not hygroscopic and does not react with carbon dioxide of the atmosphere.

*Anal.* Calcd. for $C_8H_{18}N_2$: C, 67.55; H, 12.75; N, 19.70. Found: C, 67.40; H, 13.13; N, 19.71.

**2,2,5,5-Tetramethylpiperazine dihydrochloride** was prepared by passing hydrogen chloride through a solution of I in dioxane and evaporating the dioxane. This dihydrochloride is very soluble in water, but insoluble in all organic solvents, and no means for recrystallization was found. It does not melt below 350°, but begins to darken at 310°.

*Anal.* Calcd. for $C_8H_{20}Cl_2N_2$: Cl, 32.96. Found: Cl, 32.45.

**1,4-Dibenzoyl-2,2,5,5-tetramethylpiperazine** was prepared from I in 92% yield by the usual Schotten–Baumann procedure. When recrystallized from absolute ethanol, it melted 273–276°.

*Anal.* Calcd. for $C_{22}H_{26}N_2O_2$: C, 75.40; H, 7.48. Found: C, 75.26; H, 7.82.

From the residue, remaining after the distillation of I from the hydrogenation products, was obtained 3.1 g. 5% of **2,2,5,5-tetramethyl-3-ketopiperazine** (V), which after recrystallization from toluene melted at 153–156° and boiled at 250–258°. This compound is soluble in water, ether, alcohol and benzene.

*Anal.* Calcd. for $C_8H_{16}N_2O$: C, 61.50; H, 10.33; N, 17.93. Found: C, 61.17; H, 10.17; N, 18.12.

**2,2,5,5-Tetramethyl-3-ketopiperazine hydrochloride** was prepared by passing hydrogen chloride through a solution of 0.5 g. of V in 30 ml. of dioxane and evaporating the dioxane. After recrystallization from alcohol–ether, 0.5 g. (81%) of the hydrochloride, m. p. 305–308° dec., was obtained.

*Anal.* Calcd. for $C_8H_{17}ClN_2O$: Cl, 18.4. Found: Cl, 18.2.

The hydrogenation of V, as described above for IV, gave the piperazine I in 87% yield.

The yields of I and V varied from 87% and 0% to 36% and 42%, depending on the purity of IV. The former high yield of I was obtained with a sample of IV that had been recrystallized from diethylene glycol. With less pure samples of IV, *i. e.*, those obtained by washing the crude product with methanol or water, the yields of V became significant.

(b) **The Reduction of IV with Sodium in Butanol.**—To 400 ml. of hot, absolute butanol and 25 g. (0.147 mole) of IV, contained in a three-neck, three-liter round-bottom flask equipped with a stirrer and a large bore condenser, was added 90 g. (3.48 mole) of sodium over a period of approximately ten minutes. To prevent the formation of solid sodium butoxide, another 600 ml. of butanol was added portionwise during the reduction. The solution was kept at reflux by heating on sand-bath until all the sodium had reacted. About 300 ml. of water was added then, and, after cooling, the water layer separated and 115 ml. of concentrated hydrochloric acid was added to the butanol solution. The aqueous layer was extracted with benzene to determine if any reduced product remained in it, but only a negligible amount was found. The acidified butanol layer was steam distilled to remove the butanol. To the remaining aqueous acid solution of the piperazine salt (about 750 ml.) was added 200 ml. of 50% sodium hydroxide, and the solution was extracted five times with 100 ml. portions of benzene. From the remaining aqueous layer was recovered 3 g. (12%) of the insoluble diketopiperazine (IV). The benzene solution was distilled to yield 5.0 g. (24%) of I in the fraction boiling at 165–210°, and 9.2 g. (40%) of V in the fraction boiling at 210–250°.

**1-(β-Hydroxyethyl)-2,2,5,5-tetramethylpiperazine (VI).**—In a 10-inch length of 15-mm. Pyrex tubing sealed at one end was placed 11.36 g. (0.08 mole) of I. The neck of the tube was drawn out for sealing, and, after chilling the tube in Dry Ice, 2 ml. (1.85 g., 0.042 mole) of ethylene oxide was added, and the tube sealed. The tube then was heated with shaking for two hours at 150°.

The combined contents of three of such tubes was distilled through an eight-inch Vigreux column to yield 18.8 g. of I and 15.5 g. (66% based on the ethylene oxide) of VI, b. p. 240–247°, which after recrystallization from petroleum ether (b. p. 60–68°), melted at 78–83°.

*Anal.* Calcd. for $C_{10}H_{22}N_2O$: C, 64.47; H, 11.90; N, 15.04. Found: C, 64.21; H, 11.91; N, 14.63.

From the residue (4.5 g.) of this distillation, after treatment with Norit and recrystallization from toluene, was isolated 1.83 g. (13% based on the ethylene oxide) of **1,4-di-(β-hydroxyethyl)-2,2,5,5-tetramethylpiperazine** (VIa), m. p. 110–115°. After a second recrystallization from toluene, VIa melted at 113–116°.

*Anal.* Calcd. for $C_{12}H_{26}N_2O_2$: C, 62.56; H, 11.38; N, 12.16. Found: C, 62.21; H, 11.42; N, 12.55.

When a ratio of 1.5 moles of I to one mole of ethylene oxide was used in one experiment, 54% of VI and 41% (based on the ethylene oxide) of VIa were obtained.

**1-(β-Hydroxyethyl)-2,2,5,5-tetramethylpiperazine Dihydrochloride.**—Hydrogen chloride was passed through a

(17) Adkins, "Reactions of Hydrogen," The University of Wisconsin Press, Madison, Wis., 1937, p. 112.

solution of 5 g. of VI in 100 ml. of dioxane until no further precipitate was formed. The dioxane was evaporated in a stream of air, and the residue dried overnight in a vacuum desiccator. This dihydrochloride had no definite melting or decomposition point, but began to darken at about 200°. As it is very soluble in water but insoluble in organic solvents, it was not possible to recrystallize it. However, analysis showed the compound to be quite pure.

*Anal.* Calcd. for $C_{10}H_{23}ClN_2O$: Cl, 27.36. Found: Cl, 27.18.

**1-(β-Chloroethyl)-2,2,5,5-tetramethylpiperazine Dihydrochloride (VII).**—In a 200-ml. round-bottom flask were placed 5.0 g. of the dihydrochloride of VI, 5.8 ml. of freshly distilled thionyl chloride, 2.2 ml. of pyridine, and 50 ml. of benzene. The flask was attached to a condenser fitted with a calcium chloride tube, and the solution heated to gentle reflux. After the first two to three hours of refluxing the flask was removed, and the large lumps which had formed were crushed to a powder. The flask then was replaced, and the refluxing continued for twenty hours. At the end of this time, the solution was filtered while hot. The solid on the filter was washed with benzene and absolute ethanol, after which it was placed in a 200 ml. flask, 25 ml. of absolute ethanol added, and any large lumps were broken into a powder. The alcoholic suspension was refluxed for fifteen minutes and filtered. The solid on the filter was washed with absolute ethanol and then absolute ether. After drying in a vacuum desiccator for several hours, the weight of the white powder was 5.57 g. (74.6%).

*Anal.* Calcd.: ionic Cl, 25.55; total Cl, 38.31. Found: ionic Cl (Volhard), 25.11; total Cl (Stepanow), 37.83.

**1-(β-Bromoethyl)-2,2,5,5-tetramethylpiperazine Dihydrobromide (VIIa).**—To a 50-ml. round-bottom flask were added 5 g. of VI and 25 ml. of 48% hydrobromic acid. An all-glass still head and condenser was attached to the flask, and the solution was distilled slowly for three to four hours, during which time the distilled material was replaced by hydrobromic acid. The solution then was allowed to reflux for sixteen hours, after which it was slowly distilled until the residue was a sludge. Acetone was added, and the insoluble product filtered off. After drying in a vacuum desiccator, the resulting white salt (VIIa) weighed 8.8 g. (80%).

*Anal.* Calcd. for $C_{10}H_{23}Br_3N_2$: Total Br, 58.32. Found: Br, 55.5.

The Volhard procedure gave the same halogen values as those obtained with the Stepanow procedure.

**Attempted Preparation of 2,2,5,5-Tetramethyl-1,4-diazabicyclo-(2,2,2)-octane (II). (a) By Catalytic Intramolecular Alkylation of VI.**—In a 150-ml. glass-lined bomb were placed 5.0 g. of VI, 2.0 g. of copper–chromium oxide catalyst and 20 ml. of dioxane. The bomb was filled with hydrogen and heated in various experiments at temperatures ranging from 200 to 250° for two to four hours. At the end of the heating period, the catalyst was removed from the dioxane solution by centrifuging, and the solution distilled. The recovery of VI varied from 63 to 78%; in the case of the lower recovery of VI (250°), a 13% yield of I was obtained. Repetition of the experiment at 250° using nitrogen instead of hydrogen in the bomb gave 62% of VI and 30% of I. With a nickel catalyst at 150°, 90% of VI was recovered; at 250° a 51% yield of I was obtained. There was no evidence that any di-tertiary amine (II) had formed in any of these experiments.

**(b) From 1-(β-Bromoethyl)-2,2,5,5-tetramethylpiperazine Dihydrobromide (VIIa).**—Experiments in which aqueous solutions of VIIa were treated with aqueous sodium hydroxide solutions are listed in Table I.

In experiment A, the solution containing 2.5 g. of VIIa was overlaid with ether, and 5% aqueous sodium hydroxide was added with shaking. The layers were separated, and the ether distilled from a steam-bath. Water was added to the residue from the ether solution, and the insoluble polymer, m. p. 113–120°, was separated by filtration. The filtered aqueous solution was distilled, and the distillate was found to contain 0.0006 mole of base (16% calculated as VI). This titrated solution was evaporated to dryness, treated with benzoyl chloride and 5% sodium hydroxide, and filtered. The filtrate from this treatment was distilled, and the resulting distillate showed no titratable basicity, indicating the absence of any of the di-tertiary amine II.

Table I

Reaction of Aqueous Solutions of VIIa with Alkali

| Experiment | % Solution of VIIa in water: Original | Final[a] | Moles NaOH per mole VIIa | Recovery, % as: VI | IX |
|---|---|---|---|---|---|
| A | 10 | 6 | >3[b] | 16 | 70 |
| B | 10 | 6 | 3 | 16 | 30 |
| C | 0.3 | 0.3[c] | 3 | 72 | 7 |
| D | 24 | 8 | 3 | .. | 65 |

[a] After addition of the aqueous sodium hydroxide solution. [b] An excess of 5% aqueous sodium hydroxide added. [c] The amount of water added with the alkali in this case did not change the original percentage significantly.

In B and C, the polymer was separated by filtration, after which 50% sodium hydroxide was added to the aqueous filtrate, which then was extracted with benzene. Distillation of the benzene solution gave the quantities of VI listed in Table I. No other amine was present.

In D, 4.8 g. of VIIa (54.6% bromine content) in 15 ml. of water was treated with 46 ml. of 0.706 *N* (three equivalents) sodium hydroxide solution. After four hours, the solution was filtered, and the insoluble material leached with water to remove occluded inorganic salts; no attempt was made to identify the products in the aqueous filtrates. After drying the insoluble product in an oven at 70°, it (1.88 g.) was treated with 75 ml. of absolute ethanol, and 1.12 g. of insoluble material, m. p. above 260°, was separated from the alcoholic solution. The alcoholic solution was evaporated to dryness and treated with petroleum ether (b. p. 60–68°), and 0.1 g. of an insoluble material, m. p. 160–170°, was separated. The petroleum ether solution was concentrated and chilled; 0.47 g. (11%) of the dimer IX ($n = 1$), m. p. 112–133°, separated. After one recrystallization from petroleum ether, this dimer, **1-β-(2,2,5,5-tetramethylpiperazino)-ethyl-2,2,5,5-tetramethyl-4-(β-hydroxyethyl)-piperazine,** melted at 121–129°. After another recrystallization, it melted at 123–125.5°.

*Anal.* Calcd. for $C_{20}H_{42}N_4O$: C, 67.76; H, 11.94; mol. wt., 354.5. Found: C, 67.54; H, 12.20; mol. wt. (Rast), 346.

The material melting at 160–170°, which was insoluble in petroleum ether, had a molecular weight and gave analytical values corresponding to those calculated for the trimer IX ($n$ is 2). The yield of this product amounted to 2% of the theoretical.

*Anal.* Calcd. for $C_{30}H_{62}N_6O$: C, 68.92; H, 11.95; mol. wt., 522. Found: C, 68.12; H, 12.43; mol. wt. (Rast), 511.

The major portion of the polymer, which was insoluble in ethanol and melted above 260°, was too insoluble in all solvents to permit a molecular weight determination. Although its properties indicated it to be a higher polymer IX, ($n > 2$), its analyses (C, 67.7%; H, 12.7%) were not satisfactory for such a structure (for higher values of $n$ the calcd. values for IX approach the limiting values: C, 71.5; H, 12.5, the calcd. values for IX minus water). Because of its refractory nature, this polymer was not investigated further.

When an aqueous solution of the chloro-dihydrochloride (VII) was treated with alkali in the manner described above, there was a momentary turbidity, indicating precipitation of the free base, but the solution cleared within five seconds. Within one minute a gelatinous precipitate began to separate. From such solutions the polymers

(IX) were obtained in quantities approximating those shown in Table I for the bromo compound, VIIa.

(c) **From Heating 1-(β-Chloroethyl)-2,2,5,5-tetramethylpiperazine Dihydrochloride (VII).**—This salt was heated alone and suspended in Stanolind mineral oil. The results of four such experiments are given in Table II.

TABLE II

PYROLYSIS OF VII

| Run | Condition | Temp., °C. | Time, min. | Mole HCl/mole VII evolved | I, %, recovered |
|---|---|---|---|---|---|
| 1 | Alone | 230–245 | 30 | 0.82 | 69 |
| 2 | Alone | 210–240 | 35 | .82 | 76.3 |
| 3 | In oil | 180–220 | 80 | .77 | 56.3 |
| 4 | In oil | 213–220 | 80 | .88 | 29.4 |

A typical experiment (run 3) follows: In a 200-ml. three-neck, round-bottom flask fitted with a stirrer, a thermometer, an air inlet and an outlet leading to 50 ml. of water in an erlenmeyer flask were placed 5 g. of VII and 50 ml. of Stanolind mineral oil. The flask was heated in a metal-bath and the hydrogen chloride evolved collected in water and titrated periodically with standard alkali. Above 180° the evolution of hydrogen chloride was steady. After the evolution of hydrogen chloride slowed, the oil suspension was diluted with petroleum ether (b. p. 60–68°), filtered, and the insoluble solid washed with petroleum ether; it weighed 3.48 g. after drying. The solid was dissolved in water, and the solution filtered; 0.06 g. of insoluble material remained. To the aqueous solution was added 5% sodium hydroxide solution; no precipitate formed. The solution was distilled until the distillate was no longer alkaline. Titration of the distillate with standard 1 *N* hydrochloric acid against methyl orange showed the presence of sufficient base to amount to 56.3% of I. Conversion of the salt, remaining from evaporation of the titrated solution, to the dibenzoyl derivative of I, m. p. 273–276°, identified this base as the reaction product. The filtrate from the preparation of the benzoyl derivative was distilled and a non-alkaline distillate obtained, indicating the absence of any of the tertiary, bicyclic amine II.

## Summary

The preparation of 2,2,5,5-tetramethyl-3,6-diketopiperazine (IV) from α-aminoisobutyric acid is described. This diketopiperazine has been converted to 2,2,5,5-tetramethylpiperazine (I) and 2,2,5,5-tetramethyl-3-ketopiperazine (V) by catalytic hydrogenation over copper–chromium oxide as well as by reduction with sodium in butanol.

Attempts to convert the 1-(β-hydroxyethyl)- and the 1-(β-haloethyl)-2,2,5,5-tetramethylpiperazines to the tetramethyl-1,4-diazabicyclo-(2,2,2)-octane (II) were unsuccessful. The hydroxy compound lost the 1-substituent and reverted to I; the 1-haloethyl derivatives in aqueous alkaline solution yielded the 1-hydroxyethyl derivative and polymers (IX) *via* an intermediate ethylene immonium ion, or when heated as salts, lost the 1-substituent to form the piperazine I.

# The Synthesis of Some Isomeric Dimethyl-hydroxymethylpyridines. 3,4-Didesoxypyridoxin

BY RAYMOND P. MARIELLA AND JOHN L. LEECH[1]

Recent interest in antibiotics has led us to investigate the effect of the variation of the substituents in pyridoxin on possible anti-pyridoxin activity.

It has been shown by Ott[2] that 4-desoxypyridoxin was a powerful competitor to pyridoxin in the chick, and that methoxypyridoxin[3] exhibited similar activity, but to a lesser extent. Recently,[4] 5-deshydroxymethylpyridoxin was shown to be a weak inhibitor of pyridoxin in *Saccharomyces Cerevisiae*, while more recent work with 4-deshydroxymethylpyridoxin[5] has shown that this compound also exhibited very weak anti-pyridoxin properties.[6]

In the present work 2,3-dimethyl-5-hydroxymethylpyridine (VII), and 2,4-dimethyl-5-hydroxymethylpyridine (III) (3,4-didesoxypyridoxin) were synthesized as shown in Fig. 1.

As might be expected, VII exhibited neither pyridoxin nor anti-pyridoxin activity, but III did show weak anti-pyridoxin activity when tested against *Neurospora Sitophila*.[7]

From our work and previously cited work, it would appear that those structures similar to pyridoxin (with one or two groups removed) can exhibit this effect of anti-vitamin activity, and this could be explained on the basis of failure of the organism to differentiate between the vitamin and the similar molecule. With this reasoning, however, it would be difficult to explain why 3-amino-5-aminomethyl-4-ethoxymethyl-2-ethylpyridine has turned out to be the most potent anti-pyridoxin compound yet reported.[4] Work on the synthesis of other compounds related to pyridoxin is continuing in this Laboratory and will be reported soon.

**Acknowledgement.**—The authors wish to thank the Graduate School for a grant which made some of this work possible.

## Experimental[8]

**3-Cyano-4,6-dimethyl-2(1)-pyridone.**—This was prepared from acetylacetone and cyanoacetamide.[9] The product was obtained as colorless needles, m. p. 286° (uncor.).

*Anal.* Calcd. for $C_8H_8N_2O$: N, 18.9. Found: N, 18.9.

**2-Chloro-3-cyano-4,6-dimethylpyridine (I).**—An intimate mixture of the two solids, 43 g. of the above pyridone and 66 g. of phosphorus pentachloride, was heated until gentle refluxing began, and the refluxing was continued for two hours. The generated phosphorus oxychloride was removed under reduced pressure, and the remaining brown solid broken up, mixed with ice, and made basic with concentrated sodium hydroxide. The black mixture was then steam distilled, and a yellow solid came over with the water, 37 g. (77%), m. p. 91–94°. After several recrystallizations from alcohol–water, white plates were obtained, m. p. 94.5–95.0°.

*Anal.* Calcd. for $C_8H_7ClN_2$: N, 16.8. Found: N, 16.6.

**3-Cyano-4,6-dimethyl-2-methoxypyridine (IV).**—Sodium methoxide was prepared by adding 0.35 g. of sodium to 25 cc. of methyl alcohol. To this solution, 1.0 g. of chloropyridine (I) was added, and the resulting solution was refluxed for twenty-four hours. The methyl alcohol was removed on a steam cone, and the yellow solid which remained was extracted with anhydrous ether, and the insoluble sodium chloride filtered off. Evaporation of the ether left 0.45 g. (46%) of product, m. p. 93–94°. The material was further purified by sublimation, m. p. 93.5–94.0°. A mixed m. p. with the chloro compound (I) was depressed 30°.

*Anal.* Calcd. for $C_9H_{10}N_2O$: N, 17.3. Found: N, 17.0.

**5-Aminomethyl-2,4-dimethylpyridine Dihydrochloride (II).**—To a solution of 5.54 g. of 2-chloro-3-cyano-4,6-dimethylpyridine (I) in 125 cc. of absolute ethyl alcohol were added in order, a solution of 1.18 g. of palladium chloride in 2 cc. of concentrated hydrochloric acid, 15 cc. of 15% hydrogen chloride in absolute alcohol, and 3 g. of Norit. The suspension was shaken with hydrogen at twenty pounds pressure for two hours, after which time the uptake of hydrogen had ceased. Another solution of 1.10 g. of palladium chloride in 2 cc. of concentrated hydrochloric acid was added and the reduction resumed. After an additonal six hours, the hydrogen absorption had stopped. The catalyst and support were filtered, washed well with absolute alcohol and then water. The water solution was taken to dryness and contained no solid. The alcohol solution was evaporated to 10 cc., cooled in ice, and 1.45 g. of starting compound, m. p. 91°, was obtained. The filtrate was concentrated then to 2 cc. and 50 cc. of absolute alcohol added. This caused the precipitation of 2.09 g. (41% based on recovered starting material) of a voluminous white solid. Recrystallization from a concentrated hydrochloric acid and absolute alcohol mixture, gave small prisms, m. p. 204–206°.

*Anal.* Calcd. for $C_8H_{14}Cl_2N_2$: N, 13.4. Found: N, 13.8.

**2,4-Dimethyl-5-hydroxymethylpyridine Hydrochloride (III).**—To a solution of 2.2 g. of 5-aminomethyl-2,4-dimethylpyridine dihydrochloride (II) in 10 cc. of water was added a solution of 40 cc. of concentrated hydrochloric acid in 80 cc. of water, and the resulting solution was heated to 95°. A solution of 4.5 g. of sodium nitrite in 10 cc. of water was then added, all at once, with vigorous shaking, and the temperature was maintained at 90–95° until all the gas had evolved. The solution was then evaporated to dryness and the remaining white crystalline residue extracted with three 20-cc. portions of boiling absolute alcohol. After filtering off the insoluble sodium chloride, the combined extracts were evaporated to dryness, leaving a yellow solid, 1.6 g. (87%). Subsequent recrystallizations from alcohol–dioxane gave a white product, m. p. 215–220°, which did not give the correct analytical figures. Treatment with acetyl chloride (20 cc.), refluxing one hour, boiling the resulting solution to dryness, and recrystallization of the residue from alcohol–dioxane gave beautiful white plates, m. p. 225–227°.

*Anal.* Calcd. for $C_8H_{12}ClNO$: N, 8.1. Found: N, 8.2.

**2-Chloro-3-cyano-5,6-dimethylpyridine (V).**—An intimate mixture of 20 g. of 3-cyano-5,6-dimethyl-2(1)-pyridone,[10] and 37 g. of phosphorus pentachloride was heated until gentle refluxing began, and the mixture treated in the manner described above for the isomer. The product from the steam distillation was a water-insoluble oil. This oil was extracted with ether, the ether layer dried with anhydrous sodium sulfate, and the ether then removed on a steam cone. The resulting liquid was distilled *in vacuo*, and 16 g. (71%) b. p. 141.5–142.5° at 12 mm., of colorless liquid was collected, $n^{20}D$ 1.5496.

*Anal.* Calcd. for $C_8H_7ClN_2$: N, 16.8. Found: N, 16.3.

**3-Cyano-5,6-dimethyl-2-methoxypyridine (VIII).**—To a sodium methoxide solution, prepared by adding 0.35 g. of sodium to 25 cc. of methyl alcohol, was added 1.0 g. of 2-chloro-3-cyano-5,6-dimethylpyridine (V), and the resulting solution treated in the manner described above for its isomer. Evaporation of the ether from the ether extraction left a wine-colored liquid. This was distilled *in vacuo* and a colorless liquid collected, 0.71 g. (73%), b. p. 145° at 17 mm., $n^{20}D$ 1.5278.

*Anal.* Calcd. for $C_9H_{10}N_2O$: N, 17.3. Found: N, 17.5.

**5-Aminomethyl-2,3-dimethylpyridine Dihydrochloride (VI).**—To a solution of 5.12 g. of 3-cyano-2-chloro-5,6-dimethylpyridine (V) in 75 cc. of absolute alcohol was added in order a solution of 1.55 g. of palladium chloride in 3 cc. of concentrated hydrochloric acid, 15 cc. of a 15% solution of hydrogen chloride in absolute alcohol and 3 g. of Norit. The resulting solution was shaken with hydrogen at fifty pounds pressure for three hours, at which time

(8) Microanalyses by Misses Guy, Hobbs and Hines.

(9) Wagtendonk and Wibaut, *Rec. trav. chim.*, **61**, 728 (1942).

(10) Mariella, THIS JOURNAL, **69**, 2670 (1947).

the hydrogen absorption had ceased. Another solution of 1.00 g. of palladium chloride in 2 cc. of concentrated hydrochloric acid was added and the reduction resumed. After six additional hours, the hydrogen uptake had again ceased. The catalyst and support were filtered, washed well with absolute alcohol and then water. The aqueous solution was taken to dryness on a steam cone and contained no organic material. The alcohol layer was evaporated to 2 cc. and 50 cc. of absolute alcohol added, causing the precipitation of 3.7 g. (58%) of product as voluminous white crystals, m. p. 204–207°. This material was very hygroscopic. Recrystallization from alcohol–ether gave small white needles. After drying at 100° and 1 mm. for six hours the m. p. was 216–218°.

*Anal.* Calcd. for $C_8H_{14}Cl_2N_2$: N, 13.4. Found: N, 13.3.

**2,3-Dimethyl-5-hydroxymethylpyridine and Hydrochloride (VII).**—To a solution of 2.3 g. of 5-aminoethyl-2,3-dimethylpyridine dihydrochloride (VI) in 10 cc. of water was added a solution of 40 cc. of concentrated hydrochloric acid in 80 cc. of water, and the resulting solution heated to 95°. A solution of 4.5 g. of sodium nitrite in 10 cc. of water was then added all at once, with vigorous shaking. The temperature was maintained at 85–90° until the gas evolution had ceased. The solution was then evaporated until a semi-crystalline mass remained. Attempts to obtain the crystalline hydrochloride by the method described for its isomer failed, as a liquid was always obtained. This liquid hydrochloride was then added to 10 cc. of water containing 1 g. of sodium bicarbonate. The water was removed *in vacuo*, and the residue extracted with three 15-cc. portions of boiling absolute alcohol. After filtering off the inorganic salts, the combined alcoholic extracts were concentrated until an oil remained. This was distilled and a colorless liquid, 0.45 g. (30%), b. p. 108° at 0.5 mm., was obtained.

*Anal.* Calcd. for $C_8H_{11}NO$: N, 10.2. Found: N, 9.9.

The hydrochloride was finally prepared by dissolving this free base in 100 cc. of dry ether and passing in dry hydrogen chloride gas as a voluminous white solid separated out. This was very hygroscopic. A sample dried at 40° and 1 mm. for seventy-two hours had a m. p. 103–106°.

## Summary

2,3-Dimethyl-5-hydroxymethylpyridine and 2,4-dimethyl-5-hydroxymethylpyridine (3,4-didesoxypyridoxin) have been synthesized. The former compound exhibited neither vitamin nor anti-vitamin activity, while the latter compound proved to be a weak antagonist for pyridoxin.

# 3-Substituted Thiophenes. III. Antihistaminics of the N-(3-Thenyl)-ethylenediamine Series[1]

BY E. CAMPAIGNE AND WILLIAM M. LESUER[2]

Recently it has been discovered that incorporation of the thiophene nucleus in antihistaminic compounds leads to desirable properties.[3–6] The work of Clapp, *et al.*,[5] indicates that the inclusion of a halogen atom on the thiophene ring improves the therapeutic ratio. Continuing a study of the properties of 3-thienyl analogs of physiologically active compounds,[7–9] attention was turned to the antihistaminic series. The preparation of four N-substituted dimethylaminoethylaminopyridines, containing the 3-thenyl and halogen-substituted 3-thenyl nucleus are described in this paper. The compounds prepared were: I, N,N-dimethyl-N′-(2-pyridyl)-N′-(3-thenyl)-ethylenediamine; II, N,N-dimethyl-N′-(2-pyridyl)-N′-(2-chloro-3-thenyl)-ethylenediamine; III, N,N-dimethyl-N′-(2-pyridyl)-N′-(2-bromo-3-thenyl)-ethylenediamine; and IV, N,N-dimethyl-N′-(2-pyridyl)-N′-(2,5-dichloro-3-thenyl)-ethylenediamine.

I, X = H, X′ = H
II, X = H, X′ = Cl
III, X = H, X′ = Br
IV, X = Cl, X′ = Cl

These compounds were readily synthesized by the reaction of the sodio-derivative of 2-dimethylaminoethylaminopyridine with the appropriate 3-thenyl bromide, obtained when the proper 3-methylthiophene reacted with N-bromosuccinimide.[7] In order to produce the corresponding halogenated compounds, it was necessary to extend the N-bromosuccinimide reaction to the halogenated 3-methylthiophenes, and characterize the halogenated thenyl bromides. As was expected, it was found that blocking the active 2-position with a halogen greatly improved the yield of side-chain bromination with N-bromosuccinimide. The reactions carried out in the preparation of the four antihistaminics and intermediates are outlined in the accompanying diagram. In each case the thenyl bromide was converted to the hexamethylenetetramine salt, the salt steam distilled to obtain the aldehyde, which was then oxidized to the acid with silver oxide.

The chlorination of 3-methylthiophene with sulfuryl chloride[10] was extended to the preparation

of 2,5-dichloro-3-methylthiophene, which was found to be produced in good yield by this reaction.

The pharmacological data on these compounds will be published elsewhere by Dr. A. M. Lands, of the Sterling–Winthrop Research Institute.

## Experimental

**2-Chloro-3-thenyl Bromide.**—A solution of 66 g. (0.5 mole) of 2-chloro-3-methylthiophene[10] in 150 ml. of carbon tetrachloride was mixed with 88.5 g. (0.5 mole) of N-bromosuccinimide and 1.0 g. of benzoyl peroxide was added. After refluxing for eight hours, the mixture was cooled and filtered to remove succinimide. The succinimide was washed with 50 ml. of carbon tetrachloride, and the combined filtrates fractionated under reduced pressure. A highly lachrymatory oil was collected at 85–92° (1–2 mm.), and amounted to 81 g. (0.37 mole, 75%). The main portion distilled at 88° (1 mm.), and a sample of this fraction ($n^{22}D$ 1.6119), was used for analyses.

*Anal.* Calcd. for $C_5H_4BrClS$: S, 15.16. Found: S, 15.19.

**Hexamethylenetetramine Salt of 2-Chloro-3-thenyl Bromide.**—To 37.2 g. (0.18 mole) of 2-chloro-3-thenyl bromide in 50 ml. of chloroform was added 25 g. (0.18 mole) of hexamethylenetetramine, and the mixture was shaken. Separation of the salt began immediately, but the mixture was refluxed for one hour to ensure complete reaction. After cooling the salt was filtered, washed with ether, and air dried; yield, 52 g. (84%). Recrystallization of the salt from ethanol yielded beautiful white needles which melted at 165°.

*Anal.* Calcd. for $C_{11}H_{16}N_4BrClS$: S, 9.12. Found: S, 8.80.

**2-Chloro-3-thenaldehyde.**—A solution of 40 g. (0.14 mole) of the hexamethylenetetramine salt of 2-chloro-3-thenyl bromide in 150 ml. of hot water was rapidly steam distilled until 750 ml. of distillate was collected. The distillate was acidified with hydrochloric acid, extracted with three 75-ml. portions of ether, and the extract dried over Drierite. After removing the ether, the residue solidified on cooling. It was dissolved in high-boiling petroleum ether, and crystallized at Dry Ice temperature. After filtering, the crystalline material was transferred to a small flask and distilled in vacuum. The product was a colorless oil, b. p. 100–102° (1–2 mm.), and weighed 4.2 g. (0.029 mole, 25%). It crystallized on standing at room temperature, m. p. 25°, $n^{20}D$ 1.5908.

*Anal.* Calcd. for $C_5H_3OClS$: S, 21.87. Found: S, 21.58.

The 2,4-dinitrophenylhydrazone of 2-chloro-3-thenaldehyde was formed readily by the usual procedure, giving orange needles from chloroform, which melted at 214°.

*Anal.* Calcd. for $C_{11}H_7O_4N_4ClS$: S, 9.81. Found: S, 9.98.

**2-Chloro-3-thenoic Acid.**—A solution of 0.5 g. (0.0034 mole) of 2-chloro-3-thenaldehyde in 5 ml. of ethanol was added to a thoroughly shaken suspension of silver oxide, produced by adding 0.35 g. of sodium hydroxide to 1.0 g. of silver nitrate in 25 ml. of water, and the mixture shaken for thirty minutes. The free silver was removed by filtering, washed with water, and the filtrate acidified with concentrated hydrochloric acid. The white precipitate was recrystallized from water, yielding 0.42 g. (0.0025 mole, 75%) of 2-chloro-3-thenoic acid, which melted at 163°.

*Anal.* Calcd. for $C_5H_3O_2ClS$: S, 19.72. Found: S, 19.84.

**2-Bromo-3-thenyl Bromide.**—The 2-bromo-3-methylthiophene used for this preparation was obtained as a by-product in the bromination 3-methylthiophene with N-bromosuccinimide.[7] The compound was separated by treating the mixture produced in the bromination reaction with hexamethylenetetramine in chloroform, thus removing the 3-thenyl bromide salt. The unreacted 2-bromo-3-methylthiophene and chloroform was accumulated from a number of such preparations and fractionated. The 2-bromo-3-methylthiophene was collected from 172–174°[11] and redistilled in vacuum, b. p. 52° (3 mm.). A solution of 88.5 g. (0.5 mole) of 2-bromo-3-methylthiophene in carbon tetrachloride was treated with 0.5 mole of N-bromosuccinimide and 1.0 g. of benzoyl peroxide, as described above. The product was collected at 105–120° (7 mm.), the main portion coming over at 113° (7 mm.) ($n^{20}D$ 1.6241) and weighed 84.2 g. (0.328 mole, 65%).

*Anal.* Calcd. for $C_5H_4Br_2S$: S, 12.82. Found: S, 12.79.

**Hexamethylenetetramine Salt of 2-Bromo-3-thenyl Bromide.**—This salt was formed in the usual manner from 0.32 mole of 2-bromo-3-thenyl bromide in 75% yield (94 g.). When recrystallized from ethanol, the salt melted at 171–172°.

*Anal.* Calcd. for $C_{11}H_{16}N_4Br_2S$: S, 8.09. Found: S, 7.77.

**2-Bromo-3-thenaldehyde.**—Produced by the steam distillation of 50 g. of the hexamethylenetetramine salt, the aldehyde solidified on standing, after the ether used to extract it was removed. Two recrystallizations from high-boiling petroleum ether yielded 3.7 g. (15%) of white needles, which melted at 34°.

(11) Steinkopf, *Ann.*, **515**, 273 (1935), reported the boiling point of this compound to be 175° (729 mm.).

*Anal.* Calcd. for $C_5H_3OBrS$: S, 16.78. Found: S, 17.00.

The 2,4-dinitrophenylhydrazone of 2-bromo-3-thenaldehyde crystallized from chloroform in orange needles, which melted at 230.5°.

*Anal.* Calcd. for $C_{11}H_7O_4N_4BrS$: S, 8.64. Found: S, 8.65.

**2-Bromo-3-thenoic Acid.**—One gram (0.005 mole) of 2-bromo-3-thenaldehyde was shaken with silver oxide, and the acid worked up in the usual manner. Recrystallization from a 4:1 water–ethanol mixture yielded 0.84 g. (78%) of slender white needles, which melted at 178–179°.

*Anal.* Calcd. for $C_5H_3O_2BrS$: S, 15.49. Found: S, 15.54.

**2,5-Dichloro-3-methylthiophene.**—To 296 g. (3.0 moles) of 3-methylthiophene was added dropwise 810 g. (6.0 moles) of sulfuryl chloride over a period of three hours. Spontaneous refluxing soon began and continued throughout the addition. When spontaneous refluxing subsided, heat was applied and the mixture refluxed two hours longer, and then fractionally distilled. The yield of 2-chloro-3-methylthiophene, b. p. 50° (16 mm.), $n^{20}D$ 1.5408, was 31 g. (0.235 mole, 8%). The main product, 2,5-dichloro-3-methylthiophene, distilled at 44° (1 mm.), 65° (11 mm.), $n^{20}D$ 1.5560, and weighed 316 g. (1.89 moles, 63%). The higher boiling products were not identified.

*Anal.* Calcd. for $C_5H_4Cl_2S$: S, 19.2. Found: S, 19.6.

**2,5-Dichloro-3-thenyl Bromide.**—A solution of 83.5 g. (0.5 mole) of 2,5-dichloro-3-methylthiophene was treated, as previously described, with an equivalent portion of N-bromosuccinimide and 1.0 g. of benzoyl peroxide. A violent reaction occurred when heating was begun, and it was necessary to cool externally at first to control the reaction. After refluxing ten hours, the yellow filtrate was concentrated and the product fractionated in vacuum. The yield of 2,5-dichloro-3-thenyl bromide, b. p. 104.5–106° (4 mm.), $n^{20}D$ 1.6177, was 84.7 g. (0.345 mole, 69%).

*Anal.* Calcd. for $C_5H_3BrCl_2S$: S, 13.03. Found: S, 12.92.

The hexamethylenetetramine salt of 2,5-dichloro-3-thenyl bromide was obtained in 90% yield; recrystallized from methanol, m. p. 178–80° (dec.).

*Anal.* Calcd. from $C_{11}H_{15}N_4BrCl_2S$: S, 8.30. Found: S, 8.56.

**2,5-Dichloro-3-thenoic Acid.**—Steam distillation of a solution of 42 g. (0.109 mole) of the hexamethylenetetramine salt of 2,5-dichloro-3-thenyl bromide yielded a small amount of oil having an almond odor. The crude aldehyde was oxidized with silver oxide, and the crude acid crystallized from a 50:50 water–ethanol mixture, yielding 2.3 g. (0.0125 mole, 11.4%) of 2,5-dichloro-3-thenoic acid, which melted at 146.5–147.5°.[12]

**Dimethylaminoethylaminopyridine Derivatives.**—The syntheses of all of the antihistaminic compounds were conducted in essentially the same manner. The procedure for the preparation of the 3-thenyl derivative is described, and the physical constants and yields of all are tabulated in Table I. To a stirred suspension of 3.12 g. (0.08 mole) of sodamide in 50 ml. of dry tolene was added dropwise 12 g. (0.073 mole) of 2-dimethylaminoethylaminopyridine.[13] The mixture was refluxed for two hours, cooled to 50°, and 21 g. (0.12 mole) of 3-thenyl bromide was added dropwise. When the reaction subsided, the brownish-orange mixture was refluxed one-half hour longer, cooled, and poured into 150 ml. of water. Three layers formed, water, toluene and a black oil which contained none of the desired product, but was probably the quaternary salt resulting from the reaction of 3-thenyl bromide with the dimethylamine group. The toluene layer was separated, extracted with 5% hydrochloric acid, and the hydrochloric acid layer saturated with potassium carbonate. The free base was extracted with ether, dried and fractionated. In this way, 6 g. (0.023 mole, 31.4%) of a yellow oil boiling at 169–172° (1 mm.) was obtained.

TABLE I

PROPERTIES OF THE 3-THENYL-DIMETHYLAMINOETHYLAMINOPYRIDINES

| Compounds | Yield, % | B. p., °C. (1 mm.) | $n^{20}D$ | Formula | Anal. S, % Calcd. | Found |
|---|---|---|---|---|---|---|
| I | 31.4 | 169–172 | 1.5915 | $C_{14}H_{19}N_3S$ | 12.27 | 12.24 |
| II | 28 | 156–158 | 1.5950 | $C_{14}H_{18}N_3ClS$ | 10.84 | 11.33 |
| III | 20 | 177–179 | 1.6590 | $C_{14}H_{18}N_3BrS$ | 9.42 | 9.14 |
| IV | 38 | 179–181 | 1.5968 | $C_{14}H_{17}N_3Cl_2S$ | 9.71 | 10.01 |

The monohydrochloride of N,N-dimethyl-N'-(3-thenyl-)-N'-(2-pyridyl)-ethylenediamine was prepared in the following manner from a larger quantity of the base.[14] 106 g. of the free base was dissolved in 500 ml. of isopropyl alcohol and 34 ml. of concentrated hydrochloric acid was added. After shaking, the reaction mixture was allowed to crystallize. After thorough cooling in an ice–methanol mixture, the salt was collected and washed on the filter with low-boiling petroleum ether. The salt was dried in an oven at 70°, giving 91 g. of a white solid, m. p. 169.5–170°. A second crop of 13 g. was obtained by concentrating the filtrate, making the total yield 86%.

*Anal.* Calcd. for $C_{14}H_{20}N_3SCl$: Cl, 11.93; S, 10.76; N, 14.12. Found: Cl, 11.80; S, 10.79; N, 13.97.

**Acknowledgment.**—The authors gratefully acknowledge the coöperation and financial support of this research by the Sterling–Winthrop Research Institute.

## Summary

Four new compounds containing the 3-thenyl and halogen-substituted 3-thenyl radical, have been synthesized for testing for antihistaminic activity.

The peroxide-catalyzed reaction of N-bromosuccinimide with halogen substituted 3-methylthiophenes has been shown to give good yields of the corresponding 3-thenyl bromides.

Several new 3-substituted thiophene derivatives, containing the methyl, bromomethyl, aldo and carboxyl group in the 3-position, have been synthesized and characterized.

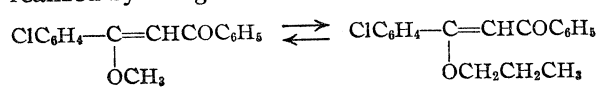
# β-Alkoxy Derivatives of 2-Chlorochalcone



BY CHARLES L. BICKEL

Earlier reports from this Laboratory described the preparation of β-methoxy-2-chlorochalcone either by the addition of methanol to *o*-chlorophenylbenzoylacetylene[1] or by the action of methanol and potassium hydroxide on α-bromo-2-chlorochalcone.[2] β-Ethoxy-2-chlorochalcone and

β-propoxy-2-chlorochalcone have now been prepared by the addition of the appropriate alcohol to *o*-chlorophenylbenzoylacetylene.

In the presence of potassium hydroxide, these alkoxy derivatives can be converted one into the other by the use of the proper alcohol as solvent and reagent. For example, β-methoxy-2-chlorochalcone is converted into β-propoxy-2-chlorochalcone when treated with propanol-1 and potassium hydroxide, and the reverse reaction is realized by using methanol and the base.

These interconversions bear a resemblance to the interchange of esters but a closer examination indicates that the resemblance is only superficial. Ester interchange is catalyzed by a trace of a base while the interconversions herein described may proceed in the presence of a quantity of base exceeding one equivalent of the β-alkoxy compound. The reaction corresponding to the saponification of an ester, the liberation of the enol form of the β-diketone, apparently does not occur since the compound thus liberated would be cleaved by the base. Moreover, ester interchange is catalyzed by acids but β-alkoxychalcones are converted cleanly into β-diketones by the action of acids.

This investigation was assisted by a generous grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

## Experimental

**Preparation of β-Alkoxy Derivatives from *o*-Chlorophenylbenzoylacetylene.**—The preparation of β-methoxy-2-chlorochalcone from *o*-chlorophenylbenzoylacetylene appeared in an earlier paper.[1] Application of the same general procedure gave the ethoxy and propoxy derivatives.

β-Ethoxy-2-chlorochalcone is extremely soluble in ether, appreciably soluble in low-boiling petroleum ether, crystallizes as stout colorless prisms and melts at 39°.

*Anal.* Calcd. for $C_{17}H_{15}O_2Cl$: C, 71.2; H, 5.28. Found: C, 70.5, 71.0; H, 5.33, 5.22.

β-Propoxy-2-chlorochalcone is very soluble in ether, sparingly soluble in low-boiling petroleum ether, crystallizes as long fibrous white needles resembling glass wool and melts at 55°.

*Anal.* Calcd. for $C_{18}H_{17}O_2Cl$: C, 71.8; H, 5.71. Found: C, 71.5; H, 5.77.

Each of the above new compounds was converted quantitatively into *o*-chlorodibenzoylmethane by concentrated hydrochloric acid.[2]

**Interconversion of β-Alkoxy Compounds.**—The same general procedure was employed in all cases and can be illustrated by the following conversion of β-methoxy-2-chlorochalcone into β-propoxy-2-chlorochalcone.

A solution of 20 g. of the methoxy compound in 50 ml. of propanol-1, containing 1.5 g. of potassium hydroxide pellets, was heated on a steam-bath for five hours. The resulting solution was cooled, water added to a pronounced turbidity, the turbid mixture seeded with the propoxy compound and placed in the refrigerator until crystallization was complete. During the crystallization, water was added from time to time in sufficient quantity to produce turbidity but not enough to precipitate the product as an oil. The solid was filtered, washed with a cold mixture of propanol and water, and then washed thoroughly with water. The dry product weighed 19 g. and melted at 53–55°, recrystallization from ether and petroleum ether giving 18.5 g. of pure white needles melting at 55°.

The yields in the conversions varied from 60 to 90%. The highest yields were realized in the preparation of the methoxy compound, undoubtedly due to its higher melting point and lower solubility; the lowest yield was obtained in the preparation of the ethoxy compound which is very low melting and has a marked tendency to separate as an oil. However, in each case the residual oily product was converted into *o*-chlorodibenzoylmethane by the action of concentrated hydrochloric acid, indicating the absence of side reactions.

**Action of Potassium Hydroxide and Methanol on the Methoxy Compound.**—In order to test the action of an excess of potassium hydroxide on an alcoholic solution of the alkoxy derivatives, a solution containing 5.00 g. of β-methoxy-2-chlorochalcone, 1.5 g. of potassium hydroxide pellets and 50 ml. of methanol was refluxed for ten hours. A recovery of 4.95 g. of the starting material was realized.

**Action of Potassium Hydroxide and Methanol on *o*-Chlorodibenzoylmethane.**—A solution containing 5 g. of *o*-chlorodibenzoylmethane, 1.5 g. of potassium hydroxide and 50 ml. of methanol was refluxed for ten hours. The extent of cleavage was about 50%, both benzoic acid and *o*-chlorobenzoic acid appearing in the cleavage products.[2]

## Summary

The interconversion of certain β-alkoxy derivatives of 2-chlorochalcone is reported.

# Mass Spectra of Some Cyclic and Straight Chain Fluorocarbons[1]

BY FRED L. MOHLER, EVELYN G. BLOOM, J. H. LENGEL AND C. E. WISE

The Mass Spectrometry Section of the Bureau of Standards has measured the mass spectra of some pure fluorocarbons prepared by George H. Cady of the Chemistry Department of the University of Washington.[1a] This paper presents these measurements in comparison with the mass spectra of the corresponding hydrocarbons. Tables of the detailed mass spectral data have been published in the Catalog of Mass Spectral Data.[2]

## Experimental

Mass spectra were obtained with a 180° Consolidated mass spectrometer which has been described in detail elsewhere.[3] Recommended procedures were followed in obtaining the spectra except that it was necessary to use a magnet current in excess of the rated current to record the ions of high molecular weight. A magnet current of 1.3 amperes was used in the range from molecular weight 50 up to a value exceeding the molecular weight of the molecule. Mass spectra were measured with ionizing potentials of 50 volts and 70 volts but only the 70-volt spectra are reported here. The temperature of the ionization chamber was automatically maintained at 245° and the electron current to the collector (catcher) was automatically held at 9 microamperes.

Relative intensities in the mass spectrum are expressed on a scale of the peak of maximum height taken as 100 and peaks as small as 0.01 can be detected. The sensitivity is commonly expressed in terms of the current at the maximum peak in arbitrary units divided by the pressure in the gas reservoir. The ratio of this sensitivity to the sensitivity to normal butane at $43^+$ gives a value independent of the arbitrary units used and it is this relative sensitivity that is given here. The resolving power of our mass spectrometer was not sufficient to resolve completely unit mass differences beyond mass 150. This introduces a little uncertainty in reading the mass peaks of the heavier ions from cyclo-$C_5F_9H$.

The boiling points of the six fluorocarbons measured are listed in Table I. The first three of these compounds were carefully separated from impurities using an 82 theoretical plate fractionating column. The same column was used for cyclo-$C_5F_9H$ but traces of impurities probably remained. The last two compounds are of good quality but inferior to the first three. The mass spectrometer analysis showed no recognizable impurities in any of the perfluoro compounds. In the spectrum of cyclo-$C_5F_9H$ there is a small peak, 0.19% of the maximum peak, near mass 250. This could be $C_5F_{10}^+$ or $C_5F_{10}H^+$. The spectrum shows that it cannot be cyclo-$C_5F_{10}$ but a trace of a perfluoropentene is possible. Another possibility is that it is $C_5F_{10}H^+$ from $C_5F_{11}H$. This compound makes an unknown but probably small contribution to the pattern recorded in Table III.

TABLE I

BOILING POINTS OF FLUOROCARBONS

| Number | Substance | Boiling point, °C. |
|---|---|---|
| 1 | Cyclo-$C_5F_{10}$ | 22.5 |
| 2 | $n$-$C_5F_{12}$ | 29.3 |
| 3 | $i$-$C_5F_{12}$ | 30.1 |
| 4 | Cyclo-$C_5F_9H$ | 37.8 to 38.2 |
| 5 | Cyclo-$C_6F_{12}$ | 51 (sublimes) |
| 6 | $n$-$C_7F_{16}$ | 82.4 to 82.6 |

TABLE II

MASS SPECTRA OF CYCLOHEXANES

Sensitivity relative to $43^+$ of $n$-butane: $C_3F_5^+$, 1.37

| $H_4$ | 1.35 | $F_4$ | 1.54 | $C^-$ | | $C^-$ | |
| $H_3$ | 3.34 | $F_3$ | 0.57 | $H_3$ | 5.35 | $F_3$ | 70.3 |
| $H_2$ | 2.23 | $F_2$ | .36 | $H_2$ | 0.42 | $F_2$ | 5.15 |
| | | | | H | .08 | F | 21.8 |
| | | | | C | .05 | C | .03 |

The hydrocarbon mass spectra given for comparison with the fluorocarbons were obtained with National Bureau of Standards Samples of purity 99.85% and better. The tables omit some smaller peaks of less than 2% of the maximum peak.

## Results

When mass spectra of fluorocarbons are tabulated in the order of increasing or decreasing molecular weight the ions with different numbers of carbon atoms and of fluorine atoms alternate in a rather confusing disorder. For convenient comparison with the more familiar hydrocarbon spectra the ions containing the same number of carbon atoms have been grouped together in the following tables.

**Cyclohexanes.**—Table II gives the mass spectra of cyclohexane and the perfluoro compound. In the hydrocarbon molecule the molecule ion (parent ion) and ions $C_5H_9^+$, $C_4H_8^+$, $C_3H_5^+$ and $C_2H_3^+$ are relatively abundant. It is of interest that $CH_3^+$ has about the same intensity in cyclics as in molecules containing $CH_3$ terminal radicals.

In the fluorinated compounds the parent ion peaks are always very small indicating that the more probable ionization process is removal of $F^-$

rather than an electron. Studies[4] of mass spectra and appearance potentials for simpler compounds such as carbon tetrafluoride support this view. Ions $C_6F_{11}^+$, $C_5F_9^+$, $C_4F_7^+$, $C_3F_5^+$, $C_2F_4^+$ and $CF_3^+$ are the most abundant ions in each carbon group.

**Cyclopentanes.**—Table III gives mass spectra of three cyclopentanes. There is a marked similarity between cyclo-$C_5F_{10}$ and cyclo-$C_6F_{12}$. The same ions $C_5F_9^+$, $C_4F_7^+$, $C_3F_5^+$, $C_2F_4^+$ and $CF_3^+$ are abundant in both spectra although in the cyclopentane $CF^+$ is greater than $CF_3^+$. There is a different type of similarity between the two hydrocarbons. In these the largest peaks in the first four carbon groups are the molecule ion and molecule ions which have lost $CH_3$, $C_2H_4$ and $C_3H_7$. As a result the larger peaks in the two spectra are different.

Substituting one hydrogen in the fluoro compound doubles the complexity of the spectrum and it is convenient to list the ions in two columns, one containing perfluoro ions and the other containing ions with one hydrogen (Table III). As noted above there are two sources of experimental uncertainty in the data on cyclo-$C_5F_9H$. A trace of $C_5F_{10}^+$ gives an unknown contribution and insufficient resolution gives some uncertainty in the height of peaks containing an H atom when there are seven or more fluorine atoms. The absence of $C_4F_7^+$ in the cyclo-$C_5F_9H$ spectrum shows that the $C_5F_{10}^+$ is not from cyclo-$C_5F_{10}$.

Table III shows a very close parallelism between ions of $C_5F_9H$ containing H and the corresponding ions of cyclo-$C_5F_{10}$. The occurrence of $C_3F_6H^+$ but no ion $C_3F_7^+$ from cyclo-$C_5F_{10}$ is an exception. Another exception is the fact that $CF^+$ is large but $CH^+$ is small. This is not surprising however as the $CH^+$ peak is of the same magnitude as is found in all hydrocarbons.

The perfluoro ions of cyclo-$C_5F_9H$ do not correspond closely to the ions of $C_5F_{10}$. The absence of ions $C_5F_9$ and $C_4F_7$ is a striking characteristic of the $C_5F_9H$ spectrum. It is suggestive that the abundance of $CF_3^+$ from $C_5F_9H$ is almost four times the abundance of $CF_2H^+$ for this is the *a priori* probability of finding H missing or present on one of the C atoms of cyclo-$C_5F_9H$. The chance of finding H missing or present on two adjacent carbon atoms is 3 to 2 while the ratio of $C_2F_4^+$ to $C_2F_3H^+$ is 2.52 to 2. In ions with more than two carbon atoms there is no evidence for such a relation.

**Normal and Isopentanes.**—Table IV shows the mass spectra of the normal pentanes and the isopentanes. In both the perfluoro compounds $CF_3^+$ is by far the largest peak which is quite unlike the hydrocarbon spectra. The difference in the $C_3F_7^+$ peaks is the most conspicuous difference in the perfluoro spectra while the $C_4H_9^+$ peaks are best for distinguishing the hydrocarbons. The largest peak in each carbon group of perfluoro-*n*-

pentane is given by losing F, $CF_5$, $C_2F_5$, $C_3F_7$ and $C_4F_9$.

**Normal Heptane.**—Table V gives the mass spectra of the *n*-heptanes. Again as in *n*-pentane the largest peak in each carbon group of the fluorocarbon comes from losing F, $CF_5$, $C_2F_5$, $C_3F_7$, $C_4F_9$ and in addition $C_5F_{11}$ and $C_6F_{13}$. It was noted above that the perfluoro cyclics gave identical ions rather than losing identical masses in the dissociation. The ion $C_7F_{15}^+$ of mass 369 is probably the heaviest ion ever recorded on this type of mass spectrometer. The perfluoro-*n*-heptane, like the perfluoropentanes, differs from the hydrocarbon in that ionization by loss of $CF_3$ is very improbable and production of $CF_3^+$ most probable.

**Metastable Transitions.**—Mass spectra usually show some small diffuse peaks which are in general at non-integral masses. These arise from ions which dissociate after they have traversed the ion accelerating field and thus have less than the full kinetic energy of the initial ion before dissociation.[5] The apparent mass $m_a$ of these ions is related to the initial mass $m_i$ and the final mass $m_f$ by the equation

$$m_a = m_f^2/m_i$$

A survey of metastable ions in hydrocarbon spectra[6] shows that metastable transition peaks are only observed when both the initial and final ions give relatively large peaks.

The same phenomenon is observed in fluorocarbons and Table VI lists the observed metastable transitions. These are all small peaks amounting to a few tenths of a per cent. of the maximum peak at the most. The table shows that these transitions frequently recur in different compounds and that only two types of transition occur, losing CF and losing $CF_2$. The three metastable transitions found in cyclo-$C_5F_9H$ correspond to the three found in cyclo-$C_5F_{10}$ with H substituted for one of the fluorine atoms in both the initial and final ions. There is no correspondence between these transitions and the metastable transitions found in the corresponding hydrocarbons.

TABLE VI

METASTABLE TRANSITIONS IN FLUOROCARBONS

| Apparent mass | Transition | Compounds showing transition |
|---|---|---|

| 59.5 | $C_3F_4H^+ \rightarrow C_2F_3H^+ + CF$ | Cyclo-$C_5F_9H$ |
| 78.3 | $C_4F_6H^+ \rightarrow C_3F_4H^+ + CF_2$ | Cyclo-$C_5F_9H$ |
| 124.7 | $C_5F_8H^+ \rightarrow C_4F_6H^+ + CF_2$ | Cyclo-$C_5F_9H$ |

## Conclusion

No difficulties were encountered in obtaining spectra of these fluorocarbons and the experiments indicate that the mass spectrometer can be very useful in analysing fluorinated compounds up to and including heptanes. This will require accumulating data on mass spectra of pure fluorocarbons. The Mass Spectrometry Section of the Bureau of Standards will be glad of an opportunity to analyse any new fluorocarbons that may be made. An advantage of this method of analysis is that very small quantities, of the order of a milligram, are sufficient for full sensitivity.

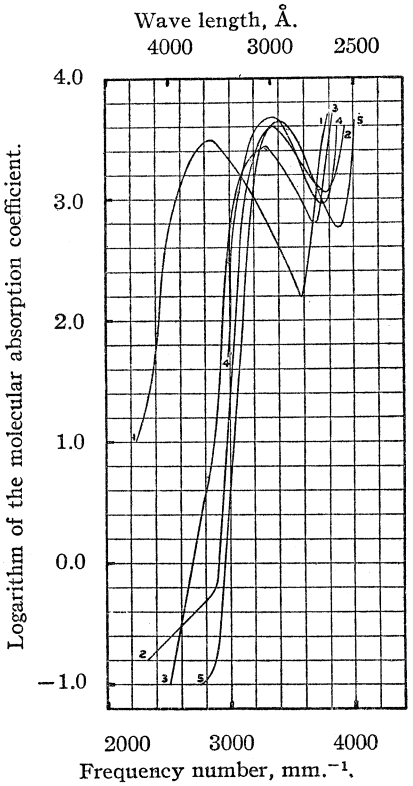
# The Absorption Spectra of the Aminopyridines

BY LEIGH C. ANDERSON AND NELSON V. SEEGER

A study has been made of the ultraviolet absorption of the three aminopyridines and of some of their derivatives in order to obtain data which might be used to indicate their structure. Curves for the quantitative absorption of ether solutions of 2-aminopyridine, 3-aminopyridine, 2-(methylamino)-pyridine, 2-(dimethylamino)-pyridine and 1-methyl-2-pyridoneimine are presented in Fig. 1.



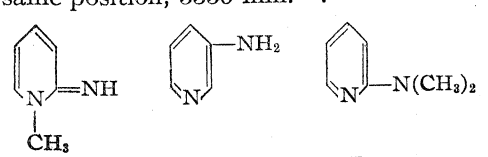


Fig. 1.—Absorption in ether solution of: 1, 1-methyl-2-pyridone-imine; 2, 3-aminopyridine; 3, 2-(dimethylamino)-pyridine; 4, 2-(methylamino)-pyridine; 5, 2-aminopyridine.

1-Methyl-2-pyridoneimine has a pyridone structure (I) and its ether solution is yellow in color with one broad absorption band at 2850 mm.$^{-1}$. 3-Aminopyridine and 2-dimethylaminopyridine can possess only a pyridine structure (II, III) and their ether solutions are colorless and have the peaks of the absorption bands at approximately the same position, 3350 mm.$^{-1}$.

I II III

The absorption curve of 2-aminopyridine has only the one broad band at 3350 mm.$^{-1}$ which is characteristic of the pyridine ring structure. If 2-aminopyridine existed in two tautomeric forms, two bands might be expected, one for the pyridone imine structure at approximately 2850 mm.$^{-1}$ and one for the pyridine structure at approximately 3350 mm.$^{-1}$. The absorption curves were determined for solutions having concentrations of nearly 40 g. per liter, yet only one band in the pyridine absorption region appeared. The conclusion drawn from these observations is that 2-aminopyridine possesses the pyridine structure exclusively and does not tautomerize in ether at room temperature.

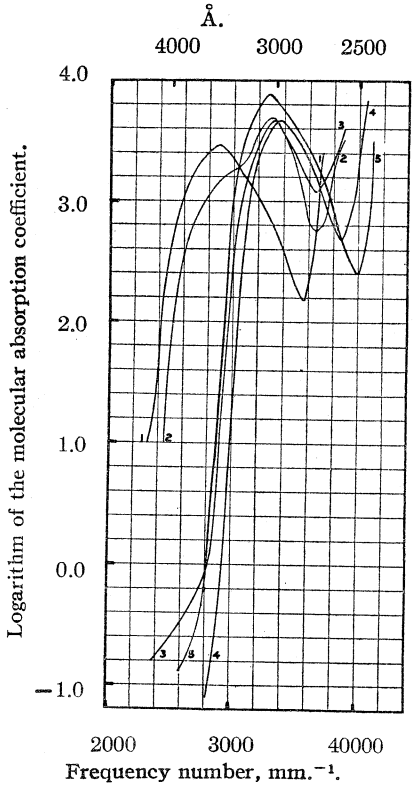
The effect on the absorption curve of substituting a methyl group for an amino hydrogen is only minor. This is illustrated by the absorption curves of 2-(methylamino)-pyridine and 2-(dimethylamino)-pyridine. There is only a slight change in position of the peak and height of the band of 2-(methylamino)-pyridine when compared with 2-aminopyridine.

The possibility of tautomerization of 2-aminopyridine in a water type solvent was studied by determining the curve of the absorption spectrum of this compound in a dioxane–water solution as given in Fig. 2. In this case, 1-methyl-2-pyridoneimine in pure dioxane and 3-aminopyridine in a dioxane–water solution (72%:28% by volume) were used as reference compounds. The curves of 2- and 3-aminopyridines are very similar, both possessing the single broad band as was found in ether solution, indicating that only the pyridine structure is present.

In order to explain the fact that the dipole moment of 2-aminopyridine decreased with increasing temperature, Goethals[1] suggested that the equilibrium between tautomeric pyridine and pyridone forms was altered by changes in temperature. To study the supposed effect of temperature, absorption curves of 2-aminopyridine in dioxane–water solution were obtained at 65 and 80° by placing the absorption cells in an electrically-heated aluminum block. However, the absorption curves at these temperatures were found to be identical with the curves determined at room temperature.

2-Aminopyridine does not diazotize readily in dilute acid solutions. Since there appeared to be a possibility that tautomerization of 2-aminopyridine to the pyridoneimine structure would render the amine difficult to diazotize, the absorption curves of 2-aminopyridine in dilute sulfuric acid solutions were determined in order to attempt to establish the structure of 2-aminopyridine under

(1) Goethals, *Rec. trav. chim.*, **54**, 304 (1935).



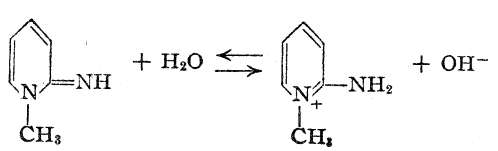


Fig. 2.—1, 1-Methyl-2-pyridoneimine in dioxane; 2, 1-methyl-2-pyridoneimine in 72%:28% dioxane–water; 3, 3-aminopyridine in 72%:28% dioxane–water; 4, 2-aminopyridine in 72%:28% dioxane–water at 25°, 65° and 80°; 5, 2-aminopyridine sulfate in 72%:28% dioxane–water.

conditions of diazotization. In Fig. 2, the absorption curve of 2-aminopyridine sulfate in dioxane–water solution (72%:28%) is given. It was found that the acid solutions have identical absorption curves over a wide range of acid concentration. No evidence of tautomerization can be observed from these curves since they contain only one absorption band characteristic of 2-aminopyridine. The curves of 2-aminopyridine in neutral and acid solutions are similar, although the curve in acid solution is slightly higher and broader. This fact has also been pointed out by Ley and Engelhardt.[2]

1-Methyl-2-pyridoneimine which is yellow, dissolves in water to form 1-methyl-2-aminopyridinium hydroxide which is colorless and strongly basic. The absorption curve of 1-methyl-2-pyridoneimine in 72%:28% dioxane–water shows clearly that in this solution an equilibrium is established as indicated by the following equation:

(2) Ley and Engelhardt, *Z. physik. Chem.*, **74**, 59 (1910).

This equilibrium is shifted to the right on the addition of more water to the solution in which case the color gradually disappears and the solution becomes more basic. The absorption band in the region of 2850 mm.$^{-1}$ appears to be a measure of the amount of 1-methyl-2-pyridoneimine present in the solution while the band at 3300 mm.$^{-1}$ appears to be a measure of the amount of pyridinium hydroxide. It will be noted that the latter band corresponds to the bands of 2- and 3-aminopyridines.

The absorption curve of 1-methyl-4-pyridoneimine (Fig. 3) was determined in 90%:10% dioxane–water solution because the compound was quite insoluble in pure dioxane. In the dioxane–water mixture the absorption curve of this compound shows the existence of an equilibrium similar to that found for the corresponding 1-methyl-2-pyridoneimine.

The absorption curves of the 2- and 4-compounds are very similar in shape but occur at different positions. The band for 1-methyl-2-pyri-

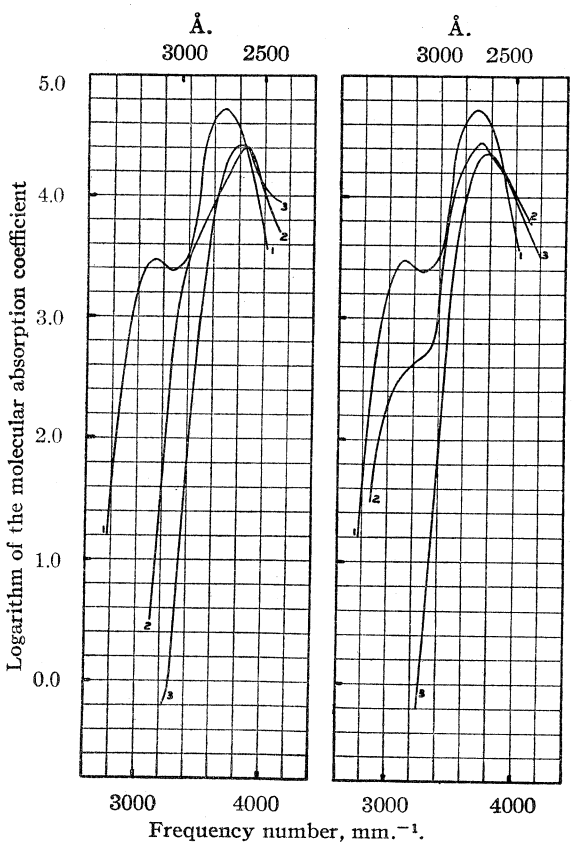

Fig. 3.—1, 1-Methyl-4-pyridoneimine in 90%:10% dioxane–water; 2, 4-(dimethylamino)-pyridine in 72%:28% dioxane–water; 3, 4-aminopyridine in 72%:28% dioxane–water.

Fig. 4.—1, 1-methyl-4-pyridoneimine in 90%:10% dioxane–water; 2, 1-methyl-4-pyridoneimine in 72%:28% dioxane–water; 3, 4-aminopyridine sulfate in 72%:28% dioxane–water.

doneimine lies at 2850 mm.$^{-1}$, whereas that for 1-methyl-4-pyridoneimine lies at 3150 mm.$^{-1}$, while the bands at 3300 mm.$^{-1}$ and 3700 mm.$^{-1}$ correspond, respectively, to the 2- and 4-aminopyridine structure.

Evidence for the structure of 4-aminopyridine has been determined in a manner similar to that used in the case of 2-aminopyridine. The curves for 4-aminopyridine and 4-(dimethylamino)-pyridine given in Fig. 3 were determined in 72%:28% dioxane–water solution due to the insolubility of 4-aminopyridine in ether. The curve for 4-aminopyridine has only a single band corresponding to the band for 4-(dimethylamino)-pyridine which is unable to tautomerize. From this evidence, it may be concluded that only the pyridine ring structure can be assigned to 4-aminopyridine, no evidence for tautomerization being shown.

The curve for the absorption spectrum of 4-aminopyridine sulfate in dioxane–water (72%:28%) (Fig. 4) indicates that sulfuric acid does not induce tautomerization of the 4-aminopyridine. Only the one band for the 4-substituted pyridine derivatives is observed, there being no bands corresponding to the 4-pyridoneimine structures. From these data it would appear that the difficulty in diazotizing 4-aminopyridine in acid solution is not due to a migration of an amine hydrogen to the ring nitrogen.

## Experimental

The absorption spectral data were obtained by methods which have been described.[3] The dioxane was fractionated by successive crystallizations and was finally distilled. All solvents were optically clear in the spectral region investigated.

**2-Aminopyridine.**—This amine was obtained by the action of ammonia on 2-bromopyridine.[4] After several recrystallizations from benzene–petroleum ether, it melted at 57–58°.

**1-Methyl-2-pyridoneimine.**—This compound resulted from the action of a concentrated solution of sodium hydroxide on the methiodide of 2-aminopyridine.[5] The product was extracted with ether and purified by distillation under reduced pressure; b. p. 108° (16 mm.).

**2-(Methylamino)-pyridine.**—This substance was prepared by the action of a concentrated aqueous methylamine solution on 2-bromopyridine in a sealed Pyrex tube heated to 150° for ten hours. After addition of alkali, the amine was extracted with ether and distilled; b. p. 200–201°. The picrate melted at 190°.

**2-(Dimethylamino)-pyridine.**—This compound, obtained by the action of dimethylamine on 2-bromopyridine[6] was purified by distillation; b. p. 196° (740 mm.). The picrate, recrystallized from absolute alcohol, melted at 182°.

**3-Aminopyridine.**—This amine was prepared by the action of ammonia on 3-bromopyridine using $CuSO_4 \cdot 5H_2O$ as a catalyst.[7] The product was extracted with ether and recrystallized from a benzene–petroleum ether solution; m. p. 64°.

**4-Aminopyridine.**—This substance was obtained by heating crude 4-pyridylpyridinium dichloride with concentrated aqueous ammonia.[8] After recrystallizing several times from water and treatment with norite, the product melted at 150°.

**1-Methyl-4-pyridoneimine.**—This imine was prepared by the action of concentrated sodium hydroxide on the methiodide of 4-aminopyridine. The product was extracted with hot benzene and the solvent evaporated; m. p. 150–151°. It liquefies in the air since it is very hygroscopic and soon becomes red in color.

**4-(Dimethylamino)-pyridine.**—This compound was obtained by heating crude 4-pyridylpyridinium dichloride with a concentrated aqueous solution of dimethylamine and was recrystallized from benzene; m. p. 114°.[9] The picrate melted at 204°.

## Summary

1. Curves for the absorption of visible and ultraviolet light by solutions of the aminopyridines and some of their derivatives in ether, dioxane, water and acid are presented.

2. No evidence was found for the presence of a pyridone structure for the 2- and 4-aminopyridines in the solutions studied.

3. The absorption spectra indicate the presence of tautomeric equilibria between pyridine and pyridone forms of 1-methyl-2- and 1-methyl-4-pyridoneimines in dioxane–water solutions.

# The Absorption Spectra of Some Methylpyridine Derivatives

BY LEIGH C. ANDERSON AND NELSON V. SEEGER

The structures of the 2- and 4-methylpyridines have not been definitely determined and one finds both the pyridine and pyridone–methide structures used for 2-methylpyridine. Tschitschibabin[1] postulated that both the 2- and 4-isomers existed as tautomeric mixtures of the two forms. Cartwright and Errera[2] presented evidence based on infrared absorption spectral curves of the 2- and 3-methylpyridines which indicated the existence of only the pyridine structure for the 2-isomer.

In order to obtain data which might be of value in determining the structure of 2-methylpyridine, the ultraviolet absorption curve of the compound was compared with that of 1-methyl-2-pyridonemethide in ether solution. The absorption curves are shown in Fig. 1. The pyridonemethide has two distinct bands at 2370 mm.$^{-1}$ and at 3620 mm.$^{-1}$ while 2-methylpyridine has only one band at 3850 mm.$^{-1}$. One would expect 2-methylpyridine to have an absorption curve with two bands if it consists of a tautomeric mixture of the 2-pyridonemethide and 2-methylpyridine forms and since it has only one band in the region where pyridine absorbs light, the conclusion must be drawn that only the pyridine ring structure can be assigned to it.

In the preceding paper, it was shown that 1-methyl-2-pyridoneimine reacted with water to give a quaternary ammonium hydroxide and there was a corresponding change from the pyridone–imine absorption type of curve to that of pyridine. The absorption curves of 1-methyl-2-pyridone in ether, hexane, 72% dioxane–28% water, and pure water are presented in Fig. 1. These curves show absorption in the same spectral region. Apparently there is little tendency to form the quaternary compound and this is also shown by the fact that a water solution of 1-methyl-2-pyridone reacts neutral to litmus. There is comparatively little change in absorption in these different types of solvent. There is a pronounced change in absorption, however, when the

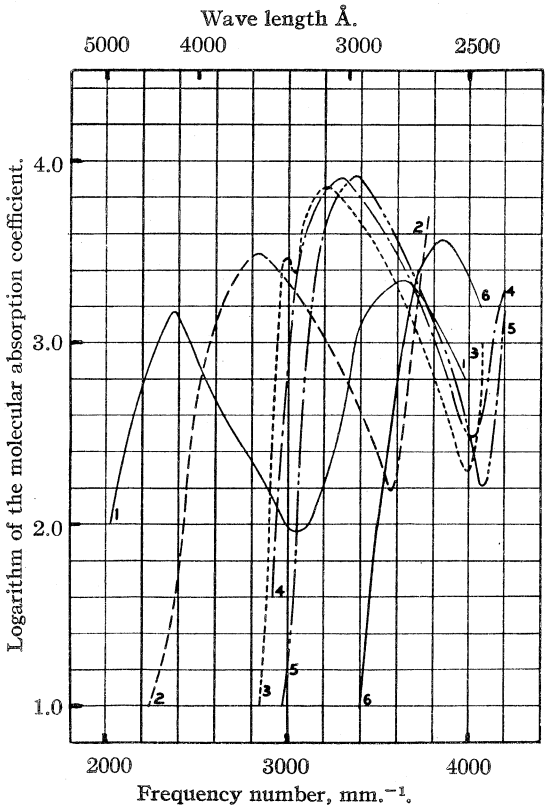

Fig. 1.—1, 1-Methyl-2-pyridonemethide in ether; 2, 1-methyl-2-pyridoneimine in ether; 3, 1-methyl-2-pyridone in ether and hexane; 4, 1-methyl-2-pyridone in 72%:28% dioxane–water; 5, 1-methyl-2-pyridone in water; 6, 2-methylpyridine in ether.

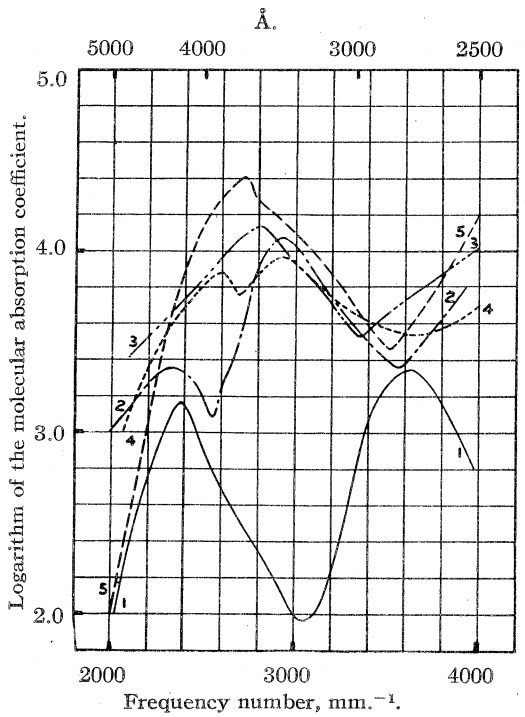

Fig. 2.—Absorption of ether solution of: 1, 1-methyl-2-pyridonemethide; 2, 1-methyl-2-pyridone-phenylmethide; 3, 1-methyl-2-pyridone-diphenymethide; 4, 1-methyl-4-pyridone-phenylmethide; 5, 1-methyl-4-pyridone-diphenylmethide.

(2) Cartwright and Errera, *Compt. rend.*, **200**, 914 (1935).

ketonic oxygen is replaced by an imine group and a still more marked change when the oxygen is replaced by a methylene group.

Figure 2 presents the curves of the following compounds wherein the methide hydrogens of 1-methyl-2- and 1-methyl-4-pyridone methides have been replaced with phenyl groups.

The compound with two hydrogens on the methide group has two bands, one at the edge of the visible, the other in the ultraviolet. Each of the compounds having one hydrogen replaced by a phenyl group also has two absorption bands but they occur much closer to each other than in the unsubstituted compound, there being a shift of the ultraviolet band toward the visible and of the band in the visible region toward the ultraviolet. When both hydrogens of the methide group have been replaced, only one intense band is found. In Fig. 3 a comparison between the curves of 1-methyl-4-pyridonediphenylmethide and of diphenylquinomethane shows a very striking similarity. The maximum absorption for both compounds is in the same region, 2750 mm.$^{-1}$ for diphenylquinomethane and 2700 mm.$^{-1}$ for the pyridone. The intensities of the bands are also very similar.

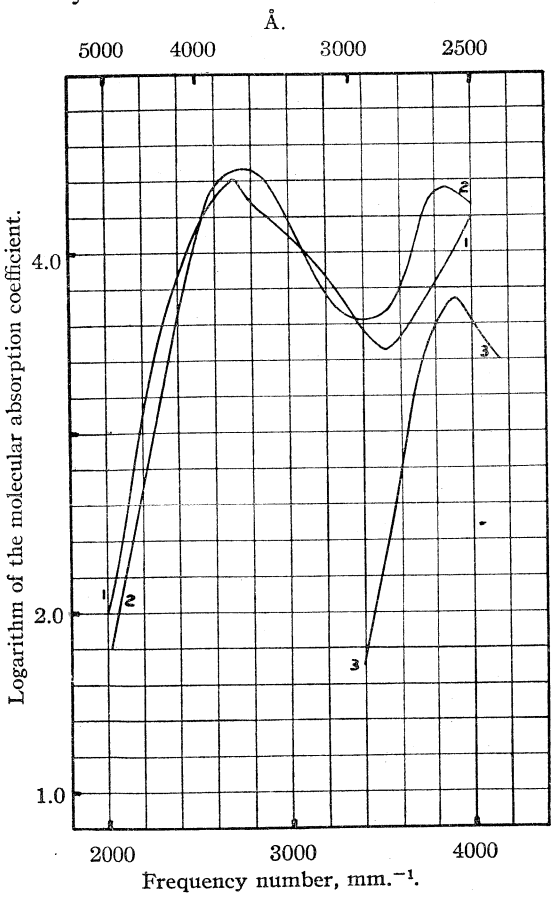

Fig. 3.—1, 1-Methyl-4-pyridone-diphenylmethide in ether; 2, diphenylquinomethane in ether; 3, 4-pyridyldiphenylcarbinol in dioxane.

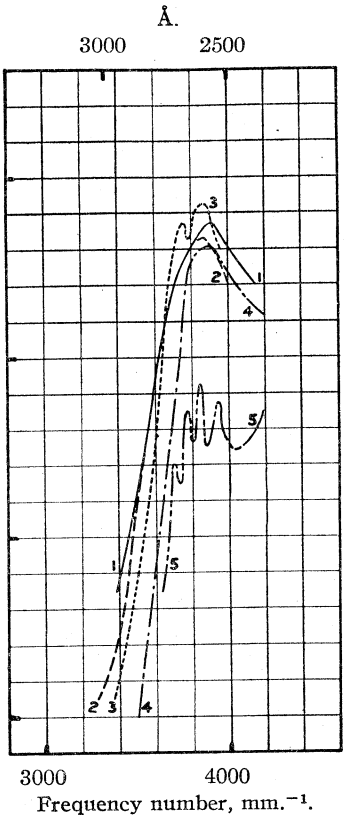

Fig. 4.—1, 4-Pyridyldiphenylcarbinol in dioxane; 2, 3-pyridyldiphenylcarbinol in ether; 3, 2-pyridyldiphenylcarbinol in ether; 4, pyridine in 72%:28% dioxane–water; 5, triphenylcarbinol in ether.

Figure 4 shows the curves of triphenylcarbinol, 2-pyridyldiphenylcarbinol and 3-pyridyldiphenylcarbinol in ether, 4-pyridyldiphenylcarbinol in dioxane, and pyridine in dioxane–water. Dioxane was used as a solvent for the 4-pyridyldiphenylcarbinol because the material was insoluble in ether. A comparison of the four carbinols shows that the replacement of a phenyl group by a pyridyl residue causes a considerable increase in the intensity of absorption. This increase is approximately the same regardless of the position of the pyridine substitution. The curves of the three pyridylcarbinols are strikingly similar to pyridine, the series of small bands in triphenylcarbinol being absent in the pyridylcarbinols except for the two peaks in 2-pyridyldiphenylcarbinol. Each of the pyridylcarbinols gives an intense red solution in concentrated sulfuric acid.

## Experimental

**2-Methylpyridine.**—Eastman Kodak Co. product was purified in the same manner as pyridine according to the method of Spiers and Wibaut[3]; b. p. 127°.

**1-Methyl-2-pyridonemethide.**—This compound was prepared by the action of concentrated potassium hydroxide on the methiodide of 2-methylpyridine[1]; it is a red oil which decomposes on distillation, even under reduced pressure.

(3) Spiers and Wibaut, *Rec. trav. chim.*, **56**, 579 (1937).

**1-Methyl-2-pyridone.**—This compound was prepared by the action of potassium ferricyanide on 1-methylpyridinium hydroxide according to the directions given in "Organic Syntheses"[4]; b. p. 250° (740 mm.).

**2-Pyridyldiphenylcarbinol.**—2-Pyridylmagnesium bromide, prepared by the method of Overhoff and Proost,[5] was added to an ether solution of benzophenone. The carbinol which resulted was recrystallized from alcohol; m. p. 103–104°.[6]

**1-Methyl-2-pyridone-diphenylmethide.**—2-Pyridyldiphenylmethane was prepared by the method of Tschitschibabin and Benewolenskaja.[7] It was recrystallized from a mixture of alcohol and water; m. p. 63°.

2-Pyridyldiphenylmethane was heated with methyl iodide in a sealed tube and the product was recrystallized from hot water; m. p. 222–224°. This methiodide upon treatment with concentrated potassium hydroxide solution gave 1-methyl-2-pyridone-diphenylmethide which crystallized from alcohol in long, dark red-violet needles; m. p. 147°.

**3-Pyridyldiphenylcarbinol.**—In order to prepare 3-pyridylmagnesium bromide, the procedure of Overhoff and Proost for the preparation of the 2-isomer had to be modified somewhat. A few drops of ethyl bromide were added to 8 g. of magnesium under 20 cc. of absolute ether. When the reaction had started, a mixture of 20 g. of redistilled Eastman 3-bromopyridine and 10 g. of ethyl bromide in 100 cc. of ether was added drop by drop with heating and constant stirring, a reddish brown precipitate being formed. The solution was boiled for two hours.

To obtain 3-pyridyldiphenylcarbinol, 36 g. of benzophenone in ether was added to the 3-pyridylmagnesium bromide solution and after some time the addition compound was decomposed with an ice-cold solution of ammonium chloride. The ether layer was extracted with dilute hydrochloric acid and the carbinol precipitated with ammonia. On recrystallization from ethyl acetate, the carbinol melted at 115–116°.

*Anal.* Calcd. for $C_{18}H_{15}ON$: N, 5.36. Found: N, 5.32.

The picrate of 3-pyridyldiphenylcarbinol was formed by adding a hot alcoholic solution of picric acid to a hot alcoholic solution of the carbinol; m. p. 195°.

*Anal.* Calcd. for $C_{18}H_{15}ON \cdot C_6H_3O_7N_3$: N, 11.42. Found: N, 11.46.

(5) Overhoff and Proost, *Rec. trav. chim.*, **57**, 184 (1938).

(6) Proost and Wibaut, *ibid.*, **59**, 971 (1940).

(7) Tschitschibabin and Benewolenskaja, *Ber.*, **61B**, 551 (1928).

**4-Pyridyldiphenylcarbinol.**—A mixture of 2- and 4-benzylpyridines was obtained by the action of benzyl chloride and pyridine according to the directions of LaForge.[8] Following the procedure of Tschitschibabin[9] this mixture was oxidized with permanganate to the 2- and 4-benzoylpyridines. For the preparation of 4-pyridyldiphenylcarbinol, previous investigators[7] used pure 4-benzoylpyridine. However, this requires a tedious separation of the mixture of 2- and 4-benzoylpyridines by means of the picrate. Therefore, in this work, the mixture of benzoylpyridines was added directly to phenylmagnesium bromide forming a mixture of 2- and 4-pyridyldiphenylcarbinols. The 2-pyridyldiphenylcarbinol dissolved readily in ether and the 4-isomer which is insoluble in ether was filtered off. After two recrystallizations from ethyl acetate, the melting point was 234–235°.

**1-Methyl-4-pyridonediphenylmethide.**—4-Pyridyldiphenylmethane was prepared by the method of Tschitschibabin and Benewolenskaja using gaseous hydrogen iodide to reduce 4-pyridyldiphenylcarbinol; m. p. 125°. To obtain the methiodide, 4-pyridyldiphenylmethane was heated with methyl iodide in a sealed tube and the product recrystallized from alcohol; m. p. 159–161°. The methiodide was treated with concentrated potassium hydroxide and 1-methyl-4-pyridonediphenylmethide was formed; recrystallization from alcohol gave yellow needles, m. p. 113°.

**1-Methyl-2- and 4-Pyridonephenylmethides.**—Each of these compounds was prepared according to the directions of Decker[10] by the addition of a concentrated solution of potassium hydroxide to the methiodides of 2- and 4-benzylpyridines.

## Summary

1. Quantitative absorption spectral data indicate that 2-methylpyridine possesses only a pyridine structure in ether solution.

2. The absorption spectrum curve for 1-methyl-4-pyridonediphenylmethide in ether solution is very similar to the curve for diphenylquinomethane.

3. Curves for 2-, 3- and 4-pyridyldiphenylcarbinols show the presence of a pyridine structure only.

# The Kinetics and Mechanism of the Uncatalyzed Alkylation of Phenol

BY HAROLD HART AND J. H. SIMONS

Although the alkylation of the aromatic nucleus has long been an important reaction to the organic chemist, there have been relatively few kinetic studies of the mechanism of this reaction. Ionic intermediates for this reaction have been postulated,[1,2] but some recent kinetic studies[3] on the hydrogen fluoride catalyzed alkylation of toluene with *t*-butyl chloride present strong evidence against any high energy intermediate for that reaction. These conclusions were based on the fact that various oxygen-containing (basic) promoters affected the rate only as a function of their concentration, and independent of the structure of the particular promoter, upon the retardation effect of hydrogen chloride, and upon the energy requirements for the reaction.

Following the discovery that phenols could be alkylated in the para-position with tertiary alkyl halides in the absence of any added catalysts[4,5]

we believed that it would be of interest to study the kinetics and mechanism of this reaction. A detailed study of the reaction has revealed several interesting facts which were not anticipated at the outset of the work.

It was found that the alkylation of phenol with *t*-butyl chloride is a homogeneous, quantitative reaction which proceeds at a measurable rate at convenient temperatures. The reaction could be readily followed by means of the increase in pressure due to the evolution of hydrogen chloride. Tertiary butyl chloride, *t*-amyl chloride, dimethylisopropylcarbinyl chloride and benzyl chloride were the halides used, and phenol and *p*-cresol were the phenols. The reactions were studied at several different temperatures in order to determine the activation energies. The effect of hydrogen chloride pressure, and of the diluents *p*-xylene, 1,4-dichlorobutane, ethylene dichloride, nitrobenzene and 1,4-dioxane was studied.

It is believed that the experimental results (a very high order rate dependency upon phenol concentration, low energies of activation, the lack of reactivity of anisole, and the very striking inhibitory power of dioxane) indicate the improbability of a simple ionic mechanism for this reaction, and a mechanism involving what has been termed the "amphoteric medium effect"[4] has been proposed which satisfactorily accounts for the experimental observations.

## Experimental

**Preparation of Materials.**—The phenol was Eastman Kodak Company material, which was fractionated at a pressure of approximately 100 mm. in a column packed with multi-turn glass helices, with approximately 20 theoretical plates. The phenol was further purified and samples prepared in the apparatus which is described below (see Fig. 1).

The *t*-butyl chloride was prepared from *t*-butyl alcohol and concentrated hydrochloric acid in the usual manner.[6] It was dried over anhydrous potassium carbonate and fractionated through a glass-helices packed column with approximately 30 theoretical plates. The middle cuts which boiled constantly at 52° and had a constant refractive index $n^{20}D$ 1.3850 were used in the sampling apparatus.

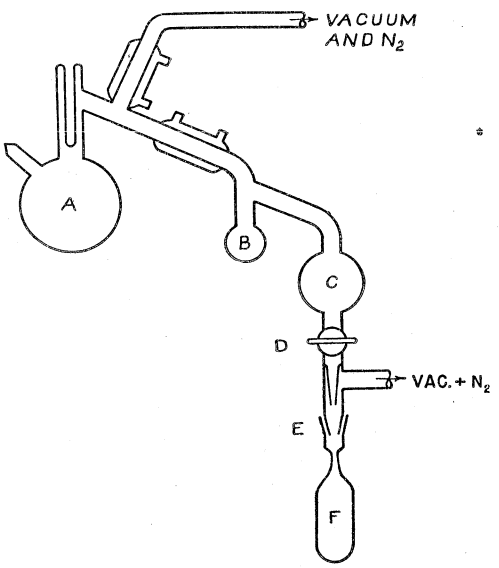

Fig. 1.—Diagram of the phenol sampling apparatus.

The *p*-cresol was Reilly Tar and Chemical Company's best grade of material. It was carefully fractionated in a manner similar to that used for the phenol. The *t*-amyl chloride was prepared and purified in a manner similar to that described above for *t*-butyl chloride. We are indebted to Dr. N. C. Cook for the dimethylisopropylcarbinyl chloride, which had been fractionated under reduced pressure in an efficient column.

Anhydrous hydrogen chloride was prepared by dropping concentrated hydrochloric acid on concentrated sulfuric acid, passing the gas through a concentrated sulfuric acid bubbler and a phosphorus pentoxide tube, and collecting the gas in a liquid air trap. The hydrogen chloride was degassed by alternate freezing, evacuation and thawing, and was then allowed to evaporate through (H) into bulb (B) in Fig. 2. It was stored there until used in the rate measurements as described below.

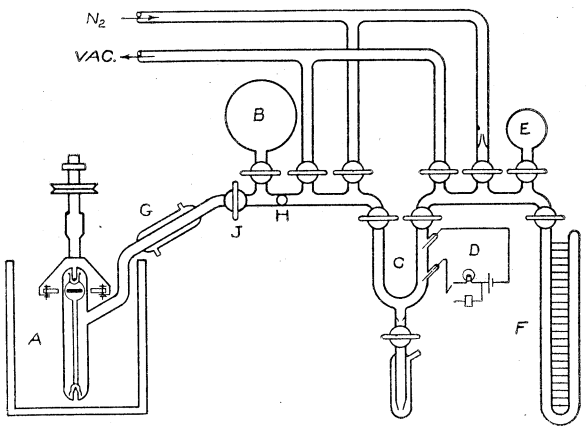

Fig. 2.—The rate measuring apparatus.

Aluminum triphenolate was prepared by dropping pieces of aluminum metal into hot phenol, which was contained in a round-bottomed flask equipped with a reflux condenser.[7] Once the reaction started, it was self-sustaining and the flame was removed. When a slight excess of the theoretical amount of aluminum was added, heat was again applied until the reaction was completed (no more evolution of hydrogen). The product was poured on Pyrex watch glasses and allowed to cool. It solidified almost immediately to a gray vitreous solid, which was readily pulverized to a grayish-white powder. This material was dried in an oven at 110° for eight hours before use.

The 1,4-dichlorobutane, ethylene dichloride, benzyl chloride, nitrobenzene, benzene, *p*-xylene and *p*-dioxane were all carefully fractionated (the last three over sodium) in packed columns. The samples were prepared in evacuated ampoules as described below. (The 1,4-dichlorobutane was kindly donated by the Electrochemical Division of E. I. du Pont de Nemours and Co.)

**The Quantitative Nature of the Reaction.**—The reaction between *t*-butyl chloride and phenol was demonstrated to be essentially quantitative. In Expt. 27 (see Table I) a determination of the quantitative nature of the reaction was made. After the reaction (carried out in *p*-xylene as a solvent) had reached essential completion (ninety hours at 40°), the volatile contents of the rate-determining apparatus were removed by evacuation with a Cenco Hy-

| 38 | .01085B | .176 | .0518D | | 91.4 | 45 | | | | | | *b* | |

The capital letters in columns (2), (3) and (4) have the following meanings: A = *t*-amyl chloride; B = *t*-butyl chloride; C = *p*-cresol; DB = 1,4-dichlorobutane; E = ethylene dichloride; H = dimethylisopropylcarbinyl chloride (2-chloro-2,3-dimethylbutane); N = nitrobenzene; X = *p*-xylene and D = 1,4-dioxane.

In column (14) experiments 37 and 38; [a] no rise in pressure after four hours, [b] a pressure rise of only 3 mm. was observed after seven hours.

Columns (1–4) are self-explanatory. The molarity of phenol in column (5) was obtained by using available data in the literature for the densities of the substances used in each experiment. The volume of each material was calculated (at the temperature of the experiment) and it was assumed that the solutions were perfect. This assumption probably did not introduce any appreciable error since in most cases one component comprised the majority of the solution. Once the total volume was calculated, the molarity of the phenol could be ascertained in the usual manner.

The values in column (6) represent the equilibrium pressure of hydrogen chloride that was added to the phenol before the *t*-butyl chloride was admitted to the reaction vessel. Column (7) indicates the temperatures of the experiments. The thermostat was kept at these temperatures ±0.01°. Columns (8) and (9) represent the initial and final equilibrium pressures, respectively. $P_0$ represents the vapor pressure of the tertiary halide plus that of phenol plus, in certain cases, the pressure of hydrogen chloride added before the start of the run, or the vapor pressure of the particular diluent employed. $P_f$ was determined experimentally in most cases, by allowing the experiment to proceed to completion. However, it could also be calculated by extrapolation of the straight line obtained by plotting $dP/dt$ *vs.* $P$ to $dP/dt = 0$. When the calculated and experimental values did not agree, the experimental value was used, and it was necessary to insert the constant *b* (column (11)) into the kinetic equation. The determination and significance of the data in columns (10–14) is discussed below. The values of *a*, *b* and *C* pertain to equation (2) below, $t_{1/2}$ is the reaction half-time, and *n* is the apparent order of the reaction with respect to phenol concentration.

Vac pump. A sodium carbonate absorption tube and a Dry Ice–acetone cold trap were placed in the line before the pump. In this manner, 98.1% of the chlorine was recovered as sodium chloride in the absorption tube, and no isobutylene was obtained in the cold trap. This indicates, therefore, that the alkylation is practically quantitative and little or no dehydrohalogenation of the *t*-butyl chloride occurs.

**The Henry's Law Constants for Hydrogen Chloride in Phenol.**—In order to ensure that no unusual solubility behavior of hydrogen chloride in the liquid phase would influence the kinetic interpretation, the Henry's law constants for hydrogen chloride in phenol were determined at 45, 50 and 55° over a total pressure range of 200 to 900 mm. of mercury. It was found that these constants, for a given temperature, varied less than ±3%, approximately the precision of the measurements. Thus, the increase in pressure due to evolved hydrogen chloride could be employed as a reliable method of following the reaction.

**Preparation of Samples.**—The samples of phenol, alkyl halides and diluents were prepared in such a manner as to exclude moisture. Small amounts of moisture would lead to incorrect data because of the generation of hydrogen chloride by hydrolysis of the alkyl halides. The phenol samples were prepared in the apparatus shown in Fig. 1. Approximately 500 g. of fractionated phenol and 10 g. of aluminum triphenolate (as a drying aid) were placed in the 1-l. distilling flask (A) through the side arm (against a counter-current of dry nitrogen). The side arm was then sealed off and the phenol was frozen in (A). It was degassed by alternate freezing, evacuation and thawing. The system was then evacuated, filled with dry nitrogen and re-evacuated several times to remove oxygen. It was finally left at about 50 mm. of mercury pressure with nitrogen and heat was applied at (A). About 75 ml. of phenol was collected in the 125 ml. receiver (B), and the distillation was discontinued. The system was then filled with dry nitrogen until the pressure was 5–10 mm. below atmospheric. Vessel (B) was sealed off and discarded. The system was re-evacuated and the distillation continued. The phenol used for samples was collected in (C).

The ampoule (F), made of 15 mm. tubing, was weighed with the female half of ground joint (E). The ampoule was then attached to the system at (E), evacuated, flushed with dry nitrogen and re-evacuated and sparked. The phenol in (C) was melted with a hot-air gun and was allowed to run through 4 mm.-bore stopcock (D) into the ampoule. The phenol was frozen in the ampoule, degassed, and then sealed off in vacuum at the constriction, leaving a capillary tip for breaking with the magnetic hammer. The two halves of the ampoule were weighed, giving the weight of the sample by difference.

When a diluent was used, the ampoule was not sealed off after the phenol was added. Instead, it was filled with dry nitrogen and weighed (a stopper was used before and after to prevent oxidation and absorption of moisture). The ampoule was then connected to a small system in which the diluent had been distilled *in vacuo* and degassed according to standard vacuum techniques. The diluent was then added to the phenol, the mixture frozen and the ampoule sealed under vacuum. The weight of the diluent was then obtained from the total weight by difference.

The tertiary halide samples were prepared in a manner similar to that described in reference 3a. Standard vacuum techniques were used for distilling the halides *in vacuo* and for degassing and sealing off the samples. Care was taken to keep oxygen and traces of moisture from the samples.

**Apparatus.**—A schematic diagram of the rate apparatus is shown in Fig. 2. The method of following the rate of the reaction is to add a known weight of tertiary alkyl halide to a known weight of phenol in a thermostatted vessel, and to measure the increase in pressure due to the evolution of hydrogen chloride in a constant volume system. In certain experiments hydrogen chloride was added to the phenol prior to the addition of the tertiary halide, and in certain experiments the phenol contained a diluent.

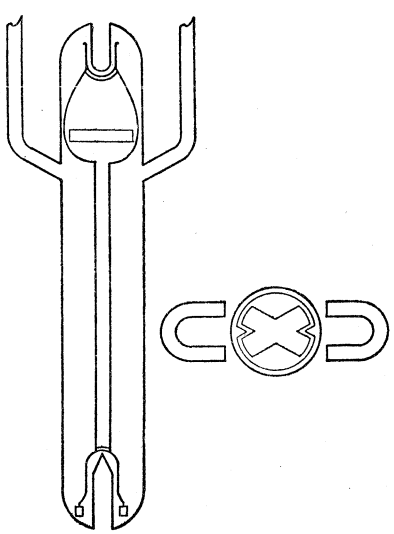

Fig. 3.—The reaction vessel.

An enlarged diagram of the reaction vessel is shown in Fig. 3. It consisted of 41 mm. tubing approximately 18 in. long, with a fulcrum extending up from the bottom and a guide tube extending down from the top. An all-glass stirrer was sealed inside the vessel. It rested on the glass fulcrum and had a tube at the top which prevented it from touching the walls of the vessel. An iron cross was sealed inside the bulb-like portion at the top of the stirrer, and the latter was operated by revolving two permanent horseshoe magnets outside the vessel, on a level with the iron cross. A bell-shaped device at the bottom of the stirrer carried four solid-glass paddles which served to stir the reaction mixture. Although there was no added lubrication, a speed of 300 r. p. m. or better was possible if the vessel was carefully constructed.

The reaction vessel contained three exit tubes immediately below the level of the bulb in the stirrer. Two of these led, through stopcocks, to the addition tubes from which the phenol and tertiary alkyl halide were added to the vessel. The third was connected to the rest of the rate apparatus. The entire reaction vessel was submerged in a thermostat.

The reagent addition tubes consisted merely of a tube which held the ampoule containing the reagent and a side-tube containing a nail sealed in glass which could break the capillary tip of the ampoule when activated with an electromagnet.

Since the reaction proceeded at a measureable rate only at elevated temperatures, it was necessary to have a condenser (G) (Fig. 2) to prevent the distillation of the reactants into the cooler parts of the system. The reaction side of the differential manometer (C) also contained a hydrogen chloride reservoir (B), lines to vacuum and dry nitrogen, and a line (H) to the hydrogen chloride generator.

The outside of the differential manometer contained an electric rest point signalling device (D) (see ref. 3a) which had both a light and a buzzer for indicating completion of the circuit. The rest of the system contained a one-liter buffer volume (E), a calibrated manometer (F) and lines leading to the vacuum and dry nitrogen sources for balancing the differential manometer. The nitrogen inlet contained a fine capillary to permit the increase in pressure on the outside of the differential manometer by very small increments.

The nitrogen source was a commercial cylinder. The nitrogen was dried over phosphorus pentoxide and the pressure was regulated by means of a mercury blowout valve set at approximately 200 mm. above atmospheric pressure. A Cenco Hy-Vac pump was the source of vacuum.

Approximately 90% of the volume of the reaction side of the system was thermostatted and the remainder of the system was at room temperature, which did not vary more than 3° during a single run.

**Measurement Procedure.**—When making measurements, the phenol was added to the reaction vessel, temperature and pressure equilibrium were established and hydrogen chloride was added in those cases in which its effect upon the reaction rate was being studied. Equilibrium was again established, the tertiary halide added, and time and pressure readings were made. The reaction was followed until at least 90% complete, and in many cases to essential completion.

The reagent addition tubes were sealed to the reaction vessel, the entire system evacuated, sparked, and checked for leaks. Mercury was then admitted to the differential manometer until contact was made with the upper tungsten lead. Both sides of the system were then filled with dry nitrogen and twice re-evacuated. This ensured the presence of very little oxygen in the system and therefore

very little oxidation of the phenol during the course of the reaction. (When the reaction was complete, the phenol solution was only very pale yellow.)

With the system evacuated, the phenol in the ampoule was melted (if not liquid already because of diluent), the tip broken with the magnetic hammer, and the phenol was admitted to the reaction vessel. The addition tube was gently flamed and analysis showed that less than 0.1% of the phenol remained in it. The stopcock to the addition tube was then closed and the stirrer started. After thirty to sixty minutes, the halide ampoule was broken, flamed, and the halide was admitted to the reaction vessel. The stopcock was opened for about thirty seconds; the stop watch was started at the initial opening of this stopcock.

For a few minutes after addition of the tertiary halide the pressure decreased, due to solution of the halide in the phenol. Thus, readings were taken on the "break" of the contact with the mercury. When solution was complete, however, and the pressure was increasing, readings were always taken on the "make" of contact. The rate curves (Figs. 4, 5) show only the rise in pressure.

Readings were taken as frequently as possible (about one every minute) at the beginning of the reaction and less frequently as the reaction proceeded. The points obtained were very self-consistent as is indicated by the curves in Figs. 4 and 5.

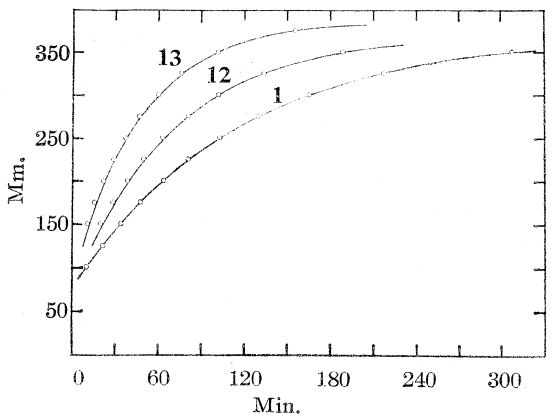

Fig. 4.—Typical rate curves for alkylation of phenol with *t*-butyl chloride at 45, 50 and 55°.

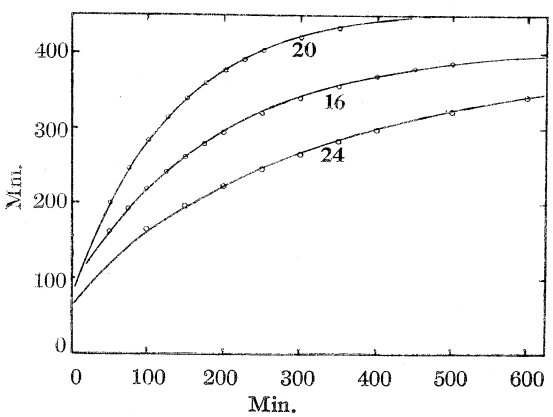

Fig. 5.—Typical rate curves for the alkylation of phenol with *t*-butyl chloride at 45° using various diluents.

When a run was completed, a break was made between stopcock (J) and condenser (G). The reaction vessel was thoroughly cleaned, dried, and re-sealed to the system for the subsequent run.

After completion of a run, the tertiary halide addition tube was removed *below* the stopcock. Ethanol was then admitted through the stopcock and the addition tube was rinsed several times with 95% ethanol. These rinsings were then analyzed for chloride by the Volhard procedure, allowing ten minutes after addition of the silver nitrate for complete reaction with the organic halide. In order to determine the weight of chloride actually used in the experiment, the weight of the alkyl halide in the ampoule was then corrected for the amount which remained behind. This correction was of the order of 1%.

## Results

Numerous kinetic experiments were carried out. Space requirements prohibit a complete tabulation of the data from each experiment. A summary of the essential results obtained from thirty-eight of the experiments is given in Table I. Columns (1)–(9) have been explained in the notes to that table. Time *vs.* pressure plots were made for each run (see Figs. 4 and 5 for typical curves). These curves show the consistency of the measurements in any one experiment. Only one experimental point out of every ten is indicated on these curves, for the sake of clarity in the drawings. The solid curve is drawn using equation (2) below, and employing for each experiment shown, the corresponding constants *a*, *b* and *C* from Table I. Thus, these drawings show the closeness of fit of the calculated curve and the experimental points. In order to determine these constants a spline was used to draw a smooth curve through the experimental points, and normals to these rate curves were drawn with a plane first-surface mirror held in a small frame at right angles to the plane of the curve. The normal was drawn when the curve itself and its image appeared to give no perceptible break.[8] The slope of the rate curve at various points was then determined as the negative recip-

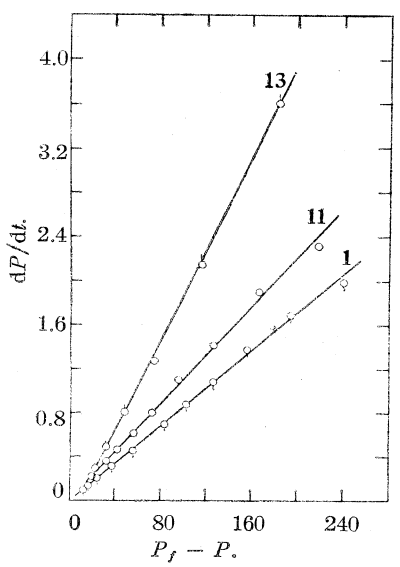

Fig. 6.—Typical derivative curves for the alkylation of phenol with *t*-butyl chloride.

(8) A. G. Worthing and J. Geffner, "Treatment of Experimental Data," John Wiley and Sons, Inc., New York, N. Y., 1943, p. 88.

rocal of the slope of the normal. About ten slopes were measured for each curve, at regular intervals with respect to time, over the curve.

It was found that in all of the experiments, the equation

$$dP/dt = a(P_f - P) - b \qquad (1)$$

represented the data satisfactorily. In this equation $P$ represents the instantaneous total pressure, $P_f$ is the final equilibrium pressure, $t$ is the time, $dP/dt$ is the slope of the rate curve, and $a$ and $b$ are constants. Thus, when $dP/dt$ was plotted against $(P_f - P)$, straight lines were obtained (see Fig. 6). The best straight line was determined by the method of least squares, and the constants $a$ and $b$ obtained in this manner are given in columns (10) and (11) of Table I. This equation is essentially that for a first-order reaction (when $b = 0$) in which $a$ is a pseudo first-order rate constant. In some of the experiments, however, it was found that the straight lines did not go through the origin, and this small deviation is represented by $b$. This constant may arise because of the uncertainty of the zero time, and if we use half-times to compare different experiments we can do so independently of constant $b$.

Upon integration of (1), one obtains

$$1/a \ln [a(P_f - P) - b] + t = C \qquad (2)$$

The integration constant was determined by fitting the integrated equations to the original kinetic curves, using some experimental point near the half-time of reaction. These constants are given in column (12) of Table I. It was also possible then, after $a$, $b$ and $C$ were determined, to calculate the values of $P_0$ and of $t_{1/2}$ given in columns (8) and (13), respectively, of Table I.

The values of $n$, the apparent order of the reaction with respect to phenol, were determined only for the reaction between $t$-butyl chloride and phenol at 45°. They were obtained in the following manner. If one will plot $t_{1/2}$ *vs.* $M$, the molarity of phenol, using any theoretical order for the rate dependency of phenol (1st, 2nd, etc.) it is evident that in the region of $M = 9.5$ to 11.2 the curve is very nearly a straight line ($M = 11.2$ was taken as the molarity of pure phenol at 45°). The data of experiments 1, 2, 3, 4, 9 and 10 were then plotted ($t_{1/2}$ *vs.* $M$) and the best straight line was drawn through these points by the method of averages. This line, extrapolated to $M = 11.2$ gave a limiting theoretical value of $t_{1/2}$ (for zero $t$-butyl chloride concentration) of fifty-one and one half minutes.

It is well known[9] that

$$t \alpha \quad 1/a^{n'-1} \qquad (3)$$

where $t$ is the time required to complete a certain fraction of a reaction, $a$ is the initial concentration of reactants, and $n'$ is the total order of the reaction. In two different experiments, we then have that

$$t_1/t_2 = (a_2/a_1)^{n'-1} \qquad (4)$$

In the particular case of the reaction being studied, it is known that the reaction rate is first order with respect to the tertiary halide. The half-life is therefore independent of the halide concentration. Thus, since $n'$ in the above equation is the total order of the reaction, $n' - 1$ may be considered as the order of the reaction with respect to the phenol. Setting $n' - 1$ equal to $n$, the order with respect to phenol, expressing the concentrations $a$ as molarities $M$, and using as our reference value the half times $t_{1/2}$, we obtain the expression

$$t_{1/2}/t^0_{1/2} = (M^0/M)^n \qquad (5)$$

where $t^0_{1/2}$ is fifty-one and one half minutes at 45°, $t_{1/2}$ is the half-time for the particular experiment (column 13 of Table I) $M^0$ is 11.2 at 45°, $M$ is the molarity of the phenol for the particular experiment (column 5 of Table I). Values of $n$, the apparent order of the reaction with respect to phenol, could be calculated. These are the values given in column 14 of Table I.

The activation energies for the reaction of phenol with $t$-butyl chloride, $t$-amyl chloride and dimethylisopropylcarbinyl chloride were determined in the usual manner from rates at 45 and 55°. For the reaction in which nitrobenzene was used as the diluent the rate constant at 45° was corrected to the same phenol molarity as was used at 35° (see expt. 23) before calculating the Arrhenius energy of activation. The results of these calculations are given in Table II.

TABLE II

ENERGIES OF ACTIVATION FOR ALKYLATION OF PHENOL (45 to 55°)

| Chloride | $E$, kcal./mole |
|---|---|
| $t$-Butyl | 17.1 |
| $t$-Amyl | 14.8 |
| Dimethylisopropylcarbinyl | 15.9 |
| $t$-Butyl[a] | 13.0 |

[a] Using nitrobenzene as a diluent, $t = 35$ to 45°.

## Discussion of Results

All of the reactions which were studied were carried out with a large (ten to twenty-fold) excess of the phenol. Thus, the rate constants $a$ which were obtained, are pseudo first order rate constants, indicating that the reactions are all first order with respect to the tertiary alkyl halide. This is readily seen from the straight line relationship between the effective concentration of the tertiary halide $(P_f - P)$ and the over-all reaction rate $dP/dt$.

The determination of the order of the reaction with respect to phenol presents a more difficult problem. The amount of $t$-butyl chloride could not have been greatly increased, because too great a pressure rise for the system would have resulted. The tertiary halide could not be used in large ex-

(9) S. Glasstone, "Textbook of Physical Chemistry," D. Van Nostrand Company, Inc., 1940, pp. 1046–1047.

cess, as was the phenol, because of its low boiling point.

However, the order with respect to phenol was determined by using relatively small quantities of diluents of varying dielectric constants. The mathematical details of this determination were described above. The first diluent employed was *t*-butyl chloride itself, which has a dielectric constant nearly identical with that of phenol ($\epsilon_{t\text{-BuCl}} = 9.4$; $\epsilon_{C_6H_5OH} = 9.7$). Thus, in experiments 9 and 10 we see that only half of the usual quantity of phenol was employed (it still was present in ten-fold excess). Although the molarity of the phenol was only slightly lowered (from about 10.6 to 9.7) it is seen from Table I that the half-time was increased from approximately eighty-five to one hundred and twenty-three minutes. These results lead to a value of approximately 6 for $n$.

Other diluents which also have approximately the same dielectric constants as phenol are ethylene dichloride and 1,4-dichlorobutane ($\epsilon = 8.9$). These diluents did not interfere with the reaction and led to values of about 3.7 and 4.5 for $n$. From experiments 15 to 19 on Table I, one may note the very large change in the reaction half-time, although the change in dielectric constant of the medium was negligible. Thus, the principal reason for the rate differences is the change in phenol concentration. Although, in the case of the 1,4-dichlorobutane diluent, the phenol concentration was only halved, the half-time ($t_{1/2}$) was increased by 1500%. Two diluents with dielectric constants lower than that of phenol, and one greater were used. *p*-Xylene ($\epsilon = 2.3$) gave a value of $n = 5.8$ and nitrobenzene ($\epsilon = 35.4$) gave $n = 2$. The dioxane ($\epsilon = 2.4$) almost completely inhibited the reaction, and an explanation for this result is discussed below.

It can be seen from experiments 5, 6, 7 and 8 that the initial hydrogen chloride pressure has little or no effect upon the reaction rate for the *t*-butyl chloride–phenol reaction. This is a significant fact when one considers that the reaction being studied is one which is typical of those catalyzed by sulfuric acid, hydrogen fluoride or aluminum chloride. Because of the fact that the kinetic activity of hydrogen chloride did not have to be considered, we can interpret the change in reaction rate with temperature as due only to the increase in available thermal energy. The values for the activation energies are indicated in Table II. The values were determined over a very small temperature range (10°) and may be in error by as much as a kilocalorie.

The relative rates of reaction for the different halides are given by *t*-butyl > *t*-amyl >> dimethylisopropylcarbinyl >>> benzyl chlorides. The half times are approximately 84, 120, 425 and 1600 minutes, respectively, at 45°. (The run with benzyl chloride (not shown in Table I) proceeded very slowly and was not carried to completion, although its $t_{1/2}$ could be estimated at 1600 min.)

The main net reaction in each case is given by

but in the case of the dimethylisopropylcarbinyl chloride, dehydrohalogenation to the olefin may have taken place to a small extent. This was indicated by the fact that when the reaction was carried out on a large scale at reflux temperature using mole for mole quantities of phenol and halide, a 42% yield of the olefin was obtained. Of course in the kinetic experiments this was diminished considerably since lower temperatures were used, and the phenol was present in a twenty-fold excess. Dehydrohalogenation to the olefin was shown to be negligible in the case of *t*-butyl chloride (see section on the Quantitative Nature of the Reaction, in the experimental part).

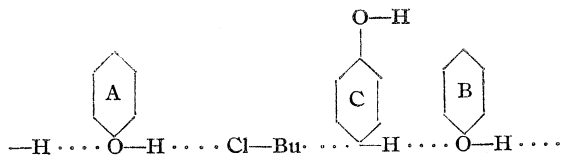
Only one experiment (no. 14) was carried out using *t*-butyl chloride with *p*-cresol as the phenol. The reaction proceeded far more slowly than with phenol itself, $t_{1/2}$ being 362 minutes. This means that ortho alkylation proceeded at about one-eighth of the rate of para alkylation per ortho position. Thus, if rate were the only factor, one should obtain about 20% *o*-*t*-butylphenol from the alkylation of phenol.[9a] That none of this material has been isolated indicates that if formed at all, it rearranges to the more stable para isomer. (The synthesis and reactions of ortho-*t*-butylphenol are being investigated, and some of the results have been submitted for publication.)

Experiments were performed in which anisole was used as the aromatic nucleus to be alkylated. In all of these, the starting materials were recovered unchanged, indicating that the hydrogen attached to the oxygen atom in phenol is essential to mechanism of the reaction, in the absence of any added catalysts.

## Mechanism

In arriving at a mechanism for the reaction under study, the following facts must be explained: (1) first order rate dependency upon the tertiary halide, (2) a high power (approximately sixth order) rate dependency upon phenol, (3) the inhibitory power of dioxane and the effect of other diluents, (4) the low activation energy and (5) the lack of reactivity of anisole under similar conditions. There are several possible mechanisms which come to mind, one of which seems preferable to the others.

First, there is the possibility of formation of the phenyl *t*-alkyl ether as an unstable intermediate followed by the rearrangement of this ether in the presence of the generated hydrogen chloride to form the *p*-alkyl phenol.[10] In this case, the rate-



(9a) R. P. Perkins, A. J. Dietzler and V. T. Lundquist, U. S. Patent 1,972,599, claim about 1.2% *o*-*t*-butylphenol from *t*-butyl chloride and phenol using aluminum chloride as the catalyst at 50–200°.

(10) The authors are indebted to one of the referees for pointing out the work of Van Alphen (ref. 5b) on phenyl trityl and similar ethers.

determining step would have to be the formation of the ether since the reaction was not autocatalyzed by hydrogen chloride formed during the reaction, nor was it catalyzed by hydrogen chloride initially present in the phenol (see experiments 5–8, Table I). Rearrangement of the ether would have, therefore, to be intramolecular, since the involvement of five other phenol molecules in the transition state is indicated in the rate-determining (ether forming) step. If this were so, one would expect to obtain some *o*-*t*-butylphenol, which is not readily rearranged by concentrated hydrochloric acid,[11] and one would also expect that *p*-cresol would alkylate as readily or more so than phenol. Actually, the alkylation of *p*-cresol occurs only at one-eighth the rate of phenol, per ortho position. One might also expect the ether formation to be acid catalyzed, and it has been shown that this reaction is not catalyzed by hydrogen chloride. At any rate, one is hesitant to postulate an unstable intermediate if alternate mechanisms are more adequate.

Another possible mechanism involves the ionization of the tertiary alkyl halide to form a free or solvated carbonium ion, followed by attack of that ion upon the para position of the phenol. Since the reaction was carried out in a very large excess of phenol, it is likely that the ionization would have to be the rate-determining step. This would involve, then, the coördination of the chlorine with approximately five to six phenol molecules (either one hydroxyl of a phenol polymer or several hydroxyl groups of phenol molecules) in the ionization process. Such a mechanism could account for the observed facts, although one can show by calculations similar to those of Pearlson and Simons[3a] that the minimum energy required to form a solvated *t*-butylcarbonium ion in phenol at 45° is about 28 kcal. per mole. The experimentally determined activation energies are considerably lower than this value (14–17 kcal. per mole).

A third and preferred mechanism is here proposed, which we term the "amphoteric medium effect."[4] This mechanism involves a one-step, condensed phase reaction which makes use of the amphoteric properties of phenol. The mechanism rests on two important principles. Firstly, it is to be considered that the reaction has been studied in the liquid phase and that a large excess of phenol was present. This means that multiple collisions will be the rule, rather than the exception. The molecules are constantly in contact with and "colliding" with other molecules. The *t*-butyl chloride molecules can be considered, therefore, as essentially surrounded by phenol aggregates. Secondly, phenol is an amphoteric associated liquid which is readily capable of proton transfer in a manner analogous to that in water. The mechanism is schematically pictured below. The solid lines indicate the bonds prior to reaction, and the dotted lines indicate the shifts in the bonds

when reaction occurs. The rest of the phenol molecules (3 or 4) which are involved in the transition state may be represented as coördinated linearly to the phenol molecules A and B, or may aid in the making and breaking of bonds by the polymolecular attack on the chlorine and the para hydrogen. The most important point is that bonds are being made and broken simultaneously (because of the amphoteric properties of phenol) and that at no time need there be present a high energy intermediate capable of independent existence. This mechanism is in some respects similar to the acid–base catalysis of Lowry[12] and the termolecular mechanisms proposed recently by Swain.[13] This mechanism adequately explains all of the facts which are enumerated above in the first paragraph of this section.

## Summary

The reaction between tertiary alkyl chlorides and phenol was shown to be homogeneous and essentially quantitative when carried out in an excess of the phenol to form the alkyl phenol and hydrogen chloride.

The relative rates of reaction of *t*-butyl, *t*-amyl, dimethylisopropylcarbinyl and benzyl chlorides with phenol at 45° are 1:0.7:0.2:0.05. *p*-Cresol is alkylated in the ortho position at one-eighth the rate of para alkylation, per ortho position.

The rate of the reaction was first order with respect to the halide and essentially independent of the hydrogen chloride pressure. The rate was very highly dependent upon phenol concentration. The order with respect to phenol depended upon the diluent used: sixth order with *p*-xylene or *t*-butyl chloride diluent, 3.5 to 4.5 order with ethylene dichloride or 1,4-dichlorobutane, and second order with nitrobenzene as the diluent. The activation energies were experimentally determined between 45 and 55°, and were 14–17 kcal. per mole. Dioxane inhibited the reaction almost completely, and anisole would not react under conditions similar to those used with phenol in the absence of a catalyst.

The mechanism is discussed and the above facts are explained by a mechanism involving the amphoteric properties of phenol ("amphoteric medium effect").

Henry's law is obeyed within 3% by hydrogen chloride in phenol from 45 to 55° at pressures from 200 to 900 mm.

# Studies on the Schardinger Dextrins. The Preparation and Solubility Characteristics of Alpha, Beta and Gamma Dextrins[1]

BY DEXTER FRENCH, MELVIN L. LEVINE,[2] J. H. PAZUR AND ETHELDA NORBERG

A distinctive character of the Schardinger dextrins[3,4,5] which facilitates their separation from crude starch digests is their ability to form crystalline insoluble complexes with many liquids notably the hydrocarbons and halogenated hydrocarbons.[6] In a search for superior precipitants for the Schardinger dextrins, the authors have collected data on the precipitation efficiency of several organic liquids. The solubilities of the pure dextrins in water and aqueous propanol, and of the dextrin acetates in a few selected solvents have been measured. These data have been incorporated into a scheme for the separation and purification of the Schardinger dextrins which does not require the acetylation and saponification steps used by Freudenberg.[4] Aqueous propanol has been found doubly useful in the purification of the dextrins since it promotes sharp crystallization with a minimum of clouding or gum formation and the crystal forms of the individual dextrins are so characteristic that it is readily possible to identify the individual dextrin propanol complexes under the microscope (Figs. 1, 2, 3, 4).

That varying the enzymolysis conditions affects the total yield as well as the proportion of the Schardinger dextrins has been recorded by McClenahan, Tilden and Hudson.[5a] These observations have been corroborated and utilized so that the starch digestion is carried out under conditions most favorable for the individual compound sought. In particular, it has been possible to obtain the gamma dextrin which has hitherto been mentioned only by Freudenberg.[4] The modifications of enzymic and separative procedures are presented in detail in the experimental section.

## Experimental

**Preparation of the Schardinger Dextrins.**—In the early part of this study, enzyme digestion mixtures[5] were separated by the method of Freudenberg and Jacobi.[4a] In this way crude dextrin stocks were acquired and the individual compounds were purified by repeated crystallization. In later preparations the enzymolysis conditions have been varied according to the individual dextrin which is desired. In order to allow for differences in amount of enzyme, concentration of substrate and temperature of the reaction, it is convenient to describe the duration of enzymolysis in terms of *conversion periods*. A conversion period may be defined as that time of reaction between enzyme and substrate which under the conditions would be just sufficient to convert an equal weight of starch to the Tilden and Hudson end-point.[5b]

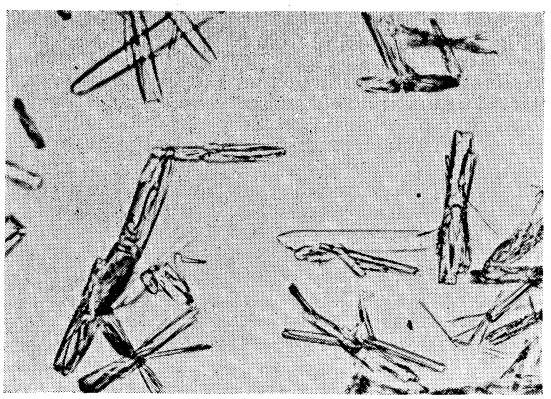

Fig. 1.—Alpha dextrin from 60% *n*-propyl alcohol, blade form.

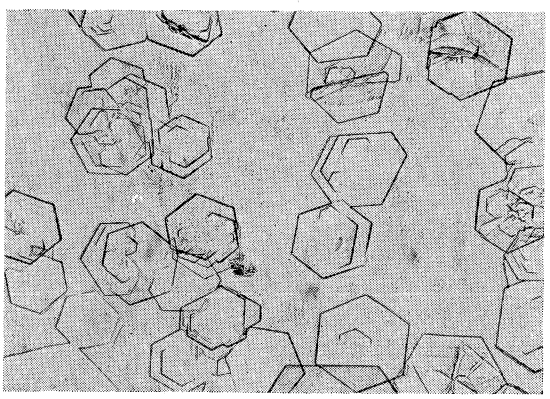

Fig. 2.—Alpha dextrin from 60% *n*-propyl alcohol, hexagonal form.

**Macerans Amylase.**—The enzyme used was prepared according to the directions of Tilden and Hudson.[5b] In order to prepare the gamma dextrin in good yield it is especially important that the enzyme be free from hydrolytic amylases. This can be determined by incubating a sample of starch with the enzyme for 50 conversion periods (using the conditions of the Tilden test, for example). At the end of this time the digest should show no more reducing power than the starch originally used, as indicated by copper or iron methods. Preparations with slight hydrolytic activity may be used for short conversions, as in the preparation of alpha dextrin.

**Alpha Dextrin.**—Enzymolysis of a 3–5% potato starch paste for 2–6 conversion periods in the absence of a dextrin

precipitant (*i.e.*, the reaction mixture should be sterile or protected against microörganisms by a microbial inhibitor such as thymol) yields a mixture from which alpha dextrin can be readily obtained by concentration to about 15% solids, precipitation with trichloroethylene and centrifugation of the crystalline complex.[7] The crude precipitate is suspended in water, boiled to remove trichloroethylene, treated with carbon and filtered. After cooling and diluting to about 2% solids concentration, bromobenzene is added to effect precipitation of any beta or gamma dextrin which may be present. The mixture is best stirred with a mechanical stirrer or shaken overnight to insure complete equilibration with the bromobenzene. The resulting suspension is filtered with suction, the filtrate boiled down to about 40% of the original volume and the bromobenzene precipitate, which is usually small, worked up with beta–gamma crudes. The solution of crude alpha dextrin is now treated with trichloroethylene or tetrachloroethane by stirring or shaking overnight and the crystalline complex separated by suction filtration. The precipitate is air-dried, boiled with about 5 parts of water until the vapors are free from precipitant, clarified by filtration with carbon if necessary, treated with 1.5 volumes of *n*-propyl alcohol, and allowed to cool. The crystalline propyl alcohol complex is filtered off after several days and recrystallized by dissolving the air dry material in four parts of hot water and adding 1.5 volumes of propyl alcohol. The final crystallization may be carried out by dissolving the pure propanol complex in water, boiling off the propanol, concentrating the solution to about 35% solids and allowing to crystallize by evaporation at room temperature for a day or two. (Alcohol-free solutions of the dextrins should be guarded against mold growth by covering while hot.) The crystals are filtered and allowed to air dry. On drying in the vacuum oven the crystals lose about 10% moisture; the specific rotation of the anhydrous material is $[\alpha]_D + 150.5° \pm 0.5°$ (*c* 1, water).[8]

**Beta Dextrin.**—Enzymolysis of 3–5% paste of potato or waxy corn starch is carried out without a precipitant for 2–3 conversion periods. The digest, which is now very fluid, is clarified by filtration through diatomaceous earth, fresh enzyme added, layered over with toluene and enzymolysis allowed to proceed for 30–50 conversion periods. Beta dextrin–toluene complex separates during the digestion and to secure a maximum yield of dextrin the digestion vessel should be agitated from time to time to promote contact between the toluene and the enzymolysis mixture. After the conversion the precipitate is most conveniently separated by the supercentrifuge. The crude material is suspended in boiling water, toluene removed by boiling until there is no odor of toluene in the vapor, treated with carbon, and the boiling hot solution filtered with pressure through a clarifying filter.[9] The concentration at this point should not exceed 20–25% solids; higher concentrations give trouble through crystallization of the beta dextrin during filtration. If it is necessary to use suction filtration, this may be carried out at a concentration of 10% solids, and the filtrate concentrated by boiling to the 20–25% level. The filtrate should be perfectly clear; if not, it is filtered hot through successively finer filters, with carbon and filter aid if necessary. The resulting solution is allowed to cool, whereupon large crystals of beta dextrin are formed. After standing overnight in the cold, the crystals are filtered, washed, and purified by repeated crystallization from 4–5 parts of boiling water. In this way is obtained a product which is ash-free, completely soluble in water to give a clear solution, and which contains about 14% water of crystallization. After drying to constant weight at 70° in the vacuum oven, the rotation is $[\alpha]_D +162.5° \pm 0.5°$ (*c* 1, water)[8].

**Gamma Dextrin.**—The enzymolysis with potato or waxy maize starch is carried out in the same manner as described above for beta dextrin, except that after the initial brief conversion and clarification, the reaction is allowed to proceed in the absence of a precipitant for 30–50 conversion periods. Gamma dextrin is scarcely detectable in the early phases of the enzymolysis when the alpha dextrin concentration is at a maximum. If the reaction mixture is not sterile, thymol may be used to inhibit molds. When the conversion is complete, the mixture is concentrated to about one-fourth the original volume, stirred with trichloroethylene, and the precipitate separated by centrifugation (see ref. 7). The precipitate is dissolved in boiling water, clarified, concentrated to about 25% solids, and allowed to stand at room temperature a day or two. Seeding with beta dextrin may be advisable to promote fairly complete removal of this component. The precipitate is removed and the clear filtrate is diluted to about 3% solids. This solution is stirred overnight with bromobenzene and the resulting suspension filtered with suction. The precipitate is washed, dissolved in boiling water and boiled to remove the bromobenzene, concentrated to about 20% solids and treated with 1.5 volumes of *n*-propyl alcohol. After standing for a few days at room temperature, the crystals of gamma dextrin–propanol complex are removed by suction filtration and allowed to air dry. Gamma dextrin is best purified by dissolving the air-dry complex in 4 parts of boiling water, filtering with carbon if the solution is colored or turbid, and treating the resulting solution with 1.5 volumes of *n*-propyl alcohol. Recrystallization should be repeated until there is no evidence for alpha or beta dextrins in the 60% propanol mother liquors. Generally two or three recrystal-

(7) The Sharples Supercentrifuge is very useful for this type of separation.

(8) Specific rotations previously reported are: ref. 4a, alpha +148°, beta +158°, gamma +160°; ref. 4b, alpha 148 ± 2°, beta 158 ± 2°, gamma +169 ± 2°; ref. 5a, alpha +150.5 ± 0.5°, beta 162.5 ± 0.5°.

(9) Horm laboratory pressure filter, F. J. Horman and Co., Brooklyn, N. Y.

lizations are required. The propanol cannot be removed from this complex by either air or vacuum drying, but is readily removed by boiling in water. By concentrating a boiled aqueous solution to 40–50% solids and standing at room temperatures a few days, large clear crystals of gamma dextrin hydrate are formed. The crystals effloresce in air; the air dry material loses 8.3% of its weight on drying at 70° in the vacuum oven. The specific rotation of the anhydrous material is $[\alpha]_D + 177.4 \pm 0.5°$ ($c$ 1, water).[8]

**Identification of the Schardinger Dextrins.**—The dextrins form characteristic crystalline complexes with iodine and potassium iodide which permit the positive identification of alpha dextrin. If alpha dextrin is present to the extent of only 2–5% of the carbohydrate mixture, it forms blue-black hexagonal crystals when a solution containing a little 0.1 $N$ iodine in 0.1 $M$ potassium iodide is allowed to evaporate on a microscope slide.[3,5b] If the proportion of alpha dextrin is higher, needles exhibiting a colorless–blue-black dichroism are formed. These may be most readily identified by removing the polarizer of a microscope and rotating the analyzer, whereupon the crystals will be seen to alternate between blue-black and colorless. The hexagonal prisms described above exhibit a similar dichroism when turned over on a prism face. With the iodine–potassium iodide test the beta and gamma dextrins form brown to yellow complexes which are considerably less dichroic. No characteristics have been noted which enable the positive identification of the beta or gamma dextrin iodine complexes.

When the dextrins in 60% propyl alcohol are crystallized on a microscope slide, crystals of each complex can be readily identified. The crystallization is best carried out by allowing a drop of the 60% alcoholic solution to evaporate to dryness. A second drop is then placed on the slide and covered with a cover glass. Within a few minutes well-formed crystals will be observed. Alpha dextrin crystallizes as blade-shaped needles or hexagonal plates, beta dextrin as parallelograms, and gamma dextrin as square plates or rectangular rods. If the mixture contains some of each dextrin, it is usually possible to see each type of crystal. Particularly in the course of purification of the alpha and gamma dextrins it is worthwhile to examine the 60% propanol mother liquors for traces of other members of the dextrin series. Photographs of the dextrins as crystallized from 60% propanol are given in Figs. 1, 2, 3 and 4.

**Solubilities of the Dextrins in Water.**—Solutions containing 20% alpha dextrin, 5% beta dextrin or 35% gamma dextrin in water deposit crystals on standing at room temperature. Such solutions were allowed to equilibrate several days at room temperature with occasional shaking. The crystals were filtered off and the concentration of carbohydrate in the mother liquors was determined by measuring the rotations: alpha, 14.5 g./100 ml.; beta, 1.85 g./100 ml.; gamma, 23.2 g./100 ml.

**Solubilities of the Dextrins in 60% Propanol.**—Solutions of the pure alpha, beta and gamma dextrins were prepared by dissolving the air dry samples in four parts of hot water and adding six parts of anhydrous $n$-propyl alcohol. The solutions were shaken overnight and allowed to stand several days at room temperature. The suspensions were filtered and the concentration of carbohydrate in the filtrates determined by measuring the rotation. With alpha dextrin, at least three distinct crystalline forms, with different solubilities, were obtained. The solubilities ranged from 0.4 to 1.2 g./100 ml., with most frequent readings at about 0.8 and 1.1. With beta and gamma dextrins, no such variation was observed: beta, 0.54 g./100 ml.; gamma, 0.27 g./100 ml.

**Solubilities of the Dextrins in the Presence of Precipitants.**—Aqueous solutions of pure alpha, beta and gamma dextrins were treated with sufficient amounts of precipitants to form a distinct layer. Generally about 5 ml. of precipitant with 40 ml. of 0.3–0.5% dextrin was used. In some cases in which no precipitate was formed at this dextrin concentration, increasing amounts of dextrin were used. After equilibration by shaking overnight and standing for a few days at room temperature (*ca.* 27°) the precipitates were removed by filtration. The concentration of dextrin in the filtrate was determined by measuring the rotation. The results are presented in Table I.

TABLE I

SOLUBILITIES OF THE SCHARDINGER DEXTRINS IN THE PRESENCE OF PRECIPITANTS

| Precipitant | Alpha g./100 ml. | Beta g./100 ml. | Gamma g./100 ml. |
|---|---|---|---|
| Petroleum ether | | 0.12 | |
| Mineral oil | | .03 | |
| Cyclohexane | 0.15 | .06 | |
| Decalin | | .08 | |
| Benzene | .8 | .07 | |
| Toluene | .9 | .06 | 0.04 |
| *p*-Xylene | .9 | .02 | .06 |
| Ethylbenzene | | .03 | |
| *p*-Cymene | 3.3 | .04 | .17 |
| Naphthalene | | .03 | |
| Methyl iodide | | .06 | |
| Chloroform | 0.8 | .07 | |
| Carbon tetrachloride | | .10 | |
| Nitromethane | | Over .3 | |
| Carbon disulfide | .08 | .07 | |
| Ethylene dichloride | | .12 | |
| Ethylene dibromide | | .12 | |
| Trichloroethylene | .26 | .03 | .03 |
| Tetrachloroethane | .08 | .12 | .03 |
| Tetrachloroethylene | .7 | .004 | .01 |
| Tetrabromoethane | .10 | .02 | |
| Isoamyl iodide | | .10 | |
| Bromobenzene | 2.4 | .03 | .01 |
| Iodobenzene | | .03 | .03 |
| *p*-Chlorotoluene | | .02 | .05 |

| *p*-Dichlorobenzene | | .18 | |
| α-Bromonaphthalene | | .02 | |
| Benzyl chloride | Over 1 | | |
| Nitrobenzene | Over 1 | .03 | .04 |
| Aniline | | Over .3 | .4 |
| Azobenzene | | .20 | |
| Butanol | | Over .3 | |
| Ethyl ether | | .66 | |
| Ethyl acetate | | Over .3 | |
| Benzyl alcohol | | Over .3 | |
| Cyclohexanol | 0.68 | | |
| Phenol | Over 1 | | |
| β-Phenylethanol | | 1.0 | |
| Thymol | | 0.14 | |

**Dextrin Acetates.**—The crude alpha dextrin, oven dry, was added in four equal parts at intervals to five parts of boiling acetic anhydride containing one-half part anhydrous sodium acetate. After the final addition the mixture was refluxed for thirty minutes, allowed to cool to room temperature, and poured with stirring into cracked ice and water. As the dextrin acetate hardened, the water was replaced. When all the acetic anhydride was destroyed, the dextrin acetate was broken and suction filtered. Pure beta and gamma dextrins were conveniently acetylated in the same manner. The crude alpha and beta acetates were crystallized from 10–15 parts of boiling toluene by cooling to room temperature. Gamma dextrin acetate was crystallized from 2–3 parts of hot butyl acetate. The dextrin acetates appear to crystallize with

solvent of crystallization which is lost on exposure to air, giving in some cases glasses which retain the exterior form of the original crystals. The specific rotations of the pure acetates were: alpha, $[\alpha]_D + 105.5 \pm 0.5°$ ($c$ 1, chloroform); beta, $[\alpha]_D + 122.0 \pm 0.5°$ ($c$ 1, chloroform); gamma, $[\alpha]_D + 138.5 \pm 0.5°$ ($c$ 1, chloroform).

**Solubility of Dextrin Acetates.**—The pure dextrin acetates were dissolved in about 15 parts of toluene, methanol, ethyl acetate and butyl acetate. If crystallization occurred on standing at room temperature, the mixtures were equilibrated for several days with frequent agitation and the concentration of material in the liquid phase determined by measuring the rotation as above. If crystallization did not occur, the solutions were evaporated until crystals separated or a glass was formed. After thorough equilibration the solubilities were determined as before. The values obtained are presented in Table II.

TABLE II

SOLUBILITIES OF THE SCHARDINGER DEXTRIN ACETATES

| Solvent | Alpha g./100 ml. | Beta g./100 ml. | Gamma g./100 ml. |
|---|---|---|---|
| Toluene | 0.22 | 0.24 | Very sol. |
| Methanol | 1.39 | 2.54 | Very sol. |
| Ethyl acetate | 8.84 | Very sol. | Very sol. |
| Butyl acetate | 0.67 | 17.8 | 11.0 |

## Summary

The preparation of pure Schardinger dextrins using differential precipitants and differential solubility in water and 60% propanol is described. For anhydrous gamma dextrin, $[\alpha]_D +177.4 \pm 0.5°$ ($c$ 1, water).[8] Characteristic crystal forms for the dextrins from 60% propanol are noted. The solubility behavior of the individual dextrins in water, 60% propanol and water saturated with various precipitants is reported.

# Studies on the Schardinger Dextrins. II. Preparation and Properties of Amyloheptaose[1]

BY DEXTER FRENCH, MELVIN L. LEVINE[2] AND J. H. PAZUR[3]

In studying the behavior of starch it is clearly desirable to have available model compounds which may be expected to exhibit characteristic starch reactions without the difficulties and uncertainties associated with native starch. Lack of homogeneous amyloöligosaccharide of chain length intermediate between maltose and amylose has led to conflicting opinions on the mode of action of the amylolytic enzymes, the relationship between chain length and iodine coloration, etc. This paper describes the preparation and properties of a maltose homolog containing seven glucose residues per molecule: amyloheptaose. The biochemical properties of amyloheptaose will be reported subsequently.

Amyloheptaose may be conveniently prepared by the controlled acid hydrolysis of Schardinger's beta dextrin, cycloheptaamylose. Since this is a cyclic molecule containing seven[4] glucose units linked together by maltose bonds,[5] rupture of any one bond per cyclic molecule leads directly to the linear heptasaccharide of the amylose series. The experimental difficulty in confining hydrolysis to one glycosidic linkage per molecule is accentuated by the fact that the beta dextrin is considerably more resistant to acid hydrolysis than corresponding linear compounds.[6] In order to avoid extensive degradation of the amyloheptaose it was necessary to establish an experimental procedure based upon the rate constants for the decyclization reaction and the subsequent heptasaccharide breakdown. The separation of the heptasaccharide from large amounts of unchanged beta dextrin was accomplished by allowing the latter to crystallize in the cold and removing the last trace as the insoluble $p$-xylene complex.[7] The dilute hydrochloric acid used as hydrolysis catalyst was exactly neutralized with lithium carbonate and the resulting lithium chloride removed by repeated precipitation of the aqueous heptasaccharide solution with absolute ethanol. The complete details of the preparation are given in the experimental section.

## Reaction Kinetics Involved

A complete mathematical analysis of the kinetics of the hydrolysis of cycloheptaamylose ($\beta$)

$$\beta \longrightarrow \text{heptasaccharide} \longrightarrow \begin{matrix}\text{hexasaccharide}\\ \text{pentasaccharide}\\ \text{tetrasaccharide}\\ \text{trisaccharide}\\ \text{maltose and glucose}\end{matrix} \qquad (1)$$

is complicated and unnecessary for the purpose at hand. It was found expedient, however, to derive expressions for the amount of heptasaccharide (H) and the number of reducing hemiacetal groups (R) as a function of time. In setting up this system $k_1$ was defined as the rate constant for the destruction of $\beta$ and $k_2$ as the *average* rate constant for the destruction of the glycosidic bonds in all the open-chain molecules.[8]
