# 404. The Basicity of Hydrocarbons. Part III.* The Distribution of Some Conjugated Hydrocarbons between Acidic and Inert Solvents. 

By V. Gold and F. L. Tye.

#### Abstract

The distribution of 1:1-diphenylethylene, 1- $\alpha$-naphthyl-1-phenylethylene, and triphenylethylene between cyclohexane and sulphuric acidwater mixtures of different acidities has been studied. By making certain assumptions about the solubilities of the hydrocarbon bases in the acid layer, it is possible to arrange the hydrocarbons in the approximate order of their basicities and to deduce that the $\mathrm{p} K_{a}$ value for the conjugate acid of 1:1-diphenylethylene is $-4 \pm 2$.

Having demonstrated that certain hydrocarbons behave as bases in strongly acid solvents, it is logical to enquire whether it is possible to determine this basicity quantitatively and to correlate basic strength with molecular structure. With most weak bases this is possible by means of the colorimetric and spectrophotometric methods described by Hammett and his collaborators (" Physical Organic Chemistry," New York, 1940, Chap. IX). Normally, measurements are carried out in solutions of an acidity such that acid and base forms are present in convenient concentrations of approximately the same order of magnitude. In this procedure it is essential that the base should remain in solution as the acidity of the solvent is reduced, a requirement which is not satisfied by the compounds and solvents employed by us. Furthermore, were it possible for both an olefin base and its conjugate acid to be present in reasonable concentrations, it is quite likely that considerable polymerization would take place.

Although these difficulties in the measurement of the basicity constants of hydrocarbons have not been overcome, it has been found possible-with certain assumptionsto compare approximately the basicities of $1: 1$-diphenylethylene, I- $\alpha$-naphthyl-1-phenylethylene, and triphenylethylene by partition experiments similar to those performed on azulenes by Plattner, Heilbronner, and Weber (Helv. Chim. Acta, 1949, 32, 574).

## Experimental

The preparation and purification of reagents and solvents have been described (Part I, $J$., 1952, 2167).

Partition Experiments.-The distribution of olefin between cyclohexane and aqueous sulphuric acids of different strengths was studied by introducing a weighed amount of olefin into the two layers, shaking, and then determining the concentration ( $C^{\prime}{ }_{\mathrm{B}}$ ) of olefin in the cyclohexane layer from the intensity of ultra-violet light absorption at suitable wave-lengths. The concentration of olefin in the acid layer $\left(C_{\mathrm{HB}^{+}}\right)$was obtained by subtraction. It was checked in a few cases that these values agree satisfactorily with values of $C_{\mathrm{HB}^{+}}$obtained by direct spectrophotometry of the carbonium-ion concentration in the acid layer. In the subtraction method it is obviously essential to have comparable amounts of solute in the two phases. It was found that for 1:1-diphenylethylene $\log _{10}\left(C_{B}^{\prime}{ }_{\mathrm{B}} / C_{\mathrm{HB}^{+}}\right)$had reached a steady value after $10-15$ minutes' shaking and, in order to minimize any errors due to secondary reactions, the values after 15 minutes were taken to be the equilibrium values. For the other two olefins the variations of $\log _{10}\left(C^{\prime}{ }_{\mathrm{B}} / C_{\mathrm{HB}^{+}}\right)$with time proved to be more serious, as shown in the example below :

## Effect of duration of shaking on distribution.

(i) 1: 1-Diphenylethylene $\left(85 \cdot 90 \% \mathrm{H}_{2} \mathrm{SO}_{4}: \lambda 2510 \AA\right.$ used for measurement of concentration).

| Time, m | 5 | 10 | 15 | 20 | 30 | 60 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\log _{10}\left(C^{\prime}{ }_{\mathrm{B}} / C_{\mathrm{HB}}+\right.$ ) | -0.19 | $-0.26$ | $-0.22$ | $-0.23$ | -0.24 | -0.3 |

(ii) Triphenylethylene ( $85.90 \% \mathrm{H}_{2} \mathrm{SO}_{4} ; \lambda 3020 \AA$ used for measurement of concentration).

| Time, mins. | 5 | 27 | 48 | 66 |
| :---: | :---: | :---: | :---: | :---: |
| $\log _{10}\left(C^{\prime} / C^{\prime} \mathrm{HB}^{+}\right)$ | +0.361 | +0.240 | +0.141 | +0.040 |

[^0]In order to get a rough comparison, the value of $C^{\prime}{ }_{\mathrm{B}} / C_{\mathrm{HB}^{+}}$was taken in each case as that obtained after 10 minutes (cf. Table 1, Part II). This is rather an arbitrary procedure and we do not claim high accuracy for the results which, moreover, suffer from the uncertainty that the time variation of the value may be different for different acidities of the acid layer.

Fortunately, the uncertainty involved, even on an extreme view ${ }^{\text {Fof }}$ the inaccuracy [say 0.2 unit in $\left.\log _{10}\left(C^{\prime}{ }_{B} / C_{\text {HB }^{+}}\right)\right]$, does not greatly affect the relative positions of the lines obtained on plotting $\log _{10}\left(C_{B}^{\prime} / C_{\mathrm{HB}^{+}}\right)$against $H_{0}$ (Fig.), where $H_{0}$ is Hammett's acidity function. The

a, Triphenylethylene (slope $=2.7$.
b, 1- $\alpha$-Naphthyl-1-phenylethylene
(slope $=2.5$ ).
c, 1:1-Diphenylethylene (slope $=$ $2 \cdot 2$ ).
observation that the slopes of these lines do not differ much from that for the stable hydrocarbon 1: 1-diphenylethylene also suggests that the time variations at different acidities may not be too dissimilar. The order of magnitude of the true distribution coefficients is therefore hardly in doubt.

## Results of distribution experiments.

## Discussion

The equilibrium between a hydrocarbon base (B) and its conjugate acid ( $\mathrm{HB}^{+}$) in the acid layer is governed by the relation

$$
\begin{equation*}
H_{0}=\mathrm{p} K_{\mathrm{HB}^{+}}-\log _{10}\left(C_{\mathrm{HB}^{+}} / C_{\mathrm{B}}\right) . \tag{1}
\end{equation*}
$$

where $C_{\mathrm{B}}$ and $C_{\text {HB }^{+}}$stand for the concentration in the acid layer of the species concerned, $\mathrm{p} K_{\text {HB }^{+}}$is the acidity constant of $\mathrm{HB}^{+}$, and $H_{0}$ is Hammett's acidity function (op. cit.). The distribution of $\mathbf{B}$ between the two immiscible phases can be formally expressed by

$$
\begin{equation*}
P=C_{\mathrm{B}} / C_{\mathrm{B}}^{\prime} \tag{2}
\end{equation*}
$$

if $C^{\prime}{ }_{\mathrm{B}}$ and $C^{\prime}{ }_{\text {HB }^{+}}$are the concentration of base and conjugate acid in the cyclohexane; $P$ is called the partition coefficient and is equal to the ratio of the solubilities of the base in the two layers. Experimentally we find that $C_{\text {HB }^{+}} \gg C_{\mathrm{B}}$ and $C^{\prime}{ }_{\mathrm{B}} \gg C^{\prime}{ }_{\text {HB }^{+}}$. We may combine equations (1) and (2) to obtain

$$
\begin{equation*}
H_{0}=\mathrm{p} K_{\mathrm{HB}^{+}}+\log _{\mathbf{1 0}} P-\log _{10}\left(C_{\mathrm{HB}^{+}} / C_{\mathrm{B}}^{\prime}\right) \tag{3}
\end{equation*}
$$

The experimental determination of the ratio $C_{\mathrm{HB}^{+}} / C^{\prime}{ }_{\mathrm{B}}$ with acid layers of known values of $H_{0}$ therefore leads to a value of ( $\mathrm{p} K_{\mathrm{HB}^{+}}+\log _{10} P$ ) but, without an accompanying measure-
ment of $P$, it is impossible to derive from this an accurate value of $\mathrm{p} K_{\mathrm{HB}^{+}}$. A direct measurement of $P$ would be very difficult in this case and has not been attempted. Plattner, Heilbronner, and Weber (loc. cit.), who have used a similar partition technique for the separation and characterization of the azulenes, another group of basic hydrocarbons, have suggested that the $H_{0}$ value at which the apparent partition coefficient $\left(C_{\mathrm{HB}^{+}} / C^{\prime}{ }_{\mathrm{B}}\right.$ ) is unity (i.e., $\mathrm{p} K_{\mathrm{HB}^{+}}+\log _{10} P$ ) could be regarded as a measure of relative basicity, called by them $H_{0}\left(K^{\prime}=1\right)$, but they were careful to point out that this treatment of the data was not rigorous.

A difficulty encountered with the application of equation (3) is the observation that ( $\mathrm{p} K_{\text {HB }}+\log _{10} P$ ) is experimentally not independent of $H_{0}$, but appears to be a linear function of $H_{0}$ of approximate slope -1. Stated alternatively, the plot of $\log _{10}\left(C_{\mathrm{HB}^{+}} / C^{\prime}{ }_{\mathrm{B}}\right)$ against $H_{0}$ is linear with a slope $\sim \mathbf{- 2}$. This has been found for the azulenes with either aqueous sulphuric or phosphoric acid in the acid layer (Plattner et al., loc. cit.); we have also found it at considerably higher acidities with the three hydrocarbons now examined. We interpret these observations as arising out of a linear decrease of the logarithm of the solubility of base molecules in the acid with increasing values of $H_{0}$ (i.e., an increase of solubility with increasing acidity). Such an effect has been reported for the basic form of organic oxygen compounds (Hammett and Chapman, J. Amer. Chem. Soc., 1934, 56, 1282), and therefore appears to be a fairly general one. This salting-in law for strongly acid solvents may alternatively be stated in the form

$$
\log f_{B}=\alpha H_{\mathbf{0}}+\text { constant }
$$

where $\alpha$ is $\sim 1$, and $f_{B}$ is an activity coefficient of $B$ relatively to any convenient standard state.

In order to arrive at a comparative estimate of the basicities of the three hydrocarbon bases examined, it is necessary to know how $P$ depends on the base concerned (for a certain fixed acid composition). For three olefins of similar structure we would predict that the partition coefficients do not differ very widely and, therefore, the order of the values of $\left(\mathrm{p} K_{\mathrm{HB}^{+}}+\log _{10} P\right)$ is probably also the order of their basicities, i.e., $\mathrm{CPh}_{2}: \mathrm{CH}_{2} \geqslant$ $\alpha-\mathrm{C}_{10} \mathrm{H}_{7} \cdot \mathrm{CPh}: \mathrm{CH}_{2} \gg \mathrm{Ph}_{2} \mathrm{C}: \mathrm{CHPh}$, with the insoluble hydrocarbons stilbene and tetraphenylethylene much less basic still. In order to change the position of triphenylethylene in this sequence it would be necessary for $P$ for the distribution of triphenylethylene between cyclohexane and a particular solvent mixture to be more than 100 times smaller than $P$ for 1 - $\alpha$-naphthyl-1-phenylethylene or more than 1000 times smaller than $P$ for $1: 1$-diphenylethylene. A consideration of the ratio of the solubilities of related hydrocarbons in a paraffin solvent and water indicates that such an upset is improbable. It is not impossible, however, that differences in $P$ may be responsible for the order of the first two compounds in the sequence; in this case the values of $P$ would have to differ by a factor $\geqslant 10$ if the order were, in fact, the reverse of that stated.

The relative solubilities of aromatic hydrocarbons in cyclohexane (paraffin solvents) and water are usually in the ratio $10^{4}: 1$ to $10^{5}: 1$. The solubility increase with acidity being borne in mind, the value of $P$ is probably changed to $10^{-3}$ to $10^{-4}(\log P=-3 \cdot 7)$ (the data of Hammett and Chapman on nitrobenzene being taken as guidance on this point). For 1 : 1-diphenylethylene
therefore

$$
\begin{equation*}
\mathrm{p} K_{\mathrm{Ph}_{2} \mathrm{MeC}^{+}}+\log _{10} P=-7 \cdot 63 \tag{seeFig.}
\end{equation*}
$$

$$
\mathrm{p} K_{\mathrm{Pb}_{2} \mathrm{MeC}^{+}}=-7 \cdot 63+3 \cdot 7=-4 \pm 2
$$

a generous estimate being taken of the uncertainties of various assumptions. This means that 1:1-diphenylethylene is at least as basic as acetophenone ( $\mathrm{p} K_{\mathrm{HB}^{+}} \sim-6$ ) and, more probably, as strong a base as 2:4-dinitroaniline ( $\mathrm{p} K_{\mathrm{HB}^{+}}=-4 \cdot 4$ ). It is certainly a stronger base than 2:4:6-trinitroaniline, anthraquinone, or nitro-hydrocarbons.
