# 474. The Electronic Orbitals, Shapes, and Spectra of Polyatomic Molecules. Part IX.* Hexatomic Molecules : Ethylene. 

By A. D. Walsh.

#### Abstract

The electronic orbitals of the ethylene molecule are described. It is concluded that the first, triplet or singlet, excited state of the molecule should have (i) a pyramidal arrangement of the bonds about each C atom, (ii) one $\mathrm{CH}_{2}$ group twisted relative to the other through $90^{\circ}$ about the $\mathrm{C}-\mathrm{C}$ bond, and (iii) each C atom possibly slightly out of the mirror plane that bisects the HCH angle of the other $\mathrm{CH}_{2}$ group. The first excited state of a molecule containing $n$ electrons should belong to the same symmetry class as the ground state of a similar molecule containing $n+1$ or $n+2$ electrons. The symmetry of the ground state of the $\mathrm{N}_{2} \mathrm{H}_{4}$ molecule affords strong support for conclusions (i) and (ii) concerning the first excited state of the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule.

Orbitals of $\mathrm{C}_{2} \mathrm{H}_{4}$.-The ethylene molecule in its ground state belongs to the symmetry class $\mathrm{V}_{h}$. The definitions of the symbols appropriate to the orbitals of such a molecule are given in the Table below. $y z$ is taken as the plane of the molecule, $z$ being the long axis. $C_{2}(z)$ and $C_{2}(y)$ denote rotations of $180^{\circ}$ about the $z$ and the $y$ axis respectively. $\sigma_{\imath}(z)$ and $\sigma_{V}(y)$ denote reflections in planes perpendicular to the $z$ and the $y$ axis respectively. $i$ denotes the operation of inversion at the centre of symmetry.

Each $\mathrm{CH}_{2}$ group, in symbols appropriate to its localized $\mathrm{C}_{2}$ symmetry, will contain orbitals $a_{1}, b_{2}$ as for HCHO (see Part VI). Orbital $a_{1}$, having fewer nodal surfaces, is the more tightly bound. Considering non-localised orbitals, we obtain from the two $a_{1}$ orbitals new orbitals-one a sum and the other a difference. The new orbitals extend over the whole molecule and it is therefore appropriate to describe them by symbols of the $\mathrm{V}_{h}$ group. The first is bonding between the two $\mathrm{CH}_{2}$ groups and is $a_{1 g}$ in type; the second is anti-bonding between the two $\mathrm{CH}_{2}$ groups and is $b_{1 u}$ in type; both are bonding in all the $\mathrm{C}-\mathrm{H}$ links.

Symbols used for molecular orbitals of $\mathrm{V}_{h}$ molecules.

| Symbol | $C_{2}(z)$ | $C_{2}(y)$ | $\sigma_{V}(y)$ | $\sigma_{V}(z)$ | $i$ | Symbol | $C_{2}(z)$ | $C_{2}(y)$ | $\sigma_{V}(y)$ | $\sigma_{V}(z)$ | $i$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $a_{1 g}$ | + | + | + | + | + | $b_{2 g}$ | - | + | + | - | + |
| $a_{1 u}$ | + | + | - | - | - | $b_{2 u}$ | - | + | - | + | - |
| $b_{1 g}$ | + | - | - | + | + | $b_{3 g}$ | - | - | - | + | + |
| $b_{1 u}$ | + | - | + | - | - | $b_{3 w}$ | - | - | + | + | - |

Fig. 1 shows the forms of the two $b_{2}$ orbitals. They give one non-localized orbital that is bonding between $\mathrm{H}_{1}$ and $\mathrm{H}_{3}, \mathrm{H}_{2}$ and $\mathrm{H}_{4}$, and another that is anti-bonding between $\mathrm{H}_{1}$ and $\mathrm{H}_{3}, \mathrm{H}_{2}$ and $\mathrm{H}_{4}$. Both are anti-bonding from $\mathrm{H}_{1}$ to $\mathrm{H}_{2}$ and from $\mathrm{H}_{3}$ to $\mathrm{H}_{4}$. The first is $b_{2 u}$ and the second $b_{3 g}$. With respect to the symmetry of the whole molecule, the orbitals that are often loosely referred to as the " $\sigma$ " and " $\pi$ " orbitals of the $\mathrm{C}-\mathrm{C}$ bond possess the labels $a_{1 g}$ and $b_{3 u}$ respectively. More explicitly, they might be symbolized $\left[\mathrm{C}(\text { hybrid })_{z}+\mathrm{C}(\text { hybrid })_{z}\right], a_{1 g}$ and $\left[\mathrm{C}\left(2 p_{x}\right)+\mathrm{C}\left(2 p_{x}\right)\right], b_{3^{u}}$ respectively. The whole groundstate configuration of the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule may therefore be written

$$
\left(a_{1 g}\right)^{2}\left(b_{1 u} u\right)^{2}\left(a_{1 g}\right)^{2}\left(b_{2 u}\right)^{2}\left(b_{3 g}\right)^{2}\left(b_{3 u}\right)^{2},{ }^{1} A_{1 g}
$$

There is general agreement that the $\left(b_{3 u}\right)$ or " $\pi$ " orbital is the most weakly bound orbital to be occupied in the ground state. An anti-bonding " $\pi$ " orbital is also possible. It may be symbolized as $\left[\mathrm{C}(2 p)_{x}-\mathrm{C}(2 p)_{x}\right), b_{2 g}$. Just as we have seen (Part VI) that the experimental facts fit with the anti-bonding " $\pi$ " orbital's being the lowest orbital unoccupied in the ground state of $\mathrm{CH}_{2} \mathrm{O}$, so we may expect the corresponding orbital to be the lowest orbital unoccupied in the ground state of $\mathrm{C}_{2} \mathrm{H}_{4}$.

[^0]It will be useful to formulate the symbols for corresponding orbitals of the isoelectronic $\mathrm{O}_{2}, \mathrm{CH}_{2} \mathrm{O}$, and $\mathrm{C}_{2} \mathrm{H}_{4}$ molecules :

It will be seen that the degeneracies of the ( $\pi_{u} 2 p$ ) and ( $\pi_{g} 2 p$ ) orbitals are split in passing from $\mathrm{O}_{2}$ to $\mathrm{CH}_{2} \mathrm{O}$. The indices refer to the number of electrons occupying the orbitals in the ground states. The energy order of the orbitals for $\mathrm{O}_{2}$ is established. It is likely that the corresponding order is maintained in $\mathrm{CH}_{2} \mathrm{O}$ and $\mathrm{C}_{2} \mathrm{H}_{4}$, except for the reversal of the two outermost orbitals occupied in the ground states of $\mathrm{CH}_{2} \mathrm{O}$ and $\mathrm{C}_{2} \mathrm{H}_{4}$. This reversal is understandable in terms given below.

Just as we showed in Part VI that the anti-bonding " $\pi$ " orbital in $\mathrm{CH}_{2} \mathrm{O}$ had maximum binding energy when the HCH angle ( $\doteqdot$ the HCO angle) was $90^{\circ}$, so it can be shown that the corresponding orbital in $\mathrm{C}_{2} \mathrm{H}_{4}$ has maximum binding energy when the $\mathrm{HCH}(\doteqdot$ the HCC angle) is $90^{\circ}$. It is sufficient to base our expectation, however, on the correspondence of the orbitals between the two isoelectronic molecules, and to conclude that the $\mathrm{C}_{2} \mathrm{H}_{4}$ transition

$$
\begin{equation*}
\cdots\left(b_{3 u}\right)\left(b_{2 g}\right),{ }^{1} B_{1 u} \longleftarrow \cdots\left(b_{3 u}\right)^{2},{ }^{1} A_{1 g} \tag{1}
\end{equation*}
$$

leads to an upper state that has a pyramidal arrangement of the bonds about each C atom. It is also possible ( $\mathrm{cf} . \mathrm{CH}_{2} \mathrm{O}$ ) that in the excited state each C atom will lie slightly out of the mirror plane of the other $\mathrm{CH}_{2}$ group that is perpendicular to the plane of that $\mathrm{CH}_{2}$ group.* These conclusions have not previously been realized. (1) is probably the lowest-energy singlet-singlet transition of the molecule. $\dagger$

This does not suffice, however, to determine the shape of the excited $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule. A further change of shape is possible with $\mathrm{C}_{2} \mathrm{H}_{4}$ that was impossible with $\mathrm{CH}_{2} \mathrm{O}$, namely, a twisting of the two $\mathrm{CH}_{2}$ groups relative to each other about the $\mathrm{C}-\mathrm{C}$ bond.

Twisting of the $\mathrm{CH}_{2}$ Groups about the $\mathrm{C}-\mathrm{C}$ Bond.-Consider first the $\mathrm{O}_{2}$ molecule. The molecular-orbital explanation of why the ground state of the $\mathrm{O}_{2}$ molecule is a triplet is simple and well-known. However, an equally simple explanation can be given as follows. $\ddagger$ Suppose the molecule to be formed by the approach of two O atoms along the $z$ direction. Suppose the configuration of each atom is

$$
\cdots 2 p_{x} 2 p_{y}^{2} 2 p_{z}
$$

Then the $2 p_{z}$ atomic orbitals overlap to form a $\sigma$ bond, while the $2 p_{x}$ atomic orbitals overlap to form a $\pi$ bond. This means that, in addition, a $2 p$ lone-pair of electrons is

[^1]present on each atom, these electrons being in orbitals pointing in the same direction. Lone pair-lone pair repulsion is thus present. The repulsion arises from four electrons trying to occupy the same orbital in the region of overlap. By the Pauli principle, they cannot do this. The difficulty can be avoided either by supposing that the two pairs of electrons repel each other, so that their orbitals do not overlap, or by constructing two new molecular orbitals (one bonding and one anti-bonding). The second alternative is adopted in the most usual orbital theory. The first is adopted here and its possibilities explored. Lone pair-lone pair repulsion is a language used, e.g., by Walsh (J., 1948, 398) to express an effect that, on more usual theory, would be described by saying that excitation of electrons to anti-bonding molecular orbitals occurs.

Of course, there is no actual distinction of the $x$ and the $y$ direction for a linear molecule, so that the proper wave functions would be combinations of those built as above and those in which the $x$ and $y$ suffixes were interchanged; but we can still conceive of a state of the $\mathrm{O}_{2}$ molecule in which all electrons are paired and wherein occur

$$
\begin{equation*}
\text { A } \sigma \text { bond }+\mathrm{a} \pi \text { bond }+ \text { lone pair-lone pair repulsion } \tag{2}
\end{equation*}
$$

The repulsion could be avoided if, as the two atoms approached, their configurations were supposed to be twisted with respect to each other so that one obtained

A $\sigma$ bond +\begin{tabular}{c}

| interaction of odd electron |
| :---: |

$+\underbrace{$

in orbitals " pointing " in of odd electron <br>
and lone pair$. \quad .$

}$_{$

in orbitals "pointing " in <br>
the$x \text { direction }$
\end{tabular}$}$.

The latter two interactions could be called " three-electron bonds." There is empirical evidence that such interactions are attractive, with a strength about one-half of that of the corresponding single bond. Theoretically, this is most simply seen by reverting for a moment to the usual orbital language and noting that two electrons would occupy the bonding $\psi_{1}(2 p)+\psi_{2}(2 p)$ orbital and one the corresponding anti-bonding $\psi_{1}(2 p)-\psi_{2}(2 p)$ orbital, giving a net effect of approximately half a filled bonding orbital. Expression (3) may thus be re-written as

$$
\begin{gather*}
\text { A } \sigma \text { bond }+\sim \frac{1}{2} \text { a } \pi \text { bond }+\sim \frac{1}{2} \text { a } \pi \text { bond } \\
\text { a } \sigma \text { bond }+\sim \mathrm{a} \pi \text { bond } . \tag{4}
\end{gather*}
$$

or
but without any repulsion effect. Comparing this with (2), one sees that it is probable that the state of the $\mathrm{O}_{2}$ molecule reached by the second mode of interaction of two O atoms lies lower in energy than the state reached by the first mode of interaction. One can therefore understand why the ground state of the $\mathrm{O}_{2}$ molecule should contain two unpaired electrons. The essential reason may be thought of as the twisting of one O atom configuration relatively to the other to eliminate the lone pair-lone pair repulsion that would otherwise be present.

Such an account at once explains why the ground state of the $\mathrm{H}_{2} \mathrm{O}_{2}$ molecule should be skew and not planar. One H atom pairs with the odd " $2 p_{x}$ " electron and the other with the odd " $2 p_{y}$ " electron of the $\mathrm{O}_{2}$ ground state.

Consider now the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule. A $\mathrm{CH}_{2}$ group is isoelectronic with an O atom and, as we have seen, the orbitals of $\mathrm{C}_{2} \mathrm{H}_{4}$ correspond to those of $\mathrm{O}_{2}$. In particular, the $b_{2}$ $\mathrm{CH}_{2}$ group orbitals correspond to the $2 p \pi \mathrm{O}$ orbitals of the $\mathrm{O}_{2}$ molecule. The electrons in the filled $b_{2} \mathrm{CH}_{2}$ group orbitals must repel each other in the $\mathrm{C}-\mathrm{C}$ bond of $\mathrm{C}_{2} \mathrm{H}_{4}$, just as the electrons in the filled, parallel, $2 p \pi$ atomic orbitals repel each other in the $\mathrm{O}-\mathrm{O}$ bond of singlet $\mathrm{O}_{2}$. This repulsion is described in alternative language by saying that two electrons occupy the $\mathrm{CH}_{2} \longleftrightarrow \mathrm{CH}_{2}$ anti-bonding ( $b_{3 g}$ ) molecular orbital. On the other hand, the repelling $b_{2} \mathrm{CH}_{2}$ group electrons are further apart (see Fig. 1) than would be repelling $\mathrm{O} 2 p \pi$ electrons. The repulsion in the ground state of the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule, analogous to the lone pair-lone pair repulsion of the $\mathrm{O}_{2}$ molecule, will therefore be comparatively weak and it is not surprising that the ground state of $\mathrm{C}_{2} \mathrm{H}_{4}$, unlike that of $\mathrm{O}_{2}$, is singlet. The magnitude of the repulsion will be indicated by the energy needed to raise the $\mathrm{C}_{2} \mathrm{H}_{4}$
molecule to a triplet state analogous to $\mathrm{O}_{\mathbf{2}}{ }^{3} \mathrm{\Sigma}_{g}-$. Estimates of this energy vary, but there is general agreement that the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule does have a comparatively low-lying triplet state. The reason for the low height can be thought of as the tendency of the two $\mathrm{CH}_{2}$ groups to twist relatively to each other in order to remove the analogue of the lone pairlone pair repulsion existing in, for example, the $\mathrm{O}_{2}{ }^{1} \Delta_{g}$ or ${ }^{1} \Sigma_{g}{ }^{+}$state. In the ground state the tendency to twist is opposed by the tendency of the " $\pi$ " $\mathrm{C}-\mathrm{C}$ bond to keep the two $\mathrm{CH}_{2}$ planes identical. In the upper state of transition (1), however, this opposition is partly removed, the effect of the anti-bonding ( $b_{2 g}$ ) electron roughly cancelling that of the bonding $b_{3 u}$ electron. One deduces that the excited state (other geometrical changes being for the moment neglected) will be most stable when the planes of the two $\mathrm{CH}_{2}$ groups are at $90^{\circ}$.

Olson (Trans. Faraday Soc., 1931, 27, 69) first suggested that the $\mathrm{C}_{2} \mathrm{H}_{4}$ absorption near $2000 \AA$ involved an upper state of this shape. The conclusion has been deduced theoretically, in language less simple than that used here, by Mulliken (Rev. Mod. Phys., 1942, 14, 265) and by Mulliken and Roothaan (Chem. Reviews, 1947, 41, 219). Mulliken called the $\mathrm{CH}_{2} \leftrightarrow \mathrm{CH}_{2}$ repulsion that is responsible " second-order hyperconjugation."

The $\mathrm{CH}_{2} \mathrm{O}$ molecule must be even closer than $\mathrm{C}_{2} \mathrm{H}_{4}$ to $\mathrm{O}_{2}$ in electronic structure. The analogue of the lone pair-lone pair repulsion will now be between the electrons in the $\mathrm{CH}_{2} b_{2}$ group orbital and those in the $\mathrm{O}\left(2 p_{y}\right), b_{2}$ lone-pair orbital. It will be stronger than the corresponding repulsion in $\mathrm{C}_{2} \mathrm{H}_{4}$. Various consequences of this may be traced in the facts relating to the $\mathrm{CH}_{2} \mathrm{O}$ molecule. For the present we note that it explains the reversal in the energy order of the two outermost orbitals occupied in the ground states of $\mathrm{CH}_{2} \mathrm{O}$

Fig. 1.

Fig. 2.

and $\mathrm{C}_{2} \mathrm{H}_{4}$. Because the lone pair-lone pair repulsion, which makes the $\left(\pi_{g} 2 p\right)$ orbital of $\mathrm{O}_{2}$ and the corresponding $O\left(2 p_{y}\right), b_{2}$ orbital of $\mathrm{CH}_{2} \mathrm{O}$ lie high in energy, is much weaker in $\mathrm{C}_{2} \mathrm{H}_{4}$, the corresponding ( $b_{3}$ ) orbital of $\mathrm{C}_{2} \mathrm{H}_{4}$ will be more tightly bound relatively to the other $\mathrm{C}_{2} \mathrm{H}_{4}$ orbitals.

Shape of the First Excited State of $\mathrm{C}_{2} \mathrm{H}_{4}$ : Evidence.-The conclusion reached above is that in its first excited state (either singlet or triplet) the $\mathrm{C}_{2} \mathrm{H}_{4}$ molecule should have (i) one $\mathrm{CH}_{2}$ group twisted though $90^{\circ}$ relative to the other, (ii) a pyramidal arrangement of the bonds about each C atom, and (iii) each C atom possibly slightly out of the mirror plane bisecting the HCH angle of the other $\mathrm{CH}_{2}$ group. That at least the first two of these conclusions are correct can be strongly supported as follows. A corollary of the molecular-orbital approach adopted in this series of papers is that the symmetry of the first excited state of a molecule containing $n$ electrons should be the same as that of the ground state of the similar molecule containing $n+1$ or $n+2$ electrons. The latter, in relation to the ground state symmetry of the molecule containing $n$ electrons, reveals how the first excited orbital of the latter tends to stabilize the molecule, a tendency possibly all the greater in the first excited state of the $n$-electron molecule because one electron may then be missing from an orbital tending to stabilize the molecule in its original shape. As examples of the corollary, the first excited state of $\mathrm{CO}_{2}$ should belong to the same symmetry class as the ground states of $\mathrm{NO}_{2}$ and $\mathrm{SO}_{2}$; the first excited state of $\mathrm{NO}_{3}{ }^{-}$should have the same symmetry as the ground state of $\mathrm{NF}_{3}$; and the first excited state of $\mathrm{CH}_{2} \mathrm{O}$ should be similar to the ground state of $\mathrm{H}_{2} \mathrm{NF}$. We can therefore test our conclusions as to the symmetry of the first excited state of $\mathrm{C}_{2} \mathrm{H}_{4}$ by means of the shape of the ground state of the hydrazine molecule. Scott, Oliver, Gross, Hubbard, and Huffman (J. Amer. Chem. Soc., 1949, 71, 2293; see also Wagner and Bulgozdy, J. Chem. Phys., 1951, 19, 1210, and Giguère and Liu, ibid., 1952, 20, 136), from the evidence of infra-red spectroscopy concluded that the molecule has a pyramidal arrangement of the bonds about each N atom, a staggered
configuration of the H atoms (somewhat as Fig. 2) being favoured. Collin and Lipscomb (Acta Cryst., 1951, 4, 10) suggest that in the crystal the H atoms lie in the opposed or eclipsed configuration. However, the barrier to rotation about the $\mathrm{N}-\mathrm{N}$ bond should be small, so that crystal forces might cause the eclipsed form to be more stable in the solid state, even though the staggered configuration is the more stable in the isolated molecule. The configuration favoured by Scott et al. is just that expected for the first excited state of $\mathrm{C}_{2} \mathrm{H}_{4}$ on the basis of (i) and (ii) above. There appears to be no evidence to support expectation (iii), but the deviation may be so small as not to be easily detected.

Vibrational Structure to be expected for the First Transition of $\mathrm{C}_{2} \mathrm{H}_{4}$. - In the light of our expectations as to the shape of the ${ }^{1} B_{1 u}$ state of $\mathrm{C}_{2} \mathrm{H}_{4}$, at least the following vibrations might be expected to appear in the transition (1) or its triplet $\leftarrow$ singlet analogue : (i) the $\mathrm{C}-\mathrm{C}$ valence vibration, $\nu_{2} a_{g}$, which has a frequency $1623 \mathrm{~cm} .^{-1}$ in the ground state; (ii) the $\mathrm{CH}_{2}-\mathrm{CH}_{2}$ twisting vibration, $v_{4} a_{u}$, which has a frequency $1027 \mathrm{~cm} .^{-1}$ in the ground state (Arnett and Crawford, J. Chem. Phys., 1950, 18, 118) ; (iii) one or both of the out-of-plane bending vibrations, $v_{7} b_{1 u}$ and $v_{8} b_{2 g}$, which have frequencies 949 and $943 \mathrm{~cm} .^{-1}$ respectively in the ground state (these are included because of the tendency of the C atoms to assume a pyramidal bond arrangement) ; (iv) one or both of the in-plane deformation vibrations, $v_{10} b_{2 u}$ and $v_{6} b_{19}$, which have frequencies 995 and $1050(?) \mathrm{cm} .^{-1}$ respectively in the ground state (these may be thought of as arising from the rotation of the two $\mathrm{CH}_{2}$ groups about axes perpendicular to the molecular plane, and are included because of the expectation that each C atom may lie out of the mirror plane bisecting the HCH angle of the other $\mathrm{CH}_{2}$ group). In addition, the following might also occur: (v) one or both of the $\mathrm{CH}_{2}$ deformation vibrations $v_{3}$ and $v_{12}$ which change the HCH angles relatively to the HCC angles [they are included because it is improbable that in the excited state angle HCH remains approximately equal to angle HCC (cf. Part VIII)] ; (vi) one or both of the CH stretching vibrations $v_{1}$ and $\nu_{11}$ (these are included because the change of bond arrangement from planar to pyramidal implies that the C valencies towards the H atoms, and hence the $\mathrm{C}-\mathrm{H}$ stretching force constants change).

If, as is probable from the arguments above, the upper state departs appreciably from $\mathrm{V}_{h}$ symmetry, the symbol $B_{1 u}$ is not strictly applicable and any symmetry restrictions on which vibrations can occur are relaxed. Unfortunately, the absorption that is best identified as transition (1) is continuous, having a maximum at ca. $1615 \AA$. It is difficult therefore to test our expectations. A system of bands observed by Snow and Allsopp (Trans. Faraday Soc., 1934, 30, 93) in the range 1935-2069 $\AA$ and yielding a frequency between 760 and $920 \mathrm{~cm} .^{-1}$ may either represent the tail of the $1615-\AA$ absorption or the ${ }^{1} A_{1 g} \longleftarrow{ }^{1} A_{1 g}$ transition suggested by Craig or part of the triplet $\leftarrow$ singlet analogue of (1) (Moffitt, loc. cit.). In the second of these possibilities the system is due to a twoelectron jump between the same two orbitals as the one-electron jump (1). In any case, therefore, the frequencies involved are likely to represent one or more of the vibrations (i)-(iv).-The biggest changes of geometry in the equilibrium form of the upper state are probably the lengthening of, and twisting about, the $\mathrm{C}-\mathrm{C}$ bond. Vibrations (i) and (ii) are perhaps therefore likely to be the most prominent. It is noteworthy that Reid ( J. Chem. Phys., 1950, 18, 1299) has observed a system of weak absorption bands in the near ultra-violet which is plausibly supposed to represent the triplet-singlet analogue of (1), and has attributed the band separation of $995 \mathrm{~cm} .^{-1}$ to the upper-state twisting frequency. It is also noteworthy that the first known absorption of cyclopentene (Carr and Stuecklen, ibid., $1938,6,55$ ) shows a long succession of narrow shallow bonds which have separations of $90-160 \mathrm{~cm} .^{-1}$ and are believed to represent puckering vibrations of the ring, which are to be expected on the basis of expectations (i)-(iv) above.

The list of possible $\mathrm{C}_{2} \mathrm{H}_{4}$ vibrations that might appear in its spectrum is a formidable one and there is little direct evidence in favour of most of the possibilities. Nevertheless, indirect support for the ideas on which the list is based is to be found in the spectrum of benzene which is briefly dealt with in the following paper.

[^0]:    - Part VIII, preceding paper.

[^1]:    * The explanation would be that excitation of an electron from the $b_{3 u} \mathrm{CC}$ orbital results in the $b_{3 g}$ $\mathrm{CH}_{2}$ group orbital being "pulled" away from the H atoms and more on to the C atoms, and that an occupied orbital that is largely built from in-plane $2 p$ orbitals on the C atoms tends to cause in-plane bending of the molecule.
    $\dagger$ Craig (Proc. Roy. Soc., 1950, A, 200, 272), however, considers the first singlet-singlet transition to be ${ }^{1} A_{10} \leftarrow^{1}{ }^{1} A_{10}$, where the upper state arises by a two-electron jump to the ( $b_{2 g}$ ) orbital. Moffitt (Proc. Phys. Soc., 1950, 63, $A, 585$ ) has criticized this.
    $\ddagger$ This explanation should be used with care, especially when it is remembered that there is no practical distinction between the $x$-and the $y$-direction for a linear molecule. Nevertheless, the author believes it to be of value in giving a very simple way of gaining some insight into the fundamental reasons for the triplet ground state of $\mathrm{O}_{2}$ and the shape of the $\mathrm{H}_{2} \mathrm{O}_{2}$ molecule, their connection with the low height and twisted nature of the $\mathrm{C}_{2} \mathrm{H}_{4}$ lowest triplet state, and several facts concerning the $\mathrm{CH}_{2} \mathrm{O}$ molecule.
