339. Chemical Constitution and the Dissociation Constants of Monocarboxylic Acids. Part XIX.* Dihydroxy- and Dichloro-benzoic Acids.

By J. F. J. DIPPY, S. R. C. HUGHES, and L. G. BRAY.

The strengths of all six dihydroxybenzoic acids and three dichlorobenzoic acids in water have been determined conductometrically. The qualitative effect of introducing a second substituent into the monosubstituted benzoic acid is consistent with expectation although in certain cases substantial departures from additivity have been observed.

THE strengths of all six dihydroxybenzoic acids in water (Table 1) have now been determined by a standard procedure, and the effect of introducing a second hydroxyl group into the monohydroxybenzoic acid system is qualitatively that to be expected from a knowledge of the polar character (-I+M) of the hydroxyl substituent $(10^5K$ for o-, m-, and phydroxybenzoic acids = 101, 3.27, and 2.94, respectively). Thus in both the salicylic acid and the m-hydroxybenzoic acid system, the introduction of a meta-hydroxyl group has the effect of strengthening the acid, whereas the entry of para-hydroxyl depresses the strength. Quantitative examination of the K data reveals, however, that only in the

1718 Dippy et al.: Chemical Constitution and the Dissociation

case of 2,4-dihydroxybenzoic acid is there absolute additivity.¹⁻³ This is doubtless connected with the fact that there is no possibility of steric or mesomeric interaction here between the two hydroxyl groups, whereas both of these additional factors might operate in 2.3- or 3.4-dihydroxybenzoic acids so as to modify their strengths. It is significant, therefore, that departures of -2.9% and -38% from additivity are observed with these

acids; the observed departure for the 2,5-acid (where the additional mesomeric factor alone operates) is -5.5%. The remarkably high strength of 2,6-dihydroxybenzoic acid, already well-known, has received confirmation; an explanation of this feature has already been advanced.4

A wholly unexpected result is the strength of 3,5-dihydroxybenzoic acid which is very little greater than that of *m*-hydroxybenzoic acid and shows a departure of -32% from additivity. It is not possible to envisage any mutual interaction between the two hydroxyl groups in this structure, and the phenomenon cannot yet be explained.

The dissociation constants of three dichlorobenzoic acids have also been determined. The introduction of a second chlorine substituent into o-chlorobenzoic acid leads, as expected, to a substantial enhancement of strength, by virtue of the -I effect, although the effect from the *para*-position (where +M operates) is less than from the *meta*-position as the data in Table 1 reveal (cf. $10^3 K$ for o-, m-, and p-chlorobenzoic acids = 1.14, 0.148, and 0.105, respectively). In 2,6-dichlorobenzoic acid the very large increment in strength is doubtless due to the additional steric factor introduced by the second substituent. Quantitative consideration of the data shows that entry of the second chlorine substituent produces a small departure (ca. +3 to +6%) from additivity in each of the three acids.

Specimens of the remaining acids of this series proved so sparingly soluble in water that even very approximate measurements of their dissociation could not be made.

These data, coupled with those published recently by us,^{2,3} go some way to making good the deficiency of reliable dissociation-constant data for disubstituted aromatic acids.

EXPERIMENTAL

Materials.—2,6-Dichlorobenzoic acid was prepared from 2,6-dichlorotoluene by side-chain bromination, followed by oxidation with alkaline potassium permanganate as described by Norris and Bearse.⁵ The remaining acids were purchased.

All acids were recrystallised from conductivity water or from aqueous acetone, except 2,5-dihydroxybenzoic acid which was recrystallised from benzene-acetone. Final specimens were dried in individual vacuum desiccators over silica gel for at least 3 weeks, and the equivalents were confirmed by alkalimetry.
