#### Abstract

As a right-hand segment with three consecutive chiral centres corresponding to the C-1-C-5 unit of erythromycin A (1), ( $2 S, 3 R, 4 S$ )-3,5-isopropylidenedioxy-2,4-dimethylpentanal (32) was synthesized from d-glucose (5) by application of MPM (4-methoxybenzyl) protection for an hydroxy function and some fairly stereoselective reactions, hydroboration and hydrogenation.

In the preceding papers ${ }^{1,2}$ we described a stereocontrolled synthesis of an important chiral synthon (6) for the total synthesis of erythromycin A (1) from D-glucose (5) by means of the MPM ( $p$-methoxyphenylmethyl) protection of hydroxy groups and some stereoselective reactions, e.g. the Wittig reaction, $\mathrm{OsO}_{4}$ oxidation and epoxidation. Compound (6) is a synthetic equivalent of the left-hand segment i (3) of dihydroerythronolide A seco-acid (2) because it has the same six consecutive chiral centres with correct configurations. In this paper we report a stereocontrolled synthesis of another segment, the right-hand segment ii (4) corresponding to the C-$1-\mathrm{C}-5$ unit of (1) with three consecutive chiral centres, from D glucose (5) (Scheme 1).

## Results and Discussion

The ketone (7), derived from (5) as described in a previous paper, ${ }^{2}$ was treated with methylenetriphenylphosphorane in order to obtain the olefinic compound (8). Wittig reaction in dimethyl sulphoxide (DMSO) ${ }^{3}$ at room temperature proceeded quite smoothly to give an olefinic product which was, however, a 1:2 mixture of the expected olefin (8) and its isomer at the C-4 position, probably because the starting ketone (7) isomerized ${ }^{4}$ to the more stable isomer before being attacked by the Wittig

$R^{2}=L$ - cladinosyl
reagent under basic conditions in the polar solvent. When (7) was treated with the Wittig reagent in tetrahydrofuran (THF) at $-70^{\circ} \mathrm{C}$ and the mixture was allowed to warm to $0^{\circ} \mathrm{C}$ for a period of 9 h , olefin (8) was isolated as the sole product, though only in $52 \%$ yield with $14 \%$ recovery of the starting material (7).

Hydroboration of (8) in THF at between $0^{\circ} \mathrm{C}$ and room temperature, followed by hydrogen peroxide oxidation, gave a 2:3 diastereoisomeric mixture of compounds (9) and (10), which were readily separated by silica gel column chromatography. The structures of both compounds were determined through conversion into their respective triacetates (13) and (14) in a sequence of conventional reactions. The minor alcohol (9) was protected as the benzyl ether (11), and then the isopropylidene group was removed by treatment with trifluoroacetic acid (TFA), followed by lead tetra-acetate oxidation to give the aldehyde (12). Lithium aluminium hydride reduction of (12) gave the diol, which was hydrogenated to remove the benzyl group and then the resultant triol was acetylated to afford the oil triacetate (13). The ${ }^{1} \mathrm{H}$ n.m.r. spectrum clearly showed that (13) was a meso compound, because only one methyl signal, at $\delta 0.96$, was observed as a doublet ( $J 7 \mathrm{~Hz}, 6 \mathrm{H}$ ). The structure of compound (13) was finally confirmed by comparison of its spectral data with those of a degradation product of natural erythromycin $A(1)$ which will be reported in the following paper. ${ }^{4}$ The major alcohol (10) was converted into the isomeric triacetate (14) in the same way (Scheme 2). In its ${ }^{1} \mathrm{H}$ n.m.r. spectrum, two methyl groups were observed as two doublets at $\delta 0.94$ and 0.99 with the same coupling constant ( $J 7.0 \mathrm{~Hz}$ ), and hence (10) was not the expected compound.

Hydroboration of (15), isometic with (8) at C-3 and C-4, was reported ${ }^{5}$ to occur stereoselectively and to give a single product, but compound (8) gave by this method a mixture of alcohols and, moreover, the expected alcohol (9) was the minor product. Therefore, an alternative route for the synthesis of segment ii (4) was next examined.

The alcohol (16) ${ }^{6}$ derived readily from D-glucose (5) was first protected with the MPM group by treatment with MPM chloride and dimsylsodium in THF. The resultant MPM ether

(17a) was converted quite easily into the ketone (21a) by a method rather similar to that described in the earlier paper ${ }^{2}$ via a series of conventional reactions. Selective removal of the 5,6isopropylidene protection of (17a) with $2 \%$ sulphuric acid, followed by toluene- $p$-sulphonation of the primary hydroxy group ${ }^{7}$ of the resultant diol gave the mono-toluenesulphonate (18a), which was cyclized into the epoxide (19a) by treatment with potassium carbonate. Alcoholysis with sodium benzyl alcoholate in THF gave the hydroxyether (20a), and finally the secondary hydroxy group in (20a) was oxidized with pyridinium chlorochromate (PCC) in the presence of molecular sieves ${ }^{8}$ to afford the ketone (21a).

In contrast with (7), ketone (21a) gave solely the stereochemically pure olefin (22a) by the usual Wittig reaction in DMSO at room temperature, because compound (21a), with a $4-\beta$-keto* group, is more stable than the corresponding $4-\alpha-$ keto compound.

Hydroboration of olefin (22a) proceeded fairly stereoselectively even under the usual conditions, e.g. diborane in THF at room temperature, and a diastereoisomeric mixture (23a) of the expected alcohol as the main product and its isomer was obtained in moderate yield. The mixture (23a) without further purification, was converted into the methanesulphonate, followed by lithium aluminium hydride reduction to afford a

[^0]diastereoisomeric mixture of deoxy compounds (24a), again in moderate yield. Although the separation of the mixture into its components was quite difficult, the ratio was easily determined to be $6.6: 1$ by means of the $\mathrm{C}-5$ methyl signals in its ${ }^{1} \mathrm{H}$ n.m.r. spectrum. This means that the above hydroboration proceeded at a diastereoselection of the same ratio. The mixture (24a) was also obtained almost quantitatively directly from the olefin (22a) by catalytic reduction in the presence of rhodium on alumina at $0^{\circ} \mathrm{C}$, though the stereoselectivity was only modest ( $2.8: 1$ ). This direct reduction was nevertheless more convenient and efficient than the method via the hydroboration.

The mixture (24a) obtained by the catalytic reduction was treated with 4 M -hydrochloric acid to remove the 1,2 -isopropylidene protection, followed by oxidative cleavage with lead tetraacetate of the resultant vicinal diol group to afford a diastereoisomeric mixture of formyloxyaldehydes (25a). Lithium aluminium hydride reduction in ether, followed by silica gel column chromatography, gave the expected alcohol (26a) (64\%) and its diastereoisomer (27a) ( $23 \%$ ).

The major alcohol (26a) was treated with tosyl chloride and then reduced with lithium aluminium hydride in the usual way to afford the dimethyl compound (28a). The stereochemical configuration of (28a) was confirmed by its conversion into the meso dimethyltriacetate (13) (Scheme 3). Both the MPM and benzyl protecting groups were removed by treatment with sodium metal in liquid ammonia to afford the trihydroxy compound, which was acetylated in the usual manner. The resultant triacetate (13) was completely identical in its spectral data with both the abovementioned compound (13) synthesized from (7) and the degradation product of erythromycin A (1).

The antipodal dimethyl compound (28b) was next synthesized from (16) basically in the same way as was its isomer (28a). Benzylation of the alcohol (16), followed by a series of conventional reactions as described above, gave the olefin (22b) via intermediates (17b)-(21b) (b series). Catalytic reduction of the alkene (22b) over rhodium-alumina at $0^{\circ} \mathrm{C}$ gave a $3: 1$ mixture of diastereoisomers (24b) as determined by the C-5 methyl signals in its ${ }^{1} \mathrm{H}$ n.m.r. spectrum. Then the fully protected furanose (24b) was converted into a mixture of diols via (25b), and chromatographic separation on a silica gel column gave the expected diol (26b) ( $53 \%$ ) and its diastereoisomer (27b) $(17 \%)$. The primary hydroxy group of (26b) was excellently reduced to afford the dimethyl compound (28b), the enantiomer of (28a), and the n.m.r. and mass spectral data of both compounds were completely identical.

The MPM protecting group of (28b) was then selectively removed quite smoothly by treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in dichloromethane containing a small amount of water at room temperature according to the procedure described earlier. ${ }^{9}$ The resultant diol (29) was protected as the six-membered acetonide (30) in the usual way, and the benzyl protection was removed by catalytic hydrogenolysis over palladium on charcoal to afford the alcohol (31). Finally, PCC oxidation of the primary hydroxy group of (31) gave the oily aldehyde (32), which is synthetically equivalent to the segment ii (4) (Scheme 4). Compound (32) was completely identical in its spectral data and specific optical rotation with a degradation product of natural erythromycin $\mathbf{A}$ (1) which will be reported in the following paper. ${ }^{4}$

Further studies on the coupling reaction of compound (32) with some derivatives of the segment $i$ to give seco-acids and their cyclization to erythronolide A derivatives are currently in progress.
