# Applications of Potential Energy Calculations to Organic Chemistry. Part 17. ${ }^{1}$ Calculations of Highly Strained Cyclopropane Derivatives. Evaluation of Several Solar Energy Storage Systems involving Valence Isomerization of Cyclopropane Rings 

Eiji Ōsawa,* Gabor Szalontai, and Akira Tsurumoto<br>Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

#### Abstract

Available computational techniques were critically evaluated for their ability to reproduce and predict heats of valence isomerization of highly strained cyclopropane derivatives. Allinger's MM2 cyclopropane parameters were examined for diverse structures including bicycio[n.1.0]alkanes, spiropentanes, and bicyclopropyls. For the bicyclopropyls, a new parameter set was introduced. Experimental structures and energies of these cyclopropane derivatives were well reproduced by MM2 calculation with these parameters. The standard deviation of the enthalpy calculation for 12 compounds was $0.63 \mathrm{kcal}^{\mathrm{mol}}{ }^{-1} . \dagger$ Quadricyclane (1) turned out to be the most difficult to calculate. Neither MM2, MNDO, nor ab initio calculations with a minimal basis set and gradient geometry optimization reproduced the heat of isomerization of (1) to norbornadiene (20). A homologous isomerization, tetracyclo [4.2.0 2, 8.05.7] octane (23) into bicyclo[2.2.2]octadiene (24), is predicted to produce an enthalpy of $30 \mathrm{kcal}^{2} \mathrm{~mol}^{-1}, 10 \mathrm{kcal}_{\mathrm{mol}}{ }^{-1}$ larger than that of the familiar reaction of (1) to (20). Two other isomerizations, ( $1 R, 3 R$ )-tricyclo[3.2.1.0 ${ }^{1,3}$ ] oct-6-ene (25) to 5 -methylenenorbornene (26), and ( $1 R, 2 R$ )-tricyclo[4.2.1.0 ${ }^{1,3}$ ]non-7-ene (27) to 5 -methylenebicyclo[2.2.2]oct-2-ene (28), are predicted to give $\Delta H^{\ddagger} 26 \mathrm{kcal} \mathrm{mol}^{-1}$. MM2 is the most convenient method to calculate isomerization of cyclopropane derivatives excepting quadricyclane.

Recent interest in the valence isomerization of highly strained cyclopropane derivatives such as quadricyclane (1) as a means of solar energy utilization ${ }^{2}$ has created the need to predict the heat of reaction in these transformations. However, the calculation of strained molecules as big as (1) poses a number of practical problems. They are generally too large for the $a b$ initio MO method with an extended basis set and force relaxation, despite the recognized success of this approach in smaller cyclopropane derivatives. ${ }^{3-7}$ Semiempirical SCF MO methods such as MNDO ${ }^{8}$ often fail with strained polycyclic molecules such as cubane, ${ }^{8,9}$ hence their credibility must be checked on a case-by-case basis. In the empirical force field method, ${ }^{10-12}$ the cyclopropane ring has been either excluded, ${ }^{13}$ regarded as a rigid body, ${ }^{14-16}$ or treated as a special system in which ring carbon atoms are given special angle bending and torsional constants. ${ }^{17,18}$ Allinger ${ }^{19}$ has elaborated the last approach in his latest force field, MM2. ${ }^{20}$ In view of the generally high performance of MM2, ${ }^{11,12,21}$ it appears desirable to extend this approach to more diverse types of cyclopropane derivatives including (1).
In this paper, we apply $a b$ initio with a minimal basis set, MNDO, and MM2 methods to calculate highly strained cyclopropane derivatives constrained in condensed ring systems and critically evaluate their performance.

## Calculations

The $a b$ initio program package IMSPAK ${ }^{22}$ was used to calculate molecules having up to 70 atomic orbitals with the STO-3G basis set combined with geometry optimization by the gradient technique. ${ }^{23}$ MNDO ${ }^{24}$ and MM2 ${ }^{19}$ programs were obtained from QCPE.

## Results and Discussion

Examination of Original MM2 Parameters for Cyclo-propane.-First, Allinger's original parameter set as given in the MM2 program ${ }^{19}$ was tested for its ability to calculate
structures and energies of cyclopropanes. Table 1 summarizes key structural parameters calculated for various types of cyclopropanes whose precise structures have been determined experimentally. Agreements between the calculated and observed values are satisfactory not only for simple alkyl derivatives but also for strained bicyclo[n.1.0.]alkanes and spiropentanes.

A few comments on bicyclo[2.1.0]pentane (2) and bicyclo[3.1.0]hexane (3) appear appropriate here in view of recent controversies on the length of the bond between bridgehead carbon atoms of these molecules. Electron diffraction analyses gave abnormally short lengths of $1.43-1.45 \AA$ to (2). ${ }^{25.26}$ The same method gave an abnormally long length for the opposite cyclobutane bond $(1.622 \AA) .{ }^{25}$ In contrast, microwave analysis ${ }^{27}$ produced more uniform lengths for these bonds. Furthermore, three crystalline derivatives [(4)-(6)] of (2) have been subjected to $X$-ray diffraction analysis ${ }^{28-30}$ and consistently gave lengths similar to those from the microwave analysis. These 'statistics' support a view ${ }^{27 b}$ that the electron diffraction data of (2) ${ }^{25}$ have been interpreted incorrectly. Thus, it is most likely that the $\mathrm{C}(1)-\mathrm{C}(4)$ bond of (2) is slightly shorter than normal (hence abnomally long for a cyclopropane bond), while $C(2)-C(3)$ bond should have typical cyclobutane length $(1.555 \AA){ }^{31}$ It is gratifying to note that MM2 structure of (2) fits well with this picture, as does the structure obtained by ab initio calculation with split valence basis set and force relaxation (Table 1).
The situation with (3) is more complicated. Among the $X$ ray analyses of derivatives of (3) [(7)-(10)] ${ }^{30-34}$ and of heteroatom analogues (11), ${ }^{35}$ three of them indicate abnormally short $\mathrm{C}(1)-\mathrm{C}(5)$ lengths ( $1.46-1.49 \AA$ ), whereas the other three gave slightly longer than normal lengths ( $1.51-1.52 \AA$ ) for the bridgehead-bridgehead bond. Again, MM2 and $a b$ initio calculations gave almost identical structure with the $\mathrm{C}(1)-\mathrm{C}(5)$ bond length of $1.51 \AA$. In view of the high reliability of ab initio calculation with double-zeta type basis set and force geometry optimization in reproducing structures of other strained hydrocarbons, ${ }^{6}$ we are inclined to regard the ab initio structure as the most reasonable.

parameter set meets with some difficulty is that of bicyclopropyl. Although Allinger implemented devices for angle bending and torsional parameters in order to distinguish between different cyclopropyl rings when they are joined in the spiro fashion as in spiropentane (12) or fused with each other as in bicyclo[1.1.0]butane (13), no such consideration was given to the bond stretch parameter. Hence, the $\mathrm{C}^{-} \mathrm{C}$ bond joining two cyclopropyl rings, e.g. in trans-bicyclopropyl (16), would have been treated simply as the usual endocyclic cyclopropane bond. This bond is known to be abnormally short according to electron diffraction $(1.499 \AA)^{36}$ and lowtemperature $X$-ray diffraction $(1.487 \AA)^{37}$ analyses, but was calculated to be much longer ( $1.534 \AA$ ) by MM2. We added two natural lengths for bonds that directly connect two cyclopropane rings: one is for the tricyclohexane (17) where the connecting bond is also a cyclobutane bond, and the other is for all other types (Table 3). While the latter, general type may be temporarily fixed at $1.487 \AA,{ }^{37}$ it is rather difficult to
decide the standard values for the tricyclohexane type. If we give a special atom type (e.g. no. 29) to $\mathrm{C}(1)$ and $\mathrm{C}(2)$ [and to $C(4)$ and $C(5)]$ of (17), not only the $C(1)-C(2)[C(4)-C(5)]$ but also the $C(1)-C(5)[C(7)-C(4)]$ bond become the 29-29 type. The $\mathrm{C}(1)-\mathrm{C}(2)$ type, which is a cyclobutane bond, appears to change greatly from compound to compound. While electron diffraction of (17) gave only the average lengths, ${ }^{38} a b$ initio (4-21 G, force relaxation) calculations ${ }^{39}$ gave a value ( $1.504 \AA$ ) which is similar to the experimental value of bicyclopropyl. ${ }^{36,37}$ However, the corresponding bond in (1) is longer than usual: $1.56-1.57$ (electron diffraction) ${ }^{39}$ or $1.541 \AA$ (ab initio). ${ }^{40}$ On the other hand, the $C(1)-C(5)[C(2)-C(4)]$ bond of (17) is predicted to be longer $(1.547 \AA)^{40}$ than the corresponding bond length of (2) (1.525 $\AA$ ) ${ }^{6 a}$ and of (1) (1.524 $\left.\AA\right) .{ }^{40}$ We place emphasis on reproducing the $a b$ initio lengths of (17) ${ }^{40}$ and gave two provisional standard lengths for these bonds (Table 2).

derivatives are compared with experimental and ab initio values in Table 3. The agreement is only moderate for (1) as expected, albeit the experimental structures of ethano-bridged bicyclopropyl (18) ${ }^{41}$ were quite satisfactorily reproduced. Whereas Braun and Traetteberg ${ }^{41}$ expected strong repulsion between the 3 - and 8 -methylene groups and the consequently distorted six-membered ring in cis-(18), our calculations indicate no severe crowding between the cis-cyclopropane rings ( $3-\mathrm{H} \cdots 7-\mathrm{H} 2.32 \AA$ ) and no significant ring distortion in this isomer compared to trans-(18) $\left(\omega_{2456}-28.9^{\circ}\right.$ for cis versus $-28.1^{\circ}$ for trans, $\omega_{4567} 52.50^{\circ}$ for cis versus $42.84^{\circ}$ for trans).

Having surveyed the structural aspects, we now turn to the energy. Only one type of bond increment parameter (29-29) had to be devised and this was used such that the heat of formation and strain energy of bicyclopropyl (16) are exactly reproduced (Table 2). Table 4 summarizes the calculated heats of formation of 15 compounds whose heats of formation have been experimentally determined. Two structures having the bicyclo[1.1.0]butane skeleton [(13) and 1,3-dimethyl-(13)] at first gave heats of formation $c a .8 \mathrm{kcal} \mathrm{mol}^{-1}$ higher than those observed, indicating that the central cyclopropane bond $\left(-7.429 \mathrm{kcal} \mathrm{mol}^{-1}\right)^{20}$ must be counted twice in the calculation of heat increments. When this measure was taken, our calculation gave reasonable agreement with experimental values.

Two other structures, trans-bicyclo[6.1.0]nonane [trans-(19)] and (1), gave discrepancies with experiment of larger than 3 $\mathrm{kcal} \mathrm{mol}{ }^{-1}$. The experimental heat of formation of trans-(19) was reported by Corbally ${ }^{42}$ together with that of the corresponding cis-isomer, and he proposed that bicyclo[6.1.0]nonane is the smallest bicycloalkane for which the trans-isomer is more stable than the corresponding cis-derivative (Table 4). We believe that the reported heat of formation of cis-(19) is correct but that of trans-(19) incorrect for the following three reasons. First, the three reported experimental heats of formation of cis-(19) agree among each other as well as with our calculated value (Table 4). Hence, it is very likely that cis-(19)
has a heat of formation of $7.5 \mathrm{kcal} \mathrm{mol}^{-1}$. Second, it is more likely that trans-(19) will be thermodynamically less stable than cis-(19). In the analogous olefin, cyclo-octene, the transisomer is $10-11 \mathrm{kcal} \mathrm{mol}^{-1}$ less stable than the corresponding cis-isomer. ${ }^{43}$ Finally, SCF MO MNDO calculations ${ }^{8,24}$ also accorded higher stability to cis-(19) compared with trans-(19) (Table 4). Furthermore, whereas Corbally ${ }^{42}$ states that the experimental heats of formation of the isomers of (19) agree with force field calculations, the Engler force field ${ }^{13}$ that they employed has not been parameterized for cyclopropanes, and therefore the agreement should be considered accidental. In our calculations of (19), an extensive search was carried out for the global energy minimum conformation of the transisomer, starting from a conformation obtained by adding methylene to the well known $C_{2}$ global minimum conformer ${ }^{10}$ of trans-cyclo-octene, and the starting conformation was confirmed to have the lowest energy (see Appendix). Based on this result, the global minimum conformation of cis-(19) was obtained by combining the $C_{t}$ global minimum structure of cis-cyclo-octene with a methylene group. ${ }^{44}$

We have not found the right way to correct for the calculated heat of formation of (1) which was $14.4 \mathrm{kcal} \mathrm{mol}^{-1}$ too high. The reason for the overestimation is probably related to our failure to reproduce its structure with a satisfactory level of precision. Clearly, (1) cannot be regarded as a molecular mechanical extension of (14). Thus, excluding (1), (16), and trans-(19), the standard deviation of the calculated heats of formation among the remaining 12 structures in Table 4 is $0.63 \mathrm{kcal} \mathrm{mol}^{-1}$, which should be regarded as falling within the practicable range. For comparison, the corresponding standard deviation of the original MM2 for 42 hydrocarbon molecules is $0.42 \mathrm{kcal} \mathrm{mol}^{-1} .{ }^{20}$

Molecular mechanics usually perform less satisfactorily in energy than in structural calculations. ${ }^{10-13,45}$ Table 5 gives a few examples which demonstrate some difficulties in reproducing small energy changes accompanied by conformational processes such as trans-to-gauche interconversions. The errors in these cases are $c a .1 \mathrm{kcal} \mathrm{mol}^{-1}$, which one would expect from the magnitude of the standard deviation in energy calculations.

Heats of Valence Isomerization of Strained, Polycyclic Cyclopropane Derivatives.-Three available methods of computation of molecular energies, namely molecular mechanics, and semi- and non-empirical SCF molecular orbital calculations, gave diverse heats of reaction for the quadricyclane $\rightarrow$ norbornadiene isomerization (Table 6). ${ }^{46,47}$ Since all the computations performed in this work involve complete geometry optimization, ${ }^{23,24,49}$ the failure of computation should reflect inherent properties of the methods. The excessive heat of reaction obtained by MM2 is due to the overestimation of strain in (1) as mentioned above. MNDO well reproduces the energy of (1), but overestimates the norbornadiene energy by $8 \mathrm{kcal} \mathrm{mol}^{-1}$. The performance of STO-3G gradient calculation is certainly disappointing.

The valence isomerization (21) $\longrightarrow$ (22), for which the heat of reaction has been determined, ${ }^{49}$ was overestimated by MNDO. This MO method overestimates the enthalpy of bicyclo[1.1.0]butane (13) by $17 \mathrm{kcal} \mathrm{mol}^{-1,8}$ and hence should be particularly unsuitable for the calculation of this isomerization. The MM2 enthalpy of (21) and MNDO enthalpy of (22) are perhaps correct, since the combination of these reproduces the observed heat of reaction.* For a hypothetical interconversion of homoquadricyclane (23) to bicyclo[2.2.2]octadiene (24), the three computational methods gave close

estimates of $c a .30 \mathrm{kcal} \mathrm{mol}^{-1}$ for the heat of reaction. We tend to believe this coincidence, because no unusual and difficult features are involved in the structures of (23) and (24), and the calculations probably worked well for this reason. If so, it is interesting to note that this series produces ca. 10 kcal $\mathrm{mol}^{-1}$ more energy than the familiar (1) $\longrightarrow(20)$ system. The predominant contributor to the increased heat of reaction is the high stability of (24) compared with (20): the enthalpy difference between (20) and (24) ( $20 \mathrm{kcal} \mathrm{mol}^{-1}$ ) is much larger
than the heat increment of methylene group ( $5.9 \mathrm{kcal} \mathrm{mol}^{-1}$ ), ${ }^{13}$ and the enthalpy difference between (1) and (23) is only 10 kcal .

For the reactions $(25) \longrightarrow(26)$ and $(27) \longrightarrow(28),{ }^{51}$ MNDO gave much higher heats of reaction than MM2. The cyano-group appears to increase the heat of reaction. Both MM2 and MNDO predict that the use of (27), a homologue of (25), decreases the heat of reaction, in contrast to the $(1) \longrightarrow(20)$ system. However, it may be noted that even the

minimum predicted heat of reaction for $(25) \longrightarrow(26)$ is the largest known among the solar energy storage systems.

## Conclusions

Highly strained cyclopropanes are generally difficult to calculate by available versions of molecular orbital methods. Molecular mechanics (MM2) is most suitable for this purpose, although the enthalpy and structure of quadricyclane (1) is badly reproduced by this method. MM2 gives good results for various types of cyclopropane derivatives except for (1). The
accuracy of MM2 in calculating energies of cyclopropanes is high, but errors may amount to $\pm 1 \mathrm{kcal} \mathrm{mol}^{-1}$. A homologue (23) of quadricyclane is predicted to produce $10 \mathrm{kcal} \mathrm{mol}^{-1}$ more energy than (1) in the valence isomerization to tricyclic diene.

## Appendix

Torsional Energy Surface Coverage of trans-Bicyclo[6.1.0]nonane trans-(19).-In order to search the energy surface as extensively as possible, five sets of three-dimensional energy surface were drawn up by using highly automated two-bond

Each surface contained three to five energy minima. Reminimization of these gave four unique energy minima (Table 7). As expected, there exists a close relation between (19) and trans-cyclo-octene. Ermer ${ }^{52}$ has detected five energy minima for the latter, of which the lowest four correspond to those of (19). Although the relative stability of M2 and M3 is reversed in (19), the global energy minimum conformation M1 is common to both molecules.

## Acknowledgements

We thank Professors T. Mukai and O. Yonemitsu for suggesting the problem, and Professor K. B. Wiberg for a pre-
print. The work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education and by Kureha Chemical Industries Co. Calculations have been carried out at the Computing Centres of Hokkaido University and the Institute for Molecular Science on HITAC M-200H systems.
