# Conformational Analysis of Methylsulphinyl Derivatives of Furan and Thiophene by Employing Nuclear Magnetic Relaxation and Lanthanide Induced Shifts 

Ugo Folli, Dario larossi, Adele Mucci, Luisa Schenetti and Ferdinando Taddei *<br>Dipartimento di Chimica, Università, Via Campi 183, 41100 Modena, Italy

#### Abstract

Relaxation parameters such as nuclear Overhauser effect (NOE) and spin-lattice relaxation times ( $T_{1}$ ) were applied to the conformational analysis of methylsulphinyl derivatives of furan and thiophene. Correlation times for molecular tumbling, $\tau_{c}$, and for methyl reorientation, $\tau_{\mathrm{i}}$, were obtained. The $\tau_{\mathrm{i}}$ values for the different molecules examined are nearly the same, the $\tau_{c}$ are twice as large in derivatives that also contain an iodine substituent in the heterocyclic ring. From non-selective, selective and bi-selective $T_{1}$ measurements and NOE values, relative to ${ }^{1} \mathrm{H}$ nuclei, and a best-fit procedure, the most probable conformational intervals for the methylsulphinyl group were located. Owing to the pyramidal structure of sulphoxides, the preferred conformers could not be fixed unambiguously. From the Lanthanide Induced Shift (LIS) technique on ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ nuclei, intervals of preferred orientations of the S-O bond with respect to the heterocyclic ring were found. Reliable conclusions about the conformational behaviour of these molecules have been drawn by matching the two sets of results. Relaxation parameters turn out to be useful for conformational analysis of small molecules when employed as a complementary tool with other experimental approaches.

The preferred orientations of the $\mathrm{S}-\mathrm{O}$ bond in the groundstates of methylsulphinyl derivatives of furan and thiophene, compounds 1-4, have been studied with MO ab initio methods ${ }^{1}$ and, in solution, by employing an experimental integrated approach ${ }^{2}$ based on ${ }^{1} \mathrm{H},{ }^{13} \mathrm{C}$ and ${ }^{17} \mathrm{O}$ chemical shifts and longrange ${ }^{n} J(\mathrm{C}, \mathrm{H})$ coupling constants. Solid-state molecular structures obtained by X-ray diffraction for the molecules also containing halogen atoms were employed ${ }^{2}$ as references for the conformational tests in solution.
Owing to the pyramidal structure of the sulphur atom of the sulphoxides, the conformation of the methylsulphinyl group cannot be unambiguously assigned when only the torsional angle of the methyl group, or that of the S-O bond with respect to the heterocyclic ring, are known. Approximate information on these torsional angles can be obtained from ${ }^{1} \mathrm{H}$, ${ }^{13} \mathrm{C}$ and ${ }^{17} \mathrm{O}$ chemical shifts. ${ }^{2}$ The long-range ${ }^{n} J(\mathrm{C}, \mathrm{H})$ coupling constants, where the carbon nucleus refers to the methyl group, have proved ${ }^{2-4}$ to depend on the conformation of the methylsulphinyl group, and, those over four bonds, ${ }^{2}$ provided useful indications of the preferred orientation of the methyl group in the derivatives of furan and thiophene.
Stereochemical relationships between groups having nuclei active in nuclear magnetic resonance can, in principle, also be obtained from measurements of spin-lattice relaxation times ${ }^{5}$ ( $T_{1}$ ) and NOEs (nuclear Overhauser effects). For compounds 1-4, relaxation of ring protons should be influenced ${ }^{5,6}$ by the position in the ring and preferred orientations of the substituent containing the methyl group. Nevertheless, application of these techniques to conformational analysis is not straightforward owing to a number of limiting factors. Firstly, in a multi-spin system the spin-lattice pathway of each proton cannot be solved simply by a non-selective experiment ( $\left.T_{1}^{\text {ns }}\right)$ but mono- $\left(T_{1}^{s}\right)$ and bi-selective ( $T_{1}^{\text {bs }}$ ) modes are also required, in order to obtain proton-proton distances and correlation times. Secondly, in the molecules examined here, internal rotation of the methylsulphinyl group around the exocyclic $\mathrm{C}-\mathrm{S}$ bond and rotation of the methyl group have to be accounted for in view of the correlation times involved in these internal motions and in molecular tumbling.
Since applications of relaxation parameters to conformational equilibria of small molecules in solution are seldom reported,
our intention here is to contribute towards verifying the applicability of these techniques to a number of problems of this kind. At the same time the results will be a useful test for the conformational conclusions obtained ${ }^{2}$ from chemical shifts and long-range coupling constants in these systems.
Complexation in the presence of lanthanide ions should occur at the oxygen atom of the S-O group, and simulation of the lanthanide induced shifts ${ }^{7,8}$ on ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ nuclei should provide information on the most probable conformational range of the $\mathrm{S}-\mathrm{O}$ bond with respect to the heterocyclic ring. These results, when coupled with the orientation of the methyl group from relaxation parameters, should define the orientation of the methylsulphinyl group.

Relaxation Parameters and Outlines of Calculations.-Three relaxation times can be defined and measured for a multi-spin proton system and, referred to proton $i$, in the approximation of the initial rate conditions, ${ }^{5}{ }^{5}$ namely, $T_{\mathrm{li}}^{\mathrm{ns}}$ (non selective), $T_{\mathrm{li}}^{\mathrm{s}}$ (selective) and $T_{\mathrm{li}}^{\text {bs }}$ (bi-selective). In the extreme narrowing limit, the direct relaxation, $\rho_{\mathrm{ij}}$, and cross-relaxation, $\sigma_{\mathrm{i},}$, terms between protons $i$ and $j$ are defined by eqns. (1) and (2), holding

$$
\begin{align*}
& \rho_{\mathrm{ij}}=\left(\frac{\mu_{0}}{4 \pi}\right)^{2} \gamma_{\mathrm{H}}^{4} h^{2} \tau_{\mathrm{c}} r_{\mathrm{ij}}^{-6}  \tag{1}\\
& \sigma_{\mathrm{ij}}=\frac{1}{2}\left(\frac{\mu_{0}}{4 \pi}\right)^{2} \gamma_{\mathrm{H}}^{4} h^{2} \tau_{\mathrm{c}} r_{\mathrm{ij}}^{-6} \tag{2}
\end{align*}
$$

for rigid molecules subjected to isotropic molecular tumbling. In these equations $\gamma_{\mathrm{H}}$ is the proton magnetogyric ratio, $r_{\mathrm{ij}}$ the distance between protons $i$ and $j$, and $\tau_{c}$ the correlation time for molecular tumbling.
Since it follows that $\sigma_{\mathrm{ij}}=(1 / 2) \rho_{\mathrm{ij}}$, the relaxation time $T_{1 \mathrm{i}}^{\mathrm{ns}}$ can be written:

$$
\begin{equation*}
\frac{1}{T_{\mathrm{li}}^{\mathrm{ns}}}=R_{\mathrm{li}}^{\mathrm{ns}}=\frac{3}{2} \sum_{\mathrm{j}} \rho_{\mathrm{ij}}+\rho^{*} \tag{3}
\end{equation*}
$$

The steady-state NOE for identical nuclei is expressed by eqn. (4), where k and i are the irradiated and observed nuclei respectively.

$X, O$-cis

\end{equation*}
$$

In compounds 1-4 two internal rotational motions, that around the exocyclic $\mathrm{C}-\mathrm{S}$ bond and that around the $\mathrm{C}\left(\mathrm{H}_{3}\right)-\mathrm{S}$ bonds, must be explicitly considered in addition to molecular tumbling. Rotation around the exocyclic $\mathrm{C}-\mathrm{S}$ bond is characterized by two minima in the energy profile, separated by energy barriers in the order of $4-6 \mathrm{kcal} \mathrm{mol}^{-1}, *$ as emerges from MO ab initio calculations. ${ }^{1}$ These molecules should therefore be found mainly in their ground-states (relative to this internal degree of freedom) and jumps from one minimum to the other should occur. This process should not significantly contribute to the effective correlation time for the interaction between any pair of spins in the molecule (for the two processes correlation times are of the order of $10^{-8}-10^{-9} \mathrm{~s}$ compared with $10^{-11} \mathrm{~s}$ ). Internal rotation of the methyl group around the $\mathrm{S}-\mathrm{C}\left(\mathrm{H}_{3}\right)$ bond should be faster and the relative correlation time, denoted by $\tau_{i}$, of the order of magnitude of $\tau_{c}$.
In employing eqns. (1)-(4) it is therefore necessary to account explicitly for molecular tumbling (assumed to be isotropic) and for internal rotation of the methyl group. This can be performed by substituting proper expressions ${ }^{10}$ for $\tau_{\mathrm{c}} / r_{\mathrm{ij}}^{6}$ terms.
From the experimental $T_{1}$ and NOE values for the different protons, the unknowns $\tau_{\mathrm{c}}, \tau_{\mathrm{i}}, \rho^{*}$ and a factor $\lambda$ (see Fig. 1) closely related to the molecular structure (changing in the different conformations) should be estimated. By employing equations relating $T_{\mathrm{li}}^{\mathrm{ns}}, T_{\mathrm{li}}^{\mathrm{s}}$ and $T_{\mathrm{ii}}^{\mathrm{bs}}$ to these unknowns, ${ }^{5,9,10}$ they can be determined by minimizing the deviations between calculated and experimental quantities by a least-squares procedure and employing eqn. (5). In this equation the $Y$ values

[^0]\[

$$
\begin{equation*}
F=\left[\Sigma\left(Y^{o b s}-Y^{\mathrm{calc}}\right)^{2} / \Sigma\left(Y^{\mathrm{obs}}\right)^{2}\right]^{\frac{1}{2}} \tag{5}
\end{equation*}
$$

\]

are $T_{\mathrm{li}}^{\mathrm{ns}}, T_{\mathrm{li}}^{\mathrm{s}}, T_{\mathrm{li}}^{\mathrm{bs}}$ and NOE values for the different protons. The $T_{1}$ values for the methyl group were not employed since a reliable treatment of this group is feasible only in the case of very fast and very slow internal motion. ${ }^{11}$

In order to extract well-defined values of all the variables from the experimental data, the system should be over-determined, but in our case owing to the small number of observables this is not possible. Therefore we restricted the use of relaxation parameters of ${ }^{1} \mathrm{H}$ nuclei to the calculation of the unknowns $\rho^{*}$ and $\lambda$, introducing $\tau_{\mathrm{c}}$ and $\tau_{\mathrm{i}}$ values obtained, for each molecule, from $T_{1}$ and NOE measurements relative to ${ }^{13} \mathrm{C}$ nuclei.
In the assumption of isotropic molecular tumbling, $\tau_{c}$ can be obtained from $T_{1}$ values of protonated carbons of the heteroatomic ring. ${ }^{9}$ For these protons the measured NOE values are a maximum (1.988). This should exclude spin rotation contributions to the relaxation mechanism, which should be of highly dipolar character ( $T_{1} \cong T_{1 \mathrm{DD}}$ ). $\tau_{\mathrm{i}}$ can be estimated from the ratio $T_{1 \mathrm{DD}}(\mathrm{CH}) / T_{1 \mathrm{DD}}\left(\mathrm{CH}_{3}\right)$ by assuming that for the internal reorientation of the methyl group, the model randomly jumps between equivalent positions. ${ }^{12,13}$

Conformational Results from Relaxation Parameters.Relaxation times and NOE values for ${ }^{1} \mathrm{H}$ nuclei are reported in Table 1, and relaxation times for ${ }^{13} \mathrm{C}$ nuclei in Table 2. For compound 2 only $T_{1}^{\text {ns }}$ values, relative to ${ }^{1} \mathrm{H}$, could be obtained owing to the small chemical shift separation of the ring protons.
Correlation times $\tau_{\mathrm{c}}$ and $\tau_{\mathrm{i}}$ were obtained from the relaxation times of ${ }^{13} \mathrm{C}$ nuclei. In Table 2 the standard deviations of these estimates in the approximation of isotropic molecular tumbling are also reported. The interval is small for $\tau_{c}$ values, whereas the error is slightly larger for the $\tau_{\mathrm{i}}$ values. Nevertheless, by employing $\tau_{\mathrm{i}}$ and an approximate formula, ${ }^{10}$ the barrier for internal reorientation of the methyl group is $2.3-2.8 \mathrm{kcal} \mathrm{mol}^{-1}$, quite in agreement with estimates of the same barrier in dimethyl sulphoxide. ${ }^{15}$
It was found that two distinct sets of $\tau_{c}$ values characterize the molecules with and without the iodine atom: for the former compounds larger correlation times are found. Furthermore, an increase in the correlation time $\tau_{c}$ is observed in 3- methylsulphinyl derivatives when the iodine atom is in position 2 (compounds 3 c and $\mathbf{4 c}$ ) with respect to the compounds with iodine in position 4 (compounds 3 b and 4 b ). The values of $\tau_{c}$ and $\tau_{i}$ were then employed for calculating $\rho^{*}$ and $\lambda$, minimizing the $F$ values given by eqn. (5). This has been performed by altering $\lambda$, which appears in the expressions of $T_{\mathrm{ii}}^{\mathrm{ns}}, T_{\mathrm{li}}^{\mathrm{bs}} T_{\mathrm{ii}}^{\mathrm{bs}}$ and NOE, through $r_{\mathrm{HH}}$ bond-distances, over the whole rotational circuit of the methylsulphinyl group (in $10^{\circ}$ steps). Molecular geometries were built from averages of bond-angles and bond-distances obtained from the X-ray molecular structures of a number of these compounds. ${ }^{2}$ Two solutions are possible as regards $\lambda( \pm \lambda)$ corresponding to two sets of identical $r_{\mathrm{HH}}$ values, and thus $\theta$ (defined in Fig. 1) can assume the values $\lambda-74.5$ and $285.5-\lambda$. For example, if $\lambda= \pm 74.5^{\circ}$, one solution corresponds to $\theta=0^{\circ}$ and the other to $\theta=211^{\circ}$ : the former is the $\mathrm{X}, \mathrm{O}$-cis conformer with the $\mathrm{S}-\mathrm{O}$ bond coplanar with the ring, and the latter a twisted X,O-trans conformer.
The most probable values of $\lambda$ and $\theta$ for the compounds examined are those reported in Table 3. This table also includes the $\rho^{*}$ terms and these should represent relaxation contributions from interactions other than intramolecular interactions. ${ }^{16}$
For compounds 1, 2, 3a and 4a the smallest value of $F$ was obtained for $\lambda= \pm 74.5^{\circ}$, i.e. a coplanar X,O-cis and twisted $\mathrm{X}, \mathrm{O}-\mathrm{trans}$ conformer are equally probable. Mixtures of these forms reproduce the experimental data equally well. The results clearly indicate that conformers different from these are less probable, but not which of these forms is the preferred one. For

orientation of the S-O bond with respect to the heterocyclic ring can, in principle, be obtained by employing reagent shifts. ${ }^{7}$ The simultaneous use of LIS on ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ nuclei, with the precaution of removing diamagnetic shifts, has given quantitative answers ${ }^{8}$ on the conformer isomerism and structures of aromatic aldehydes and ketones. The pseudocontact shift $\Delta M$ was obtained from $\mathrm{Yb}(\mathrm{fod})_{3}$ reagent and the diamagnetic corrections $\Delta D$ with $\mathrm{La}(\mathrm{fod})_{3}$ : the $\Delta M-\Delta D$ values for ${ }^{13} \mathrm{C}$ nuclei and $\Delta M$ for ${ }^{1} \mathrm{H}$ nuclei are reported in Table 4. The experimental LIS values were simulated with the LIRAS-3 package, ${ }^{8}$ assuming a $1: 1$ substrate-lanthanide complex and a four-site complexation model. The molecular geometries were those employed in the simulation of relaxation parameters. Complexation was assumed to occur at the oxygen atom of the S-O bond, in view of previous evidence. ${ }^{17}$ The results of LIS analyses are collected in Table 5.

The simulation model assumed for the lanthanide-substrate complex provided the same agreement factor ( $R_{\text {cryst }}$ ) for $\pm \theta$. Simulation was carried out either on single conformations as a function of $\theta$ or on combinations of two conformations with different $\theta$ values. In a number of cases different solutions gave the same minimum of $R_{\text {cryst }}$. Before examining comparatively the results from LIS simulation and from relaxation parameters in order to attempt conformational conclusions, some immediate information can be obtained from a qualitative survey of the LIS values reported in Table 5. The relative magnitude of the induced shift indicates, approximately and within the same molecule, the distance between the oxygen atom of the S-O bond and the ${ }^{13} \mathrm{C}$ or ${ }^{1} \mathrm{H}$ nucleus. The comparison between the LIS values of compounds $\mathbf{3 b}$ and $3 \mathbf{c}$, which should have ${ }^{2}$ opposite orientations of the S-O bond, shows that for C-4 and C-2 these amount to nearly 20 and 28 ppm , respectively, in
compound $\mathbf{3 b}$, and this trend is reversed in compound $\mathbf{3 c}$. These shifts are in qualitative agreement with the orientation of the $\mathrm{S}-\mathrm{O}$ bond opposite to the iodine substituent. The same occurs for compounds $\mathbf{4 b}$ and $\mathbf{4 e}$. For compounds $\mathbf{3 a}$ and $\mathbf{4 a}$ the LIS values on $\mathrm{C}-2$ and $\mathrm{C}-4$ (and on $\mathrm{H}-2$ and $\mathrm{H}-4$ ) are similar and this may indicate that, for these molecules in chloroform solution, an equilibrium mixture of rapidly interchanging conformers should be present. From theoretical calculations ${ }^{1}$ the presence of about $60 \%$ of the X,O-cis conformer is predicted in chloroform solution and this form becomes less preferred in more polar solvents. For compounds 1 and 2 direct comparison of induced shifts is less indicative since results relative to compounds with a fixed orientation of the S-O bond are lacking. Nevertheless a prevailing X,O-trans orientation can be excluded.

Conformational Conclusions from Relaxation Parameters and LIS Analysis.- The simultaneous use of the conformational indications obtained from the experimental techniques enables conclusions to be drawn on the conformational behaviour of compounds 1-4 in solution. These are summarized in Table 6.

For compound 1 the common solution from the two approaches indicates a prevailing presence of the $\mathrm{O}, \mathrm{O}-\mathrm{cis}$ conformation, with the $\mathrm{S}-\mathrm{O}$ bond coplanar with the ring. An alternative orientation, with the $\mathrm{S}-\mathrm{O}$ bond highly twisted, fits LIS simulation. According to MO calculations, ${ }^{1}$ two groundstate conformations are present for this molecule, the O,O-cis conformation with $\theta=62^{\circ}$ and the O,O-trans conformation with $\theta=175^{\circ}$, the latter is more stable in the vapour phase. In polar solvents, according to theoretical predictions, ${ }^{1}$ two O,O-cis conformers become stable (equally twisted above and below the heterocyclic plane, $\theta \cong \pm 60^{\circ}$ ), and together are

Table 6 Summary of the conformational indications from relaxation parametrs and LIS analyses and comparison with the most probable conformational results obtained in other approaches

${ }^{a}$ Ref. 2, results obtained in solution from ${ }^{1} \mathrm{H},{ }^{13} \mathrm{C}$ and ${ }^{17} \mathrm{O}$ chemical shifts and ${ }^{n} J(\mathrm{C}, \mathrm{H})$ long-range coupling constants. ${ }^{b}$ Ref. 2, X-ray analysis.
more abundant than the O,O-trans form. Simulating the relaxation parameters which such a mixture of conformers, the $F$ value did not turn out to be higher than that corresponding to one conformer with $\lambda= \pm 74.5^{\circ}$. On the basis of these experimental results it would seem impossible to differentiate the situation corresponding to a prevailing $\mathrm{O}, \mathrm{O}$-cis planar conformation from that of a prevailing mixture of the two equally twisted conformers. Compound 2 should be preferentially in the S,O-cis form with a low degree of twist, confirming the results of previous approaches. ${ }^{2}$

For compounds $\mathbf{3 a}$ and $\mathbf{4 a}$, the equilibrium mixture of the two conformers, evidenced previously, ${ }^{2}$ emerges again from this study, yet their amount is not well defined, in view of the fact that changes occur in different solvents. ${ }^{2}$ The X,O-trans form should nevertheless be higher than $50 \%$. The halogen atom in the ring determines a clear orientation of the $\mathrm{S}-\mathrm{O}$ bond away from the former substituent. For compounds $\mathbf{3 a}$ and $4 a$ the preferred conformer is in agreement with the solid-state structure. ${ }^{2}$

In conclusion, these results show that relaxation parameters can provide useful indications of the conformational trend in solution even in the case of molecules of relatively small size. Nevertheless, for reaching conclusive results for the orientation of substituents such as the methylsulphinyl group, complementary information from other experimental approaches is
necessary. NMR techniques including LIS simulation, chemical shifts of ${ }^{1} \mathrm{H},{ }^{13} \mathrm{C}$ and ${ }^{17} \mathrm{O}$ nuclei and long-range coupling constants, when conformationally dependent, provide valuable auxiliary answers.

## Experimental

The syntheses of the compounds have been reported in a previous paper. ${ }^{2}$

NMR Measurements.-The relaxation parameters were obtained with a Bruker WP-80 spectrometer. For $T_{1}$ measurements on ${ }^{1} \mathrm{H}$, solutions in $\left[{ }^{2} \mathrm{H}_{6}\right]$ acetone $\left(0.1 \mathrm{~mol} \mathrm{dm}{ }^{-3}\right.$ or less) were employed. The samples were repeatedly degassed at $5 \times 10^{-3}$ mbar after being kept overnight on molecular sieves ( $4 \AA$ ) previously dried in an oven at $400^{\circ} \mathrm{C}$ for 5 h . The non-selective relaxation times, $T_{1}^{\text {ns }}$, were obtained from the conventional inversion-recovery method: $\mathrm{D}-P_{180}-V_{\mathrm{D}}-P_{90}-A_{\mathrm{t}}$, in which $10-16 V_{\mathrm{D}}$ values were included in the analysis of the data and the delay was at least five times the longest $T_{1}$ value. The selective, $T_{1}^{\mathrm{s}}$, and bi-selective, $T_{1}^{\mathrm{bs}}$, values were measured by applying selective $P_{180}$ pulses with the decoupling unit. Apparent bi-selective pulses were obtained by applying separate successive pulses when the chemical shift of the protons to be irradiated are sufficiently separated, or a pulse able to invert
two nuclei simultaneously in the case of small chemical shift separation ( $<10 \mathrm{~Hz}$ ). The precision of the values $\sigma\left(T_{1}\right)$ was estimated according to Weiss and Ferretti. ${ }^{14}$
Differential NOE measurements were obtained from the samples used in $T_{1}$ experiments, with acquisition of $128+128$ (or $256+256$ ) transients in groups of eight. The methyl group was irradiated on- and off-resonance. Before each group of eight transients, 2-4 dummy scansions were performed and a relaxation delay between each transient of $3 T_{1}-5 T_{1}$ ( $T_{1}$ is the longer relaxation time) was employed. The relaxation times and NOE values of ${ }^{13} \mathrm{C}$ nuclei were measured by employing non degassed samples in $\left[{ }^{2} \mathrm{H}_{6}\right]$ acetone solution $\left(0.5 \mathrm{~mol} \mathrm{dm}^{-3}\right)$ and a Varian XL-200 spectrometer.

Lanthanide induced shifts were measured for ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ nuclei on the same sample using the Bruker WP-80 spectrometer. The shift reagent employed is $\mathrm{Yb}(\mathrm{fod})_{3}$, dried in vacuo (phosphorous pentaoxide) added in known and increasing amounts to $\left[{ }^{2} \mathrm{H}\right]$ chloroform solutions $\left(0.3 \mathrm{~mol} \mathrm{dm}^{-3}\right)$ of the substrate examined. The maximum molar ratio between $\mathrm{Yb}(\mathrm{fod})_{3}$ and the substrate was 0.1 . The correlation coefficients for the plots relating chemical shifts to the lanthanide/substrate ratio were always found $\geqslant 0.999$ and the intercepts identical with the unshifted spectra.
