#### Abstract

Partial resolution of the title compound 2 into its optical antipodes was achieved by enantioselective chromatography on triacetylcellulose. The absolute configuration of the enantiomers has been tentatively assigned on the basis of their CD spectra. Empirical force-field calculations were performed to characterize the minimum energy conformers of 2 and it was found that the two $C_{2}$ symmetrical isomers are ca. $3.7 \mathrm{kcal}_{\mathrm{mol}}{ }^{-1}\left(15.5 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ more stable than those of $C_{i}$ and $C_{1}$ symmetry. Calculated geometrical parameters of one $C_{2}$ symmetrical conformer of 2 are in good agreement with those found by single-crystal X-ray analysis of the $N, N^{\prime}$-ditosylparacyclophane precursor 1. The barrier to racemization has been estimated to be $>35 \mathrm{kcal}^{\mathrm{mol}}{ }^{-1}$ ( $>146.5$ $\mathrm{kJ} \mathrm{mol}{ }^{-1}$ ).

In a previous paper ${ }^{1}$ we reported the synthesis of the novel cyclophane $N, N^{\prime}$-ditosyl-5,8,15,18-tetramethyl-2,11-diaza[3.3]paracyclophane 1 and also described its $C_{2}$-symmetrical solid-

state structure determined by single-crystal X-ray analysis; NMR spectra in chiral environments for the free diamino derivative $\mathbf{2}$ indicated the presence of the two non-interconverting enantiomers. We now wish to report the resolution of 2 into its optical antipodes, their absolute configurations and the results of empirical force-field calculations used to characterize the minimum energy conformations.

## Results and Discussion

Partial resolution of $\mathbf{2}$ into its optical antipodes was achieved by enantioselective chromatography on triacetylcellulose using a 'cycle-technique' ${ }^{2}$ (eluant: ethanol, $96 \%$; column: $30 \times 2.5$ cm , thermostatted at $40^{\circ} \mathrm{C}$; adsorbent particle size: $15-25 \mu \mathrm{~m}$; sample size: ca. 20 mg ). Because of excessive tailing, the partially resolved sample was eluted after passing the column twice. Several fractions of moderate optical activity (first fraction: $[\alpha]_{\mathrm{D}}=-17.5^{\circ},[\alpha]_{578}=-16.5^{\circ},[\alpha]_{546}=-13.6^{\circ},[\alpha]_{436}=$ $+27.2^{\circ},[\alpha]_{365}=+227^{\circ}$ ) were collected. The CD spectra of the first eluted fractions, with a significant positive Cotton effect at $264 \pm 1 \mathrm{~nm}$, were exact mirror images to those of the last ones. Attempts to estimate the enantiomeric excesses by NMR methods failed.
Fig. 1 shows the CD spectra of both enantiomers. According to the work of Nakazaki et al. on optically active [8.8]paracyclophanes of known configuration, the sign of the transition at 264 nm is related to the conformation of the distorted

Fig. 1 CD spectra of 2 in ethanol
benzene ring, which itself is related to the absolute configuration. ${ }^{3}$ On the basis of a comparison of our CD spectra with those reported by Nakazaki et al., and taking into account that a positive Cotton effect corresponds to an $S$-planar chirality, ${ }^{3}$ the $S, S$ absolute configuration was tentatively assigned to the first eluted enantiomer of 2 , as shown here.

Interconversion of the enantiomers of $\mathbf{2}$ can take place via a two-step process: (i) starting from a molecule with $S, S$ configuration, a flip of one arene ring by $c a .180^{\circ}$ will result in an achiral structure with $R, S$ configuration; (ii) rotation of the second arene ring will then give the enantiomeric $R, R$ structure. In order to determine the overall energy barrier for this process, we tried to racemize the optically-active cyclophane 2 by heating a solution of the compound in diethylene glycol dimethyl ether. Heating the solution for 2.5 h at $150^{\circ} \mathrm{C}$ did not result in a significant change of the CD spectrum; however, heating at $150^{\circ} \mathrm{C}$ for 10 h induced decomposition of the cyclophane into at least three different compounds, as indicated by TLC. By assuming an error of measurement of $5 \%$ and taking into account the fact that heating for 2.5 h at $150^{\circ} \mathrm{C}$ did not change the intensities of the CD transitions, we can calculate a lower limit for the racemization barrier, namely $k=5.7 \times 10^{-6}$ $\mathrm{s}^{-1}$ and $\Delta G_{423}^{\ddagger} \geqslant 35 \cdot(2) \mathrm{kcal} \mathrm{mol}^{-1}\left(147 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. This finding is consistent with that of Staab ${ }^{4}$ for tetramethoxydithia[3.3]-

paracyclophane, and is also in agreement with our results of the empirical force-field calculations.

Empirical Force-field Calculations.-All conformations of cyclophane $\mathbf{2}$ were minimized using Allinger's MM2(87) forcefield program. ${ }^{5}$ These calculations yielded four energy minima corresponding to two structures with $C_{2}$ symmetry and structures of $C_{\mathrm{i}}$ and $C_{1}$ (close to $C_{\mathrm{s}}$ ) symmetry (Fig. 2). The ground-state structure $\mathbf{A}$ is of $C_{2}$ symmetry, with the $C_{2}$ axis passing through the arene centroids. The second $C_{2}$ symmetrical conformer $\mathbf{B}$, with the $C_{2}$ axis bisecting the arene rings, is higher in energy by only $0.07 \mathrm{kcal} \mathrm{mol}^{-1}\left(0.3 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$, whereas the $C_{1}$ and $C_{\mathbf{i}}$ structures $\mathbf{C}$ and $\mathbf{D}$ are higher in energy by 3.59 and $3.68 \mathrm{kcal} \mathrm{mol}^{-1}$ ( 15.0 and $15.4 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ), respectively, indicating that the $C_{2}$ symmetrical conformers are the only ones present under thermodynamic control. This is in agreement with the finding that the synthesis of the ditosylcyclophane precursor 1 yielded just one diastereoisomer with $C_{2}$ symmetry in the solid state. ${ }^{1}$
In solution, all four conformers may interconvert by two different interconversion modes: (a) inversion of the configuration of one bridging nitrogen will interconvert the $C_{2}$ symmetrical conformers $\mathbf{A}$ and $\mathbf{B}$, as well as the two conformers
of higher energy ( $\mathbf{C}$ and $\mathbf{D}$ ), whereas (b) an arene flip by ca. $180^{\circ}$ will interconvert both, A and $\mathbf{D}$ as well as $B$ and $C$.
If only mode (a) is operating on the time scale of observation, molecular $D_{2}$ symmetry will result from the interconverting $C_{2}$ conformers $A$ and $B$ but $C_{2 h}$ symmetry from $\mathbf{C}$ and $D$. The experimental proton spectrum is in accordance with both $D_{2}$ and $C_{2 \mathrm{~h}}$ symmetry, but the optical activity is in agreement only with $D_{2}$.

The results of the calculations show that both $C_{2}$ conformations are under a considerable degree of strain, as judged by the puckering of the aromatic rings (by ca. $9^{\circ}$ ) and by the elongation of the $\mathrm{N}-\mathrm{CH}_{2}$ bonds, as well as by the enlargement of the $\mathrm{C}-\mathrm{N}-\mathrm{C}$ angles. In both conformers the $p$-xylyl rings lie in parallel planes, with the $C_{2}$ axis passing through the centroids of both rings in the ground-state conformer $\mathbf{A}$ but bisecting those planes in the second $C_{2}$ symmetrical structure $\mathbf{B}$. It is interesting to note that the $C_{2}$ solid-state structure found for 1 is not identical with that of the calculated ground-state structure of 2 , but rather is very similar to that of B.

Table 1 lists geometrical parameters (bond lengths, bond angles and torsional angles) of 1 obtained by X-ray analysis and those calculated for the related conformer B. Comparison of

${ }^{a}$ Only symmetry-independent values are reported. ${ }^{b}$ In the original X-ray structure ${ }^{1}$ the values of torsional angles refer to the enantiomeric structure (signs are inverted).
these data show that the overall agreement is quite satisfactory, the only remarkable difference being the torsional angles involving the nitrogen atoms. This is not very surprising, since the X-ray structure was solved for the ditosyl derivative 1 whereas the calculations were performed on the free diamine. Furthermore, the $N$-tosyl substitution could be the reason for the fact that the X -ray structure and the calculated ground-state structure are not identical, although on the other hand the calculated energy difference between the two $C_{2}$ conformers is so small that crystal packing forces will easily account for such a conformational change.
Unfortunately the calculations of the rotational barrier of an aryl flip [rotation of one aryl ring by ca. $180^{\circ}$; interconversion by mode (b)] were not successful. All attempts to calculate the barrier resulted in uncontrolled elongation of at least one C-C single bond; on the other hand, use of the bond stretching potential without the cubic term gave extremely high and unrealistic barriers. Nevertheless, this fact further supports the
experimental finding that the racemization barrier of 1 should be $>35 \mathrm{kcal} \mathrm{mol}^{-1}$ ( $146.5 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ) and very close to that of bond rupture processes.
