# Gas phase and condensed phase $\mathbf{S}_{\mathrm{N}} \mathbf{i}$ reactions. The competitive six and seven centre cyclisations of the 5,6-epoxyhexoxide anion. A joint experimental and ab initio study. A comparison with $\mathrm{S}_{\mathbf{N}} \mathrm{i}$ reactions of homologous epoxyalkoxide anions $\dagger$

Received (in Cambridge) 12th November 1998, Accepted 22nd December 1998
A. Ab initio calculations [at the MP2 $\mathrm{Fc} / 6-31+\mathrm{G}(\mathrm{d})$ level of theory] indicate that the barriers to the transition states for the competitive six and seven centre $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ cyclisation processes of the 5,6 -epoxyhexoxide anion are 35.0 and 39.7 $\mathrm{kJ} \mathrm{mol}^{-1}$ respectively. Experimental studies show that (i) in solution, the 5,6 -epoxyhexoxide anion cyclises (and at the same time opens the ethylene oxide ring) to give tetrahydropyran-2-methanol as the predominant product on workup, and (ii) collisional activation of the 5,6-epoxyhexoxide anion in the gas phase gives the 2-tetrahydropyranmethoxide anion as the exclusive anionic product. It is proposed that frequency factors (Arrhenius $A$ factors) control the courses of these kinetically controlled gas phase reactions. A comparison of the calculated harmonic vibrational partition functions for the two possible transition states confirms a higher value of $Q_{\mathrm{vib}}$ for the reaction proceeding through the six-membered transition state.
B. A comparison is made of the reported competitive $\mathrm{S}_{\mathrm{N}}$ i reactions for 2,3-epoxypropoxide, 3,4-epoxybutoxide, 4,5 -epoxypentoxide and 5,6 -epoxyhexoxide anions. For all but the 3,4 -epoxybutoxide system, the exclusive or major product is that which contains the smaller of the two ring systems for both gas phase and condensed phase reactions. In the case of the 3,4-epoxybutoxide system: (i) in the gas phase, both four and five membered ring $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ products are formed in comparable yield, and (ii) in the condensed phase, the major product is that with the larger ring.

## Introduction

We have reported the competitive gas phase $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ reactions of systems of the type shown in Scheme 1 where $n=1-3 .{ }^{1-4}$

Scheme 1
Baldwin's rules ${ }^{5-7}$ (which refer to stabilised carbanion cyclisations) pertain when $n=1$ and 3, i.e. the predominant cyclisation is that which forms the smaller of the two possible ring systems. The kinetics of these reactions are influenced by the barrier to the transition state and/or the Arrhenius factors $A$.

In this paper we (i) report the behaviour in both the condensed phase and gas phase of the next homologue, i.e. where $n=4$, and (ii) consider all systems so far reported in terms of the parameters influencing the competing cyclisations.

## Results and discussion

Part A. The 5,6-epoxyhexoxide system

1. A theoretical approach. There are two major factors which

[^0]determine the relative rates of the two possible cyclisation processes, viz. the barriers to the transition state and the Arrhenius (frequency) factor $A$. Both are considered separately below.
a. The results of ab initio calculations for competing cyclisations of the 5,6-epoxyhexoxide anion (1). The results of an $a b$ initio computational study using Gaussian $94^{8}$ for the system where $n=4$ are summarised in Fig. 1. The geometries of the local minima and the transition states were optimised at the RHF/6-31+G(d) level of theory, with energies determined at the MP2-Fc/6-31+G(d) level of theory. Energies of 1-3, A and $\mathbf{B}$ together with the geometries of the two transition states are listed in Table 1. Full geometric data for 1-3 are listed in the Supplementary Data.

The data presented in Fig. 1 and Table 1 show that the barriers to the two transition states $\mathbf{A}$ and $\mathbf{B}$ are 35.0 and $39.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ at the level of theory indicated. If these modest barriers are controlling the relative rates of the two processes, both $\mathbf{2}$ and $\mathbf{3}$ should be formed following collision activation of $\mathbf{1}$ in the gas phase, with $\mathbf{2}$ being marginally favoured. Factors which may influence the height of the barriers are as follows. (i) The OCO angles for $\mathbf{A}$ are $154.42^{\circ}$ (dihedral angle $172.93^{\circ}$ ) and for $\mathbf{B}, 156.38^{\circ}$ (dihedral angle $172.25^{\circ}$ ). These values are very similar: the higher value of $156.38^{\circ}$ may, in principle, favour reaction through B (cf. ref. 7), however any such effect will be marginal. (ii) The larger electrophilicity of the substituted carbon of the ethylene oxide ring (according to Mulliken charge calculations, ${ }^{8} \mathrm{C}^{1}=0.168$ and $\mathrm{C}^{2}=0.419$ ) favours nucleophilic attack at the more substituted carbon; i.e. formation of 2 through transition state $\mathbf{A}$. (iii) The changes in ring strain from $\mathbf{1}$ to transition states A and $\mathbf{B}$ should be marginal in determining relative kinetics: in contrast, the release in ring strain from 1 to products, makes $\mathbf{2}$ more thermodynamically stable than $\mathbf{3}$ [2 is some $11 \mathrm{~kJ} \mathrm{~mol}^{-1}$ more negative in energy than product 3 (strain energy of ethylene oxide, tetrahydropyran and oxepan are 112.5, 6.3 and $26.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ respectively ${ }^{9}$ )].
b. The calculation of Arrhenius factors. Frequency factors for the two competitive $\mathrm{S}_{\mathrm{N}}$ i processes shown in Fig. 1 may be influ-

${ }^{a}$ Calculations at MP2(fc)/6-31+G(d) level. All energies include zero point energy scaling (factor 0.9676 ). ${ }^{b}$ See Supplementary Data.
enced by (i) the initial nucleophilic attack to form the transition state (i.e. the ability of the nucleophile to access the appropriate channel, and the depth of that channel), and/or (ii) the nature of the transition state [i.e. whichever is 'looser' (more disordered) will give the higher rate]. To determine the relative abilities of the nucleophile to access the two channels requires an intimate knowledge of the potential surface maps for those processes. We do not have these data. However, the entropic natures of the two transition states may be determined by calculating the relative $A$ factors.

To assess the relative Arrhenius $A$ factors for the two competing cyclisation channels, we have used transition state theory, ${ }^{10}$ viz. eqn. (1), where $k_{\mathrm{B}}$ is Boltzman's constant, $h$ is Planck's

$$
\begin{equation*}
k(T)=\left(k_{\mathrm{B}} T / h\right)\left(Q^{\ddagger} / Q_{\mathrm{R}}\right) \exp \left(E_{\mathrm{o}} / k_{\mathrm{B}} T\right) \tag{1}
\end{equation*}
$$

constant, $E_{\mathrm{o}}$ is the energy difference between reactant and transition state at 0 K , and $Q^{\ddagger}$ and $Q_{\mathrm{R}}$ are the molecular partition functions of transition state and reactants respectively. The partition function can be factorised into partition functions for translation, rotation, vibration and electronic state, ${ }^{10} \mathrm{viz}$. eqn. (2).

$$
\begin{equation*}
Q=Q_{\text {Trans }} Q_{\text {Rot }} Q_{\text {Vib }} Q_{\text {Elec }} \tag{2}
\end{equation*}
$$

Fig. 1 Ab initio calculations at MP2-Fc/6-31G(d) level (Gaussian 94) for the reactions $\mathbf{1} \rightarrow \mathbf{2}$ and $\mathbf{1} \rightarrow \mathbf{3}$. Energies in $\mathrm{kJ} \mathrm{mol}^{-1}$. See Table 1 for the geometries of transition states A and B. Structures 1,2 and $\mathbf{3}$ have a number of stable conformers. Those shown are the most stable (see Supplementary Data for geometries and energies of the most stable conformers).

Since we are dealing with anions, it seems reasonable to assume that $Q_{\text {Elec }}=1$. We are dealing with unimolecular rearrangements, so $Q_{\text {Trans }}$ of the reactant and transition state are identical, and we assume (to a first approximation) that the same is true for $Q_{\text {Rot }}$. Thus approximation of the $A$ factor for each process simplifies to evaluating $Q_{\text {vib }}$ for the reactant and for the competing transition states. However it must be noted that the anions in a mass spectrometer, especially following collisional activation, will not follow a Boltzman (thermalised) distribution of internal energies. Thus the following calculations must only be considered in a qualitative sense.
We have calculated, at the HF/6-31+G(d) level of theory, the harmonic vibrational frequencies of each structure using Gaussian 94 [cf. ref. 11]. These values (scaled by a factor of 0.9131 ) are listed as Supplementary Data to the paper. A difficulty which often occurs with such an evaluation arises due to the problem of hindered rotors. ${ }^{12}$ The calculated vibrational partition functions may underestimate the actual hindered rotor partition functions. Since we are concerned with the ratio of the $A$ factors of two competing cyclisation channels which have the same reactant, we have not addressed the hindered rotor problem. The value of $Q^{\ddagger}{ }_{\text {vib }}$ for the transition state leading to the the six-membered ring product (2) is 63.1 , whereas that for the seven-membered product (3) is 26.3 , so the transition state leading to the formation of $\mathbf{2}$ is 'looser' than that giving 3 (see Supplementary Data for details). The $A$ factor for the formation of $\mathbf{2}$ is thus larger than that for the formation of 3, within the approximations we have employed.

In summary, (i) $a b$ initio calculations indicate that the barriers to the formation of both $\mathbf{2}$ and $\mathbf{3}$ from $\mathbf{1}$ are modest, that both 2 and 3 should be formed under conditions of collision activation, with 2 being the major product. (ii) The relative Arrhenius factors indicate that $\mathbf{A}$ is the looser transition

${ }^{a}$ Ratios determined by measuring the areas under each GC peak. Each measurement was carried out twice-error $\pm 2 \%$.

Fig. 2 MS/MS Data for 1. ZAB 2HF spectrometer. For experimental procedures see Experimental section. Peak widths at half height, $\mathrm{m} / \mathrm{z}$ (volts $\pm 0.2$ ): 97 (27.4), 85 (33.1) and 67 (30.7).
state by a significant factor. Taken together, these calculations suggest that 2 should be the major cyclisation product in gas phase conditions.
2. The experimental approach. $a$. The competitive cyclisation reactions in the condensed phase. The reactions of 5,6-epoxyhexanol with $10 \%$ aqueous sodium hydroxide are summarised in Table 2. Tetrahydropyran-2-methanol is the major product formed at $20^{\circ} \mathrm{C}$, with the product ratio of tetrahydropyran-2methanol to 3-oxepanol being $65: 35$ after one hour. The analogous ratio obtained at $100^{\circ} \mathrm{C}$ is $60: 40$. There is no significant change in these product ratios (at constant temperature) with increasing time. Tetrahydropyran-2-methanol and 3-oxepanol are not interconvertible under these conditions, and neither reverts to 5,6-epoxyhexanol. Thus the two competing $S_{N} i$ reactions of deprotonated 5,6-epoxyhexanol are kinetically controlled under these reaction conditions.
b. Gas phase cyclisation of the 5,6-epoxyhexoxide anion. Alkoxide ions 1, 2 and 3 (shown in Fig. 1) were formed in the gas phase by nucleophilic displacement of the appropriate acetate in the ion source of the VG ZAB 2HF mass spectrometer. Forming the alkoxide ions indirectly is necessary, since gas phase deprotonation of the alcohols by $\mathrm{HO}^{-}$will occur both at OH and elsewhere on these molecules. The collision induced mass spectra of the three alkoxides $\mathbf{1}-\mathbf{3}$ are recorded in Figs. 2-4. Peak widths at half height for the major

Fig. 3 MS/MS Data for 2. Peak widths at half height, 97 (27.7), 85 (33.1) and 67 (30.7).

Fig. 4 MS/MS Data for 3. Width at half height of $m / z 97=33.4$ volts.
peaks in these spectra are recorded in the legend to each figure. Data pertaining to product ion studies are listed in Table 3, and the mass spectra of two ${ }^{18} \mathrm{O}$ labelled derivatives are recorded in Table 4.

The spectra of $\mathbf{1}$ and 2 (Figs. 2 and 3) are the same within experimental error, including identical peak widths at half height of the major peaks $m / z 97,85$ and 67 . These spectra are quite different from that (Fig. 4) of 3. This indicates that $\mathbf{1}$ and $\mathbf{2}$ are fragmenting through a common intermediate (perhaps following cyclisation of $\mathbf{1}$ to 2 ), but that cyclisation of $\mathbf{1}$ to $\mathbf{3}$ is not occurring under the reaction conditions. We now need to confirm that (i) the fragment ions from $\mathbf{1}$ and 2 have the same structures, (ii) there are differences between these structures and those of the fragment anions of $\mathbf{3}$, and (iii) fragmentations observed in the spectra of $\mathbf{1}$ occur following conversion of 1 to 2 .

All data concerning product ion studies are collected in Table 3. Whenever possible, both collisional activation and charge reversal (positive ion) ${ }^{13}$ mass spectra of source formed product anions are compared with those of authentic anions formed by independent syntheses. In some cases, the collisional activation spectra of the fragment ions are either not characteristic (e.g. $m / z 67$ ), or are too weak to make meaningful comparison (e.g. $m / z 59$ ). In these cases, identification is based on the charge reversal spectra. The results of these comparisons are consistent with the data summarised in Scheme 2. The product anions in the spectra of $\mathbf{1}$ and $\mathbf{2}$ are the same, but different from those in the spectrum of 3 .

$(67)^{g}$

${ }^{a}$ The abundances in both collisional activation and charge reversal spectra are dependent on both source conditions and the collision gas pressure. As a general guide when comparing spectra, the abundance of an individual peak should be correct to $\pm 10 \%$. ${ }^{b}$ Formed by deprotonation of the appropriate alcohol with $\mathrm{HO}^{-}$. ${ }^{c}$ Weak spectrum: difficult to measure the abundance of the peak formed by loss of $\mathrm{H}_{2}$ because of baseline noise. ${ }^{d}$ Formed by decarboxylation of $\mathrm{HOCH}_{2} \mathrm{CH}_{2} \mathrm{CH}=\mathrm{CHCH}_{2} \mathrm{CO}_{2}{ }^{-}$. ${ }^{e}$ Formed by deprotonation of $\mathrm{MeCH}_{2} \mathrm{CH}=\mathrm{CHCH}_{2} \mathrm{OH}$ with $\mathrm{HO}^{-}$. ${ }^{f}$ Formed by deprotonation of penta-1,3-diene with $\mathrm{HO}^{-} .{ }^{g}$ Formed by deprotonation of cyclopentene with $\mathrm{HO}^{-} .{ }^{h}$ Reported by spectrum, see ref. 3.

The data considered to date show that $\mathbf{1}$ and $\mathbf{2}$ have identical fragmentations but do not indicate whether $\mathbf{1}$ cyclises to $\mathbf{2}$ before fragmentation occurs. This problem is resolved from a consideration of the spectra (Table 4) of ${ }^{18} \mathrm{O}$ labelled derivatives (of $\mathbf{1}$ and $\mathbf{2}$ ). These spectra demonstrate the equilibration of the two oxygens of $\mathbf{1}$ (and $\mathbf{2}$ ) prior to fragmentation: in the case of $\mathbf{1}$, such equilibration requires rearrangement of $\mathbf{1}$ to 2 prior to fragmentation. The fragmentations of 2 have been considered previously: it has been proposed that the oxygen equilibration occurs by the proton transfer/ring opening equilibria summarised in Scheme 3. ${ }^{14}$ Fragmentation of the ring opened structures, particularly $4 / 5$ and $6 / 7$, account for both the oxygen equilibration and the structures of the product ions (Scheme 2) formed by the respective losses of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{CH}_{2} \mathrm{O}$.

We have not carried out labelling studies on the 3-oxepanol anion 3: our primary interest in $\mathbf{3}$ was to determine whether its fragmentations are different from those of $\mathbf{1}$ and $\mathbf{2}$. Even so, the formation of $m / z 59$ (Scheme 2) is straightforward, while the structure of $\mathrm{m} / \mathrm{z} 97$ is consistent with the fragmentation pathway shown in Scheme 4.

Conclusions to Part A. 1. Ab initio and Arrhenius factor calculations indicate that $\mathbf{1}$ should cyclise to both 2 and $\mathbf{3}$. The barriers to transition states A and B are modest (computed as 35.0 and $39.7 \mathrm{~kJ} \mathrm{~mol}^{-1}$ respectively), and the Arrhenius factor is larger for the formation of $\mathbf{2}$ than for $\mathbf{3}$. Thus $\mathbf{2}$ is predicted to be the favoured product.
2. Experimentally, $\mathbf{1}$ cyclises to give only $\mathbf{2}$ in the gas phase: product $\mathbf{3}$ is not detected. It is proposed that the larger

${ }^{a}$ Unresolved peaks. ${ }^{b}$ The ${ }^{18} \mathrm{O}$ label is in the side chain of $\mathbf{1}$ : cyclisation of $\mathbf{1}$ will give $\mathbf{2}$ with the ${ }^{18} \mathrm{O}$ label in the ring. Thus the relative ratios of $m / z$ $99: 97$ and $87: 85$ will be reversed in the two spectra, as observed. ${ }^{c}$ The relative abundances of the major fragment peaks in the spectra of $\mathbf{1}$ and $\mathbf{2}$ are critically dependent on collision gas pressure. This explains the major abundance differences in the two spectra above (cf. e.g. m/z 67) (the two spectra were measured six years apart, see ref. 14): this does not affect the $99: 97$ and 87:85 ratios.

Arrhenius factor for reaction $\mathbf{1}$ to $\mathbf{2}$ is a major contributing factor to the exclusivity of this reaction (i.e. entropically, transition state $\mathbf{A}$ is 'looser' than transition state $\mathbf{B}$ ).
3. Treatment of $\mathbf{1}$ in $10 \%$ aqueous sodium hydroxide at reflux yields both $\mathbf{2}$ and $\mathbf{3}$ in kinetically controlled reactions, with $\mathbf{2}$ being the predominant product.

## Part B. Comparison of the competing reactions of Scheme 1 where $\boldsymbol{n}=\mathbf{1 - 4}$.

We now summarise the results for the four homologous systems for which competing $\mathrm{S}_{\mathrm{N}} \mathrm{i}^{1}$ processes have been studied in the gas phase. ${ }^{1-4}$ A number of parameters which influence the formation of the eight transition states of the four systems ( $n=1$ to $4 ; c f$. Scheme 1) are listed in Table 5. These kinetic parameters are calculated for gas phase reactions, i.e. for reactions occurring in the absence of solvent. The transition states are numbered as follows: $1.1 \quad(n=1)$-the Payne rearrangement, $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ through three centre state, $\mathbf{1 . 2}(n=1)-\mathrm{S}_{\mathrm{N}} \mathrm{i}$ through the competing four membered transition state; 2.1 ( $n=2$ )- $\mathrm{S}_{\mathrm{N}}$ ithrough four centre state, $2.2(n=2)-\mathrm{S}_{\mathrm{N}} i$ through the competing five centred state, etc. The parameters listed are (i) the $\mathrm{O}-\mathrm{C}-\mathrm{O}$ angle for the $\mathrm{S}_{\mathrm{N}}{ }^{i}$ process at the transition state, together with the corresponding dihedral angle, (ii) the computed barrier from reactant to the transition state (in $\mathrm{kJ} \mathrm{mol}^{-1}$ ), (iii) the Mulliken charge ratio (the relative electrophilicities) of

$\mathrm{C}^{1}$ and $\mathrm{C}^{2}$ (the two carbons on the ethylene oxide ring) of the reactant, and (iv) the Arrhenius factor ( $Q_{\text {vib }}$ ) for each reaction (determined as outlined in Part A). The bond lengths of the breaking and forming bonds in the various transition states are not listed because they are comparable for all systems (except for symmetrical $\mathbf{1 . 1}$ where the $\mathrm{O}-\mathrm{C}$ bonds are both $1.89 \AA^{1}$ ), i.e. the forming bonds are longer (in the range 2.08-2.10 $\AA$ ) than the breaking bonds (within the range $1.74-1.89 \AA$ )..$^{2-4}$ The major (and minor) products obtained both in the gas and condensed phases from each pair of transition states are also listed in Table 5.

Three of the four systems show significant correspondence between the experimental gas phase (and condensed phase) data and the theoretical data ( $n=1,3$ and 4 ), while one ( $n=2$ ) shows some deviation. When $n=1$, the Payne rearrangement is the major process in the gas phase: a feature in accord with $a b$

[^1]Table 5 Parameters influencing the kinetics of competitive $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ processes. Major products

${ }^{a}$ At MP2-Fc/6-31+G(d) level. ${ }^{b}$ The Mulliken charge distribution is that of $\mathrm{C}^{1}$ and $\mathrm{C}^{2}$ in the reactant, see ref. 8. ${ }^{c}$ Calculations as described earlier in this paper. ${ }^{d}$ Carried out in $10 \%$ aqueous sodium hydroxide at reflux (for full details see refs. 2-4). ${ }^{e}$ Calculations at G2 level in these two cases. ${ }^{f}$ Not performed. However alkyl substituted 2,3-epoxypropoxide anions exclusively undergo the Payne rearrangement in solution, cf. ref. 1. ${ }^{g}$ Gas phase experiments only indicate that both are formed in approximately comparable yield, see ref. 3 .
initio data. The Payne rearrangement (which proceeds through transition state 1.1) is favoured by the lower barrier of 45 kJ $\mathrm{mol}^{-1}$ (cf. $122 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for 1.2). The major contributor to the larger barrier to transition state $\mathbf{1 . 2}$ is the unfavourable geometry of the transition state, i.e. angle $\mathrm{O}-\mathrm{C}-\mathrm{O}$ is computed to be $116.5^{\circ}$ (cf. $160.1^{\circ}$ for 1.1: the closer the $\mathrm{O}-\mathrm{C}-\mathrm{O}$ angle is to the ideal $\mathrm{S}_{\mathrm{N}} 2$ angle of $180^{\circ}$, the more favoured will be the reaction if other parameters are equal). Although the larger Arrhenius factor also favours the formation of transition state 1.1, the large barrier difference is a major factor influencing the competing $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ reactions when $n=1$.

The gas phase results for systems where $n=3$ and 4 are perhaps surprising but they are consistent and qualitatively similar to the predictions of the $a b$ initio studies. The computed barriers for each of the competing reactions when $n=3$ and 4 are comparable in each system ( $48 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for 3.1 and $\mathbf{3 . 2}$; 35 and $40 \mathrm{~kJ} \mathrm{~mol}^{-1}$ for 4.1 and 4.2), yet in both cases there is only one product formed in the gas phase, viz. those formed through
3.1 and 4.1 respectively. The Arrhenius factor must control the gas phase reaction when $n=3$. The same scenario probably also pertains when $n=4$. Although the barriers are different ( 35 and $40 \mathrm{~kJ} \mathrm{~mol}^{-1}$ ), they are very modest, and if they are a major influence in determining the product ratio, then products should be observed from both processes. We propose that frequency factors are controlling the gas phase $\mathrm{S}_{\mathrm{N}} \mathrm{i}$ reactions where $n=3$ and 4 . The condensed phase reactions (in $10 \%$ aqueous sodium hydroxide at reflux) show the expected trend. The smaller of the ring systems is formed predominantly in each case.
The situation with regard to the system when $n=2$ is not as clear as those of the three systems described above. The potential profile summarising the $a b$ initio calculations ${ }^{3}$ is recorded in Fig. 5 to assist the discussion. This system shows similarities to that where $n=3$, i.e. the barriers to the two processes are comparable (see Fig. 5 and $c f$. Table 5) as are the Mulliken and the Arrhenius $Q_{\text {vib }}$ ratios (see Table 5).

Baldwin's rules. ${ }^{5-7}$ When $n=2$, both products are formed in comparable yield.
(ii) The corresponding condensed phase reactions preferentially give the smaller ring system in higher yield when $n=1,3$ and 4 . When $n=2$, the larger ring system is formed in the higher yield.

## Experimental

## Mass spectrometric methods

Collisional activation (CA) mass spectra (MS/MS) were determined with a VG ZAB 2HF mass spectrometer. ${ }^{15}$ Full operating details have been reported. ${ }^{16}$ Specific details were as follows: the chemical ionisation slit was used in the chemical ionisation source, the ionising energy was 70 eV , the ion source temperature was $100^{\circ} \mathrm{C}$, and the accelerating voltage was 7 kV . The liquid samples were introduced through the septum inlet with no heating [measured pressure of sample $1 \times 10^{-6}$ Torr ( 1 Torr $=133.322 \mathrm{~Pa})$ ]. Alkoxide anions $\mathbf{1}-\mathbf{3}$ were formed by $\mathrm{S}_{\mathrm{N}} 2$ displacement from the appropriate acetate using $\mathrm{HO}^{-}$(from $\mathrm{H}_{2} \mathrm{O}$ : measured pressure $1 \times 10^{-5} \mathrm{Torr}$ ). The estimated source pressure was $10^{-1}$ Torr. Argon was used in the second collision cell (measured pressure, outside the cell, $2 \times 10^{-7}$ Torr), giving a $10 \%$ reduction in the main beam, equivalent to single collision conditions. CID MS/MS measurements involved using the magnet to choose the ion under study, collision activating it (see above), and scanning the electric sector to analyse the resultant product anions. Charge reversal (CR) (positive ion) MS/MS data for negative ions were obtained as for CA MS/MS data, except that the electric sector potential was reversed to allow the transmission of positively charged product ions (for full details see ref. 13). The recorded peak widths at half height are an average of ten individual measurements and are correct to $\pm 0.2$ volts.

## Ab initio calculations

The Gaussian $94^{8}$ suite of programs was used for all calculations, which were carried out on Silicon Graphics Power Challenge. The geometries of the local minima and the transition states were optimised at the RHF/6-31+G(d) and MP2 (Fc)/6$31+G(d, p)$ levels of theory. Harmonic frequency analyses were performed on each stationary point in order to characterise them as either a local minimum or transition state. A local minimum is characterised by possessing all real vibrational frequencies and its hessian matrix possessing all positive eigenvalues. A transition state is characterised by possessing one (and only one) imaginary frequency and its hessian matrix possessing one (and only one) negative eigenvalue. Intrinsic reaction coordinate (IRC) calculations were performed (beginning from both transition structures) to verify that each transition structure connected particular local minima. Final energies are quoted at the MP2 $\mathrm{Fc} / 6-31+\mathrm{G}(\mathrm{d})$ level of theory, and include a scaled ( 0.8929 ) zero point vibrational energy correction [which is based on the RHF/6-31+G(d) optimised geometry].

## Materials

Tetrahydropyran-2-methanol, penta-1,3-diene and pent-4-en1 -ol were commercial samples. Tetrahydropyran-2-methanol acetate, ${ }^{17}$ 5,6-epoxyhexanol, ${ }^{18}$ 5,6-epoxyhexyl acetate, ${ }^{19} 3$-oxepanol, ${ }^{19}$ hexa-3,5-diene-1-ol, ${ }^{20}$ and hexa-2,5-dien-1-ol ${ }^{21}$ were made by reported procedures.

3-Acetoxyoxepan. 3-Oxepanol ( 0.1 g ) was acetylated by a standard procedure ${ }^{17}$ to yield 3 -acetoxyoxepane (bp 121$123^{\circ} \mathrm{C} / 760 \mathrm{mmHg} ; 0.11 \mathrm{~g}, 81 \%$ yield). Found, C, 60.6; H, $9.2 \%$ : $\mathrm{C}_{8} \mathrm{H}_{14} \mathrm{O}_{3}$ requires C, $60.7 ; \mathrm{H}, 8.9 \% . \mathrm{MH}^{+}=159$ ( $18 \%$ ), base peak $m / z 43 .{ }^{1} \mathrm{H}$ NMR $\left(300 \mathrm{MHz}, \mathrm{CDCl}_{3}\right) \delta 1.35-1.52(4 \mathrm{H}, \mathrm{m})$, $1.70-1.82(2 \mathrm{H}, \mathrm{q}), 2.01(3 \mathrm{H}, \mathrm{s}), 3.4(2 \mathrm{H}, \mathrm{d}), 3.69(2 \mathrm{H}, \mathrm{t}), 4.1$
$(1 \mathrm{H}, \mathrm{m}) .{ }^{13} \mathrm{C} \operatorname{NMR}\left(\mathrm{CDCl}_{3}\right) \delta 21.1\left(\mathrm{CH}_{3}\right), 21.39\left(\mathrm{CH}_{2}\right), 27.5$ $\left(\mathrm{CH}_{2}\right), 31.82\left(\mathrm{CH}_{2}\right), 64.1(\mathrm{CH}), 70.4\left(\mathrm{CH}_{2}\right), 170.5(\mathrm{C}=\mathrm{O})$.
[1- ${ }^{18}$ O]5,6-Epoxyhexan-1-ol. Hex-5-en-1-ol (2 g) was oxidised ${ }^{22}$ to hex-5-enoic acid ( $1.9 \mathrm{~g}, 83 \%$ ), which was stirred at $20^{\circ} \mathrm{C}$ with oxalyl chloride ( $1.5 \mathrm{~cm}^{3}$ ) and $N, N$-dimethylformamide ( 1 drop) in anhydrous diethyl ether ( $30 \mathrm{~cm}^{3}$ ) for 3 h . Removal of the solvent in vacuo followed by distillation gave hex-5-enoyl chloride ( $1.4 \mathrm{~g}, 73 \%$ ), which was allowed to stir with $\mathrm{H}_{2}{ }^{18} \mathrm{O}\left(0.26 \mathrm{~g}, 96 \%{ }^{18} \mathrm{O}\right)$ and tetrahydrofuran $\left(10 \mathrm{~cm}^{3}\right)$. The solution was dried $\left(\mathrm{MgSO}_{4}\right)$ and concentrated under reduced pressure to afford a clear oil which was added dropwise to a suspension of lithium aluminium hydride ( 0.5 g ) in diethyl ether $\left(20 \mathrm{~cm}^{3}\right)$ and heated at reflux for 2 h . The mixture was cooled to $0^{\circ} \mathrm{C}$, aqueous hydrogen chloride ( $30 \%, 2 \mathrm{~cm}^{3}$ ) was added, the organic layer separated, the aqueous layer extracted with diethyl ether $\left(2 \times 5 \mathrm{~cm}^{3}\right)$, the combined organic extracts dried $\left(\mathrm{MgSO}_{4}\right)$, concentrated in vacuo, and the residue distilled to give [ $1-{ }^{18}$ O]hex-5-en-1-ol ( 0.75 g ), which was epoxidised ${ }^{18}$ and distilled ( $60-70{ }^{\circ} \mathrm{C} / 20 \mathrm{mmHg}$ ) to afford the ${ }^{18} \mathrm{O}$ labelled alcohol ( $0.5 \mathrm{~g}, 58 \%$ yield; ${ }^{18} \mathrm{O}=48 \%$ ).

The corresponding acetate was made by a standard technique. ${ }^{19}$

## Condensed phase reactions

Products of the base catalysed reactions of 5,6-epoxyhexanol, tetrahydropyran-2-methanol and 3-oxepanol were analysed using a Finnigan GCQ mass spectrometer. Conditions: Column phase RTX-SMS (length 30 cm , ID 0.25 , GC fused silica capillary), He carrier gas. Initial column temperature, held at $50^{\circ} \mathrm{C}$ for 2 min , then the temperature increases at $15^{\circ} \mathrm{C}$ per min. Retention times: 5,6-epoxyhexanol ( 7.00 min ), tetrahydropyran-2-methanol ( 6.02 min ) and 3-oxepanol ( 6.32 min ).

A mixture of 5,6-epoxyhexanol ( 0.5 g ) and aqueous sodium hydroxide ( $10 \%, 5 \mathrm{~cm}^{3}$ ) was allowed to stir for 60 h , (i) at $20^{\circ} \mathrm{C}$, and (ii) at $100^{\circ} \mathrm{C}$ (see Table 2). The reaction mixtures were sampled at various times. Each sample was acidified with aqueous hydrogen chloride ( $10 \%$ ) until the pH was 6 , extracted with dichloromethane $\left(5 \mathrm{~cm}^{3}\right)$, the organic extract dried $\left(\mathrm{MgSO}_{4}\right)$ and concentrated. The product composition was analysed by GC/MS (see Table 2).

Tetrahydropyran-2-methanol and 3-oxepanol were each treated with aqueous sodium hydroxide as detailed above. No reaction was observed in either case.
J. M. H., M. S. T and S. D. thank the ARC for a PhD scholarship, a research associate position and a research assistant position respectively.

## Acknowledgements

This research was financed by the Australian Research Council.

[^0]:    $\dagger$ Supplementary material is available for this paper (SUPPL. NO 57479,9 pp.). For details of the Supplementary Publications Scheme see 'Instructions for Authors', J. Chem. Soc., Perkin Trans. 2, available via the RSC web page (http://www.rsc.org/authors). The supplementary data are also available on the RSC's web server, http://www.rsc.org/ suppdata/p2/1999/457/.

[^1]:    $\ddagger$ The second structure may be transient or alternatively the formation of the third structure from the first may be concerted. The second structure is included in the Scheme in order that the mechanism for ring opening is clear.
