(*b*) The formation of $\beta(Ca,Mn,Pb)SiO_3ss$ requires that both MnO + SiO_2 be incorporated into $\alpha(Ca,Pb)SiO_3ss$. Addition of MnO and SiO_2 as $MnSiO_3$ is impractical since three days or more are required for the reaction to reach equilibrium. This result is not surprising since $CaSiO_3$ and $MnSiO_3$ must have about the same lattice energy as evidenced by their extensive solid solution series. If MnO and SiO_2 are mixed with $\alpha(Ca.Pb)SiO_3ss$, $MnSiO_3$ forms more readily than the quaternary solid solution and again the reaction is very sluggish in reaching completion. However, $\beta(Ca,Mn,Pb)SiO_3ss$ can be formed in 2-3 hr at 1160°C by reacting $MnCO_3$ plus $\alpha(Ca,Pb)$ SiO_3:SiO_2. Using this method it is necessary to add sufficient excess silica in the preparation of $\alpha(Ca,Pb)$ SiO_3ss to account for all of the Mn in the quaternary composition.

Silica is not soluble in $\alpha(Ca,Pb)SiO_3$ at concentrations greater than about 1 mole %, although there may be slight solubility below this amount. Only silica which is in contact with α calcium silicate will react with MnO to form $\beta(Ca,Mn,Pb)SiO_3ss$. Isolated

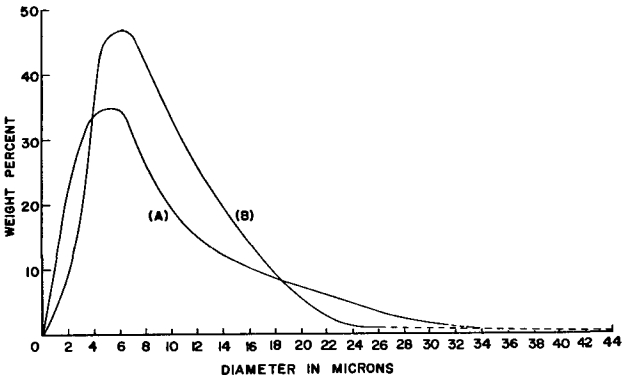

Fig. 3. Particle size distribution curves of $CaSiO_3$:Mn + Pb phosphors. (A) CaO + PbO + MnO + $SiO_2 \rightarrow \beta$(Ca, Pb, Mn) SiO_3 ss; (B) α(Ca, Pb) SiO_3 ss + $Mn^{2+} \rightarrow \beta$(Ca, Pb, Mn) SiO_3 ss.

SiO_2 particles react with MnO to form $MnSiO_3$ which effectively removes Mn from the reaction.

Microscopic examination of samples obtained by quenching after various times clearly revealed the course of the reaction. MnO + SiO_2 diffuse rapidly along grain boundaries of the $\alpha(Ca,Pb)SiO_3$ aggregates. Inversion of $\alpha(Ca,Pb)SiO_3$ begins at the periphery, and as each crystallite of $\alpha(Ca,Pb)SiO_3$ inverts to $\beta(Ca,Mn,Pb)SiO_3$ sufficient contraction occurs to permit the crystallite to separate from the matrix. Thus, this process leads to the disintegration of the aggregates of $\alpha(Ca,Pb)SiO_3$.

(c) The Pb which is volatilized from the quaternary solid solution appears to react with excess silica to form a lead silicate film which causes slight sintering. Sintering can be minimized by employing as short a firing time as possible and by using as little excess silica over stoichiometry as practical.

Lead silicate on the surface of the $\beta(Ca,Mn,Pb)$ SiO_3ss crystals also stabilizes higher oxidation states of Mn. Consequently the surface film serves as a filter which considerably lowers the fluorescent brightness of the phosphor. The film may be removed by refiring with NH_4Cl.

The product obtained has substantially smaller particle size than phosphor produced by initially firing together CaO+MnO+PbO+SiO_2. Phosphor prepared by reaction [2] showed less than 1 wt % oversize on 325 mesh sieve whereas conventional material gave 10-15 wt % oversize. Particle size distribution curves are shown in Fig. 3. It is evident that reaction [2] serves to minimize aggregate growth rather than to yield smaller crystallites since either technique yields a maximum of material in the 5 to 7 μ range. The area under curve "A" for material produced by initially firing together CaO+ MnO+PbO+SiO_2 represents 85-90 wt % of the total material since 10-15 wt % is greater than 44 μ or 325 mesh. On the other hand, curve "B" for phosphor produced by reaction [2] represents 100 wt % since substantially all of the material is less than 325 mesh. Either technique yields phosphor with the same fluorescent properties.

Acknowledgment

The authors thank E. S. Palik for determining the particle size distributions of phosphor powders.

The Dielectric Behavior of Solids Embedded in a Homogeneous Medium

Barlane R. Eichbaum

Product Development Laboratory, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Dielectric constant and tan δ of powdered crystal phases of alumina, quartz, and wollastonite were determined. Since it is very difficult to obtain dielectric measurements of very fine (powdered) crystals, a technique of embedding the solids in a homogeneous medium was used. The relationship between particle shape and volume present in the composite to the dielectric properties of such fine powders was in accord with that indicated by Niesel's theory.

The dielectric properties of large single crystals of inorganic materials can be determined since there is sufficient mass present to use standard measuring techniques. Although large single crystals of many inorganic materials are not available, it would be desirable to determine the dielectric properties of granular or pulverized crystallites in order to study their dielectric contribution in composite mixtures. The object of this research is to present a method for determining the dielectric properties of such fine powdered crystallites.

Niesel proposed a theory to compute dielectric properties of solids embedded in a homogeneous medium (1, 2). This theory considers the volume and particle shape of the crystalline materials embedded in the homogeneous medium. In order to overcome the variations which would be encountered if compressed powders were studied, a technique of embedding inorganic powders in a homogeneous medium was devised and used throughout this investigation.

Theory.—Several theories have been developed to predict dielectric properties of polycrystalline mixtures. A theory developed by Lichtenecker (3) in 1926 gives a good approximation for mixtures having a maximum dielectric constant of 10. In 1935 Bruggeman (4) developed equations for determining dielectric constants of mixtures of materials with crystal shapes approximating spheres or lamellae. Niesel (1, 2) gave a method for calculating both the dielectric constant and loss angle of an aggregate consisting of crystals (assumed to be ellipsoids) mixed with a homogeneous material.

The equations derived by Niesel for the isotropic cases of spheres, lamellae, and long cylinders embedded in a homogeneous medium are as follows:

(*a*) Spheres

$$1 - Vi = \frac{\epsilon i - \epsilon}{\epsilon i - \epsilon a} \sqrt[3]{\frac{\epsilon a}{\epsilon}} \qquad [1]$$

(*b*) Lamellae (randomly oriented)

$$= \frac{3\epsilon a + 2Vi(\epsilon i - \epsilon a)}{3\epsilon i - Vi(\epsilon i - \epsilon a)} \qquad [2]$$

(c) Long cylinder (needles)

$$1 - V = \frac{\epsilon i - \epsilon}{\epsilon i - \epsilon a} \frac{(\epsilon i + 5\epsilon a)}{\epsilon i + 5\epsilon} \qquad [3]$$

where ϵi = dielectric constant inside ellipsoid, ϵa = dielectric constant outside ellipsoid, ϵ = resulting dielectric constant, and Vi = volume fraction occupied by ellipsoids.

If δ_1 is the loss angle of the crystal phase and δ_2 that of the medium, then the resulting loss angle δ_{res} is given by

$$\tan \delta_{res} = m_1 \tan \delta_1 + m_2 \tan \delta_2 \qquad [4]$$

If the loss angles of the two ingredients are known it is necessary to determine the values of m_1 and m_2

(energy fractions) which are derived by Niesel to be as follows for the three cases:

(*a*) Spheres

$$m_2 = \frac{(\epsilon_1 - \epsilon)(2\epsilon_2 + \epsilon_1)}{(\epsilon_1 - \epsilon_2)(2\epsilon + \epsilon_1)} \quad [5]$$

(*b*) Lamellae

$$m_2 = \frac{\frac{K_1}{1 + K_1} + 2K_1}{\frac{K_{12}}{1 + K_{12}} + 2K_{12}} \quad [6]$$

(*c*) Cylinder additions

$$m_2 = \frac{\frac{2K_1}{1 + \frac{1}{2}K_1} + K_1}{\frac{2K_{12}}{1 + \frac{1}{2}K_{12}} + K_{12}} \quad [7]$$

where

$$K_1 = \frac{\epsilon_1 - \epsilon}{\epsilon} \quad [8]$$

$$K_2 = \frac{\epsilon_1 - \epsilon_2}{\epsilon_2} \quad [9]$$

$$m_1 + m_2 = 1 \quad [10]$$

and ϵ = dielectric constant of combined phases, ϵ_2 = dielectric constant of glass phase, ϵ_1 = dielectric constant of crystal phase, m_1 = energy fraction of crystal phase, and m_2 = energy fraction of glass phase.

Sample Preparation

In order to test Niesel's theory it was necessary to devise a method of embedding the inorganic crystals in a homogeneous medium; the dielectric properties were then determined. Polystyrene was selected as the homogeneous medium in which to embed the crystals since it has very low loss properties.

Known volumes of five inorganic powders were dispersed in a known volume of polystyrene and carbon tetrachloride solution. This solvent was selected because it has a dielectric constant and tan δ similar to that of polystyrene (5, 6), and, if it should not evaporate completely, little effects would be contributed. The mixtures were completely dried out, then hot pressed into disks having a 1¼ in. diameter and approximately 0.05 in. thick. In all cases the volume of powdered inorganic material does not exceed 65% or the specimen will not be dense, hence, a true evaluation will not be obtained.

The values of dielectric constant and tan δ were determined with the Boonton Q-meter type 160A at 1 megacycle.

Preliminary investigation.—In order to determine the correlation between the theoretical and experimental values for mixtures having known, measured dielectric constant and tan δ, two glasses, Vycor and window glass, were selected for study by embedding in polystyrene. These glasses were ground wet and screened through 100 and 200 mesh sieves prior to combining with polystyrene. The ground glass is considered an isotropic powder material in this case.

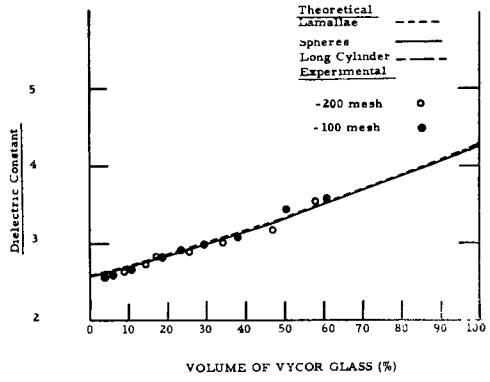

Fig. 1. Volume of Vycor glass on polystyrene vs. dielectric constant and tan δ.

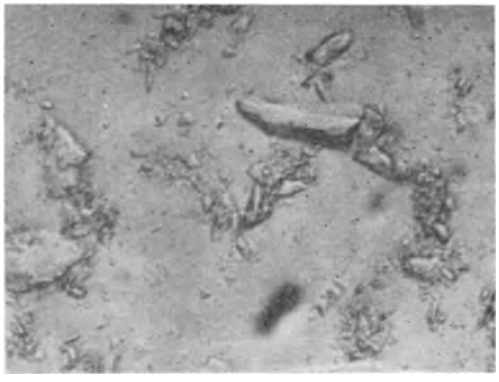

Fig. 2. Photomicrograph of Vycor glass particles. Magnification 1000X.

Two glasses were used because their dielectric properties were quite different and this could be used as a means of verifying the validity of Niesel's equations. Dielectric properties were determined on a square piece of each glass 2 in. by 2 in. by approximately 1/5 in. thick. These glasses were crushed to —100 and —200 mesh grain sizes. Both glasses were investigated using grains of two particle sizes in order to check if the particle size has any effect with either low or high loss glass. Niesel claims that the particle size of the powdered material should have no effect on the results; therefore, it was necessary to substantiate this claim.

Vycor glass-polystyrene mixture.—The two different particle sizes of Vycor glass were embedded in polystyrene. The dielectric properties of the two materials are:

	ϵ	tan δ
Polystyrene	2.55	0.00022
Vycor glass	4.28	0.00084

Since the values for the two end members are known, calculations were made on the basis of lamellar, spherical, and long cylinder (needle) particle shapes in order to determine if the experimental values obtained compare with any of the theoretical curves. Calculated values for the three particle shapes and the experimental value are listed in Table I. All of these values are plotted vs. volume of glass present in Fig. 1.

As can be seen from the graph of Fig. 1, the curves for theoretical dielectric constant are so close together that it is difficult to distinguish between them. The symbols used to denote experimental values for both —100 and —200 mesh sizes follow right in line with the theoretical curves.

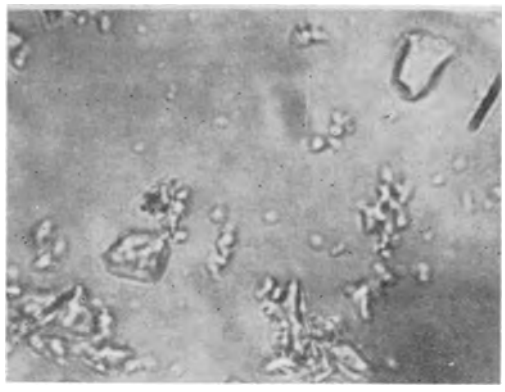

Fig. 3. Photomicrograph of window glass particles Magnification 1000X.

The theoretical curves for tan δ on Fig. 1 are easily differentiated. The curve for spherical particles is almost a straight line, whereas that for randomly oriented lamellae has a greater upward curvature, and the curve for randomly oriented needles has a rapid increase which levels off to almost a straight line. Experimental values obtained for both the —100 and —200 mesh particles fall right in line with the long cylinder addition curve. This was not expected because it was assumed that the particles would most closely approach a spherical shape. However, when examined with a petrographic microscope, many of the particles were noted to be a long needle shape as can be seen in the photomicrograph of Fig. 2.

These results were very enlightening, showing that this difference of particle shape has a definite effect, that the particle size difference has no marked effect, and that the experimental and calculated values of both dielectric constant and tan δ vs. volume per cent are almost identical for the case of the long cylinder shaped additions.

Window glass-polystyrene mixtures.—In the experiments using glass-polystyrene mixtures as with the Vycor glass-polystyrene mixtures both —100 and —200 mesh glass grains were embedded in polystyrene for the determination of dielectric properties.

The values of the 100% product in this case at 1 mc and 25°C are;

	ϵ	tan δ
Polystyrene	2.55	0.00022
Window glass	7.95	0.012

The particle shape of this glass (ground) was investigated and assumed to approach a spherical symmetry as can be seen in Fig. 3. Since the particles did not appear to be elongated as many were in the case of Vycor glass, theoretical calculations were performed only for spherical and lamellar particle shapes. Theoretical values obtained for these two shapes vs. volume per cent as well as the experimental values obtained for the two particle sizes are listed in Table II. Curves plotted for theoretical calculations and symbols designating the experimental values are plotted in Fig. 4.

As can be seen in Fig. 4 the lamellar curves for both dielectric constant and tan δ do not approach

the experimental values, but both the −100 and −200 mesh particle size symbols are very close to the spherical curves. Calculated values of dielectric constant are slightly larger than experimental values, whereas calculated tan δ values are slightly less than experimental values.

However, the curves, being very close, show that the particle shape of the window glass, approaching sphericalness, can be used to make very close approximations to the true experimental values. This helps to substantiate and justify the use of Niesel's theory as does the case for Vycor glass-polystyrene mixtures.

Since the experimental values obtained for the Vycor glass-polystyrene and window glass-polystyrene mixtures so closely approach the theoretical values obtained with Niesel's equations, the same approach is used to determine the 100% volume values for the three crystalline materials, alumina, quartz, and wollastonite.

Dielectric Properties of Alumina, Wollastonite, and Quartz Crystallites

Since Niesel's equations fit the experimental data for the two cases using glasses as the dispersed ingredient, the same technique was used to determine the dielectric properties of the crystal phases of alpha alumina, wollastonite, and low-temperature quartz.

Alumina-polystyrene mixtures.—A very pure grade of fused alumina[1] was used for determining the dielectric properties by embedding in polystyrene. von Hippel (7) determined the dielectric properties of a clear sapphire[2] to be:

$$\epsilon = 8.6 \pm 0.02, \tan \delta = 0.001$$

perpendicular to the optic axis

and

$$\epsilon = 10.55 \pm 0.02, \tan \delta = 0.001$$

parallel to the optic axis

when measured at one megacycle.

This is a single crystal form of alumina and not a powdered form which is randomly oriented.

The alumina grains used in this study appear to have a spherical shape symmetry (Fig. 5). Since these particles appear to be spherical, calculations were made only for spherical shaped particles and not for the other two shapes. Experimental values were first determined for alumina additions up to 61% by volume as shown in Table III. These dielectric constants and power factors are plotted vs. volume per cent of alumina on Fig. 6. Three of the points at volumes of 10.4, 42, and 50.5%, respectively, which fall on a curve drawn through all

Experimental					
Alumina volume, %	ϵ	tan δ	Alumina volume, %	ϵ	tan δ
0	2.55	0.00022	0	2.55	0.00022
2.3	2.62	0.00024	10.4*	2.91	0.00027
10.4	2.91	0.00027	25.6	3.55	0.00033
20.9	3.33	0.00031	42.0*	4.36	0.00040
32.0	3.71	0.00036	50.5*	4.82	0.00043
42.0	4.36	0.00040	53.6	5.00	0.00044
50.5	4.82	0.00043	100	8.42	0.00061
61.0	5.29	0.00045			

* Experimental values used to calculate theoretical 100% value.

points, were selected for making calculations of the 100% alumina end point. The calculated values are:

Volume alumina, %	ϵ	tan δ
10.4	8.45	0.00061
42.0	8.42	0.00062
50.5	8.40	0.00060
Avg	8.42	0.00061

With these values other theoretical points were calculated for completing the plot of the theoretical curves on Fig. 6. All theoretical and experimental values are listed in Table III.

As can be seen in Fig. 6 the theoretical curves and symbols for experimental points show good agreement. The dielectric constant and tan δ of these randomly oriented alumina grains approach the values obtained for single crystals by von Hippel.

Quartz-polystyrene mixtures.—Using a very pure grade of low-temperature quartz,[3] which is 99% pure SiO_2, the dielectric constant and tan δ were determined when mixed with polystyrene. Navias (7) determined the average dielectric constant and tan δ of a single crystal of quartz to be

$$\epsilon = 4.44, \tan \delta = 0.00025 \text{ (prism)}$$

$$\epsilon = 4.44, \tan \delta = 0.00024 \text{ (basal)}$$

at 8600 megacycles.

Again, as in the case for alumina, these values are for single crystals and not for fine powders, which

[3] Supplied by Pennsylvania Pulverizing Co.

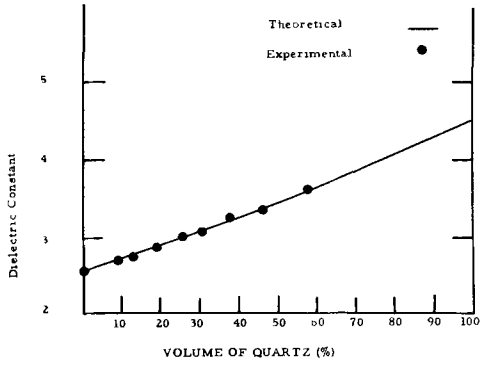

Fig. 8. Volume of quartz in polystyrene vs. dielectric constant and tan δ.

may have similar values regardless of size, but the effects when combined with a continuous phase need to be determined. For the theoretical calculations these quartz grains were considered to be spherical (Fig. 7).

Several experimental values were determined on specimens containing up to 58.3% quartz by volume; these are listed in Table IV. Three sets of values for quartz volumes of 9.6, 25.7, and 58.3% were used for computation to obtain an average dielectric constant of 4.52 and a tan δ of 0.00031 for the quartz grains. Using these values in Niesel's formulas several other theoretical points for quartz volumes up to 100% were calculated and are listed in Table IV. All theo-

retical and experimental dielectric constant and tan δ values are plotted against volume of quartz on Fig. 8. Both the dielectric constant and tan δ are coincident with the symbols designating the experimental values.

The values of the dielectric properties of these quartz grains are very close to the average values obtained by Navias for single crystals.

Wollastonite-polystyrene mixtures.—Wollastonite has been used successfully as a major ingredient in recently developed low loss insulation. Since no values of the dielectric properties of single crystals of wollastonite are available and synthesis of large wollastonite crystals for measurements would be almost impossible, because pseudo-wollastonite is the stable phase at the high temperature required for synthesis, the values obtained will be considered to approach the average values of a single crystal. The purest commercial grade of wollastonite available[4] was used in this investigation.

The particle shape of C-1 grade wollastonite is shown in Fig. 9. Calculations were made only for long cylinder shape particles in polystyrene because the wollastonite grains are definitely of this shape.

From the several experimental values obtained for the volume of wollastonite in polystyrene listed in Table V three sets of values were selected at 11.0, 24.9, and 62.0% volume for determining the theoretical 100% wollastonite aggregate dielectric properties. The average dielectric constant is 6.15 and the tan δ is 0.00045. Using these values for wollastonite, the theoretical values vs. volume were calculated

and are listed in Table V. These values are plotted on Fig. 10.

Summary

The dielectric properties of solids embedded in a homogeneous medium have been determined with the aid of Niesel's theory which is based on particle shape and volume per cent of the solids. Niesel's theory was first verified by embedding two glasses (one having a high loss and the other a low loss) of 2 specific particle sizes in a homogeneous medium. Since the dielectric properties of both were known (measured) theoretical calculations were made which were almost identical with experimental values on samples with both glasses of 2 different particle sizes. Since such good correlation was observed with these inorganic materials of known dielectric properties the same techniques were used to determine the dielectric properties of alumina, quartz, and wollastonite.

Acknowledgment

The author wishes to acknowledge the U. S. Signal Corps for their sponsorship of this research. He would also like to thank Mr. Sam DiVita, Professor John H. Koenig, Dr. Robert B. Sosman, and Dr. Harold T. Smyth for their assistance and guidance during the course of this research. The author would like to thank Dr. Thomas D. Callinan for his assistance in the preparation of this manuscript.

Manuscript received Sept. 29, 1958. This research was submitted by the author as partial fulfillment for the requirements for his Ph.D. degree at Rutgers University in 1956.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Growth of Whiskers by Reduction of Halogenides

H. Wiedersich

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

By reduction of $SiCl_4$ with Zn, silicon was produced and similarly by reduction of $FeCl_2$ with H_2, iron. In both cases variations of the growth conditions changed the forms of the crystals from equiaxed into thin, long ones (whiskers). Thermodynamic and kinetic considerations lead to the conclusion that the partial pressure of $SiCl_4$, resp. $FeCl_2$ or HCl determine the growth forms. The hypothesis is suggested that the adsorption of these components makes certain crystallographic plane growth inactive and therefore produces whisker growth.

The phenomenon of filamentary or fibrous growth of metal crystals has been known for more than a hundred years (1). During the past few years these crystals have gained new interest especially due to the discovery that some of them exhibit almost the theoretical strength (2). It became evident that quite a number of different mechanisms are responsible for fibrous growth. Only three basically different categories will be mentioned: (*A*) Growth from the elementary metal: Whiskers grow spontaneous (3) or with applied external pressure (4) from the solid metal or platings. They grow from the root presumably by a dislocation mechanism whereby a stress gradient and/or surface oxidation supplies the necessary energy. (*B*) Growth by reduction of ionic crystals: Compounds inclined to fibrous growth are usually either oxides or sulfides, have a low vapor pressure, and the metal ions have high mobilities in the lattice. The filaments grow from the root. The mechanism suggested by Wagner (5) involves the precipitation of excess metal ions, created by the reduction, at the compound-metal interface. (C) Growth occurs from the vapor phase, either from the elementary vapor (6, 7) or in connection with the reduction of a volatile compound (8-10). The filaments in this group grow from the tip contrary to the two previously mentioned groups.

For growth from the elementary vapor phase, Sears (11) has given a satisfactory theory based on a screw dislocation mechanism. Atoms are adsorbed over the whole surface of the whisker and migrate by surface diffusion to the tip where they attach themselves to a continuous growth step caused by a screw dislocation along the axis of the whisker. Such a whisker should be a perfect crystal apart from one screw dislocation, and its side faces should be atomically smooth.

The present investigation was intended to enlighten the more complex phenomenon of whisker growth by reduction of volatile halides. The following reactions were used:

$$SiCl_4 + 2Zn \rightarrow Si + 2ZnCl_2$$

and

$$FeCl_2 + H_2 \rightarrow Fe + 2HCl$$

which were known to produce whiskers (8-10).

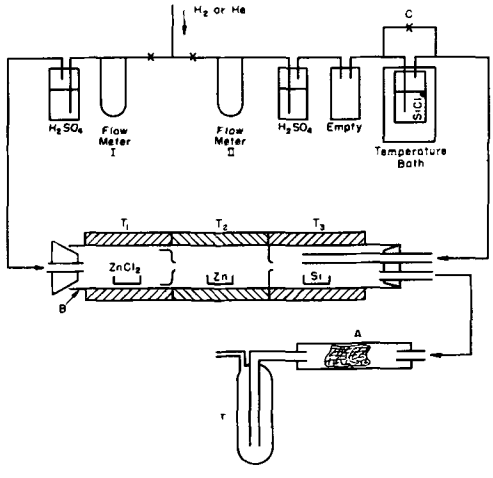

Fig. 1. Experimental setup (schematic)

Experimental

Figure 1 shows schematically the experimental setup for growing silicon crystals. He or H_2, dehumidified by bubbling through concentrated sulfuric acid, was passed through flowmeter I into the left side of the furnace and through flowmeter II and a $SiCl_4$-saturator, which had a bypass C, into the right side of the furnace. The furnace had three separately controlled windings at the positions marked by $ZnCl_2$, Zn, and Si, to provide three different temperature zones for the evaporation of $ZnCl_2$ and Zn, and for the reaction which took place in the zone marked as Si. The interior of the furnace consisted of a Vycor tube with a fixed Vycor baffle between the Zn and Si zones and a removable baffle between the $ZnCl_2$ and Zn zones. There was a short inlet tube for H_2 on the left side and a long one for the H_2-$SiCl_4$ mixture on the right side. The outlet for the gases, on the right side of the tube, leads through chamber A which was filled with glass fibers for the complete removal of $ZnCl_2$, and a trap T immersed in liquid nitrogen to condense the unreacted $SiCl_4$.

The experimental procedure was as follows. The whole tube, B, containing alundum boats filled with $ZnCl_2$ and Zn and an empty boat at the Si location was inserted in the hot furnace to reduce the preheating times and thereby the evaporation of $ZnCl_2$ and Zn before starting the reaction. Then the whole

system was flushed with He before H_2 was introduced. As soon as the furnace was again at the desired temperature the reaction was started by simply closing the bypass C and allowing the $SiCl_4$ vapor to enter the system.

After the run (1 to 4 hr) the bypass C was opened again, the furnace turned off, and the system flushed with He. In order to remove traces of $ZnCl_2$, which precipitated on the grown Si crystals during the cooling period, the boat with the Si crystals was annealed under a vacuum of a few mm Hg at 800°C for an hour. The chemicals used were: Zn (99.99%), $ZnCl_2$(C.P.), and technical $SiCl_4$.

The setup for growing iron crystals was very similar to that described before. The hydrogen was deoxidized by a palladium catalyst and dried by a liquid nitrogen trap. The furnace had a constant temperature throughout. The $SiCl_4$ saturator was omitted, and $FeCl_2 \cdot 4H_2O$ (C.P.) was introduced in place of the $ZnCl_2$ and Zn. In this case the Vycor tube was inserted into the cold furnace, the system connected to the house vacuum, and then heated up to the operating temperature within about 15 min. During this time it was necessary to pass a small flow of hydrogen through the system to prevent condensing of water in the entrance tubes. The water contained in the $FeCl_2$ was practically completely evaporated after the heating-up time, and the flow rates and pressure (1 atm) were adjusted and kept constant throughout the rest of the experiment (6-24 hr).

Results

Silicon.—By controlling the temperature of the temperature bath and the zones T_1 and T_2 of the furnace, the composition of the reacting gases could be controlled. The temperature T_3 of the reaction zone could be fixed independently. The total pressure was practically atmospheric pressure. Table I summarizes the results of the 15 different runs performed. The partial pressures of the different components (indicated by subscripts) in the two entering gases are given by p^*; v_{SiCl_4}, and v_{Zn} are the flow rates of the two different entering gas mixtures. The temperature in the reaction zone is also given. The line before the last states whether whiskers did or did not grow.

All experiments which did not yield whiskers have in common that the initial partial pressure $p^*_{SiCl_4}$ of $SiCl_4$ was comparatively low. The flow rates and the presence or absence of $ZnCl_2$ in the initial mixture do not seem to have an influence. Figure 2 shows silicon whiskers from run XIII. Not all crystals in Fig. 2 can

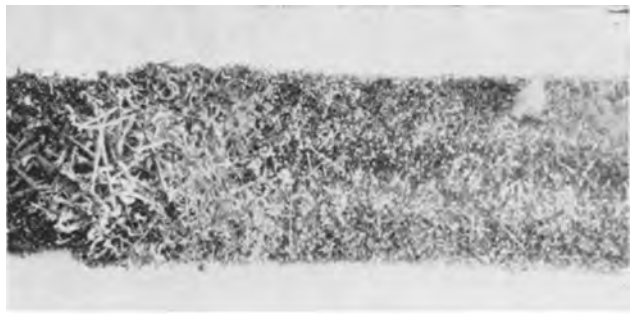

Fig. 2. Silicon whiskers grown in experiment XIII. Magnification 2X before reduction for publication.

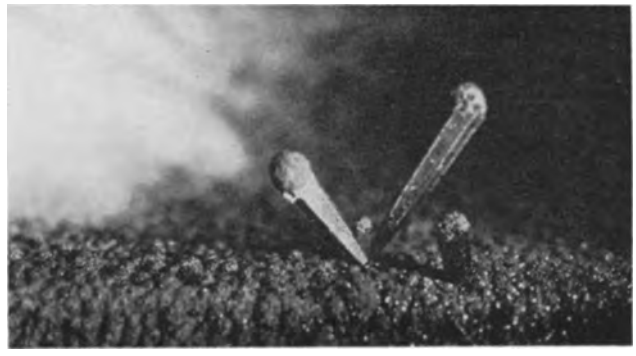

Fig. 3. Silicon crystals grown in experiment X. Magnification 15X before reduction for publication.

be classed as whiskers. Many of those on the left side are not straight and do not have the characteristic smooth surfaces associated with whiskers. However, fine, straight whiskers can be seen. Many of the whiskers, sufficiently large for light microscopic observation, are found to have hexagonal cross section. The diameter of the whiskers ranged from about 5×10^{-5} to 5×10^{-4} cm. Figure 3 shows the types of growth in experiment X. The roughly spherical type of crystals covering the edge of the alundum boat were observed in all experiments which did not yield whiskers but were not observed in those yielding whiskers. Pyramidal crystals were found only in experiment X.

Iron.—Fewer variations in growth conditions were made for iron crystals, since the only aim was to show that the growth mechanism is very much the same as for silicon. Table II summarizes the experiments performed. The symbols used correspond to the ones in Table I. One part of the flow of $H_2(v_1)$ was passed over solid $FeCl_2$ thus converting to the equilibrium mixture of H_2, HCl, and $FeCl_2$ in the presence of solid $FeCl_2$ and Fe. Since the temperature of the furnace was kept constant throughout at $T = 658$°C this mixture had always the composition

Whiskers	Some	Many	None	None	Many	Some

Values common to all runs: $p^*_{FeCl_2} = 7.25 \times 10^{-3}$, $p^*_{HCl} = 0.156$, $p^*_{H_2} = 0.837$ at; temperature 658°C; $S_{max} = 1.12$; r_{max} (calc.) = 10^{-14} cm/sec; $r_{exp} = 5 \times 10^{-5}$ cm/sec.

$p^*_{HCl} = 0.156$, $p^*_{H_2} = 0.837$, and $p^*_{FeCl_2} = 7.25 \times 10^{-3}$ at. Equilibrium data of Kangro and Peterson (12) and vapor pressure data of Mayer (13) were used to obtain the values of the partial pressures. Into this mixture pure H_2 was introduced with the flow rate v_2.

A decrease of the ratio v_2/v_1 (this means smaller amounts of H_2 get introduced into a given volume of the equilibrium mixture) causes an increase in the tendency to form whiskers. Figure 4 shows the growth resulting from the runs G, I, and H. Above the centers of the boats an iron wire is suspended from which most but not all of the whiskers grew. Small crystals were found, in all experiments, growing on the boats, the wires, and the surrounding Vycor tubes. They were mostly cubes with indications of (110) and (111) planes as shown in Fig. 5. The whiskers as shown in Fig. 6 and 7 frequently had

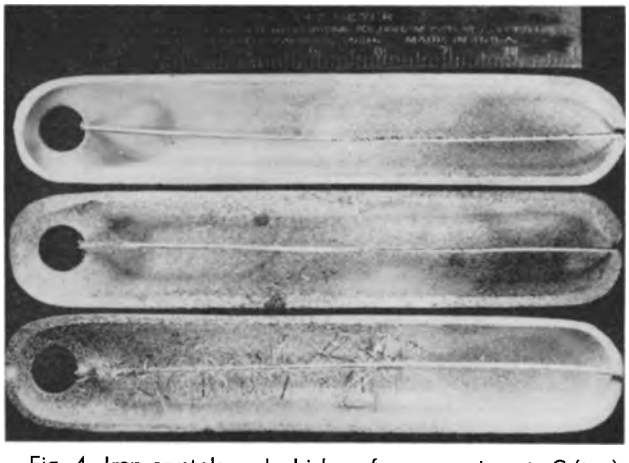

Fig. 4. Iron crystals and whiskers from experiments G (top), I (middle), and H (bottom).

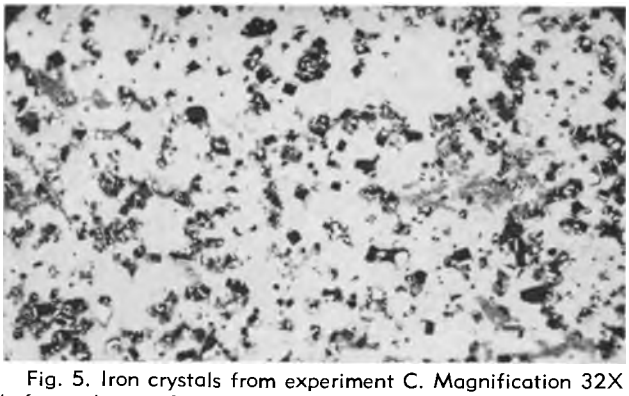

Fig. 5. Iron crystals from experiment C. Magnification 32X before reduction for publication.

right angle kinks and varied in thickness from about 5×10^{-4} cm to 8×10^{-2} cm. The cross section was usually square or rectangular; a few hexagonal ones were found. Sometimes the cross section decreased toward the tip. Figure 8 shows the tip of a whisker apparently bounded by (100) planes and one (111) plane.

Discussion

There are principally three different processes involved in the growth of the crystals in the present kind of system: (*a*) intermixing of the two incoming

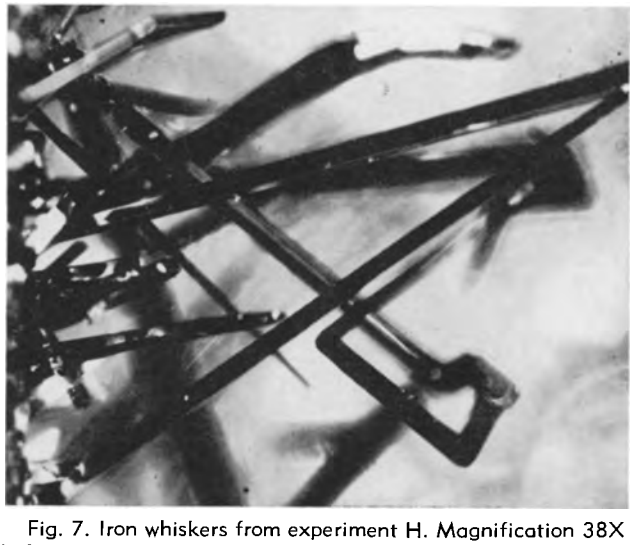

Fig. 7. Iron whiskers from experiment H. Magnification 38X before reduction for publication.

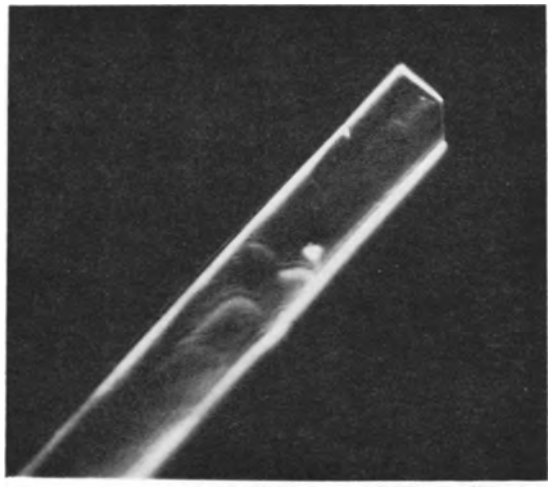

Fig. 8. Tip of an iron whisker. 300X before reduction for publication.

gases by convection and diffusion; (*b*) chemical reactions; and (*c*) precipitation on the growing face of the crystal.

Since no simple way of estimating the intermixing by convection is available, we consider only the process of diffusion. From kinetic gas theory one obtains for the diffusion constant in gases the expression (14)

$$D = \frac{32}{9\pi}\left(\frac{kT}{\pi}\right)^{3/2}\frac{1}{\delta^2 p\sqrt{m}}$$

where k = Boltzmann constant, T = absolute temperature, δ = collision diameter, p = pressure, and m = mass of the molecules. Using reasonable average numbers for these quantities ($T = 1150°K$, $\delta = 3$ Å, $p = 10^0$ dynes/cm^2, $m = 2 \times 10^{-22}$ g); a rough estimate for D is:

$$D = 1.5 \text{ cm}^2/\text{sec}$$

Thus one can expect that for a tube of radius 1 cm complete mixing is achieved in less than 1 sec. This is to be compared with the time the gas mixture remains in the hot part of the reaction zone (≃10 cm), which ranged between 1 and 20 seconds. So the reacting gases are expected to have mixed completely in all experiments, especially since convection is favoring the mixing.

Very little is known about the details of the second of the above mentioned processes, the chemical reaction. We shall asume that it takes place mainly in the gaseous phase and shall try to derive some conclusions about the growth of the crystals which are based on this assumption.

Due to the nature of the experiments it is not possible to derive values of the actual supersaturation S (defined as ratio of the partial pressure in the gas p to the equilibrium pressure p_{equ}) during growth. Yet one can easily obtain an upper limit for S assuming one can apply the ideal gas law.

Silicon.—The main, and probably the exclusive, reaction taking place is

$$SiCl_4 + 2Zn \rightarrow Si + 2ZnCl_2 \qquad [1]$$

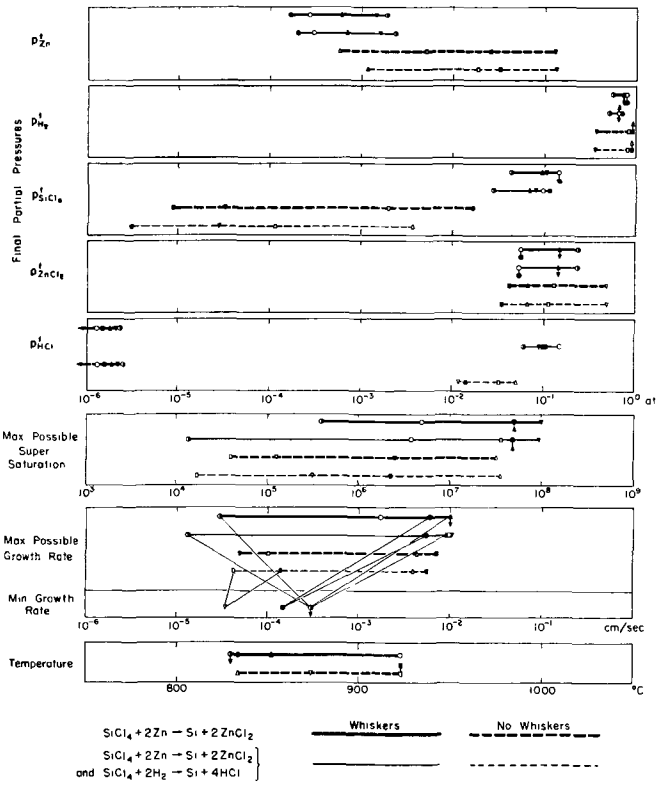

Fig. 9. Range of variables during growth of Si crystals

Preliminary experiments have shown that hydrogen by itself is not able to reduce $SiCl_4$ at the temperatures used even though thermodynamic equilibrium data (15) predict a reaction

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \qquad [1a]$$

should yield measurable amounts of Si. In the following it is therefore assumed that only reaction [1] has taken place in the experiments. Yet in Fig. 9 the values obtained by taking in addition [1*a*] into account are added. From Gibbs free energy data given by Kellogg (15) and vapor pressures (14, 16) one obtains the equilibrium constant K^2 [1] in the law of Mass Action for reaction [1]

$$K^2 = \frac{p_{SiCl_4} \times p^2_{Zn}}{p_{Si} \times p^2_{ZnCl_2}} \qquad [2]$$

the p's denote the partial pressures of the chemical Species indicated by subscripts in the gas mixture. A supersaturation $S > 1$ ($S = 1$ means equilibrium between gas and solid phase) is obtained only if the homogeneous reaction in the gas phase is faster than the heterogeneous one of precipitation. The maximum value of S which could be achieved would occur if the first reaction reaches equilibrium before the second has proceeded in any appreciable amount. Taking this into account one derives from [2] in a straight forward way the limits of S:

$$1 \leqq S \leqq \frac{1}{K^2 \times (p_{Si})_{equ}} \frac{p_{SiCl_4} \times p^2_{Zn}}{p^2_{ZnCl_2}} \qquad [3]$$

In case all three components $SiCl_4$, Zn, and $ZnCl_2$ are introduced, one can use on the right side of the Eq. [3] the partial pressures before the reaction since the

[1] The square is used to be in agreement with Kellogg's definitions.

amount reacted in the gas phase to achieve equilibrium is extremely small as long as practically no precipitation has taken place.

In case no $ZnCl_2$ is added, the change in p_{ZnCl_2} due to the reaction has to be taken into account and one obtains:

$$1 \leqq S \leqq \frac{1}{(p_{Si})_{equ}} \sqrt[3]{\frac{p_{SiCl_4} \times p^2_{Zn}}{4K^2}} \qquad [4]$$

Now Eqs. [3] and [4] have to be expressed in terms of the partial pressures p^* in the entering gases. The two gas mixtures characterized by $p^*_{SiCl_4}$ and by p^*_{Zn} and $p^*_{ZnCl_2}$ enter the reaction chamber and mix by convection and interdiffusion. Assuming the diffusion constants are equal (actually they will differ by less than the factor 10) one can obtain the possible upper limit of S in terms of the composition of the entering gases. One volume unit of the final mixture may be composed of "a" units of (Zn, $ZnCl_2$, H_2) and (1 — a) units of ($SiCl_4$, H_2). Then the partial pressures in the final mixture are, neglecting the reaction:

$$p_{SiCl_4} = (1 - a)\, p^*_{SiCl_4}$$

$$p_{Zn} = a\, p^*_{Zn}$$

$$p_{ZnCl_2} = a\, p^*_{ZnCl_2}$$

Inserting these expressions into [3] and [4] and maximizing with respect to "a" gives finally the maximum supersaturations which are possible:

$$S_{max} = \frac{1}{K^2 (p_{Si})_{equ}} \cdot \frac{p^*_{SiCl_4} \times p^{*2}_{Zn}}{p^{*2}_{ZnCl_2}} \qquad [5]$$

$$S_{max} = \frac{0.53}{(p_{Si})_{equ}} \sqrt[3]{\frac{p^*_{SiCl_4} \times p^{*2}_{Zn}}{4K^2}} \qquad [6]$$

The values of S_{max} for the different runs are contained in Fig. 9.

Iron.—Similar considerations lead to

$$S_{max} = \frac{1}{K (p_{Fe})_{equ}} \frac{p^*_{FeCl_2} \times p_t}{p^{*2}_{HCl}} \qquad [7]$$

for the maximum possible supersaturation during the growth of iron crystals. The p^*'s are the partial pressures in the equilibrium mixture entering the reaction chamber, p_t is the partial pressure of the pure H_2 entering (which was always $\simeq$1 at.), and K is defined as

$$K = \frac{p_{FeCl_2} \times p_{H_2}}{p_{Fe} \times p^2_{HCl}} \qquad [8]$$

The value of $K \times (p_{Fe})_{equ}$ was taken from (12, 13). In all experiments S_{max} was equal to 1.12.

One other set of values was obtained by conventional application of the Law of Mass Action. These are the final partial pressures p' in the gas after complete equilibrium with the precipitated phase is achieved. The values of the p''s for the various components are given in Fig. 9 for silicon and in Table II for iron. These values are a good approximation for the partial pressures in contact with the growing crystals so long as the growth proceeds at low supersaturations.

The following should be mentioned in connection with the third of the previously mentioned processes, the precipitation on the growing face of the crystals. From kinetic gas theory one can obtain the number Z of impacts per unit area of a surface per second:

$$Z = \frac{p}{(2\pi\, mkT)^{1/2}} \qquad [9]$$

where p is the partial pressure of the gas. If one assumes every impinging atom sticks at the place it hits, the rate of linear growth would be

$$r = \frac{Zm}{\rho} \qquad (\rho = \text{density}) \qquad [10]$$

The maximum possible growth rate obtained at the maximum supersaturation, r_{max} (calc), is given in Fig. 9 and in Table II and is compared with a rough estimate of the growth rate r_{exp} obtained from some experiments simply by dividing the length of the longest whiskers by the time the experiment lasted. This assumes that the whiskers have grown at a constant rate throughout the experiment and r_{exp} is therefore an estimate of the lower limit of the maximum growth rates in these experiments. Although r_{max} in several cases is larger than r_{exp}, runs XIII and XIV for silicon and the experiments with iron show clearly that one cannot explain the growth of the whiskers simply by the direct attachment of the impinging atoms at the growing face. One has to take into account a surface diffusion process similar to that proposed by Volmer and Estermann (17).

Discussion of Results

A comparison of the experimental range of the values of the variables which could be critical to the form of growth of the Si crystals is made in Fig. 9 for the two observed growth forms. It should be mentioned that the ends of the lines are not necessarily the actual limits for the occurrence of one or the other type of growth; they give only the range which these variables covered in the performed experiments. The final partial pressure of $SiCl_4$ was $\geqq 4.5 \times 10^{-2}$ ($\geqq 2.8 \times 10^{-2}$) at. for all cases where whiskers grew and $\leqq 1.7 \times 10^{-2}$ ($\leqq 3.8 \times 10^{-3}$) for all other experiments. The limits for the case that H_2 should take part in the reaction are added in parenthesis; then the partial pressures of HCl do also not overlap (they have the limits $\geqq 6.4 \times 10^{-2}$, respectively, $\leqq 5.2 \times 10^{-2}$ at.). All the other variables cover, for both growth forms, nearly the same range, or they overlap to a wide extent. This seems to indicate that the silicon tetrachloride (and/or hydrogen chloride) partial pressure has the main influence on the growth form of the Si crystals.

A similar situation was found for the growth of iron crystals. While temperature, maximum supersaturation, and maximum possible growth rate are identical for all experiments, an increase of the final partial pressures of $FeCl_2$ (1.4×10^{-3} to 4.3×10^{-3} at.) and of HCl (0.05 to 0.11 at.) leads from practically no whisker growth to pronounced whisker growth. The small relative change in the final H_2 partial pressure (0.89 to 0.95 at.) would hardly cause the change in growth form. On the basis of the present

experiments it is not possible to decide whether a high $FeCl_2$ partial pressure or a high HCl partial pressure or the combination of both is necessary for whisker growth.

The final partial pressures are a good approximation for the actual partial pressures of these components in contact with the growing crystal as long as the growth proceeds at relatively low supersaturations. The latter is surely true for the growth of iron ($S \leqq 1.12$). It can be shown that the statement that higher $SiCl_4$ partial pressures are necessary to produce whiskers than to produce equiaxed crystals still holds qualitatively, even if silicon grew at high supersaturations.

The findings suggest the following growth mechanism for silicon and iron whiskers: If the density of certain adsorbed species of molecules ($SiCl_4$, $FeCl_2$, or HCl) exceeds a critical value, a further growth of some crystallographic planes gets suppressed. These planes form the side faces of the whisker [(100) for iron, (112) or (110) for silicon]. The growing tip will usually consist of different kinds of planes and hence be able to attach new atom layers. The growth itself may proceed by a screw dislocation mechanism as suggested by Sears (11) for mercury whiskers, yet the possibility that each new atom layer starts with a surface nucleus could not be ruled out by an estimate of the supersaturation necessary for a high enough surface nucleation rate.

Manuscript received June 24, 1957. This paper was prepared for delivery before the Washington Meeting, May 12-16, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Electrolytic Production of Boron

George T. Miller

Hooker Chemical Corporation, Niagara Falls, New York

ABSTRACT

Elemental boron was produced by the fused salt electrolysis of potassium fluoborate. A study was made of anode and cathode materials of construction, particularly the effect of various grades of graphite as anode material. The effect of additives to the electrolyte (including potassium, aluminum, calcium, vanadium, nickel, Inconel, water, and sulfate ion) on boron yield and purity was investigated. A method of passivating elemental boron was developed.

Isotopic boron-10 was produced under contract with the U. S. Atomic Energy Commission by the Hooker Chemical Corporation, using Commission-owned facilities at Model City, New York. The plant was divided into two phases: isotope enrichment and elemental boron production.

The product of the isotope enrichment phase of the plant was a boron trifluoride-dimethyl ether complex. The designed capacity was 40 kg per month of boron-10. Because crystalline elemental boron was required and the isotopically enriched boron in the complex involved considerable cost of manufacture (over $500/lb), an efficient means of reducing the complex to the elemental form was sought. Fused salt electrolysis was investigated and ultimately employed for this purpose.

During the research and development stage and through the process improvement stage, a number of conclusions were reached and also a number of perplexing questions manifested themselves. This paper reviews some of the conclusions and manifested questions believed to be significant.

Basically, the process investigated was the fused salt electrolysis of potassium fluoborate and potassium chloride (1). Based on electrolyte analyses which disclosed the rate of KF production to be approximately 7-8 times that of boron production on a weight basis and on effluent gas analysis which disclosed an F_2 to Cl_2 weight ratio of approximately 3 to 1, the over-all reaction may be expressed by the following equation.

$$4KBF_4 + 2KCl \rightarrow 4B + 6KF + 5F_2 + Cl_2$$

The electrode processes have not been resolved.

The following factors affected cell design. Elemental fluorine and chlorine are produced at ap-

proximately 800°C. The proportion of potassium fluoride in the melt increases during electrolysis. The boron product is removed in solid form because of its high melting point.

General Description (2, 3)

The cell, as finally designed, consisted of a 23 cm ID x 58 cm deep graphite anode crucible protected on the outside by Inconel or nickel. The crucible was heated by a circumferential electrical resistance heater. A Monel cathode was suspended in the potassium chloride, potassium fluoride, potassium fluoborate melt. A reducing atmosphere was maintained above the melt level to avoid corrosion of the cathode. A current of 550 amp, equivalent to approximately 80 amp/dm^2, was used. To provide for periodic cleaning, the whole cell and furnace was mounted on trunnions to permit turning the cell to a horizontal position.

Normal operation of the process involved the addition of 2.5 kg potassium fluoborate to the molten (750°-800°C) electrolyte of 11.5 kg potassium chloride and potassium fluoride. After placement of the cathode, electrolysis at 550 amp and 5-6 v was effected for 3½ hr. The cathode with adherent product was raised above the electrolyte level and precooled to approximately 400°C by an internal flow of air. The cathode was then removed from the cell and quenched in water to effect rapid removal of the product from the cathode. Product was purified by water and acid leaching of the material after crushing operations. Final drying and packaging consummated the operation.

Materials of Construction (2, 4)

Since the purity of the boron would be dependent to a large extent on the materials of construction, this was selected as the subject of initial research work.

Cathode material was selected from a list of nonferrous metals which did not form borides readily. Further, the material had to retain strength at 900°C. Selection narrowed down to copper. To minimize failure due to grain growth, the cathode was cooled internally with nitrogen or carbon dioxide to control its temperature at about 600°-700°C. The copper cathode was satisfactory except for an erratic life of from about 4 to 12 runs, after which it became porous. Subsequently it was found that a Monel cathode developed a protective coating of a very hard and adherent boride. The Monel cathodes did not require cooling and their life was increased to more than 20 runs. Monel was considered a satisfactory material of construction for the cathode.

Since chlorine and fluorine were liberated at about 800°C, graphite was the only suitable material for the anode. The anode material problem soon reduced itself to the selection of the most suitable grade of graphite (Table I).

Note that fine graphite grain size materially improved the quality of boron product as did decreased porosity of the graphite. The comparatively coarse and porous arc furnace electrode graphite spalled badly, rapidly contaminating the electrolyte. For the same grade, graphite yielded a slightly purer product than carbon in addition to the advantages of better electrical conductivity. The ash content of the graphite affected the purity of the boron product adversely. However, the effect due to ash content was secondary to the effect of density and grain size.

Table I. Effect of anode material

Anode material	Ash in %	Apparent density, g/cc	Average % boron in product
Furnace electrode grade graphite	1.9	1.64	69
Extruded high-purity graphite	0.01	1.65	89
Extruded high-density and purity carbon	0.1	1.70	91
Extruded high-density and purity carbon	0.04	1.72	94
Resin impregnated graphite	1.4	1.85	94
Molded — very fine grained graphite	0.1	1.71	97

The highest density, finest grained material obtainable at the time this research was in progress was National Carbon's ATJ grade of graphite. This material yielded the highest purity product of all anode materials tested. However, this graphite was both expensive and not always in stock. When these factors exerted sufficient weight, a compromise was sought. High-purity stock graphite, such as National's AUC or Great Lakes' HPL-9, was machined to shape and then made essentially impervious by the Graph-I-Tite[1] process. This treatment deposits graphite in the voids. The resultant product is most dense near the surface and progressively less dense toward the center. Initial use of the crucible was approximately comparable to National's ATJ grade, but continued operation was not as satisfactory. This was due to corrosion of the surface of the graphite, thus exposing progressively less dense material. The Graph-I-Tite treated material was better than untreated graphite but not as satisfactory as the high density, fine grained graphite, the choice thus becoming one of economics and availability.

Because external electrical heating was employed, a shell was used to protect the Nichrome wire from corrosive salts passing through the anode wall. Initially this shell was made of nickel, which promptly developed cracks. However, after Virgo[2] treatment (fused salt descaling treatment), nickel did not develop cracks and was most satisfactory. Here again the laws of supply and demand were felt and Inconel was substituted. This resulted in contamination of the boron with products of corrosion of the Inconel shell. Most of these contaminations, especially chromium, could be removed by acid leaching. Although more attention had to be paid to the boron purification steps when using Inconel, availability dictated its use. While conducting corrosion tests in molten electrolyte without an applied potential, it was noted that nickel, Inconel, and Hastalloy-B corroded ap-

preciably only at the liquid-air interface. Under comparable conditions, it was noted that nickel weld rod, ASTM code E3N11, was attacked only slightly.

Cell Design Considerations (2, 3, 4)

Initial laboratory work utilized a hydrogen atmosphere in the cell to minimize oxidation of the graphite. When an inert gas, such as helium, was tried, the copper cathode was rapidly and severely attacked at the electrolyte surface. It soon became evident that chlorine and fluorine liberated in the cell at about 800°C attacked copper vigorously, but HCl and HF did not. The final cathode design is shown in Fig. 1.

Provision was made in this design to concentrate the hydrogen flow at the cathode-electrolyte interface. This proved very effective and permitted satisfactory operation at about 1/3 prior hydrogen flow rates when a nondirected hydrogen flow was used. The cover was sealed by a powdered salt seal ring. This proved an effective and simple technique for control of the cell atmosphere as well as assuring that vent gases would be directed toward the exhaust system. The lack of bolts assured against damage in case of hydrogen failure and a resultant explosion due to air entering the cell. The balance of the structure provided for positioning the cathode above the melt or in the melt, internal cooling, and d-c circuitry. The most desirable temperature control point was found to be in the annular space between the graphite anode and its protective shell.

Table II. Recommended operating details for the electrolytic production of boron

Electrolyte:	70% KCl, 12% KF, 17.8% KBF_4, 0.2% H_2O
Temperature:	750°-800°C
Current:	80 amp/dm²
Voltage:	5-6 v
Power:	55 kwhr/kg
Ampere efficiency:	74%
Cell atmosphere:	H_2 purge directed at electrolyte surface near cathode. Rate: 20 liters/min at 550 amp
Cathode:	Monel
Anode:	High-density, fine grained graphite

Operation (2, 4)

Composition of the electrolyte had a significant effect on yield and/or purity of the boron product (Table II). The first run using a new charge of KCl invariably resulted in poor yield and purity of boron. If the KCl-KF weight ratio was permitted to decrease below approximately 2.5-1, the boron yield decreased. The KCl-KF weight ratio therefore was maintained between 3-1 and 6-1 by partial removal of the electrolyte after a run and replenishing it with KCl.

Purity of the elemental boron was impaired severely when commercial grade KCl was substituted for C.P. grade KCl. A knowledge of the constituent of commercial grade KCl responsible for degrading the boron product was considered desirable in order to effect improvement in purity of normal production. The seemingly obvious approach of determining the foreign material in the product did not yield a solution. Apparently the responsible material entered into side reactions which contaminated the boron product with carbon primarily.

A major difference between technical and C.P. grade KCl is a tenfold difference in the sulfate ion. To ascertain if high sulfate would affect boron purity adversely, 1% of K_2SO_4 in KBF_4 was used. As shown in Table III, it had no apparent adverse effect on the yield or purity of the boron product. The opportunity to explore the effects of bromine was not realized, although the effects of other possible contaminants were investigated.

This work was conducted in three different cells having different grades of graphite. The effect of an additive is thus evidenced by comparing per cent yield and per cent B with product obtained from the same cell without an additive.

Calcium chloride affected the adherence of the product to the electrode causing the deposit to fall out. The purity appeared unaffected. The effect of calcium could be a valuable asset in the design of a continuous cell. Addition of vanadyl sulfate to the electrolyte resulted in decreased purity, apparent decreased yield, and erratic adherence of the product to the cathode.

Aluminum fluoride monohydrate was added in one series of tests and found to yield a dense product of normal yield and purity. Elemental aluminum addition resulted in a slightly higher purity and yield of a very dense product.

The results of drying salts before addition to the melt had given inconclusive results which seemed

Table III. Effect of electrolyte additives

Additive	Concentration in electrolyte		Average % B	Average % yield	Comparison without additive		Cell No.
	g	% by wt			% boron	% yield	
K_2SO_4	25	0.18	95.0	81.5	94.7	75.5	1
$CaCl_2$	100	0.72	93.0	Fell off cathode	92.8	87.8	2

$AlF_3 \cdot H_2O$	56	0.40	94.7	86.8	95.0	87.0	3
Aluminum	14	0.10	95.5	83.5	94.7	75.5	1
Water	25	0.18	95.8	88.0	94.7	75.5	1
Nickel	38.8	0.28	90.9	73.3	94.7	75.5	1
Inconel	39.2	0.28	88.7	59.2	94.7	75.5	1

to indicate improved yield and purity in the absence of water. It was, therefore, a most surprising result when the addition of 1% water to the KBF_4 before charging resulted in a high density end product of improved yield and purity. This was probably due to a build-up of potassium oxide in the cell which reduced a tendency toward anode effect, a phenomenon otherwise experienced in the cell at approximately 600 amp. This effect of water addition was experienced by Kroll in his work on titanium (5).

Noncathodic nickel or Inconel was severely attacked during electrolysis resulting in decreased cell performance. It clearly confirmed the adverse cell operation that resulted when the graphite anode crucible was porous, cracked, or corroded through.

The first electrolytic run made on a new charge of KCl and KBF_4 resulted in a lower yield and purity of product than the second run. By using a partial charge of KBF_4 and considering the first run as a pre-electrolysis, the yield and purity of subsequent runs could be maintained at acceptable levels. Approximately 30 to 40 runs would be made before total discharge and recharge. The addition of a small quantity of elemental potassium to the pre-electrolysis electrolyte resulted in normal yields and purity of product. Such additions had no discernible effect on subsequent runs. The effect of pre-electrolysis and elemental potassium addition was probably to establish the oxide content referred to under water addition.

Table IV. Effect of drying conditions on purity of boron

Drying conditions	Batch No.	% Boron in dried product: With air purge	With oxygen purge	With argon purge
110°C, 24 hr, no agitation, atmospheric pressure	240	97.0		96.3
	251	97.7		96.8
	213	96.4		94.8
110°C, 1½ hr, agitated, 18 in. vacuum	213	96.4		95.5
100°C, 2.5 hr, agitated, 29 in. vacuum broke vacuum @ 100°C	293	95.3	96.9	
100°C, 2.5 hr, agitated 29 in. vacuum broke vacuum @ 35°C	293	96.2	97.0	
100°C, 24 hr, no agitation, 29 in. vacuum	S-19	94.1	94.4	
100°C, 24 hr, no agitation, atmospheric pressure	S-19	94.0	94.3	

Processing of Cell Product (6)

The product from the electrolytic cell was essentially an agglomerate of boron crystals and electrolyte. To free the boron of soluble impurities, the product was crushed in a rod mill to pass 100 mesh, leached with boiling water and finally boiling HCl. After due washing, rinsing with alcohol, and oven-drying, the product was packaged in polyethylene bags. It was found, when checking analyses for shipping, that the total boron analysis decreased 2-3% after several months' storage. This was traced to boron acting as a getter, adsorbing gases from the air. By drying boron at 100°C in a vacuum oven with an oxygen purge and preferably with agitation for the minimum time needed to effect drying, the boron was passivated. The resultant purity was higher than when dried in an inert atmosphere purged oven (Table IV).

Boron oxide wets elemental boron very well. The observed result of higher boron analysis when using an air or oxygen atmosphere is therefore attributed to a very thin protective film of boron oxide formed on the surface of the boron.

The final product had a size specification of 100% through 100 mesh and 90% through 200 mesh. Approximately 20% passed through 325 mesh and a trace was colloidal. X-ray diffraction demonstrated that the product was mostly crystalline with some scattering due to amorphous material or very fine particle size. When the less than 325 mesh fraction was removed, the remaining material was crystalline.

The purity of the final product was 94-96% boron. Principle impurities were carbon, nickel, chromium, silicon, magnesium, potassium, water, oxygen, and copper.

Overvoltage and Catalysis

Paul Rüetschi

Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

Analogies between heterogeneous catalysis on solid-gas interfaces and electrochemical kinetics on solid-liquid interfaces are discussed. The surface potential of a solid-gas interface corresponds to the Galvani potential difference of a solid-liquid interface. These potentials depend to a first approximation linearly on the number of adsorbed potential-determining particles. A corresponding linear variation adsorption energy is explained on the basis of electrostatic or induced interaction between adsorbed particles. This behavior is coherent with a logarithmic dependence of the number of adsorbed particles on the bulk concentration or pressure in the liquid or gaseous phase (Temkin isotherm) and a linear dependence of the activation energy of adsorption on the number of adsorbed particles (Becker-Zeldovich equation). It is shown that the Temkin isotherm corresponds to Nernst's formula for electrode potentials and the Becker-Zeldovich equation to Volmer's equation for the rate of electrochemical reactions, and that these equations follow immediately from the theory of charge-transfer adsorption or electrostatic interaction between (activated) potential-determining species or complexes. This treatment leads to a new interpretation of the charge-transfer coefficient and of the influence of the electronic properties of the electrode material and of specifically adsorbed foreign species on hydrogen overvoltage, oxygen overvoltage, and metal deposition overvoltage.

The kinetics and thermodynamics of electrochemical phenomena at solid-liquid interfaces and of catalytic phenomena at solid-gas interfaces are closely related. It is the object of this paper to point out correspondences between the two fields and to derive the fundamental laws of electrochemical thermodynamics and kinetics, in particular the Nernst equation and the Volmer-Tafel equation, from these considerations.

Adsorption and Interaction

The relation between the number of adsorbed species on a solid-gas or solid-liquid interface and bulk concentration (or pressure) of the adsorbable species is described by isotherms. The Langmuir isotherm is derived on the assumption that adsorption occurs at fixed sites and that the energy of adsorption is independent of the number of particles adsorbed. Fixed site adsorption is, however, unlikely for many reactions proceeding on electrodes and catalysts. The energy of adsorption usually decreases with increasing number of adsorbed particles. The Freundlich isotherm is therefore more likely to be obeyed since it allows for the latter effect. However, very few experimental results suggest a logarithmic decrease of the energy of adsorption with increasing number of adsorbed species, as derived from the Freundlich isotherm. Very often the energy of adsorption decreases nearly linearly with the number of adsorbed particles. Such a behavior is accounted for by the Temkin isotherm. The latter can be derived for intermediate ranges of coverage from a fixed site Langmuir-type isotherm by allowing for a linear variation in adsorption energy (1) and, more generally, for mobile adsorption as follows.

Using Boltzmann statistics, the concentration n_i^* (number of particles per cm^3) of species i in the adsorption zone is given by

$$n_i^* = n_i \exp\left[-(w_i^* - w_i)/kT\right] \qquad [1]$$

where n_i is the corresponding concentration in the bulk, and w_i^* and w_i are the energies of a particle i in the adsorption zone and in the bulk, respectively. Here, we assume the entropies of the (mobile) particle in the adsorption zone to be not much different from the entropy of the particle in the bulk. It is now important to consider that, because of the nonideal behavior of the adsorbed particles, n_i^* and w_i^* are connected by an activity function. For such a function of exponential character (activity coefficient varying exponentially with the concentration n_i^* in the adsorption zone), w_i^* becomes a linear function of n_i^* (2) and, neglecting the variation of the term linear in n_i^* compared with the variation of the term exponential in n_i^*, one obtains from [1]

$$n_i^* \cong a \ln n_i - b \qquad [2]$$

where a and b are constants. Equation [2] is the Temkin isotherm.

A linear decrease of adsorption energy with increasing number of adsorbed particles is widely observed. On the other hand, the surface potential solid-gas of the Galvani potential difference elec-

trode-electrolyte depend approximately linearly on the number of adsorbed particles n_i^*. Boudart (3) and Mignolet (4) have discussed the relation between change in surface potential and change in energy of adsorption for solid-gas interfaces. The adsorption energy was expressed in terms of a charge-transfer process, involving the excitation of an electron of the conduction band into a vacant surface orbital provided by the adsorbed species and the surface. The energy difference $w_i^* - w_i$ becomes then a linear function of the surface potential or the Galvani-potential difference

$$\Delta(w_i^* - w_i) = \alpha z_i e_o \Delta(\phi_I - \phi_{II}) \qquad [3]$$

where $\Delta(\phi_I - \phi_{II})$ is the change in surface potential or in Galvani potential difference, $z_i e_o$ the charge of the adsorbed particle i, and α the so-called "structural factor" (5). The latter is a characteristic fraction of the total Galvani potential difference. Experimentally, Boudart finds for adsorption of hydrogen on metals $\alpha \sim \frac{1}{2}$.

It will be shown now that the value of α can be derived from classical electrostatic considerations in a surprisingly simple manner. One can apply the model of a flat-plate electric condenser. For electrochemical interfaces, this model is particularly useful and the capacity of the electric double layer can be determined experimentally. The electrostatic energy content of a charged electric condenser is given by

$$U = \int_o^q V dq = \int_o^V CV dV = \frac{1}{2} CV^2 = \frac{1}{2} qV \qquad [4]$$

where V is the voltage, q the charge, and C the capacity. The energy content per particle with a charge $Z_i e_o$ varies then with the voltage as follows

$$\Delta(Vz_i e_o/q) = \frac{1}{2} z_i e_o \Delta V \qquad [5]$$

This equation is identical to [3] since, by correspondence, $\Delta(Vz_i e_o/q) = \Delta(w_i^* - w_i)$, and $\Delta V = \Delta(\phi_I - \phi_{II})$. This means that α must be equal one-half as long as the adsorption capacity C, due to species i, is independent of voltage or charge. For a variable capacity, Eq. [4] must be integrated, taking into account this dependence which would lead to values of α different from one-half.

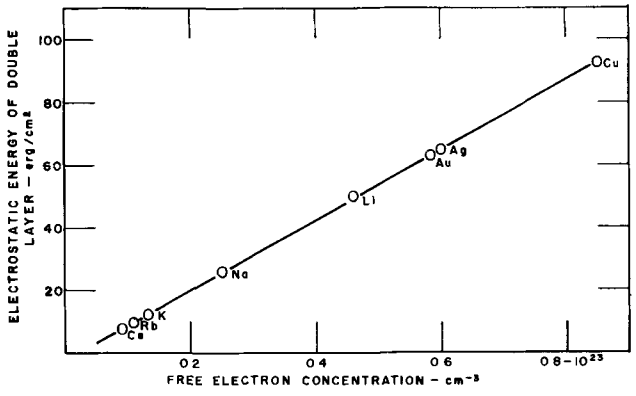

Fig. 1. Electrostatic energy of the double layer on a metal surface against vacuum as a function of free electron concentration.

The interpretation of adsorption on the basis of charge transfer has gained wide acceptance in modern work on catalysis (6, 7). The concepts have been substantiated not only by measurements of changes in work function and contact potential but also by changes in electric resistance (8) and by changes in magnetic behavior (9) of thin solid films during the adsorption process. The surface potential or the Galvani potential difference depends generally on the competitive adsorption of a variety of different species 1, 2, 3—. However, adsorption is generally specific enough to one particular species i such that, at least over limited regions, the variations in adsorption of other species can be neglected. In considering adsorption of the species i on a surface modified by the presence of other species 1, 2, 3— i, the surface potential or the Galvani potential difference, as modified by the presence of these other species, determines according to [3] the adsorption energy of i.

For a bare metal surface against vacuum the electron concentration in the metal is the main parameter characterizing the surface potential barrier. The relation between surface potential and electron concentration becomes evident from Fig. 1. Here, the electrostatic energy of the double layer on a surface against vacuum is plotted against electron concentration.[1] The surface potential (dipole term) is only a relatively small fraction of the total work function (10). Therefore, the work function plays a direct part in the determination of surface potentials and Galvani potential differences only insofar as the dipole term is concerned. However, the dipole term is often a more or less fixed fraction of the total work function.

It has been shown (11) that the energy of cohesion of metals is related to the electron concentration. For alkali metals the energy of sublimation is proportional to $\rho^{2/3}$ where ρ is the free electron concentration. The surface energy is also a function of the electron concentration. According to Breger and Zhukhovitskii (12) the surface energy can be calculated by

$$\sigma = (3\rho/\pi)^{4/3} (\pi h^2/128m) \qquad [6]$$

where h is Planck's constant and m the electronic mass. A recent review on atomic theories of surface energy has been given by Ewald and Juretschke (13). It is known that particularly for solids of the same crystallographic type the surface energy is a fixed fraction of the cohesion energy or heat of sublimation. Since surface potential, cohesion energy, and surface energy are functions of the electron concentration, relations to other quantities depending on electron concentration, e. g., lattice constants, compressibilities, electronic work function (14), are to be expected. For alkali metals one finds, e.g.,

$$L \cong \frac{3}{5} \phi \qquad [7]$$

where L is the sublimation energy and ϕ is the work function (11).

Adsorption energies at zero coverage, calculated on the basis of a charge transfer model, are equally

[1] Data obtained from R. Stratton, *Phil. Mag.*, 44, 1236 (1957).

related to the electronic properties of the metal. For an ionic bond (and electron transfer from the adsorbed particle to the surface) one has used

$$-(w_i^* - w_i) = \phi - I + e_o^2/4K_o r \qquad [8]$$

where I is the ionization energy, r the image force distance (15), and K_o is the Coulomb's Law constant $= 4\pi e_o$ where e_o is 8.854 x 10^{-12} amp sec volt^{-1} m^{-1}. For formation of a negative ion the signs of ϕ and I reverse. Electronic work function and image force distance depend on electron concentration. Adsorption has also been interpreted successfully strictly on the basis of image forces for electrons and protons of adsorbed species for apparent covalent surface bonds (16). The parameter determining the energy of adsorption is then the distance r between the adsorbed particle and the surface mirror plane. For hydrogen atoms on metals, the following equation has been derived

$$-(w_i^* - w_i) = e_o^2/4K_o r)\,(1 + qa_o^2/2r^2) \qquad [9]$$

where a_o is the Bohr radius. The distance r will vary with lattice parameter and electron concentration. For covalent bonds the Pauling formula has been used

$$-(w_i^* - w_i) = \frac{1}{2}D(M-M) + \frac{1}{2}D(A-A) + 23.06(X_M - X_A)^2 \qquad [10]$$

to calculate adsorption energies (17) at zero coverage. Instead of conventional (chemical) electronegativities, the bond moments of the adsorption bonds must be used. The bond moments depend on electron concentration and work function. Stevenson (18) has suggested that $X_M = 0.355\phi$ could be used in Eq. [10], whereas, according to Gordy and Thomas (19), the true (chemical) Pauling electronegativities are related to the work function as follows: $X_M = 0.44\phi - 0.15$. Heats of adsorption can be calculated for any type of bonding from the charge-transfer complex theory as developed by Mulliken (19-21).

As pointed out, Eqs. [8], [9], and [10] refer to the energy of adsorption at zero coverage. The variation of adsorption energy with coverage is due to interaction between adsorbed particles and can, in many cases, be described by Eqs. [3] and [5].

Rate equations describing the kinetics of heterogeneous reactions have hitherto been formulated often without taking into account the activity of intermediate species or activated complexes. However, Horiuti has pointed out that this is incorrect (2). It has been shown above how electrostatic interaction leads to a linear variation of adsorption energy with coverage.

If adsorption energies vary linearly with the number of adsorbed particles, a similar behavior might be expected for activation energies of adsorption (22). Activated complexes formed at interfaces must in fact be considered as adsorbed species. Hereby it is basically immaterial whether the energy level of the species in the adsorbed "activated" state is higher or lower than in the bulk (23). Activation energies of adsorption are (negative) adsorption energies of the activated complex. The activation energy changes then according to [3] linearly with the number of adsorbed "activated" complexes. Therefore the rate of adsorption depends exponentially on the number of adsorbed particles. Such a behavior is indeed widely observed and has been described by Becker (24) and Zeldovich (25) in the form

$$d\theta/dt = a(1-\theta)\exp(-b\theta) \qquad [11]$$

The variation introduced by the factor $1-\theta$ is to be neglected in comparison with the variation introduced by the exponential term. For mobile adsorption $1-\theta$ loses much of its meaning anyway.

We shall now derive the Volmer-Tafel equation for electrochemical reactions from the theory outlined above. The energy difference between a point at the critical distance X^* from the electrode interface, in the region of the activated complex where the electron transfer takes place, is composed of a constant "chemical" term and a variable electric term, respectively. According to [3] and [5] $w_i^* - w_i$ is a linear function of the Galvani potential difference

$$w_i^* - w_i = \alpha Z_i e_o \Delta(\phi_I - \phi_{II}) + \epsilon^* - \epsilon \qquad [12]$$

where $\epsilon^* - \epsilon$ is the "chemical part" of the activation or adsorption energy. The $\Delta(\phi_I - \phi_{II})$ must be measured with reference to the Galvani potential difference $(\phi_I - \phi_{II})_o$, corresponding to the point where n_i^* becomes zero. At this point the charge of the double layer is due to the foreign inert species only. The current of the electrochemical reaction is simply proportional to the number of activated complexes n_i^*, and using [1] and [12] one obtains

$$i = \nu Z_i e_o n_i^* \delta = \nu Z_i e_o \delta n_i \exp[-\alpha Z_i e_o(\phi_I - \phi_{II})/kT] \cdot \exp\{[\alpha Z_i e_o(\phi_I - \phi_{II})_o - (\epsilon^* - \epsilon)]/kT\} \qquad [13]$$

where ν is a frequency factor and δ the thickness of the reaction zone. The exponential dependence of current on voltage described by [18] is the Volmer equation. Over the regions where the charge of the electrode double layer varies predominantly due to accumulation of reacting species and where $(\phi_I - \phi_{II})_o$ remains constant, $(\phi_I - \phi_{II})$ is a linear function of the charge of the double layer condenser due to n_i^*. This illustrates the analogy between the Becker-Zelovich equation [11] and the Volmer equation [13]. Both rate expressions contain a term exponentially dependent on the number of adsorbed particles n_i^*.

The "transfer coefficient" or "structural factor" α can be determined experimentally from the slope of a Tafel-plot. The model from which α has been derived here is different from the one of Volmer (26), who considered the transport of a charge halfway through an electric field without taking into account the interaction with, or energy increase of the other charges of the double layer condenser. The present derivation of the current-voltage relation is more satisfactory.

In order to define an electrochemical equilibrium, at least two (independent) electrode reactions must proceed at an electrode. The two reactions are to produce electrochemical currents in opposite direction at equal rates. If the final products of one reac-

tion are not identical with the initial reactants of the other reaction, a "mixed electrode potential" is established (27). A true equilibrium is observed when the products of the forward reaction are equal to the reactants of the backward reaction. If for the product 1 and the reactant 2 a rate equation of type [13] is valid, one derives for equilibrium ($i_1 = -i_2$) the Nernst equation. Since ($\phi_I - \phi_{II}$) is a linear function of n_i*, the Nernst equation has the form of the Temkin isotherm [2].

The general rate equations for heterogeneous reactions contain the Galvani potential difference $\phi_I - \phi_{II}$. It is pointed out here that they can also be formulated in a similar manner using the experimentally measurable Volta potential differences. Galvani potential differences and surface potentials of condensed phases against vacuum are not measurable but could be calculated in principle on the basis of a sufficiently detailed knowledge of the configuration of the nuclei and electrons in the interior and surfaces of the phases (28, 29). The surface potentials are obtained semi-empirically by comparing the chemical potential μ_i of a charged species i in the bulk of the phase with the experimentally measurable real potential (negative work function) of this species. The surface dipole term is usually a small fraction of the total negative work function and is not appreciably altered by electrostatic surface-charge (10). The surface potential of a condensed phase against vacuum or a gas phase and the Galvani potential difference for this interface have the same physical meaning since a gas phase or vacuum has a zero surface potential. The experimentally measurable Volta potential differences are the result of electrostatic excess charges. They can be induced by changes in surface potentials (30-33).

It has sometimes been assumed that the electrochemical interface is composed of several different double layers. However, it seems that electrostatic interaction (or overlap) is so strong that it is better to consider only one over-all dipole barrier. Also, the Galvani potential difference has been split into a dipole term and an ionic term. However, it is difficult to differentiate these two terms since dipoles can be treated as two separate charges. Furthermore the dipole term should be dependent on the ionic term since dipole adsorption and polarization change with field strength. It is preferred here not to make this differentiation.

Potentials of Zero Charge

Potentials of "zero charge," corresponding to a state of maximum interfacial energy and/or a minimum in electrode double layer capacity (37) are of importance for the interpretation of the term $(\phi_I - \phi_{II})_a$ in the rate equation. The electrode potential at which the charge on the electrode is virtually zero has been determined experimentally for conditions where electron transfer can take place more or less completely (ideal reversible electrode) or is practically impossible (ideal polarized electrode). There is conclusive experimental data that the potential of zero charge is different for the two cases (38).

The electrode potential of ideal polarized electrodes is determined by the externally applied voltage like the tension of a metal-dielectric type condenser. Differences in zero-charge potentials of various electrode metals are to a large extent accounted for by differences in work functions (39, 40) and depend therefore on the particular crystalline face exposed (41). A strict linearity between zero charge potentials and work functions could be expected if adsorption of species at the interface would be purely "electrostatic" in nature (42, 43).

The electrode potential of ideal reversible electrodes is determined thermodynamically by the bulk concentrations of potential-determining species. At the potential of zero charge the concentrations are adjusted such that adsorption of negative and positive ions is balanced to produce a maximum interfacial energy. Some experimental evidence has been accumulated (38, 40) showing that potentials of zero charge of ideal reversible electrodes tend to be independent of the electrode material. This would mean that the electrochemical interface behaves analog to a contact metal-metal. For redox potentials where the emf is (theoretically) independent of the nature of the inert electrode, the state of zero charge would be maintained when the inert electrode is exchanged for some other metal. For a metal electrode in a solution of its own ions, a different ion concentration must be provided for each metal to produce the state of zero charge.

Although the difference in zero charge potentials between polarized and reversible electrodes is due to different adsorption characteristics between "specifically adsorbed" and "inert" species, the physical nature of the state of zero charge is the same in both instances, namely, a state of maximum surface energy. Differences in zero charge potentials are related to differences in the closest approach of the various species to the electrode surface. Potential determining or "specifically adsorbed" ions generally can approach the electrode more closely than "inert" ions. The influence of the nature of the species in the electrolyte and their adsorbability is particularly well demonstrated by the pH-dependence of zero-charge potentials (44). Electrodes which adsorb hydrogen and establish reversible hydrogen potentials show a variation of zero charge potentials with pH. This shows that potential-determining ions are specifically adsorbed.

It should be pointed out that, in analogy to metal-gas interfaces, some sort of strong adsorption forces must always be expected on electrode surfaces. An independence of zero charge potentials of the electrolyte often simply means that the species of the solvent (H^+ ions or OH^- ions or water dipoles) are adsorbed rather than the solute. There is no clear-cut distinction between the two types of zero charge electrodes. The differentiation is in fact one of degree. The process of strong adsorption generally can be considered as an electrode reaction, forming a surface product. The particles taking part in this reaction must be considered as specifically adsorbed, and the electrode potential varies then approximately logarithmically (according to a Temkin isotherm)

with the bulk concentration of these particles (45, 46).

Application to Problems in Electrode Kinetics

In recent discussions on the mechanism of hydrogen evolution a distinction has been made (47-52) between the so-called Volmer-Tafel (discharge-recombination) mechanism

$$2H^+(aq) + 2e^- \rightarrow 2H(ads)$$

$$H(ads) + H(ads) \rightarrow H_2$$

and the so-called Volmer-Horiuti (ion-atom reaction)

$$H^+(aq) + e^- \rightarrow H(ads)$$

$$H(ads) + H^+(aq) + e^- \rightarrow H_2$$

Without specifying the actual configuration and energetic state of the particular activated complex involved and experimental evidence thereof, these formulations are of little help. Any number of other theoretical reaction routes, like for instance (53)

$$2H^+(aq) + 2H(ads) + 2e^- \rightarrow 2H_2$$

$$H_2 \rightarrow 2H(ads)$$

(which does not require the Volmer discharge step) can be postulated. On the basis of the model developed earlier in this paper the differentiation is unnecessary. The electric double layer contains, on the solution side of the interface, protons in various energetic states corresponding to various stages of discharge, which means that their positive charge is shielded to various degrees by overlapping electrons and by negative ions. These adsorbed protons are mobile, like most species in electrochemical double layers. The adsorption follows a Temkin-isotherm and the adsorption (or activation) energy will vary linearly with the number of adsorbed protons. For an approaching proton the surface then looks energetically uniform, and each proton has statistically the same chance to follow the easiest reaction path, which is simply a charging of the double layer condenser. Because of electrostatic interaction there will be no "bare" spots on the surface. The introduction of the degree of coverage θ or the fraction of free surface $1 - \theta$ as a concentration term in the rate equation does not have much meaning. According to the outlined model there is no saturation coverage and the Galvani potential difference keeps increasing more or less linearly (as long as the adsorption capacity is constant) with the number of adsorbed potential-determining ions. This is the reason why the linear relation between logarithm of current and potential prevails to very high rates and why generally no limiting value is reached (54). The metal electrons of the surface are able to be transferred to particles on the solution side over relatively large distances, e.g., during electrochemical reduction of azobenzene on a smooth liquid mercury electrode (55), due to the high electric field at the interface. Recombination of "discharged" protons can occur at various distances as far from the interface as the electron waves can reach (56, 57). The critical distance X^* from the interface where electron transfer takes place may be smaller statistically on one metal than on another. The discharge probability is simply proportional to the number of protons in the double layer.

At this point mention should be made of the stoichiometric numbers ν_i, introduced by Horiuti (58, 59) and commonly defined as number of times the postulated rate-determining step is repeated when the over-all reaction, as represented by the stoichiometric equation, occurs once. In the formulation of Parsons (60) the over-all process requires the formation and decomposition of ν_i activated complexes. Makrides showed from considerations of reaction rates at states close to equilibrium that stoichiometric numbers can take any positive value and are usually equal to the ratio of two small integers (61). If, on the basis of the outlined theory, the activated complex for the hydrogen evolution reaction is assumed to consist of one excited proton only and an electron in the metal, the concentration of activated complexes is immediately given by [1] and [12] and the current-voltage relation by [13]. If the activated complex is considered to consist of two excited protons and two electrons in the metal, one obtains formally the same result since the protons must share the activation energy in equal parts, which can be described alternatively by electrostatic interaction or by the existence of strong resonance between the protons, or by the formation of hydrogen molecule ions. In this manner stoichiometric numbers do not enter the considerations, which is fortunate as can be seen from the recent controversy betwen Horiuti and Bockris (62, 63). From this point of view, the present theory is able to unify various overvoltage theories advanced previously, based on hypothetical existence of atomic hydrogen (64, 65), protons (26), and hydrogen molecule ions (66). The fact that deposition of atomic hydrogen into palladium metal lattice requires a considerable overvoltage would at first suggest that the activated complex consists of single protons rather than molecules. However, on the basis of the present theory strong interaction between adsorbed protons must be present, and with the condenser model all the particles in the interface must actually be included in the activated complex. The interaction between adsorbed particles in the double layer gives also an explanation of the experimentally observed separation factors (67).

It has been shown above that the transfer coefficient α assumes preferably the value $\alpha \cong \frac{1}{2}$. Careful experimental work by Schuldiner (68) on noble metals and noble metal alloys yielded values of α larger than one, or Tafel slopes smaller than 0.058 v at overvoltages below 100 mv. The apparent slope of 0.029 has been explained by the recombination theory of Tafel; however, this explanation is not satisfactory. One must also consider that noble metals have high exchange currents and the backward reaction is of strong influence at low overvoltages. Knorr and co-workers (69) have recently shown that overvoltages below 100 mv on noble metals are

due mainly to diffusion overvoltage of molecular hydrogen.

Bockris and co-workers have developed what they termed "diagnostic criteria" to determine the "rate-controlling step" in hydrogen evolution (70). In deriving their theoretical Tafel slopes they have used $\alpha \cong \frac{1}{2}$ throughout. However, as shown in Eq. [13] α assumes this value only under the special condition that $(\phi_I - \phi_{II})_o$ is constant. The variation in Galvani potential is then due to accumulation of protons only, and the adsorption capacity a constant. The results of the "diagnostic analysis" do not seem to be unambiguous either since on Ni, e.g., electrochemical desorption (71), slow discharge (47) and electrochemical desorption (50) have been named rate determining. The lattice heterogeneity of the electrode surface is not accounted for in the present theory. There are some indications that this heterogeneity is not of primary importance. This is also brought out by MO calculations for adsorption bonds at zero coverage on linear atomic chain models (72).

Some theories have been advanced about electrochemical reduction of water instead of hydrated protons. Usually, it has not been considered that the dissociation equilibrium of water is established with a rate constant of 10^{-5} sec^{-1} and protons are continually produced by this preceding reaction (55, 73). The field effect at the interface can even enhance this reaction rate.

Temkin and Frumkin (74) have suggested that because of the apparent independence of the preexponential factor A in the equation $i = A \exp(-E/RT)$ from the nature of the metal (75), one should expect approximately equal values of the activation energy E for equal current rates i. Generally one should expect a dependence of the frequency factor on the activation energy (76).

In comparing overvoltages of different metals it is necessary to keep the composiiton of the electrolyte the same. This has been taken into account in the work by Rüetschi and Delahay (77) but has not been considered by others (74). Adsorption of anions decreases overvoltage in the sequence $SO_4^{--} < Cl^- < Br^- < I^-$ (43). According to [13] the terms $\epsilon^* - \epsilon$ and $\alpha z_i e_o (\phi_I - \phi_{II})_o$ determine the influence of the electrode material on overvoltage since n_i^* and $\Delta(\phi_I - \phi_{II})$ are constant for a given current. The first term is a measure for the covalent adsorption energy, which can be calculated with [10], omitting electronegativities. Experimental support for a linear relation between covalent adsorption energy and overvoltage has been found (77).

With respect to this conclusion, the present theory gives the same result as considerations of potential energy surfaces according to Horiuti and Polanyi (78). Rüetschi and Delahay used equation [10] without electronegativities to calculate $\epsilon^* - \epsilon$ which is, according to the above argument, the correct procedure. Energetic terms due to polarity of the M-H bond are taken care of by the Galvani potential difference. Bond moments of M-H bonds are anyway quite small. Using bond moments, the last term in Eq. [10] becomes $23.06\ \mu^2$.

Eyring and co-workers (81) have used the value $\mu = 0.46$ for the M-H bond, derived from contact potential measurements by Bosworth (82) for tungsten. However, Mignolet (83) has shown that Bosworth's value is too high. On the basis of Mignolet's results one obtains $\mu = 0.212$ for the tungsten-hydrogen bond and $\mu = 0.183$ for the nickel-hydrogen bond. The moment for the copper-hydrogen bond is even smaller (84). These values show that the contribution of the last term in [10] must be quite small, in the order of one kilocalorie or so. This is the reason why adsorption energies calculated without considering the dipole term agree surprisingly well with experimental results. According to [13] hydrogen overvoltage should generally decrease linearly with covalent adsorption energies $\epsilon^* - \epsilon$ which is in qualitative agreement with Bonhoeffer's experiments (85). The decrease of overvoltage with adsorption energy has recently been derived in a similar manner by Krishtalik (86). It must however be pointed out that exceptions to this rule might be found, since $\epsilon^* - \epsilon$ can contain other terms, e.g., adsorption energies for water.

Various attempts have been made recently to explain an apparent maximum in the curve of overvoltage vs. adsorption energy (50-52), since it had been observed that metals like Mo, Ta, W, Zr, with very high adsorption energies for hydrogen show relatively high values of hydrogen overvoltage. It should be pointed out here that these metals also have an extremely high adsorption energy for other species than hydrogen, e.g., oxygen (and oxygen in water dipoles), and that the experimental hydrogen overvoltage values necessarily refer to somehow oxidized or hydrated surfaces. It is known that cathodic polarization of these metals does not remove the oxide layers completely, which also is related to the fact that these metals cannot be plated out from aqueous solutions. It is pointed out here that hydrogen overvoltage depends not only on the adsorption energy of hydrogen but also on the adsorption characteristics of foreign, inert species, e.g., anions. The influence of the adsorption of foreign inert species which do not take part in the electrode reaction is expressed in [13] by the term $(\phi_I - \phi_{II})_o$. This term is related to the zero charge potentials and electronic work functions.

Since covalent adsorption energies increase according to [10] with the strength of the metallic bond (cohesion energy or sublimation energy) one deduces from [7] a qualitative relation between adsorption energy and electronic work function. On the basis of these considerations Rüetschi and Delahay have explained for the first time the dependence of overvoltage on work function (87), observed empirically by Bockris (47). From equations [6] to [10] it follows that overvoltage can be related to various other electronic properties of the electrode metal, in particular electron concentration, surface energy (88, 89), interatomic distances (90), compressibility (91), cohesion energy (92), melting point (93), and others.

Bockris and Potter (47) had explained the dependence of overvoltage on work function from the fact that the Galvani potential difference of the contact interface between the metal of the reference electrode and the metal of the electrode under investigation changes with the electronic work function of this metal. These authors, and similarly Lorents (91), have not considered that the Galvani potential difference electrode-electrolyte of the reversible hydrogen electrode also changes, in the opposite direction, with the work function of the electrode metal, which becomes apparent from the fact that the (theoretical) hydrogen electrode potential, as measured against a reference electrode, does not depend on the nature of the electrode metal.

Recently, Conway and Bockris (50) have adopted the use of Eqs. [7] and [10] in explaining the relation between electronic work function, adsorption energy, and overvoltage according to Rüetschi and Delahay. However, Conway and Bockris used polar instead of covalent adsorption energies for $\epsilon^* - \epsilon$. Moreover, they used chemical (Pauling) electronegativities for single atoms as given by Gordy and Thomas (94). The present theory shows that the use of large terms of this sort is incorrect, since $\epsilon^* - \epsilon$ is a covalent, chemical term. Any bond moment terms are taken care of energetically by the Galvani potential difference. The present theory is able to account for the influence of specifically adsorbed foreign species, in particular anions, on overvoltage by the term $(\phi_I - \phi_{II})_o$.

Progress in this direction has been made previously by Frumkin, Iofa, Kabanov, and others (54). The considerations have in general been limited to the diffuse part of the double layer (95), whereby the electric work involved, to transfer a hydrogen ion from the bulk to the outer Helmholtz plane, was separated out. However, electrochemical reactions always involve "specific" adsorption and often high electrolyte concentration, and the diffuse part of the double layer (in which the potential depends logarithmically on the charge) is less important than the compact part. The introduction of the adsorption potential of the outer Helmholtz plane also tends to obscure the pH-dependence of overvoltage. According to Frumkin the overvoltage-current relation can be expressed by (54)

$$\eta = a + (2RT/F) \ln i + \psi_I - (RT/F) \ln H^+$$

if one uses $\alpha = \frac{1}{2}$. Since $\psi_I \cong (RT/F) \ln H^+ +$ constant, one would derive a relative independence of η on pH, which is not supported experimentally. Therefore, it is preferred to use the simple condenser model, which accounts for electrostatic interaction of adsorbed protons.

The slow variation of overvoltage with time during prolonged polarization can be explained by changes in the electrode surface area and by dissolution of hydrogen in the metal. With some metals, embrittlement becomes apparent under these conditions. The penetration of atomic hydrogen into the metal lattice changes the electronic configuration, the electron concentration (96), and the covalent adsorption energy. These changes should be taken into account in the interpretation of experiments with bipolar hydrogen diffusion electrodes (97).

It is easy to derive on the basis of the present theory the general laws for build-up and decay of overvoltage. Since at high polarization the electrode potential is simply proportional to the number of adsorbed potential determining species, overvoltage should increase linearly with time under constant current conditions. This is generally observed. On the other hand, overvoltage should decay, after interruption of the polarizing current, logarithmically with time since one derives from [13]

$$n_i^* \sim dn_i^*/dt \sim d(\phi_I - \phi_{II})/dt \sim \exp[-\alpha z_i e_o (\phi_I - \phi_{II})/kT]$$

The slope of the voltage-log time curve must approximate the (negative) Tafel slope of the voltage-log current plot. It is interesting to note that in 1928 Baars formulated the desorption of hydrogen from electrodes analog to the Becker-Zeldovich equation [11]. This early work of Baars (98) is in complete agreement with the present theory.

The presence of the activated adsorbed species at electrode interfaces becomes evident from many experimental observations. The rate of decay and build-up of overvoltage proves the adsorption capacities involved are usually much larger than normally observed for a double layer with inert or nonspecifically adsorbed particles. If the polarizing current is reversed for a very short period of time and the electrode potential forced down rapidly toward the open-circuit potential and then cut off, the overvoltage recovers considerably before the electrode potential falls slowly to the open-circuit value. For very large surface-area porous electrodes, as used in storage batteries, the amount of gas evolved after interruption of current can actually be measured, and it can be shown that the voltage decreases linearly with the amount of desorbed gas (99), which is a direct support for the condenser-theory. The presence of activated species during metal deposition and dissolution has also been demonstrated by Gerischer (100) with potentiostatic techniques. Phenomena relating to adsorption and electrostatic interaction are particularly pronounced in oxygen overvoltage experiments on oxide electrodes (101).

Manuscript received Sept. 17, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

On the Conductivity of Dispersions

Robert E. De La Rue[1] and Charles W. Tobias

Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

Experiments on suspensions of glass beads in electrolytes indicate that Bruggemann's approximation represents the dependence of effective conductance on volume fraction very satisfactorily when the dispersed phase contains a broad range of particle sizes. Data on narrow size ranges fall in between values predicted by the Maxwell and Bruggemann equations. These findings are consistent with the physical assumptions implicit in both theoretical developments.

Presence of gas bubbles or solid dielectrics[2] in electrolytes causes a drop in conductivity relative to the gas- or solid-free condition. Of major interest is the manner in which the effective conductance of the dispersion depends on the volume fraction of the nonconducting phase. In the present study emphasis is placed on particles of spherical shape occupying less than half the volume of the dispersion. Such dispersions occur frequently in industrial electrolytic processes in which gas evolution takes place at one or both electrodes.

According to Maxwell (1) the effective conductivity K_e of random suspensions of spherical particles of uniform diameter and conductivity K_d in a continuous medium of conductivity K_c is related to the volume fraction f of the dispersed phase as follows:

$$\frac{K_e/K_c - 1}{K_e/K_c + 2} = f\frac{K_d/K_c - 1}{K_d/K_c + 2} \qquad [1]$$

If the conductivity of the dispersed phase $K_d = 0$, Eq. [1] simplifies to:

$$\frac{K_e}{K_c} = \frac{1 - f}{1 + \frac{f}{2}} \qquad [2]$$

Rayleigh's treatment (2) of dispersions of spheres of uniform diameter, where the particles occupy cubic lattice positions, leads to an expression identical to Eq. [2] for the case where $K_d = 0$, and $f \to 0$.

In the derivation by Maxwell the assumption has been made that the average distance between the particles of the discontinuous phase is large enough so that the fields around individual particles are undisturbed by the presence of the other particles. This condition is rigorously satisfied only as $f \to 0$. In Fig. 1 we have plotted the potential field around a spherical nonconducting particle, when at large distances from the particle the potential ψ is a linear function of y only, where y is a vector pointing from left to right. In this case

$$\psi = -(S/r^2 - r_o/r)\sin^2\theta \qquad [3]$$

where r_o is the radius of the sphere, $S = -K(dx/dy)_{r\to\infty}$, a constant, r is the distance from the center of the sphere, θ is the angle between r and y, and K is the conductivity of the continuum.

It is apparent from Fig. 1 that the disturbance in the linear field becomes very small at short distances from the sphere. Therefore, in moderately dilute dispersions Maxwell's equation should be an excellent approximation. However, a concentration of $f = 0.25$ already corresponds to an average distance of $0.6\ r_o$ between spheres, and the interaction of fields around the spheres becomes significant. Equation [1] should then no longer represent the relation between volume fraction and conductivity with acceptable accuracy.

Although, according to theory, Eqs. [1] and [2] are subject to limitations, in the past numerous workers have found that experimental data may be

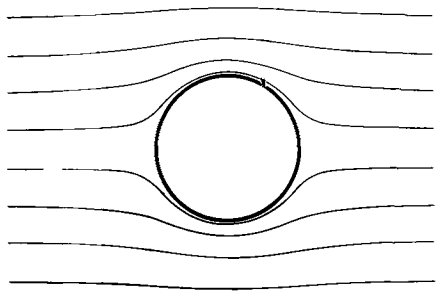

Fig. 1. Potential field around sphere, an insulator, placed in a homogeneous and isotropic conductor. Field is linear at great distances from sphere.

[1] Present address: Stanford Research Institute, Menlo Park, Calif.

[2] Particles exhibiting electronic conduction also may act as insulators, provided the potential gradient in the dispersion is such that the potential difference over a distance corresponding to the largest dimension of the particle in the direction of the field does not exceed the decomposition voltage of the system under consideration.

represented satisfactorily by use of these relations even in moderately concentrated dispersions. Electrical conductivity data obtained on various concentrations of cream in milk were found by Fricke (3) to fit Eq. [2] within experimental error. Eucken (4) reported results of measurements involving the systems water-benzene and water-phenol with KCl and KI, respectively, as solutes. Over the entire range of volume concentrations ($0<f<1$) agreement with Eq. [1] was reported. In a recent review on non-Newtonian fluids Metzner (5) refers to data by Orr and Dalla Valle (6) who measured thermal conductivities[3] of metal shot dispersed in 2% agar gel. Agreement of the experimental data with Eq. [1] within 3% over a large range of volume concentration was again claimed.

Not all investigators found the agreement between the Maxwell-Rayleigh relations and their experimental data satisfactory. Slawinski (7, 8) conducted experimental investigations using enameled metal spheres of approximately 0.5 cm diameter in KCl solutions, in the range of $0.35 < f < 0.6$. His data fitted within 0.4% a curve corresponding to substantially lower effective conductances than would have been predictable by Eq. [2]. This curve corresponded to a relation developed from a physical model in which Slawinski evaluated the integral mean lengths and mean cross sections between spheres arranged in several different lattice orders

$$K_e/K_c=\{1+(f/p)[(1+0.3219p)^2/(1-p)-1]\}^1 \quad [4]$$

where $p = n \cdot f^{2/3}$. Value of parameter n depends on the volume fraction range:

for $0.15 > f$	$n = 0.806$
for $0.15 < f < 0.6$	$n = 0.806 + 0.1333\,f$
for $0.6 < f$	$n = 0.9046$

Data presented by Slawinski for moderate and low volume concentration in random distributions were in far less satisfactory agreement with Eq. [4] than at high concentrations. Unfortunately Slawinski's treatment does not take into account the fundamental principles of the theory of potential, according to which the distribution of potential throughout the conducting medium satisfies the Laplace equation. His equation also contains an adjustable parameter in addition to the volume fraction of the dispersed phase.

More recently Mashovets (9) reported measurements of conductivities of dispersions of glass and hard rubber spheres in $CuSO_4$ solutions where the spheres were fixed in lattice positions. The effective conductances measured were lower than values predictable from Maxwell's equation [2], and by least squares treatment of the data following equation was obtained: $K_e/K_c = 1 - 1.78f + f^2$. Reliability of this equation may be questioned on grounds of lack of adequate description of experiments and failure to indicate reproducibility and confidence limits. It is also doubtful whether the few experimental points taken form an adequate basis for proposal of an empirical equation. Pearce (10) recently presented experimental permittivity values obtained on oil-water emulsions. The data was in good agreement with values calculated by Bruggemann's approximation (11) (see Eq. [6] below). Conductivity measurements on two-dimensional array of metal and bakelite hemispheres submerged in tapwater yielded different results depending on whether the hemispheres occupied lattice positions, or were arranged in a random manner. In the former case Pearce found agreement with Eq. [1], while for random arrangement the Bruggemann approximation seemed to have given a better fit. The two-dimensional model of random arrangement by Pearce, however, does not represent the three-dimensional case accurately enough to base meaningful conclusions on it. Further, Pearce's data on random arrangement of spheres was taken only in the low volume concentration region (up to $f = 0.12$) where, judging from the few experimental points presented in his graphs, the experimental errors may have been comparable to the magnitudes of the possible deviations from Maxwell's or Bruggemann's equations. A comparison of data by the various investigators reveals that the discrepancy between experimental findings is by no means negligible, reaching approximately 10% near $f = 0.5$. Such a large difference in conductivity ratio values cannot be justified on the basis of inherent limitations in the type of measurement. Much rather, one is led to believe that some of the investigators may have taken less caution in defining their systems and in the execution of their experiments than would have been necessary to establish firmly the functional relationship between K_e/K_c and f.

The present work was undertaken with the aim of obtaining data with sufficient confidence in its accuracy to permit the evaluation of the limitations of Maxwell's equation [2] in the range $0 < f < 0.4$. Further, by using a comparatively large range of sizes both in separate fractions and also mixed together within one suspension, it was hoped that differences in conductance behavior between homogeneous and mixed-size dispersions may be detected.

Experimental

Glass beads of excellent shape characteristics[4] were used in the experimental series on spherical nonconducting particles. The beads were separated into size fractions by air elutriation. The diameter range selected for study is given in Table I. Within

[3] Thermal and electrical conductivity of dispersions depend on volume fraction of dispersed phase in an identical manner.

each size range (I-VI) approximately 75% of the beads were within a range of 10% of the mean diameter (Fig. 2a).

The sands[5] were wet-sieved after washing with water and the electrolyte, and only the fraction passing through sieve number 80 and remaining on 100 was used (approximate size range: 0.15-0.175 mm) (Fig. 2b and 2c).

Polystyrene cylinders[6] were cut from fibers of uniform diameter (0.3 mm) to a length of 3 ± 0.3 mm (Fig. 2d).

The specific gravity of the electrolyte was selected to be just slightly below that of the dispersed phase to prevent fast settling. Of the available alternatives, a near saturated solution of $ZnBr_2$ was selected as the continuous phase for the measurements with glass beads and sand. The saturated solution at 20°C has a specific gravity of 2.725 and a conductivity of 0.066 ohm^{-1} cm^{-1}. The specific gravities of the glass beads and of the sand were approximately 2.50 and 2.60, respectively. The density of each size fraction was determined to within unit accuracy in the third decimal figure. For polystyrene cylinders 0.1*N* KCl solution was chosen as the continuous phase.

Conductivity cell.—Following preliminary work with conventional type cells, the main series of measurements were executed with a cylindrical cell (Fig. 3) consisting of two sections, each 2¾-in. long, which could be interconnected by removal of a center electrode. A ¾-in. hole was drilled into Lucite blocks, providing the cylinder sections. Top and bottom electrodes were platinum, surface-welded onto ¼ in. copper plates. Center electrode consisted of a 25 mil platinum plate attached at two sides to ⅛ in. copper bars which served as guides. Sections of the cell were assembled using 1/16 in. Teflon gaskets, and the assembly was held together by bronze studs.

The conventional-type Wheatstone bridge circuit employed in the measurements is illustrated in Fig. 4.

Procedure.—Before each series of measurements the cell was filled with the electrolyte and the cell constants for each cylindrical section determined. Following this, the desired volume fraction of solid phase was weighed on an analytical balance and poured into the cell. The resulting mixture then was stirred with a glass rod for approximately 3 min to remove entrained air. The top electrode was closed and the cell was shaken to insure uniform electrolyte composition and temperature. When the dispersed phase settled below the level of the center electrode, the electrode was closed. Next the resistance of the upper compartment (containing no solids) was

[5] Death Valley Sand or Merck "Sea Sand."

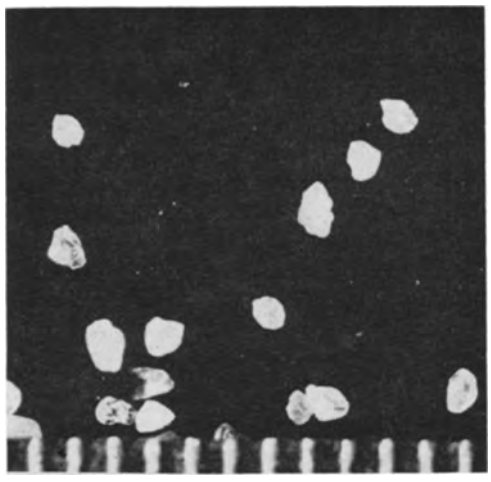

Fig. 2c. " Sea Sand," size range 0.15-0.175 mm

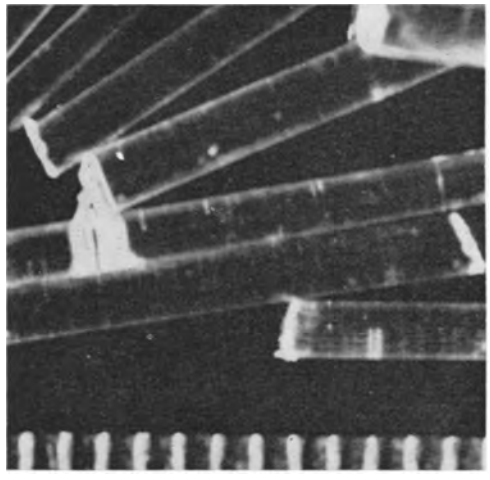

Fig. 2d. Polystyrene cylinders, diameter 0.3 mm, length 3 mm.

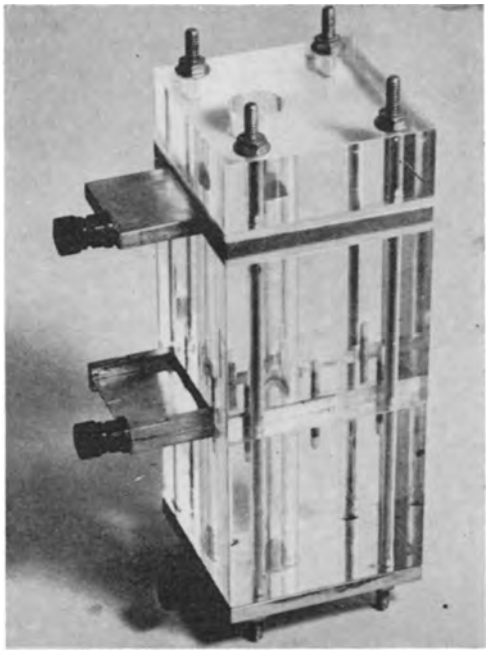

Fig. 3. Assembled conductivity cell, with top and center electrodes in "open" position.

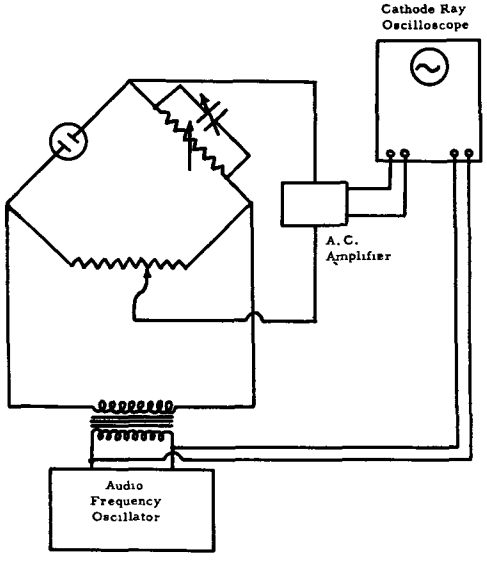

Fig. 4. Schematic diagram of the Wheatstone bridge circuit

measured. The resistance of the lower compartment (containing the known volume fraction of solids) was obtained while the cell was shaken by hand with a rotating, up, down, and sideward motion until a "steady-state" image was obtained on the screen of the cathode-ray oscilloscope. With continued shaking the actual value of the resistance of the dispersions was obtained by adjustment of the slide wire until the image, which was an ellipsoid, would become a line in the vertical gain, the point at which the Wheatstone bridge circuit was balanced.

After the first pair of measurements were completed, to check whether thermal equilibrium existed between the two compartments, the central electrode was opened, and the contents of the compartments thoroughly mixed. Again the solids were allowed to settle into the lower compartment and, after closing the central electrode, conductivity measurement was repeated as described above. In most cases the conductivity ratios obtained by the second pair of measurements were in agreement with those by the first within ±0.2%. If not, the contents of the compartments were again mixed, etc., until the difference between conductivity ratios between two successive measurements was within the limits given above.

Table II. Per cent difference between minimum and maximum values of K_e/K_c measured in three series of runs

f	%
0.1	0.19
0.2	0.17
0.3	1.2
0.4	1.75

To detect any systematic errors such as might be due to weighing and handling of solids, possible imperfect elimination of entrained air, etc., complete series of runs involving measurements at several volume fractions were repeated two or three times. As illustrated in Table II, per cent differences between minimum and maximum values obtained for K_e/K_c at the same volume fractions were only approximately 0.2% at up to f values of 0.2; however at $f = 0.4$ reproducibility was less satisfactory (1.75%).

Data

Figures 5-8 serve to illustrate the results obtained in the 20 series of measurements, each series consisting of four to eight individual measurements of conductivities at approximately evenly spaced volume fractions of solids. On most single- and mixed-size fractions enumerated in Table I and with each sand species and the polystyrene cylinders duplicate measurements were taken. Graphical representation of the data reveals that all the experimental points fall below the line corresponding to Maxwell's equation (Eq. [2]), and this deviation increases with

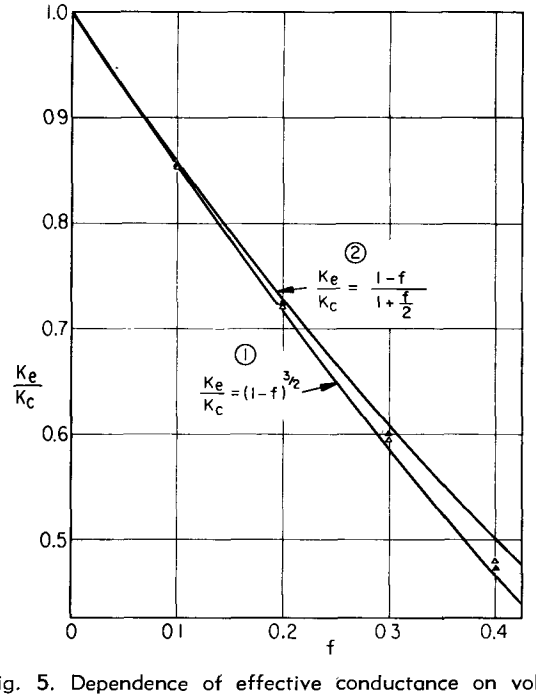

Fig. 5. Dependence of effective conductance on volume fraction of dispersed phase. Size range of spheres: 175-210 μ. ▲, Series I; △, Series II.

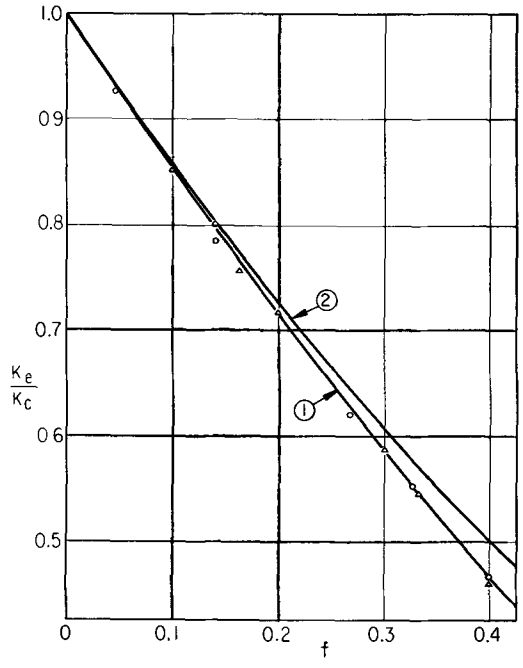

Fig. 6. Dependence of effective conductance on volume fraction of dispersed phase consisting of spherical particles. △, equal weight fractions of size ranges I-VI; ○, equal weight fractions of size ranges I-VI. Curves 1 and 2 as on Fig. 5.

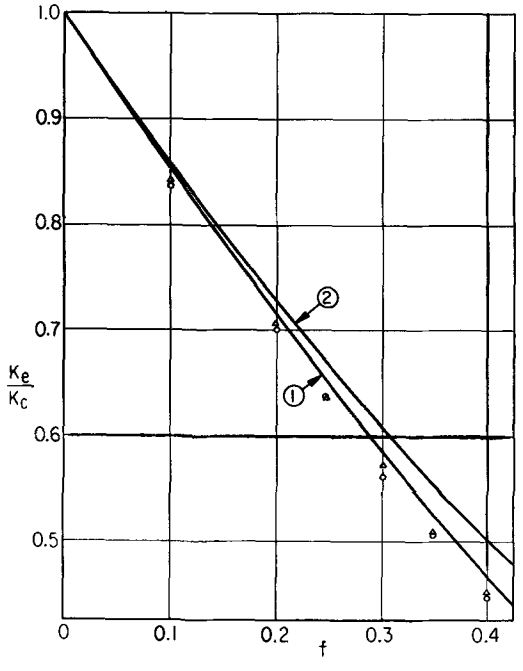

Fig. 7. Dependence of effective conductance on volume fraction of suspended sand. △, "Sea Sand"; ○, "Death Valley Sand." Curves 1 and 2 as on Fig. 5.

volume fraction of the dispersed phase. Further, values of the conductivity ratio on mixed size ranges are slightly but distinctly below the ones obtained on single size ranges. Data on both the polystyrene cylinders and on the two kinds of sands show more substantial differences from Eq. [2] than any on spherical particles.

Best Curves Representing Data

All series were subjected to least squares treatment, using the equation

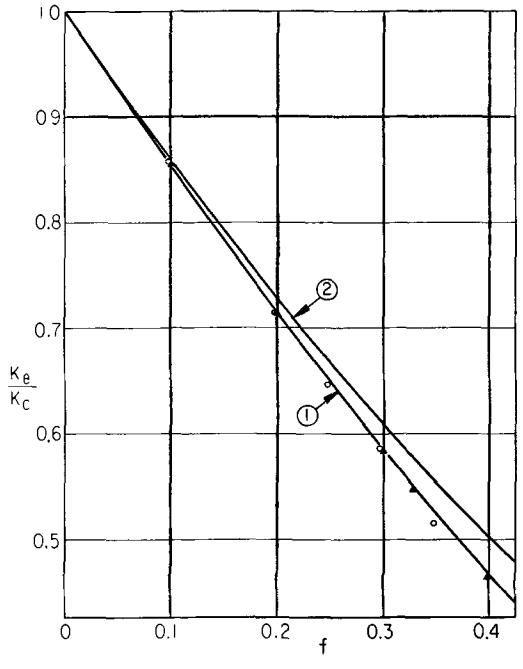

Fig. 8. Dependence of effective conductance on volume fraction of suspended polystyrene cylinders. △, Series I; ○, Series II. Curves 1 and 2 as on Fig. 5.

$$K_e/K_c = X(1-f)^Y \qquad [5]$$

Table III summarizes the least squares values of X and Y. If we assign a value $X' = 1.00$ (which should be satisfied for obvious physical reasons), the modified exponent Y' is obtained. The table also includes the standard deviation S and S'. All coefficients of correlation were greater than 0.998. S and S' are measures of the scatter of data about the curves defined by X, Y, or Y' in units of the ordinate. Twice the standard deviation gives approximately the 95% confidence limits on either side of the curve.

Discussion

While differences between the set of data on single-size fractions and on mixed sizes may be regarded as too small to draw sharp conclusions, the least squares equation representing data on mixed sizes is for all practical purposes identical to the equation proposed on theoretical grounds by Bruggemann (11) in which $Y' = 1.5$ (see Eq. [6] below). That such an agreement for a large diameter range of spherical particles in the dispersed phase confirms reasonable expectations follows from the physical approximations implicit in Bruggemann's mathe-

Table III. Least squares curves representing conductance data in terms of Eq. [5]. X' fixed at 1.00

Cylinders	0.994	1.51	0.010	1.53	0.010

matical treatment. If one adds a relatively large spherical particle to a dispersion containing much smaller particles, the disturbance of the field around the large sphere due to the small spheres may be considered negligible. On this basis, the effective conductance of such a system may be evaluated by considering the surroundings of the large sphere as a continuum having an effective conductance K'_e, and apply the Maxwell equation, since the system is "dilute" as far as the large sphere is concerned. The change in K'_e with the volume fraction of the dispersed phase may then be expressed in differential form:

$$dK'_e/df = [-3K'_e/(1-f)][(K'_e-K_d)/(2K'_e+K_d)]$$

Integrating with the boundary conditions $K'_e/K_c = 1$ as $f = 0$ and at the upper limit $K'_e = K_e$, one obtains

$$\frac{K_e/K_c - K_d/K_c}{(K_e/K_c)^{1/3}(1-K_d/K_c)} = 1-f$$

for the case when both phases are conductors, and the Bruggemann equation

$$K_e/K_c = (1-f)^{3/2} \qquad [6]$$

when the dispersed phase is an insulator, or $K_d = 0$. For single sizes or narrow size fractions, the physical conditions necessary for justifying the Bruggemann approximation are not satisfied. Conductivities of such dispersions when $K_d = 0$ must be lower than the value obtained from Maxwell's equation and higher than predicted by Bruggemann's approximation. The series of measurements represented in Table III conform to this qualitatively correct argument.

Size Effect

With the exception of the one series on the 105-177 μ range, where the scatter of data was unusually large, the exponent Y' shows a slight, gradual increase with particle size. There is no reason why particle size should have any effect on the effective conductance, unless the diameter of the spheres becomes comparable to the dimensions of the vessel containing the dispersion. There is no doubt that the larger exponents found for the size fractions V and VI, respectively, reflect wall effects.

It should be noted that while Maxwell's equation is valid strictly only when the dispersed phase consists of spheres of a single diameter, and of course at that only at very low volume concentrations, Eq. [6], both on the basis of the present experimental results and because of the conditions assumed in the derivation by Bruggemann (11), applies best for random distribution of sizes.

Although the present study was not designed to clarify what effects shapes other than spherical would have on the conductivity ratio K_e/K_c, four series of measurements with sand and two with polystyrene cylinders were also performed. The results as presented in Fig. 7 and 8 and in Table III indicate that Eq. [6] again represents the data fairly well. This agreement however should be viewed with caution. The sand particles used were of "smoothed off" polyhedrical shape for which the approximations incorporated in Eq. [6] may be considered to apply rather well. The "Death Valley Sand" gave slightly lower conductivity ratios than the "Sea Sand" reflecting the more elongated shape of the former (12).

As to the cylinders, Fricke's treatment (13) of the conductivities of prolate spheroids in dilute dispersions yields values close to those one obtains by using Eq. [6]. Therefore at least at low concentrations of the solid, the agreement between the present data and Eq. [6] is not surprising. However, at higher volume fraction of the dispersed phase, there is no adequate theoretical basis by which one can safely generalize the agreement found between the data for cylinders of approximately 10:1 length to diameter ratio and the values predictable from Eq. [6], which has been developed for spheres only.

Conclusions

Experiments of reasonably high precision and reproducibility confirmed expectations based on theory, e.g., that the conductivity of electrolytes is lowered by the presence of randomly distributed spherical nonconductors to a larger extent than predictable from the well-known Maxwell relation. Conductivity data obtained on a large size range of glass spheres in aqueous $ZnBr_2$ solutions aligned closely to curves represented by Eq. [5] with $X = 1.00$ and $1.43 < Y < 1.51$. This form of the equation and the upper limit of the exponent find theoretical support in the approximation first proposed by Bruggemann.

It is recommended that for random dispersions of spherical insulators with a large size-range of spheres, such as occurs in gas-electrolyte emulsions, the Bruggemann equation (Eq. [6]) be used to predict effective conductivity. When the size-range of spheres is narrow it may still be used with about the same or lower probable error than the Maxwell equation, although in that case the Bruggemann equation predicts slightly low values for the effective conductance. For shapes other than spherical Eq. [6] is generally not applicable, particularly not if the particles are greatly elongated or when they contain cavities.

Effect of Gas Evolution on Current Distribution and Ohmic Resistance in Electrolyzers

Charles W. Tobias

Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

Volume fraction of gases in electrolyzers increases in the direction of net movement of gases, causing a corresponding variation in the ohmic resistance between electrodes. The resulting nonuniformity in current distribution and the increase in over-all resistance is shown to be characterized by a single dimensionless parameter which incorporates the key process variables. The leveling effect of polarization is shown to be significant.

Although the effect of gas holdup in electrolytic cells on the resistance of the electrolyte has long been recognized (1), quantitative interpretation of the effects observed has not been attempted until recent years. Ipatieff, Schischkin, and Jurieff (2) have presented simple calculations relating the total current to volume of gas present in water electrolyzers. Implicit in their treatment is the assumption that the effective resistivity of the electrolyte between the vertical electrodes does not vary in the vertical direction. While this assumption greatly simplifies the physical model, it also deprives the model used by these workers of reality. In addition to neglecting the current density variation caused by differences in gas concentration, these authors expressed the volumetric effect of gas bubbles on conductivity in an erroneous manner.

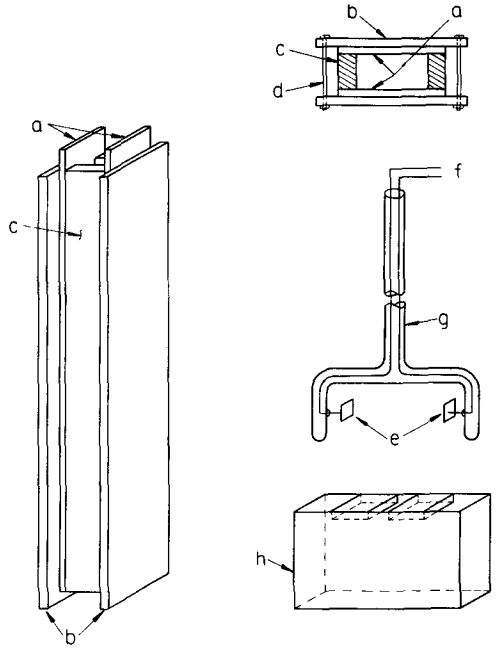

Fig. 1. Experimental cell and conductivity probe used by Baker (2). a, Steel electrodes, 32 x 6 x ⅛ in.; b, Bakelite backing sheets; c, plexiglass separators, 31 x 1 x 1 in.; d, fastening bolts; e, platinized platinum electrodes, 0.5 x 1.0 cm, 7 cm apart; f, shielded leads; g, glass tube, 1 cm OD; h, plexiglass shield fitting over horizontal part of glass tube.

According to measurements of the effective resistance as a function of cell depth (Fig. 1) reported by Baker (3) between parallel electrodes, the volume fraction of gas at a given depth in a given electrolyte is approximately a linear function of current density (Fig. 2). Baker calculated the volume fractions from resistance data obtained by use of a shielded resistivity probe. An experimental plot of the variation of gas volume fraction as a function of distance from cell bottom is shown in Fig. 3.

Current density decrease from bottom to top of a water decomposition model cell was shown by Murakawa and Nagaura (4) by means of direct measurements of branch currents using a "sectioned" electrode (5). Their results conform, at least in a qualitative sense, to expectations based on first principles. When gas evolves along a vertical electrode surface, bubbles ascend under the buoyancy force (and if the electrolyte is in motion, also due to drag forces). The time required for a gas bubble evolved at a point on the surface to reach the surface of the electrolyte will be approximately proportional to the distance of this point from the surface. Consequently the volume fraction of gas in the electrolyte gradually increases with elevation, causing the conductivity of the suspension to diminish along the same direction.

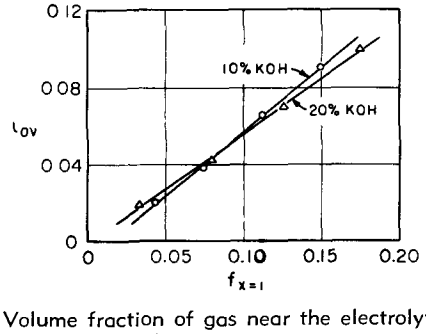

Fig. 2. Volume fraction of gas near the electrolyte surface [from data by Baker (3)].

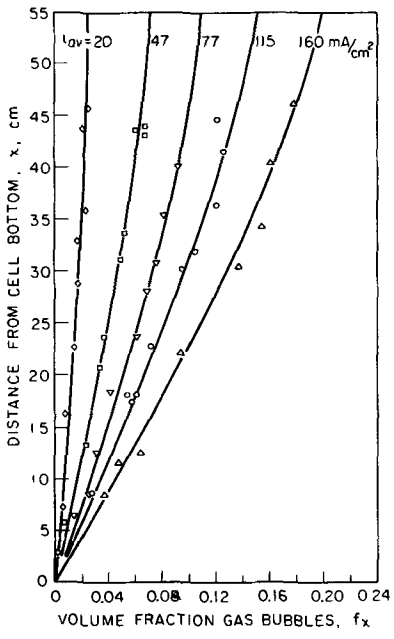

Fig. 3. Experimental volume fractions at different cell depths

The aim of the present work is to establish a theoretical treatment by which the most important design and process variables are combined in functional relationship, quantitatively describing the effect of gas evolution on current distribution and cell voltage. In order to lend clarity and simplicity to the mathematical treatment, certain reasonable physical assumptions must be made, which however should not detract from the general validity of the results.

Nomenclature

b' — $b'_a - b'_c$
b'_a, b'_c — anodic and cathodic linear Tafel slopes, ohm cm²
C — dimensional constant, $RT/PmFs\delta$, cm amp^{-1}
D — bubble diameter, cm
E — portion of applied cell voltage that depends on current, $E = E + i_x R_x$, volts
E_p — current dependent part of polarization voltage, $E_p = b'i_x$
E_D — constant in "linear" Tafel equation, volts approximately the current-independent part of the cell voltage, or the "decomposition" voltage
F — Faraday, coulombs/gram equivalent
f_x — volume fraction of gas in electrolyte at level x, dimensionless
f_{av} — average volume fraction of gas in cell, dimensionless
h — height of electrolyte column in cell (with or without gas), cm (Fig. 4)
I_T — total current passing through cell, amp
i_x — local current density at level x, amp/cm²
i_{av} — average current density in cell, amp/cm²
K — dimensionless parameter $CEh/\rho\delta = RTEh/PmFs\rho\delta^2$
m — number of Faradays passing through the cell, per mole of gas liberated at both electrodes, g-equivalent/mole
P — partial pressure of gas liberated at electrodes, atm, $P = P_T - P_V$
P_T — total pressure (approximated by ambient pressure plus arithmetic mean of hydrostatic pressure in cell)
P_v — vapor pressure of electrolyte at the operating temperature
R — gas constant, cm³ atm/°K g mole
R_e — resistance of gas-free electrolyte between the two electrodes, ohms
r_x — effective resistance of a 1 cm² prism of electrolyte containing gas bubbles, between the two electrodes at elevation x, ohm cm², $r_x = \rho_x\delta = \rho\delta(1 - f_x)^{-3/2}$
R_{eff} — total ohmic resistance of electrolyte and gas in cell, ohms
s — average rising velocity of bubbles, cm/sec
T — absolute temperature, °K
u — velocity of a gas bubble, cm/sec
u_s — steady-state velocity of a gas bubble, cm/sec
dv_x — volume of gas in volume element $w\delta dx$ of electrolyte at level x, cm³ (Fig. 4)
w — width of electrodes, cm (Fig. 4)
X — dimensionless reduced vertical distance, $X = x/h$
x — vertical distance from bottom of electrodes, cm (Fig. 4)
δ — electrode separation, cm (Fig. 4)
θ — time, sec
μ — $b'/\rho\delta$, polarization parameter, dimensionless
ν — dynamic viscosity, g cm^{-1} sec^{-1}
ρ — resistivity of gas-free electrolyte, ohm cm
ρ_x — resistivity of electrolyte containing gas bubbles at level x, ohm cm
σ_e, σ_g — density of electrolyte and gas, respectively, g/cm³
ϕ — cell parameter $\phi = I_T C/w = I_T RT/PmFs\delta w$, dimensionless

Cell Model and Physical Assumptions

The geometry of the cell model is shown in Fig. 4. The following assumptions were made:

1. The electrode on the metal side is equipotential, i.e., there is no "terminal effect."

2. Size distribution of bubbles at all levels is the same, and within the range of current densities this size range and distribution may be regarded as constant.

3. The bubbles assume their steady-state (instantaneous) velocity, u_s, essentially immediately after separation from the surface. It can be shown by the solution of the differential equation from u, the velocity of motion of a gas bubble in the gravitational force field, using Stokes law, that

$$u = u_s[1 - \exp(-18\nu\sigma_e\theta/D^2\sigma g)] \qquad [1]$$

Substitution of reasonable values of the physical constants into Eq. [1] indicates that quasi steady

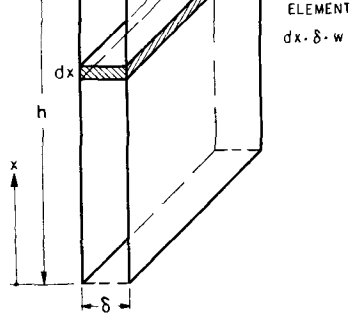

Fig. 4. Model of gas evolution cell

state is reached within 0.01-0.001 sec after release.

4. Velocity of rise is independent of depth. In fact bubbles expand on decrease in hydrostatic pressure. Since the buoyancy force is proportional to D^3 while the drag force is proportional to D^m (where $1<m<2$), ascending bubbles accelerate. In the region of interest velocity of bubbles varies approximately in inverse ratio to the 1/3 to 2/3 power of the pressure; therefore the increase of velocity amounts to only a few per cent, provided the cell depth is not very great. Incorporation of variable velocity into the treatment to be presented, however, would confuse the issue more than it would contribute to the accuracy of the end results.

5. Velocity of rising bubbles is independent of volume concentration of gas. In fact the bubble motion decelerates as the volume concentration of bubbles in the electrolyte increases. Quantitative functional representation of the effect of volume concentration on the departure of velocity from the "free" rate of ascendance however has not been developed so far.[1]

6. Secondary effects on bubble motion, such as those due to coalescence or convection currents in the electrolyte for example, are disregarded.

7. The assumptions under 2-6 above permit the definition of an average velocity, s, at which the gases liberated at the electrodes rise, independent of depth and current density. Within a given electrolyte, however, this velocity depends on pressure, temperature and electrode material.

8. Polarization is linear over the range of current densities occurring within a cell (see Fig. 5). Substitution of a linear relation for a relatively narrow range of current densities has been an accepted technique in treating current distribution problems (6, 7).

9. The flow of current is unidirectional, or at least the curvature of the lines of flow is negligible. It has been shown (6) that for linear geometry this is a good assumption, provided δ/h is small.

[1] Studies by Hanratty, *et al.*, on hindered settling of spherical solids (9) have shown that in the Stokes law region the effective rate of settling may be evaluated if, instead of the density of pure liquid, one substitutes the average density of the suspension (a variable, function of depth), and if one also takes into account the change of effective viscosity with the changing volume concentration. Although the exact functional dependence is more complex, Hanratty's data may be reasonably well represented by $s_x/s_0 = (1 - f_x)^4$ when $f_x < 0.35$, where s_0 corresponds to the free settling rate, and s_x denotes the actual rate of settling at elevation x.

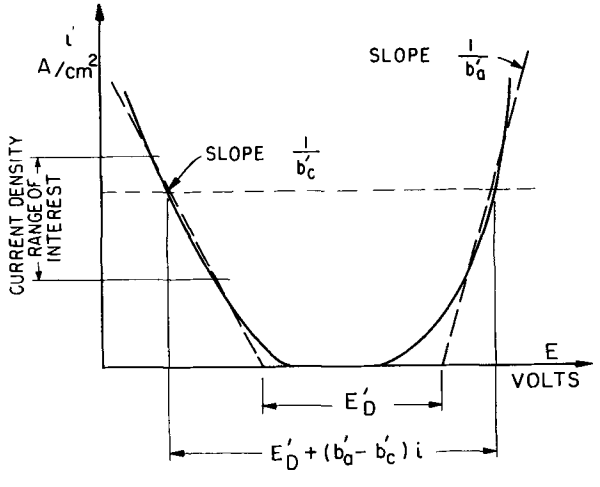

Fig. 5. Linear polarization approximation

Mathematical Treatment

In the steady state, the volume of gas dv_x present in the volume element $w \cdot \delta \cdot dx$ (Fig. 4) is

$$dv_x = (RTwdx/PmFs) \int_0^x i_x dx \qquad [2]$$

Equation [2] may be derived as follows. The quantity w times the integral equals the total current flowing through the cell between the bottom and level x. This current divided by mF gives the total number of moles of gas produced and, multiplied by RT/P, the total volume of gas produced in the cell per second between the bottom and x. This volume of gas is moving upward a distance of s cm in 1 sec. Therefore, the fraction dx/s of it will be in the given volume element at any given instant of time, and this is the volume dv_x. The volume fraction of gas in the same element is then

$$dv_x/w\delta dx = f_x = C \int_0^x i_x dx \qquad [3]$$

For a given geometry, P, T, m, and s, C is a constant having the dimensions of length per unit of current. Equation [3] relates the volume fraction of a gas at height x to the total current passing below that level.[2]

As shown by De La Rue and Tobias (8), dependence of the ohmic resistivity ρ_x at level x on the volume fraction of gas is given by the Bruggemann equation

$$\rho_x = \rho(1 - f_x)^{-3/2} \qquad [4]$$

The current-dependent portion of the electrode potentials E_p may be represented by (Fig. 5)

$$E_p = b' i_x \qquad [5]$$

The dependence of potential on current density, resistance, and polarization is then obtained by combination of [4] and [5]

$$E = (b' + r_x) i_x \qquad [6]$$

Note that, in the present application, E is independent of x by virtue of assumption 1 above. The square centimeter resistance r_x is equal to $\rho_x \delta$.

Substitution and rearrangement of [6] yields

$$E/\rho\delta = [\mu + (1 - f_x)^{-3/2}] i_x \qquad [7]$$

The meaning of the polarization parameter μ has been given by Wagner (7) among others.

The differentiation of [3] yields

$$df_x = C i_x dx \qquad [8]$$

The current density i_x may be eliminated between Eqs. [7] and [8] and the resultant equation integrated

$$(CE/\rho\delta) \int_0^x dx = \int_0^{f_x} [\mu + (1 - f_x)^{-3/2}] df_x \qquad [9]$$

[2] Although constant velocity of rise s has been assumed in this derivation, incorporation of velocity dependence on volume fraction of gases as represented, for instance, by the approximation formula in footnote 1, causes no difficulty. Equation [3] transforms to $f_x(1 - f_x)^4 = C \int_0^x i_x dx$ and the integration of the modified equation replacing Eq. [9] may be readily accomplished. The resulting form however is implicit in f_x, and does not permit therefore derivation of convenient expressions showing the dependence of key process variables. In the following treatment only the simpler relations involving the constant velocity assumption are presented.

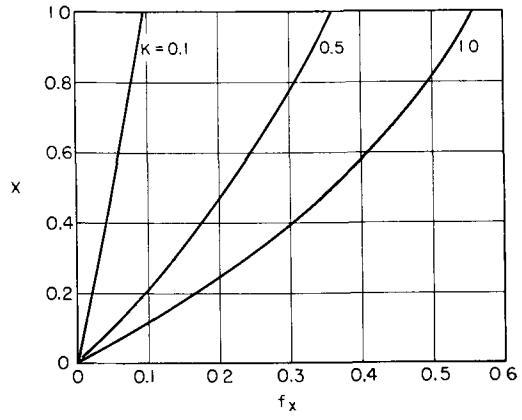

Fig. 6. Volume fraction of gas as a function of reduced height

To obtain a solution in closed form for f_x, let us for the present assign the value $\mu = 0$ (corresponds to constant polarization), and then integrate between the limits given. The solution is

$$f_x = [(KX)^2 + 4KX]/(KX + 2)^2 \qquad [10]$$

where K, the gas effect parameter, and X, dimensionless vertical height, have been introduced to reduce the number of symbols carried. A plot of f_x as a function of X is given in Fig. 6 for $K = 0.1$, 0.5, and 1.0.

Combination of Eqs. [7] and [10] leads to the important relation between local current density and vertical distance

$$i_x = 8K/hc(KX + 2)^3 \qquad [11]$$

Mathematical Results

A number of useful relations may now be derived by simple combinations of the equations derived in the preceding section.

1. The relation between the total current I_T and the current-dependent part of the voltage

$$I_T = i_{av}hw = w\int^h i_x dx = wf_x h/C =$$

$$w(K^2 + 4K)/C(K + 2)^2 \qquad [12]$$

In Fig. 7 the ratio of local to average current density i_x/i_{av} has been plotted by use of Eqs. [11] and [12] for $K = 0.1$, 0.5, and 1.0.

2. Solving [12] for K, we obtain the dependence of K on average current density

$$K = 2[1 - (1 - 1/Chi_{av})^{-1}]^{1/2} - 2 \qquad [13]$$

Equation [13] has been plotted in Fig. 8 The vertical scale is Chi_{av}. Note that for low values of K (<0.15)

$$K \cong Chi_{av} \qquad [14]$$

In this region, K is directly proportional to applied current and depth of cell and, from the definition of C, K is inversely proportional to average velocity of rise of bubbles and to electrode separation.

3. The average effective ohmic resistance of electrolyte R_{eff} relative to gas-free resistance R_e, when the cell depth is the same, is given by

$$R_{eff}/R_e = (K + 2)^2/(K + 4) \qquad [15]$$

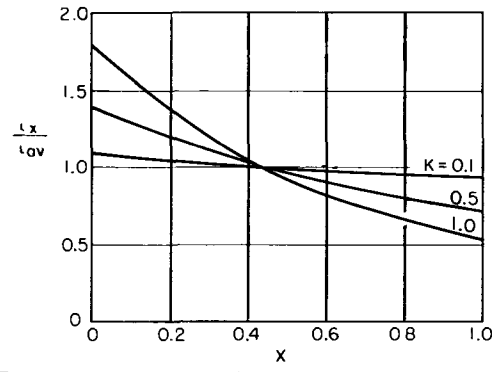

Fig. 7. i_x/i_{av} as a function of reduced height along electrode

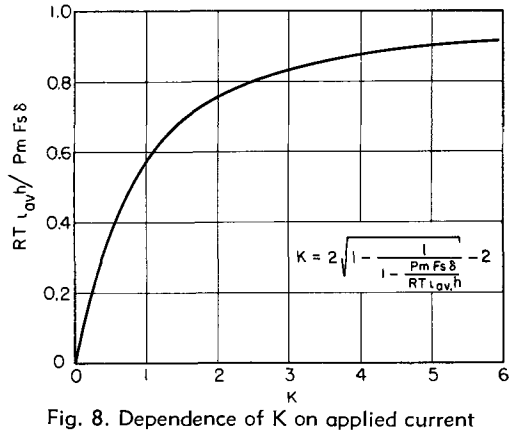

Fig. 8. Dependence of K on applied current

4. The average volume fraction of gases is given by

$$f_{av} = {}_0\int^1 f_x dX = K/(K + 2) \qquad [16]$$

Figure 9 illustrates Eqs. [15] and [16], showing that the per cent effect on resistance is greater than the per cent average gas holdup. Figure 10 shows a plot of f_{av} against a dimensionless grouping ϕ including I_T.

Optimal distance of electrodes.—Because of the effect of gas bubbles on the resistivity of electrolyte, setting the electrodes closer together will not result in a proportionate reduction of ohmic voltage drop. As a matter of fact it is easy to realize that bringing them together below a certain distance should result in an increase of voltage drop. (The volume fraction of gas varies in inverse proportion to the electrode separation, while the effective resistance of the dispersion between the electrodes increases more rapidly than does the volume fraction of gas.) For simplicity's sake let us consider only at what average volume fraction f_{av} of gas the effective ohmic resistance will be at a minimum:

$$R_{eff} = A/f_{av}(1 - f_{av})^{3/2} \qquad [17]$$

where all terms not depending on distance have been grouped into a constant A.

Differentiating with respect to f_{av}, and setting the derivative equal to zero, we obtain $f_{av} = 0.4$, i.e., the ohmic resistance will be at its minimum when the electrodes are at such a distance that the average volume fraction of gas between them is 0.4. Although such a high holdup volume seems to be out of the common design and operational range, it should be noted that the ohmic resistance diminishes rather slowly with distance even when $f_{av}>0.2$. Therefore

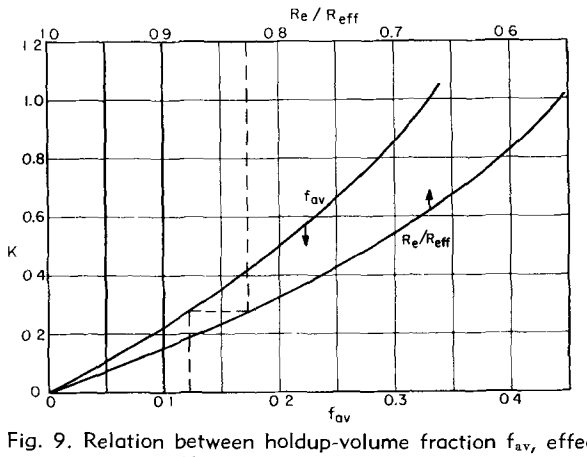

Fig. 9. Relation between holdup-volume fraction f_{av}, effective resistance, and K for gas evolution between plane parallel electrodes.

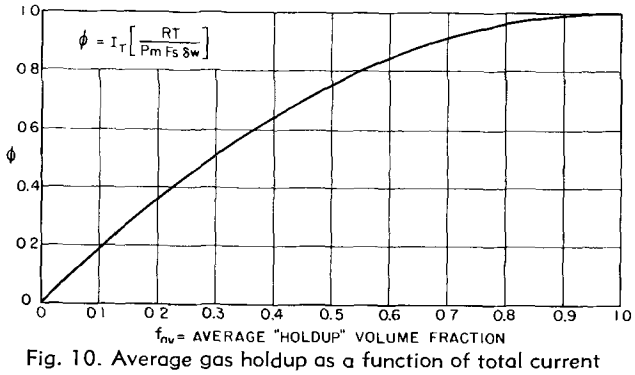

Fig. 10. Average gas holdup as a function of total current

only little can be gained by setting the electrodes closer together than corresponds to $f_{av} = 0.2$.

In attempting to evaluate the effect on the voltage drop of reducing the interelectrode distance, one should keep in mind that in all the developments presented above it has been assumed that the average velocity of gas bubbles is independent of electrode separation. Although for large separations this appears to be a reasonable approximation, it is quite certain that, when the electrodes are so close together, the volume fraction of gas becomes significant, s depends on electrode separation, and the optimal separation will be larger than that corresponding to $f_{av} = 0.4$.

Effect of Polarization

The value $\mu = 0$ has been assigned so far in order to obtain a solution in closed form for the current density distribution, and to show in the manner easiest to follow how the common design and process variable are interrelated.

The relation between X and f_x from the integration of equation [9]

$$KX = \mu f_x + 2(1 - f_x)^{-1/2} - 2 \qquad [18]$$

does not yield an explicit form in f_x and therefore i_x cannot either be expressed in a closed form as a function of X. A reasonable approximation may be obtained however if one replaces[3] the term in Eq. [7] which represents the effect of gas volume fraction on resistance $(1 - f_x)^{-3/2}$ by the first two terms of its binomial expansion $1 + 3/2 f_x$. With this substitution the current density variation as a function of X, K, and μ may be obtained by simple algebraic steps

$$i_x/i_{av} = \frac{3}{2} K[(\mu + 1)^2 + 3KX]^{-1/2} \cdot \{[(\mu + 1)^2 + 3K]^{1/2} - (\mu + 1)\}^{-1} \qquad [19]$$

[3] Use of this expression for conditions where $f_{av} > 0.2$ leads to appreciable errors.

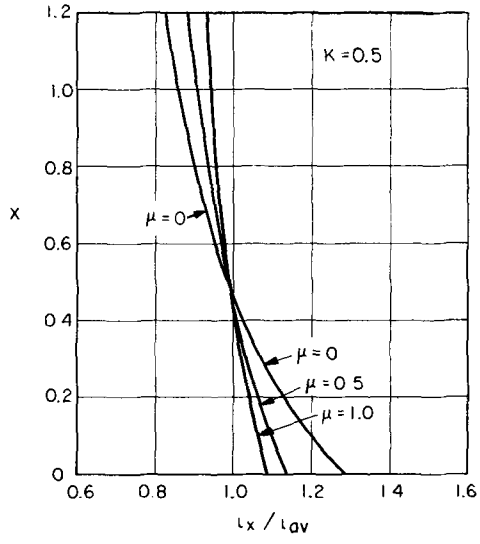

Fig. 11. Leveling effect of polarization on nonuniform current distribution caused by gas evolution.

Figure 11 shows the considerable leveling effect of polarization for a practical range of values of the polarization parameter μ.

When the polarization is strongly dependent on current density and therefore μ is comparable to or larger than unity, the nonuniformity of current distribution is diminished to a significant degree. Under such conditions it is advisable to use Eq. [19] and the correspondingly modified forms of the relations expressing effective resistance, etc.

Note: The fact that the effect of gas evolution on current distribution depends on a single dimensionless parameter should be helpful both in design procedures and when it is desirable to know what effects changes in operational conditions will have.

The foregoing treatment should be regarded as valid only within the physical assumptions made. Therefore, whenever any of the variables (such as size, total current) are changed significantly one must examine whether or not dependent quantities have been affected by phenomena not considered in setting up the physical model. A particularly vulnerable assumption is that relating to the constancy of the average rising velocity of bubbles. Large variations in cell depth or electrode separation will undoubtedly influence s, as will changes in electrode materials. The effect of deceleration of bubble motion due to decrease in bulk density and increase of viscosity cannot be considered quantitatively until further experimental and theoretical developments improve our understanding of the dynamic behavior of suspensions of gases in liquids. The analogy with hindered settling is plausible but not proven. In any case, other factors, such as bulk entrainment of electrolyte and secondary flows caused by descending, relatively gas-free eddies, may so seriously influence bubble motion that conclusions reached by considering the deceleration due to viscosity and density changes alone could be misleading.

The average bubble velocity, s, and its dependence on cell geometry, current density range, and materials used may be established in model experiments. Estimates of s may be obtained by measurement of increase

of electrolyte level due to gas holdup (see Eq. [16]), and the variation of average velocity with total current established by comparing the dependence of K on i_{av} with the values calculated by use of Eqs. [13] and [14].

Manuscript received Feb. 9, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Technical Note

Preparation and Properties of ZnS-Type Crystals from the Melt

Albrecht G. Fischer[1]

Large Lamp Department, General Electric Company, Nela Park, Cleveland, Ohio

The important semiconducting phosphor materials ZnS, CdS, and ZnSe cannot be melted at normal pressure because they decompose several hundred degrees below their melting points. This tendency is due to the mixed homo-heteropolar nature of their bond. As the diamond lattice requires that the ions be incorporated in a predeformed state and under stress, unstable surfaces result (1, 2).

The first experiments to melt ZnS and CdS in a high-pressure bomb were carried out several decades ago (3), and recently interest has revived in the subject. Accurate values for the melting points and vapor pressures of ZnS and CdS have been reported (4, 5) and a technique of growing crystals of these materials from the melt under high argon pressure has been developed (2, 6).

ZnSe can also be recrystallized from the melt (2). In continuation of earlier work it was found that crucibles of pure graphite and of zirconia can be used. Quartz glass, although rather soft at the melting point of ZnSe, is also suitable as a crucible material since it is not chemically attacked by the melt.

Using a melting point indicator similar to that described in (2) and a Pt-Pt/Rh thermocouple, the melting point of ZnSe has now been determined to be at 1515° ±20°C. $CuGaS_2$ melts at 1280°C.

The vapor pressure at the melting point was determined by a new direct method. A sealed-off evacuated quartz tube filled with ZnSe prefired in vacuum was heated up to the melting point of ZnSe. When the outer pressure in the autoclave was somewhat higher than the decomposition pressure developed in the tube, the walls of the plastic quartz tube were compressed. When, on the other hand, the outer pressure was lower than the inner pressure, the bulb dilated and formed a bubble. In a series of experiments with varying external pressure, it was possible to determine the pressure in the bulb within close limits. In the case of ZnSe it is around 1.8 atm, while it is about 2.5 atm for CdS. This method is also suitable for substances with lower melting points where other glasses have to be used, for instance for certain $A_{III}B_V$ compounds where indirect methods had to be used previously.

The facts that the vapor pressure is comparatively low and that quartz, although already soft at 1500°C, is chemically stable, suggested a new method for the preparation of ZnSe single crystals from the melt. It

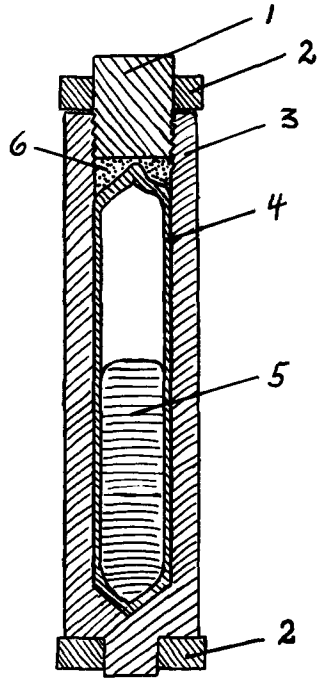

Fig. 1. 1, Graphite stopper; 2, boron nitride rings to prevent electrical shorting of the heater; 3, graphite crucible; 4, quartz bulb; 5, ZnSe or CdS melt; 6, graphite powder.

[1] Present address: RCA Laboratories, Princeton, N. J.

is also suitable for CdS. A quartz tube is filled with ZnSe, heated in vacuum and sealed off. This tube is inserted into a closely fitting thick-walled graphite crucible which can be closed with a plug. The remaining empty space is filled with graphite powder (see Fig. 1). If this assembly is heated up, the softening quartz tube expands, driven by the interior pressure, until the rigid graphite container takes up the mechanical forces and the quartz hull serves merely as a gas-tight lining. The vessel with the molten ZnSe can then be cooled down with any desired temperature gradient in order to crystallize the melt. To prevent devitrification of the quartz it is desirable to use pure graphite with smooth surfaces. Instead of the simple graphite crucible shown in Fig. 1 which has to be destroyed each time a crystal is removed, more elaborately designed vessels can be used which allow disassembly and reassembly.

The method described is expected to find wider application because it allows the growing of large single crystals from the melt in a reproducible way and with simple, inexpensive means; no high-pressure autoclave is needed.

For ZnS or ZnS-rich mixtures, it is better to use high-density zirconia crucibles with stoppers, which are sealed into evacuated, closely fitting quartz tubes and heated in an autoclave. The pressure applied from the outside has to be higher than the decomposition pressure inside. The thermoplastic quartz envelope then forms a gas-tight lining around the ZrO_2 crucible; this permits growing of the crystals in a defined atmosphere and controlling the vacancy equilibrium in the crystals.

It has been found that the pure compounds ZnS, CdS, and ZnSe, or mixtures containing at least about 80% of any one of the constituents, crystallize much more readily than mixtures with lower contents, which have the tendency to stay polycrystalline.

Thermoelectric measurements have shown that undoped ZnSe crystals as well as samples doped with Al and In are n-type, whereas ZnSe crystals doped with Cu or Ag are p-type. The n-type samples are strongly photoconducting, whereas coactivated samples are luminescent.

Solid-state diffusion occurring during the firing of crystals rich in ZnSe or CdS and packed in ZnS powder having the same activator concentration led to spread-band-gap surfaces. This could be observed by a short wave-length shift of the photo- and cathodoluminescence from the interior of the crystals toward their surface. Formation of mixed crystals of ZnSe with ZnTe or GaAs (7) reduces the band gap of ZnSe.

Technical Review

The Manganese Dioxide Electrode

W. C. Vosburgh

Department of Chemistry, Duke University, Durham, North Carolina

Manganese dioxide has been an important battery reactant since about 1890 when the Zn-MnO_2 cell proposed by Leclanché (1) began to be used in the dry-cell form. Because of the importance of the Leclanché cell and of other uses of MnO_2 a voluminous literature has grown up. A review of the Leclanché cell by Heise and Cahoon (2) was published in 1952 and at the same time reviews of two newer cells with MnO_2 electrodes by Morehouse (3) and Herbert (4). The present review brings together some of the more recent contributions to the structure and properties of MnO_2 and the discharge mechanism of the MnO_2 electrode. Related topics that are not included are the carbon of the Leclanché-cell bobbin, the electrolyte, reactions of the Leclanché cell not closely related to the discharge mechanism, the standard potential and the open-circuit potential of the MnO_2 electrode, and practical features of batteries with MnO_2 electrodes.

Structural Forms of Manganese Dioxide

Reviews of the structure of MnO_2 have been given by Wadsley and Walkley (5) and Brenet (6). Some later contributions have been made by Buser and Graf (7). The large number of more or less differing substances of the approximate composition

MnO_2 (with or without other elements) have been classified as belonging to a relatively few general types which occur naturally. The crystal structures of these have been determined and diagrams of the structures are given in the above references.

The minerals pyrolusite and ramsdellite are MnO_2 with no other element as an essential part of the structure. Ramsdellite in well-crystallized form is rare. Pyrolusite has a more compact crystal structure than ramsdellite (6,8).

Psilomelane is given the type formula $(Ba,H_2O)_2Mn_5O_{10}$ in which the relative amounts of Ba and H_2O are variable (9). The Ba is present as Ba^{++}, and compensation for the charge is made by reduction in the charge of an equivalent number of Mn atoms (9).

The minerals cryptomelane, hollandite, and coronadite are alike except for the additional element present along with the MnO_2, these being K, Ba, and Pb, respectively (10, 11). The type formula is given as KMn_8O_{16}, with K replaceable by other metal atoms, with suitable adjustments of the charge of the Mn.

Lithiophorite and chalcophanite have layer structures in which the MnO_2 forms two layers enclosing other metal ions and water, or hydroxides (12).

Well-crystallized artificial pyrolusite, known also as β-MnO_2, can be prepared. The accepted standard MnO_2 electrode with an acid electrolyte is a β-MnO_2 electrode (13). Well-crystallized ramsdellite has not been prepared, but the artificial material known as γ-MnO_2 and the naturally occurring γ-MnO_2 now usually are considered to be related to ramsdellite (14, 5, 6) although a closer relation of some samples to pyrolusite on the basis of the x-ray diffraction pattern has been pointed out (15). It is suggested (11) that the ramsdellite structure of γ-MnO_2 is partially changed to the more stable pyrolusite structure by as mild a treatment as heating under boiling water. This would make possible a series of disordered intermediate forms. Both natural γ-MnO_2 ores and electrodeposited γ-MnO_2 preparations are used in batteries.

Well-crystallized artificial cryptomelane, or α-MnO_2, has been prepared. Electron microscope photographs of α-MnO_2 showing definite crystal form, are given by McMurdie (16) and Buser, Graff, and Feitknecht (17). In similar photographs of γ-MnO_2 no crystal form can be seen. McMurdie's α-MnO_2 was prepared by the digestion of γ-MnO_2 with NH_4Cl solution either at 100°C or under pressure at 150°C and presumably contained NH_4^+ in its structure. The α-MnO_2 of Buser, Graf, and Feitnecht was prepared with K^+ present.

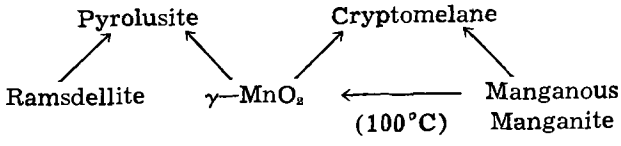
Electrodeposition of MnO_2 from a bath of $MnSO_4$ and H_2SO_4 gives γ-MnO_2 (14, 6). However, if one of the cations that can take part in the α-MnO_2 structure is present α-MnO_2 may be obtained (18, 19), although Cole, Wadsley, and Walkley (14) obtained γ-MnO_2 in two preparations in which K_2SO_4 was present.

Precipitation processes in which Mn^{++} is oxidized or MnO_4^- reduced (or both) give four different oxides, depending on conditions. The one most commonly formed is γ-MnO_2, but in the presence of K^+ or other similar cations α-MnO_2 or mixtures of α and γ may be formed (14, 20, 21). Some conditions of precipitation give δ-MnO_2 (16), and still other conditions give two forms of a material called manganous manganite (22, 23). As the last name implies, this material contains Mn(II) as well as Mn(IV), and the amount of Mn(II) is variable. Buser, Graf, and Feitknecht (17) showed that δ-MnO_2 and manganous manganite are alike in structure. The crystals are thin plates consisting of two layers of Mn(IV) and O atoms with a variable amount of $Mn(OH)_2$ between the layers. The Mn(II) of the $Mn(OH)_2$ can be replaced by other metals, for example Zn, giving a series of manganites. When the $Mn(OH)_2$ content is small, the material is δ-MnO_2. Compounds $3MnO_2 \cdot Mn(OH)_2 \cdot xH_2O$ and $4MnO_2 \cdot xMn(OH)_2 \cdot 2H_2O$ have been prepared, the latter in well-crystallized form. This preparation indicates that manganous manganite is not a poorly crystallized α-MnO_2 as has been suggested (16,24). Buser and Graf (25) consider that the two forms of manganous manganite are similar in structure to the minerals chalcophanite and lithiophorite, mentioned above. On heating manganous manganite or δ-MnO_2 under water α-MnO_2 is formed if the preparation contains enough K^+, and γ-MnO_2 is formed if the K^+ content is below a certain small minimum (22, 17). Dried δ-MnO_2 containing K^+ was not appreciably converted to α below 300°C (21).

Some Properties of MnO_2

Most of the properties of MnO_2 are well known and need no review here. However, some recent work on certain of the properties should be mentioned.

Changes on heating.—The changes on heating MnO_2 at temperatures between 350° and 450°C serve to show the relative stabilities of the various varieties. Cole, Wadsley, and Walkley (14) represent the changes as follows, most of which they have confirmed. The arrows represent heating at 350° to 450°C except in the one case noted; this



latter change seems to have been carried out only under hot water (17). Pyrolusite, or β-MnO_2, and cryptomelane, or α-MnO_2, are the most stable forms, and of the two α-MnO_2 is much the more stable if it contains K^+ as the additional cation. Whether γ-MnO_2 and manganous manganite are converted to α-MnO_2 or to β-MnO_2 depends on the presence or absence of a suitable cation.

Heating at temperatures of 150° to 350°C affects the properties of γ-MnO_2 (26, 27). The potential of the MnO_2 (that is, the electrode potential when a MnO_2 electrode is made with the material in question, with an ammonium salt electrolyte unless otherwise specified) is decreased by heating. The discharge capacity is also decreased. Combined water is driven off at these temperatures and the

crystal form altered in the direction of increased crystallinity and partial conversion to a pyrolusite structure (11). The decreased discharge capacity may be related to both the decreased water content of the MnO_2 and its change in structure. The electrode potential is determined by the composition of the exterior of the oxide (28). Heating γ-MnO_2 at still lower temperatures, 90° to 140°C, affects the shape of the discharge curve, when electrode potential is plotted against time at constant current (29).

However, when the electrolyte is a solution of HCl and $MnCl_2$ the results are different. Maxwell and Thirsk (21) made electrodes from a number of different MnO_2 preparations, unheated and heated at various temperatures up to 500°C. Heating the MnO_2 either had little effect or caused an increase in the electrode potential, followed by a decrease at the highest temperatures. It is worthy of note also that the various artificial preparations of α-, γ-, and δ-MnO_2 all had electrode potentials higher than artificial β-MnO_2, the differences ranging from 30 to 80 mv.

Surface area.—Measurements of the surface area of MnO_2 by the gas adsorption method have revealed that the area in most cases is very large. For γ-MnO_2 areas of 20-60 m^2/g have been reported (25, 28). This is of the order of 10^5 times the surface of a gram of MnO_2 in the form of a smooth cube. For δ-MnO_2 a surface of 300 m^2/g was found (30), in agreement with the very thin crystal structure proposed for this variety.

The catalytic activity of any one sample of MnO_2 for the decomposition of H_2O_2 is dependent on the surface area, but different samples may differ widely in catalytic activity (5). Variation in the overpotential of similar preparations of electrodeposited MnO_2 electrodes with the temperature and current density of electrodeposition can be explained entirely as caused by variations in surface area (29). However, in general the electrochemical activity of MnO_2 is more dependent on the state of the surface than on the particle size (31).

Ion exchange and isotope exchange.—Manganese oxides, especially when freshly prepared, adsorb a wide variety of cations from solution with liberation of hydrogen ions. This has been considered an exchange adsorption (32), and MnO_2 when hydrated, as most samples are, is a weak acid (33). In the manganous manganites, $4MnO_2 \cdot Mn(OH)_2 \cdot 2H_2O$ and $3MnO_2 \cdot Mn(OH)_2 \cdot xH_2O$, the Mn(II) can be replaced by Zn or various other cations in a reversible ion-exchange reaction (7, 34).

Exchanges between radioactive Mn^{++} and inactive MnO_2 that range from very small to complete have been observed (7). The amount of exchange varies widely with the nature of the MnO_2 and the conditions. With compact lattice structures as in β- and α-MnO_2 and the minerals ramsdellite and chalcophanite exchange of radioactive Mn^{++} takes place only at the surface. There is no diffusion in the lattice. The more open α-MnO_2 structure gives more exchange. Samples of α- and β-MnO_2 having nearly the same surface area per gram gave exchanges of 12% for α and 0.1% for β. In compounds of similar structure and surface area, exchange varies with the amount of disorder. Increase of temperature increases the amount of exchange; a β-MnO_2 that exchanged 2% at room temperature exchanged 15% in a boiling solution (7).

Connected with the ion-exchange property is the observation that each MnO_2 ore or preparation has a characteristic iso-acidic point. This is an electrolyte *p*H of such a value that no change in *p*H takes place when the electrolyte is put in contact with the MnO_2. When MnO_2 is stirred with an electrolyte of higher or lower *p*H than the iso-acidic point the electrolyte *p*H is changed in the direction to approach this point. This change must be taken into account in measuring the change of MnO_2 electrode potential with *p*H. The iso-acidic point is not the same as the isoelectric point which was found to be at the fixed *p*H 6.5 (35).

Magnetic susceptibility.—The magnetic susceptibilities of a number of manganese dioxides have been measured by Selwood, *et al.* (36). Crystalline pyrolusite is a magnetically concentrated substance; that is, the manganese atoms are so close together that they affect each other magnetically. Artificial γ-MnO_2, a gel form of MnO_2, and Gold Coast and Brazilian ores were found magnetically dilute, indicating a more attenuated structure, in agreement with other data. These have the magnetic behavior expected of a Mn(IV) compound. It was found possible to follow the discharge of a dry cell by measurement of its magnetic behavior, since reduction of Mn(IV) causes an increase in susceptibility.

Conductivity.—It is known that MnO_2 is a semiconductor. Four samples of MnO_2 under high pressure (7×10^8 g/cm^2 or 1×10^5 $lb/in.^2$) gave resistivities of 37-77 ohm-cm (37). Electronic semiconductivity is large when electrons can pass easily from one cation to another. This is the case when ions of one element of different electrical charge occupy equivalent positions in the crystal lattice (38).

Activity.—The term "activity" of a MnO_2 sample is used in describing the practical performance of the material in batteries. Brenet (39) states: "A high activity corresponds practically to the possibility of releasing a maximum quantity of electricity with a maximum potential difference at the cell terminals, over as long a period as possible." This is a tentative definition and he points to the need for a satisfactory method of measuring activity other than by making cells and discharging them. Also, the relation of activity to other properties is not well enough understood.

Lower Oxides of Manganese

The lower oxides and hydroxides of manganese are of interest as possible products of the reduction of MnO_2 in the discharge of the MnO_2 electrode. Two forms of the next lower oxide, Mn_2O_3, have been described and are designated as α- and γ-Mn_2O_3 (40). The more stable is α-Mn_2O_3 which is formed by heating β-MnO_2 to constant weight at 600°C

(41, 40). The less stable oxide, γ-Mn_2O_3, is thought to play a part in the discharge of the MnO_2 electrode (42). It is converted to α-Mn_2O_3 by heating in a vacuum at 500°C or on standing for a year at room temperature (40). The x-ray diffraction pattern of γ-Mn_2O_3 is nearly identical with that of Mn_3O_4, indicating a similarity in structure of these two compounds.

The compound MnOOH occurs as the mineral manganite and can be prepared by oxidation of a Mn(II) salt under carefully controlled conditions. It is a final product of the discharge of the MnO_2 electrode (42-45) and of the reduction of MnO_2 with Mn^{++} at *p*H 4 to 5 in the absence of Zn^{++} (46). Heating MnOOH at 250° in a vacuum gives γ-Mn_2O_3 (40).

The compound $ZnO \cdot Mn_2O_3$, or $Zn(MnO_2)_2$, which occurs naturally as the mineral hetaerolite, is another final product of the discharge of the Leclanché cell (45, 47) and is formed in the reduction of MnO_2 by Mn^{++} in the presence of Zn^{++} (46). Conditions for its formation in the dry cell have been studied (47). It cannot be the only product of the discharge, or alternatively not a primary product, because its formation would not involve the increase of *p*H in the bobbin electrolyte that is observed during discharge (44).

All oxides and hydroxides of Mn when heated in air to temperatures in the vicinity of 1000°C are converted to Mn_3O_4, which occurs naturally as the mineral hausmannite.

The compounds MnO and $Mn(OH)_2$ are easily oxidizable by oxygen. It is remarkable that MnO can be oxidized most of the way to Mn_2O_3 before the x-ray diffraction pattern of MnO disappears completely and that of Mn_2O_3 appears (40).

The valence of Mn in some of the lower oxides is a matter on which there is lack of agreement at present. Krishnan and Banerjee (48) measured the magnetic anisotropy of MnOOH and concluded that this compound must be composed of equal parts of Mn(II) and Mn(IV). Brenet (42) prefers to assume only Mn(II) and Mn(IV) in the compounds involved in the MnO_2 electrode reaction. Verwey and de Boer (38) have presented evidence that Mn_3O_4 is composed of Mn(II) and Mn(IV) ions from the electrical conductivity and the crystal structure. On the other hand they presented similar evidence that γ-Mn_2O_3 contains only Mn(III). Since γ-Mn_2O_3 can be prepared by the dehydration of MnOOH in a vacuum at 250°, Mn(III) is suggested for the latter compound, in disagreement with the evidence from magnetic anisotropy. Bhatnagar, *et al.* (41) found a magnetic moment for α-Mn_2O_3 that indicates Mn(III).

The Discharge Mechanism

Early theories.—One of the early theories of the discharge of the MnO_2 electrode was that hydrogen was the primary discharge product, this being subsequently oxidized by the MnO_2. The MnO_2 thus acted as a depolarizer. No definite evidence in favor of this theory has been advanced, and the facts concerning the discharge mechanism can be explained more satisfactorily otherwise.

Another theory involved the formation of Mn^{+4} ions in the electrolyte. Against this is the fact that physical contact between the MnO_2 and the metallic conductor (carbon in the Leclanché cell) is necessary for the effect of the MnO_2 to be detected (49). Also, no appreciable amount of oxidizing substance is found in an NH_4Cl solution digested with MnO_2 (50).

Divers (45) in 1882 explained the polarization of the MnO_2 electrode as the result of the accumulation on the surface of the MnO_2 of the products of the reaction, which he correctly identified as MnOOH and $ZnMn_2O_4$. Divers' explanation of the polarization seems not to have received the attention it deserved. Relatively recent experiments have led to a similar view of the mechanism.

Newer experimental data.—Some of the newer experiments have been carried out on dry cells, but more often special MnO_2 electrodes have been constructed that avoid some of the complications of the dry-cell bobbin. In any case the MnO_2 is brought into intimate contact with either carbon or platinum, by pressure or by electrodeposition of the MnO_2. Except in dry cells, a relatively large volume of electrolyte usually is employed to keep changes in composition small. In what follows it will be assumed that the electrolyte is NH_4Cl solution, with or without added $ZnCl_2$, unless otherwise specified. Potential measurements usually have been made with the help of a reference electrode.

In a dry-cell bobbin an increase in *p*H takes place on continuous discharge, and a decrease takes place near the zinc electrode. The increase in *p*H, resulting from the release of NH_3 in the electrode reaction, is partially compensated by the formation of $Zn(NH_3)_2Cl_2$ and other similar complex salts (44). This increase in *p*H shows that $Zn(MnO_2)_2$ is not the primary product of the discharge of the MnO_2 electrode of the Leclanché cell, as mentioned above.

Even when appreciable *p*H changes are avoided, or corrections made, the electrode potential of a discharging MnO_2 electrode decreases. The decrease is fairly rapid at first and may be slow later. If the circuit is opened the potential rises fairly rapidly at first, then more and more slowly for a period of days, but does not reattain the initial potential (51). The potential decrease during discharge may be described as a decrease in open-circuit potential combined with a rather large polarization. The growth and decay of this polarization is much slower than in most electrode systems, indicating that it is not simple activation polarization or concentration polarization involving the solution (52, 53). Substitution of other ammonium salts for NH_4Cl makes little or no difference (51) and discharges in 4.4M KOH give much the same results (54).

In the absence of $ZnCl_2$ two products of discharge are observed under most conditions. Mn^{++} is found in solution (55-57) and when the discharge is carried to the point of rapid decrease in potential which terminates the useful part of the discharge an oxide (or oxide mixture) of the composition $MnO_{1.6}$ remains (56, 57). In this solid MnOOH can be recognized by its x-ray diffraction pattern (42).

Analysis of the bobbins of discharged dry cells shows Mn in three forms. Some Mn can be extracted from the bobbin material by a solution of NH_4Cl and $ZnCl_2$ and presumably comes from Mn(II) compounds in the bobbin. The insoluble portion contains both MnOOH and $Zn(MnO_2)_2$. The formation of these products by reduction of MnO_2 accounts quantitatively for the current passed in the discharge (58).

Data on the formation of Mn^{++} as a product of the discharge reveal something of the discharge mechanism. With an electrolyte of H_2SO_4 and $MnSO_4$ it is the only discharge product, other than H_2O (59). At *p*H 5 in the discharge of γ-MnO_2 electrodeposited on graphite with NH_4Cl or $(NH_4)_2SO_4$ electrolyte, Mn^{++} is formed throughout the discharge. At *p*H 7.5 or 8 under the same conditions no Mn^{++} is formed in the early part of the discharge (56, 60). The amount of Mn^{++} formed at any one *p*H is independent of the volume of the electrolyte. The presence of Zn^{++} in the electrolyte reduces the amount of Mn^{++} (61).

Changes in the x-ray diffraction pattern of the oxide during a discharge have been observed (42). Starting with γ-MnO_2, the diffraction patterns indicate an expansion of the crystal lattice as the discharge proceeds. With α-MnO_2 the expansion is not as evident, but is believed to take place. After discharge of a little less than half of the theoretical capacity of the MnO_2 a sudden change in the pattern takes place. The new pattern is that of either γ-Mn_2O_3 or Mn_3O_4 (these being nearly the same), and of the two the γ-Mn_2O_3 is considered the more probable. Finally the pattern of MnOOH appears. When β-MnO_2 is reduced electrolytically only the change to MnOOH is observed.

Interpretation of the experiments.—The slow rate of decay of polarization led Coleman (52) to propose that a solid-state diffusion process is involved. Lower oxide formed on the surface of the MnO_2 is thought to cause the polarization, and a diffusion process operates to remove it (51, 56). This involves the assumption that the composition of the surface of the oxide determines the electrode potential (27, 28). The decay of polarization can then be interpreted as an increase in the available oxygen content of the surface as the result of removal of lower oxide. However, another probable contributing factor is discussed below.

The diffusion process involved in the discharge need not be considered an actual diffusion of Mn and O atoms. The same effect can be attained and electroneutrality preserved within the solid by diffusion of protons and electrons only. Since MnO_2 is a semiconductor we may suppose that electrons can pass through it by being transferred between Mn atoms in different stages of oxidation but at equivalent positions in the crystal lattice (38). Protons can be attached to $O^=$ ions to give OH^- ions. If protons can be transferred from surface OH^- ions to underlying $O^=$ ions and at the same time electrons move from surface Mn ions to underlying ones, the lower oxide on the surface has effectively moved and MnO_2 has moved outward. This should cause the expansion of the MnO_2 lattice that is observed, because Mn^{+3} is larger than Mn^{+4} and OH^- is larger than $O^=$.

The changes taking place during discharge can be explained similarly. To reduce MnO_2 requires electrons for the Mn atoms and protons for attachment to the O atoms. Electrons come from the electrode and with physical contact between electrode and oxide they are available anywhere within the MnO_2. Protons are available from NH_4^+ ions of the electrolyte or from H_2O. The reaction may be considered to take place where the electrons and protons meet, for it may be considered that here the oxide is reduced. Qualitatively, the meeting place can be considered to to be at the surface of the MnO_2 exposed to the solution. One reason for postulating this location is the formation of Mn^{++} in the solution. The indications are that the Mn^{++} is dissolved from a surface oxide by action of the electrolyte (61). The reduction reaction on the surface is followed by reaction of part of the lower oxide to give Mn^{++} and inward diffusion of the remainder.

A somewhat different view is that during the discharge the protons penetrate the oxide and meet the electrons in the interior (42, 57). Some of the reaction must still be considered to be on the surface to explain the formation of Mn^{++} and the growth and decay of polarization in terms of an increase in the amount of lower oxide during current flow and its decrease when the circuit has been opened (62).

To decide between the two suggested locations of the reaction one may ask whether diffusion inward from the surface is fast enough to account for the reduction of MnO_2 during a discharge to an oxide of the composition $MnO_{1.6}$. Some recent experiments in the author's laboratory indicate that it is not, and we must assume with Brenet (42) and Naumann and Fink (57) that protons from the solution can penetrate to the interior of the oxide during a discharge.

There is a disagreement as to the valence of Mn in the solid primary product of the electrode reaction. Brenet (42) points to the instability of Mn^{+3} in solution and to the evidence that the final product, MnOOH, is composed of equal amounts of Mn(II) and Mn(IV), and prefers to assume that Mn^{++} [or $Mn(OH)_2$] within the oxide structure is the primary product. This eventually combines with an equivalent amount of MnO_2 to give MnOOH. Others (55, 56) have assumed the formation of a Mn(III) compound as the first step in the reduction. This may be followed by further reduction to Mn^{++}, especially on the surface, accounting for the large fall in potential during discharge.

There can be little doubt that Mn^{+3} is the first reduction product of Mn^{+4}, because the simultaneous entrance of two electrons into a Mn^{+4} ion is improbable. The question is whether this ion is stable on the surface of, or within, a MnO_2 structure or must be immediately reoxidized or reduced to Mn^{++}. While Mn^{+3} is unstable in solution, some of the Mn(III) complexes are quite stable. This is true, for example, of the pyrophosphate complex, which is soluble and sufficiently stable to be the reaction product in a precise titration (63). The bonds to oxygen joining the Mn to the complex must be somewhat similar to the bonds between Mn and O in the solid oxide.

Because there is a possibility of the stable existence of a Mn(IIII) oxide (or oxyhydroxide) on (or in) the MnO_2 it will be assumed in what follows that this is the primary product of the reduction of MnO_2. The discussion would be little different if $Mn(OH)_2$ were assumed.

The discharge mechanism.—A definite discharge mechanism can be formulated on the basis of the above experiments and conclusions. It is constructed to apply to electrodeposited MnO_2 on a graphite rod, but should be easily adaptable to a bobbin.

When current starts, electrons from the electrode and protons from the solution meet at the surface of the MnO_2 exposed to the solution and also beneath the surface, many of the protons penetrating the crystal lattice of the MnO_2. The electrons are retained by Mn atoms and the protons are attached to $O^=$ ions to form OH^- ions.

$$MnO_2 + H^+ + e^- \rightarrow MnOOH$$

The surface of the MnO_2 is very large, so the true current density is small, and with a concentrated electrolyte the ordinary concentration polarization is small. There is no evidence of appreciable activation polarization. However, as the surface composition changes from largely MnO_2 to one containing much MnOOH the electrode potential decreases. This decrease is slow because the surface is large and because much of the lower oxide is formed beneath the surface. There is in addition a diffusion toward the interior where there is less lower oxide. With γ-MnO_2 the decrease in potential is slower than with α-MnO_2 or with γ-MnO_2 that has been heated (29). It may be concluded that in α-MnO_2 and heated γ-MnO_2 the penetration of the protons is less than in the unheated γ-MnO_2, and consequently the surface gains lower oxide more rapidly.

When enough MnOOH has accumulated on the surface of the MnO_2 further reduction to $Mn(OH)_2$ takes place.

$$MnOOH + H^+ + e^- \rightarrow Mn(OH)_2$$

Then Mn^{++} appears in the electrolyte and as the surface is reduced further giving a larger surface concentration of Mn(II) the potential continues to fall.

The lower oxides on the surface will react with the electrolyte if the composition and *p*H are suitable. At *p*H 5 MnOOH can react.

$$2MnOOH + 2H^+ \rightarrow MnO_2 + Mn^{++} + 2H_2O$$

As the *p*H increases the surface must be further reduced to react appreciably.

$$Mn(OH)_2 + 2H^+ \rightarrow Mn^{++} + 2H_2O$$

These reactions are slow and do not come to equilibrium in short discharges (60). They are not dependent on current flow and continue after the circuit is broken. Therefore, more Mn^{++} is formed in an intermittent discharge than in a continuous one (56).

When after a period of discharge the circuit is broken, the excess lower oxide on the surface decreases fairly rapidly at first and then more and more slowly. Inward diffusion of the lower oxide takes place and if conditions are favorable the oxide also reacts with the electrolyte to give Mn^{++}. The potential therefore rises, but since the MnO_2 as a whole now contains less available oxygen than initially the potential never reattains the initial value.

A discharge terminates with a relatively rapid decrease in potential when the formation of reduction products on the surface is considerably faster than their disposal. What causes this condition is not clear. The only suggestion is that the lattice hardens and protons can no longer penetrate it (57).

Daniel-Bek (64) has presented a different theory to account for the polarization and recovery of the MnO_2 electrode. He observed that the potential of graphite or carbon in contact with NH_4Cl solution is very stable and is less than that of MnO_2. Also, a mixture of MnO_2 and carbon in contact with NH_4Cl solution has a smaller potential than MnO_2 alone. This was also observed by Jennings and Vosburgh (50). MnO_2 in contact with carbon and electrolyte is considered to constitute a short-circuited local cell. Such a cell is like a local cell on a metal surface, but with larger resistance in the electronic portion of the circuit. With the electrode as a whole on open circuit the current in the local cell is small because of polarization, but because of the appreciable resistance between MnO_2 and carbon the potential of the carbon is smaller than that of the MnO_2. Both are smaller than the true open-circuit potential of the MnO_2.

When the MnO_2 electrode is discharged the potential of the carbon decreases more than that of the MnO_2 and its surface (which is of low capacity) is partly discharged. The potential of the carbon determines the measured potential of the electrode as a whole. When the external circuit is broken the carbon must be recharged by the local-cell current before a steady state is reattained.

The theory of Daniel-Bek accounts qualitatively for the polarization and recovery of the MnO_2 electrode and is in accord with the effect on the electrode behavior of variation of the surface area of the carbon. It seems probable that both this and the theory based on the changes in composition of the MnO_2 will need to be taken into account in a complete theory of the MnO_2 electrode process.

A mechanism has been proposed by Cahoon and coworkers (55, 58) that differs somewhat from the one described above. They consider the MnO_2 to be reduced electrochemically directly to Mn^{++} which passes into solution. The Mn^{++} then reacts with MnO_2 to give MnOOH, or with MnO_2 and Zn^{++} to give hetaerolite. This is quite similar to the mechanism of Brenet (42). He considers that the electrochemical reaction is reduction to Mn^{++} within the MnO_2 lattice. The Mn^{++} passes into solution (but not necessarily immediately) and forms $Mn(OH)_2$ which is oxidized to MnOOH. More research is needed to reconcile the different theories that have been proposed.

Acknowledgment

The preparation of this paper was supported in part by the Office of Ordnance Research.

Manuscript received Feb. 25, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Brief Communication

Investigations on the Silver-Zinc Alkaline Storage Battery by the Aid of Radioactive Isotopes

Theodore Z. Palágyi

Central Research Institute for Chemistry, Hungarian Academy of Sciences, Budapest, Hungary

The failure of silver-zinc storage batteries is generally caused by the negative electrode, and less often by the separator or the positive electrode (1, 2). Both silver and zinc have isotopes with suitable hard gamma radiation and half-life of about ¾ year; consequently these isotopes can be used easily for labelling of electrodes. This fact induced us to employ Zn^{65} and Ag^{110} isotopes for the purpose of life tests and for investigating processes taking place during storage of the cells.

Our method was based on the hypothesis that, if Zn^{65} isotope is deposited on one of the negative plates of the cell, then the path of the ions while cycling can be followed by the aid of the radioactive contamination of the surface of the nonlabelled plates. The same principle was used to label with Ag^{110} isotope the positive electrode of experimental cells and to follow the path of the dissolved silver ions.

The experiments were performed with cells of 10 amp-hr nominal capacity. Both the zinc and the silver isotopes were deposited on the electrodes by electrolysis. The quantity of the deposited isotope was controlled partly by measuring the activity change of the electrolysis solution and partly by measuring the activity on the electrode itself, with a cylindrical GM-tube, as well as by the autoradiographic method.

The investigations were performed with cells assembled in three different ways: loosely, normally, and more tightly than normal. Each cell contained only one labelled (positive or negative) plate. After formation, some of the experimental cells were cycled and the others were subjected to storage. One charging-discharging cycle lasted 24 hr. After each tenth cycle a measuring discharge was performed.

As far as possible examinations were performed simultaneously on the cells assembled in the three different ways. The cells were opened after the first 20 cycles and after each 20 subsequent cycles, and the degree of contamination of the individual plates with isotope was examined. Then the electrodes were replaced in the cells and the cycling was continued, with the exception of the tightly assembled cells in which the electrodes could not be replaced.

On the basis of contamination with isotope of the nonlabelled electrodes, our experiments show that the zinc ions dissolved from the labelled negative plate can reach not only the other negative plates but the positive electrodes too. The degree of migration of the zinc ions considerably depends on the mode of building in of the electrodes and on the quantity of the electrolyte; in tightly assembled cells having little electrolyte the migration of the zinc ions is of lower degree. The failure of the loosely assembled cells was usually caused by coming to an end of the reversibility of the negative electrode as well as by the formation of acicular zinc crystals, resulting in short circuit. Failure of the tightly assembled cells was caused rather by the separator losing its insulating properties; moreover, the active material of the positive electrode dissolved and reached the negative electrode. Our investigations with Ag^{110} isotope related to this problem and to the storage of cells are still under way.

Manuscript received May 14, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Oxide Films Formed on Copper Single Crystal Surfaces in Pure Water

I. Nature of the Films Formed at Room Temperature

Jerome Kruger

National Bureau of Standards, Washington, D. C.

ABSTRACT

A study was made of the nature of the films that formed on carefully prepared surfaces of single crystals of copper immersed in water containing varying amounts of oxygen, with the surrounding atmosphere both controlled and uncontrolled. It was found that the amount of oxidation depended on the crystallographic orientation of the metal surface. Cu_2O was the oxide observed if $pH \leqq 5.7$. Intense white light markedly retarded film formation in water. When Cu_2O was formed, it had a preferred orientation and exhibited epitaxial relationships to the metal similar to those found in high-temperature oxidation. The films formed were not continuous but were composed of small nuclei of Cu_2O. Both Cu_2O and CuO were formed at pH 7 when the water was in equilibrium with an atmosphere of pure O_2. Lowering the pH converted CuO to Cu_2O.

The oxide films that form on a metal surface are one of the very important factors influencing most corrosion processes. These films affect the potential that the surface exhibits and influence the transport of metal ions away from it. Both of these aspects are interrelated and have an important influence on the corrosion of metals. In connection with work on the fundamentals of corrosion sponsored by the Corrosion Research Council, the subject selected for study was the growth of films on metal surfaces in contact with pure water containing oxygen. This system was chosen because most corrosion encountered in practice involves metal, water, and oxygen, plus a number of other substances. Thus if some understanding can be gained of this simple system, it would serve as a basis for study of the complicated systems that are related more closely to practical cases.

The metal chosen to initiate this study was copper, because it has a simple structure, and high-purity metal is available from which single crystals may be prepared easily. Its oxides are few and simple, and a great deal of fundamental data on its properties is available.

Work on the growth of films on Cu in water in the past (1-4) has been done generally on poorly characterized metal surfaces under conditions where the nature of the surrounding atmosphere and the purity of the water was not rigidly controlled. Much work has been done on the corrosion of Cu in aqueous solutions of many different compositions. However, with the possible exception of the work of Miller and Lawless (5) on single crystals, the surfaces used were in general poorly characterized. As a consequence the studies carried out are not as significant from a fundamental standpoint as they should be.

The work described here employs surfaces whose nature is better known than the surfaces used in most of the corrosion studies of Cu in aqueous media. The approach in this investigation was to use single-crystal surfaces, carefully prepared so that they would be as clean as possible and free from strain (6). This paper is concerned with some qualitative studies of the nature of the films formed on Cu in pure water containing oxygen. A subsequent paper will report studies of the rate of film formation.

Experimental Procedure

Materials.—The crystals used in this investigation were grown using OFHC Cu which has a purity of 99.99%.[1] The Bridgman technique of slowly cooling a melt was used to grow crystals in the shape of spheres ⅜ in. in diameter with a cylindrical shaft ¼ in. in diameter and ¾ in. in length. The water was obtained from the Physical Chemistry Section of the National Bureau of Standards and had a conductivity of 7×10^{-7} mhos.

Preparation of the metal surface.—In a number of experiments the as-cast single-crystal sphere was used after following appropriate cleaning and polishing procedures. These consisted in washing the crystal successively in water, ethyl alcohol, diethyl ether, and again in ethyl alcohol and water prior to electrolytically polishing the crystal in a phosphoric acid-water solution 50% by volume. After the electrolytic polishing was completed (1 hr the first time after casting, 10-20 min all times thereafter) the crystal was washed very carefully to remove traces of phosphate ions, following the schedule described by Young, Cathcart, and Gwathmey (6), who found that this washing procedure left a surface that oxidized reproducibly. In the case of experiments carried out in the room atmosphere, the crystal was immediately immersed while still wet in distilled water. When it was introduced into

[1] Spectrographic analysis showed that the Cu used contained 0.001 to 0.01% Ag and < 0.0001% Si, Al, Fe, Mg, Ni, and Pb.

the reaction chamber of the apparatus designed for carrying out the process under controlled conditions, the water remaining on the crystal was evaporated by evacuation of the system. Whenever the crystal was handled, preflamed gold-plated tongs were used to hold the shaft of the crystal.

For some studies three flat surfaces were cut parallel to the {111}, {110}, and {100} crystallographic planes. After cutting these surfaces the crystal was etched in nitric acid to remove the strained layer resulting from this operation. The orientations of the surfaces were checked and corrected, if they differed by more than 2° from the desired orientation. These surfaces then were polished mechanically with metallographic polishing papers through No. 0000 and lapped on a metallographic wheel with a water suspension of Linde B abrasive. From this point on the procedure was as described above.

Reaction apparatus and procedure.—Two different groups of experiments were carried out using Cu crystal surfaces prepared as described above. In the first group the nature of the surrounding atmosphere was not controlled. The procedure in this case was simply to immerse the crystal after electropolishing and washing directly, and while still wet, in 100 ml of distilled water. The crystals were mounted in glass holders and gas washing bottles were used as reaction vessels.

In the second group of experiments the nature of the surrounding atmosphere was controlled by carrying out the reaction in the enclosed apparatus shown in Fig. 1. The crystal, after polishing and washing, was introduced together with the glass crystal holder into the reaction chamber through its top, using a preflamed platinum hook. Introducing the crystal into the apparatus in this manner eliminated the need for greased ground joints with the attendant possibilities for contamination. The top of the chamber then was sealed. An oxy-hydrogen flame was used in the sealing process rather than the ordinary natural gas-oxygen flame because the latter was found to introduce contaminants. The high-purity water was introduced into the freeze-down tube and boiled before sealing and pumping. Half of the water in this tube was distilled in vacuum into the water-introduction tube by placing a Dewar flask of liquid nitrogen around this tube.

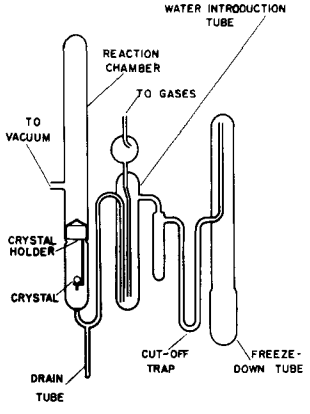

Fig. 1. Apparatus for oxidizing Cu single crystal in water under controlled conditions.

The frozen water so collected was thawed and then pushed into the reaction chamber by helium. The purpose of this part of the procedure was to rinse off any impurities that might have collected on the crystal during the time when it was being placed into the reaction chamber. The water was removed by breaking open the drain tube and pushing it out with a positive pressure of helium. The drain tube then was resealed, and the water remaining in the freeze-down tube was kept frozen in liquid nitrogen until required. Liquid nitrogen also was placed around the cut-off trap as an added measure to prevent any water from reaching the reaction chamber while it was being baked at 500°C overnight at a pressure of 10^{-5} mm. After this baking procedure, with the water still frozen in the freeze-down tube, the crystal was annealed in purified dry hydrogen at 500°C for 2 hr to remove the air-formed oxide film present on the crystal surface. The system then was evacuated, brought to room temperature, and the water in the freeze-down tube distilled over to the water-introduction tube by cooling this tube in liquid nitrogen. This water was thawed, pushed into the reaction chamber by the desired gas (e.g., dry purified oxygen), and the corrosion process allowed to start. To halt the reaction, the water was drained by cracking open the drain tube, resealing, and evacuating the system to dry the crystal. The crystal then was removed for examination by cracking open the top of the reaction chamber.

Results

Corrosion in Water with the Surrounding Atmosphere Uncontrolled

In these experiments, which were essentially preliminary in order to explore and determine the nature and magnitude of the effects to be studied, the Cu was immersed in water that was in contact with the room atmosphere. The spherical single crystal offers an ideal tool for exploratory experiments of this type because all of the crystallographic planes are represented as poles on the surface of the sphere and thus all of them can be studied simultaneously.

The following results were obtained from these experiments:

1. Oxidation was the most readily apparent reaction taking place.

When a crystal was placed in water deoxygenated by boiling, and either hydrogen or helium was bubbled in, no film formation was observed and the crystal remained bright. When oxygen was present, however, a film whose presence was indicated by the appearance of interference colors on the Cu was formed after exposure to the water.

2. At room temperature, oxide films formed on the Cu surface considerably faster in water than in air.

If a Cu crystal was allowed to stand in dry air or oxygen at room temperature no interference colors, which give an indication of the thickness of the films growing on the metal surface, were observed after weeks of standing. In water, however, colors

started to develop after standing only 30 min. Within 6 hr films exhibiting interference colors indicating thicknesses greater than 1000Å were observed.

3. The rate of oxidation varied with the crystallographic plane.

The thickness and thus the color of films formed on Cu exposed to air-saturated water varied with the crystallographic plane on which they were growing. Since all of the crystallographic poles could be observed simultaneously on the spherical crystal these differences could be seen easily. After a given time of exposure a symmetrical pattern made up of many different colors was obtained on the sphere, thus indicating a variation in the amount of film growth with crystallographic orientation. Such a pattern is shown in Fig. 2. Because the patterns formed on the single crystal spheres were extremely sensitive to a very minute change in environment or surface condition, many different patterns were observed unless the nature of the surrounding atmosphere, and the cleanliness of the water and the metal surface, were controlled rigidly. Thus, on the basis of these preliminary experiments carried out in the room atmosphere, it is not possible to list definitely the various crystallographic planes in the order of their relative rates of oxidation.

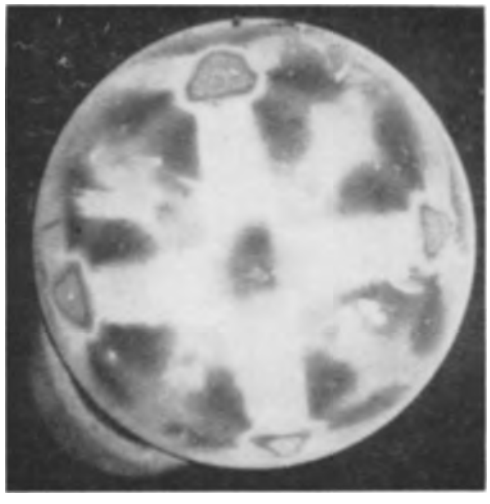

Fig. 2. Pattern formed when Cu single-crystal sphere is corroded in air-saturated distilled water at room temperature.

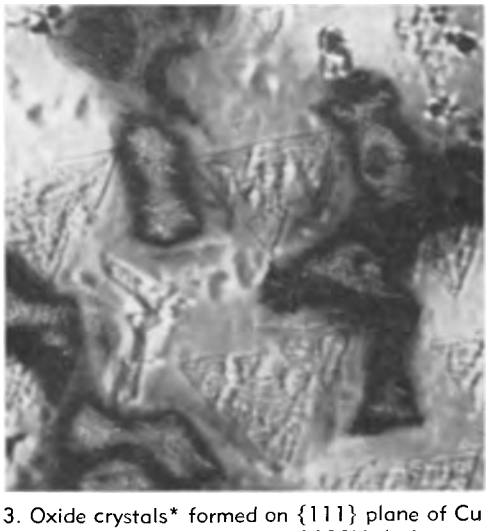

Fig. 3. Oxide crystals* formed on {111} plane of Cu crystal oxidized in water. Magnification 1000X before reduction for publication.

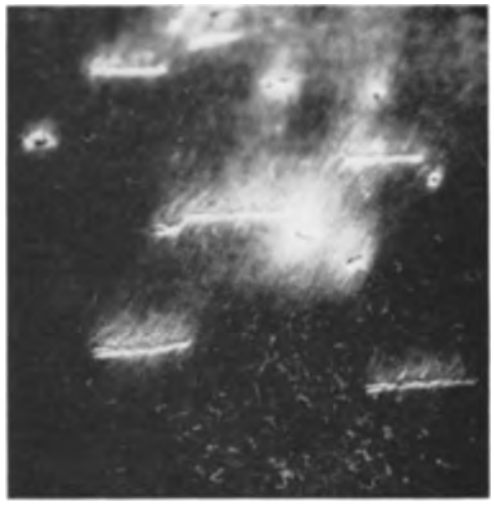

Fig. 4. Oxide crystals* formed on {110} plane of Cu crystal oxidized in water. Magnification 1000X before reduction for publication.

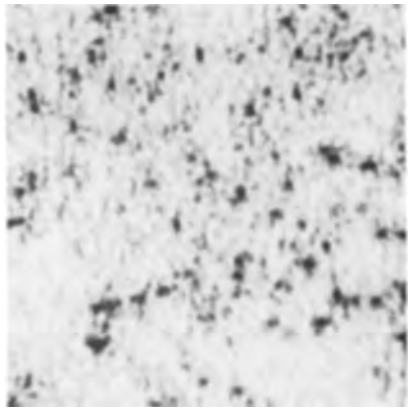

Fig. 5. Oxide crystals* formed on {100} plane of Cu crystal oxidized in water. 1000X.

4. The oxide films were not continuous.

When observed with unaided eye, the oxide films appeared to be uniform. However, microscopic examination indicated that the oxide films were made up of particles or nuclei. Figures 3, 4, and 5 show these oxide nuclei formed on a Cu surface exposed to water on three different crystallographic planes.

5. The degree of orientation and epitaxy of the oxide films depended on the crystal faces upon which they were grown.

X-ray diffraction studies, using the oscillating crystal technique described by Lawless and Gwathmey (7), were carried out to determine the chemical nature of the films and their epitaxial relationship to the metal substrate. Studies of the films formed on Cu crystals exposed to distilled water in an uncontrolled atmosphere for 18 hr showed them to be composed of Cu_2O made up of many crystallites exhibiting a preferred orientation with respect to the Cu substrate. In general, the degree of preferred orientation was higher for the {111} and {110}

* Note that the shape of some of the crystallites are indicative of the symmetry of the crystallographic orientation of the plane on which they are growing.

Table I. Epitaxial relationships between Cu and Cu_2O

{111}	{111}
{110}	{110}
{100}	{111}

planes than that for the {100} plane. The epitaxial relationships, i.e., the mutual orientation relationship between the Cu_2O and the Cu substrate, are shown in Table I.

These relationships agree with those found by others (7-9) on Cu single crystals oxidized in dry oxygen at temperatures considerably above room temperature.

6. Light had a marked influence on the oxidation process in water.

A number of attempts were made to obtain time-lapse motion pictures of the corrosion process of a Cu single crystal in air-saturated water. These were not successful because it was found that the light used to illuminate the crystal had a marked influence on the corrosion process (10). As a consequence, it was decided to study the effect of light on the oxidation process of Cu in water. A water-jacketed vessel, light-tight except for a small hole which allowed light to impinge on half of a crystal sphere, was employed, as shown in Fig. 6. When the crystal was immersed in air-saturated water in this vessel, illuminated by a tungsten 3200°K lamp, and kept at room temperature by the water jacket for 3 hr, the amount of oxidation on the area of the sphere exposed to the light was markedly different from that of the shaded area (see Fig. 7 and 8). Using a simple electroreduction technique similar to that of Miley and Evans (11) to estimate film thickness, it was found that the illuminated part of the crystal had a thickness of roughly 120Å or less,

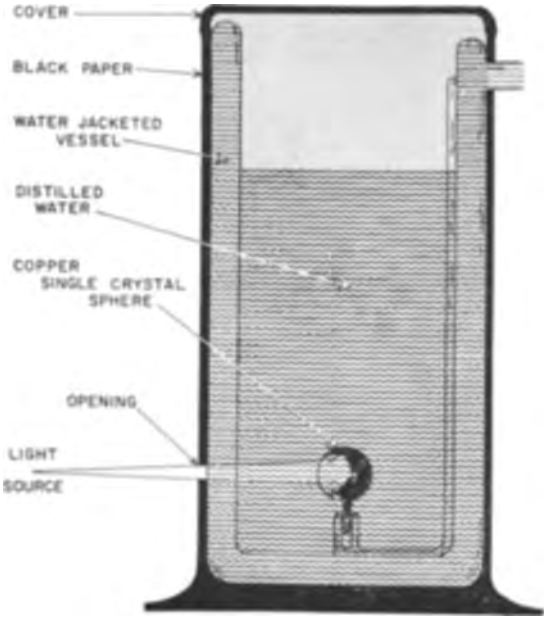

Fig. 6. Apparatus for studying influence of light on oxidation of Cu crystal in water.

Fig. 7. Copper single crystal oxidized in air-saturated distilled water at 25°C. Lower side was exposed to light from a 3200°K tungsten lamp, upper side kept dark.

Fig. 8. Boundary between dark and illuminated areas of Cu single crystal surface oxidized in air-saturated distilled water at 25°C. Upper region kept dark, lower illuminated. 500X.

while the part that was kept dark had an average thickness of approximately 550Å. Further, if light were allowed to impinge on part of a Cu crystal immersed in water and already containing a water-formed oxide film about 1000Å thick or greater, some of the oxide on the illuminated portion dissolved after a period of 2-3 hr and became thinner than the part kept dark. X-ray diffraction studies of the films formed on both the dark and the illuminated parts of the crystal showed that the films were composed of well-oriented Cu_2O.

Mott's theory (12) for Cu-Cu_2O photocells may provide an explanation for this effect. On the basis of this theory, illumination would cause a flow of electrons from the semiconductor film, Cu_2O, into the metal. A flow of electrons in this direction when the film is growing would thus inhibit growth. It is interesting to point out that for Al_2O_3 and Ta_2O_5, which are cation excess semiconductors, illumination enhances oxidation, while Cu_2O, a cation deficient semiconductor, oxidation is inhibited. Besides

this explanation, based on the effect of illumination on the electrons on the solid side of the solid-liquid interface, another explanation based on the influence of light on chemical reactions at the metal-solution interface should be considered also. These reactions may be important, for it is known (13) that light promotes the oxidation of cuprous ions to cupric. Thus any Cu_2O that forms may be oxidized to CuO. Since the latter is the more soluble of the two, it may go into solution rather than form a film, as in the case of the Cu_2O.

Corrosion in Water with Surrounding Atmosphere Controlled

In these experiments the techniques described in the Experimental Section for preparing the crystal surface and reacting it with pure water in a controlled atmosphere were utilized. The results obtained differed considerably from those observed under uncontrolled conditions.

In the controlled experiment the Cu crystal was immersed in high-purity water, which was stirred and kept saturated by bubbling O_2 through it at a rate of approximately 50 ml/min at 1 atm and 25°C. Oxidation was considerably slower in these experiments than in the experiments where the nature of the atmosphere was uncontrolled. It was found that after 1 hr the film thickness was roughly 70Å, and after 8 hr the thickness had not changed appreciably. After 50 hr of exposure the average value of the thickness was about 110Å. Also it was noted that some solid powder had settled to the bottom of the reaction chamber. The electroreduction technique was used to estimate the film thicknesses. This method was not precise enough to allow any definite statements to be made regarding the differences in the thickness of the films on the three crystallographic planes since the differences between them were less than the experimental error.

When the solution, saturated and in equilibrium with 1 atm of O_2, was not stirred but instead allowed to remain quiescent, the corrosion process was quite similar to that in the stirred solution for the first few hours, but after 7 hr a visibly thick brownish black to purplish black film of oxide had formed. This film had a powdery appearance and could be removed partially by wiping with a tissue. Beneath it another film exhibiting interference colors could be observed sometimes.

If the partial pressure of the O_2 in equilibrium with the water were reduced by introducing mixtures of O_2 and He containing varying proportions of these two gases, the time required for the appearance of CuO increased as the partial pressure of O_2 decreased. Thus, with 100% O_2, 7 hr elapsed before CuO was observed by the unaided eye, while with 20% O_2 the time was twice as long, and with 10% O_2, over 24 hr elapsed.

X-ray diffraction examinations of {111}, {110}, and {100} faces, reacted in the presence of oxygenated water under controlled conditions, revealed the presence of polycrystalline randomly oriented CuO. In a few cases Cu_2O also was found to be present along with the CuO. When this was so, the Cu_2O showed the same type of preferred orientation and epitaxial relationships as described for the experiments conducted in uncontrolled atmospheres. This Cu_2O probably was responsible for the film that exhibited the interference colors when the CuO was wiped off. When CuO was present, the film, as observed by the unaided eye and by microscopic examination, was thinnest on the {110} planes and thickest on the {100}, with that on the {111} being intermediate. The electroreduction technique could not be used to measure CuO film thickness because of the great difficulties encountered in reducing the CuO.

It is believed that the reason CuO was not formed on the Cu surface when the solution was agitated was that cuprous ions, on reaching the solid-liquid interface through the Cu_2O film, were caused by the agitation to oxidize in the body of the solution and precipitate as $Cu(OH)_2$ or CuO, whereas under quiescent conditions the cuprous ions were oxidized to cupric ions at the interface and formed CuO there. In all cases Cu_2O is present next to the Cu as CuO is reduced in the presence of Cu.

It is evident that the behavior of the Cu was markedly different when immersed in oxygenated water in the room atmosphere than when the environment was controlled more rigidly. In the first case films of oriented Cu_2O were formed on the Cu surface after a relatively short exposure to water. These films exhibited interference colors and formed beautifully symmetrical patterns. When the conditions were controlled, the Cu oxidized much more slowly and formed dark randomly oriented CuO films. Beneath the CuO films thin films of Cu_2O probably were present also. In an effort to duplicate the experiments in which the water was in contact with the room atmosphere under controlled conditions, it was found that by lowering the *p*H to 5.7 (the *p*H observed in water exposed to the room atmosphere), Cu_2O was observed. The *pH* was lowered by the introduction of CO_2. With still lower *p*H's, Cu_2O also was observed. The influence of CO_2 was demonstrated by an experiment in which CuO was formed on Cu in a closed system by exposing the Cu to water saturated with pure oxygen. Carbon dioxide was bubbled in for 1 min and the corroded crystal then was exposed to this water for 24 hr. At the end of this period, all of the CuO had been converted to Cu_2O. X-ray diffraction examination of the Cu_2O formed in this fashion revealed, however, that it was much more poorly oriented

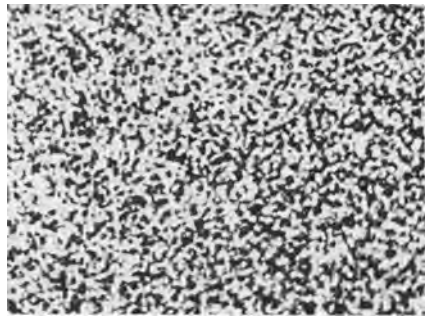

Fig. 9. {100} plane of Cu oxidized in oxygen-saturated water under controlled conditions. 1000X.

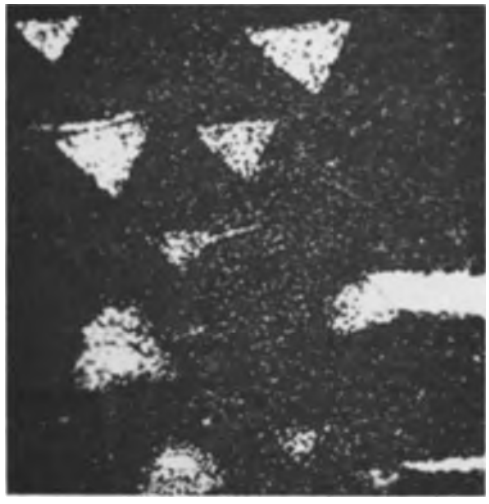

Fig. 10. {111} plane of Cu oxidized in oxygen-saturated water under controlled conditions. Magnification 1000X before reduction for publication.

than where CO_2 was present from the beginning of the oxidation process.

The morphology of the oxide films as revealed by the microscope was of great interest. After the oxidation had proceeded to the point where CuO could be observed, the film on the {110} plane was similar to that on the {100} plane (Fig. 9). Most of the surface of the {111} plane, however, was covered with the black CuO film but, as shown in Fig. 10, there were triangular areas that appeared Cu colored. It is interesting to note that some of the triangles had orientations that are 180° with respect to each other. This indicated that perhaps some nuclei of Cu_2O existed next to the Cu surface. Cu_2O could exist in these two orientations because of the epitaxial relationships found between Cu_2O and a {111} plane of Cu (7). Figures 11, 12, and 13 show the {111}, {110}, and {100} faces, respectively, after the CuO had been converted to Cu_2O by the introduction of CO_2.

Discussion

The first fact which was noted from these studies concerned with the nature of the oxides is that Cu_2O

Fig. 11. Cu_2O formed on {111} plane of Cu by conversion of CuO which was present initially. The change was caused by introduction of CO_2 into aqueous solution. Magnification 1000X before reduction for publication.

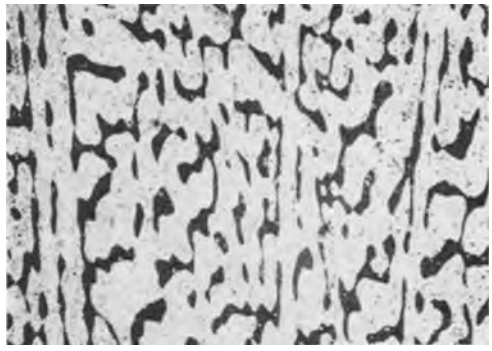

Fig. 12. Cu_2O formed on {110} plane of Cu by conversion of CuO which was present initially. The change was caused by introduction of CO_2 into aqueous solution. Magnification 1000X before reduction for publication.

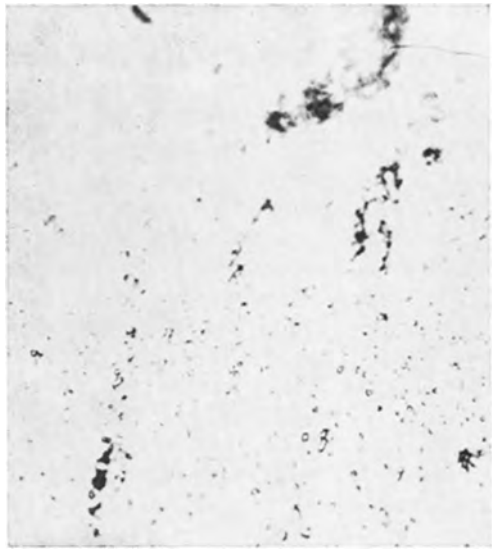

Fig. 13. Cu_2O formed on {100} plane of Cu by conversion of CuO which was present initially. The change was caused by introduction of CO_2 into aqueous solution. 1000X.

was formed when Cu was exposed to water in equilibrium with air, the *p*H of the water being about 5.7. This is the oxide formed initially by dry air oxidation. Further, the epitaxial relationships between the Cu_2O and the metal substrate were the same both for oxidation in solutions and in dry gases. Finally, the extent of oxidation depended on the crystallographic orientation of the surface in both cases.

The one very evident difference between oxidation in air and oxidation in water was that at room temperature oxidation occurred more rapidly in water (exposed to air) than it did in air. It is also known from the work of Miller (14) that, if Cu is immersed in a solution of cupric sulfate, the reaction is even more rapid than if Cu is immersed in pure water. Cu_2O is the product formed in copper sulfate solution and the epitaxial relationships between oxide and metal are the same as those mentioned above. The nuclei contained in films formed during oxidation in solutions were larger than those formed during oxidation in gases. Finally, the influence of light was much more pronounced when oxidation occurred in solutions than when it occurred in gases. A few attempts were made to see if illumination had any influence on the oxida-

tion of Cu in pure oxygen at 250°C but no marked effects were noted.

These differences between oxidation in air-saturated water and oxidation in air, are probably due to the ability of metal ions during aqueous oxidation to move through the water and take part in reactions at sites on the surface that differ from those from which these ions emerged initially. This transport of ions through a solution is, of course, an all-important factor in electrochemical reactions occurring on metal surfaces immersed in an electrolyte. It is not the purpose of this paper to discuss the mechanism of oxidation in water but to be concerned only with the nature of the films formed. However, because of the ability of the water to transport ions, soluble substances can be removed from a surface or insoluble substances can be deposited onto a surface. On account of these processes the oxides formed in water in equilibrium with 1 atm of pure oxygen at room temperature differ from those formed by gaseous oxidation at room temperature. Thus, besides the Cu_2O commonly present at room temperature CuO was also observed.

This has not generally been found in most of the previous studies of the films that form on Cu in contact with aqueous solutions because most of these experiments were carried out under conditions where the presence of CO_2 was not rigorously excluded. The formation of CuO when CO_2 is absent is to be expected on the basis of the diagram of Pourbaix (15). This diagram enables the prediction of the thermodynamically stable phases present under a given set of conditions. On the basis of this diagram it may also be concluded that by lowering the pH and the partial pressure of oxygen there would be a tendency for the CuO to go over to Cu_2O.

However, the thermodynamic considerations on which the Pourbaix diagram is based are not sufficient to allow the prediction of the solid phases present. Thus, for the conditions existing during the oxidation of Cu in water saturated with air and exposed to the room atmosphere (pH = 5.7, $pO_2 = 10^{-0.699}$ atm) the formation of CuO would be expected, although Cu_2O was observed. The rate at which cupric ions build up in solution is also of utmost importance in determining the oxide observed. Thus, if enough time were allowed and if all of the components of the system were kept in intimate contact with each other, CuO would be observed at pH 5.7 in air-saturated water. Actually, what appeared to happen was that at this pH the CuO was soluble to such an extent and the rate of cupric ion formation by oxidation of cuprous ions was sufficiently slow so that only the considerably less soluble Cu_2O was observed.

At a pH of 7, however, the solubility of CuO is less than at the lower pH and with the water in equilibrium with 1 atm of oxygen, the time required to observe the formation of CuO visually was about 7 hr. Experiments with pure water in equilibrium with different partial pressures of oxygen show that apparently the rate of cupric ion formation did depend on the partial pressure of the oxygen, for the time to observe CuO formation increased with a decrease in partial pressure. During this time, before the appearance of CuO, only Cu_2O was observed. When the pH was lowered from 7, after the formation of CuO by the introduction of CO_2, the solubility of CuO was increased and it went into solution.

The Cu_2O that is always next to the Cu was then the only oxide observed and its thickness actually started to increase at the lower pH where it was still quite insoluble. This indicated that the rate of cuprous ion formation was probably faster than the rate of oxidation of cuprous ions to cupric. This question of the rate of film formation and the rate of cupric and cuprous ion formation will be discussed in a more quantitative fashion in the next paper in this series. These details must be investigated before a more nearly complete understanding of the corrosion of Cu can be achieved.

An Electron Microscopic Study of the Formation of Oxide on Copper Single Crystals Immersed in an Aqueous Solution of Copper Sulfate

G. Tyler Miller, Jr.[1], and Kenneth R. Lawless

Cobb Chemical Laboratory, University of Virginia, Charlottesville, Virginia

ABSTRACT

Electron microscope and electron diffraction techniques were used for the examination of the different faces of a single crystal of copper which had been immersed in an aqueous solution of $CuSO_4$ containing dissolved oxygen. During the reaction a thin film of Cu_2O was formed initially and continued to grow in the form of well-defined oriented polyhedra of oxide. For immersion times of 24 hr or more, etching of the metal surface and of the oxide polyhedra occurred due to a decrease in the pH of the solution. An attempt was made to interpret the oxide growth in terms of the electrochemical theory of corrosion and the dislocation theory of crystal growth.

Although the reactions of metals with aqueous salt solutions are among the commonest of reactions and have been the subject of many investigations, the influence of surface structure on these reactions is only poorly understood. Most previous studies have been carried out on fine-grained polycrystalline specimens, and the interpretation of the results is complicated by the presence of grain boundaries and by differences in activity of the different crystal faces. In addition to this, an understanding of the reactions involved is frequently difficult because little or no information is available on the structure of the surface before and after the reaction.

This study is concerned with the electron microscopic and electron diffraction examination of the different faces of a carefully prepared single crystal of copper which has been immersed in an aqueous solution of copper sulfate containing dissolved oxygen. During the reaction oxide is formed and some etch pits are developed. The epitaxial relationship of these oxide films with the metal surface as determined in this study are described in detail in another paper (1).

Interesting types of oxide structures were found, and an attempt was made to interpret the oxide growth in terms of the electrochemical theory of corrosion, the structural relationships of the oxide to the underlying metal, and the dislocation theory of crystal growth. The results indicate clearly that the understanding of one of the simplest of reactions, important in an understanding of corrosion, is dependent on a careful study of surface structure.

Experimental Procedure

The experimental procedure consisted of exposing known crystallographic surfaces of copper single crystals to an aqueous solution of cupric sulfate at a known concentration, temperature, and pH. The oxygen concentration in the solution was approximately constant. After definite periods of immersion the surfaces of the specimens were examined with the aid of optical and electron microscopes and by electron diffraction.

Copper single-crystal rods of 99.999% copper were grown from the melt and machined into the form of spheres 5/8 in. in diameter. Flat faces parallel to specific crystallographic planes were cut on the spheres. The surfaces of these crystals were mechanically polished and then electrolytically polished, followed by thorough washing and drying as previously described (2). The Laue back-reflection technique was used to take x-ray diffraction photographs after every three or four experiments to make sure that each face remained within 1° of the desired orientation. Great care was taken in the preparation of these specimens in order to obtain known surfaces as free as possible from chemical contaminations and structural imperfections.

The copper specimens after being washed and dried were placed in a Pyrex reaction chamber. The system was then evacuated, purified hydrogen admitted, and the specimen annealed at 500°C for 1 hr to remove any oxide present on the surface and to relieve any residual strains in the crystal. The specimen was cooled to 25°C in an atmosphere of hydrogen, and then, without exposing it to the air, the crystal was lowered to the bottom of the reaction chamber which was immersed in a water thermostat maintained at 25° ±0.02°C. An aqueous solution of $CuSO_4$ could be admitted into the reaction chamber through a Pyrex tube which was ring-sealed to the base of the chamber. The top end of the tube was ground flat so that a flat face of a crystal could be placed on it and a reaction carried out on only one face. A glass cup was sealed to the upper part of this tube so that the crystal could be suspended within the cup and sufficient solution admitted to cover the whole crystal if desired. After being exposed to the aqueous solution for the de-

[1] Present address: Department of Chemistry, Hampden-Sydney College, Hampden-Sydney, Virginia.

sired length of time, the crystal was removed, washed thoroughly in distilled water to remove any $CuSO_4$, and dried in a jet of nitrogen.

Solutions of $CuSO_4$ were prepared using 50 g/liter of doubly recrystallized reagent grade $CuSO_4 \cdot 5H_2O$ and distilled water. The *p*H of the solution was measured before and after each experiment with a L&N *p*H indicator. The *p*H of the solution initially was 3.8 for all experiments. The oxygen concentration in this solution was approximately 10^{-4} moles per liter.

After reaction the surfaces of the copper crystals were examined using both optical and electron microscope techniques and in many cases electron diffraction techniques. It was not possible to examine the surfaces directly with the electron microscope, and it was therefore necessary to use a replica technique. For all of these studies carbon replicas approximately 100Å thick were made of the surfaces (3). These were removed using a stripping solution such as 10% KCN, 1:1 orthophosphoric acid water or 10% ammonium persulfate. The stripped replicas were mounted on the usual 200 mesh, ⅛ in. diameter grids, and these were then shadowed with Cr, Pt-20% Pd, or Pd (4). The angle of shadowing varied from 5° to 30°, depending on the appearance of the surface as indicated in the optical microscope, the lower shadowing angle being used for the smoother surfaces. The shadowed replicas were examined with the RCA EMU-3B electron microscope operated at 50 or 100 kv.

In a few cases, the reaction product was stripped from the copper surface using a modification of the electrolytic stripping technique described by Harris, Ball, and Gwathmey (5). These stripped films were then examined by transmission electron microscopy and electron diffraction. In order to determine the surface products and their structural relationships to the metal substrate, representative specimens were examined with high voltage electron diffraction (60-80 kv), utilizing reflection techniques (6). In these cases, after reaction, washing, and drying, the specimens were transferred immediately to the diffraction apparatus in order to minimize the possibility of surface contamination.

To determine the importance of copper ions in the solution, several experiments were carried out using a solution of 50 g/liter of K_2SO_4 instead of $CuSO_4$.

Experimental Results

Oxidation of a spherical crystal of copper in dry oxygen gas gave a symmetrical "oxidation pattern" of brilliant colors (2). A black and white photograph of such a pattern is shown in Fig. 1a. Such a pattern was due to the interference colors formed with different thicknesses of oxide on different crystal faces. In the present study, similar oxidation patterns were formed when electropolished crystals were immersed in an aqueous solution of $CuSO_4$ at 25°C which contained dissolved oxygen. With careful surface preparation, these patterns were easily reproducible. A typical oxidation pattern formed under these conditions after an immersion time of 1 min is shown in Fig. 1b. Reflection electron diffraction showed that the surface product was Cu_2O. It was obvious for the immersed specimens that there were differences in the oxidation on the different crystal faces, although the patterns were not as striking as in the case of dry oxidation in oxygen. Transmission electron diffraction studies on stripped oxide films and measurements of shadow heights on electron micrographs of replicas indicated that most of the oxide was greater than 1000Å thick after an immersion time of 5 min in the $CuSO_4$ solution. This is to be compared with an oxide thickness of less than 100Å for dry oxidation of copper at 25°C over a period of months, (7) and of 70Å for oxidation of copper in pure water at 25°C for a period of 8 hr (8). The rate of oxidation was therefore much faster for crystals immersed in $CuSO_4$ solution than for those exposed to dry oxygen or to water containing oxygen at the same temperature.

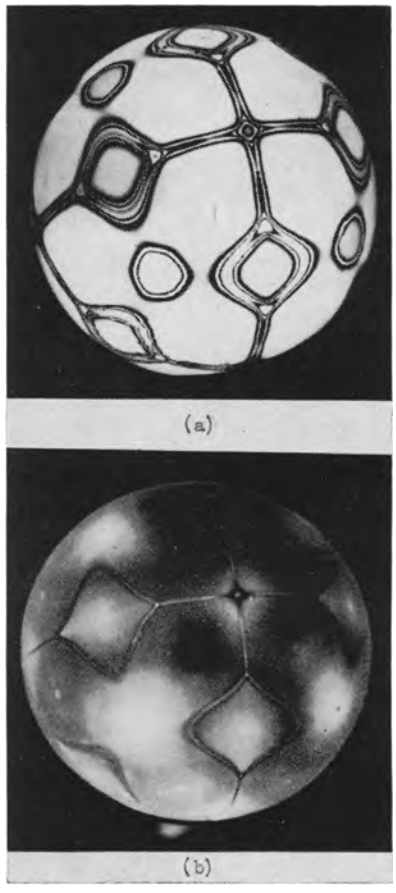

Fig. 1. Oxidation patterns on spherical copper single crystals: a, 20-min oxidation in oxygen at 250°C at atmospheric pressure; b, 1-min oxidation in aqueous $CuSO_4$ at 25°C, pH 3.8.

In order to observe the structural details of the oxide formation on the different crystal faces of copper, flat faces parallel to specific crystal planes were immersed in $CuSO_4$ solutions. In this way differences due to crystal face and the effects of time of immersion could be studied.

Back reflection x-ray diffraction patterns of the flat faces indicated that the cold worked surface layer produced by the mechanical polish was removed by the electropolish. Electron micrographs of

carbon replicas of the metal surface after electropolishing and annealing show no indications of pitting, facet development, or other type of roughness. The surfaces were very smooth with only a slight waviness of the order of 2°. The micrograph is not reproduced here since it would appear only as a plain gray area. Electron diffraction patterns showed sharp Kikuchi lines.

The effect of time of immersion on the oxidation was studied on five crystal faces, the (110), (100), (111), (210), and (311) for immersion times from 30 sec to 90 hr at a solution temperature of 25°C. Figure 2 shows the results of this study on the (110) face for representative immersion times of 30 sec, 24 hr, and 60 hr. Figure 3 shows the results on the (100), (111), (210), and (311) faces for an immersion time of 60 hr. The results at 30 sec and 24 hr for these faces were similar to the (110), the major differences being the shapes of the oxide growths and the relative coverage of the surface by the oxide.

Well-shaped polyhedra of Cu_2O single crystals varying in diameter from 300-3000Å were present on all faces after 30 sec in $CuSO_4$. The coverage of the surface varied from face to face, but in no case was there a complete coverage of the surface by the polyhedra. For oxide crystals 1000Å in diameter the heights of these polyhedra as determined from shadow lengths were roughly 500-700Å. The oxide polyhedra grew larger with time. This growth was both parallel and normal to the copper surface. After 24 hr the oxide polyhedra had grown together so as to give a more complete coverage of the surface, with many individual crystals 20,000-30,000Å in diameter, although some of 1000Å or less were still present. The pH of the solution had changed from 3.8 to 3.4 in this period of time.

After 60 hr in $CuSO_4$, the appearance of the surface was much more complicated. The coverage of the surface was rather uneven, some areas being almost completely covered with large oxide polyhedra which had grown together as in Fig. 3b and 3c. Other areas were only partially covered as in Fig. 3a and 3d, and some areas were almost free of large oxide figures as shown in Fig. 4. These latter regions frequently showed a considerable amount of etching of the metal surface, in addition to small oxide polyhedra. This etching was usually in the form of well-shaped etch pits. This is shown in Fig. 4. It was also apparent that some etching of the larger oxide polyhedra had taken place (Fig. 3c). Some of the oxide crystals were as large as 300,000Å (30 μ) in diameter, whereas others were only of the order of 1000Å. The pH of the solution at the end of 60 hr had changed from 3.8 to 3.2.

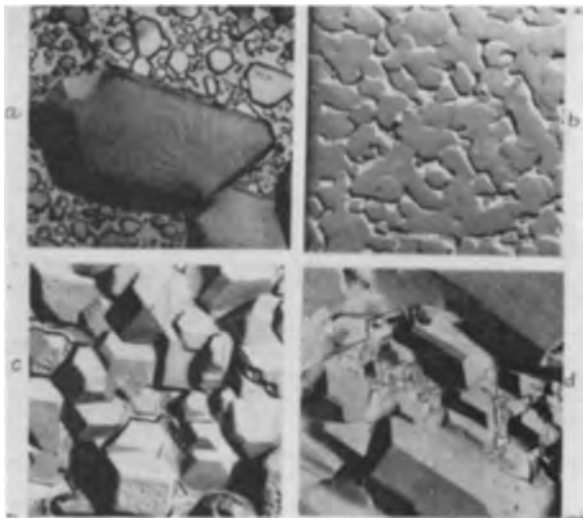

Fig. 3. Appearance of surfaces after 60-hr immersion in $CuSO_4$ solution at 25°C, pH 3.2; a, (100) face; b, (111) face; c, (210) face; d, (311) face. Magnification 3500X before reduction for publication.

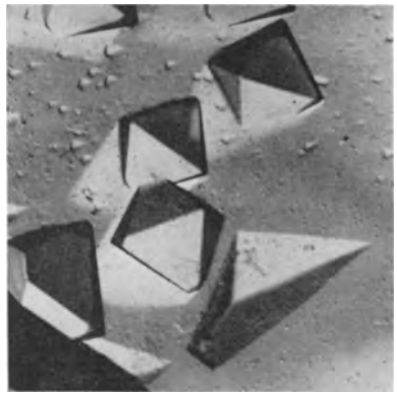

Fig. 4. Etch pits and oxide polyhedra on (210) face after 60-hr immersion in $CuSO_4$ solution at 25°C, pH 3.2. Magnification 6200X before reduction for publication.

After 90 hours' immersion the specimen surfaces were similar to the 60-hr specimens, except that considerably more etching both of the oxide and of the metal surface had taken place.

Both optical and electron microscopic examination of specimens after 24-, 60-, and 90-hr immersion showed that the larger oxide polyhedra usually had complex step and spiral structures present on their surfaces. In most cases the spirals were present on the (111) surfaces of the oxide. The spirals were observed only once on another oxide face, the (100). Figure 5 shows an example of a spiral on the (111)

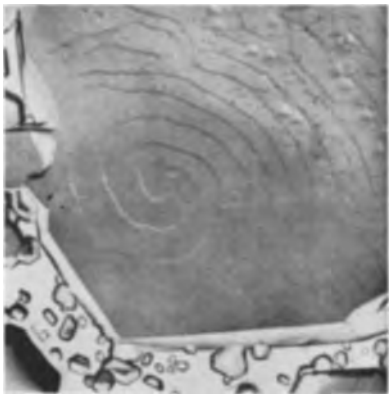

Fig. 5. Spiral growth on (111) surface of Cu_2O formed on the (100) face of copper immersed for 60 hr in $CuSO_4$ solution at 25°C, pH 3.2. Magnification 6200X before reduction for publication.

face of Cu_2O. The step height of the spirals was determined from the shadows and was in the range 100-200Å. No spirals were observed on the smaller oxide growths. In general the spiral systems were more complex than that shown in Fig. 5 and frequently more than one spiral system was present on a given oxide crystal. A more complex spiral system can be seen on the large oxide polyhedron in Fig. 3a.

Both electron diffraction and electron microscopy showed that the oxide grew such that there were specific epitaxial relationships between the oxide and the metal on the different crystal faces. These results will be reported in more detail elsewhere (1). In general the orientation relationships were the same as those previously determined for dry oxidation by Lawless and Gwathmey (9), and for oxidation in pure water by Kruger (8), and Lawless (7).

The very early stages of the oxide growth were studied on specimens which had been immersed for 15 sec. The oxide film was stripped from the copper electrolytically and examined by the electron microscope. Figure 5a shows the appearance of the oxide on the (100) face of copper. The similarity of this to electron micrographs of the early stage of dry oxidation at 150°C (5, 7) was striking. At higher magnifications the dark oxide crystals showed the same shapes as appear in Fig. 3. Electron diffraction (Fig. 6b) indicated that not only well-oriented single crystal particles of oxide but also a continuous polycrystalline thin film of Cu_2O were present. These diffraction studies indicated that the thickness of this thin film was certainly less than 50Å and probably less than 20Å.

Cu_2O also formed on crystals which were immersed in an aqueous solution of K_2SO_4, but at a rate much slower than that for crystals immersed in an aqueous solution of $CuSO_4$. The amount of oxide formed in an hour was of the same order of magnitude as the amount formed on a crystal immersed in distilled water (8).

The oxide on the surface of a copper crystal could be dissolved by dipping the crystal in a 10% HCl solution for about 15 sec. When this experiment was carried out for a crystal on which oxide had been formed by immersion in $CuSO_4$, the oxide dissolved leaving a bright copper surface showing no apparent roughness or etching of the metal surface. When the same experiment was carried out using a crystal with an oxide film of comparable thickness which was formed by oxidation in dry oxygen gas, the surface appeared roughened and faceted.

Discussion

The results of this study revealed some of the extreme complexities arising in the oxidation of a metal in an aqueous salt solution. Any completely satisfactory mechanism for the reaction of copper in aqueous $CuSO_4$ solution must explain the rapid growth of individual Cu_2O polyhedra, the presence of spirals on the oxide, and the presence of both etch pits and oxide figures on the same surface.

Formation of oxide on the copper immersed in this solution was dependent on the *p*H of the solution. Cu_2O was the only oxide observed in these studies in which the *p*H ranged from 3.8 to 3.2. At a *p*H below 3 only etching of the copper was observed. The results under these conditions do not appear to be important to this discussion and will be treated elsewhere. The formation of Cu_2O only was to be expected on the basis of the work of Pourbaix (10) since this is the only oxide stable in the *p*H range 3.8 to 3.2.

It was obvious from the irregular thickness of the oxide as shown in the micrographs that rate measurements, in the usual sense of the word, would have limited value for reactions of this nature, even when made on carefully prepared single-crystal surfaces. However, it was apparent that the total amount of oxidation on a given area of surface

was much greater when the crystal was immersed in the $CuSO_4$ solution than when immersed in pure water or when oxidized in dry oxygen at the same temperature for the same length of time. The role of the aqueous salt solution is probably a twofold one of providing an easier path for the flow of electrons and ions and a readily available source of copper ions, thus enabling a more rapid oxidation to occur.

A consistent mechanism which can explain the oxide formation can be arrived at from the data available in the micrographs and diffraction patterns and from theoretical considerations. A thin polycrystalline film of Cu_2O, 20-30Å thick, was formed almost immediately, covering the whole metal surface. The electron diffraction patterns indicated that such a film was formed in these studies, and experimental and theoretical work by Hoar and Evans (11) suggested that the formation of a thin compact oxide film was the initial stage for many reactions in aqueous salt solutions. Studies on oxidation in dry oxygen (5) also indicated that the formation of a thin polycrystalline oxide was the initial stage of oxidation in that case.

This initial oxide film contained many grain boundaries and probably a large number of imperfections. In air at 25°C the subsequent growth of this base film was extremely slow, whereas in aqueous $CuSO_4$ solution certain oxide nuclei in the base film continued their growth at a very rapid rate, as seen in Fig. 2-6. Why should certain of these oxide crystals have continued to grow rapidly while others essentially stopped growing or, at best, grew only slowly? First, it was apparent from the diffraction patterns that the crystals which grew rapidly were well oriented with respect to the base metal. Second, during the later stages of growth it was apparent that imperfections in the oxide polyhedra were playing an important role in the continued growth of the oxide. It is probable that imperfections in the initial thin film were important as well. It seems likely, therefore, that the oxide crystals in the base film which continued to grow rapidly were those which had a specific orientation with respect to a particular face, and which had the proper number and type of imperfections necessary for continued rapid growth.

It is now necessary to explain how these specific oxide crystals could grow so much faster in aqueous $CuSO_4$ than in pure water or dry oxygen. The fact that oxide formation was much slower in an aqueous solution of K_2SO_4 than in $CuSO_4$ is an indication of the importance of the copper ions in the solution. In addition, the fact that the metal surface was not roughened appreciably by the formation of a thick oxide is perhaps further evidence that the bulk of the copper ions converted to oxide came from the solution rather than from the metal. It seems likely, therefore, that after the initial formation of the thin oxide film, for which copper ions would be available both from the metal and from the solution, the bulk of the oxide is produced by reaction of copper ions from the $CuSO_4$ solution.

The initial oxide film could be produced either by reaction of copper with oxygen adsorbed on the surface from solution

$$2Cu + \tfrac{1}{2} O_2 \rightarrow Cu_2O \qquad [1]$$

or by reaction of cuprous ions with water or hydroxyl ion

$$2Cu^+ + 2\,OH^- \rightarrow Cu_2O + H_2O \qquad [2]$$

In these experiments it was not possible to distinguish between these possibilities.

The subsequent growth of the oxide could take place either by reaction [2] above or by the reaction of Cu^{++} ions with water at suitable sites on the surface where electrons would be available [3].

$$2Cu^{++} + 2e^- + H_2O \rightarrow Cu_2O + 2H^+ \qquad [3]$$

This is of course essentially the same reaction as [2], only assuming the reduction of cupric ion to cuprous ion at suitable reduction sites on the oxide surface. Since this is a reduction, an oxidation reaction is necessary also. Two possible oxidation reactions are

$$Cu \rightarrow Cu^+ + e^- \qquad [4]$$

and

$$Cu \rightarrow Cu^{++} + 2e^- \qquad [5]$$

According to Hoar and Evans (11) it would be possible for metal ions to go into solution with migration of these ions through an oxide film on the metal surface. This would be expected to take place at imperfections in the oxide such as would be created by lattice defects or grain boundaries, or at very thin regions of the oxide. Since we are concerned with a very thin oxide film, tunnelling of electrons can take place setting up a strong electric field which would assist the movement of metal ions through the oxide (12).

If the copper surface is not completely covered with an oxide film, in addition to reactions [4] and [5], an additional reaction can occur

$$Cu + Cu^{++} \rightarrow 2Cu^+ \qquad [6]$$

Although it seems likely that in the oxygen containing $CuSO_4$ solution a continuous film of oxide would be present on the copper surface, it is not possible from these experiments to conclude definitely that there are no regions on the surface which are free of oxide. There is therefore a possibility that reaction [6] does occur in the aerated solution. The fact that appreciable etching of the copper surface does not occur until the pH has decreased considerably would indicate that the extent of this reaction is at best rather small in the early stages of the reaction. If a copper crystal having a thin air-formed oxide film on its surface is immersed in aqueous $CuSO_4$, additional oxide is formed. This is further evidence that reaction [6] is not important in the early stages of the reaction.

In some preliminary experiments using deaerated aqueous $CuSO_4$ it was found that oxide formed on the copper crystal apparently as rapidly as in the experiments with aerated $CuSO_4$. Similarly, over a

period of 24 hr the pH of the deaerated solution decreased from 3.8 to 3.2. Electron microscope observations of the surfaces of copper crystals immersed in deaerated $CuSO_4$ solution showed the same type of oxide structures as observed with oxygen containing solutions. The regions between the oxide polyhedra seemed, however, to be etched to a greater extent in the experiments with deaerated solution. This could be a result of reaction [6].

The similarity between the behavior of copper in aerated and deaerated $CuSO_4$ solutions indicated that basically the same oxide formation process was occurring in both cases. This is apparently reaction [2],

$$2Cu^+ + 2\,OH^- \rightarrow Cu_2O + H_2O \qquad [2]$$

El Wakkad (13), however, states that the solubility product for this reaction is not exceeded for solutions of the concentration and pH used in these experiments. Since Cu_2O is definitely formed in these experiments it seems probable that the value for K_{sp} of 7.18×10^{-14} taken by El Wakkad (13) is too large and that the value given by Feitknecht (14) of 1.5×10^{-15} is more reasonable.

A calculation of the thickness of oxide formed on the copper based on the stoichiometry of Eq. [2] was made from the pH change and gave a figure of the right order of magnitude. It was not possible to make an exact comparison since the thickness irregularity of the oxide growths made it impossible to get more than an approximate average thickness for the actual oxide formed. The exact concentration of Cu^+ ion in the original solution was not measured, but the maximum concentration possible can be calculated from the solubility product. This amount of Cu^+ ion is less than the amount needed to form the observed amount of oxide and therefore additional Cu^+ ions must be formed either from the metal by reaction [4], from the solution by reduction of Cu^{++} ions at suitable reduction sites on the surface, or by reaction [6] if bare places are available on the metal surface.

It is possible that in the aqueous solution of $CuSO_4$ containing oxygen which was used for most of these experiments that the reaction

$$\tfrac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2\,OH^- \qquad [7]$$

is of importance. This reaction at the oxide surface could produce locally a higher OH^- concentration making it easier to exceed the K_{sp} in aerated solutions. From the experiments with deaerated solutions, however, reaction [7] does not seem to be necessary for the oxide formation in these experiments.

It seems probable, therefore, that reaction [2] is the main process responsible for the oxide formation with either reaction [3], [4], or [6] being responsible for the conversion of additional copper or cupric ions to cuprous ions. This latter point cannot be settled conclusively from the experimental data available at this time. This reaction [2] would lead to a decreased pH as observed. The reaction would take place on the surface of particular oxide crystallites where the oxide growth is energetically most favorable. The oxide will form rapidly since initially copper ions are readily available from the solution for reaction without the necessity for diffusion through the bulk of large oxide crystals. The oxide polyhedra can then continue to grow provided a suitable mechanism for their growth is available.

It has been shown theoretically (15) and experimentally (16) that the emergence of a screw dislocation on a crystal face provides a mechanism for continued rapid crystal growth without the necessity of two-dimensional nucleation on the surface. In this study the larger oxide polyhedra invariably showed spiral or step growth features for times of immersion of 24 hr or more. This indicated strongly that the rapid growth of these polyhedra in the later stages of growth was due to the presence of screw dislocations in the oxide. The presence of complete spirals on the surfaces was also a good indication that the growth was continuing by means of volume diffusion of copper ions and not by surface diffusion or diffusion through the bulk of the oxide. It is probable that the spirals were not observed at the earlier stages of oxidation because of the small size of the oxide particles and the difficulty of shadowing such small step heights. The screw dislocations apparently had large Burgers vectors which were stabilized by the presence of impurities (17). This type of imperfection could arise at any stage in the oxide growth because of stresses in the oxide or the growing together of two or more slightly disoriented oxide crystals.

Copper specimens immersed for 24 hr or more in the $CuSO_4$ solution showed etching of both the metal and the oxide polyhedra. This occurred with an attendant decrease in the pH of the solution. According to reaction [2], a decrease in the pH of the solution was to be expected because of the decrease in hydroxyl ion during the reaction. At a pH of 3.2, a state very close to equilibrium is attained and it might be expected that some solution of the oxide would occur at high energy sites of the oxide. Since the thin oxide film probably consisted of many imperfect crystals with numerous grain boundaries. it would be more subject to attack than the more perfect oxide polyhedra. Thus the thin oxide would dissolve or partially dissolve at specific sites and etching of the metal could occur. The thin oxide film is probably re-formed at these sites fairly rapidly after its solution. Imperfections in the oxide polyhedra would also provide high energy sites which would be subject to attack by the H^+, as observed.

The exact function of the dissolved oxygen in the $CuSO_4$ solution is not understood. It will be necessary to continue experiments in which the oxygen has been removed completely from the solution before this point can be clarified.

Summary

When a copper crystal was immersed in an aqueous $CuSO_4$ solution of pH 3.8, a thin film of Cu_2O, 20-30Å thick, formed immediately over the whole surface. Particular oxide crystals in the base film continued to grow at a rapid rate forming well-defined oriented polyhedra showing only (111),

(100), and (110) faces. Growth spirals were observed on the larger oxide polyhedra after immersion time of 24 hr or more. With long periods of immersion in the aqueous solution the *p*H of the solution decreased to 3.2, and etching of both the metal surface and the oxide occurred. The rapid formation and growth of the isolated oxide polyhedra was explained on the basis of a readily available supply of copper ions, both from the metal and from the solution, an electrochemical mechanism of reaction, and a dislocation mechanism of crystal growth.

This investigation has indicated the importance, and indeed the necessity, of using both electron microscope techniques and carefully prepared single-crystal surfaces if studies of surface reactions are to have any meaning. Details of the metal surface or of the thin oxide film structure, which are too small to be resolved or seen clearly with the optical microscope, can be of the utmost importance in determining the course of a chemical reaction such as oxidation or etching. It is through the study of such structural factors at the high magnifications possible only with the electron microscope, that a better understanding of corrosion processes can be obtained.

Acknowledgment

The authors would like to thank Drs. A. T. Gwathmey, N. Cabrera, and R. E. Cunningham for many discussions pertaining to this work. We would also like to thank Dr. R. H. Kean for carrying out the preliminary studies with the deaerated $CuSO_4$ solutions. This research was supported by a grant from the Office of Naval Research.

Manuscript received Oct. 20, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Influence of Silicon on the High-Temperature Oxidation of Copper and Iron

J. W. Evans and S. K. Chatterji

Department of Metallurgy, University of Manchester, England

ABSTRACT

The effects of 1 at. % of silicon on the oxidation behavior of pure copper at 850°-1000°C and of pure iron at 950°-1200°C have been studied by means of a thermobalance. Silicon has a marked effect on the oxidation of iron but relatively little on that of copper. The distinctive behavior is attributed mainly to the different diffusivities of oxygen in the base metals. The depth of subscale formed in the iron alloy suggests that the diffusivity of oxygen in iron is much faster than is commonly supposed.

The high-temperature oxidation resistance of many metals is improved by small additions of silicon. The beneficial effects of Si in steel have been demonstrated frequently and the general pattern of oxidation behavior established (1-5). During oxidation several distinct layers are formed. At the outside surface there is a very thin Fe_2O_3 layer; next to this is a somewhat thicker magnetite layer and this is followed by the thickest layer adjacent to the metal (about 90% at 800°-1000°C) which is wüstite or nonstoichiometric FeO. Because the oxidation of the Fe in the Si steel occurs almost entirely by the outward diffusion of ferrous ions to the surface, the Si concentrates at the oxide-metal interface to form a thin, coherent layer. This layer may consist of fayalite ($2FeO \cdot SiO_2$) or silica, depending on the Si content and temperature.

Silicon has less effect on the oxidation resistance of Cu than it has on Fe. A review of the oxidation behavior of Cu alloys relating to work up to about 1950 has been given by Tylecote (6). The oxidation of a Cu-Si alloy proceeds similarly to that of Fe in

which cationic diffusion outwards of Cu ions occurs. The scale is principally cuprous oxide with a thin outer layer of cupric oxide. Unlike Si in Fe, however, the Si does not invariably concentrate at the oxide-metal interface but may well accumulate in the alloy, the precise behavior depending on the Si concentration initially and the temperature. For example, Preece and Dennison (7) found that a 2% Si-Cu alloy gave a layer of silica at the metal-oxide interface only below 800°C. This layer was absent above this temperature, and above 900°C the Si accumulated in the alloy to such an extent that a liquid Cu-Si phase was formed.

A distinctive feature of the oxidation of Cu alloys is the formation of an extensive subscale caused by the relatively rapid inward diffusion of oxygen into the alloy which precipitates finely disseminated silica throughout the metal matrix. Subscale formation in Cu alloys has been investigated thoroughly by Rhines, Johnson, and Anderson (8), who demonstrated that the depth of subscale was determined principally by oxygen diffusivity. Subscale formation in Fe-Si alloys has been observed but not quantitatively investigated.

In this present work, precise rate laws and their temperature dependence have been determined for pure Cu and Fe. The influence of about 1 at. % Si on the oxidation rate of the pure metals has been studied at temperatures between 800° and 1200°C. The distinctive behavior of Si in each of these metals is shown to be dependent on the extent of subscale formation and this behavior has been partly confirmed by selectively oxidizing Si in the alloys by the use of a controlled gas mixture of hydrogen and water vapor.

Experimental

Materials.—High-purity iron (C, 0.003%; Si, 0.002%; Mn, 0.004%; S, <0.005%; P, <0.001%; Cr, 0.001%; Al, 0.001%) was obtained from the National Physical Laboratory, England.

High-purity (OFHC) Cu and high-purity Fe-Si and Cu-Si alloys containing 0.52% and 0.61% Si, respectively, were supplied by Johnson & Matthey Ltd.

Specimens for oxidation tests were cut from ⅛ in. rolled strip, polished with metallurgical emery paper, and finished with 4-0 grade to give a mirror finish. Specimens were degreased with carbon tetrachloride and acetone immediately before inserting in the furnace.

Oxygen and hydrogen (<10 ppm oxygen) of commercial purity were supplied by the British Oxygen Company.

Apparatus.—The reaction rate of the pure metals and alloys was determined by means of a thermobalance. A Pt-wound resistance furnace was used with an impervious mullite reaction tube mounted vertically. Temperature control was maintained to ±5°C over a 3 in. central zone by means of a mechanical controller operated by a Pt/Rh thermocouple. Connections to the mullite tube were made in Pyrex glass with Araldite cement and these joints were water cooled.

The balance consisted simply of a precision glass spring (obtained from Still and Cameron, London) suspended from the inside of a ground glass joint above the furnace. The sensitivity of the spring was approximately 43 mg/cm extension under a load of 1 g; Hooke's law was obeyed over extensions of several centimeters. The entire spring was maintained virtually at room temperature, and specimens were suspended in the hot zone of the furnace by a fine silica rod; Pt wire was used to support the samples. The weight changes were obtained by measuring the changes in spring extension with a traveling microscope focused on a fine datum mark on the spring. Weight changes of better than 0.1 mg could be observed without difficulty.

The usual arrangements were made for evacuating the furnace tube and for passing dry or wet gases through the system.

The usual procedure for making a measurement was as follows. The furnace was brought to temperature and the ground glass joint removed. The spring with its silica rod and metal sample suspended from it was carefully attached to the hook. While a rapid stream of argon was flowing through the furnace tube, the joint and spring assembly were lowered into position. This could be done in a few seconds and the furnace then was evacuated. The traveling microscope was focused on the mark on the spring to obtain the initial reading. Dry oxygen was admitted and the weight gains followed by adjusting the microscope at suitable intervals to coincide with the datum mark; initially, readings were taken every minute and for longer intervals after the first hour; runs up to 5 hr were made. Pretreatment of certain specimens was carried out by heating them in a stream of hydrogen, saturated with water vapor at room temperature, for 3 hr at the temperature of subsequent oxidation.

Microsections were studied on many specimens and the thickness of various oxide layers estimated.

Results

Pure Copper.—The oxidation of pure Cu followed a smooth parabolic law; results for 906°, 960°, and 1002°C are shown in Fig. 1. The logarithm of the

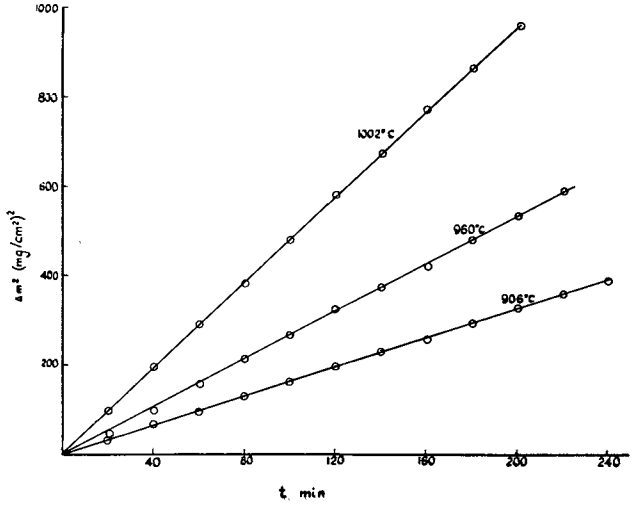

Fig. 1. Oxidation of pure Cu

1002	0.002	0.622

Table II

Temperature, °C	CuO, mm	Cu_2O, mm	Subscale mm
862	0.003	0.167	0.010
912	0.004	0.257	0.117
952	—	—	0.137
1006	0.002	0.456	0.143

parabolic rate constant is plotted against the reciprocal of the absolute temperature in Fig. 3; from the slope of this line, the usual Arrhenius equation yields an activation energy of 34.8 kcal for the oxidation process. In all cases the oxide scale was firmly adherent and when broken disclosed a dark red layer of Cu_2O underneath the gray-black surface CuO. The relative thicknesses of the two oxide layers are given in Table I.

Copper—0.61% silicon.—As with pure Cu the oxidation of the alloy followed a smooth parabolic law: results for 862°, 912°, 952°, and 1006°C are shown in Fig. 2. The rates are slightly but significantly slower than the corresponding values for pure Cu.

The logarithm of the parabolic rate constant against the reciprocal of the absolute temperature is plotted in Fig. 3. The slope of this line is very close to that for pure Cu, giving a calculated activation energy of 36 kcal for the process.

The oxide scale was similar to that on Cu but was less adherent and tended to flake off during cooling. In addition to the characteristic oxide layers of Cu_2O and CuO, the microstructure of the underlying metal showed a clearly defined subscale, presumably of precipitated silica at grain boundaries.

The relative thicknesses of the various layers are given in Table II.

Copper—0.61% silicon after pretreatment in wet hydrogen.—Even after pretreatment in wet hydrogen, the oxidation proceeded smoothly following a parabolic rate law; results for 952° and 1006°C are shown in Fig. 4. The rates are slower than for both pure Cu and the untreated alloy.

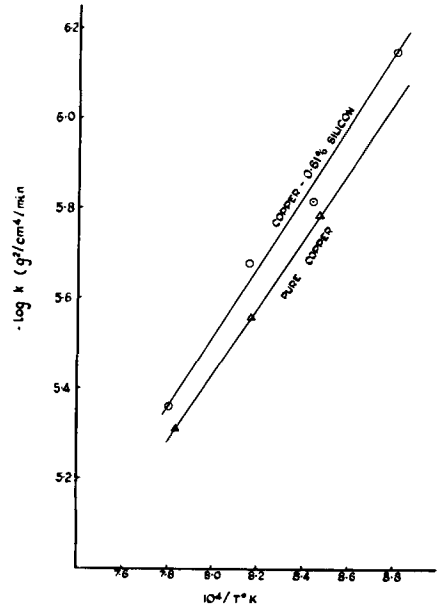

Fig. 3. Log k vs. 1/T for Cu and Cu-0.61% Si

After pretreatment, but before oxidation, the metal surface appeared quite bright and free from a surface film.

Pure iron.—The oxidation curves for pure Fe followed smooth parabolas; results for 810°, 864°, 910°, 984°, and 998°C are shown in Fig. 5. From the graph of the logarithm of the rate constant against the reciprocal of the absolute temperature (Fig. 6), the activation energy for the process is calculated to be 34.3 kcal.

Below 900°C, the surface layer had a velvet, dark red appearance whereas above this temperature the color was metallic gray. The scale was firmly adherent, but it could be removed by light hammering. Microscopically, three oxide layers could be readily distinguished, viz., a very thin outer layer of Fe_2O_3, a thicker layer of Fe_3O_4, and finally a mixed layer of FeO and Fe_3O_4 adjacent to the metal.

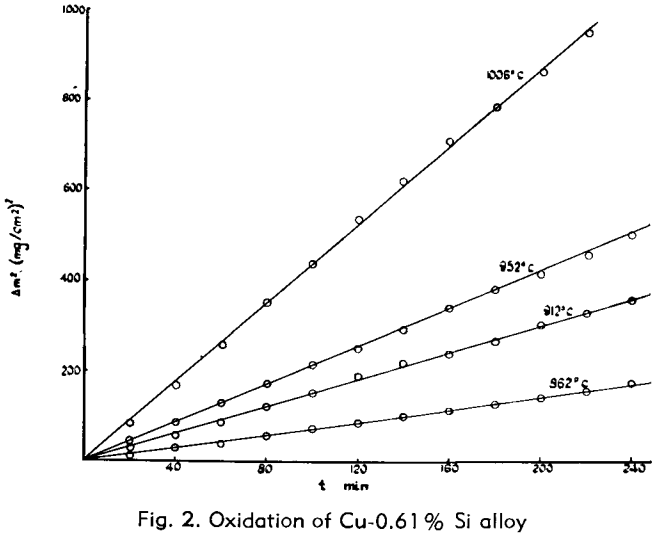

Fig. 2. Oxidation of Cu-0.61% Si alloy

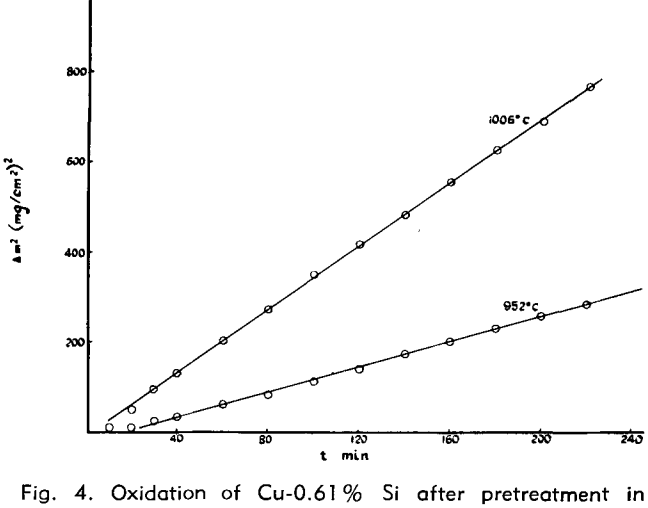

Fig. 4. Oxidation of Cu-0.61% Si after pretreatment in wet hydrogen.

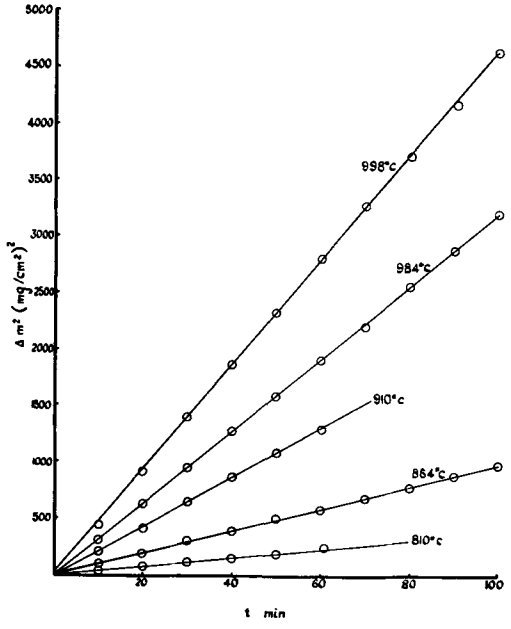

Fig. 5. Oxidation of pure Fe

This latter mixed layer may well result from the partial decomposition of wüstite on cooling. There appears to be no abnormal change in the oxidation process at the α-γ transition in Fe (910°C), but a small difference would be undetected.

Iron—0.52% silicon.—Unlike the behavior of Si in Cu, Si in Fe has a pronounced effect on both the rate and mechanism of oxidation of Fe.

Results for 950°, 998°, 1055°, 1103°, 1131°, and 1165°C are shown in Fig. 7. Up to about 1100°C, the reaction is initially quite slow; after a time depending on the temperature, the oxidation increases, following an approximately smooth curve. At higher temperatures, this initial slow period disappears. At about 1170°-1180°C, the oxidation was catastrophic and no rate data could be obtained above this temperature, because of the melting point of fayalite (1180°C).

The scale was grayish black and closely adherent but could be removed by slight hammering. The exposed metal surface was roughly corroded; there were no obvious signs of silica precipitation at the metal interface, but on the specimen oxidized at

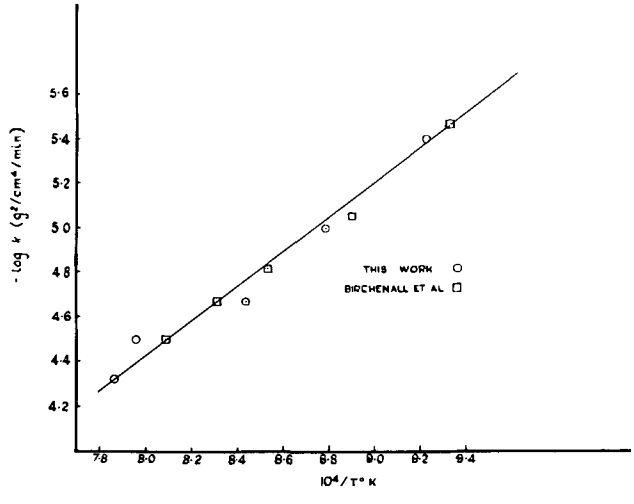

Fig. 6. Log k vs. 1/T for pure Fe

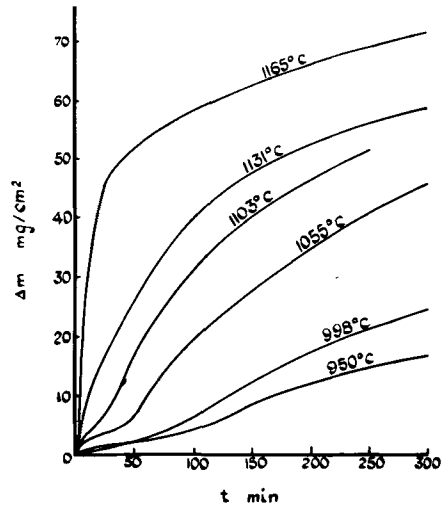

Fig. 7. Oxidation of Fe-0.52% Si

1160°C specks of a partly molten phase could be seen. A microsection of the oxidized specimen showed a number of oxide layers. The external layer was a very thin compact layer of hematite which occasionally showed needle-like growths on specimens oxidized above 1050°C. Beneath this, there was a dense layer of magnetite; below this was a less well-defined and rather more porous structure of wüstite mixed with some magnetite, and finally, adjacent to the metal, there was a thin compact layer of wüstite with fayalite. Within the metal there was a very thin subscale. Approximate relative thicknesses of the various layers are shown in Table III.

Iron—0.52% silicon after pretreatment in wet hydrogen.—After pretreatment in wet hydrogen the oxidation curves showed very similar behavior to that of the untreated alloy, although the rates of oxidation appear somewhat faster. Results are shown for temperatures of 1010°, 1060°, and 1110°C in Fig. 8. The curves are irregular and the oxide scales showed cracking and blistering.

Discussion

Oxidation of Pure Copper and Iron

The parabolic rate constants for pure Cu and Fe derived from the experimental results are:

For Cu (900°-1000°C) $k = 0.076 \exp(-34{,}800/RT)$ $g^2\ cm^{-4}\ sec^{-1}$

For Fe (800°-1000°C) $k = 0.578 \exp(-34{,}300/RT)$ $g^2\ cm^{-4}\ sec^{-1}$

The results for Cu are in general agreement with other workers, e.g., Valensi (9) and Feitknecht (10).

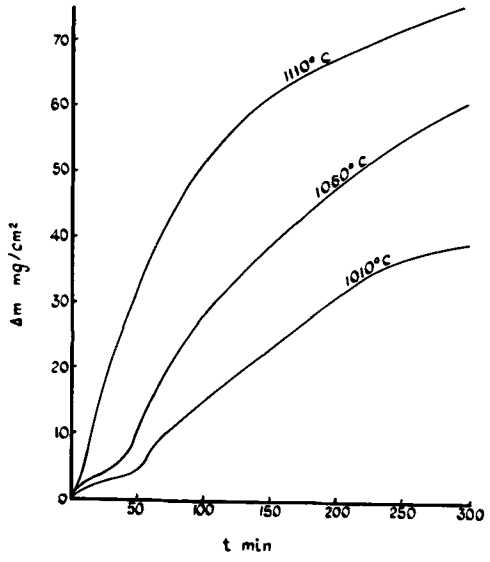

Fig. 8. Oxidation of Fe-0.52% Si after pretreatment in wet hydrogen.

In this temperature region the growth of the oxide layer is controlled by the diffusion of cuprous ions through cuprous oxide. Moore and Selikson (11) measured the diffusivity of Cu^+ in Cu_2O using radiocopper and obtained an activation energy of 36.1 kcal for the diffusion process which agrees reasonably well with the experimental activation energy of 34.8 kcal for the scaling process.

For pure Fe the results compare well with the measurements of Davies, Simnad, and Birchenall (12) in this temperature range; their results are plotted in Fig. 6. Himmel, Mehl, and Birchenall (13) have shown that the controlling process in the oxidation of Fe is the diffusion of ferrous ions in wüstite. They have measured the diffusion rates of cations in the various Fe oxides and obtained a value of 29 kcal for ionic diffusion in wüstite which may be compared with the value of 34.3 kcal for the oxidation process.

Many workers have studied the oxidation of Fe in air, oxygen, and at other controlled oxygen pressures, but the results have not been concordant; part of the discrepancy almost certainly arises from the relative purity of the Fe employed and to a less extent to the use of humid air or oxygen.

When the slight difference in activation energy is taken into account, the parabolic rate constant for the oxidation of Fe is about ten times that for Cu at corresponding temperatures. In both oxides the controlling process is cationic diffusion through a nonstoichiometric oxide, probably via vacant lattice sites. From a consideration of Wagner's theory of parabolic oxidation, it is clear that the difference in scaling rates of the two metals lies in the different ionic conductivities of the two oxides. For FeO the electrical conductivity (13) is 107 ohm^{-1} cm^{-1} for an oxygen partial pressure corresponding to the dissociation pressure of magnetite at 1000°C and the cation transport number is 2×10^{-4}; for Cu_2O the conductivity (14) is 4.8 ohm^{-1} cm^{-1} at an oxygen partial pressure corresponding to the dissociation pressure of CuO at 1000°C and the cation transport number is 4×10^{-4}.

Oxidation of Silicon Alloys

The oxidation of Cu and Fe containing a small amount of Si differs significantly. Silicon in Cu has little effect on the scaling rate of pure Cu, whereas Si in Fe modifies the oxidation mechanism as shown by the irregular oxidation curves. A further point is that the subscale in Cu is substantially thicker than in Fe for the corresponding temperature.

The difference in subscale thicknesses arises principally from the difference in diffusivities of oxygen in Cu and Fe, although the difference in oxygen solubility in both metals, the scaling rate of the base metal, and the relative diffusivities of Si all play their part.

Darken (15) has analyzed the formation of subscale in dilute alloys, and, with certain assumptions, showed that the depth of subscale x during scaling is given by the equation

$$x = (D/r) \ln (1 + u/v)$$

in which D is the diffusivity of oxygen in the alloy, r is the scaling rate, u is the solubility of oxygen in the pure base metal, and v is the initial concentration of Si. This relation shows that the depth of subscale increases with increasing diffusivity and solubility of oxygen and decreases with increasing rate of scaling and Si content of the alloy.

From the diffusivities and oxygen solubilities at 1000°C shown in Table IV, the difference in oxygen diffusivity would appear to be decisive. The very large differences in oxygen diffusivities ought to be reflected in the relative depths of subscale. (Tables II and III, however, show that this is not so.) The value for oxygen in Fe in Table IV is based on one value of Bramley, *et al.* (17), but the depth of subscale in our experiments suggests that their value for diffusivity is at least 1000 times too low. This is partly confirmed by Darken (15) who implies a value for oxygen in iron of the order of 10^{-7} cm^2 sec^{-1} without citing experimental evidence.

The effect of Si in Cu is such that during scaling Si cannot accumulate at the oxide-metal interface but becomes progressively oxidized in depth by virtue of the rapid inward diffusion of oxygen. On the other hand, during the scaling of Fe, Si can diffuse and concentrate at the metal-oxide interface, becoming converted initially to silica which builds up a coherent and partially protective layer. The form of the Si-Fe oxidation curves suggests that, during the initial period of oxidation, silica is first precipitated at the interface and the oxidation rate is appreciably reduced because of the protective nature of the silica (18). However, after this slow initial period the silica undergoes a solid state reaction with FeO to form fayalite. This is itself a semiconductor, and the alloy then begins to oxidize at a

Table IV*

Table V

	Exptl. gas mixture	Cu-Cu_2O	Fe-FeO	Si(1 at. %)-SiO_2
H_2O/H_2 ratio at 1000°C	2.5×10^{-2}	5×10^{3}	0.5	7×10^{-5}

faster rate by ionic diffusion through this layer. The initial slow period decreases with increasing temperature which would be expected as the solid-state reaction becomes more rapid. A similar two-stage process was observed by Ipatev and Orlova (5) during the oxidation of a Si steel containing 1.4% Si.

Pretreatment in Wet Hydrogen

A controlled gas mixture capable of oxidizing Si but not Cu or Fe was obtained easily by saturating hydrogen with water at room temperature. The H_2O/H_2 ratio under these conditions is 2.5×10^{-2}. Corresponding ratios for the formation of cuprous oxide and ferrous oxide and for the precipitation of silica from a 1 at. % silicon alloy is shown in Table V.

The calculation for silica is based on approximate activity coefficient of Si in both Cu and Fe of 0.01 (19). It is clear from this table that wet hydrogen should, theoretically, readily precipitate silica but not form either copper or iron oxide.

The formation of subscale in the absence of continuous scaling of the base metal has been studied carefully by Rhines, Johnson, and Anderson (8). They studied a number of dilute binary alloys with Cu as the base metal and correlated their results with a theoretical equation which for Si alloys can be expressed:

$$x^2/t = (2D_o c_o - 1.92\, D_{Si}\, c_{Si})/(1.14\, c_{Si} + 0.33\, c_o)$$

where x is depth of subscale; t, time; D_o and D_{Si}, diffusivities of oxygen and silicon in the alloy, respectively; c_o, solubility of oxygen in the base metal and dependent on the external partial pressure of oxygen; c_{Si}, initial concentration of Si in the alloy.

Since c_o is usually much less than c_{Si}, the depth of subscale and indeed whether any subscale forms or not depends on the relative values of $D_o c_o$ and $D_{Si} c_{Si}$, i.e., not merely on the relative diffusivities of oxygen and silicon.

The solubility of oxygen in Cu at the limiting oxygen pressure of Cu_2O is 0.009%. It is reasonable to assume that oxygen dissolved in solid Cu obeys Sieverts' law, viz., the solubility is proportional to the square root of the partial pressure of oxygen. For H_2O/H_2 mixtures this means that the solubility will be simply proportional to the H_2O/H_2 ratio. From Table V it is seen that the maximum oxygen solubility under the experimental conditions is:

$$0.009 \times \frac{2.5 \times 10^{-2}}{5 \times 10^{3}} = 4.5 \times 10^{-6}\ \text{wt \%}$$

By substituting this value for c_o and the other values from Table IV it is seen that $D_o c_o$ is much less than $D_{Si} C_{Si}$ which implies that no subscale can form and Si will, therefore, diffuse to the surface of the alloy forming a layer of silica. The corrosion behavior of pretreated specimens in oxygen shows that they are significantly more resistant than the untreated alloy although a completely protective silica skin has not formed.

For Si-Fe the oxygen solubility under wet hydrogen conditions is

$$0.003 \times \frac{2.5 \times 10^{-2}}{0.5} = 1.5 \times 10^{-4}\ \text{wt \%}$$

With Bramley's value (17) for the diffusivity of oxygen, $D_o c_o$ is again much less than $D_{Si} c_{Si}$ so that no subscale would be expected, and silica should precipitate at the Fe surface. The oxidation of pretreated silicon iron, however, does not confirm this since the oxidation apparently is enhanced after pretreatment. These experimental results suggest that subscale has formed and depleted the surface of the alloy in Si. This could only happen if the diffusivity of oxygen was in fact much faster than Bramley's value or alternatively that the oxygen solubility was much higher.

Conclusions

Small amounts of Si affect the scaling of Cu and Fe in different ways. For Cu, Si in the alloy tends to be precipitated mainly as subscale during external scaling with the result that little or no silica is formed at the metal-oxide interface. Therefore, the oxidation rate compared with pure Cu is lowered only slightly and moreover the mechanism of oxidation is unchanged.

Because of the slower diffusivity of oxygen in Fe, silica tends to precipitate at the metal oxide interface to give some protection during oxidation. However, a solid-state reaction between iron oxide and silica occurs after a comparatively short time depending on the temperature, and the resulting iron silicate is sufficiently conducting to give a fairly rapid scaling rate. The extent of subscale formation in Fe-Si alloys suggests that the diffusivity of oxygen in Fe is much faster than is commonly supposed.

By the use of controlled oxygen pressures it is possible to selectively oxidize Si to form silica on the surface which may give some measure of protection. The conditions for this selective oxidation can be estimated reasonably from a knowledge of diffusivities of oxygen and Si in the metal. Preliminary experiments with higher Si-Cu alloys have demonstrated that a considerable improvement in oxidation resistance can be obtained in this way.

In an Fe-Si alloy it is a relatively easy matter to produce silica only, but as soon as normal oxidation occurs some iron oxide must form and consequently the highly protective silica is converted into the much less protective iron silicate.

Translucent Phosphor Coatings in High-Pressure Mercury-Vapor Lamps

C. H. Haake

Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The optical conditions in quasi-infinitely thick phosphor plaques and in translucent phosphor coatings of closed lamps are studied. Theory shows, and experiments carried out on magnesium fluorogermanate phosphors activated with Mn confirm, that the correlation between the brightness of plaques and of translucent coatings in closed lamps is rather involved. Although prolonged phosphor firing time monotonically increases the former, the latter reaches a maximum and then decreases. This and other unpredictable results render dubious the value of crude plaque brightness tests of phosphors meant for translucent coatings in lamps. Reliable measurements of phosphors for such coatings must include for the main wave lengths of excitation relative quantum efficiencies, reflectances of quasi-infinitely thick phosphor layers, and also differential reflectivities or absorptivities in a thin phosphor layer of a known density.

The intensity of the visible radiation from the discharge in high-pressure mercury-vapor (HPMV) lamps is about 60% of that of the ultraviolet radiation (1). Therefore, HPMV lamps are good light sources; however, they exhibit a radiation deficiency in the red region of the spectrum. To correct for this deficiency the outer bulb of HPMV lamps is often coated with a layer of an ultraviolet-absorbing, red-emitting phosphor (Fig. 1). The layer is kept so thin that an excessive loss of visible radiation is avoided and yet radiation is added in the red region of the spectrum which amounts to about 8% of the total luminous output of the lamp. (In the future, for the sake of simplicity, we will refer to the radiation of this part of the spectrum as "red-lumens".) Typical such phosphors are magnesium fluorogermanate (2) and magnesium arsenate (3) both activated with manganese.

An inherent difficulty when preparing these phosphors is the judgment of their expected performance. Ultimately one is interested only in the behavior of the phosphor in a coated lamp. Phosphor tests in lamps, however, are rather tedious and in practice one usually restricts the tests to the very conveniently and quickly carried out plaque brightness measurements (emission brightness of quasi-infinitely thick phosphor layers for given excitation conditions) (4). This method is sensible only if a direct correlation exists between the plaque brightness and the red emission of phosphor coatings in a finished lamp such that an increase of the former is concomitant to an increase of the latter.

The purpose of this study is the investigation of the

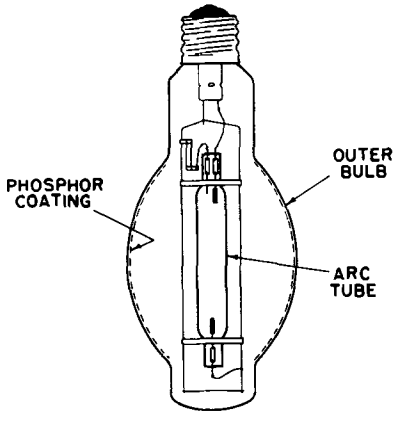

Fig. 1. High-pressure mercury-vapor lamp (Westinghouse JH-1, 400 watts).

behavior of thin phosphor layers in HPMV lamps. Equations which govern the emission from such layers are derived and discussed on the basis of experimental findings obtained from a Mn-activated magnesium fluorogermanate phosphor (MFG) in a Westinghouse 400-watt HPMV lamp. Particular interest is directed toward any possible significance of plaque brightness measurements on phosphors to be used in HPMV lamps.

Theory

The optical conditions of translucent phosphor coatings on plane substrates have been described and discussed by several authors (5, 6). The pertinent equations for the reflectance, transmittance, and absorptance[1] apply to grainy phosphor layers whose thickness is much larger than the average particle size of the phosphor crystals. The average density of the phosphor coating in HPMV lamps is about 1-2 mg/cm^2 and the particle size usually ranges from 3 to 5 μ. However, the particles in the layer do not arrange themselves in anything near a close-packed structure. When viewed under a microscope the layer appears porous and mountainous. The estimated average elevation of the phosphor layer over the surface of the bulb wall is about 30 μ. The coated bulb shows a fair degree of optical scattering and very little transparency. It seems, therefore, that in good approximation the existing equations for translucent phosphor coatings are also applicable to the present case. It will be assumed further that the reflection of the glass substrate for the exciting radiation is much smaller than that from the grainy layer and, therefore, can be neglected.

We will first present the equations for the reflectance, R, the transmittance, T, and the absorptance, A, of plane translucent phosphor coatings (6).

$$R = \frac{(r/p)\sinh(ps)}{\cosh(ps) + [(a+r)/p]\sinh(ps)} \qquad [1]$$

$$T = \frac{1}{\cosh(ps) + [(a+r)/p]\sinh(ps)} \qquad [2]$$

and

$$A = 1 - R - T \qquad [3]$$

where

$$p = \sqrt{a^2 + 2ar} \qquad [4]$$

The layer thickness is given by s, measured either in cm or mg/cm^2. The optical properties of the layer material are described by an absorptivity a and a reflectivity r, both measured either in cm^{-1} or in cm^2/mg, since as and rs are dimensionless arguments. These are the coefficients of absorption and reflection for a phosphor layer of the thickness ds. For practical purposes it is convenient to relate a and r to an easily measurable quantity, the reflectance, R_o, of a quasi-infinitely thick phosphor layer. In this case $\sinh(ps) = \cosh(ps)$ and Eq. [1] gives

$$R = R_o = \frac{r}{p + a + r}$$

from which follow

$$\left.\begin{aligned} \frac{r}{a} &= \frac{2R_o}{(1-R_o)^2} \\ \frac{a}{p} &= \frac{1-R_o}{1+R_o} \\ \frac{r}{p} &= \frac{2R_o}{1-R_o^2} \end{aligned}\right\} \qquad [5]$$

If a thin phosphor layer is applied to the inside wall of the outer bulb of a HPMV lamp, any exciting radiation reflected from the layer will reach the layer somewhere on the opposite side of the bulb, etc. Hence, the effective transmittance of exciting radiation through the bulb becomes approximately

$$\tau = T\sum_{i=0}^{\infty} R^i = T/(1-R) \qquad [6]$$

With Eq. [1], [2], and [5] using exponential terms one finds

$$\tau = \frac{1+R_o}{R_o\exp(-ps) + \exp(ps)} \qquad [7]$$

It is realized that the sum in Eq. [6] is somewhat affected by the uncoated portions of the bulb and the interior parts of the lamp. This effect, however, is small and will be neglected in the calculation, although later in this paper some comments will be made on this matter.

The effective absorptance of the phosphor coating on the bulb is

$$\alpha = 1 - \tau \qquad [8]$$

If $N(\lambda)$, the number of quanta per sec. emitted in the discharge line at λ, the effective absorptances $\alpha(\lambda)$ of the coating and the quantum efficiencies $\eta(\lambda)$ of the phosphor are taken into account, the total quantum emission, I_L of the phosphor coating becomes

$$I_L = \sum_i N(\lambda_i)\,\eta(\lambda_i)\,\alpha(\lambda_i) \qquad [9]$$

On the other hand, the quantum emission of a quasi-infinitely thick phosphor layer under the same excitation conditions is

$$I_p = \sum_i N(\lambda_i)\,\eta(\lambda_i)[1 - R_o(\lambda_i)]\cdot F(\lambda_i) \qquad [10]$$

$F(\lambda_i)$ is the ratio of the radiation generated to the radiation actually escaping the phosphor layer on the side on which the exciting radiation is incident. In the special case of MFG:Mn phosphors the quantum emission I_p is proportional to the plaque brightness since the emission spectrum is independent of the wave lengths of excitation (2).

Experimental Data

For a quantitative discussion of the equations and the dependence of their parameters on the preparation conditions of MFG:Mn, five phosphor samples of the same composition (3.5MgO, 0.5MgF_2, 1GeO_2, 0.01Mn) were studied. These samples were drawn from a large batch:

[1] These equations in a general form were originally derived by Schuster (7) although not specifically for phosphor powders.

Sample A: after 2 hr firing at 1100°C in air

Sample B: after 3 hr ball milling of sample A

Sample C: after 20 hr refiring of sample B at 1100°C in air

Sample D: after 12 hr refiring of sample C at 1100°C in air

Sample E: after 14 hr refiring of sample D at 1100°C in air.

Numerous quantities were measured:

(*a*) The relative plaque brightness, I_p (λ), of the quasi-infinitely thick phosphor layers for λ = 254, 313, 365, 405, and 436 mμ as exciting wave lengths; (*b*) the reflectance, R_o (λ), of the same phosphor layers for the same wave lengths as in (*a*); (c) the relative total lumens, I_T; and (*d*) the relative red lumens, I_R, of a HPMV arc tube with phosphor-coated bulbs; (*e*) the relative total lumens, I_{T_o}, of the same HPMV arc tube with an uncoated bulb; (*f*) the effective transmittance, τ(λ), of the exciting Hg-lines through the coated bulbs; (*g*) the density, *s*, of the phosphor coating on the bulbs.

Methods of Measurement

(*a*) *and* (*b*).—The arc tube of a 400W HPMV lamp (Westinghouse EH-1) served as excitation source whose lines were selected and transmitted through an ultraviolet monochromator onto a thick phosphor layer. The emitted radiation, $I_p(\lambda)$, was measured as photocurrent from a photomultiplier (RCA 1P28). A cut-off filter prevented the exciting radiation from entering the photomultiplier. After this filter was exchanged for one which transmits only the exciting radiation, the reflected radiation was measured as photocurrent. The container with the phosphor was then replaced by a similar one filled with MgO and the photocurrent was read again. Multiplication of the ratio of the former reading to the latter by 0.95 (averaged reflectance of MgO in the wave-length range of interest) gave the reflectance, $R_o(\lambda)$, of the phosphor. The plaque brightness, $I_p(\lambda)$, is proportional to the quantum efficiency, $\eta(\lambda)$, to the exciting radiation absorbed in the phosphor layer, $1 - R_o(\lambda)$, and to the ratio $F(\lambda)$ (see Eq. [10]). An expression for F has been derived by Coltman, *et al.* (5) which, for thick phosphor layers, becomes

$$F(\lambda) = \frac{1}{2} \cdot \frac{1 + R'_o(\lambda)}{1 + p'(\lambda)/p(\lambda)}$$

The primed quantities are those for the emitted radiation. It could be shown that for the five samples studied $F(\lambda)$ did not change by more than 1% at any one particular wave length of excitation. Since in the following the quantum efficiencies η are given relative to those of sample E, the ratio $F(\lambda)$, therefore, need not be considered here.

(*c*), (*d*) *and* (*e*).—Each phosphor sample was ball milled in an equal amount of nitrocellulose for a given length of time under the same conditions. BT-37 bulbs (as used in Westinghouse 400W JH-1 and EH-1 lamps) were coated and lehred for 10 min at about 600°C. They were then sleeved over an EH-1 arc tube mounted in a 60 in. integrating sphere. The arc tube itself was sealed into a slender quartz tube. Relative lumens were measured in a conventional way Weston Photronic cell + Viscor filter #594 Y.R.V., for total lumens and Weston Photronic cell + Viscor filter #594 Y.R.V. + Corning filter #2418 for red lumens).

(*f*).—A double-monochromator with a photomultiplier (RCA 1P28) at its exit slit was placed in front of a small hole in the integrating sphere. A baffle in the sphere shielded the hole from direct light from the lamp. For λ = 313, 365, 405, and 436 mμ, photocurrent readings were taken with the coated bulbs and a clear bulb in place, respectively. The ratio of the two readings gave the effective transmittance, τ(λ), through the phosphor coated bulb. Since the bulb glass does not transmit the 254 mμ line, τ(254) could not be measured.

(*g*).—After completion of the measurements (c) to (*f*) the total amount of phosphor in each bulb was recovered and weighed. The weight divided by the known area coated (500 cm²) gave the coating density, *s*, in mg/cm².

The data obtained are shown in Table I, II, and III. The first six columns of Table II show the sample identification; the wave length of excitation, λ; the plaque brightness, I_p; the reflectance, R_o; the effective transmittance, τ; and the relative quantum efficiency, η, respectively. Since from samples A to E only the relative changes of the values measured or computed are of interest, I_p and η of the sample E were arbitrarily chosen to be 1.00 regardless of the wave length of excitation. In the 7th and 8th column are shown the differential absorptivity *a*, and the differential reflectivity, *r*, which one obtains from Eq. [5] after determining *p* by inserting *s* (Table I), τ and R_o in Eq. [7]. In the 9th column is tabulated $\eta\alpha = \eta(1 - \tau)$. These values show how for each wave length of excitation the emission intensity of the coating in the lamp changes from phosphor A to phosphor E. Since the varying density of the coating with phosphors A to E, as encountered here for experimental reasons, does not lend itself to arriving at general conclusions, one can compute the values of $\eta\alpha$ (listed in Table II as $\eta\alpha^*$) using η, *a*, *r*, and R_o as determined earlier, and $\bar{s} = 1.290$ mg/cm² as mean coating density. If large numbers of lamps were to be prepared with phosphors A to E in the coatings, small variations of the density would cancel out and the averaged values of $\eta\alpha$ for each phosphor at each wave length of excitation would be $\eta\alpha^*$. Likewise on the basis of an averaged density $\bar{s} = 1.290$ mg/cm² computed values of τ are listed in the 11th column as τ^*.

It should perhaps be explained at this point to what extent the values of *a*, *r*, and particularly τ^*

and ηa^* are affected by the somewhat idealistic assumption that no exciting radiation reflected from the phosphor coating into the lamp is lost for the process of interreflections, either by absorption in lamp parts or by transmission through the uncoated end parts of the lamp. Actually these losses do occur to some extent and they modify the equations slightly. It can be shown that the values of a and r are somewhat lower than those appearing in Table II. Conversely, within the accuracy desired, the values of τ^* and ηa^* remain unchanged. This is because p (and thence a and r) is obtained from the inverted Eq. [7]. Later after this equation has again been inverted one finds τ^* and thence ηa^* using an average coating thickness $\bar{s}$. Thus a modification of Eq. [7] due to losses has virtually no effect on τ^* and ηa^*.

In Table III are shown the red lumen percentages (based on the total lumens of a clear lamp as 100) of the coated bulbs, and also the per cent loss of total lumens due to absorbed visible radiation in the coating.

Discussion and Conclusion

It can be seen from Eq. [10] that, for constant quantum efficiencies $\eta(\lambda)$, the plaque brightness *increases* with decreasing reflectances $R_o(\lambda)$. On the other hand, an analysis of Eqs. [5] and [7]-[9] shows that, again for constant $\eta(\lambda)$, the emission from a phosphor bulb of a HPMV lamp *decreases* with decreasing reflectance, if, as often is the case, the absorptivity a remains essentially unchanged. This adverse trend of I_p and I_L rules out any meaningful judgment of phosphors based on measurements of plaque brightness, a method which still is widely practiced for selecting phosphors to be used in HPMV lamps [see, e.g., Ref. (4)]. Thus, if one were to choose certain conditions for preparing phosphors merely guided by plaque brightness measurements, phosphors might be discarded which would exhibit an excellent performance in translucent coatings on bulbs, and vice versa.

Table III. Lumen ratios of coated bulbs

Phosphor	$100\ I_R/I_{T_o}$	$100\ (1 - I_T/I_{T_o})$
A	8.5	5.0
B	8.7	5.0
C	8.6	2.5
D	8.9	2.5
E	9.0	2.5

Also in the present case the reflectances $R_o(\lambda)$ decrease (from B to E). At the same time, however, the efficiencies $\eta(\lambda)$ increase. Thus with prolonged firing time ηa^* and, hence, the red lumens emitted from a coated bulb should approach a maximum and then decrease. This maximum is concealed in the values of ηa and I_R/I_{T_o} shown in Table II and Table III, because in the present experiments the coating thickness could not be held constant from A to E. However, the maximum clearly appears in the values of ηa^* as computed for a constant coating thickness. In order to further substantiate this result we coated eight bulbs with MFG:Mn phosphor which had been fired for 10 hr and for 48 hr, respectively. When we measured the red lumen percentage, we actually found a decrease from (9.9 ± 0.1) % for the phosphor fired for 10 hr to (9.2 ± 0.3) % for the phosphor fired for 48 hr. It, therefore, becomes apparent that a limited firing time is required for the

phosphors to obtain optimum performance. There is, however, also the requirement of as high a transmission through the coating for the visible radiation of the discharge as possible. As can be seen from the values of I_τ/I_{τ_0} in Table III this transmission increases slightly from phosphors B to E with firing time, but it soon reaches a saturation at a point where the latter requirement may no longer be conflicting with the former.

There is another interesting phenomenon. The reflectance R_0 at 405 mμ (violet) and 436 mμ (blue) decreases from phosphors B to E. This is tantamount to an increasing yellowish body color of the phosphors which usually is considered objectionable. When used for coatings in HPMV lamps the phosphor will absorb violet and blue radiation of the discharge which is needed for good color rendition. Since phosphor E exhibits a yellowish body color deeper than that of B, one is lead to believe that also in a thin coating phosphor E should show effective transmittances for violet and blue light which are lower than those of phosphor B. It is interesting to note from the values of τ^* in Table II that just the opposite holds true: τ^* (405mμ) and τ^* (436 mμ) *increase* from B to E. This seemingly odd behavior can again be explained by Eqs. [5] and [7]. Since the reflectances $R_0(\lambda)$ decrease from B to E and the absorptivities virtually do not change, p in Eq. [5] decreases and, hence, τ in Eq. [7] increases.

For the purpose of achieving good uniformity of the phosphor the MFG:Mn was ball milled between the first and second firing (sample B). Small pebbles were used whose main action was the breakage of agglomerates. This, as can be seen in Table II, leads to an increase of the reflectance, R_0, to a decrease of the effective transmittance, τ^*, and hence to an increase of the effective absorptance, α^*, of the phosphor coatings. Since also the quantum efficiencies increase, one can expect a rather strong increase of $\eta\alpha^*$ and of red lumens emitted from the phosphor coating. In fact, phosphor B gives the highest values of $\eta\alpha^*$ for $\lambda_{exc} = 365$, 405, and 436 mμ. The increase of η induced by ball milling is rather surprising, as ball milling has a detrimental effect on other phosphors, particularly those of the ZnS type (8). At this time we cannot offer more than a suggestion as to the reason for the increase in η. The arrangement of the oxygen ions which surround the emitter ion (Mn^{+4}) has a strong effect on the efficiency, η, of quantum conversion in the center. Any distortion of the system, possibly frozen in after firing, can result in a small η. It seems feasible that such internal strains are released during mild ball milling of the phosphors.

Summary

Translucent coatings of MFG:Mn phosphors such as are used for color correction in HPMV lamps exhibit performance parameters markedly different from those obtained with quasi-infinitely thick phosphor plaques. By firing the phosphor for a prolonged period of time the emission intensity of the coating increases to a maximum value and then decreases, whereas the emission intensity of the phosphor plaques increases monotonically.

Prolonged firing time will also lead to an increasingly yellow body color of the phosphor plaque, i.e., to an increasing absorption of violet and blue light. Contrary to this, the translucent phosphor coatings in lamps exhibit an increasing effective transmittance for the violet and the blue mercury lines with increasing firing time.

Therefore, a valid judgment of phosphors which ultimately will be used in translucent coatings of HPMV lamps cannot be based on simple plaque brightness measurements. It is mandatory to determine various phosphor parameters whose evaluation will result in the optimum preparation conditions of the phosphor, or to coat bulbs, sleeve them over the same arc tube, and measure the red lumen output.

Manuscript received March 23, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Use of Organo-Substituted Hydrolyzable Silanes on Silicon Devices

B. Schwartz

Hughes Semiconductors, Newport Beach, California

ABSTRACT

The formation of silicone polymers directly from the monomers, on the surface of silicon diodes, has resulted in devices with low reverse currents. Transistors treated in this way react in different ways due to the conditions imposed by the specific surface potentials involved.

Silicone resins, varnishes, and greases have been used in the fabrication of semiconductor devices, since these materials provide a hydrophobic environment for the device and at the same time have the thermal stability necessary for proper operation. All these materials are in a polymeric form prior to application to the device. This paper concerns techniques for forming a silicone polymer directly on the surface of the device by the use of organo-substituted hydrolyzable silanes so that enhanced electrical properties result (1).

The general formula for an organo-substituted hydrolyzable silane, which is the starting point from which all silicones are derived (2), is $R_{4-i}SiX_i$ (i=1, 2, 3,), while R is an organic radical. For use on semiconductor devices a short-chain hydrocarbon is preferred, since the shorter the chain, the better the thermal stability. The X refers to the hydrolyzable part of the compound and can be a halide, ethoxide, or other radical which will react with water.

In order to see how a silicone polymer is formed from this class of compounds, consider the hydrolysis of the difunctional reagent dimethyldichlorosilane. In the presence of water this compound reacts spontaneously to form dimethyldihydroxysilane and HCl. The dimethyldihydroxysilane is unstable, and by intermolecular dehydration a silicone polymer is formed which in this case would be polydimethylsiloxane. Compounds also are available with either 1 or 3 organic radicals in the so-called monomer, so that not only can linear polymers be made, as just described, but space polymers can be realized also by having some trifunctional silane present during the reaction.

In the case of the ethoxy system, the reaction with H_2O is not so straightforward, and one must provide either an acidic or basic medium for the hydrolysis to proceed. Since most of the silicon device work to be reported on here was done using the chlorosilanes, all reference is to this system. Somewhat analogous results were obtained when the ethoxy system was used in place of the chloro system.

Methods and Results

The techniques that one might use in forming the silicone on the surface are: (*a*) exposure of a premoistened unit to the vapors of the silane mixture (3); (*b*) total immersion of the unit in the silane mixture itself; and (*c*) immersion of the unit in a solution of the silane mixture. The method of total immersion in the silane mixture has given the best results, and this technique is the one preferred to during the rest of this paper.

Figure 1 shows the effect of silaning on the electrical characteristics of a grown p^+n silicon junction. Curve A illustrates the reverse diode characteristics of the unit before etching where the crystal surface contained a good deal of work damage. Curve B illustrates the junction properties after the unit had been acid etched to remove the work damage and baked at 200°C for 15 min. Curve C shows the properties of the same junction after it had been silaned with a mixture of methyl and phenyl chlorosilanes and baked for 1 hr at 250°C. In this particular measurement no attempt was made to reach the full breakdown voltage of the unit, since this device was to be used for a special series of surface experiments which required only a 500 v or better peak inverse voltage.

In Table I the reverse characteristics of 10 experimental large-area evaporative-fused-junction p^+n silicon diodes are listed. E_b and E_s are the voltages necessary to pass 2 and 10 μa, respectively, in the reverse direction; I_b is the reverse current measured at 125 v. For the silaning operation a 50-50 mixture

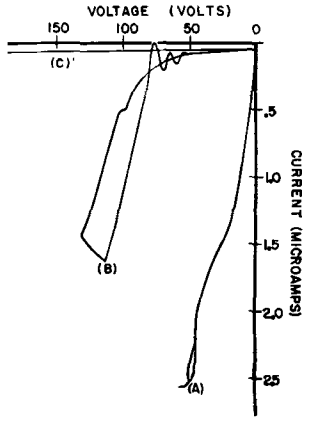

Fig. 1. Reverse characteristics of a group p+n silicon junction diode (A) before etching, (B) after etching in a mixture of hydrofluoric acid and nitric acid, and (C) after silaning.

of dimethyldichlorosilane and methyltrichlorosilane was used. One should not attempt to compare the individual units in this table, since they were not tabulated in the same order before and after silaning. Notice that where originally there was only 1 unit with a reverse current less than 100 mμa, there were 7 units with reverse currents of less than 100 mμa after silaning. Again, these units were not tested above 500 v. Other units, similarly treated, were taken out to breakdown, and no adverse effects were noticed unless too much current was allowed to pass in the reverse direction.

Table II shows the necessity of a curing cycle to bring out the improvement in diode properties after silaning. The units were not kept in order so that individual comparisons are not valid. Here again a 50-50 mixture of methyl and dimethylchlorosilanes was used for surface treatment. Initially there were only 3 units that had reverse currents of 220 mμa or less. After silaning, but prior to baking, all the units had poor characteristics; but after baking for ½ hr at 100°C, there were 7 units with reverse currents of 220 mμa or less; in fact, 6 of the units showed less than 50 mμa reverse current.

Heat Treatment and Stability

Some experiments were performed to establish the influence of the baking part of the silane-treatment cycle without the silanes having been applied. Table III shows the results of an experiment where a lot of approximately 700 units, which had been processed simultaneously, was arbitrarily divided in two, and only one half were silaned, using a mixture of mono-, di-, and tri-methylchlorosilanes. Both sets

of units then were baked at 200°C for 2 hr.

It was also established by experimentation that prolonged air baking, of the order of hours, (i.e., 3 hr or more), at elevated temperatures (approximately 200° to 250°C) would result in improved devices, without silaning, but the reproducibility was poor and further heating might very well cause the units to deteriorate appreciably. Therefore, it is felt that the improvements noted after silaning were due to the formation of the silicone film on the surface of the device and were not merely the result of baking the unit for the stated periods.

Some silaned transistors which have been aging in air for more than two years since they were treated were retested recently. The emitter and collector diode reverse currents on these units were found to be essentially the same as when the units were first silaned, indicating a good stability factor for this type of treatment.

The thermal stability of silaned units was investigated by aging the units at elevated temperatures and periodically checking the reverse current for degradation. At 250°C and below, no noticeable degradation took place; in fact, if anything, the units improved. At 300°C degradation appeared after about 8½ hr of aging. For 350°, 375°, and 400°C, the times for the onset of degradation were approximately 6½ hr, 3½ hr, and ½ hr, respectively.

The solvent resistance of the silaned units was investigated by boiling the units in various solvents for 5 to 15 min, again using the diode reverse current as the indicator of stability. If the units were not properly cured before being exposed to the solvent, degradation was immediate and universal. If the units were cured properly, then boiling in acetone, carbon tetrachloride, benzene, methyl alcohol, or trichloroethylene had no adverse effect.

Surface Channels and Surface Recombination Velocity

In Fig. 2 the effect of silaning on channels (4) on a fused-junction rectifier is shown. To the left of the origin is the p-region and to the right is the n-region. Figure 2A is a plot of the photoresponse of the freshly etched silicon rectifier as a function of distance. The sharpness of the peak indicates the absence of a channel. Figure 2B is a plot of the photoresponse of the same diode after it had been allowed to age in air for two weeks. The channel-type response over the n-region, indicating p-type conversion at the surface, can readily be seen. In Fig. 2C the photoresponse of the same diode is plotted after re-etching and silaning. In Fig. 2D the photoresponse of the same silaned unit after it had been allowed to age in air for six months is plotted; notice the absence of the channel.

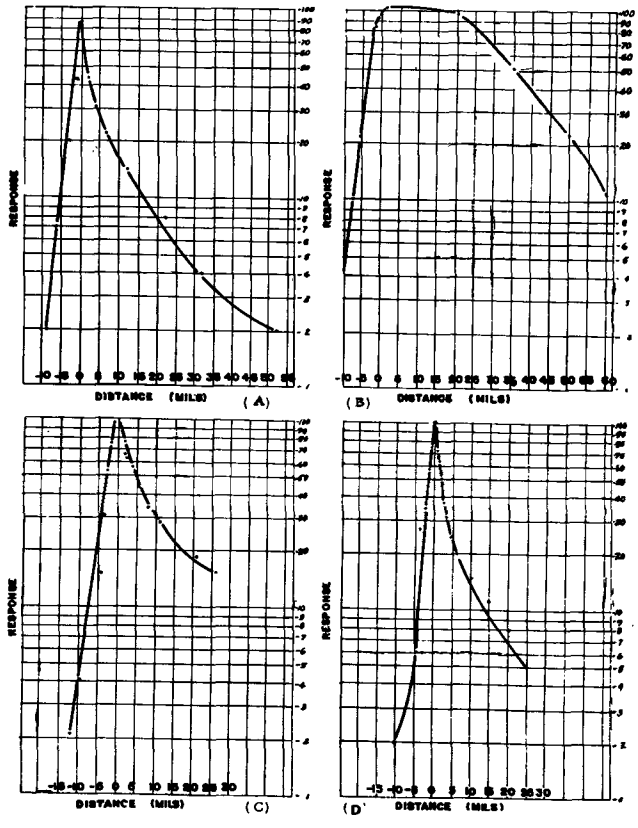

Fig. 2. Photoresponse of a fused p⁺n silicon junction diode as a function of distance from the junction.

A few experiments have been performed where the surface recombination velocity (s) of silicon filaments was measured before and after silaning. Improvement of s was noted, but stability was quite poor and degradation to the initial value occurred within 6 hr. When this treatment was tried on p-n-p transistors, units made by a diffusion technique showed improvement in the current amplification factor while evaporative fused junction transistors degraded in this parameter. These results can be explained on the basis that silaning causes the surface potential to become more positive, i.e., more n-type, a fact which can be seen by observing the results in Fig. 2 and which was verified in a gas cycling study (5). If the surface potential of the base region of the evaporative fused junction transistor is about −0.15 e.v.[1] and considering the relationships between current amplification factor, surface recombination velocity, and surface potential (6-9), then one can, by increasing ϕ_s, produce a decrease in the current amplification factor. It is believed, though, that the base region of the diffused device has a surface potential high enough (i.e., strongly n-type), due to the high doping density at the surface, that the "bell-shaped" functional relationship between surface recombination velocity and surface potential actually can result in an improvement in the current amplification factor by increasing the surface potential. The amount of change in surface potential due to silaning has not been measured as yet, so that more quantitative results cannot be stated at this time.

It has been observed that the structure of the polymer has an important influence on the resulting properties of the device. Long-chain polymers appear to reduce reverse currents more than short-chain systems. Also, stability appears to be structure dependent, and the presence of a tri-functional compound in the system seems to aid in achieving more stable properties in the units so treated. This agrees with the findings of Hall (10), who reports an actual bonding of the film that is formed into the surface of the substrate silicon when a tri-functional compound is present.

In conclusion, it is seen that when organo- substituted hydrolyzable silane monomers are polymerized on a silicon device, creating a silicon coating on the surface, the diode characteristics for the device can be improved. Furthermore, since this approach utilizes the so-called monomers of the silicones, additives and copolymerization agents can be chosen so as to produce additional benefits in semiconductor devices.

[1] "Channel" experiments in this laboratory always have shown conversion of type over the base region of these transistors. Preliminary experiments have shown that the surface potential is of this magnitude when the unit is allowed to age in air. These results will be published at a later date.

Acknowledgment

The author wishes to express his gratitude to Mrs. E. Lu for her assistance in this work, to Mr. A. Drasein for the data used in Table III, and to Mr. M. J. Barrett for the devices used in this study as well as his many helpful comments and suggestions.

Manuscript received June 2, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Arc Decomposition of Rhodonite

Victor Harris, John D. Holmgren, Samuel Korman, and Charles Sheer

Vitro Laboratories, Division of Vitro Corporation of America, West Orange, New Jersey

ABSTRACT

A developmental pilot line for the arc treatment of Colorado rhodonite has been built and operated to investigate the applicability of the high-intensity arc process to the extraction of manganese from siliceous ores. The rhodonite is incorporated into 2-in. diameter electrodes to the extent of 75-85% by weight and vaporized in a d-c high-intensity arc operating in the range 40-60 kw. Vaporization in the arc decomposes the manganese silicate content of the rhodonite to MnO and SiO_2. The product is collected as a mixture of the respective oxides in finely particulated form. The manganese, now readily soluble, is leached from this mixture. The effects of significant process variables are discussed.

This paper describes the design and operation of a developmental pilot plant for the arc decomposition of Colorado rhodonite by means of a new process known as the Sheer-Korman "Hierarc Process" (1, 2). The primary purposes of this program were to demonstrate the technical feasibility of treating rhodonite and to obtain process design and evaluation data.

Rhodonite, a manganese silicate, is found in several sections of the United States and abounds in the southwestern area of Colorado. While deposits represent a significant quantity of Mn, the material is of such a refractory and stable nature that it has never been used as a major Mn source; instead it has been described as worthless gangue material in lead and zinc mining operations. Theoretically, pure rhodonite contains 42% Mn. Mined and milled in conjunction with lead-zinc operations, concentrates ranging up to 33, or perhaps 36% Mn, might be expected.

The Hierarc Process, utilizing the high-intensity arc, serves to decompose the manganese silicate into a mixture of two discreet, finely particulated materials, manganous oxide and silica. In this form, the Mn is readily dissolved by leaching. For example, over 95% of the Mn in samples of arc product dissolved in dilute HCl at room temperature.

Using an anode consisting of an homogeneous mixture of ore and carbon—the ore content may be as high as 80-85%—the high-intensity arc provides an effective means of heating the material to temperatures of decomposition without the necessity of heating crucibles or other containing vessels.

Elements of the Process

The rhodonite, ground to 100% minus 50 mesh, is mixed with carbon source materials, in this case coal and pitch. This mixture, with the addition of an extrusion aid material, is placed in an hydraulic press and ore-bearing electrodes are extruded. These are baked with a controlled schedule rising to a maximum temperature of 900°-1000°C. Electrodes of ⅝-in. diameter are completely baked within 2-3 hr, while 2-in. electrodes are baked 12-20 hr, depending on the desired characteristics.

The pilot plant was operated using electrodes 2 in. in diameter and 44 in. long. A direct current arc was used. Therefore, only the anode is ore-bearing; the cathode is a 1-in. diameter graphite rod. The baked electrode is placed in the arc chamber and the arc current applied. For this application the arc is operated in air at atmospheric pressure. Air, swept into the system, provides excess oxygen to the reaction, rapid quenching of the arc product gases, and arc product transport to the product collector. The arc chamber and product collector are shown schematically in Fig. 1. The simplicity of the system is evident.

Since in this application this process serves only as a means of decomposition, the Mn content of the product will usually be essentially the same as that of the feed material. Generally speaking, the values of recoveries, yields, and processing costs will remain about the same independent of the Mn concentrations in the feed. Over-all process economics, of course, are affected importantly by the Mn content of the feed material.

The arc chamber, 36 in. in diameter and 5 ft high, is ⅛-in. boiler plate; ducts are of 18-gauge galvanized iron. Air is swept into the chamber and circulated in such a way that the chamber wall temperatures do not exceed 200°F when operating at the normal level of around 50 kw.

The homogeneous electrode, being made largely of nonconductive material, has a relatively high electrical resistance, as much as two orders of magnitude greater than a pure carbon electrode. Therefore, to minimize power losses it is necessary to in-

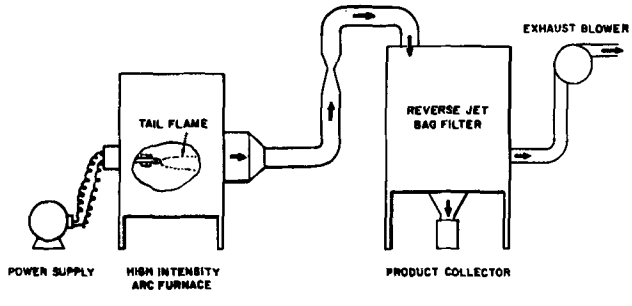

Fig. 1. Arc chamber and product collector

Fig. 2. Anode brush assembly showing anode crater. Graphite cathode can be seen as the smaller diameter electrode.

troduce the arc current as near to the arc crater as possible. A system of sliding brushes is used. Figure 2 shows the brush assembly and also provides a good illustration of the arc crater after the arc is extinguished. The brushes are water-cooled and spring loaded and in this case provided with replaceable graphite shoes. The round plate through which the 2-in. anode projects is water-cooled and electrically neutral, to shield the brush assembly from damage by the arc. The 1-in. cathode in its normal operating position can also be seen.

Operating Data

There are three dependent process variables of primary importance. These are: unit power consumption (in kwhr/lb of anode vaporized), erosion rate (in lb/hr of anode vaporized) and per cent slag (the ratio of the weight of spalled and melted material to the total weight loss of the electrode). These are affected most importantly by the following four independent process variables: anode carbon content (in per cent), arc current (in amperes), anode resistivity (ohm/cm^3), and anode apparent density (g/cc). A comprehensive investigation of the relations of these variables was carried out based on statistical analysis of the results of over 300 test runs. Some typical data are illustrated. Figure 3a shows the effect on unit power consumption of varying arc current and carbon content. This is for electrodes having a specific resistivity in the region of 0.05 ohm/cm^3 and density in the region of 1.75 (g/cc). The heavily inked portions of the curves represent the regions in which experimental data are available. The light portions represent the regions of statistical extrapolation. Curves which are entirely in light ink represent extrapolation of the results obtained with other carbon percentages.

Caution is necessary in viewing the extrapolated data, especially toward the extremes of their extension. They are useful primarily for indicating trends. Referring again to Fig. 3a, it cannot be said, for example, that a 10% carbon electrode can be processed at 300 amp with a unit power consumption of 1 kwhr/lb. However, it can be said that at lower currents the 10% carbon electrode will probably give better results than the higher carbon electrodes, while at higher currents the converse will be true.

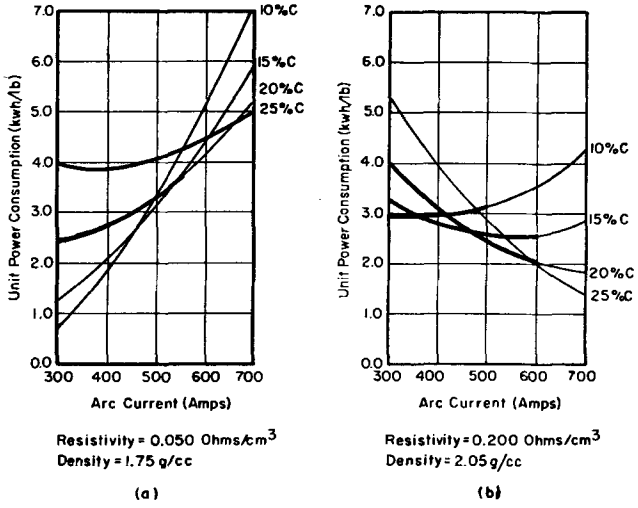

Fig. 3. Effect of arc current and carbon content on unit power consumption.

Figure 3b provides a comparison of the same factors for electrodes having a resistivity of about 0.2 ohm/cm^3 and a density of about 2 g/cc. The considerable difference in character of these curves is apparent. Improved performance is evident. Performance generally improves with current, and under these conditions a 20% carbon electrode provides better operation at higher currents than any of the electrodes in the previous figure.

A comparison of erosion rates can also be made in the same manner. Figure 4a shows the erosion rate for the low resistivity, low density type of electrode in terms of pounds of electrode vaporized per hour. It will be noted that at 600 amp the curves fall in the area below 10 lb/hr. In contrast Fig. 4b shows the same information for the high resistivity, high density anode. In this case it can be seen that at 600 amp operation is in the region of 20 lb/hr.

A similar comparison of per cent "slag" shows that the same conditions which tend to improve unit power consumption and erosion rate tend also to increase per cent slag. This material is not slag in the usual sense. It is material which either spalls from the electrode or melts and drips from the crater without being vaporized. Figure 5a shows the per

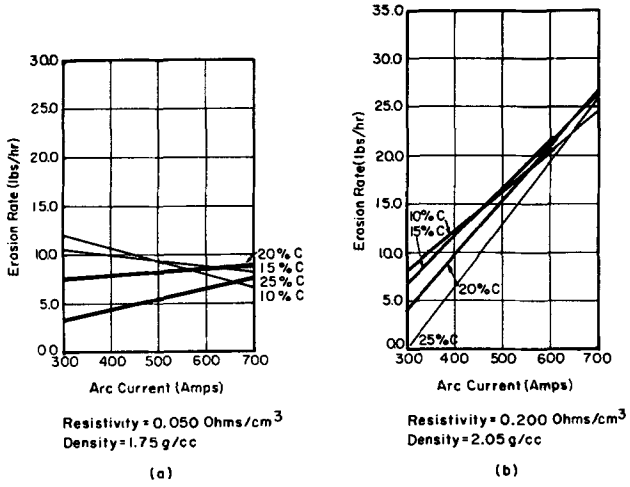

Fig. 4. Effect of arc current and carbon content on erosion rate.

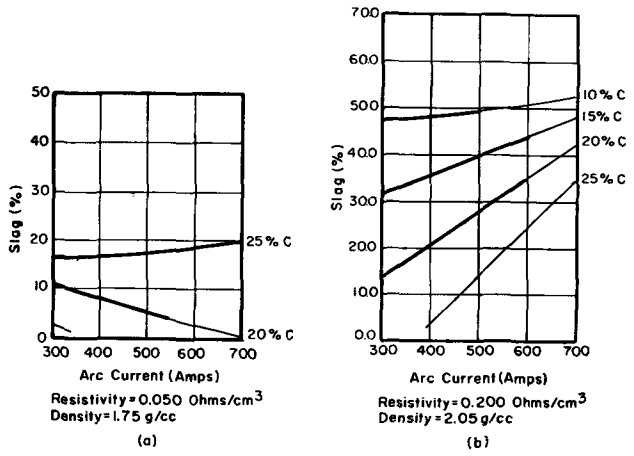

Fig. 5. Effect of arc current and carbon content on "slag" per cent.

cent slag for the low resistivity, low density electrode. The 20% carbon electrode, for example, falls entirely in the region below 10%. In Fig. 5b it is seen that, with the conditions that give better unit power consumption and erosion rate, slag is above 10%.

On the basis of these and other similar data a group of electrode characteristics were evolved as follows: apparent density in the region of 2, specific electrical resistivity in the range of 0.25 to 0.3 ohm/cm³, and carbon content in the range of from 16 to 18% after baking.

Electrodes of these characteristics were subjected to a series of runs extending over half-shift periods of about 4 hr. Typical results are shown in Table I.

Note that the slag per cent is lower than might have been expected from the statistical test results just discussed. This is because those test runs were short, involving considerable on-off operation and corresponding heating and cooling of the system. The sustained runs always exhibit better results and, of course, are more representative of production conditions.

Operations were not carried to the point of actually recycling this slag. However, with its recycling, Mn recovery in the process would be expected to approach 100%, since there is little true loss anywhere in the system. The ore used in these operations contained approximately 25% Mn. Before treatment, on the basis of analysis, over 90% of the Mn in the ore was in insoluble form. After treatment over 90% of the insoluble Mn was found to be converted to soluble form in the arc product.

Table I. Typical operational data

Current	700 amp
Power	50 kw
Anode feed	103 in./hr 24 lb/hr
Slag	16.5 % (wt)
Anode vaporized	20 lb/hr
Unit power consumption (d-c side of generator)	2.5 kwhr/lb of electrode vaporized
Production rate	13 lb/hr of arc product
Cathode consumption	0.5 lb/hr of graphite

It should be emphasized that these results represent a certain stage of development in process application. Further improvement can be expected. Development in the techniques of electrode fabrication for higher strength will permit reduction in slag per cent and operation at higher currents with higher production rates. The use of larger diameter electrodes can be expected to provide some additional improvements in unit power consumption and, of course, also higher production rates. Many other aspects of this development system are subject to engineering refinement. Work in refining the high-intensity arc in process applications is continuing.

Conclusion

This work demonstrates the technical feasibility of applying the Hierarc Process to the decomposition of Colorado rhodonite ore to provide manganese in a readily soluble form. Most importantly, this was done with rapid baked electrodes and over-all values of unit power consumption in the region of 2.5 kwhr/lb.

On the Measurement of the Temperatures of Unenclosed Objects by Radiation Methods

A. G. Emslie and H. H. Blau, Jr.

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

The functional relationships between apparent temperature and true temperature for the total radiation pyrometer, the optical pyrometer, the two-color pyrometer, and the two-temperature pyrometer are developed and discussed. It is shown that it is impossible to measure the temperature of an unenclosed object in the range 2000°-4000°K with accuracy greater than about 10% without prior knowledge of the emissivity. If the emissivity is known within 20%, the temperature can be determined within 1 or 2% by means of an optical pyrometer, particularly if the instrument is operated at the blue end of the spectrum. The accuracy obtainable with the other instruments under equivalent conditions is significantly lower.

Since the last war there has been a growing need to operate various devices at higher and higher temperatures in order, for example, to obtain more efficient rocket motors or faster airplanes. As a result a rapid increase is now taking place in research on the properties of all conceivable kinds of materials at higher temperatures. Such tools as the solar furnace, the plasma jet, the pulsed electric discharge, and the shock tube are used in these furnace techniques in several important respects.

An ordinary furnace usually has a fairly uniform internal temperature distribution, including the sample under test, and so the sample temperature can be found quite readily by means of a thermocouple inserted anywhere in the furnace or by an optical pyrometer applied to a sighting hole which emits essentially black-body radiation. With the new methods, on the contrary, there is generally no enclosure at the temperature of the sample, and the sample itself usually has sizeable temperature gradients. Under these conditions it cannot be assumed that the sample acts as a black-body radiator. Also, because of the gradients, it is very difficult to produce an artificial black-body cavity, for example, by drilling a hole in the sample. Thus the optical pyrometer cannot be used routinely to determine the temperature. Furthermore, in many cases of interest the sample temperature is above the limits of measurement by thermocouples.

How, then, can one measure the temperature of a sample under these conditions? The purpose of this paper is to evaluate the various radiometric methods under the assumption that the sample is completely unenclosed and that there is no prior knowledge about the emissivity of the sample.

Total Radiation Pyrometer

In the total radiation pyrometer the radiation from a given area of the sample is integrated over all wave lengths by a thermopile that has been calibrated against a black-body radiator.

The relation between the apparent absolute temperature T_A corresponding to an assumed average emissivity of ½ and the true temperature T corresponding to the real average emissivity $\bar{\epsilon}$ is given by

$$\frac{1}{2}\sigma T_A^4 = \bar{\epsilon}\sigma T^4 \qquad [1]$$

where σ is the Stefan-Boltzmann constant. The fractional error in the absolute temperature is

$$\frac{T_A - T}{T} = (2\bar{\epsilon})^{1/4} - 1 \qquad [2]$$

The graph of this relation, shown in Fig. 1, indicates that an error of about 20% is made when the true emissivity is 0.2 rather than the assumed value of 0.5.

The Optical Pyrometer

In the case of the optical pyrometer, radiation from the sample in a narrow band of wave lengths centered at 0.65 μ is compared with the radiation from a calibrated glowing filament. Assuming as before that nothing is known about the emissivity of the sample and that a value of ½ is guessed, we

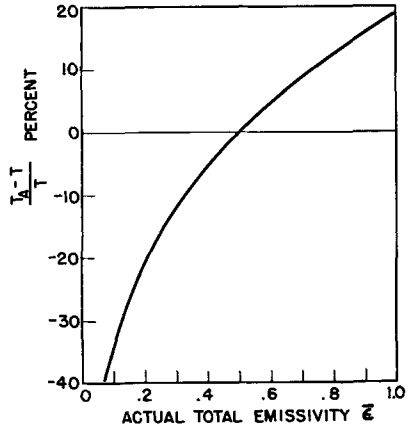

Fig. 1. Error of total radiation pyrometer vs. actual total emissivity for an assumed total emissivity of ½.

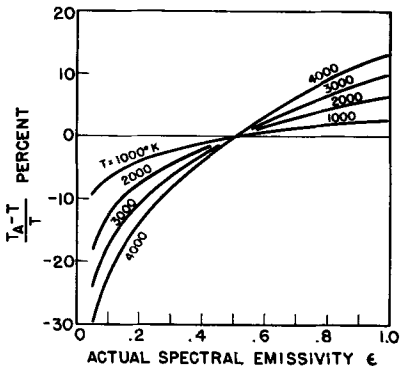

Fig. 2. Error of optical pyrometer vs. actual spectral emissivity at $\lambda = 0.65\ \mu$ for an assumed spectral emissivity of ½.

find from Wien's law the following relation between the apparent and true temperatures:

$$\frac{1}{2}\, e^{-c_2/\lambda T_A} = \epsilon\, e^{-c_2/\lambda T} \qquad [3]$$

where λ is the wave length at the center of the transmission band of the instrument, ϵ is the spectral emissivity of the sample, and $c_2 = 1.44 \times 10^4$ micron degrees.

From Eq. [3] we obtain for the relative error in the temperature

$$\frac{T_A - T}{T} = \frac{(\lambda T/c_2)\ \ln 2\epsilon}{1 - (\lambda T/c_2)\ \ln 2\epsilon} \qquad [4]$$

Figure 2 shows how the error depends on the true spectral emissivity ϵ for various fixed values of the true temperature T. For example, if the true emissivity is 0.2 instead of the guessed value of 0.5, the error is 7.5% at 2000°K and 14% at 4000°K.

Since, according to Eq. [4], the error is approximately proportional to λ, better results would be obtained by operating an optical pyrometer at as short a wave length as possible. At temperatures above 2000°K there should be enough short wavelength radiation to permit the construction of an electronic instrument with a filter in the neighborhood of 0.4 μ.

The Two-Color Pyrometer

The basis of the two-color pyrometer is that the unknown emissivity can be eliminated by taking the ratio of the radiant intensities from the sample at two different wave lengths. Unfortunately, this can only be done if the emissivity is the same at the two wave lengths. If ϵ_1 and ϵ_2 are the actual emissivities at the wave lengths λ_1 and λ_2, the radiated intensities in wave-length bands $\Delta\lambda_1$ and $\Delta\lambda_2$ are

$$\left.\begin{aligned} W_1 &= \epsilon_1 c_1 \lambda_1^{-5} \Delta\lambda_1 e^{-c_2/\lambda_1 T} \\ W_2 &= \epsilon_2 c_1 \lambda_2^{-5} \Delta\lambda_2 e^{-c_2/\lambda_2 T} \end{aligned}\right\} \qquad [5]$$

assuming that λ_1 and λ_2 are both in the region where Wien's law applies. The ratio of the intensities is

$$\frac{W_1}{W_2} = \frac{\epsilon_1}{\epsilon_2}\,\frac{\lambda_1^{-5}\Delta\lambda_1}{\lambda_2^{-5}\Delta\lambda_2}\, e^{(c_2/T)[(1/\lambda_2)-(1/\lambda_1)]} \qquad [6]$$

The apparent temperature T_A is the value derived from the instrument on the assumption that $\epsilon_1 = \epsilon_2$ and is therefore given by

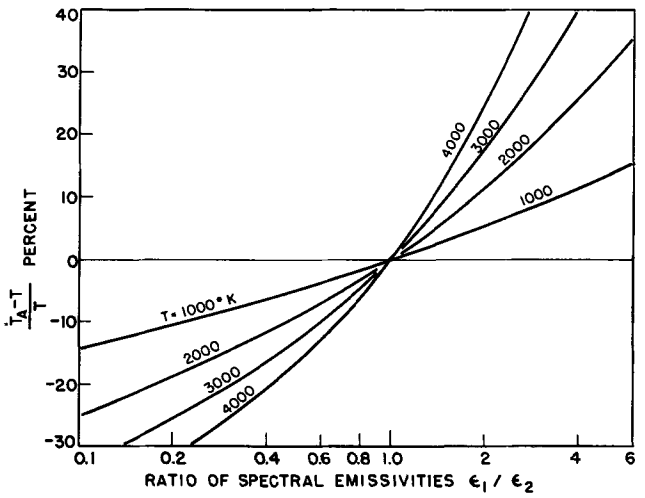

Fig. 3. Error of two-color pyrometer vs. ratio of spectral emissivities at wave lengths of 0.40 and 0.65 μ.

$$\frac{W_1}{W_2} = \frac{\lambda_1^{-5}\Delta\lambda_1}{\lambda_2^{-5}\Delta\lambda_2}\, e^{(c_2/T_A)[(1/\lambda_2)-(1/\lambda_1)]} \qquad [7]$$

The relation between the true and apparent temperature is found by equating [6] and [7]:

$$\frac{1}{T_A} - \frac{1}{T} = \frac{\ln(\epsilon_2/\epsilon_1)}{c_2\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)} \qquad [8]$$

The error $(T_A - T)/T$ calculated from this expression is shown in Fig. 3 as a function of the ratio of the spectral emissivities for different values of T, with $\lambda_1 = 0.40\ \mu$ and $\lambda_2 = 0.65\ \mu$.

The error is zero when the underlying assumption that the emissivities are the same is valid. In practice, the ratio of the emissivities at the two wave lengths can differ considerably from unity. If the ratio is 2, for example, the error is 11% at 2000°K and 25% at 4000°K.

It may be thought that the effect of the variation of emissivity with wave length may be evaded by taking the two wave lengths λ_1 and λ_2 very close together. Equation [8] shows that this idea is fallacious. The difference $1/T_A - 1/T$ is clearly proportional to the slope of the chord of the ln ϵ vs. $1/\lambda$ curve. This quantity merely becomes the slope of the tangent to the curve when $\lambda_1 \to \lambda_2$ and there is no *a priori* reason why the tangent should have a smaller slope than the chord.

The idea of the two-color pyrometer can be extended, in principle, to a multi-color pyrometer. A three-color pyrometer, for example, will give the correct temperature if the emissivity varies linearly with wave length. But in general the curvature of the emissivity vs. wave length characteristic is not zero and will produce as large an error in temperature as the slope does with the two-color pyrometer.

Two-Temperature Pyrometer

A new type of pyrometer that we have investigated, and which has also been considered by K. C. Vul'fson (1), depends on the idea that if the spectral distribution of intensity from the sample is measured at two temperatures, the spectral emissivity can be eliminated by dividing one spectral distribu-

tion by the other. Let T and T' be two temperatures. Then the two spectral distributions are given by Planck's law:

$$W = \frac{c_1 \epsilon(\lambda) \lambda^{-5} \Delta\lambda}{e^{c_2/\lambda T} - 1} \quad [9]$$

$$W' = \frac{c_1 \epsilon(\lambda) \lambda^{-5} \Delta\lambda}{e^{c_2/\lambda T'} - 1} \quad [10]$$

The ratio of the distributions is

$$\frac{W'}{W} = \frac{e^{c_2/\lambda T} - 1}{e^{c_2/\lambda T'} - 1} \quad [11]$$

It will be noted that the spectral emissivity has cancelled out.

In Eq. [11] the ratio W'/W can be determined experimentally as a function of wave length λ. Since only two unknown quantities, namely, T and T', appear in the equation, it is sufficient in principle to make measurements at only two wave lengths in order to determine both T and T'. However, more accurate results should be obtainable by using data over the whole spectrum. This can be done by preparing a set of master graphs of the function

$$\frac{W'}{W} = \frac{e^{xT'/T} - 1}{e^x - 1} \quad [12]$$

which is obtained from Eq. [11] by the substitution

$$x = c_2/\lambda T'$$

Figure 4 shows the master graphs of W'/W vs. x for various values of T/T' with x plotted on a logarithmic scale.

To determine T and T' from the experimental data, the experimental values of W'/W are plotted against λ with the same scales as in Fig. 4. The experimental graph is now moved horizontally over the master chart until the best fit with one of the master curves is obtained. By reading any pair of corresponding points on the two abscissas, one finds a value of λ and a value of $c_2/\lambda T'$. Thus T' is found. The matched master curve gives T/T', so T is also determined.

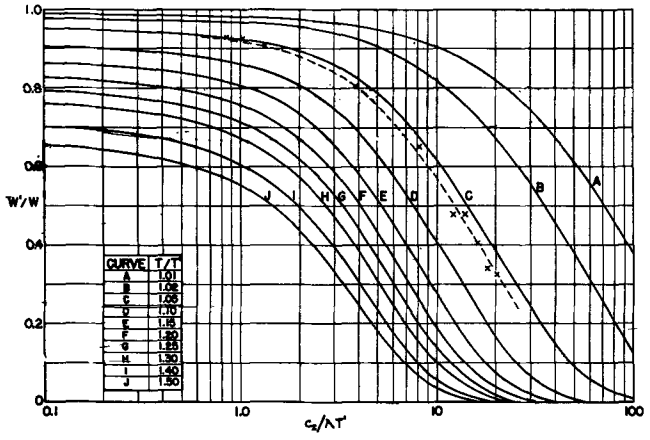

Fig. 4. Master graphs for the two-temperature pyrometer showing intensity ratio for two temperatures vs. $c_2/\lambda T'$. The crosses represent the best fit of experimental data for a hot Globar source.

The crosses on Fig. 4 represent the best fit of experimental data for a hot silicon carbide source taken with a Perkin Elmer infrared spectrometer. The position of the crosses indicates that $T'/T = 1.052$, and the horizontal position of the experimental wave-length scale (not shown in Fig. 4) gives $T' = 1126°K$. The actual temperature determined by a thermocouple embedded in the silicon carbide gave a reading of $T' = 1320°K$. The error is therefore about 15% which is comparable with the errors of the other radiometer methods.

The error in the temperature determination appears to be due to the assumption that the spectral emissivity is independent of temperature. If $\epsilon(\lambda)$ is a function of temperature, then it cannot be divided out by taking the ratio of Eq. [9] and [10].

The effect of the temperature coefficient of emissivity can be calculated most easily for the case of a two-temperature pyrometer that measures the radiation from the sample at only two wave lengths λ_1 and λ_2. For precision in fitting the two-point experimental graph to the master graphs of Fig. 4 the two wave lengths should be on opposite sides of the black-body peak.

The intensity radiated at the shorter wave length λ_1 is given by Wien's law:

$$W = c_1 \epsilon \lambda_1^{-5} \Delta\lambda_1 e^{-c_2/\lambda_1 T} \quad [13]$$

The rate of change with temperature is

$$\left(\frac{1}{W}\frac{dW}{dT}\right)_{\lambda_1} = \left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_1} + \frac{c_2}{\lambda_1 T^2} \quad [14]$$

The intensity at the longer wave length λ_2 follows Rayleigh's law:

$$W = \frac{c_1}{c_2} \epsilon T \lambda_2^{-4} \Delta\lambda_2 \quad [15]$$

and the rate of change is

$$\left(\frac{1}{W}\frac{dW}{dT}\right)_{\lambda_2} = \left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_2} + \frac{1}{T} \quad [16]$$

An equation for the true temperature T is obtained by eliminating dT from Eq. [14] and [16]:

$$\frac{\left(\frac{dW}{W}\right)_{\lambda_1}}{\left(\frac{dW}{W}\right)_{\lambda_2}} = \frac{\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_1} + \frac{c_2}{\lambda_1 T^2}}{\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_2} + \frac{1}{T}} \quad [17]$$

The apparent temperature T_A that would be obtained from the master graphs is found by assuming that the temperature coefficient of emissivity is zero in Eq. [17]. Thus

$$\frac{\left(\frac{dW}{W}\right)_{\lambda_1}}{\left(\frac{dW}{W}\right)_{\lambda_2}} = \frac{\frac{c_2}{\lambda_1 T_A^2}}{\frac{1}{T_A}} \quad [18]$$

On combining Eq. [17] and [18] we find:

$$T_A = T \cdot \left[1 + T\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_2} \right] \Big/ \left[1 + \frac{\lambda_1 T^2}{c_2}\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_1} \right] \quad [19]$$

The error in temperature is therefore, approximately,

$$\frac{T_A - T}{T} = T\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_2} - \frac{\lambda_1 T^2}{c_2}\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_1} \quad [20]$$

If $\lambda_1 = 0.4\ \mu$ and $T = 2000°K$, then $\lambda_1 T/c_2 = 0.06$. Thus the short wave-length contribution to the error is negligible compared with the long wave-length contribution and Eq. [20] reduces to

$$\frac{T_A - T}{T} = T\left(\frac{1}{\epsilon}\frac{d\epsilon}{dT}\right)_{\lambda_2} \quad [21]$$

Figure 5 shows a plot of the error vs. $(1/\epsilon)(d\epsilon/dT)$ for various values of T. The circles on the 2000°K line give the errors obtained from published values (2-4) of the temperature coefficients for tungsten, rhenium, and molybdenum. The errors are quite large enough to explain the discrepancy observed in the case of silicon carbide and are of the same order of magnitude as the errors involved in the other radiometer methods.

Conclusions

The general conclusion to be drawn from our analysis is that it is impossible to measure the temperature of an unenclosed sample in the range 2000°-4000°K with an accuracy greater than about 10% by observing only the radiation emitted by the sample and without any prior knowledge of the emissivity. On the other hand, even a 20% measurement of the emissivity at a single wave length will allow determination of temperature to 1 or 2% by means of the optical pyrometer, especially if the instrument is operated at the blue end of the spectrum.

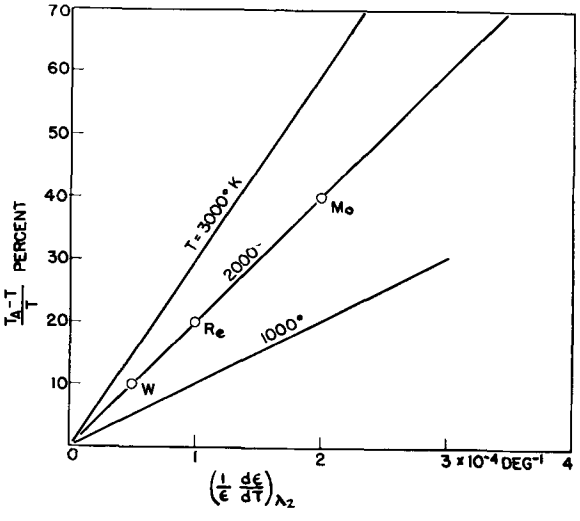

Fig. 5. Error of two-temperature pyrometer vs. temperature coefficient of emissivity. The circles indicate the calculated errors for tungsten, rhenium, and molybdenum at 2000°K.

The problem of measuring the temperature of an unenclosed object therefore hinges on being able to determine the emissivity. Since the emissivity varies quite markedly with temperature it is unsafe to extrapolate low-temperature values to the high-temperature range. Thus the emissivity has to be measured at the high temperature and, since the temperature is unknown, this can only be accomplished by finding the reflection coefficient of the sample at the operating wave length of the pyrometer. If it is assumed that the pyrometer views the surface of the sample at normal incidence, then the reflection coefficient of interest is $\rho_\lambda = I_r/I_o$ where I_o is the intensity of a beam of light at normal incidence and I_r is the intensity of the reflected light integrated over the whole hemisphere. An equivalent arrangement, using the principle of reversibility, is to flood the sample with light uniformly from all directions and measure the reflected light in a small solid angle at normal incidence. In both methods care has to be taken that any specularly reflected light is included in the measurement. Since the hot sample itself emits light in all directions, the reflection experiment requires chopped radiation. The normal emissivity is easily determined from the reflection coefficient by means of Kirchhoff's law $\epsilon_\lambda = 1 - \rho_\lambda$.

In the case of a sample heated in a solar furnace, Laszlo (5) has suggested using reflected sunlight to determine the emissivity. A total radiation pyrometer designed by Gardon is used to determine the incident and reflected radiation fluxes, the ratio of which gives the total reflectivity and hence the total emissivity ϵ_t. The temperature may then be found from the energy balance

$$P = \epsilon_t T^4$$

where P is the incident flux. This equation assumes, however, that the sample loses energy by re-radiation only.

Another method mentioned by Laszlo is use of an optical pyrometer in conjunction with a value of the spectral emissivity ϵ_λ calculated from a measured value of the total reflectivity. It is not clear how a unique value of ϵ_λ can be obtained in this way, except for the case of a gray body.

Manuscript received Sept. 8, 1958. This paper was prepared for presentation before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Behavior of Rhenium in Electron Tube Environments

Gordon B. Gaines, Chester T. Sims,[1] and Robert I. Jaffee

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Rhenium, tungsten, and rhenium-coated tungsten have been exposed to carburizing atmospheres and to water-cycle attack, rhenium and tungsten to aluminum oxide at 1750°C for 7000 hr, and rhenium to boron-containing atmospheres. It was confirmed that rhenium, unlike most other refractory metals, does not form a carbide. Rhenium forms a boride, which forms a eutectic with another boride or with rhenium, and melts under 2250°C. Thoriated rhenium maintains microstructural and mechanical integrity after long exposure in vacuum at 1750°C in contact with alumina. Rhenium and rhenium-coated tungsten are highly resistant to water-cycle effects.

Extensive work has been reported recently on the metal rhenium, both in this country and abroad (1, 2). Rhenium is a strong, ductile, refractory metal which melts at 3180°C and possesses chemical and metallurgical properties which are in some respects characteristic of the precious metals and in others characteristic of the refractory transition metals. Rhenium is potentially useful in vacuum tubes and other electronic devices. The behavior of Re exposed to reactive environments that might be encountered in such devices at high temperatures is of considerable interest. In this work, Re, W, and Re-coated W have been exposed to carburizing atmospheres and to water-cycle attack; Re and W were heated in contact with aluminum oxide (in commercial vacuum), and Re was heated in boron-containing atmospheres. Following exposure, the materials were evaluated to determine chemical and mechanical stability.

Carburizing Environment

The possibility that Re does not form a carbide was first suggested by Tzyrbiatowski (3). This was confirmed by Hughes (4) who studied arc-melted Re-C alloys and found that the terminal α Re solid solution was in equilibrium with graphite. A eutectic reaction occurs at 2480°C and 16.9 at. % C (1.3 wt %). Rhenium dissolves up to 11.7 at. % C at 2480°C. The solubility of C in Re decreases rapidly with decreasing temperature to about 4.5 at. % at 2000°C. The absence of a compound in the Re-C system is unique among refractory transition metals; W, Ta, Mo, and Nb, all form carbides. In this respect, Re behaves similarly to the Pt-group metals.

In this study, unalloyed Re and W filaments and a Re-coated W wire were heated in the presence of a C-bearing atmosphere to study high-temperature reactivity. The materials used were 0.020-in. annealed Re wire fabricated by conventional techniques, 0.014-in. wrought commercial W wire, and Re-coated W wire prepared by deposition of an 0.007-in. Re coating on the 0.014-in. wrought W by halide decomposition. The deposition process consisted of first preparing rhenium pentachloride by the direct action of chlorine on Re metal at 750°-850°C The rhenium pentachloride then was vaporized in vacuum in the presence of the resistance-heated W wire. The pentachloride was decomposed thermally, depositing Re metal on the hot W wire. During this process, the 0.014-in. W-wire core was resistance heated to a temperature of 900°-1000°C for a period of about 2 hr. The final Re deposit was 0.007 ± 0.001 in. thick, adherent, bright, and quite uniform in thickness along the length of the wire. Some surface roughness was apparent, which is not unusual for coatings prepared by the halide vapor decomposition process.

For carburization, the three different filaments first were heated by self-resistance to 1982°C in flowing hydrogen. Dry hydrogen at the rate of 4.2 l/min and hydrogen-toluene vapor at 0.84 l/min then were passed through the chamber for 2 min. The hydrogen-toluene vapor flow was terminated, and dry hydrogen then was allowed to flow through for an additional 30 sec before cooldown. Thus, the filaments were at temperature somewhat longer than 2 min. Portions of the filaments were mounted for metallographic inspection, and the appearance and the results of Knoop microhardness traverses for unalloyed W and Re, together with a typical wrought structure for unexposed W, are shown in Fig. 1. Uncontaminated, annealed Re wire would have an equiaxed grain structure and an average hardness of about 400-500 Knoop across the diameter.

Upon exposure to the carburizing atmosphere, the W wire recrystallized, and carbide formed at the surface. Recrystallization resulted in a hardness drop to about 400 Knoop throughout the core. The layer on the surface of the W is tungsten carbide, confirmed by the hardness values of about 1900 Knoop. The carbonized W filaments were extremely brittle and fractured at the slightest touch.

The carburized rhenium shown in Fig. 1c retained a single-phase structure. This is supporting evidence that Re does not form a carbide. However, the entire cross section of the wire exhibits rather high hardness for an annealed Re wire of this diameter, and the hardness values are rather scattered. It is believed that C has diffused completely through the Re wire and the structure shown is that of a Re-

base, interstitial-carbon solid solution. The rapid diffusion rate of C through Re is verified by results of the studies of Re-coated W, where W_2C formed underneath a Re layer in a short time period. Thus, although Re does not form a carbide, diffusion of C into Re occurs rapidly with considerable hardening. Although insufficient material was available for quantitative bend tests, the wire showed ductility when bent by hand. This suggests that Re metal is not hardened to the point of embrittlement when heated in carbonaceous atmospheres. This should enhance the usefulness of Re considerably.

A longitudinal section of Re-coated W wire in the as-deposited condition is shown in Fig. 2a. The large-grain, high-purity Re deposited from decomposition of the pentachloride has a somewhat lower hardness (350 Knoop) than fabricated Re filaments (400-500 Knoop). The wrought W core is slightly softer than the W of Fig. 1a, possibly because of stress relief at 900°C during preparation of the Re coating. A portion of the composite wire was exposed in pure hydrogen for 2 min at 1980°C with no C present. The resulting structure and hardness are shown in Fig. 2b. The W core has largely recrystallized, and hardness reduced to about 450 Knoop. The Re cladding is essentially unchanged. A small amount of interdiffusion has commenced between the W core and the Re cladding, causing a narrow, dark layer of a new phase to form at the interface. This phase has a relatively high hardness which may be considerably higher than that shown by measurements as the phase layer is too narrow to yield accurate readings. This new layer probably is either σ-phase (W_2Re_3) or an α-Mn-type W-Re intermetallic, or both (5). Exposure to C, as previously described, results in the structure shown in Fig. 2c. The Re coating hardened from about 350 to 700 Knoop at the surface as a result of C diffusion. This increase is similar to that noted for unalloyed Re wire which hardened from 450 to an average of 850 Knoop. Two new zones were found in the W-Re interface. Using filtered Fe radiation, x-ray diffraction measurement on the new zones showed two major phases, α—W_2C and W_2Re_3 (σ-phase). Weak diffraction lines also observed might have been due to the Re-W-Mn-type phase.

The outer interfacial zone, which has a hardness of over 2000 Knoop, is undoubtedly the W_2C formed from reactions between W and C which diffused through the Re coating. The inner zone, with a hardness of 1500 Knoop, is the diffusion product, W_2Re_3. Thus, Re coatings do not protect underlying W from reactions with ambient C-containing atmospheres, even with thick coatings, as in the present case. Reaction with the underlying W is slowed down, however, and there is no doubt that the carburized Re-coated W filament is not affected so severely by C as unalloyed W, and may be capable of some mechanical service. For instance, the wire was capable of being handled without fracture following carbonization. Although it possessed no measurable ductility, the wire exhibited a room-temperature ultimate tensile strength of 45,000 psi.

Boron-containing Atmospheres

Since Re does not form a carbide, it was thought that it might have somewhat lower reactivity with B than most other refractory metals which form borides. Boron-containing materials are potentially useful in electron-tube technology. If Re does not form a boride, it might be useful for supporting B-containing substances which are good thermionic emitters.

Three individual 0.01-in. Re filaments were heated by self-resistance to different temperatures in an atmosphere of flowing gas, which consisted of a mixture of dry hydrogen and boron trichloride. One filament was heated to 1330°C (black-body temperature), one to 1750°C, and one to 2250°C. During the adjustment of the voltage of the filaments to get the desired temperature, the filaments were in an atmosphere of flowing dry hydrogen. The filaments then were allowed to cool, and boron trichloride was introduced to give a hydrogen:boron trichloride ratio of 7:1. Filament power then was applied for a period of 2 min, following which the filaments were allowed to cool in the B-containing atmosphere.

About 10 to 15 sec after exposure commenced, the filament at 2250°C burned in half. The remaining two filaments lasted for the entire 2-min period.

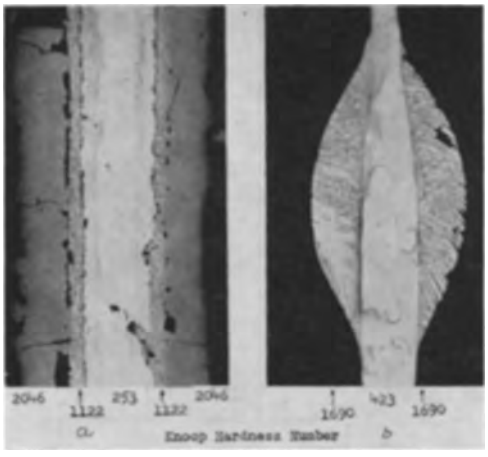

Fig. 3. Longitudinal sections and hardness of unalloyed Re wire exposed to a boron-containing atmosphere under the conditions designated. a, Exposed 2 min at 1750°C; b, exposed 15 sec at 2250°C. Magnification 100X before reduction for publication.

The filaments heated to 1330° and 1750°C appeared to have developed a coated or scaled appearance, while the burned-out filament appeared beaded. A longitudinal section of the filament exposed at 1750°C is shown in Fig. 3a and a similar section of the filament exposed at 2250°C is shown in Fig. 3b, each with pertinent hardness information.

The specimen exposed at 1750°C developed an extremely hard outer crust which readily cracked. A hard intermediate zone also was apparent. An appreciable fraction of the Re core remained unreacted. It is assumed from the appearance and hardness data for the exposed filament that the outer layer shown is a rhenium boride. The intermediate layer may be a solid solution of B in Re or a lower boride, and the inner core is essentially unreacted Re. Thus, Re is not resistant to B at high temperature and undoubtedly forms a boride or borides.

Exposure of the Re wire to B at 2250°C caused melting and burnout. The molten product froze as small beads on the filament, one of which is shown in Fig. 3b. Since the central Re core has a higher hardness than normal, it appears probable that B diffused through the 0.010-in. section at 2250°C. The bead probably is an eutectic mixture of the boride and the phase shown in the intermediate zone of Fig. 3a, which melts below 2250°C.

Life Tests on Thoriated Rhenium and Tungsten Filaments in Contact with Solid Alumina

A 0.020-in. Re-0.85ThO_2 (wt %) wire and 0.015-in. commercial W wire of the type described previously were wrapped on small high-purity (Degussa) Al_2O_3 cylinders and the assemblies were placed in a U-tube container evacuated to a pressure of about 10^{-7} mm Hg. The tube was not gettered. The temperature of the wires was held at approximately 1750°C black-body temperature for 7000 hr. The alumina cylinders were supported by the filaments. The appearance of the test device and the filaments and cylinder surfaces following exposure for 7000 hr are shown in Fig. 4.

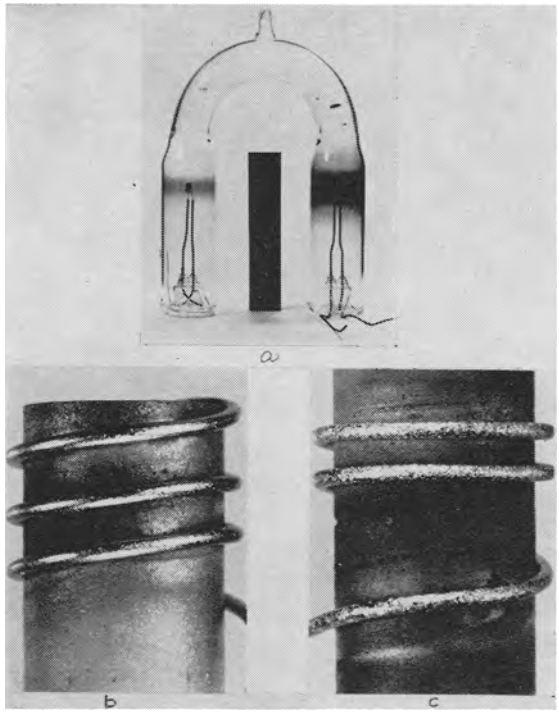

Fig. 4. Appearance of evacuated U-type and of Re and W filaments on alumina sleeves following life testing for 7000 hr at 1750°C. a, Evacuated U-tube; b, Re filament; c, W filament.

The 7000-hr life test resulted in no major changes in geometry or in mechanical or electrical failure. However, a certain amount of local reaction took place, as shown in Fig. 4. At places on the alumina cylinders where physical contact with the filaments was maintained for a long time, eroding of the alumina is evident. The surface appearances of the two filaments had been affected. The W wire possessed a much rougher surface than the Re-ThO_2 wire, although neither was as smooth as drawn wire.

The surface roughing and the black deposits on the glass walls probably are due almost wholly to the water-cycle mechanism. It is known that this mechanism affects Re much less than it does W, and this certainly is suggested by the much larger deposits around the W filament. The water-cycle attack would not be expected to be substantial at a pressure of 10^{-7} mm Hg.[1] However, the tube was ungettered and unbaked, and it is highly probable that the pressure during much of the 7000 hr was of the order of 10^{-5}—10^{-6} mm Hg and that the tube atmosphere contained a substantial amount of water vapor. Another mechanism for explaining the deposits on the tube walls and the grooves in the alumina is a reaction between alumina and tungsten, giving aluminum and tungsten oxide gases. Using published thermodynamic data (6), a simple calculation indicates that, at a pressure of the order of 10^{-6} mm Hg and a temperature of 1750°C, this possibility cannot be ruled out. Unfortunately, an analysis of the deposits was not made, so as to settle this point. It is possible, also, that atomic hydrogen and oxygen, present as a

[1] The authors are grateful to a reviewer for pointing this out.

[c] Too brittle to be measured.

result of the water-cycle reaction, contributed to the attack of alumina.

The Re-alloy filament did not fracture during its removal from the tube or its handling prior to mechanical testing. The 7000-hr test produced only moderate changes in its over-all mechanical properties as compared to unexposed metal. As shown by the data in Table I, this alloy, which is somewhat less strong and ductile than unalloyed Re, showed only slightly reduced tensile strength as a result of the test. Ductility, as measured by elongation and bend tests, also dropped slightly. As expected, the recrystallized W filament possessed little mechanical integrity compared to Re or to fibered W.

Subsequent microstructure examination showed that the thoria in the Re filament has shown some tendency to agglomerate into larger particles, see Fig. 5. In addition, the W filament developed a heavy concentration of voids scattered uniformly throughout the grain structure, while no voids were found in the Re. No reason for the voids is apparent. Analyses[2] of the W revealed no unexpected or excessive impurities. However, tungsten and alumina are not compatible over about 1400°C (7), and contact with the alumina cylinder may have contributed to the void formation

[2] Impurities in the W by spectrographic analysis were as follows (wt %): Fe, 0.01-0.1; Si, 0.005-0.05; Mg, 0.005-0.05; Mo, 0.001-0.01; Ca, 0.001-0.01; Cu, Ni, K, Mn, <0.001; Th, Na, <0.05; Cr,

Water-Cycle Life Tests for Tungsten, Rhenium, and Rhenium-Coated Tungsten

Rhenium is considerably more resistant to the water-cycle effect at elevated temperatures than tungsten, as has been shown previously (8, 9). Accordingly, the possibility of protecting W from this phenomena by Re coatings has been suggested. In the present work, 0.005-in. wrought commercial W, 0.005-in. unalloyed Re, and Re-coated W wires were exposed to water vapor at a pressure of approximately 4×10^{-4} mm Hg[3] at two temperatures, 1300° and 1750°C. The Re coating was applied by the halide-decomposition process, as described previously in the study of attack by carburizing atmosphere. The coating was approximately 0.007-in. thick and was applied to an 0.014-in. W wire. Exposure of all specimens was for 7800 hr, each filament being heated individually by its self-resistance, and all were exposed to the same atmosphere.

Data from the life test are given in Table II. The data confirm that Re is less susceptible to water-cycle attack at all temperatures than W, and the differences is most marked at 1750°C where all of the materials react more severely. Least attack occurs on the Re-coated W, which possessed better water-cycle resistance than unalloyed Re. This is somewhat surprising, particularly since the surface of the Re-coated W was slightly rougher than that of the unalloyed Re wire. The as-deposited Re cladding is probably of higher purity than the unalloyed Re wire, which may account for the difference in rates of attack.

For the conditions of moderate water-vapor attack studied, rather heavy coatings were used in

[3] Vapor pressure over ice at −80°C.

Table II. Weight-loss data for W, Re, and Re-coated W exposed to water-cycle attack for 7800 hr

Material	Exposure temperature, °C		Total wt loss, mg	Attack in 7800 hr, mg/cm²
	Initial	Final		
W	1300	1275	0.5	1.50
	1750	1660	2.6	8.25
Re	1300	1200	0.2	0.65
	1750	1660	0.3	0.98
Re-clad W	1300	1310	0.8	0.48
	1750	1700	1.0	0.57

the present studies. With attack so light, much thinner coatings, such as those applied by electroplating, would probably be adequate protection.

Conclusions

1. It is confirmed that Re metal, unlike most other refractory metals, does not form a carbide. Although C diffuses rather rapidly through Re, causing hardening and some deterioration of mechanical properties, Re maintains dimensional stability and some mechanical integrity. Rhenium coatings on tungsten wire do not prevent carbon from diffusing to the tungsten core and reacting to form tungsten carbide, but the reaction is much slower than that when uncoated tungsten is exposed.

2. Rhenium forms a boride, which forms a eutectic between another boride, or rhenium. The eutectic melts under 2250°C.

3. Thoriated rhenium maintains structural, microstructural, and mechanical integrity after long-time (7000 hr) exposure in vacuum at 1750°C in contact with solid aluminum oxide.

4. Unalloyed rhenium has been shown again to have excellent resistance against the water cycle up to 1750°C, particularly when compared with tungsten. Rhenium coatings protect tungsten from attack by the water cycle.

Acknowledgments

The authors wish to acknowledge with thanks the help given by J. B. Baker, W. W. Kleinschmidt, and W. E. Nexsen, Jr., in carrying out the experiments and by D. F. Rosenbaum in providing rhenium-coated tungsten samples.

Oxides on the Silver Electrode

Charles P. Wales and Jeanne Burbank

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

Silver electrodes were studied by means of potentials and x-ray diffraction patterns. The silver was charged anodically in 35% KOH by means of either constant current or constant potential, and discharged at a low or high rate. Attempts were made to form an oxide higher than AgO by means of anodization. The products of anodization of silver in 2*N* H_2SO_4 were determined. The basis for the theory that the oxides of silver are formed by the introduction of oxygen into the octants of the face-centered cubic silver lattice was examined.

Alkaline storage and primary batteries containing positive silver electrodes have been used, in recent years, for special purposes requiring light weight or the ability to discharge at high rates. There is considerable confusion in the literature, however, as to the reactions taking place on these electrodes. In addition the potential distribution and eletcron transfer may be complex on oxide surfaces with different conducting or semiconducting properties.

A typical charge of a silver electrode in alkaline solutions shows three potential plateaus. There is general agreement with the work reported by Luther and Pokorny (1) in 1908 that the first plateau corresponds to the formation of Ag_2O. A possible subsidiary step of short duration was noted by Hickling and Taylor (2) at the beginning of this first plateau, which they suggested may represent some adsorption of oxygen prior to the production of Ag_2O, or may be the formation of a silver suboxide.

The results of Luther and Pokorny further indicate that at the second potential plateau Ag_2O is changed quantitatively and reversibly to AgO. On the other hand, Hickling and Taylor report that an oxide of Ag containing more oxygen than AgO is formed at this second plateau, and that this unstable higher oxide, perhaps Ag_2O_3, decomposes to give AgO; i.e., the AgO forms purely as a secondary product. The results of Jones, Thirsk, and

Wynne-Jones (3) are not in accord with those of Hickling and Taylor but agree partially with those of Luther and Pokorny in that they show the direct oxidation of Ag_2O to AgO. However, Jones, *et al.* claim that only 30% of the current is used to form AgO at this potential, the remaining 70% going to O_2 evolution, and they conclude that the statement about the oxidation of Ag_2O proceeding quantitatively and reversibly (1) is without foundation.

At the third potential plateau the electrode reaction is almost entirely the evolution of O_2. It has been concluded (3, 4) that an oxide higher than AgO is formed at this step, and this Ag_2O_3 potential has been reported by others (5, 6). The present investigation was undertaken to clarify these conflicting statements regarding silver electrodes in alkali. During this work it also became desirable to examine the anodization of silver in sulfuric acid.

Experimental Procedure

The positive (test) electrodes were made by cutting in half silver plates taken from a commercial Ag-Zn storage battery. The test electrodes measured about 28.5 x 66.5 x 0.7 mm and had a capacity of 1.8-2.0 amp-hr. A 3-mm-thick U-shaped plastic frame, with inside dimensions slightly larger than the positive electrode, was wrapped with several layers of separator material of the type used in Ag-Zn batteries. The electrode was then inserted into the frame. This arrangement allowed the electrode to be removed for examination and then to be replaced readily, without unwrapping or tearing the separator. X-ray diffraction patterns were obtained with a General Electric XRD-5 spectrogoniometer using Cu Kα radiation after the electrode was rinsed briefly in distilled water and blotted dry with tissue paper. The x-ray examination of the electrode surface could begin within 5 min after anodic or cathodic treatments and would characterize the deposit within a layer 0.01 mm thick.

The Ag, Ag_2O/OH^- reference electrode used for all of the potential measurements was made by packing Ag_2O into a glass tube which had a Pt wire sealed through its wall, adding a KOH solution as the electrolyte, and, after 24 hr, cathodically reducing part of the Ag_2O onto the Pt, using another Pt wire as the second electrode. This reference half-cell gives a stable potential, after being allowed to stand a few days to establish equilibrium, and electrodes of this type have been used continuously for over two years at this laboratory. The stability of a Ag/Ag_2O electrode was shown recently by Hamer and Craig (7).

A silver screen, wrapped with separator material, served as the negative electrode. The electrodes were assembled in a closed plastic container in an electrolyte of 35% KOH. The instrumentation and techniques previously described (8) were used to measure and record the potential as well as to control the cell current or potential. On a few occasions silver sheet, 0.13 mm thick, was used as the positive electrode in either 35 or 5% KOH, and in addition both types of electrode were anodized in

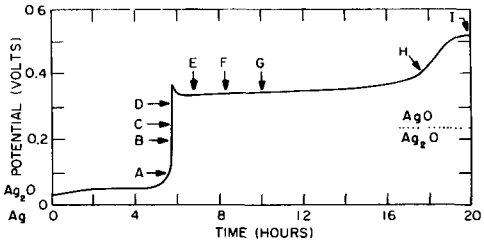

Fig. 1. Typical 100-ma charge of the Ag electrode. Letters refer to points at which x-ray diffraction patterns have been obtained. Potentials are given with respect to a Ag/Ag_2O reference electrode.

2*N* H_2SO_4. All work was carried out in a controlled temperature of 26°-27°C.

Results and Discussion

The three potential plateaus occurred at 0.03 to 0.05 v, 0.33 to 0.37 v, and 0.51 to 0.52 v, positive with respect to the Ag/Ag_2O reference electrode, during a typical 20-hr charge at 100 ma (Fig. 1). The reversible Ag_2O/AgO potential is 0.23 v,[1] and the AgO/Ag_2O_3 potential is 0.39 or 0.40 v, with respect to the reference electrode used here (1, 2).

A discharged silver electrode was charged anodically at 100 ma until its potential was 100 mv above the reference electrode potential (point A, Fig. 1), and the potential then was held at 100 mv. When the charge was interrupted after 21 hr the current had fallen to 0.47 ma, and the electrode was 20% charged (based on the discharge capacity). An x-ray diffraction pattern showed strong Ag lines with weaker Ag_2O lines, but no lines were found which could be attributed to a suboxide. When the potential was held at 200 mv for 6.5 hr, the x-ray diffraction pattern of this anode (point B, Fig. 1) was still strong in Ag, although the amount of Ag_2O had increased. This confirmed the statements that the reaction at the lower potential plateau consists only of the oxidation of Ag to Ag_2O. The same diffraction pattern was obtained when the potential was held at 250 mv for 6.7 hr (C, Fig. 1), 20 mv above what has been believed to be the reversible Ag_2O/AgO potential. It should be noted, however, that in this investigation the Ag_2O/AgO equilibrium potential was normally found to be about 267 mv (measured by charging the electrode to AgO and allowing it to stand until its potential became constant). This is 0.03-0.04 v higher than the value which is usually given (1,2) (see however, Bonk and Garrett, footnote 1).

The potential of the silver electrode then was increased to 308 mv (D, Fig. 1)and held there for 22 hr, but only 0.043 additional amp-hr of charge (2% of the total capacity) could be added. Diffraction patterns, however, showed that some AgO had formed, that the amount of Ag_2O had increased, and that there was now only half as much Ag present on the surface. AgO could not be detected by x-ray diffraction on an electrode held at 275 mv for 175 hr, although the open-circuit potential of 180 mv did indicate the presence of AgO. The fact that AgO

[1] Recent work by J. F. Bonk and A. B. Garrett (7a) indicates that this value should be 0.26 v instead of 0.23 v.

can be formed at a potential well below the Ag_2O_3 potential supports the belief (1,3) that AgO is the primary anodic oxidation product at the second plateau of a charge, but this same fact opposes the theory (2) that the primary product is Ag_2O_3, which then decomposes to AgO.

The concentration of AgO increased rapidly during a charge at the upper potential (E and F, Fig. 1) and at the same time the amount of Ag_2O decreased. It could not be determined from the x-ray patterns whether or not any Ag_2O remained by the time the electrode was half charged (G, Fig. 1), although metallic Ag was still fairly strong. X-ray patterns showed only AgO and metallic silver, both at the end of this potential plateau (H, Fig. 1) and after gassing (I, Fig. 1). When a charge was ended after 5% of the electrode capacity had been added at the second potential plateau (E, Fig. 1), comparison of x-ray patterns before and after the electrode was allowed to stand on open circuit for 24 hr indicated that Ag_2O had increased and the Ag had decreased, while only traces of AgO remained. Similar results required a 7-day stand, after 13% of the charge took place at the second step (F, Fig. 1). This confirms the report (9) that Ag and AgO react during a stand.

The first reaction at the second potential plateau appears to be Ag_2O oxidizing to AgO, since Ag_2O seems to anodize more rapidly than Ag. Then, or perhaps simultaneously, much of the remaining Ag goes to AgO, with any Ag_2O which may be formed in this process being preferentially oxidized to AgO. The reaction $Ag + AgO \rightarrow Ag_2O$ probably does not occur appreciably during a charge, since it appears to be very slow under the conditions of the experiment.

Although trickle charges lasting several days did convert more of the remaining Ag to AgO, overcharges at the normal or even higher rates were more effective in oxidizing the Ag and gave the sharpest diffraction patterns. Strong oxygen gassing appeared to perfect crystallinity. For example, the AgO lines were very sharp after a 200% charge at 100 ma, with only a very small amount of metallic Ag remaining visible in the x-ray diffraction patterns, perhaps arising from the grid mesh. Similar results were obtained by anodizing the charged electrode for 20 hr at 750 ma, at a potential of 0.68-0.71 v. No lines were ever found in the x-ray patterns which could be attributed to a higher oxide, such as Ag_2O_3, despite any of these lengthy treatments well above the equilibrium potential reported for AgO/Ag_2O_3. The transient high open-circuit potentials noted by Jones, *et al.* (3) at the end of a lengthy charge need not be attributed to higher oxides. It seems likely that the transient potentials on silver were probably potentials of the HO_2^--OH^- system. This potential would continue until enough Ag_2O was formed to establish the Ag_2O/AgO equilibrium potential. It was reported by Pleskov (4) that monovalent Ag oxidized to trivalent Ag at high potentials. His results could be interpreted in other ways. This matter is being given further consideration.

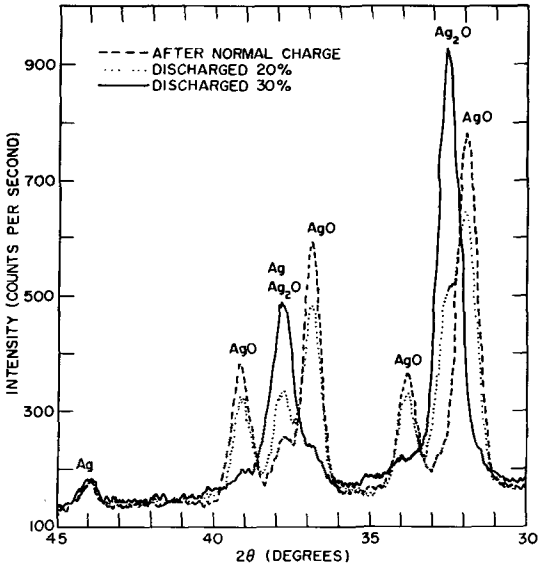

Fig. 3. Spectrogoniometer x-ray diffraction patterns of a charged and partially discharged Ag electrode.

A typical low-rate discharge (Fig. 2) showed the two steps which are associated with silver electrodes. Ag_2O had appeared on the electrode after it was partially discharged at the upper step (J, Fig. 2). The amount of AgO had decreased and metallic Ag remained constant, compared with a charged electrode. The electrode was discharged an additional 10%, reaching the lower potential plateau (K, Fig. 2). X-ray diffraction showed that practically no AgO remained on the surface at this point, and the x-ray pattern of Ag_2O was very strong, with Ag unchanged. The diffraction patterns for this marked change in surface composition are shown in Fig. 3. There is no doubt that the interior of the electrode still contained much AgO, but the x-ray diffraction patterns and the electrode potential only showed what was present near the surface. An electrode discharged 70% showed more Ag than Ag_2O (L, Fig. 2), and at the end of the discharge Ag alone was detected (M, Fig. 2). The only reaction detected

at the upper potential plateau was $AgO \rightarrow Ag_2O$. After the surface is covered with Ag_2O, the surface reaction (which determines the potential) appears to be $Ag_2O \rightarrow Ag$, although there probably is a large amount of AgO in the interior of the electrode which is discharging at this lower potential.

When the electrode was discharged for 7% at a high rate, x-ray diffraction patterns showed that Ag_2O had formed (N, Fig. 2), and after a 20% discharge the amount of Ag_2O had increased (O, Fig. 2). A comparison of the diffraction patterns showed that metallic Ag increased very little if at all during the first 20% of this discharge, despite the fact that the potential of the electrode was more than 0.4 v below the reversible Ag/Ag_2O potential.

Comparison of charge and discharge capacity showed a very high efficiency, in contrast to the report (3) that only 30% of the current charged the electrode at the second potential level. Gas evolution of a commercial 100-amp-hr Ag-Zn storage battery was measured during a 5-amp charge (Fig. 4). The potential changes shown represent changes in the silver plate, since the positive plate became fully charged before the negative one. No oxygen evolution was detected until near the end of a charge. This confirms the earlier report (1) that the oxidation is quantitative and reversible. The contradictory results obtained by Jones, *et al.* (3) may be due to their rapid charging rate.

Structure of Silver Oxides

The structure of Ag_2O had already been established as being a face-centered cube with a side a_o of 4.72Å when Jones and Thirsk (10) described a material thought to be AgO with a similar face-centered cubic structure ($a_o = 4.96$Å), and also gave evidence for a silver suboxide with a cubic structure ($a_o = 4.56$Å). However in 1924 Levi and Quilico (11) had prepared supposed suboxides by several methods, but examination by x-ray diffraction had shown only the patterns of Ag and Ag_2O. Jones, Thirsk, and Wynne-Jones (3) proposed, on the basis of the report of Jones and Thirsk, and of their own

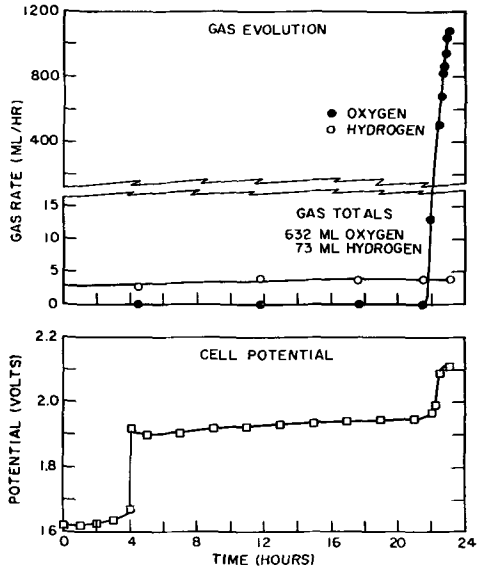

Fig. 4. Potential and gas evolution for a typical low-rate charge of a Ag-Zn storage battery.

work, that the oxides of Ag are formed by the introduction of oxygen into the octants of the face-centered cubic silver lattice, and in order to complete this series they proposed Ag_2O_3 as an intermediate between AgO with half-filled octants and the hypothetical AgO_2 with completely filled octants. The data on which these investigators have based their conclusions may be interpreted otherwise.

There were no diffraction data for AgO in the literature at the time that Jones and Thirsk (10) anodized Ag in H_2SO_4. They assumed that their final product was AgO. In order to check this, they prepared silver peroxynitrate (and presumably boiled it to decompose it), and reacted a silver salt with a persulfate. They reported that all three preparations showed the same x-ray pattern, which they published as AgO. The results of Mulder (12), and Skanavi-Grigor'eva and Shimanovich (13), however, showed that the so-called silver peroxysulfate Ag_7SO_{12} is the product of electrolysis of a Ag_2SO_4 solution. Since the first anodic reaction of Jones and Thirsk was the formation of Ag_2SO_4, it is seen that their second anodic reaction should be formation of silver peroxysulfate.

The two preparations used by Jones and Thirsk for the check of their "AgO" are rather similar. Depending on reaction conditions, a silver salt solution with a persulfate may give either AgO or a compound with a formula like Ag_7SO_{12} (14). The close relationship between silver peroxysulfate and silver peroxynitrate has been noted for many years. Luther and Pokorny (1) prepared these compounds in three ways: by anodizing Ag in dilute H_2SO_4, by electrolysis of a $AgNO_3$ solution, and by electrolysis of a Ag_2SO_4 solution. They used these compounds for the "Ag_2O_3" potential measurements which are so often cited in the literature. It was concluded by Luther and Pokorny that neither the sulfate nor the nitrate was an integral part of these peroxy compounds, since both of the compounds gave the same potential and decomposed cathodically in KOH to AgO, then to Ag_2O, and finally to Ag. Therefore they reported the potential of these compounds with respect to AgO as the Ag_2O_3/AgO potential. However, Sulc (15), Mulder and Heringa (16), Tanatar (17), Watson (18), and Brown (19) all found that the compound, which they obtained by electrolysis of a $AgNO_3$ solution under various conditions, always had the empirical formula Ag_7NO_{11}. In 1954 this was confirmed again by Skanavi-Grigor'eva and Shimanovich (20), and they also reported the similarity in composition and valency of the compounds obtained by anodizing $AgNO_3$ or AgF solutions. This has recently been denied by Graff and Stadelmaier (21), but only on the grounds that a compound with the same structure was obtained by anodizing either AgF or $AgNO_3$ solutions, although they did not report analyses of their products. Yet in 1935 similar x-ray patterns had been found by Brækken (22) for what he considered to be Ag_2O_3 stabilized by either Cl, F, N, or S, with the best results from the compound with N (i.e., Ag_7NO_{11}). The same diffraction pattern for Ag_7NO_{11} has been reported more recently (23, 24), and a similar pattern has been obtained by

allowing O_3 to react with Ag and Ag_2O (25). Apparently all of the diffraction patterns reported for silver peroxy compounds are practically identical. Table I shows that the anodic product which Jones and Thirsk (10) reported as AgO has the same lines as Ag_7NO_{11} and probably was in reality the so-called silver peroxysulfate.

In order to check these conclusions a silver electrode was charged at 100 ma in 2*N* H_2SO_4. The initial reaction was $Ag \rightarrow Ag_2SO_4$, as reported (10). Then the potential rose sharply (by 1.3 v), and black spots appeared on the plate. This black material decomposed readily in the acid with vigorous evolution of gas. An electrode which was partially covered with this black material was examined. The diffraction pattern, which was started within 10 min after the end of electrolysis, showed the lines of four substances: Ag, Ag_2SO_4, a compound with lines like those shown in Table I, and traces of AgO. After being allowed to stand in dry air for 8 days, this electrode showed only Ag, Ag_2SO_4, and a strong diffraction pattern for AgO. Obviously the peroxysulfate had decomposed to AgO.

It had been stated by Jones and Thirsk (10) that a minimum of 3 hr elapsed between electrolysis and examination of the specimen. This would allow formation of some AgO before their x-ray diffraction examination. Their patterns may have been similar to those observed in this study: a mixture of Ag, Ag_2SO_4, AgO, and the peroxysulfate. If the lines of the patterns they attributed to "AgO" and those of Ag and Ag_2SO_4 are subtracted from the pattern of the suggested mixture, the lines remaining belong to the true pattern of AgO. Jones and Thirsk appear to have subtracted the lines of Ag_2O from such a remaining pattern, since they stated that Ag_2O was present (although none was found under these conditions in this present study). The lines which then remained were attributed to traces of a face-centered cubic substance having $a_o = 4.56$Å, which was suggested as belonging to a suboxide of silver. Table II shows that the pattern of AgO, by an unfortunate coincidence, contains many of the lines of Ag_2O, and that the remaining lines, none of which are strong, could be indexed as belonging to a cube with $a_o = 4.56$Å. Jones, Thirsk, and Wynne-Jones (3), probably relying on this earlier work, reported only Ag, silver suboxide, and Ag_2O on their fully charged electrode from alkaline solution. It is likely that they actually had Ag and AgO.

The weak Ag_2O line for $d = 3.35$, which is listed in Table II, was never observed at this laboratory. The AgO values given in this table agree closely with those previously reported (21, 25, 26) except that the weak line reported at $d = 2.95$ (21, 26) was not observed on silver anodized in 35% KOH despite repeated attempts with both the sintered silver electrode and a silver sheet, nor was the peak at $d=2.78$ resolved into the two lines which have been reported (21, 26). When sheet silver was charged in 5% KOH this peak could be resolved into two lines, and often the weak peak at $d = 2.95$ could be observed.

The lack of resolution of the $d = 2.78$ doublet on specimens anodized in 35% KOH may be attributed to limited perfection in the crystal lattice, or it may be caused by particle-size broadening of the x-ray lines. A third possible cause of this effect, and of the lack of line $d=2.95$, may be variation in the positions taken up by the oxygen atoms within the electrochemically formed lattices. Scatturin, Bellon, and Zannetti (26) used the line $d = 2.95$ corresponding to (hkl) of (110) to assign the distribution of the oxygen atoms. The lack of this line on specimens anodized in 35% KOH may denote a particular distribution of oxygen in the lattice positions, leading

to sufficient change in parameter to bring the doublet at $d = 2.78$ into coincidence. The resolution of these questions and their possible relation to the electrochemical activity and utilization of the battery oxide merit further study.

Summary

X-ray diffraction patterns of a silver electrode showed only the lines of Ag and Ag_2O when the electrode was charged anodically at potentials up to 250 mv above the Ag/Ag_2O potential. AgO could be formed at a potential as low as 308 mv, which indicates that the primary product at the second potential plateau is not a higher oxide which then decomposes to AgO. After the Ag_2O on the surface of the electrode oxidizes to AgO, much of the Ag deeper in the electrode then oxidizes. The silver electrode charges efficiently at the first two potential plateaus. Since the reaction $Ag + AgO \rightarrow Ag_2O$ takes place very slowly, it probably has little effect on charges of a silver electrode under normal conditions. At the end of a normal charge, the electrode contained only AgO and a little Ag. The AgO crystallinity was perfected by holding the electrode at potentials well above the gassing potential. No higher oxide was detected, even with lengthy anodization 0.3 v above the reported $AgO/"Ag_2O_3"$ potential.

The surface of a AgO electrode becomes covered with Ag_2O at the time when its potential reaches the lower plateau during low-rate discharges. Even though a high-rate discharge failed to show the first potential level and discharged at least 0.4 v below the Ag/Ag_2O potential, metallic Ag did not form in appreciable amounts during the early parts of this discharge.

The charge of a silver electrode in $2N$ H_2SO_4 goes first to Ag_2SO_4 and then to the so-called peroxysulfate. The latter compound decomposes on standing in dry air to give AgO. Neither Ag_2O nor a silver suboxide was found in acid. The existence of a suboxide on anodized silver is doubtful.

Manuscript received Feb. 27, 1959. This paper was prepared for delivery before the Columbus Meeting. Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Hydrogen Overvoltage on Bright Platinum

III. Effect of Hydrogen Pressure

Sigmund Schuldiner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The effect of hydrogen pressure on the hydrogen overvoltage of bright platinum was determined in acid. From the anodic and cathodic overvoltages, kinetic parameters were determined. A mechanism controlled by slow combination of hydrogen atoms adsorbed on the platinum surface fits the experimental data. From the Langmuir adsorption isotherm it is shown that the surface of the active platinum electrode at equilibrium is sparsely covered with hydrogen atoms.

Several investigators (1-6) have established that hydrogen overvoltage η at a given current density in the Tafel region on a cathode evolving hydrogen is related to the hydrogen pressure by the expression $\eta = \eta_o + (RT/2\mathbf{F}) \ln P_{H_2}$, where η is the potential difference between the working electrode and a reversible hydrogen reference electrode in the same solution, η_o is the overvoltage at 1 atm of hydrogen, P_{H_2} is the partial pressure of hydrogen above the solution, and R, T, and $\mathbf{F}$ have their usual significance. Vetter and Otto (6) in an investigation of the effect of pressure on anodic and cathodic overvoltage of an inactive platinum electrode in acid solution were able to determine the kinetic parameters and to establish reaction mechanisms that fitted their experimental findings. This investigation is a continuation of previous work (7, 8) on hydrogen overvoltage on an active, smooth platinum electrode.

Experimental

The general experimental techniques were the same as before (7, 8). The cell was constructed of Teflon and was a simplified version of the one shown in Fig. 1 of reference (8). The platinum (99.99%) cathode was a small sphere at the end of a very short length of exposed wire (apparent area 0.084 cm^2). The solution was in all cases 1M H_2SO_4. Purified gases consisting of either pure hydrogen, a prepared mixture of 5% hydrogen in nitrogen, or mixtures of hydrogen and helium were bubbled through the acid solution in the cell. The hydrogen-helium mixtures were prepared by mixing hydrogen and helium directly from their cylinders through rotameters into the gas purification train. This gave a composition of the two gases which remained constant for any given setting of the flow rates. The pressure of the gas introduced into the cell was always 1 atm. The partial pressure of hydrogen was determined by measuring the potential difference between a reversible hydrogen electrode and a saturated α Pd-H electrode in the cell. Since it was established (9) that the potential-determining reaction on the saturated α Pd-H electrode is independent of hydrogen pressure, the potential difference, E, between it and the reversible hydrogen electrode in the same solution obeyed the Nernst relation $E = 0.05 + (RT/2\mathbf{F}) \ln P_{H_2}$. From this potential the partial pressure of hydrogen flowing through the cell was determined.

After the solution was pre-electrolyzed and the Pt electrode was further cleaned by anodic polarization, the pseudo-capacitance test (7) was used to determine surface cleanliness and also the IR drop between it and the reference electrode (a Pt gauze electrode in the same solution). Repeated measurements were taken at each partial pressure of hydrogen under both anodic and cathodic polarization. Overvoltages at each current density were time independent. The data given are average values of individual runs. The precision of an individual reading was better than 0.5 mv. The spread of each particular reading for a given experiment was ±1 mv. The temperature was 25° ± 1°C.

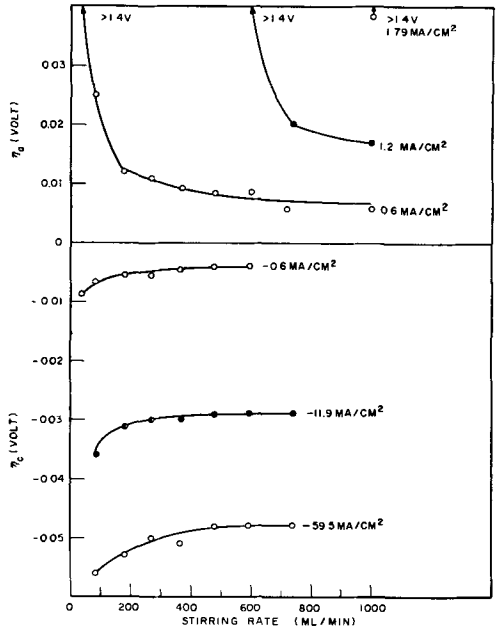

Fig. 1. Effect of stirring rate on η_a and η_c at 1 atm of hydrogen.

Experimental Results

Concentration polarization effects were minimized by stirring the solution with gas at rates for which a further increase in stirring rate would not affect the measured overvoltage. Figure 1 shows the effect of stirring rate on overvoltage for pure hydrogen flowing through the solution. The data show that at the higher current densities flow rates of at least 500 ml/min are required. It should be noted also that the dependence on stirring rate is much more pronounced for anodic than cathodic polarization. This is because for anodic polarization molecular hydrogen must diffuse to the surface at a sufficiently fast rate to maintain a given concentration of atomic hydrogen on the surface. This would be similar to the case described by Frumkin and Aikasjan (10). In the case of cathodic polarization the difference between the hydrogen pressure in the bulk of the solution and at the electrode surface is not as pronounced.

Plots of cathodic overvoltage η_c, vs. logarithm of apparent negative current density at different hydrogen pressures are shown in Fig. 2. It should be noted that the Tafel b slopes are 0.025-0.026 v rather than 0.0295 v expected at 25°C. This confirmed previous results (8). Figure 3 shows plots of anodic overvoltage η_a vs. logarithm of current density. At low currents there is a linear relationship between anodic and cathodic overvoltages and current density (Fig. 4). From experimental data shown in Fig. 2-4, kinetic parameters can be determined and a reaction mechanism suggested.

Derivation of Kinetic Equations

Cathodic overvoltage.—It is assumed that the cathode overvoltage mechanism is primarily a discharge of hydronium ions in the double layer followed by a slow combination of hydrogen atoms to molecules, that is

$$H^+ + e = H \qquad \text{(discharge step)} \qquad [1a]$$

$$2H = H_2 \qquad \text{(combination step)} \qquad [1b]$$

Assuming a Langmuir isotherm, kinetic equations for the discharge step can be written

$$\vec{i}_d = \vec{k}_d(H^+)\,(1-\theta)\,\exp\,(-\alpha\eta_c\mathbf{F}/RT) \qquad [2a]$$

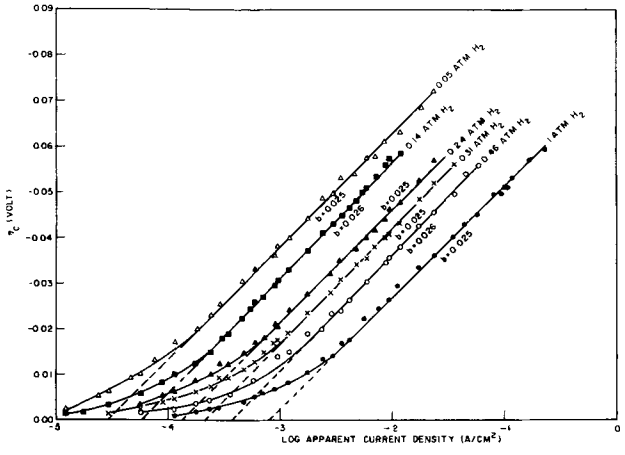

Fig. 2. Relations for η_c vs. log $(-i_c)$ at different partial pressures of hydrogen.

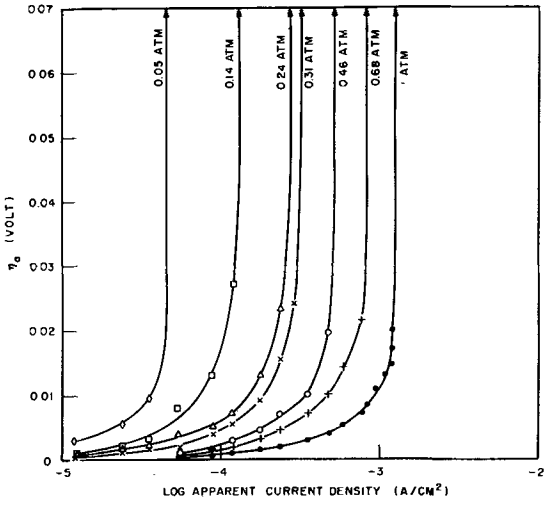

Fig. 3. Relations for η_a vs. log i_a at different partial pressures of hydrogen.

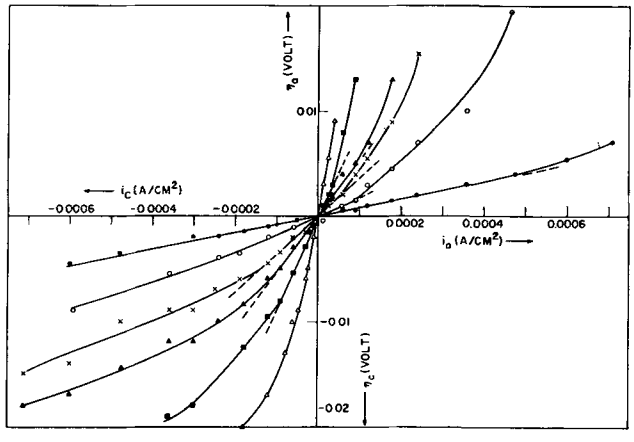

Fig. 4. Low current density relations for η vs. i. Partial pressures of hydrogen as in Fig. 2.

$$\overleftarrow{i}_d = \overleftarrow{k}_d\theta\,\exp\,[(1-\alpha)\eta_c\mathbf{F}/RT] \qquad [2b]$$

where $\vec{i}_d$, $\overleftarrow{i}_d$ represent forward and reverse current densities, respectively. The convention that cathodic current is negative and anodic current is positive is used; $\vec{k}_d$, $\overleftarrow{k}_d$ are forward and reverse rate constants which are negative and positive, respectively. (H^+) is the hydronium ion concentration in the double layer which in 1M H_2SO_4 remains virtually constant in the current density range investigated, θ is the fraction of available surface covered with atomic hydrogen, and α is the transfer coefficient. The discharge step is assumed virtually at equilibrium, hence $\vec{i}_d = -\overleftarrow{i}_d$. Therefore

$$\theta/(1-\theta) = -\mathrm{K}'\,\exp\,(-\eta_c\mathbf{F}/RT) \qquad [3]$$

where K′ is a constant. For the slow combination step

$$\vec{i}_c = \vec{k}_c\theta^2 \qquad [4a]$$

$$\overleftarrow{i}_c = \overleftarrow{k}_c P_{H_2}\,(1-\theta)^2 \qquad [4b]$$

Here the partial pressure of hydrogen at the metal solution interface is considered independent of i_c. This is based on the proposition that the diffusion

of molecular hydrogen is not rate-determining. Hence the net cathodic current density i_c is the algebraic sum $i_c = \vec{i}_c + \overleftarrow{i}_c$, where the magnitude of $\vec{i}_c$ is not less than the magnitude of $\overleftarrow{i}_c$. At equilibrium, i_c is zero, and $\vec{i}_c = -\overleftarrow{i}_c = i_{o,c}$, where $i_{o,c}$ is the cathodic exchange current density (negative). Hence

$$\vec{k}_c\theta_o^2 = -\overleftarrow{k}_c P_{H_2}(1-\theta_o)^2 = i_{o,c} \qquad [5]$$

where θ_o is the fraction of available surface covered with atomic hydrogen at equilibrium. Therefore, from [4] and [5]

$$i_c = i_{o,c}[(1-\theta)^2/\theta_o^2]\{\theta^2/(1-\theta)^2 - \theta_o^2/(1-\theta_o)^2\} \qquad [6]$$

Substituting for $\theta/(1-\theta)$ from Eq. [3], and noting that at equilibrium $\eta_c = 0$ so that $K'^2 = \theta_o^2/(1-\theta_o)^2$, we obtain

$$i_c = i_{o,c}[(1-\theta)^2/(1-\theta_o)^2]\cdot\{\exp(-2\eta_c\mathbf{F}/RT) - 1\} \qquad [7a]$$

At low coverages, the factor involving the θ's reduces to unity. Equation [7a] can be expressed in logarithmic form at 25°C and at low coverages as

$$\eta_c = -0.0295 \log[(i_c/i_{o,c}) + 1] \qquad [7b]$$

This is in effect the equation first derived by Hammett (11).

Anodic overvoltage.—Here the reaction can be written as the inverse of the cathodic case, i.e., a slow dissociation of H_2 followed by ionization of H. The kinetic equations for the ionization step are

$$\vec{i}_i = \vec{k}_i\,\theta\exp(\alpha\eta_a\mathbf{F}/RT) \qquad [8]$$

$$\overleftarrow{i}_i = \overleftarrow{k}_i\,(H^+)(1-\theta)\exp[-(1-\alpha)\eta_a\mathbf{F}/RT] \qquad [9]$$

where $\vec{i}_i$, $\overleftarrow{i}_i$ are forward and reverse current densities for ionization; $\vec{k}_i$, $\overleftarrow{k}_i$ are forward and reverse rate constants and are positive and negative, respectively. The α used here is not the same as before. The ionization step is considered at equilibrium, hence $\vec{i}_i = -\overleftarrow{i}_i$. Therefore

$$\theta/(1-\theta) = -K_i'\exp(-\eta_a\mathbf{F}/RT) \qquad [10]$$

For the slow dissociation step

$$\vec{i}_a = \vec{k}_a P_{H_2}(1-\theta)^2 \qquad [11a]$$

$$\overleftarrow{i}_a = \overleftarrow{k}_a\theta^2 \qquad [11b]$$

The net anodic current density i_a is the algebraic sum $i_a = \vec{i}_a + \overleftarrow{i}_a$, where the magnitude of $\vec{i}_a$ is not less than the magnitude of $\overleftarrow{i}_a$. At equilibrium, i_a is zero, and $\vec{i}_a = -\overleftarrow{i}_a = i_{o,a}$ where $i_{o,a}$ is the anodic exchange current (positive).

Therefore

$$i_{o,a} = \vec{k}_a P_{H_2}(1-\theta_o)^2 = -\overleftarrow{k}_a\theta_o^2 \qquad [12]$$

Following the same analysis as above, one obtains

$$i_a = i_{o,a}[(1-\theta)^2/(1-\theta_o)^2]\{1 - \exp(-2\eta_a\mathbf{F}/RT)\} \qquad [13]$$

At 25°C and low coverages, Eq. [13] reduces to the logarithmic form

$$\eta_a = -0.0295 \log[1 - i_a/i_{o,a}] \qquad [14]$$

Calculation of Kinetic Parameters

The value of $i_{o,c} = -i_{o,a}$ was determined from Eq. [7a] in its limiting low coverage form. The graphs of i_c vs. $[\exp(-2\eta_c\mathbf{F}/RT) - 1]$ for various values of P_{H_2} are shown in Fig. 5. The relationship given by Vetter and Otto (6), which can be derived from Eqs. [4], [5], [11], and [12] when $\theta_o << 1$, is $\theta_o^2 = -i_{a,L}/i_{c,L}$, where $i_{a,L}$ and $i_{c,L}$, the limiting anodic and cathodic current densities, can be used to determine θ_o. It was assumed that $i_{c,L}$ is not algebraically greater than -10 amp/cm^2. This is a reasonable assumption since the Tafel slope in Fig. 2 for pure hydrogen is maintained down to negative currents approaching -1 amp/cm^2. In addition, a calculation by Salzberg and Schuldiner (12) indicated that on a Pt electrode the maximum coverage of the surface with adsorbed atomic hydrogen at -1 amp/cm^2 would be about 2%. Hence using the arbitrary value of -10 amp/cm^2 for $i_{c,L}$ and obtaining $i_{a,L}$ for various hydrogen pressures from Fig. 3, θ_o^2 can be calculated for each pressure. It should be mentioned that $i_{c,L}$ is independent of hydrogen pressure; in other words, $i_{c,L}$ is only dependent on the rate of hydrogen evolution at the cathode. Using θ_o^2 values, which indicate a low coverage with atomic hydrogen, obtained in this way, the rate constant $\vec{k}_c = \overleftarrow{k}_a = -12.08$ was calculated from Fig. 6 using Eq. [5]. The rate constant $\overleftarrow{k}_c = \vec{k}_a = 0.00143$ was calculated using Eq. [5] also. Figure 7 shows the linear relation between P_{H_2} and $i_{o,c}$ which was used to determine this rate constant.

The rate constant $k = \pm(di/d\eta)_{\eta\to 0}$ (negative for cathodic, positive for anodic directions) for the over-all reaction near equilibrium, where there is a linear relation between η and i, was determined from Fig. 4 for various hydrogen pressures. These values

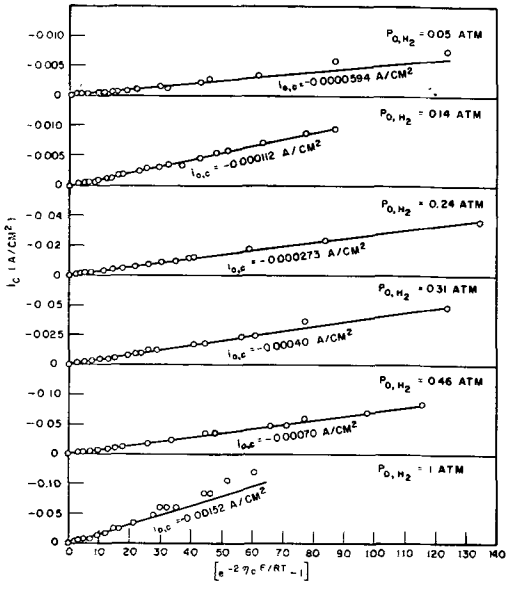

Fig. 5. i_c vs. $[\exp(-2\eta_c\mathbf{F}/RT - 1]$

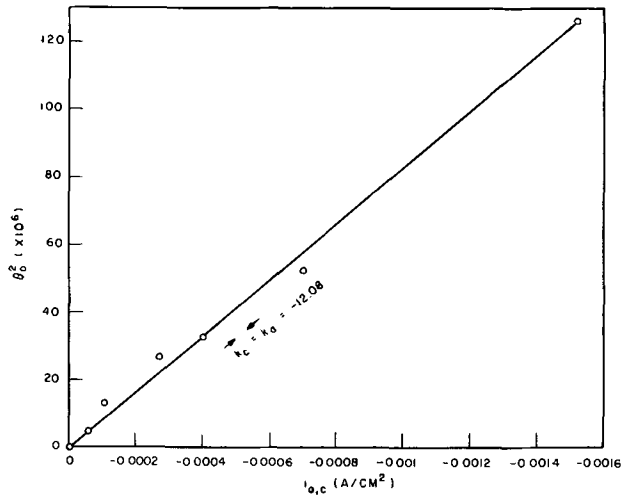

Fig. 6. θ_o^2 vs. $i_{o,\,c}$

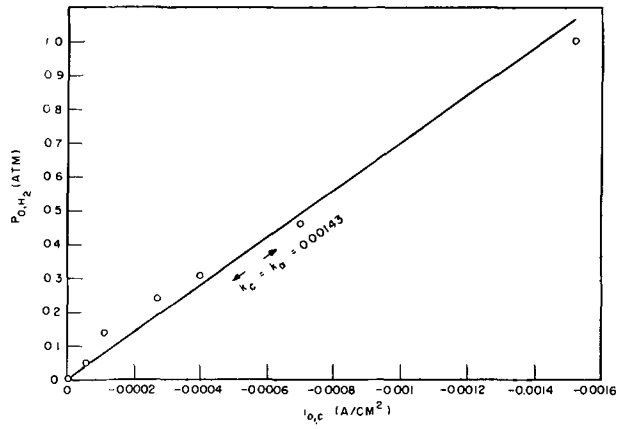

Fig. 7. P_{H_2} vs. $i_{o,\,c}$

are shown in Table I. Also shown are stoichiometric numbers μ calculated from the Horiuti relationship (13) $\mu = 2i_{o,c}\mathbf{F}/kRT$.

Discussion

The assumption that the surface of the active smooth Pt electrode used in this investigation was sparsely covered with atomic hydrogen at equilibrium can be verified by determining the Langmuir adsorption isotherm. This isotherm is $\theta_o^2/(1-\theta_o)^2 = KP_{H_2}$. At low coverages $\theta_o^2 = KP_{H_2}$. The linear data of Fig. 6 and 7 can be combined to give a reasonably good linear isotherm with a K value of 116×10^{-6}. The fact that this isotherm holds throughout the range of hydrogen pressures investigated, with a zero intercept, virtually proves that the surface of the platinum at zero current is only sparsely covered with atomic hydrogen. If one changes $i_{c,L}$ from -10 amp/cm^2 to a value smaller by one to two orders of magnitude, or to any larger value, this still would not affect the linearity of the isotherm, but would merely change K.

The linear relations shown in Fig. 5 confirm the mechanisms assumed, namely, that the hydronium ion discharge is followed by a rate-determining slow combination step. Another way of showing this is to plot anodic and cathodic overvoltages vs. the logarithmic relationships given in Eqs. [7b] and [14]. This should give a straight line with a slope of 0.0295 v. Figure 8 shows this relation for all partial pressures of hydrogen and confirms that the mechanism assumed is a reasonable one. Additional proof is given by the fact that the stoichiometric numbers

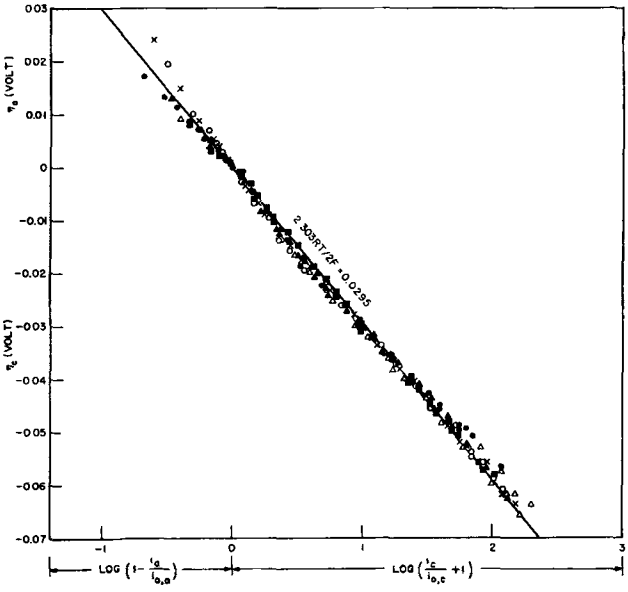

Fig. 8. Hammett relations for η vs. i. Partial pressures of hydrogen as in Fig. 2.

μ for the series of hydrogen pressures shown in Table I are all approximately equal to one.

The Tafel relation derived from the curves in Fig. 2 is only an empirical equation which proves to be compatible with theoretical Eq. [7b]. However at higher current densities one would expect a definite upward curvature from the straight lines shown in Fig. 2. At log $(-i_c) = 0$, the curvature would be such that η_c for 1 atm would be -0.083 v rather than -0.076 v as obtained by extrapolating the linear portion in Fig. 2. Similarly for the other hydrogen pressures there will be an increasing curvature as the pressure is decreased. Experimentally there was an indication of such a deviation at high current densities. However, there exists also a significant concentration overvoltage effect which is undoubtedly owing to the diffusion away of molecular hydrogen from the metal solution interface (14), and it is experimentally difficult to eliminate this effect at higher overvoltages. It should also be noted that an extrapolation of the Tafel lines in Fig. 2 to zero overvoltages give current density values which are much lower than the $i_{o,c}$ values obtained from Eq. [7b].

A Porcelain Reference Electrode Conductive to Sodium Ions for Use in Molten Salt Systems

Roger J. Labrie and Vernon A. Lamb

Chemistry Division, National Bureau of Standards, Washington, D. C.

ABSTRACT

A reference electrode for use in molten salt systems is described. It consists of a porcelain capsule conductive to sodium ions, containing a silver electrode immersed in a melt of silver chloride and sodium chloride. The electrode is reversible to sodium ions. It is stable, reproducible, and temperature-reversible and can be used at temperatures 400° to 500° higher than can similar electrodes made of glass. The capsule-type construction prevents the salt inside the electrode from contaminating the melt under study. Electrodes made from specially prepared porcelains and also from a commercial porcelain were used. Data are presented on the resistivity of the specially prepared porcelains and on the mechanism of conduction by the porcelain.

Accurate data on electrode potentials in molten electrolytes are of importance in electrodeposition from molten salts, corrosion by molten salts, and in studies of the thermodynamic properties of molten salt systems. The amount of research in these fields has increased in recent years because of interest in the production of refractory metals by electrodeposition from molten salt solutions, in the development of molten salt batteries, and in the various applications of molten salt processes in the atomic energy program.

Several types of reference electrodes have been used in previous researches in these fields, such as the Ag/AgCl electrode with a liquid junction (1, 2); the Pt electrode (3, 4); an Ag/AgCl electrode in a graphite sheath for use in fluoride melts (5); the Cl^-/Cl_2 (graphite) electrode (6); and electrodes in glass capsules with the internal electrode in the glass capsule consisting of Na (7, 8), Na-Hg (9), Na-Sn (10, 11), and Ag in a mixture of AgCl-LiCl-KCl (12).

A reference electrode has been developed in this laboratory which is similar to that described by Bockris, *et al.* (12), but differs in that the glass capsule used by them is replaced by a porcelain capsule conductive to sodium ions. The main advantage of the porcelain electrode is that it can be used at much higher temperatures than can glass. In common with the glass capsule electrodes, it also has the advantage that salts in the capsule cannot intermix with those outside the capsule. The porcelain is reversible to sodium ions in the melt under study, and since the inner Ag/AgCl electrode is reversible, the entire electrode system is reversible. Electrodes of the design described below have been used at temperatures up to about 900°C. They should be capable of use at temperatures up to the melting point of silver. If the design were modified to make possible the retention of molten silver, the electrodes might be serviceable at temperatures approaching the softening point of the porcelain.

Preparation of Electrodes

Preparation of porcelain.—The composition of the porcelain from which most of the capsules were made was approximately: Na_2O, 2.5%; SiO_2, 73.1%; Al_2O_3, 24.4%, by weight. The objective in preparing this porcelain was to obtain a material that was nearly free of alkali metals other than sodium and of alkaline-earth metals, with the thought that such porcelain might be conductive only to sodium ions. The sodium content was chosen arbitrarily. In later work, a commercial porcelain and a porcelain containing a higher proportion of sodium were used.

The porcelain containing 2.5% Na_2O was prepared as follows: A glass of the composition $Na_2Al_2Si_2O_8$

was made by dry-milling together in a jar mill with flint pebbles an equimolar mixture of Na_2SiO_3, Al_2O_3, and SiO_2, followed by firing of the mixture at 1100°C, after which the fired mass was reground. A portion of the glass (186 g) then was milled in a 1-gal jar mill with flint pebbles for 10 to 12 hr, together with 388 g of Kentucky ball clay, 520 g of Georgia kaolin, 696 g of flint, 820 ml of water, and 0.5 g of sodium silicate or sodium carbonate. The sodium silicate (or carbonate) was added to effect deflocculation of the slip.

Construction of electrodes.—The construction of the porcelain electrode is shown in Fig. 1. The slip was formed into electrode tubes by slip-casting in a split mold of plaster of Paris, which had been formed over a glass pattern of the electrode tube. The slip-casts were dried in the mold, removed, and usually were fired to 1285°C, but some were fired as high as 1400°C. Although the higher firing temperature caused blisters to form, the tubes still were serviceable.

A T-tube of Nonex glass was sealed to the porcelain tube. At its working temperature, the glass wets the porcelain readily to form a good seal. (The porcelain that contains 10% Na_2O, described in the section on Electrical resistivity of porcelain, was joined to a T-tube of Kovar sealing glass, Corning No. 7052.)

The inner Ag electrode was made as follows: A length of 1 mm W wire, the tip of which had been cleaned by filing, was inserted into a ceramic tube of 1 mm i.d. (McDanel high-temperature porcelain) to within about 1-in. of the end of the tube. The tube was supported vertically in a clamp with the open end upward. A short length of 1 mm Ag wire was inserted into the tube and melted by applying a torch flame, first where the Ag wire touched the W and then higher as the Ag melted, so that the Ag flowed into intimate contact with the W wire and completely filled the tube. Electrical continuity between the Ag and W was checked with an ohmmeter. All of the Ag electrodes used in the cells described in this paper were constructed in this manner, so that the W-Ag thermoelectric potentials cancel. The W wire was then beaded with U glass (Corning No. 3320) and sealed into the T-tube at a position such that the tip of the Ag electrode extended nearly to the bottom of the porcelain bulb. Care must be taken in making this seal to insure that the inner electrode does not touch the inner surface of the porcelain tube. The porcelain is sufficiently translucent so that the location of the inner electrode can be checked by viewing it against a strong light.

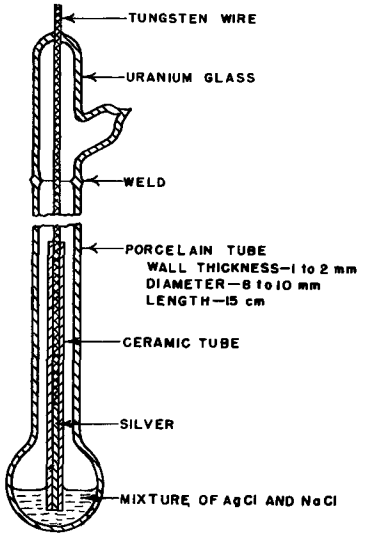

Fig. 1. Construction of porcelain electrode

The assembled electrode was filled with the desired mixture of AgCl and NaCl through the sidearm of the T-tube, which then was sealed off while evacuating the electrode through it. Evacuation and sealing are not essential, but this procedure was preferred. Various proportions of AgCl and NaCl have been used, but a mixture high in AgCl is preferred because of its lower melting point and because fewer capsules break when re-used if they contain such a mixture. Complete cells usually were assembled with two porcelain electrodes and one or two electrodes of some other type, dipped into a melt in a short cylindrical container.

Characteristics of Porcelain Electrodes

Reproducibility and stability.—Reproducibility of the porcelain electrodes was checked by measuring the potentials of cells in which identical electrodes were opposed. In the following cell, P represents the porcelain membrane; the numbers are the mole per cents of each component.

Ag/AgCl 40, NaCl 60/P/AgCl 4.76, NaCl 47.6,

KCl 47.6/P/AgCl 40, NaCl 60/Ag (I)

The results of measurements of the emf of cell (I) are shown in Table I for five replicate electrodes, represented as a to e.

It is seen that there was a difference of 5-7 mv betwen electrodes a and b, which was probably caused by a small difference in the concentrations of the electrode solutions. These were prepared separately, and an error of about one percentage unit in concentration would account for the discrepancy. The temperature of cells c/d and d/e was varied irregularly over long periods. The results show that the emf of the porcelain electrodes was stable and reproducible to within a few millivolts under temperature cycling over a period of nearly six days. These experiments also showed that the

						141	800	0.0

porcelain electrode is re-usable since electrode d was used in two separate experiments. This is a distinct advantage for a reference electrode.

The period of time required for the porcelain electrode to reach equilibrium, following a shift in temperature or other disturbance, usually ranged from a few minutes to about 30 min. Occasionally a cell potential did not become stabilized until after several hours. The cause for the variation is not known.

Temperature reversibility.—Temperature reversibility is indicated by the results shown in Table I. Additional experiments bearing on the variation of the emf of the porcelain electrode with temperature are described in this section.

Electromotive forces of the following concentration cell were measured over a range of temperature from 646° to 850°C (numbers are mole per cents).

Ag/AgCl 40, NaCl 60/P/AgCl 9.6, NaCl 45.2,

KCl 45.2/P/AgCl 78, NaCl 22/Ag (II)

The temperature was cycled within this range in a random manner over a period of several days. Repeat readings at the same temperature agreed within about 1 mv. Data are plotted in Fig. 2. The temperature at the break in the curve corresponds reasonably well with the liquidus temperature given in International Critical Tables (ICT) for the AgCl-NaCl system at a mole ratio of 40/60 (from ICT, 675°C; from Fig. 2, 688°C).

The emf of cell (II) may be written

$$E = (2.303\,RT/F)\log(0.78 \times 0.60/0.40 \times 0.22) \quad [1]$$

where mole fractions are used in the log term and activity coefficients are taken as unity. This equation is obtained by combining the equation for the emf of a concentration cell without transference with the equations for the two membrane potentials. The latter are based on the assumption that only sodium ions are transferred through the membranes. With this assumption, the over-all cell (II) process for one faraday is

AgCl (78 mole %) + NaCl (60) =

AgCl (40) + NaCl (22) [2]

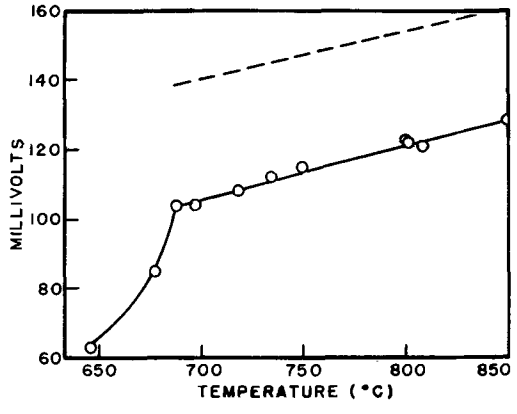

Fig. 2 Emf of cell (II) as a function of temperature. The dashed curve is calculated from Eq. [1].

Equation [1] gives the emf of this process and yields a value of E/T of 0.000144 v/deg. The slope of the curve in Fig. 2 beyond the break, i.e., in the range of temperature at which the salt phase in the left-hand electrode of cell (II) is completely molten, is 0.000148 v/deg. The agreement indicates that the porcelain electrodes behave normally with respect to temperature change.

Theoretically, the curve in Fig. 2 should extrapolate to zero emf at absolute zero. The dashed line shows the position of the theoretical curve calculated from Eq. [1]. It lies about 34 mv above the experimental curve. The difference may be due to deviations of the activity coefficients from unity, or to an effect of the potassium ions in the melt on the membrane potential (see section on Effect of potassium ions in the melt on the potential of the porcelain electrode).

Membrane asymmetry.—Theoretically, the potential of a half-cell including a sodium ion-conductive membrane in contact with a given external melt should be independent of the composition of the membrane. However, it is conceivable that unsymmetrical surface effects might result in an asymmetry potential. To check this point, cells were set up in which two capsule-type electrodes were dipped into the same melt contained in a small crucible. Melts in the two half-cells were identical, but the membranes were different, as shown in cell (III) (numbers are mole per cents).

Ag/AgCl 50, NaCl 50/P/Na-K-Sr

chloride/G/AgCl 50, NaCl 50/Ag (III)

In this cell, the membrane P was a porcelain capsule made from porcelain containing 2.5% Na_2O, fired at 1350°C, and G was a capsule of Pyrex glass. Measurements were made on two additional cells, like cell (III), except that in one cell, capsule G was replaced by a porcelain capsule that had been fired at 1400°C, and in the other by a capsule made from a commercial porcelain. (McDanel high-temperature porcelain in the form of a thermocouple protective tube, 1/2 in. OD, 1/16 in. wall; composition by weight: Al_2O_3, 56.2%; SiO_2, 43.0%; K_2O + Na_2O, 0.32%; C, Mg, and Fe oxides, 0.62%.) Temperatures ranged from about 550° to 750°C, depending on the material of the capsule. The potential of each of these three cells was less than 1 mv.

Since no significant membrane asymmetry potential was found in comparing these unlike membranes, it is unlikely that an asymmetry potential will be a complicating factor in the use of the porcelain-type electrode. The result with the commercial porcelain is especially significant, since the use of commercially available porcelain makes the rather tedious preparation of a special porcelain unnecessary. However, further work on the relationships between the composition of a porcelain and its selective permeability to specific ions might be fruitful.

Effect of the concentration of sodium chloride within the porcelain capsule.—Porcelain electrodes represented as Ag/AgCl(x), NaCl ($1-x$) porce-

lain, in which $1-x$, the mole fraction of sodium chloride, varied from 0.05 to 0.40, have shown reproducible, stable potentials. It is probable that both higher and lower proportions of sodium chloride could be used.

Effect of potassium ions in the melt on the potential of the porcelain electrode.—The effect of potassium ions on the potential of the porcelain electrode was studied by comparing cells having different ratios of sodium chloride to potassium chloride. Data for the following two cells are illustrative (numbers are in mole per cents).

Ag/AgCl 25, KCl 70, NaCl 5/P/

AgCl 50, KCl 45, NaCl 5/Ag (IV)

and

Porcelain electrode/AgCl 75,KCl 20, NaCl 5/Ag (V)

where "Porcelain electrode" designates the left electrode of cell (IV) up to and including the P membrane. The emf values for cells (IV) and (V) at 750°C, were 0.111 and 0.201 v, respectively. By use of assumptions analogous to those employed for calculating the emf of cell (II), the following theoretical values are obtained

	Cell IV v	Cell V v
Porcelain reversible to Na^+ only	0.061	0.097
Porcelain reversible to both Na^+ and K^+	0.097	0.194

The emf values calculated on the assumption that the porcelain membrane is reversible to both Na and K ions are much closer to the experimental values than those calculated from the assumption that only Na ions determine the membrane potential. It must be concluded that the porcelain electrode does not act solely as a Na electrode. However, in view of its stability and reproducibility, this result does not affect its potential usefulness as a reference electrode in any given system.

Current reversibility of the porcelain electrode.—An important property of an electrode is its ability to return to equilibrium after accidental passage of current. To check this property, cell (II) was polarized by passing a current of about 0.1 amp for 20 sec at 800°C. A polarization of 6 mv was measured immediately after passage of current. The polarization decayed to about 1 mv within 5 min. Reversal of the polarizing current gave an equal but opposite polarization, which decayed within 5 min to about 0.3 mv. Within 20 min the residual polarization was less than 0.1 mv. It is concluded that the porcelain electrode is reversible to passage of current.

Electrical resistivity of the porcelain.—Approximate measurements were made of the resistivity of porcelains of two compositions. One of the porcelains had the composition described in the section on Preparation of Electrodes; the other had a higher content of Na_2O. The composition of the latter was Na_2O, 10%; SiO_2, 54%; Al_2O_3, 36% by weight. Sodium was introduced into this porcelain as before in the form of a glass, but in this case the glass was prepared from Na_2SiO_3, SiO_2, and Al_2O_3, plus about one-third of the clays, followed by firing. The clays were added to render the glass less soluble in the slip mixture. The slip-casts were fired at 1170°C. Resistivity was estimated by measuring the voltage drop across the porcelain for a known direct current. The porcelain conductor was an electrode capsule in the case of the low-sodium porcelain. The resistivity of the porcelain containing 10% of Na_2O was so low that a conductor in the form of a U-shaped bar was used. In both cases the porcelain was in contact with a molten mixture of sodium salts having an appropriate melting point. Resistivity data are given in Table II. Even though the results are only approximate, it is believed they are of interest.

The low resistivity of the porcelain containing 10% Na_2O is noteworthy. It is of the order of 100 times that of molten alkali halides and is much lower than that of glasses. For example, the resistivity of soda-glass at 400°C is about 80,000 ohm-cm.

Mechanism of conduction by the porcelain.—Since application of the porcelain membranes to some experiments on conductivity and transference was planned, information on the mechanism of conduction through the porcelain was desired. The cell consisted of a porcelain capsule and a Ag anode dipped into a crucible that contained molten NaCl. The capsule contained a melt of AgCl-NaCl and a Ag cathode. Separate experiments were carried out with the low- and high-Na porcelains. Results are shown in Table III.

The gain in weight shown in the last column was calculated from Faraday's law on the assumption that only sodium ions pass through the porcelain. The agreement is within the limits of experimental error. In the experiment with the low-Na porcelain, examination of the inside of the bulb after the electrolysis showed blackening, probably due to reduction by the Na deposited on the cathode after complete deposition of the silver ion present in the melt. In the experiment with the high-Na capsule, Na was not deposited, and the porcelain was not

Table II. Resistivity of porcelains

900	430	20
940	380	
1000	300	

Table III. Ion conductance of porcelain

Porcelain composition	Current, ma	Time, min	Temp, °C	Wt gain, g	Calc wt gain, g
Low-Na	50	300	850	0.215	0.215
High-Na	85	240	850	0.295	0.292

visibly changed, even though the amount of sodium ion transferred was sufficient to replace all of the Na contained in the porcelain.

The above results indicate that the porcelain conducts solely by transfer of sodium ions and not by transfer of electrons or oxygen ions.

Resistance of porcelain electrodes to breakage.— The likelihood of accidental breakage of these electrodes is about the same as that of similar glass electrodes. However, electrodes made with glass capsules usually break on cooling after being used once, whereas the porcelain electrodes usually can be used at least twice. In the course of this work, 26 porcelain electrodes were used. Of this number, 20 operated satisfactorily for one or more experiments, and 6 failed during initial use. Failure was due to breakage of the bulb, breakage of the glass-porcelain seal, or contact defects associated with the Ag-W junction or the porcelain sheath over the Ag. It is probable that improvements in design and construction might make them more durable.

An Application of the Porcelain Electrode

A porcelain reference electrode has been used successfully by another group in this laboratory working on the deposition of Ti from molten salt solutions. In these experiments, changes in the potential of Ti cathodes were followed during electrolyses of solutions of $TiCl_2$ or $TiCl_3$ in a eutectic melt of LiCl-KCl-NaCl at 600°C. The porcelain reference electrode, which was made from the low-Na porcelain, was used repeatedly over a period of five weeks. It was cooled, washed with water, and stored dry during intervening periods of nonuse. At both the beginning and the end of this period, its equilibrium potential against Ti in a fresh, carefully prepared melt was 1.23 v. Since a precision of one centivolt was adequate in these experiments, the data were not recorded to millivolts, but the constancy of the electrode was in fact significantly better than 1 centivolt.

Prolonged immersion of the electrode in the Ti solutions caused a film of Ti to form. A brief dip in a 25% solution of hydrofluoric acid (1 part concentrated HF to 1 part water by volume) removed the Ti film without damage to the electrode.

Acknowledgments

The authors acknowledge the contributions of Gwendolyn B. Wood and Paul A. Krasley, who carried out the work described in the section on Application of the Porcelain Electrode, and of Seymour Senderoff, now at National Carbon Research Laboratories, Parma, Ohio, who initiated this project. Acknowledgment is also made to the Atomic Energy Commission, Division of Research, Chemistry Branch, for financial support and for permission to publish this material.

Galvanic Behavior in Fused Electrolytes

II. Discharge of the System Mg/LiCl-KCl-K_2CrO_4/Ni

Sidney M. Selis[1] and Laurence P. McGinnis

Diamond Ordnance Fuze Laboratories, Washington, D. C.

ABSTRACT

The discharge of the system Mg/LiCl-KCl-K_2CrO_4/Ni at current densities of several microamperes per square centimeter yields a potential-time curve with discrete potential plateaus. Two of the plateau potentials are controlled by nickel oxides formed by the oxidation of nickel by chromate ion. Another plateau potential is controlled by the reduction of hydroxide ion at the cathode.

An effect of added silicon dioxide is the stabilization of initial equilibrium potentials. Another effect of silicon dioxide, or other solid acidic oxides, is the diminution of coulombic output. These effects are attributed to a buffering of oxide ion activity and a removal of hydroxide ion from the electrolyte.

In a recent paper (1), the authors considered the galvanic system Mg/LiCl-KCl/Ni. Lithium chloride is a hygroscopic substance and, if not specially purified, it will contain small amounts of water and hydroxide ion even after it has been melted; the impurity content is on the order of 10^{-3} mole/liter (1-3). The proton of this hydroxide ion is the cathodically reducible material in the above system, and at temperatures below 450°C the cathode half-cell reaction is

$$2\,OH^- + 2e^- \rightarrow H_2 + 2\,O^= \qquad [1]$$

It is of interest to consider the effects of an oxidizing agent stronger than hydroxide ion. Potassium chromate is a convenient choice because it has reasonable thermal stability. Furthermore, it is found that magnesium is not attacked rapidly in the molten electrolyte LiCl-KCl-K_2CrO_4. The investigation of the system including chromate ion has been made by measuring potentials of cells at equilibrium and under resistive load. Relative coulombic capacities have also been determined. Data are presented for cells with and without added solid acidic oxides.

Experimental

Materials.—The chemicals used in this study were all of reagent grade and not purified further. As far as possible they were handled in an atmosphere with a relative humidity of 6% or less. The sheet magnesium and nickel, both 99.5% pure, have been described before (1). The cylindrical magnesium electrodes were machined from stock which was 99.97% pure, the impurities being small amounts of calcium and zinc. The nickel cups were prepared by electrodeposition on a chromium-clad mandrel. The nickel was over 99% pure, the major impurities being cobalt, manganese, iron, and possibly carbon. The sintered nickel, used to prepare nickel-nickel oxide electrodes, has been described by Fleischer (4).

[1] Present address: Research Laboratories, General Motors Technical Center, Warren, Mich.

Procedure.—The procedure followed in studying cells with strip or sheet electrodes has been discussed by Jennings (5) and by us (1). The silver-silver chloride glass reference electrode has already been described (1). The cylindrical cell design is shown in Fig. 1 (for clarity, the horizontal dimension has been exaggerated in Fig. 1). Spacing flanges and a nickel lead wire were welded to the top of the cup, the carefully weighed electrolyte components were added, and the cup was positioned in a Pyrex tube envelope. The latter was then placed in a furnace controlled at 300°C. The sidearms accommodating the wires were sealed, the envelope was capped, and the cup was evacuated to about 20 μ Hg for 18 hr so as to remove excess gas from the elec-

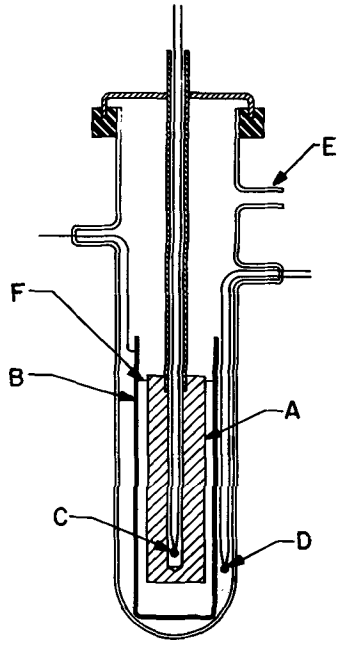

Fig. 1. Diagram of the cylindrical cell. A, magnesium electrode; B, nickel cup cathode; C, measurement thermocouple; D, control thermocouple; E, vacuum sidearm; F, electrolyte level.

trolyte. (This gas is mainly water and hydrogen chloride generated by hydrolytic reactions.) The temperature was then raised to 440°C, thereby melting the salt.

In assembling the anode, a small hole was first drilled nearly through the whole length of a magnesium cylinder of fixed diameter. The upper part of the hole was then enlarged and threaded to accept a threaded brass tube. Through this and the anode could be inserted the measurement thermocouple as distinguished from the control thermocouple located outside the cup (the thermal emf of the magnesium-brass junction was shown to be negligible). The brass tube was then screwed all the way through a threaded hole in the cap shown in the diagram.

After the pre-pumping, the system was opened, and the anode assembly was positioned and properly braced. Using a predetermined reference mark on the brass tube, the anode was lowered to the proper level, and all possible leaks were closed with a wax. The cell was evacuated to 0.5 mm Hg, and final temperature adjustments were made to 440° ± 1°C. Stable initial emf's could be recorded 24 hr later, and the resistive load could then be applied. Available equipment permitted the use of a fixed resistance, and discharge of the cells through this resistance satisfactorily provided the data needed for the discussion presented below.

Voltage-time data were obtained with a recording oscillograph having an input impedance of 9 megohms. Since discharges lasted as long as two days, periodic calibration of the oscillograph was necessary, and the apparatus was calibrated automatically every hour. Additional cell and thermocouple emf measurements were made with a student-type null-balancing potentiometer. Because the changes in cell voltage occurred exclusively at the positive electrode, as will be discussed later, the observed voltages may be considered as electrode potentials referred to the magnesium electrode.

The mixture of electrolyte salts was composed of 55.2 mole % LiCl, 40.0 mole % KCl, 4.83 mole % K_2CrO_4. For each cell, 20.0 ± 0.1 g was used. The amount of added solid oxide was 1 g, which was sufficient to saturate the electrolyte.

The interelectrode distance on the side was 4.4 ± 0.1 mm and was 14.0 ± 0.5 mm at the bottom. After certain runs, the electrolyte level was determined, and from this current densities were estimated for a given potential. Currents were calculated by dividing potential by the external load resistance (it was demonstrated that cell impedances were <1 ohm). For the maximum potential of 1.80-1.81 v, anode and cathode current densities for the 50-ohm load were 552 and 334 $\mu a/cm^2$, respectively; for the 2000-ohm load they were 13.8 and 8.34 $\mu a/cm^2$.

Results and Discussion

A typical potential-time curve for cells discharged across the 2000-ohm load at 440°C is shown in Fig. 2. It will be noted that there is a series of discrete potential plateaus corresponding to 1.80-1.81, 1.76, 1.70, and 1.67 v. A large number of these cells were studied and the plateau potentials were

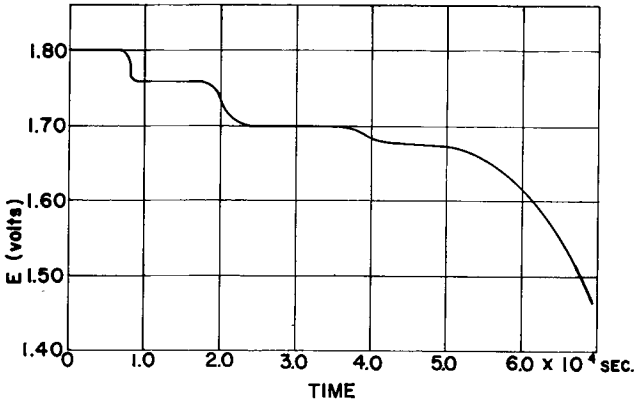

Fig. 2. Potential-time curve for discharge of a cell with SiO_2 through a 2000-ohm resistance.

reproducible to within less than 10 mv. However, as will be shown later, all of the various levels could be obtained dependably only when the electrolyte was buffered by the addition of SiO_2.

Changes in cell potential can be attributed solely to effects at the positive electrode. This was demonstrated by introducing a silver-silver chloride glass electrode in cells with electrodes of sheet magnesium. Measurements of the polarized potentials of these magnesium electrodes, corresponding to the current densities of interest, showed that polarization of magnesium was negligible.

Most of these potentials could be obtained by other means. If, for example, sintered nickel is rubbed with commercially available "black nickel oxide" and its potential is measured against magnesium in the LiCl-KCl electrolyte, the value obtained is 1.76 v. This potential persists for a while and then suddenly falls to 1.70 v. Concurrent with this potential drop, the color of the coating changes from black to green.[2] Green nickel oxide (NiO), rubbed on sintered nickel and measured against magnesium in LiCl-KCl, gives a stable potential of 1.70 v.[3] The 1.67-v potential has been considered before (1); it is obtained with the hydroxide ion-nickel electrode in LiCl-KCl at 440°C.

The following inferences can be made from this work. It is suggested that, during the 24-hr immersion in the electrolyte LiCl-KCl-K_2CrO_4, the nickel becomes coated with successive layers of oxidation products. Next to the metal there is probably a phase which includes nickel (II) ion; upon this, there is nickel in a higher state of oxidation (possibly the dark colored phase already mentioned). To account for the 1.80 v potential there may be nickel in a yet higher state of oxidation, presuming that the chromate ion is a sufficiently strong oxidizing agent so that this phase could be generated. Upon discharge, the potential for the first plateau is determined by the outer layer. As the latter is depleted there is a counter tendency for the higher oxide to be re-formed by the oxidative

[2] Hill, Porter, and Gillespie (6) prepared a "black nickel oxide" *in situ* at 658°C. This was accomplished by bubbling oxygen at unit pressure through a molten Li_2SO_4-K_2SO_4-CaO electrolyte in which was dipped a nickel wire. On decreasing the oxygen pressure, the dark-colored phase behaved in the same way as described above.

[3] The behavior of this electrode has already been measured and discussed (1).

action of the chromate ion. Apparently, however, it is discharged faster than it can be formed. When it eventually disappears, the cell voltage becomes governed by the next lower oxide. Such an explanation is offered for each solid layer. Finally, it is presumed that the cell potential is determined by reaction [1] until the hydroxide ion becomes fairly well depleted.

A few remarks should be made concerning the possible nature of such solid phases. The idea of simple oxides must be discarded. Brewer (7) states in summary that there is only one nickel oxide (nominally NiO with a NaCl-type cubic structure), although its composition range extends to nearly NiO_2. On the other hand, it is a different matter if alkali metal ions can be included in the oxide lattice. Verwey and his co-workers (8, 9) have presented strong evidence that the inclusion of lithium ion in the NiO lattice will induce the formation of Ni(III) ions. Dyer, Borie, and Smith (10) report the preparation of a stable $LiNiO_2$; here the formal valence number is three but the authors suggest that the lattice may actually include a mixture of Ni(II) and Ni(IV) ions. A compound with Ni(IV) ions, i.e., K_2NiO_3, has been characterized by Wahl, Klemm, and Wehrmeyer (11); the evidence is strong for the existence of this phase. But possibly of most pertinence is the observation of Hill, *et al.* already noted above, that a discrete phase producing a higher potential can be formed with oxygen in a fused salt electrolyte.

An explanation has been offered for the observed potential plateaus in terms of different reducible phases at the cathode. Certainly an explanation based on the direct electrochemical reduction of chromate ion would not be reasonable since, in this case, the potential would change continuously rather than in discrete steps. On the other hand, the chromate ion would function in oxidizing the nickel as indicated by reaction [2].[4] Here Cr_2O_3 is shown as a product; it has been identified by x-ray powder diffraction techniques. In any case, the matter is not highly pertinent to the present discussion. Reaction [2] would be followed by the half-cell reaction [3]

$$2xCrO_4^{=}(l) + 3Ni(c) \rightarrow 2xO^{=}(l) + xCr_2O_3(c) + 3NiO_x(c) \quad [2]$$

$$NiO_x(c) + 2(x-y)e^- \rightarrow NiO_y(c) + (x-y)O^{=}(l) \quad [3]$$

For reasons not pertinent to the information presented in this paper, the effects of including silicon dioxide and other solid acidic oxides were studied. One important effect is shown by the data in Table I which presents initial equilibrium voltages for a number of cells with and without SiO_2. The difference in reproducibility of emf is of immediate interest, but the difference of 40 mv in the averages is of doubtful significance.

Another interesting effect was the difference in coulombic delivery with and without added solid acidic oxides. Such comparisons are presented in Fig. 3 and in Table II. Relative coulombic deliveries were obtained to an arbitrary cutoff potential of 0.60 v by measuring the areas under the potential-time curves and dividing these by the external load resistance of 50 ohms. The data presented here were obtained from cells which had an initial potential of 1.80-1.81 v. Table II shows that the coulombic deliveries of cells with added solid oxides is from 38 to 53% of that for cells without added material.

[4] Reactions [2] and [3] have been written in terms of nickel oxide phases. It is to be remembered that these would be stabilized by the presence of alkali metal ions in the oxide lattices.

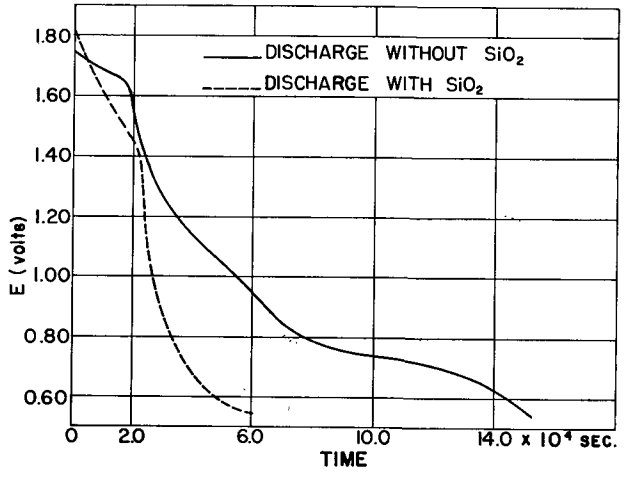

Fig. 3. Effect of added SiO_2 on discharge through a 50-ohm resistance.

To postulate an explanation for these effects of emf stabilization and differences in coulombic delivery, reference is made to reaction [2] in which it is seen that the oxide ion activity is a variable factor. Since it is at least partially governed by originally entrapped water of hygroscopicity, this quantity will depend on the specific batch of lithium chloride used, as well as on room humidity conditions and inadvertent differences in cell preparation. It is possible that, from one cell to the next, variations in oxide ion activity could determine the particular nickel oxide which governs the initial cell emf. But with added silicon dioxide a buffering effect could occur in terms of reaction [4].

$$SiO_2(c) + 2Li^+(l) + O^{=}(l) \rightarrow Li_2SiO_3(s, amorph) \quad [4]$$

Table I. Equilibrium potentials of nickel, with and without silicon dioxide in the melt, referred to magnesium electrode

With SiO_2		Without SiO_2

Table II. Effect of acidic oxides on the relative coulombic capacities of cells with nickel oxide electrodes

Added material	Capacity (coulombs)
None	3015 ± 115
SiO_2	1145 ± 45
B_2O_3	1585 ± 45
Al_2O_3	1475 ± 55

The presence of solid lithium silicate was confirmed by chemical methods, and an equilibrium involving two solids would fix the oxide ion activity which is the one variable in reaction [2].

The present authors prefer this explanation which involves the concept of different initial potentials being based on different potential-determining couples. An alternative explanation might have been offered in terms of reaction [3] for which potential is conceivably a continuous function of oxide ion activity. However, it is observed, as stated above, that plateau potentials are always reproducible to within less than 0.01 v. If an initial equilibrium potential was less than 1.81 v, then the plateau corresponding to this latter potential was simply never observed.

Regarding the diminution of coulombic delivery due to the addition of solid acidic oxides, a decrease in capacity might be due to the removal of hydroxide ion, and a material such as SiO_2 could provide for this. Hydroxide ion participates in the equilibrium shown in reaction [5],

$$2\,OH^-(l) \rightarrow O^=(l) + H_2O(g) \qquad [5]$$

and the removal of oxide ion by SiO_2 would result in the equilibrium being shifted to the right. In fact, when SiO_2 is added to these electrolytes, the evolution of water is immediately discernible. The authors believe that the added boron oxide or aluminum oxide would behave in a manner analogous to that of silicon dioxide.

Acknowledgment

The authors wish to thank the Dow Chemical Company for the pure magnesium rod used in this work.

Technical Notes

The Diffusion of Corrosion Hydrogen in Aluminum Alloys

W. E. Tragert

Research Laboratory, General Electric Company, Schenectady, New York

Essentially pure aluminum and many aluminum alloys corrode catastrophically in pressurized water at temperatures above say 275°C. It has been proposed (1) that the resistance of an aluminum—1% nickel alloy (X8001) to such oxidation is due to the presence in the surface of second phase Al_3Ni particles which function as cathodic sites for the evolution of corrosion product hydrogen. Such hydrogen is considered responsible for the usual accelerated oxidation by a mechanism of diffusion through the surface oxide film, discharge at internal pores or grain boundaries in the metal, and resultant blistering of the aluminum and disruption of the otherwise continuous surface oxide film. The local cathodic discharge of hydrogen at the surface thus inhibits entry of hydrogen into the aluminum and prevents catastrophic failure. The present experiment was devised to test the above described hypothesis.

Test samples were aluminum cans, 9.5 in. by 1.44 in. diameter with a wall thickness of 0.030 in. These were filled about 1/3 with distilled water and sealed with solid end plugs which were inert arc welded in place. A small nipple on each plug, pierced with an 0.030-in. hole, served as a vent during welding and was subsequently welded shut. The cans and end plugs were of two alloy compositions, Alloy 1245 (99.45% Al minimum) and Alloy X8001, mentioned above.

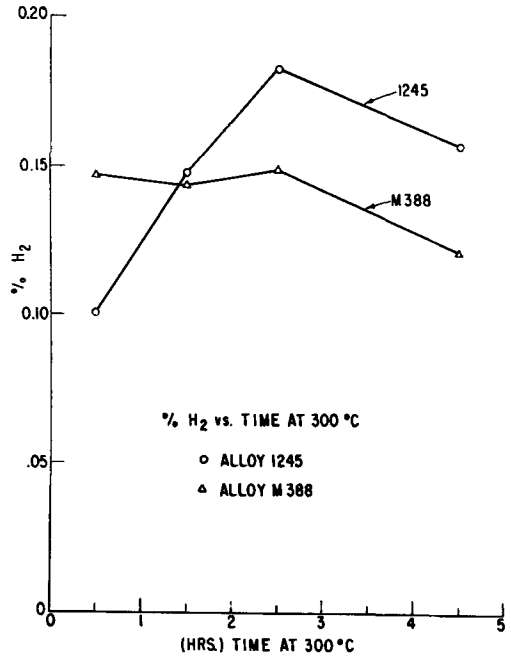

Fig. 1. Hydrogen content of the autoclave atmosphere as a function of time at 300°C.

The experimental procedure was to place a sealed aluminum alloy can in a stainless steel autoclave of internal dimensions 12 in. by 3 in. diameter, and then evacuate and purge the sealed autoclave with pure helium. The autoclave was resistance heated and the water vapor pressure within the aluminum can (inferred from temperature measurements) was compensated by valving helium into the autoclave during heating. When the system had reached 300°C, the atmosphere of the autoclave was sampled periodically, the samples being taken into evacuated 100 cc flasks. The flask contents were analyzed mass spectrographically for water and hydrogen. No water was detected in the several experiments, and data for hydrogen are presented graphically in Fig. 1 as a percentage of the total gas sample collected. The individual values are significant analytically to within 2%. That the proportion of hydrogen appears to diminish with time in these experiments can be attributed to several factors. First, the initial reaction of both aluminum alloys is quite rapid, the rate more or less diminishing as filming occurs; second, the oxide film is thinner and presumably more permeable at the outset than later in the experiment; third, hydrogen is lost from the pressure system by virtue of the samples taken and by diffusive loss through the heated walls of the autoclave.

A blank sample was run on the heated autoclave system and yielded no detectable hydrogen. A second blank was run on the system containing a can of Alloy 1245 that had been filled only with helium and sealed according to the procedure outlined above. No hydrogen was detected prior to heating, during heating, or at 300°C. At the conclusion of each of the corrosion gas sampling experiments, the can was cooled under supporting helium pressure, removed from the autoclave, and cut open. Unfortunately, no measure was made of the residual hydrogen gas pressure in the sample cans. Upon visual examination, there was noted superficial oxidation of the internal surfaces of the X8001 can and extensive oxidation of the 1245 can, although in the latter case one might have expected greater attack than was observed. It has been noted (2) that the transport of corrosion hydrogen appears from these data to be higher than would be expected from published diffusion data (3). It should be further noted, however, that the literature values for Q and D_o are unusually high and may reflect experimental difficulties as judged from the large scatter in the individual diffusion data points.

The present data and observations indicate that corrosion hydrogen diffuses through both Alloy 1245 and X8001. It must be considered, however, that the experimental configuration employed here is not typical of corroding systems; that is, corrosion hydrogen is not usually contained within the material under test. Consequently, it cannot be concluded that under normal conditions of corrosion, where the ambient hydrogen pressure may be small, hydrogen diffuses into either of these alloys to any great extent, although such may in fact be the case. The significance of these data is that, under conditions of hydrogen permeation, Alloy X8001 remained relatively uncorroded while Alloy 1245 was extensively oxidized. According to the galvanic protection hypothesis, the proton flux should have produced accelerated oxidation of both alloys in these tests.

It thus appears that rather than functioning as local cathodes, the second phase particles in Alloy X8001 serve, on oxidation, to alter the nature of the corrosion product film and to render it less permeable to the diffusing reactants. Although the concentration of hydrogen in the oxide film and basis metal may exert an influence on the reaction kinetics, this effect must be considered of secondary importance relative to the rate-controlling mechanism.

Manuscript received April 13, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

On the Crystallization of Simple Rhombohedral Boron from Platinum

F. Hubbard Horn

Research Laboratory, General Electric Company, Schenectady, New York

Since the report on the preparation of a simple rhombohedral (red) allotrope of boron by pyrolysis of a boron halide or hydride on a filament below a temperature of about 1200°C (1), it has seemed of interest to determine whether this allotrope can be obtained by crystallization from a melt. Requisite to such a process is a solution of boron from which boron and not boron compounds will crystallize below about 1200°C. The boron-platinum system is known to have a low melting eutectic. The remainder of the phase diagram apparently has not been published. A compound PtB or Pt_3B_2 has been reported (2).

Boron-Platinum Alloy System

An attempt to investigate the solidus-liquidus by a normal thermal-arrest procedure was not successful. However, the eutectic was determined by thermal arrest. The crucible was hot-pressed boron nitride which is not appreciably attacked by molten boron (3). The thermocouple was calibrated at the freezing temperature for silver. The eutectic temperature was determined as 825° ± 5°C. The eutectic exists over the composition range explored, from 5 to 87.5 at. % boron. The alloys were prepared from commercial grade platinum and granular boron of 99.8% purity.

The liquidus-solidus for boron-rich alloys was determined by immersing a small boron nitride probe into a melt of predetermined composition and noting the lowest temperature at which the probe could be removed from the melt without any solid (boron) adhering to the probe. In order to assure that the boron freezing on the probe was the first boron to freeze anywhere in the system, it was necessary to approach the liquidus-solidus temperature from a temperature well above it. Once boron had frozen to the probe, the temperature that was just sufficient to melt it could also be determined. With care, it was found possible to reproduce the conditions to about ±5°C. The temperatures measured are probably somewhat higher than true equilibrium temperatures since some additional heat must be supplied to compensate for losses such as those along the probe. Temperature was measured by optical pyrometer sighted on the clean melt surface near the center of the crucible. No correction for emissivity has been made since a calibration of the temperatures obtained by optical pyrometer against those from the embedded thermocouple agreed within 10°C over the temperature range 1200°-1400°C.

Data obtained for the liquidus-solidus line for the boron-platinum alloys investigated are plotted in Fig. 1. A curve through the points indicates a eutectic composition of about 40 at. % boron in platinum. There is no suggestion of compound formation for compositions between the eutectic and pure boron.

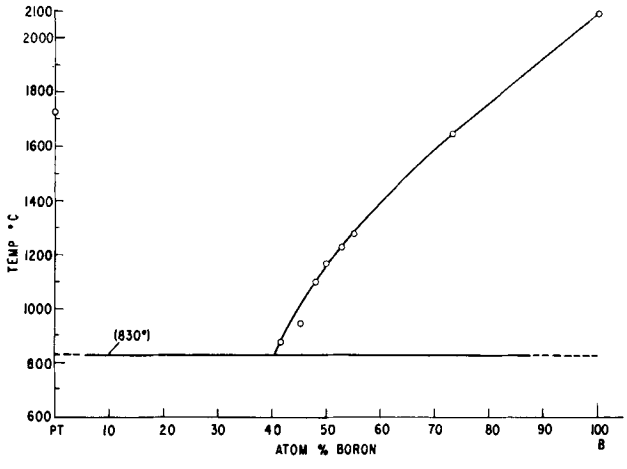

Fig. 1. Phase diagram of boron-platinum system

Attempts to use the probe method to complete the solidus-liquidus line were unsuccessful for alloys richer in platinum than the eutectic composition. The material freezing would not adhere to a boron nitride or graphite probe and probes of Ni, Fe, W, Mo, and Ta were attacked by the alloys.

Crystallization of Simple Rhombohedral (red) Boron

The simple rhombohedral form of boron is stable for a long period of time at 1200°C. It is seen from Fig. 1 that an alloy of about 50 at. % boron in platinum is molten at this temperature. Thus, from such an alloy cooled slowly to the eutectic temperature, boron will crystallize. If the simple rhombohedral form is stable at these temperatures, the boron crystallizing may be of this structure.

Typically, a 50-50 at. % alloy of boron and platinum was prepared from commercial platinum and zone-refined boron. The first melt was allowed to solidify and the surface and sides of the ingot ground away in order to remove a slag found frequently on initial melts. The alloy was transferred to a crucible of boron nitride having a conically tapered bottom. After melting the alloy in vacuum, the crucible was lowered gradually through the high-frequency heating coils. The rate of lowering has been about 0.04 mm/min. As the melt approaches the eutectic temperature it is allowed to freeze suddenly.

A cut and polished section through such a solidified melt shows crystallization of black (boron) in the bottom tip; moreover, regions of translucent red crystals are seen embedded in the remainder of the

section. The red crystals are highly reflecting and may be easily missed in the matrix if with vertical illumination the incident light is not polarized. The red crystals may be recovered by crushing the brittle platinum-boron matrix. They may be separated from the dust of the matrix by performing a gravity separation. The red crystals and some black solids float on bromoform. This fraction is skimmed and the solids allowed to settle by adding acetone. The settled material is rinsed with acetone and dried. Red crystals are readily separated visually from black solids using a microscope.

Powder x-ray diffraction analysis identifies the red crystals as entirely simple rhombohedral boron (4).

Crystals that have been recovered to date are very small, the largest being tenths of millimeters. Thus no attempt has been made to characterize their properties. There is no foreseen reason why larger crystals may not be grown.

It is of interest that the simple rhombohedral boron crystallized is translucent red; this suggests rather high purity. Either the solubility of impurities present must be very small at the low temperatures of formation or some purification may take place during the freezing of the boron in the tip of the ingot prior to crystallization of the simple structure. By x-ray diffraction the identification of the black material that separates with the red crystals or the black material crystallizing in the tip of the ingot is not positive; there is, however, some similarity to the pattern for the complex rhombohedral form of boron. Preliminary results suggest there may be a number of intermediate structures between the complex and simple rhombohedral forms.

Manuscript received May 15, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Technical Review

Report of the Chlor-Alkali Committee of the Industrial Electrolytic Division for the Year 1958

Clifford A. Hampel

Skokie, Illinois

Nelson J. Ehlers

Columbia-Southern Chemical Corporation, Pittsburgh, Pennsylvania

Chlorine-Caustic

Production and Sales

Consistent with the general chemical sales decline, U. S. chlorine production in 1958 decreased 8.8% from 1957 and was about 3,600,000 tons. For the first time in twelve years, the annual production was lower than that of the previous year. U. S. capacity at the end of 1958 is estimated at near 12,360 TPD, which means the industry operated at about 80% of capacity during the year. Apparent per capita chlorine consumption was 41.2 lb as compared to 22.2 lb in 1948 and 6.7 lb in 1938.

Concerning production in 1959, some sources predict a return to the 1957 production of about 3,950,000 tons and, of course, it is hoped that subsequent annual production tonnages will follow the traditional chlorine growth curve.

Chlorine production in Canada was 268,000 tons in 1958 as compared to 226,000 tons in 1957. Indications are that about 275,000 tons will be produced in 1959.

Caustic soda production for 1958 was at a 4,055,000-ton level, which meant a 6.7% decrease from 1957. Apparent per capita consumption was 44.2 lb compared to 29.9 in 1948 and 11.2 in 1938. Indications are that 1200 TPD lime soda caustic was produced as an average for the first eight months of 1958. This marks an increase for this period of about 260 TPD over the 1957 average and represents about 10.8% of the total caustic production in 1958 as compared to 7.9% in 1957. The Bureau of Census, after August 31, 1958, is not separating lime soda and electrolytic caustic production figures.

In general, the industry was more in balance between chlorine and caustic than in 1957. Again in

Table I. Sources of chlorine

	1957		1958 (preliminary)	
	Tons	%	Tons	%
Cl_2 equiv. of NaOH	3,548,579	89.9	3,234,813	89.9
Cl_2 equiv. of KOH	47,714	1.2	43,717	1.2
Cl_2 equiv. of Na	204,958	5.2	170,002	4.7

Cl_2 total gas produced	3,947,668	100.0	3,599,714	100.0

* By difference.

1958 soda ash was used to produce lime soda caustic in several plants in the U. S., and Dow Chemical Company, Freeport, Texas, continued to produce soda ash from electrolytic caustic.

Approximately 75.8% of chlorine capacity in 1958 was in diaphragm cells, 18.4% in mercury cells, 5.1% in sodium cells, and 0.7% in nonelectrolytic processes. The estimated sources of chlorine comparing 1958 with 1957 appear in Table I.

New Plants and Expansions

Approximately 640 TPD new U. S. chlorine capacity is estimated to have come on line in the U. S. in 1958, as follows: Columbia-Southern Chemical Corporation, Natrium, W. Va., 160 TPD (Uhde mercury cell); Dow Chemical Company, Plaquemine, La., 300 TPD (Dow bipolar cell); E. I. du Pont de Nemours & Company, Memphis, Tenn., 100 TPD (Downs sodium cell); and Weyerhaeuser Timber Company, Longview, Wash., 80 TPD (DeNora mercury cells).

The Arkansas Louisiana Chemical Corporation started operating the chlorine-caustic plant at Pine Bluff, which is rated at 75 TPD, in 1958, after Diamond Alkali Company terminated its lease.

Among the new plants or expansions to be completed in 1959 are: Diamond Alkali Company, Deer Park, Texas, 200 TPD (DeNora mercury cells); Jefferson Chemical Company, Port Neches, Texas, 150 TPD (Hooker S-3B cells); Stauffer Chemical Company, Niagara Falls, N. Y., 30 TPD (expand and modernize); and Wyandotte Chemical Corporation, Geismar, La., 300 TPD (Diamond diaphragm cell). Diamond Alkali Company announced early in 1959 plans to modernize chlorine cell facilities at Painesville, Ohio.

A listing of U. S. chlorine plants and estimated capacity appears in the March 7, 1959 issue of *Chemical Week*.

In Canada, the estimate of chlorine capacity by the end of 1958 was about 850 TPD. In 1958, among the new plants and expansions were: Shawinigan Chemical Company, Shawinigan Falls, Quebec, 50 TPD (mercury cell); and Western Chemicals Company, du Vernay, Alberta, 20 TPD (diaphragm cell). Dow Chemical Company in Canada has announced an integrated chemical plant at Fort Saskatchewan, Alberta. The chlorine-caustic unit will be built first and other units are to follow. Western Chemicals has announced an additional 20 TPD capacity scheduled to come on the line late in 1959. A chlorine plant for the St. John, New Brunswick area has been announced by K. C. Irving.

Markets and End-Use Patterns

There appears to be no significant change in the end-use pattern of chlorine and caustic soda during 1958. In the production of ethylene oxide, the oxidation process continues to increase in importance relative to the chlorination process. The reduction in military requirements for titanium adversely affected the demand for chlorine. In 1958, the use of chlorine increased in the pulp and paper, and water and sewage treatment areas. The decline in general business levels reduced the other chlorine uses. Latest end-use patterns appearing in the literature are shown in Table II.

Technical Developments

Some chlorine manufacturers are now using or installing germanium and silicon rectifiers for conversion of a-c to d-c power. Diamond Alkali Company, Deer Park, Texas, is installing germanium rectifiers. Columbia-Southern Chemical Corporation, Natrium, W. Va., has used germanium rectifiers commercially for chlorine production since early 1958. Hooker Chemical Corporation has installed silicon rectifiers at its Niagara Falls, N. Y., plant.

Hooker Chemical Corporation and Diamond Alkali Company continue to offer licenses for their processes to recover blow-off chlorine. The Hooker process calls for dilute chlorine gas to be absorbed in water destined for direct-contact cooling of hot cell gas. In the Diamond process, the gas stream containing chlorine to be recovered contacts carbon tetrachloride in a packed tower under pressure. Further stripping and cooling gives liquid chlorine.

A patent by H. H. Heller (U.S. 2,836,551) discloses the advantages of forcing brine through a mercury type cell at high velocities. A German patent (1,014,080) was issued to Dow Chemical Company for a "slot" type mercury cell.

Platinized titanium anodes were publicized by Imperial Chemical Industries, Ltd., for chlorine, chlorate, and other production uses.[1]

1 "Bright Future for ICI's Newly Developed Electrodes," *Chemical Age*, Jan. 3, 1959, and "Titanium Anodes," *Chemical Trade Journal*, Jan. 2, 1959.

Monsanto Chemical Co. is operating a cell designed by DeNora for recovery of chlorine from hydrochloric acid. The cell is believed to be economically feasible for many situations.

Among articles of interest appearing recently were: "For Cell Operators: What Price Efficiency?" *Chemical Week,* April 19, 1958, p.41-48; A debatable analysis on caustic soda was published in *Chemical Week,* Jan. 18, 1958, p. 69-76, entitled "Caustic—Plenty for Now and Future"; *Chemische Industrie,* June 1958, p. 309, cited research by VEB Farbenfabrik Wolfen to manufacture chlorine by nonelectrolytic means; "Too Much Chlorine," *Barrons,* March 24, 1958, p. 17-19; and "Thermal Data for Chlorine and HCl," *Chemical Engineering,* Feb. 10, 1958, p. 144-146.

Soda Ash

For the last two years, total production of soda ash has decreased. Production in 1958 was 4,955,200 tons, which was 7.1% below 1957. The apparent per capita consumption at 55.73 lb for 1958 was the lowest since 1941. Total domestic consumption in tons per year reached the all-time high in 1955 of 5,444,560 tons and has been on a decline since then. Natural soda ash production for both 1958 and 1957 accounted for 12.6-12.7% of the total soda ash produced. Total capacity of the soda ash plants in the U. S. is near 7,000,000 tons; therefore, it may be concluded that the industry operated at near 70% of capacity.

During 1958, Olin Mathieson Chemical Corporation completed facilities at its Saltville, Va., plant for production of dense ash. Columbia-Southern Chemical Corporation began production of soda ash and sodium sesquicarbonate at a new plant at Bartlett, Calif. The plant reportedly triples the output of an older unit there, now being scrapped. Food Machinery & Chemical Corporation has announced that a major expansion of soda ash production facilities at its Wyoming plant will be completed during the first half of 1959. Solvay Process Division of Allied Chemical Corporation is reported to be doubling dense soda ash capacity at its Baton Rouge, La., plant. Total ash capacity remains the same.

An estimated capacity for U. S. plants appears in *Chemical Week,* May 3, 1958, p. 72. The latest end-use pattern for soda ash appearing in the literature is shown in Table III.

Miscellaneous Chemicals

Potassium hydroxide.—Production of KOH (88-92%) decreased about 8.3%, from 83,898 tons in 1957 to a preliminary figure of 76,870 tons in 1958. Most of the newer caustic potash expansions have been by the mercury cell process. Caustic potash is making gains in the detergent field as a result of greater acceptance of some of the newer types of liquid detergents.

Chlorates.—American Potash & Chemical Corporation started operation of its sodium chlorate plant of 15,000 TPY capacity at Aberdeen, Miss., in early 1959. Reported for American Potash is a company capacity of 45,000 TPY. Hooker Chemical Corporation expanded sodium chlorate production at Columbus, Miss. Standard Chemical Limited announced the start of construction of a plant to produce sodium chlorate at Beauharnois, Que. During 1958, Electric Reduction Company of Canada claimed to be the world's largest producer of sodium chlorate as the result of expansion that doubled capacity of the firm's Buckingham, Que., plant. It has been estimated that U. S. sodium chlorate capacity will exceed 100,000 TPY in 1959 when announced new plants and expansions are on line. Production increased from 59,142 tons in 1957 to 67,247 tons in 1958, about 13.7%.

Perchlorates.—The importance of perchlorates in the production of solid fuels for missiles is highlighted by the announcements of additional plants for their preparation. HEF, Inc., jointly owned by Foote Mineral and Hooker Chemical, began construction on a 4,000,000 lb/yr ammonium perchlorate plant at Columbus, Miss. Pennsalt Chemicals Corporation announced a plant for production of ammonium perchlorate at Portland, Ore.

Two papers on the preparation and use of lead dioxide anodes in the electrolytic conversion of sodium chlorate to sodium perchlorate were published in this JOURNAL by Grigger, Miller, and Loomis of Pennsalt Chemicals Corporation and Schumacher, Stern, and Graham of American Potash & Chemical Corporation. Lead dioxide deposited on tantalum was found to be a suitable substitute for platinum in perchlorate cells.

Miscellaneous Metals

Aluminum.—Electrolysis processes are vital to the production of many of the metals, both old and new, used in this country. The aluminum industry, which consumes 5 to 6% of the total electricity generated in the U. S., continues to grow. At the end of 1957, the aluminum ingot capacity was some 1,842,000 TPY located in 18 plants of 4 companies. By 1960, this will rise to 2,604,000 tons in 23 plants of 6 companies. In Canada, the corresponding tonnages are 821,000 tons at the end of 1957 and 956,000 tons in 1960.

Magnesium.—Consumption of primary magnesium in the U. S. is expected to total about 45,000 tons in 1959. Consumption of scrap and secondary will account for another 10,000 tons or so. Consumption of this order is not a record for peacetime but does represent a resumption of the upward trend

Table IV. 1958 Sodium end-use pattern (estimated)*

	%
Tetraethyl lead	71.0
Sodium cyanide	11.2
Sodium peroxide	6.9
Metal reduction	4.7
Miscellaneous	6.2
Total	100.0

* Source, *Chemical Week*, Jan. 24, 1959, p. 78.

following the recent recession. Production in 1959 will be about 30,000 tons because of a large inventory carry-over. A large inventory was built up in 1957 when Dow Chemical Company was uncertain about the disposition of the then government-owned plant at Velasco, Texas (the plant eventually was sold to Dow, the higher of two bidders). Magnesium uses are roughly 40% structural, 60% nonstructural. Applications are divided about 50-50 between commercial and military.

Sodium.—Capacity for sodium production was reported to be 153,000 TPY as of Jan. 1, 1958. Production in 1958 was 110,298 tons as compared to 132,977 tons in 1957, a decrease of 17%. The Woodstock, Tenn., plant of du Pont for the production of sodium went on the line early in 1959. Capacity was reported as 45,000,000 lb/yr. This new installation, plus recent expansions of other producers, will increase U. S. capacity to about 400,000,000 lb/yr. The general reduction in sodium use since the peak in 1956 is attributed to loss of the fatty alcohol market and the drastic reduction in titanium metal use. The largest use of sodium continues to be in production of tetraethyl lead, and this use is increasing a small percentage each year.

The present status of the sodium industry is given in *Chemical Week*, Jan. 24, 1959, p. 76. The estimated sodium end-use pattern is given in Table IV.

Titanium.—Production of titanium sponge metal in 1958 at 4585 tons was about 27% of the 1957 output; however, the consumption of sponge metal and production and consumption of titanium ingot were, respectively, about one-half that of 1957. Total sponge held by General Services Administration at the end of 1958 was 22,400 tons.

There has been a continued increase in consumption of sponge since early 1958, and by the end of 1958 it was at least 50% of the peak rate in the brightest days of the industry. Use of titanium for its corrosion-resistant properties is increasing.

Zirconium.—The major U.S. production of zirconium metal is for the Atomic Energy Commission program. Carborundum Metals Corporation, Mallory-Sharon Metals Company, and Columbia-National Corporation are the three AEC sponge suppliers. These three producers have contracted to supply about 2,200,000 lb/yr of hafnium-free zirconium sponge.

Mallory-Sharon and Columbia-National began operations in 1958. Carborundum and Columbia-National processes involve the magnesium reduction of zirconium tetrachloride, while Mallory-Sharon uses sodium reduction. Wah Chang Corporation, Albany, Ore., has shut down its zirconium facilities and is now converting hafnium oxide to hafnium metal for the Atomic Energy Commission.

No expansion of zirconium facilities is planned at the present time.

Lithium.—Lithium, made by the electrolysis of fused lithium chloride admixed with potassium chloride, is finding increased use in such fields as the preparation of boron fuels. Olin Mathieson Chemical Corporation has installed electrolytic cells for lithium production at its Model City, N. Y., boron fuel plant, and Foote Mineral Company announced expansion of lithium production.

Manganese.—The use of manganese ore for the production of the metal in the U. S. in 1958 was over 10,000 tons. Production capacity is located in the plants of Foote Mineral Company, Knoxville, and Union Carbide Metals Company, Marietta, Ohio. The electrolytic process is the only one producing pure metal.

Chromium.—High-purity chromium metal is made by electrolysis of ammonium chromium sulfate solution in the Union Carbide Metals Company Marietta plant.

Uranium.—Most uranium metal is derived from the reduction of uranium tetrafluoride with magnesium. While the demand for uranium depends on the scope of the nuclear power plant development and the amount of uranium oxide used in fuel elements, estimates of 50,000-100,000 TPY in 1970 or 1975 have been made. Not only new metal requires magnesium for preparation, but magnesium is also used in reprocessing spent fuel elements.

Beryllium.—Pure beryllium metal is made in the U. S. from the reduction of beryllium fluoride with magnesium. New plants constructed by The Beryllium Corporation at Hazelton, Pa., and The Brush Beryllium Corporation at Elmore, Ohio, produce beryllium metal for nuclear and other applications. Each of these firms had a contract for annual delivery of 100,000 lb each of beryllium ingot to the Atomic Energy Commission, but the contracts were revised and the new production level set at 37,500 lb of ingot per year for each company.

Tantalum and columbium.—Tantalum production was estimated to be 225,000 lb in 1958 and is expected to reach 300,000 lb in 1959. Most of the metal is obtained either by electrolysis of fused potassium fluotantalate or by sodium reduction of this and other tantalum compounds. Columbium, the sister metal of tantalum, reached a production in 1958 estimated at 50,000 lb. While it is made chiefly by reaction between columbium carbide and columbium oxide, it can be made by the process used for tantalum, i.e., sodium reduction.

Stauffer Chemical Company announced construction of a $300,000 semiworks plant to make tantalum and columbium pentachlorides at its Richmond, Calif., research laboratories. National Research Corporation, Mallory-Sharon Metals Company, and Union Carbide Metals Company all had their processes for producing tantalum and/or columbium de-

scribed in articles published in 1958. Each used some form of sodium reduction of metal compounds to produce the metals. Recently, Haynes Stellite Company exhibited the largest tantalum sheet ever produced, the size being 28 x 60 x 0.030 in. The availability of large sheet should increase the use of tantalum in chemical equipment. Other producers of tantalum and/or columbium include du Pont, Fansteel Metallurgical Corporation, Wah Chang Corporation, Kawecki Chemical Company, Kennametal, Inc., and Molybdenum Corporation of America.

Manuscript received June 8, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Brief Communication

Action of Alkali on Caustic Cell Slimes

S. Wawzonek and P. D. Klimstra

Department of Chemistry, State University of Iowa, Iowa City, Iowa

Used graphite anodes have been the only source of material from which the caustic color compound has been isolated (1, 2). The report (3) that anode graphite slimes from chlorine-alkali cells contained 0.3-0.5% chloride suggested a study of various slimes from diaphragm and mercury cells to determine whether these could serve as a source of the caustic color compound.

Three samples of slimes have been treated with 50% sodium hydroxide at 100° for varying periods of time and the colors produced examined.

A sample of graphite particles removed from the bottom of one of the used anode plates after it had been used for the production of chlorine and caustic soda for approximately six months in a de Nora mercury cell gave the typical bluish-purple color associated with the caustic color compound.

A second sample consisting of graphite particles which were separated from the depleted brine stream after it had flown through the mercury cells gave under similar treatment a cherry red coloration. The possibility that this color was caused by colloidal ferric hydroxide was eliminated by the inability to discharge the color with sodium sulfide solution. This color, however, did not change to the blue on further heating with alkali.

A third sample consisting of the anode slimes from a diaphragm Tucker Windecker Cell operating with untreated anodes gave no color with 50% caustic.

Results obtained indicated that the caustic color compound or its precursor is produced in the mercury cell in the anode compartment but is effectively screened out by the circulating mercury which picks up the sodium in the mercury cell electrolyzer and subsequently releases the sodium as caustic soda in the denuder.

The absence of the caustic color compound in the anode slimes from a diaphragm cell suggests that most of the precursor may have been extracted by the caustic soda.

Acknowledgment

The authors wish to thank C. C. Silsby, Jr., of the Diamond Alkali Company, for the samples which were obtained from the Painesville and Muscle Shoals plants, and for his helpful discussion and advice.

Manuscript received June 12, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Anodic Oxidation of Cadmium

II. Electrical Properties of the Film

Phyllis E. Lake and E. J. Casey

Defence Research Chemical Laboratory, Defence Research Board, Ottawa, Ontario, Canada

ABSTRACT

Cadmium electrodes under anodic oxidation in hydroxide and carbonate electrolytes have been examined by analysis of the decay of overpotential after current interruption.

After passivation while oxygen is being evolved, except for a small instantaneous (<1 msec) ohmic drop, the potential decays logarithmically with time in the manner usually found for the decay of activation overpotential of a gas electrode. Before passivation while the metal is actively being oxidized, however, except for the small ohmic drop, the potential decays exponentially with time in two steps. This behavior is not described by activation theory.

Determinations were made of the capacitance of both the oxidizing and the passivated cadmium, both from potential decay curves and from superimposed a.c. All the a-c values correspond to those of a normal double layer, as do those obtained from decay measurements after passivation has occurred. However, the values obtained from decay curves before passivation are two orders of magnitude higher early in the oxidation but drop rapidly toward the a-c values as oxidation proceeds.

It is proposed that next to the Helmholtz double-layer at the CdO-electrolyte interface, there exists a highly polarized inner double-layer in which the reaction $OH^- \rightarrow O^= + H^+$ takes place. When the field strength across the inner double layer becomes high enough for the reaction $OH^- \rightarrow OH + e^-$ to take place instead, oxygen is evolved and the electrode passivates.

The roles of adsorption of OH^- to form the Helmholtz layer and of interference by $CO_3^=$ are discussed in terms of the results.

In a previous paper (1) experimental observation of the anodic oxidation of cadmium in basic solutions was described, and on the basis of the results a general mechanism for the formation of the anodic film was proposed. Two important features of the reaction were recognized: first, conduction of ions must occur through the solid layer of primary reaction product;[1] and second, there exists a rather critical reaction in which the primary reaction product (essentially CdO) is converted to a secondary product [$Cd(OH)_2$ in pure KOH] at a rate which is strongly dependent on electrolyte composition and other experimental conditions. The conversion takes place through the liquid phase. The nature of the cadmium in this phase has since been shown (14) to be $Cd(OH)_4^=$. The purpose of the present work was to investigate the electrical properties of the underlying layer of primary reaction product, and to determine which electrical property is in fact responsible for anodic passivation.

Experimental Method

The samples of cadmium for oxidation were prepared as described previously (1). The test cell was a rectangular lucite box (5 cm long x 3 cm wide x 5 cm high) of which the cadmium anode and nickel cathode formed the ends.

[1] Since the preparation of the present paper, the definitive work of Dr. Croft has appeared (17), in which he found strong evidence (from an entirely different experimental approach involving verification of the laws of film growth) to support the existence of solid-state conduction of ions through reaction product.

Part of the cadmium metal area was covered with stop-off lacquer, which left a square working area of 2.54 cm on a side. The electrode was cleaned in nitric acid and pre-reduced, as described in the earlier work (1).

The potential of the working electrode was measured against a cadmium reference electrode, a piece of charged negative plate from a sintered-plate nickel-cadmium battery chosen because of its large surface area as well as its good voltage stability. Decay curves were recorded on an instrument with an input resistance of at least 10^6 ohms. The open-circuit potential of the electrolytically reduced cadmium test electrode was 0 ± 5 mv. No junction potentials existed in any of the experiments with this arrangement.

Several times during each oxidation experiment the current was interrupted and the decay of the total overpotential η recorded. Two methods were used: (A) Decays of up to 100 msec were displayed on a Tektronix 535 Oscilloscope equipped with type 53/54C preamplifier (input resistance 10^6 ohms), and photographed. Reference voltages were displayed on each trace. (B) Decays up to 5 sec were recorded on a Brush Recording Oscillograph No. BL902, with auxiliary amplifiers (input resistance 1.5×10^9 ohms). Typical voltage traces are shown in Fig. 1(a). Voltages and times were conveniently read off the oscilloscope photographs after enlargement to 8 x 8 in. through a microfilm reader whose

face plate was equipped with a 2 mm grid; and off the Brush charts through a small hand lens. Figure 1(b) shows the transposed traces.

In addition to measurements of the decay of total overpotential, during several of the oxidation experiments a-c impedance measurements were made using an ESI Model 250 Impedance Bridge. Because of the very high capacitances per unit area of the electrodes, it was necessary to reduce the electrode area to ~1 mm² for these experiments. The error in area thus is appreciable, and this is taken into account in the discussion.

Experiments were done mostly at 25°C, but some were done at O° and −20°C. KOH concentrations ranged from 0.72-14.4N; and K_2CO_3 concentrations from 0.72-7.2N. Oxidation current densities were from 1-15 ma/cm².

Analysis of Decay Curves

The decay curves recorded fell into one of three general types (i) and (ii) before passivation, and (iii) after passivation:

(i) *Resistive decay.*—In all cases during the early stages of the oxidation, and also for longer periods, either in highly concentrated solutions or at low temperatures, the decay consisted principally of an instantaneous (<1 msec) drop plus a very small further decay to a value assymptotic to the open-circuit potential. Other than the determination of the magnitude of the initial drop, no analysis was attempted.

(ii) *Compound decay.*—Throughout most of the oxidation when $t < t_p$, [t_p is time at which passivation occurs (1)], the decay curve after current interruption consisted of an instantaneous drop, followed by a smooth exponential (log E vs. t) decay, which finally went over into a small and slow activation overpotential-like decay toward the open-circuit potential. The form of the tail end of the curve is discussed more fully later.

A plot of the experimental values of η and t, obtained from the oscilloscope trace, as log E vs. t ($E = \eta - E_x$, where E_x is the voltage to which the E has dropped after "infinite" time), it was possible to extrapolate the straight line back to zero time and obtain the value of E just at the instant of current interruption (henceforth called E°_{DL}). Thus it was possible to separate the rapid condenser-like decay from the resistive decay. From the slope of the log E vs. t curve, the value of E°_{DL} and the value of the current density before interruption, an apparent capacitance was calculated.

Inertia of the oscillograph pen rendered unreliable the voltages observed in the first 100 msec after current interruption. Values at $t > 100$ msec were quite reliable, but since voltages were small, and the reading error significant, no firm conclusions could be drawn from these results. It was apparent, however, that the curve changed form in the region of 200 msec and that the initial part of the curve was indeed a continuation of the log E vs. t decay observed on the oscilloscope. The latter part of the curve could be accounted for quite well as either a second slower log E vs. t decay, or as an E vs. log $(t + \theta)$ decay. The voltage obtained by extrapolation of the straight line to zero time (henceforth called E°_{act}), and the calculated capacitances were of the same order for both methods.

(iii) *Activation overpotential decay.*—After passivation, the decay curve was of a different form: a very small instantaneous drop was followed by a long activation overpotential-like decay [i.e. $\eta \propto \log (t + \theta)$; see ref. (4) and (8)], with no evidence of the condenser-like decay. In this respect the decay was normal for that following gas discharge at an electrode. Thus, a plot of the experimental values as η vs. log $(t + \theta)$ permitted graphical separation of the resistive drop from the activation overpotential ($E_{act(O_2)}$) decay. From the slope of the latter decay ($-b$), the value used for θ, and the current density before current interruption, the associated double-layer capacitance was obtained.

Results and Discussion

Components of η°

Concentration overpotential was not considered to be a significant factor determining the course of

the oxidation reaction partly because a log η vs. t relationship for the decay of a concentration polarization would demand that the concentration change as log log c vs. t, which seems most unlikely (10); and partly because values for concentration polarization estimated by Glasstone's method [see ref. (9)] were found to be <1% of η° at 20°C in the highly conducting alkaline solutions under study.

The activation overpotential-like decay at the tail of the decay curves (i.e., between 200 msec and 5 sec) obtained before passivation was small, not very reproducible, and difficult to analyze. An extrapolation of E_{act} to zero time gave the value of E°_{act}, which was between 5 and 20 mv over all the conditions studied. Theta (θ) values and Tafel b values varied considerably from run to run, but with no systematic variation: $0.01 < \theta < 0.6$ sec; $0.005 < b < 0.013$ v per decade of time. Capacitances calculated were always high, the values ranging from 10^4 to 10^5 μfd/cm^2, not unlike those observed on the nickel hydroxide electrode (5) and on some dry, compound oxides (7). Since E°_{act} consistently provided only a small fraction of the total η°, the values obtained need not be discussed further. As mentioned already, a plot of log E_{act} vs. t, actually favored on theoretical grounds for $\eta < 20$ mv, was also linear, and the capacitances obtained were of the same order of magnitude as those obtained from the E vs. log $(t + \theta)$ plot. Similar high values of capacitance at the tail end of decays of cathodic overpotential have been observed and attributed to "the last stages of desorption" (13).

Thus the major portion of the total overvoltage before passivation is made up of a resistive component which decays instantaneously and a capacitive component which decays rapidly and exponentially. Since current must be carried through the underlying CdO film by ions, the resistive part of the decay is assumed to be due to ionic resistance and is referred to as IR_i. Because: (a) Grahame's (4) theory of the capacitance of the electrical double layer predicts a linear log E vs. t plot during decay if forward and backward reactions are of nearly equal magnitude; and (b) in any case, a leaky condenser of fixed dimensions has this type of voltage

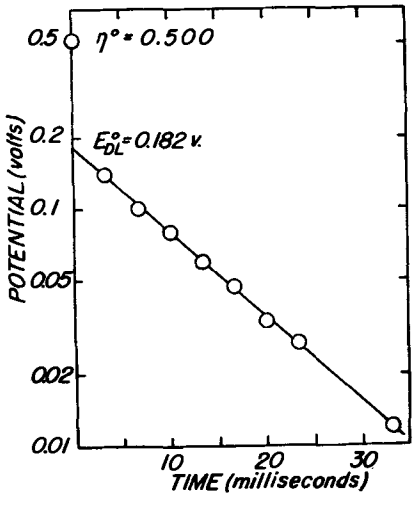

Fig. 2. Analysis of exponential part of decay curve; log $(\eta - E_x)$ vs. t.

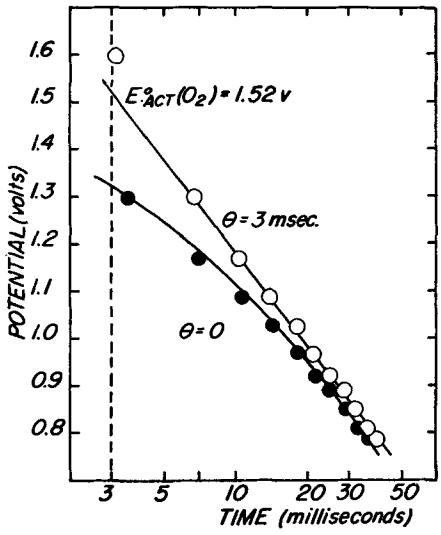

Fig. 3. Analysis of activation overpotential decay after passivation; η vs. log $(t + \theta)$.

decay and later in the paper is considered to be associated with the double-layer in a particular manner: the capacitive part is referred to as E_{DL} during decay or E°_{DL} just at current interruption. Figure 2 illustrates the method used to determine IR_i and E°_{DL} from a particular decay curve.

After passivation the resistive drop was small, there was no evidence of a condenser-like decay, and most of η° was made up of activation overpotential $E^\circ_{act(O_2)}$ associated with oxygen evolution. The small resistive component is thought to be due to only fair electronic conduction across the CdO film and is referred to as IR_e. Figure 3 illustrates the separation of these two components. Since the decay curves of type (iii) follow the theoretical plot for the decay of activation overpotential so rigorously, E°_{DL} after passivation must either (a) be very small compared to $E^\circ_{act(O_2)}$, or (b) refer to the same process and therefore be inseparable from $E^\circ_{act(O_2)}$.

Table I contains the results of determinations of the various components of η° at various times during two experiments, one in KOH and the other in K_2CO_3, both at 7.2N.

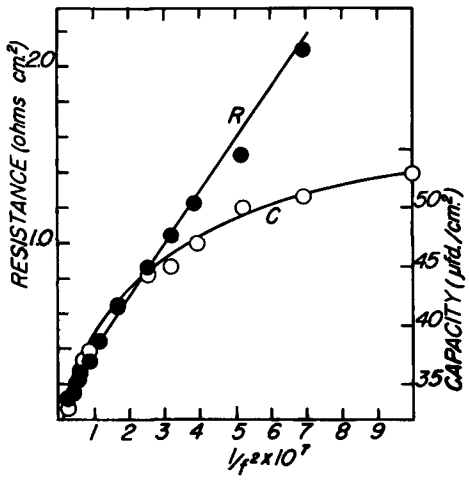

Fig. 4. Variation of series resistance and capacitance with $1/f^2$ for electrode passivated in 7.2N K_2CO_3, at room temperature at 1 ma/cm².

From the results, which are typical of analyses of current interruptions of oxidations at three temperatures, four concentrations, three current densities, and for both KOH and K_2CO_3, it is apparent that the approximate description of the total overpotentials of active (η°_A) and passive (η°_P) cadmium are given by:

$$\eta^\circ_A = IR_i + E^\circ_{DL}$$

$$\eta^\circ_P = IR_e + E^\circ_{act(O_2)}$$

At the moment of passivation then

$$IR_i + E^\circ_{DL} = IR_e + E^\circ_{act(O_2)}$$

and the problem reduces to interpreting E_{DL} and formulating a self-consistent mechanism which permits the transition from cadmium oxidation to oxygen evolution when passivation sets in. Consideration must first be given to capacitance measurements.

Capacitance Measurements

After Passivation: The passivated surface ($t/t_p > 1.0$) is the simplest and will be considered first. The a-c measurements made at 1000 cps during flow of oxidizing current gave values 36-180 μfd/cm²; the values were generally larger the larger the current density used to passivate the electrode. Capacitances determined from the decay of activation overpotential $E_{act(O_2)}$ from $C = 2.3\ i\theta/b$ were about the same, 50-500 μfd/cm². Since Grahame (6) found that double layer capacitances on clean mercury surfaces range up to 40 μfd/cm², a surface roughness factor of 1-5 is suggested for CdO underlayers after the electrodes have been passivated.

Frequency dependence of the series capacitance C_s and resistance R_s associated with the passivated surface also was measured from 1000-6000 cps while current was flowing. Since $R_P^2C_P^2\omega^2 >> 1$, both R_s and C_s should be linear functions of $1/f^2$ if the equivalent circuit for the electrode can be expressed as a pure R and C in parallel. The R vs. $1/f^2$ plot (Fig. 4) was linear, but the C vs. $1/f^2$ plot seems to approach a limiting value at the lower frequencies. Thus abnormally high capacitances at low frequencies are not indicated. Randles (15) found an inverse 0.5 power dependence of double layer capacitance on frequency from 60-1100 cps on clean amalgam electrodes. However, the frequency dependence of C_s on passivated cadmium surfaces studied here follows more closely an inverse 0.28 power dependence (determined from a plot of log C_s vs. log f from 1000-6000 cps) and is not interpretable at present. This property needs further study.

Before Passivation: At times before passivation, the a-c bridge capacitance C_s of the actively oxidizing metal was essentially constant throughout the oxidation, and on any one specimen the capacitance was the same before passivation as after (Table II). Hence there seems to be no essential difference in the composition and dimensions of the Helmholtz double layer before and after passivation.

In contrast, the capacitances obtained from the decay of E_{DL} were two orders of magnitude higher than the a-c values early in the oxidation, but dropped rapidly during the oxidation until at 0.9 t_p they were within a factor of two or three of the a-c values (Table II). [It is recalled that these values result from the experimental fact that the early part of the decay follows a log E vs. t plot, a decay which is far too rapid and with too much curvature to be accountable in terms of concentration polarization in the outer film (10).] The high initial values and the rapid fall of C as oxidation proceeds, the concurrent rapid rise in parallel resistance, and the results of a-c capacitance measurements suggest that the system is one which contains an inner or "crystal" (16) double layer structure in series with the normal Helmholtz double layer: and further that the inner double layer has relatively fixed dimensions and is capable of severe polarization [high dielectric

constant (12)] early in the oxidation. Since the inner structure is in series with, and has a capacitance larger than, the outer, it is the latter only which is detected in the a-c measurements. The model which has been most useful in describing qualitatively the experimental results is shown in Fig. 5, and a brief description of a possible mechanism of oxidation, based on this model, follows:

Following reduction prior to the oxidation experiment, the cadmium metal has a double layer due to adsorbed OH^- ions. With the first passage of current, OH^- is activated by removal of H^+ (i.e., $OH^- \rightarrow O^= + H^+$) and a cadmium ion in an active site loses its electrons and forms a CdO "molecule" attached to the surface. This process continues until a monolayer is built up, after which cadmium ions penetrate through the CdO layer to the oxide-electrolyte interface where the film-formation reaction takes place. The Helmholtz double layer then exists at the oxide-electrolyte interface. As the film thickens, after activation oxide ions are in the oxide film, i.e., chemisorbed, forming with the adsorbed OH^- an inner or crystal double layer. When the film is thin, capacitance is high because polarization of $O^=$ is high. As the film grows thicker, and $O^=$ ions diffuse into the film, the field strength (v/cm) across the crystal double layer drops, the dielectric constant decreases, and the capacitance drops. The model suggests that early in the oxidation the slowest step is activation; as film thickens, transport of ions across the film becomes equally slow.[2] Meanwhile the conversion reaction of CdO through soluble complex to $Cd(OH)_2$ or $CdCO_3$ proceeds at the oxide electrolyte interface, gradually building up an outer film, loosely adherent and porous. The activity of OH^- is high enough that the rate of conversion is never transport controlled by ions in solution.

This model accounts for the fact that the impedance bridge methods measure the smaller of the two capacitances in series, in this case the outer double layer. Interruption of the oxidizing current gives a decay of overpotential of which the chief component is the voltage across the inner double layer, whose charge leaks away exponentially with time because of the fixed dimensions.

[2] This point now seems to have been proven by Croft (17).

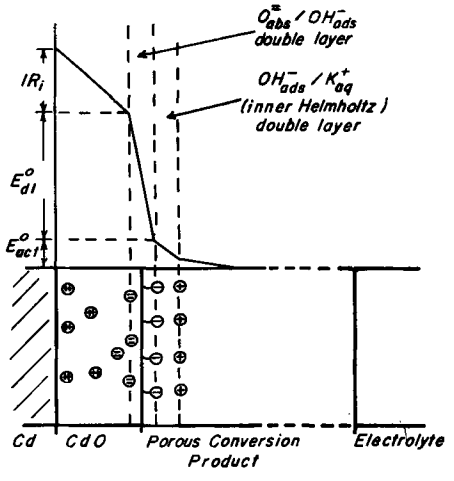

Fig. 5. Model of oxidizing electrode.

* Rates of change assumed, not measured.

Toward t_p the surface charge of OH^-, which is current dependent, drops off because the film of conversion product closes over near the CdO surface, slows down the escape of complex through the inner Helmholtz double layer, and thus introduces a barrier to OH^- adsorption. The charge separation across the inner double layer increases rapidly until the field strength becomes high enough to remove electrons from OH^- to produce OH and ultimately O_2.

The model suggests further that before passivation E_{DL} decays by $Cd^{++} + O^= \rightarrow CdO$, or by $H^+ + O^= \rightarrow OH^-$ at the $O^=$ site (i.e., without change of dimensions) at a rate which depends on the first power of the concentration of $O^=$; this leads directly to the log E vs. t behavior observed during decay. After passivation, the decay is essentially that of adsorbed OH and/or O, similar to oxygen overpotential decay on a noble metal surface, where complicating films are absent.

Results of Changing Experimental Conditions

Before passivation: Table III is a summary of trends observed from the results of determination of the components of overpotential as a function of current density, electrolyte concentration, temperature, and oxidation time. Detailed examination of this table will reveal that the qualitative facts contained are consistent with the model proposed. Although the details of the results need not be discussed here, it is useful to examine the changes with experimental conditions of the major components involved in the passivation, viz., E°_{DL}, IR_i, and $E^\circ_{act(O_2)}$. Thus Fig. 6a and 6b show how E°_{DL} and IR_i build up as oxidation proceeds toward t_p in KOH and K_2CO_3. Figure 7 shows how E°_{DL} varies with time with increasing concentration of KOH. The value of E°_{DL} remains low until t approaches t_p and then climbs rapidly. It is thus this component which is responsible for the increased potential which ultimately liberates oxygen. At high KOH concentrations the rate of the conversion reaction is higher, and the surface charge density of OH^- remains high longer; hence E°_{DL} has a lower value in the higher KOH concentrations for the same number of coulombs passed. The fact that dE°_{DL}/dI is zero is further support that E°_{DL} is not a common polarization.

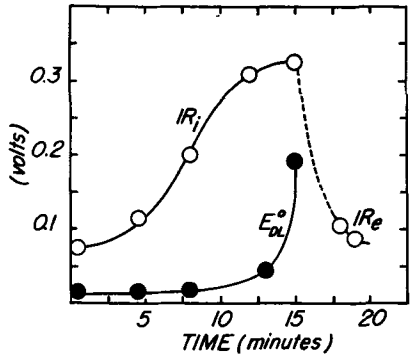

Fig. 6a. Variation of IR_i and $E°_{DL}$ with time, 7.2N KOH, 0°C, 3.83 ma/cm².

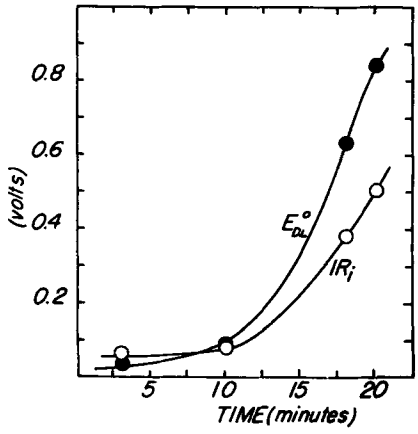

Fig. 6b. Variation of IR_i and $E°_{DL}$ with time, 7.2N K_2CO_3, 0°C, 3.83 ma/cm².

After Passivation: After the electrodes have passivated, it is possible to study properties of the oxide film in a steady-state condition and to compare films formed under different circumstances. A plot of $E°_{act(O_2)}$ vs. log I for an electrode passivated at 0.5 ma/cm² in 7.2*N*-KOH at 25°C was linear, with a slope $b = 0.15 \pm 0.01$ v. This value is close to the value of 0.12 expected (11) for a reaction in which discharge of hydroxyl ions to radicals is rate determining. In Fig. 8 are shown the results of measurements of $E°_{act(O_2)}$ all the points having been determined independently: i.e., on different electrodes, on films which were formed at different current densities, and in both KOH and mixed KOH-K_2CO_3 electrolytes. In terms of the different surface roughness factors of the underlying CdO films formed under such a wide range of conditions, the grouping around the line of slope 0.15 is remarkable.

The *b* values obtained indirectly from the slopes of the decay curves, however, were 2-3 times larger (Table IV) than the values obtained directly by current density variation; that is, the decay was 2-3 times more rapid than was expected. It is suggested that the reason for this is that, in contrast with current variation experiments in which the underlying film of CdO is in a steady-state condition, during voltage decay experiments (following current interruption) the conversion reaction proceeds unchecked at an appreciable rate [~0.3 ma/cm² initially, see Fig. 5 of Ref. (1)]. Thus the CdO layer is being etched away during the decay and carries with it the inner double layer. This chemical attack supplements the normal overpotential decay and increases the *b* value observed. Further, since the complexing reaction is in competition for OH^- with the oxygen discharge reaction, the greater the stability of the complex the greater its ability to decrease the surface activity of OH^- and hence to increase the potential drop across the inner double layer. The facts that the *b*'s from decays in carbonate generally are larger than in caustic and are larger at lower temperature support this view, and support the further

notion that $E°_{DL}$ rises rapidly at passivation for the simple reason that the rate of absorption of OH^- through the double layer is reduced by the presence of the complex; in other words, the CdO surface becomes poisoned by reaction product which competes for active sites with reactant OH^-. The effect of poisoning should be less the higher the activity of OH^-, and greater the higher the activity of carbonate ion. Figure 9 shows values of $E°_{act(O_2)}$ measured as function of concentration of OH^- and $CO_3^=$, and plotted as a Freundlich adsorption isotherm. The trends are as suggested and support the proposed mechanism. The large (500 mv/factor of ten change in concentration) negative value of $d\eta/d \log a_{OH^-}$ is very difficult to explain on the basis of activation theory, which predicts a value of zero (11).

Further, the fact that the b value of 0.15 is 25% higher than that predicted for a one-electron discharge reaction supports the suggestion of inhibition by reaction products. The higher the current density at which the passivated electrode is being anodized, the greater the surface concentration of still-sorbed complex. The role of adsorption indicated by the electrochemical behavior observed needs further examination.

Summary

The two equations $\eta°_A = IR_i + E°_{DL}$ and $\eta°_P = IR_e + E°_{act(O_2)}$ adequately describe the composition of overpotential when the electrode is active and passivated respectively. In the term $E°_{DL}$ are included the voltage across the normal Helmholtz double layer, as well as that across a second inner or crystal double layer at the outer edge of the film, a charge separation which can build up to high voltages and decay rapidly in the manner of a condenser.

The relative sizes of the components making up the total overpotential are controlled by experimental conditions. It is ultimately the "inner" double layer and the field strength across it which determine when $\eta°_A = \eta°_P$ and the electrode goes from the active to the passivated state.

A mechanism which accounts qualitatively for the experimental results is proposed and discussed.

SYMBOLS

1. η — total overpotential at any time, measured against $Cd/Cd(OH)_2$ reference.
2. $\eta°$ — total overpotential just at current interruption.
3. $\eta°_A$, $\eta°_P$ — total overpotential while current is flowing: electrode active (A), passivated (P).
4. E_∞ — voltage to which exponential part of overpotential has dropped after "infinite" time (~100 msec).
5. E_{act} — value of logarithmic part of overpotential when $t < t_p$ (metal being oxidized).
   $E°_{act}$ — value of E_{act} just at current interruption.
6. $E_{act(O_2)}$ — value of logarithmic part of overpotential when $t > t_p$ (oxygen being evolved).
   $E°_{act(O_2)}$ — oxygen activation overpotential value of $\eta°_P - IR_e$.
7. E_{DL} — $(\eta - E_\infty) - E_{act}$.
   $E°_{DL}$ — value of E_{DL} just at current interruption.
8. IR_i — ionic resistance drop $\eta°_A - E°_{DL}$.
9. IR_e — electronic resistance drop $\eta°_P - E°_{act(O_2)}$.
10. $E°_{CP}$ — concentration polarization.

The Oxidation of the Silver Electrode in Alkaline Solutions

Thedford P. Dirkse

Department of Chemistry, Calvin College, Grand Rapids, Michigan

ABSTRACT

The formation of Ag_2O and AgO was studied by means of constant current and constant potential processes. The efficiency of these oxide formations was determined by measuring the gain in weight of Ag electrodes under various conditions of charge, and the extent of the polarization of these processes was measured by using an interrupted current technique.

The electrolytic behavior of silver in alkaline solutions has been studied, but diverse opinions have been expressed as to the reactions taking place. Luther and Pokorny (1) plated silver on platinized platinum and observed its behavior in 1*N* NaOH solutions. They obtained the typical anodic (Fig. 1) and cathodic curves. They considered the first step of the anodic curve to correspond to the quantitative and reversible change of Ag to Ag_2O, and the second to correspond to the quantitative and reversible change of Ag_2O to AgO. Although they had evidence that a higher oxide, perhaps Ag_2O_3, was stable in alkaline solution, they could not produce it by oxidation of AgO in the NaOH solution. Instead, a third stage of the anodic curve corresponded to the evolution of oxygen.

Denison (2) worked with a system more nearly resembling a battery. His electrodes were made by pasting Ag_2O on a platinum gauze and reducing it to Ag. The electrolyte was a 25% KOH solution. He measured changes in weight of the electrode during anodic and cathodic processes. His results showed that by decreasing the current density a greater amount of weight was gained by the electrode, but he never quite obtained complete conversion to AgO. The anodic potential-time curves occasionally showed peaks but these were not interpreted. These curves also showed that the second stage was longer than the first. Furthermore, his final product always showed the presence of silver, indicating that the anodic process was not completely efficient.

Hickling and Taylor (3) studied an electrode made by plating silver on a platinum wire. The electrolyte was 1*N* NaOH and the results were recorded oscillographically. They found the second stage to be relatively short and interpreted it as due to the formation of Ag_2O_3 which then, being unstable, decomposed to form AgO.

More recently Jones, *et al.* (4) made a similar study of silver wire electrodes in 1*N* KOH solutions. They considered the second stage to be an inefficient one in which both oxidation of Ag_2O and evolution of oxygen occurred. Further, they gave evidence for the formation of Ag_2O_3 but only in small amounts and after completion of the second stage.

The work reported here is an attempt to resolve these differences with respect to the oxidation processes and to suggest a mechanism for them.

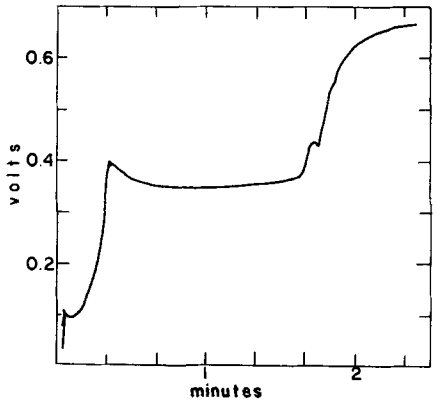

Fig. 1. Charging curve for silver in 15% KOH at room temperature, with a current density of 5 ma/cm^2.

Experimental

The electrodes were subjected to three kinds of treatment. In the first of these, the electrodes were charged at constant potential. The charging circuit is shown in Fig. 2. C is a 1.5-v source, F is a 100-ohm Helipot resistor from which a controlled voltage can be applied to the electrodes. In this way electrode B, the working electrode, can be kept at a definite potential above electrodes A. These latter electrodes were comparatively large electrodes made by pasting Ag_2O on silver screen. E has a resistance of 25,000 ohms so that the loss through this resistor is not large. D is a precision resistor of about 1 ohm which was used in recording the current passed through the system. Although this work was actually carried out at constant cell potential, yet, because of the low current density and relatively large amount

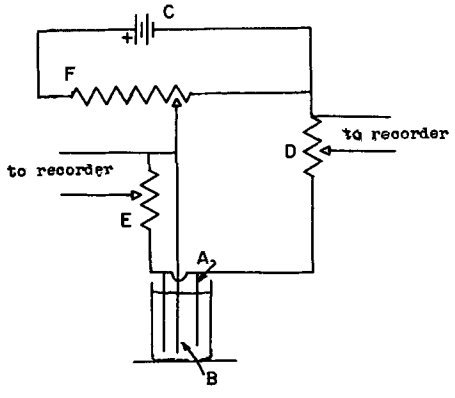

Fig. 2. Schematic diagram for constant-potential charging.

of material on electrodes A, the process in effect was a constant electrode potential one.

The electrodes were also subjected to a constant current oxidation. This circuit consisted of a high voltage source fed through a variable resistor and controlled by means of a Weston Model 534 d-c current relay. In carrying out these runs three currents were used: 1, 5, and 10 ma. The real current densities are unknown since the actual surface area of the silver electrodes was not measured. Four different electrolyte concentrations were used: 8, 21, 28, and 42% KOH.

The third type of treatment involved the use of interrupted current with silver wire electrodes. This technique and procedure have already been described (5).

For the first two methods of oxidation, the working electrodes were made by pasting a small amount of Ag_2O on a platinum screen. The area of the screen covered by the Ag_2O was about 2 cm^2 so that the total area exposed to the solution was about 4 cm^2. The Ag_2O was then reduced to Ag by heating at about 500°C for 15-30 sec. This electrode was placed between the two larger (2.5 cm^2) electrodes A. The 3 electrodes were placed in a polystyrene cell case which held about 35 ml of electrolyte. Unless otherwise indicated, all runs were made at room temperature.

After an electrode had been charged, it was soaked in distilled water for at least 8 hr, then it was dried in a stream of purified nitrogen at room temperature, and finally placed in a desiccator for at least 24 hr. All these operations were carried out in the absence of light. After this the electrode was weighed and the gain in weight was considered to be due to oxygen which had combined with the silver.

In the constant-current process the charging was continued until the voltage reached a certain predetermined value. In the constant-potential process the charging was continued until the current dropped to nearly zero or until 48 hr had elapsed, whichever occurred first.

All voltages are expressed with reference to the Ag-Ag_2O potential in alkaline solution.

Results

Ag *to* Ag_2O.—In the constant current processes the silver electrodes were oxidized until the voltage was 0.2 v. The electrode was then removed, dried, and weighed. Under all the conditions studied, the transformation of Ag to Ag_2O took place at a potential of about 50 to 100 mv. At the highest current densities very little of this transformation took place in the lower electrolyte concentrations. In no case was the Ag completely converted to Ag_2O, even though the current efficiencies (number of Faradays needed to produce the oxygen/number of Faradays actually used) were in the vicinity of 100%. The per cent conversion was usually less than 60%. The actual values will depend to some extent on such factors as the density of the silver.

In general, Ag_2O was produced on the surface of the working electrode. Its presence was verified by x-ray analysis and by emf measurements between the working electrode and the Ag-Ag_2O electrodes. It appears then that the Ag at the electrode-electrolyte interface is converted to Ag_2O, and when this has been completed the voltage increases abruptly and another process takes place—oxidation to AgO. The layer of Ag_2O produced on the Ag undoubtedly increases the electrical resistance of the electrode (5).

There is evidence that this electrical resistance of Ag_2O does limit the electrode process. An electrode similar to those used in this work was prepared using a grid of silver screen rather than of platinum. When this electrode was treated anodically in 20% KOH for some time at the lowest current density used in this work, the voltage rose to the higher level (about 0.35 v) after several days of treatment. Yet when this electrode was removed the surface appeared to be unattacked. It still had the appearance of reduced silver. However, on this material it was found that the active material next to the grid had been oxidized and that formation of Ag_2O seemed to proceed from the grid outward. This, of course, offered resistance to the flow of current from the grid to the surface of the active material and, although there was plenty of unoxidized Ag at the electrode-solution interface, the voltage rose to the level corresponding to the transformation of Ag_2O to AgO.

Another electrode was prepared by pasting a platinum screen with Ag_2O. When this was oxidized (without being reduced first) AgO was formed and, again, it was formed at the grid rather than at the electrode-solution interface. Thus the resistance of the Ag_2O seemed to make it easier for AgO to form at the grid where the amount of electrolyte was small rather than at the electrode surface where there was plenty of electrolyte.

In the constant potential processes Ag_2O was the

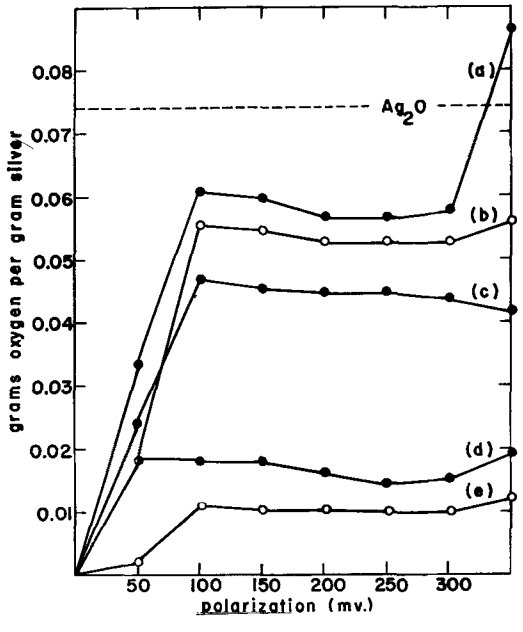

Fig. 3. Weight change for Ag electrode during constant-potential charge for 24 hr in KOH solutions at room temperature: (a) 23% KOH; (b) 20% KOH; (c) 42% KOH; (d) 8% KOH; (e) 23% KOH. Ag grid for (e), Pt grid for others.

product at potentials below 0.3 v. In general, the conversion of Ag to Ag_2O took place with a current efficiency of about 100%. The process appears to be a quantitative one but again, as with the constant current method, the Ag was not completely converted to Ag_2O. The maximum conversion, about 80%, took place in 28% KOH.

In carrying out this constant potential work it was found that on occasion an electrode lost rather than gained weight (6). To investigate this further, a series of experiments was carried out in which several electrodes were charged at constant potential for 24 hr, then dried and weighed. Each electrode was then charged further, without being reduced, at a potential 50 mv higher for 24 hr, and again weighed. This was repeated for several such increments of voltage increase. The results of the weight changes are shown on Fig. 3. It is noted that at potentials under 0.30 v the Ag was not completely converted to Ag_2O. Furthermore, at potentials above 0.10 v there appears to be a loss in weight. This, however, can be traced to a loss of Ag from the electrode. Such a loss was observed in each case and was of the proper magnitude to account for the decrease noted in oxygen content of the Ag_2O. As the electrode is held at a given potential some of the Ag_2O apparently is dissolved from the electrode. However, the results show also that once the initial film of Ag_2O is formed, raising the potential produces no further oxidation until the oxidation of Ag_2O to AgO takes place at potentials above 0.30 v. This is also noted on Fig. 4 where the current accepted by the electrode is practically zero at potentials above 0.10 v. In Fig. 4 each curve represents the current during the series of constant potential charges referred to above and on Fig. 3. The platinum grid is not responsible for this loss in weight. An electrode having a silver grid shows the same behavior, Fig. 3, curve e.

The results heretofore obtained show that the electrochemical oxidation of Ag to Ag_2O is an efficient one. It is the only one taking place under the conditions outlined above. However, the above results were obtained by using Ag pasted on a platinum screen grid. It is possible that the presence of the platinum may modify this process. To check on this, some commercial Ag electrodes were treated anodically under various conditions. These electrodes were about 4 cm square and contained on an average about 6.2 g of Ag. These were treated at 40 and 200 ma. Typical voltage-time curves were obtained. To change all the Ag in these electrodes to Ag_2O would require about 1.5 amp-hr. Using the current rates mentioned above, and KOH concentrations ranging from 8 to 40%, only 0.24 to 0.64 amp-hr were used to oxidize the Ag to Ag_2O. After this the voltage increased and the transformation to AgO took place. Here again the formation of Ag_2O was incomplete, only about 20 to 40% of the Ag being converted to the oxide. However, when this charging was continued at the higher voltage level, the conversion to AgO was above 80%.

Treatment of silver wire electrodes with interrupted current shows that the anodic overvoltage is relatively small while appreciable amounts of unoxidized Ag remain, but the *IR* drop increases as the surface coating of Ag_2O increases, Fig. 5. When a high current density at a temperature of −20°C was used, however, very little oxidation took place and the voltage rose rapidly. Under these conditions the low mobility of the OH^- ion was not sufficient to sustain the reaction.

Ag_2O *to* AgO.—After the oxidation of Ag to Ag_2O no longer takes place, the voltage rises to a higher level where AgO is formed. This is preceded by a peak shown on Fig. 1. The significance of this peak has been discussed earlier (5).

In the constant current processes the electrode containing Ag and Ag_2O was treated until the potential rose to about 0.5 v. The electrode was then removed, dried, and weighed to determine the oxygen gained while the potential ranged from 0.2 to 0.5 v. The amount of oxygen added to the electrode in this voltage range was practically always greater than that added in the range 0 to 0.2 v. The surface material in each case was AgO. This was determined by x-ray analysis. In no case, however, was Ag com-

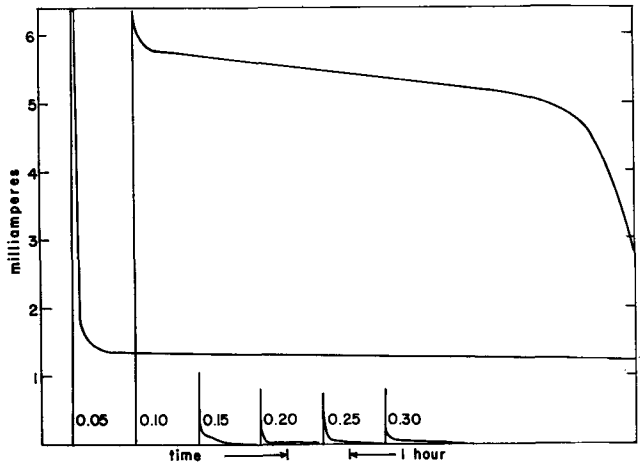

Fig. 4. Variation of current with change in extent of polorization for an Ag electrode in 23% KOH at room temperature. The numbers give the extent of polarization in volts.

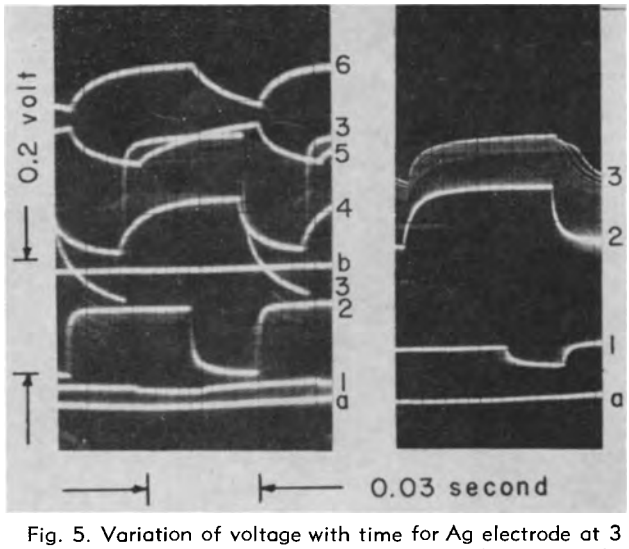

Fig. 5. Variation of voltage with time for Ag electrode at 3 ma/cm²; room temperature. Left picture, 10% KOH; right picture, 5% KOH. (a) Ag-Ag_2O potential; (b) Ag_2O-AgO potential. The numbers give the order in which these curves appeared during the charging process.

pletely changed to AgO. The current efficiencies varied with the current rate. They were about 100% when the process required about 8 hr. They were less at higher and at lower current densities.

With constant potential treatment, no AgO was formed at less than 0.3 to 0.35 v. When the overvoltage was high enough to bring about formation of AgO, the current efficiencies were close to 100% in all KOH concentrations studied. The current was high at the outset, then fell to a low value, then again increased, Fig. 6. The voltage also rose to a peak at the outset and then decreased, Fig. 7.

Furthermore, large amounts of oxygen could be introduced into the electrode by this constant potential process. When the electrode was kept at an overvoltage of 0.40 to 0.45 v for weeks or even months, increasing amounts of oxygen were added to the electrode. In one case, analysis showed a composition corresponding to $AgO_{1.6}$. This is approximately the composition of Ag_2O_3. Yet in preparing this material the electrode was kept at a potential less than that generally considered to be that of the AgO-Ag_2O_3 couple (1, 3). Moreover, the emf of this electrode was the same as that of AgO and the x-ray pattern, although less distinct, showed only lines of AgO, Fig. 8. This preparation was rather stable. A sample kept dry and in the dark showed practically no loss in weight over a period of several months.

The results obtained when a silver wire coated with Ag_2O was subjected to interrupted current showed a difference between this process and the formation of Ag_2O. The shape of the voltage curve was different, Fig. 5, the polarization was greater, and the voltage rise was slower than that for the Ag to Ag_2O transformation. The polarization for this process is 100-150 mv. This was determined over a KOH concentration range of 5-43% and with a variety of current densities. Measurements were also made at 0° and −20°C. At this lowest temperature the polarization was greater and the rate of voltage decay was much slower. This can be attributed to the increased viscosity of these solutions at this low temperature.

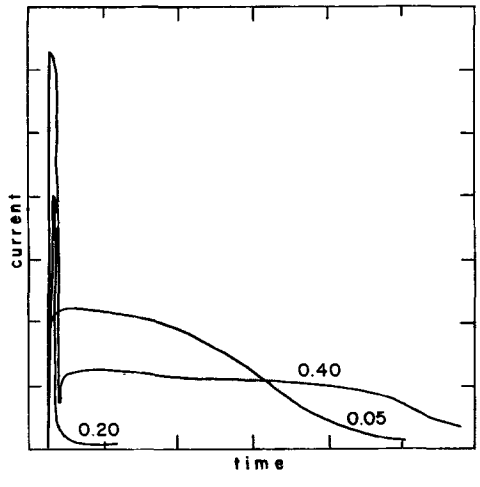

Fig. 6. Variation of current with time during constant-potential charge of an Ag electrode in 30% KOH at room temperature. The numbers give the polarization in volts above the Ag-Ag_2O potential. The scale is not the same for each curve.

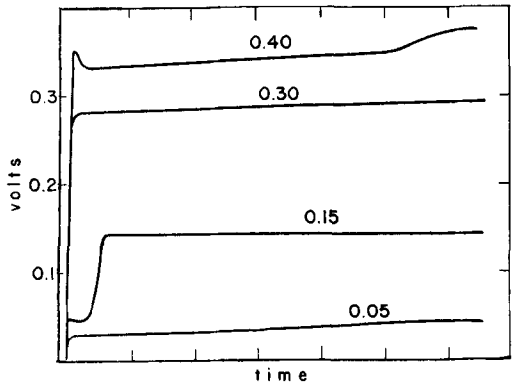

Fig. 7. Variation of potential of Ag electrode during constant-potential charge in 30% KOH at room temperature. The numbers give the polarization in volts above the Ag-Ag_2O potential.

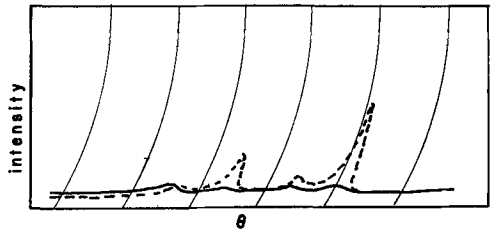

Fig. 8. X-ray patterns for AgO preparations; solid line, $AgO_{1.6}$; dotted line, AgO.

Using the method suggested by Brodd and Hackerman (7), the relative surface areas of Ag, Ag_2O, and AgO are 1 : 2.7 : 7.7. This was determined by measuring the double layer capacitance of a silver wire electrode and then also the capacitance of the same electrode after it was coated with Ag_2O, and finally when it was coated with AgO.

Oxygen evolution.—The third level of the charge curve is associated with the evolution of oxygen. Usually there is a gradual rise in voltage from the second to the third level. However, in experiments with silver wire electrodes it was noted that there were breaks in the part of the voltage curve between the second and third levels. These breaks occurred during a constant current charge and were noted whether the solution was agitated with nitrogen or oxygen, or was quiescent. Two breaks were noted in many instances, Fig. 1, but they did not appear on the discharge curve. These breaks were also observed when a sintered silver plate was charged in excess electrolyte.

When silver wire electrodes were treated with interrupted current, a break was often noted in the decay curve after oxygen evolution had begun, Fig. 5, right panel. This break was at a potential of about 0.4 v at room temperature and 0.33 v at 0°C. These breaks were observed for no more than a second or two, and occurred as the general voltage trend was upward. No such breaks were noted during the closed circuit part of the process.

Discussion

In seeking to account for the behavior of the silver electrode in alkaline solutions it is apparent that the OH^- ions are the solute species involved. They are involved in the oxygen evolution process (8, 9) and

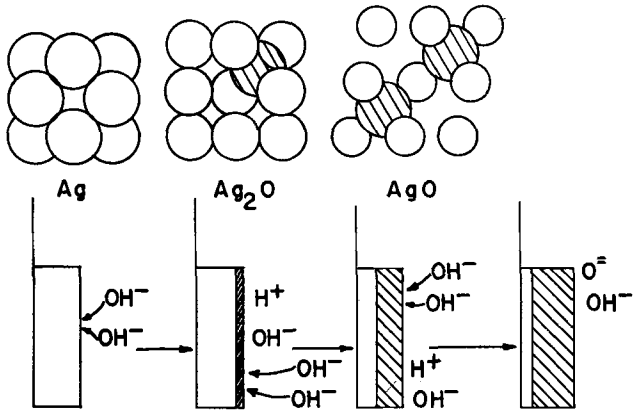

Fig. 9. Possible mechanism for silver oxide formation

are likely also involved in the other reactions. If water were the active species, then at constant current one would expect less formation of Ag_2O, e.g., at high KOH concentrations than at low concentrations. At the high KOH concentrations there would be comparatively fewer H_2O molecules and they would be less mobile because of the increased viscosity of the system. In actual fact, the per cent Ag converted to Ag_2O at constant current was greater in 42% KOH than in 8% KOH at all current densities used.

A possible mechanism for these oxidation processes is illustrated in Fig. 9. The lattice structures in the top panel are drawn to scale (10-12). The open circles represent Ag and the shaded circles oxygen. Since no data could be found for the ionic radius of Ag^{++}, an estimated value of 1.1Å was used. The other ionic radii used are those given by Pauling (13).

As a positive charge is placed on silver, the outermost valence electron is removed from each silver atom, producing Ag^+. This causes an expansion of the silver lattice and allows room for the inclusion of oxygen atoms or ions. The OH^- ions are drawn to this charged silver and the oxygen becomes separated from the hydrogen. The $O^=$ ions are then drawn into the Ag^+ lattice, forming Ag_2O.

	H°, kcal/mole	Reference
$H^+ (g) \rightarrow H^+ (aq)$	−255	(14)
$O^= (g) \rightarrow O^= (aq)$	−125	estimated
$OH^- (aq) \rightarrow OH^- (g)$	+92	(14)
$OH^- (g) \rightarrow O^= (g) + H^+ (g)$	+640	(15*a*)
$OH^- (aq) \rightarrow H^+ (aq) + O^= (aq)$	+352	

The lattice energy of Ag_2O is −715 kcal/mole (15*b*). According to the above data, this separation is energetically allowable.

The $O^=$ ions are rather immobile in this lattice and soon this reaction ceases because no more $O^=$ ions can be accommodated in the Ag^+ lattice. This is indicated also by the behavior of the silver electrode as shown on Fig. 3. This Ag_2O layer acts as a barrier to the flow of electrons and permits no ions to leave it except for a few Ag^+ ions which may go into solution. This accounts for the loss in weight shown on Fig. 3.

To continue the flow of current after the Ag_2O layer is formed, the potential on the electrode must be increased. This withdraws another electron from each Ag^+. There is then a greater repulsive force between the silver ions, and more $O^=$ ions must enter the lattice to preserve electroneutrality. As a result, the silver lattice is further distorted and expanded. Reaction then proceeds and the electrode gains in weight as AgO is formed. Because of the expanded lattice the $O^=$ ions can penetrate more deeply and thus the formation of AgO is greater than that of Ag_2O on the same electrode. This mechanism allows for the possibility that Ag can be transformed to AgO directly without the intermediate formation of Ag_2O. This appears to take place at constant potential charge with a polarization greater than 350 mv, Fig. 7.

The formation of AgO continues until the $O^=$ ions can no longer be absorbed by the electrode material at the rate demanded by the current flow. The potential then rises and another reaction takes place. The rise in potential here is slow compared to that between the formation of Ag_2O and that necessary for the formation of AgO. This rise corresponds to the occurrence of an additional reaction and not the replacement of one reaction by another. This additional reaction is the evolution of oxygen. The increase in potential is not sufficient to remove additional electrons from the Ag^{++} ions. The AgO formed is a fairly good electron conductor and the electrons needed for the flow of current may then arise from another reaction and be transferred through the AgO layer.

The potential rises here because, to continue the flow of current, $O^=$ ions can no longer migrate fast enough and more electrons cannot be removed from the Ag^{++} ions in the lattice. It is possible then that electrons are removed from the OH^- ions which are at the electrode surface,

$$OH^- \rightarrow OH + e \qquad [1]$$

and that these OH radicals then combine to form H_2O_2 which decomposes to give the oxygen.

$$2\ OH \rightarrow H_2O_2 \qquad [2]$$

$$H_2O_2 + OH^- \rightarrow H_2O + HO_2^- \qquad [3]$$

$$HO_2^- \rightarrow \tfrac{1}{2}\ O_2 + OH^- \qquad [4]$$

A serious objection to this mechanism is that the potential needed for reaction [1] is about 1.7 v on the scale used here (15*c*). This is considerably higher than that at which oxygen evolution occurs.

The evolution of oxygen does take place at potentials above that associated with the formation of HO_2^- (16). Furthermore, the breaks in that part of the voltage-time curves corresponding to oxygen evolution, Fig. 1 and 5, also occur at about the potential of the $OH^- - HO_2^-$ or $OH^- - O_2^-$ couples (15*e* and *c*). In general, at low current densities, the break is noted at the lower potential ($OH^- - O_2^-$), while as the current density increases the potential corresponds to the $OH^- - HO_2^-$ couple. Silver catalyzes the decomposition of peroxide and so the evolution of oxygen could easily proceed this way.

These facts suggest two possibilities for the oxy-

gen evolution reaction. Reactions [5]-[7] illustrate a mechanism

$$OH^- \rightarrow O^= + H^+$$

or

$$OH^- \rightarrow O^- + H^+ + e \quad [5]$$

$$2\,O^- \rightarrow O_2^- + e \quad [6]$$

$$O_2^- \rightarrow O_2 + e \quad [7]$$

involving the $OH^- - O_2^-$ couple. It is possible that the $O^=$ or O^- ions may emigrate from the AgO lattice as well as be formed from the OH^- ions in solution.

The other possibility is illustrated by a series of reactions consisting of [5], [8], [4]. Here again the oxygen ions from the solid may be involved.

$$O^- + OH^- \rightarrow HO_2^- + e \quad [8]$$

It is difficult to make a choice between these mechanisms. Both are permissible according to the ideas of Rüetschi and Delahay (8). Perhaps the latter is more consistent with the results and suggestions of Anbar and Taube (9). Measurement of the oxygen overvoltage could conceivably shed some light on this mechanism, but these measurements are, at best, difficult to make.

The ideas suggested here stress the fact that the mobility of the OH^- ion is an important factor in these oxidation processes. When this mobility is impaired, e.g., at low temperatures or at high KOH concentrations, the extent of oxide formation is also less because the OH^- ions cannot migrate fast enough to allow reaction to take place at the rate set by the current.

It has been noted that the polarization necessary to carry out the oxide formation is not very sensitive to current density. This indicates that the cause of the polarization is not primarily resistance. On the basis of the mechanism suggested here, this polarization would be due to the splitting of the OH^- ion. This would appear in the formation of each of the two oxides. In addition to this the formation of AgO would be polarized by the migration of $O^=$ ions in the Ag^{++} lattice.

Effect of Sodium Pyrophosphate on Polarization and Corrosion of Tin

I. A. Ammar[1] and S. Riad

Department of Chemistry, Faculty of Science, Cairo University, Cairo, Egypt, U.A.R.

ABSTRACT

Corrosion rates and corrosion potentials have been measured for tin in eight different acid, alkaline, and neutral solutions. The corrosion potential, measured against the saturated calomel electrode, has been found to increase toward more active potentials with increase of concentration. It has been observed that sodium pyrophosphate decreases the corrosion rate and increases the corrosion potential toward more active values. This increase is proportional to the amount of pyrophosphate added. Cathodic and anodic polarization measurements have been carried out in an attempt to explain the function of sodium pyrophosphate as a corrosion inhibitor. The results have been compared with previous work on the inhibition of iron corrosion by polyphosphates.

Measurements of the rate of corrosion of tin and the related corrosion characteristics are important since tin is used as a protective coating for iron and copper (1). Inhibition of the corrosion of tin in hydrochloric and acetic acid solutions, by incorporating about 5% antimony in tin, was studied by Hoar (2). The corrosion of tinplate and its inhibition by chromate-containing solutions was studied by Kerr (3, 4). Electrodeposited coatings of Sn-Zn (5) and Sn-Ni (6) alloys were found to resist the corrosion of steel. Corrosion of tin in solutions containing chloride ions was studied by Britton and Michael (7) who observed that addition of sodium carbonate, bicarbonate, orthophosphate, chromate, and silicate prevented the corrosion of tin.

The present investigation was undertaken to study the possibility of using sodium pyrophosphate as an inhibitor for the corrosion of tin and to investigate the effect of this substance on the cathodic and anodic polarization measurements. Polyphosphates were found to have an inhibiting effect on the corrosion of iron (8). Pyrophosphate was chosen for the present investigation because it is more stable than metaphosphate (9). The mechanism of inhibition of iron corrosion by polyphosphates sometimes (10) was attributed to the laying down of a calcium carbonate film favored by the presence of polyphosphate. The present investigation, therefore, was extended to study the effect of calcium chloride on the rate of corrosion of tin.

Experimental

The electrolytic cell used for polarization measurements was similar to that used in overpotential work (11). It had two separate compartments for anode and cathode. One of these two compartments was provided with a capillary leading to a salt bridge via a glass tap. The barrel of a syringe, 10 cm long and 1 cm in diameter, was joined to the top of this compartment and was used to lower the test electrode so as to touch the tip of the capillary without introducing air inside the cell. A saturated calomel was used as a reference electrode. The cell was guarded against atmospheric oxygen with the use of ground glass joints and water-sealed taps. A subsidiary platinum electrode, in the form of a disk 1 cm^2 in area, was used in connection with the tin electrode. The cell also was used for the measurements of corrosion potentials. For measurements in air-free solutions, purified nitrogen was introduced into the cell and was divided between the two compartments by means of two taps. Nitrogen was purified by passing it through NaOH and pyrogallol solutions and then over copper heated to 450° to remove traces of oxygen left. Bubbling of nitrogen was stopped during potential measurements.

Tin electrodes were prepared from pure tin foil (over 99.99% Sn) in hydrogen atmosphere. This was carried out in a glass apparatus having a side arm (3 mm ID) containing a piece of platinum wire the middle of which was sealed to glass. After introducing the tin foil, the apparatus was closed by a ground glass joint and was deaerated by passing hydrogen for several hours. The metal then was melted and the melt was introduced into the side arm. The metal was allowed to cool under hydrogen, and the side arm was cut off the main apparatus. Part of the tin electrode was exposed by cutting the appropriate length of glass. The electrode then was sealed to the piston of the syringe, the barrel of which was joined to one of the compartments of the cell.

For corrosion tests, tin rods were prepared as described above and then were rolled into sheets 1 mm in thickness. Specimens (2 x 1.5 cm) were cut. They were abraded to 00 emery paper, degreased in hot benzene, and then were dried and weighed. Corrosion tests were carried out in a wide 100 ml jar provided with a loosely fitting wooden cover from which the electrode was suspended by a thread. In this manner oxygen concentration cells from top to bottom were minimized. All corrosion tests were carried out in aerated unstirred solutions for a period of three days. The specimen then was removed,

[1] Present address: Institut fur anorganische Chemie, Berlin, Germany.

rinsed with conductivity water, swabbed with a towel wetted with benzene, and finally was dried and weighed.

Measurements were carried out in solutions of hydrochloric, acetic, citric, and maleic acids, sodium hydroxide, sodium carbonate, sodium benzoate and sodium chloride. These were chosen to represent some of the solutions which contact tin in its various industrial applications. Solutions were prepared from "Analar" grade reagents and conductivity water. The sodium pyrophosphate[2] used contained 0.1% orthophosphate and 0.025% impurities such as Fe, K, and Pb. Solutions of pyrophosphate were prepared directly before the tests in order to minimize any possible reversion to the orthophosphate. All measurements were carried out at 30° in an air thermostat controlled to ±0.5°. Results were duplicated and the mean was computed. The spread in the corrosion rate was less than 1 mdd. All potentials were recorded vs. the saturated calomel electrode potential. The current density was expressed in amp/cm².

Results

Corrosion rates, in air-saturated solutions, are given in Table I for five concentrations ranging from 0.05 to 1.0M. The effect of sodium pyrophosphate on the corrosion rate was studied in 0.1M solutions for various concentrations of pyrophosphate. Results are given in Table II. Data for the corrosion rate in the presence of 0.01M $CaCl_2$, and in the presence of a mixture of 0.01M $CaCl_2$ and 0.01M $Na_4P_2O_7$ are given in Table III for six different solutions. The effect of $Na_4P_2O_7$ on the *p*H in 0.1M solutions is given in Table IV. The *p*H values in pure 0.1M solutions are included in Table IV for comparison. The *p*H values in presence of $CaCl_2$ are given in Table V. Measurements of the *p*H were carried out under the conditions of corrosion rate measurements.

The dependence of the potential of corroding tin on time was studied in deaerated and air-saturated solutions. Corrosion potentials were measured over a wider concentration range than corrosion rates. Except in Na_2CO_3 solutions, the steady-state corrosion potential E_c is reached within 5 min from the moment the electrode contacts the solution. In all solutions studied, E_c is active with respect to the saturated calomel potential. In deaerated solutions, E_c is more active than the corresponding value in air-saturated solutions. The effect of concentration on the corrosion potential was studied by measuring time-potential relations for five different concentrations in deaerated and air-saturated solutions. Except in NaCl solutions, E_c increases toward more active potentials with increase of concentration. The relation between E_c and log C, where C is the molarity, is linear for both deaerated and air-saturated solutions. Results are shown in Fig. 1 and 2 for aerated and deaerated solutions, respectively. In NaCl solutions (not shown in Fig. 2), E_c remains practically constant (560-570 mv more active than the saturated calomel potential) with increase of concentration from 0.05 to 1.0M. The effect of sodium pyrophosphate on the corrosion potential was

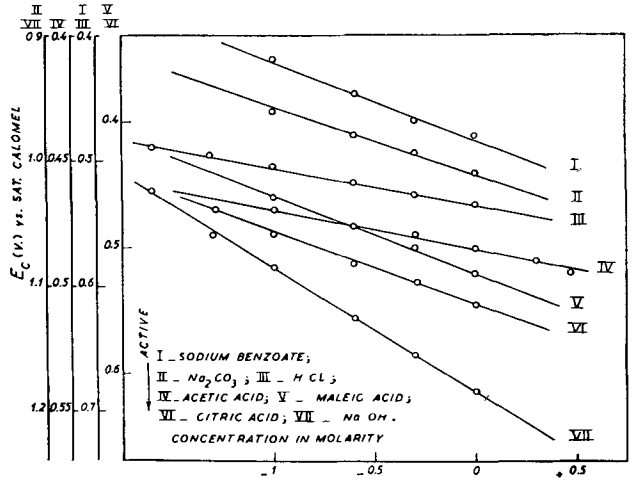

Fig. 2. Effect of concentration on corrosion potentials in deaerated solutions.

studied in 0.1M solutions. In presence of as little as 0.01M $Na_4P_2O_7$, E_c increases toward more active potentials in both deaerated and air-saturated solutions. Furthermore, this effect is proportional to the pyrophosphate concentration as is clear from the results, in deaerated 0.1*N* HCl, shown in Fig. 3.

Cathodic polarization measurements were carried out in deaerated 0.1M solutions of NaOH, HCl, acetic, and maleic acids. Measurements were started from low to high current densities. At each setting of current, the electrode was left polarized until the steady-state potential was reached. This usually took less than 5 min. Results in maleic acid and NaOH are shown in Fig. 4 and 5, respectively. Cathodic polarization curves for HCl and acetic acid are similar to those of maleic acid. It is clear from Fig. 4 and 5 that $Na_4P_2O_7$ increases the cathodic polarization toward more active values. This increase is proportional to the concentration of pyrophosphate added. The relation between cathodic polarization and the logarithm of the concentration of $Na_4P_2O_7$ is similar to Fig. 3. $CaCl_2$, however, does not change the cathodic polarization appreciably (Fig. 4). Similar conclusions are drawn for HCl and acetic acid. Previous work on iron (12) similarly has indicated that polyphosphates increase the cathodic polarization toward more active potentials.

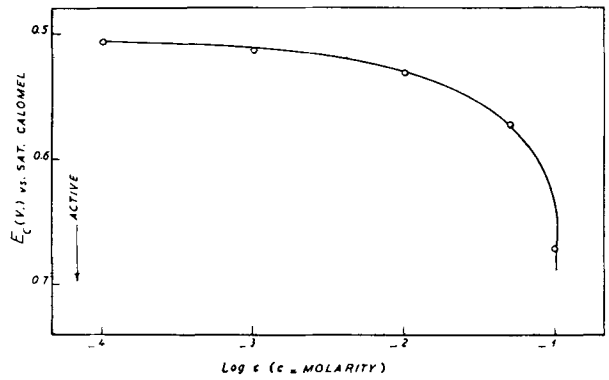

Fig. 3. Effect of pyrophosphate concentration on corrosion potential in deaerated 0.1N HCl.

Anodic polarization measurements were carried out in aerated 0.1M solutions of maleic acid and NaOH. In order to minimize the time effect, the electrode was left unpolarized until the corrosion potential was attained. Polarization then was commenced at a low current density, and the electrode was left polarized for nearly 1 hr until the steady-state potential was reached. With this slow technique, the potential changed from the active to the noble direction. Following this, measurements at higher current densities were taken. Results, at high current densities, are shown in Fig. 4 and 5, from which it is clear that $Na_4P_2O_7$ decreases the anodic polarization (potential becomes less noble) in 0.1N NaOH, and it has no effect on the anodic polarization in 0.1M maleic acid solution.

Discussion

It is clear from the data given in Table I that, in aerated solutions, the rate of corrosion of tin increases with increase of concentration. However, this increase is not marked in NaCl solutions as compared to the results in other solutions studied. The maximum rate of attack is observed in maleic acid solutions. Table II indicates that the corrosion rate, in acid and alkaline solutions, decreases with the increase of pyrophosphate concentration. In NaCl solution, the corrosion rate is decreased only

by 1 mdd at high pyrophosphate concentrations, whereas in sodium benzoate solution it is independent of pyrophosphate concentration. Hence, pyrophosphate is an effective inhibitor for the corrosion of tin in the acid and alkaline solutions studied. Previous work (8), on the inhibition of the corrosion of mild steel, has shown that polyphosphates are effective corrosion inhibitors in presence of dissolved oxygen. Moreover, it has been observed that addition of $CaCl_2$ accelerates the corrosion of mild steel in presence of dissolved oxygen (8). In the case of tin, $CaCl_2$ decreases the corrosion rate as it is clear from results given in Tables I and III. Addition of pyrophosphates to the solution containing $CaCl_2$ produces a further decrease in the corrosion rate in HCl, citric, and maleic acids (Table III).

The shift of cathodic polarization toward more active values (Fig. 4 and 5), produced by the addition of pyrophosphate, may be ascribed to the adsorption of pyrophosphate on tin cathodes thus lowering the available surface area for the cathodic reaction. Adsorption of pyrophosphate on local cathodic areas also may account for the change of corrosion potentials [given by the point of intersection of the anodic and cathodic polarization curves (13)] toward more active values, observed in solutions containing pyrophosphate. Thus, if the polarization of local cathodes is increased in presence of pyrophosphate (Fig. 4 and 5), while the polarization of local anodes is decreased (Fig. 5) or not affected (Fig. 4), the corrosion potential is shifted toward more active values. In the first case, the corrosion rate may not be affected as it is evident from the results in 0.1*N* NaOH (cf. Tables I and II). On the other hand, when cathodic polarization is increased in presence of pyrophosphate and anodic polarization is not affected, the corrosion rate decreases as is clear from the results in maleic acid solutions, given in Tables I and II.

The present investigation indicates that the rate of corrosion of tin in acid and alkaline solutions is greater than that observed in NaCl and sodium benzoate solutions (Table I). This may be explained on the basis of the amphoteric character of tin according to which tin is expected to dissolve in the acid and alkaline pH range more than in the neutral pH range (cf. Table IV). It is clear from Table IV that addition of pyrophosphate to acid solutions increases the pH to the neutral range, and, hence, it is expected that tin does not go into solution as readily in this pH range as it does in the extreme acid range. In alkaline solutions pyrophosphate has no appreciable effect on pH (Table IV). However, the possibility exists that, in such solutions, pyrophosphate may have a complexing action on tin with the result that the anodic polarization is decreased in presence of pyrophosphate as compared to the values in absence of pyrophosphate (Fig. 5). This effect is, however, compensated by the increase of cathodic polarization in presence of pyrophosphate. In salt solutions, pyrophosphate increases the pH (Table IV) and has no appreciable effect on the corrosion rate (Table II). This increase in pH would require more dissolution of tin, i.e., decrease of the anodic polarization. However, for the corrosion rate to remain constant, this effect also must be compensated by the increase of cathodic polarization.

It is clear from the results of the present investigation that $CaCl_2$ is not necessary for pyrophosphate to function as a corrosion inhibitor, in contradiction to the suggestion of Raistrick (10) that inhibition by polyphosphates is due to the laying down of a calcium carbonate film favored in presence of polyphosphates. However, $CaCl_2$ has no appreciable effect on pH (Table V) and it decreases the corrosion rate (Table III). This is not easy to explain since $CaCl_2$ has no effect on the cathodic polarization measurements (Fig. 4) while its effect on anodic polarization is irreproducible.

Thin Film Formation on Zirconium

Robert E. Meyer

Chemistry Division, Oak Ridge National Laboratory,

operated by Union Carbide Corporation for the U. S. Atomic Energy Commission, Oak Ridge, Tennessee

ABSTRACT

Using an electrochemical method, rates of film growth in oxygenated sodium sulfate solutions have been measured on polycrystalline zirconium at temperatures ranging from 25° to 88°C. The resulting rate-time plots are roughly hyperbolic. A model is proposed which when treated by electrode kinetics is shown to give this type of behavior.

Recently, correlations have been observed between the polarization resistance of a corroding electrode and its corrosion rate (1-3). The polarization resistance of an electrode is defined as the derivative $dE/dI_{E\to E_r}$ where I is the net current flowing through the electrode at a measured potential E, and E_r is the rest potential. Theoretical justification for this correlation has been provided by Stern and Geary (4) who derive the following equation from the Tafel equation for the case where the rest potential of a corroding electrode is determined by the intersection of two logarithmic polarization curves

$$\frac{dE}{dI_{E\to E_r}} = \frac{b_a b_c}{(2.3)(I_{corr})(b_a + b_c)} \qquad [1]$$

Here, I_{corr} is the corrosion rate of the electrode, and b_a and b_c are the Tafel slopes ($dE/d \log I$) for the anodic and cathodic reactions. This equation has been derived from more fundamental quantities by Posey (5), who has presented a complete discussion of the kinetics of polyelectrodes under activation control. If the conditions for the use of Eq. [1] can be met, it provides an excellent method for measuring rates and should be applicable especially to systems whose rates may be too small for weight-loss or analytical methods. Because rates can be measured quickly while the sample remains in the solution without significantly disturbing the system, this method is applicable particularly to the determination of rate-time plots.

In order to use this method, it must be shown that the open-circuit potential is determined by the intersection of two logarithmic polarization curves, one anodic and one cathodic. Furthermore, there must be no oxidation process other than the corrosion process under consideration, i.e., one must make sure that no portion of the anodic current is the oxidation of hydrogen, water, ferrous ion, or other oxidizable species.[1] It should be evident also that the presence of a film does not necessarily preclude the method, for logarithmic potential-current behavior is possible also on film-covered electrodes.

[1] It is, of course, possible in many cases to take a second oxidation reaction into account and determine the corrosion rate from electrochemical measurements alone, but this involves the analysis of far more complex polarization behavior [see Stern (6) and Posey (5)].

In the experiments reported here, this method was applied to the measurement of film growth on zirconium immersed in oxygen-saturated 0.1 F Na_2SO_4 of *p*H 3.5. The reaction believed to occur is the oxidation of zirconium to zirconium oxide (7), ZrO_2. The cathodic or reduction process is therefore the reduction of oxygen and the anodic or oxidation process is the oxidation of zirconium. Because of the great insolubility of ZrO_2, all oxidized zirconium is assumed to be incorporated into the film. Other possible cathodic processes are the reduction of hydrogen ions or water and the reduction of the film. The latter process is thermodynamically improbable at these potentials, and measurements of hydrogen evolution (to be reported in a later publication) showed that the rates are negligible under the conditions encountered in these experiments.

The possible interfering anodic processes are the oxidation of impurities and the oxidation of water. Careful purification of the solution and cell can eliminate the former and also at the same time eliminate impurities that may interfere with the kinetics of the cathodic process. Significant water oxidation on these systems is not observed until one obtains potentials at least 1.5 v above the highest potentials encountered in this work. Therefore, it is probable that the rate of water oxidation is negligible at potentials near SCE.

Typical polarization behavior of this system is shown in Fig. 1. Here it is demonstrated that the reduction of oxygen follows an equation of the form

$$I_c = I_{o,c} \exp \frac{-\alpha_c z_c E\,\mathrm{F}}{RT} \qquad [2]$$

where α_c is the transfer coefficient of the cathodic process, z_c is the charge number, and $I_{o,c}$ is a constant whose numerical value depends on the reference potential to which values of E are referred. This equation is the Tafel equation written in the exponential form with $b_c = RT/\alpha_c z_c \mathrm{F}$.

An analogous equation is assumed for the anodic current, I_a, at constant film thickness, as follows

$$I_a = I_{o,a} \exp \frac{+\alpha_a z_a E\,\mathrm{F}}{RT} \qquad [3]$$

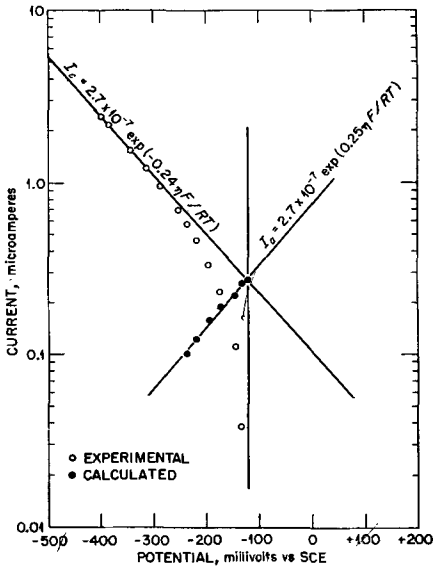

Fig. 1. Experimental current-potential plot in oxygenated Na_2SO_4 solution at 88°C.

where α_a and z_a are the transfer coefficient and charge number, respectively, of the anodic reaction. This assumption is made reasonable by the theoretical considerations described below which led to the derivation of Eq. [6]. An equation of the form of Eq. [3] has been reported valid for the anodizing of zirconium at constant film thickness by Adams and Van Rysselberghe (8).

Equation [1] can be solved for I_{corr} and rewritten in terms of the variables in Eq. [2] and [3] as follows

$$I_{corr} = \frac{dI}{dE_{E\to E_r}} \times \frac{RT}{F} \times \frac{1}{(\alpha_a z_a + \alpha_c z_c)} \quad [4]$$

The quantities $\alpha_c z_c$ and $\alpha_a z_a$ can be determined from Tafel slopes, but generally it is better to determine $\alpha_a z_a$ indirectly. Excessive anodic polarization can affect the surface materially by forming significant quantities of film, and therefore it is best to avoid large anodic polarizations entirely. An indirect method[2] of determining $\alpha_a z_a$ which does not involve excessive polarization is illustrated in Fig. 1. Here the anodic polarization points are determined by the difference between the net current and the extrapolated cathodic current. The Tafel slope, and hence $\alpha_a z_a$, is determined then from the slope of the line through these points. At the end of an experiment, when there is no need for further measurements, it is possible to check the value of $\alpha_a z_a$ by direct anodic polarization. Of course, the voltage rises with time when zirconium is anodized at constant density, but if the current density is small enough, the voltage rise during the measurement will be negligible. At the end of an experiment, these small current densities are sufficient to obtain a Tafel slope, from which $\alpha_a z_a$ may be estimated.

The quantity $dI/dE_{E\to E_r}$ can be determined by plotting I vs. E on a linear scale and by determining the slope at $E = E_r$. Since the I vs. E plot is linear over a short potential range about the rest potential, the slope can be determined very easily from several polarizations at small overvoltages.

In general, $\alpha_a z_a$ and $\alpha_c z_c$ do not vary rapidly in an experiment and therefore need be determined only occasionally. Rate-time curves can be determined therefore by a series of small polarizations, which determine $dI/dE_{E\to E_r}$, along with a few complete cathodic polarization curves.

Normally it is desirable to obtain a longer linear Tafel region than shown in Fig. 1, but concentration polarization is likely to interfere if the current density is further increased. The linear Tafel slope was verified by a great many plots similar to Fig. 1, many of which had considerably longer linear regions.

It should be noted here that this method of measuring rates is independent of mechanism since it only requires that equations of the form of Eq. [2] be obeyed formally over the potential and current ranges used.

Experimental

The measurements were carried out in 100 cc Pyrex cells which contained the zirconium electrode, an inlet and exit for oxygen, a platinum polarizing electrode, and a Haber-Luggin capillary leading through an all-glass closed stopcock to a separate chamber which contained a saturated calomel electrode. Oxygen was introduced through the inlet vigorously in order to provide sufficient stirring and to insure saturation. No greases or waxes of any kind were used in the cell, the only nonglass material used being Teflon. The zirconium electrodes, which were machined from fine-grained ¼ in. crystal bar rod and had an area of 2.2 cm^2, were cylinders ⅜ in. long and ¼ in. in diameter. They were mounted on ¼ in. Teflon rod holders which effectively masked off one end of the cylinder, electrical contact being maintained by a stainless steel rod threaded into the center of the masked-off end of the cylinder. The steel rod was masked completely from the solution by passing it through a hole drilled down the axis of the ¼ in. Teflon rod.

Before immersion in the cell, the electrodes were cleaned and immersed in a H_2O-HNO_3-HF chemical polishing bath long enough to remove several mils of metal. They then were rinsed with triply distilled water several times and finally immersed for 2 min in boiling triply distilled H_2O. This procedure was carried out by rapidly transferring the electrode from beaker to beaker so that the liquid never was allowed to dry on the surface. If the polishing solution were allowed to dry on the surface, a white insoluble residue would be left which defied all attempts at removal except by a repeated immersion in the polishing solution. The electrodes then were placed in a dynamic greaseless vacuum system and annealed for several hours at 750°C. The hottest portion of the furnace contained a supply of zirconium chips which acted as a getter. The electrodes so treated undoubtedly had a residual thin film on the surface even before the 1-min exposure to air during the process of mounting the electrodes on the Teflon holder. The initial rates observed were still

[2] This and another method for determining the anodic Tafel slope knowing the complete cathodic polarization curve have been described by Stern and Roth (9).

faster than could be measured by the methods used, so that there seemed to be no point to taking elaborate precautions to minimize the initial film.

The solutions used were made up from triply distilled water, doubly recrystallized sodium sulfate, and a small amount of C.P. H_2SO_4. One of the water distillations was made from alkaline permanganate solution. The solutions were pre-electrolyzed between platinum electrodes a minimum of 24 hr at about 10 ma before use. At this current the potential of the cathode was well below the lowest potential observed on the zirconium electrode.

The cells were cleaned with ordinary dichromate cleaning solution and with a hot mixture of equal parts of water, concentrated HNO_3, and concentrated H_2SO_4. The latter solution very efficiently removed the last traces of greases and other contaminants from the surface of the cell. The cells then were rinsed thoroughly with triply distilled water, one of the rinses including a 24-hr soaking with hot stirred water.

Potentials were measured with a L&N Model 7664 pH and emf meter which was modified slightly so that its output could be fed into a 10-mv Brown recorder. This whole unit was calibrated periodically with a potentiometer, and the absolute accuracy was about ±1 mv on a 1000 mv range or ±0.5 mv on a 100 mv full-scale range. The high input impedance of the pH meter, about 10^{11} ohms, effectively prevented any polarization of the electrode by the measuring circuit and also made the meter suitable for measuring small currents by measuring the potential drop over high-value resistors.

The small currents used were supplied by a bank of radio "C" batteries connected in series so that up to 230 v could be obtained. In order to maintain constant current a large resistance was placed in series in the polarizing circuit. The resistors were connected to a battery of decade switches so that any resistance from 0 to 10^9 ohms could be obtained quickly. This variable resistance plus a second switch which selected several voltages provided a convenient way of obtaining any necessary current.

A typical experiment was carried out as follows: the cell was cleaned, and the solution and electrode prepared as described above. At the completion of the cooling period after the vacuum anneal the electrodes were mounted quickly on the electrode holder and immersed in the prepared solution with the potential-measuring device on. The potential was recorded continuously during the experiment, and both small and complete polarization curves were taken at appropriate intervals. Care was taken to insure that the polarization did not alter the course of the experiment significantly. In most cases a duplicate experiment was made without any polarization in order to see whether the potential-time behavior duplicated and to compare rates at the end of the duplicate experiment to rates of those experiments which had the normal amount of polarization.

Calculations and Results

Because each of the experiments necessarily involves a large amount of data, results are presented as plots of rates vs. time and the values of the polarization resistance and α will not be given. In order to draw a smooth curve between the experimentally determined points, a semi-empirical method of determining the rates from the potential was used. As was pointed out above, the cathodic current is given by Eq. [2]. Experimentally it was found that the constants $I_{o,c}$ and $\alpha_c z_c$ changed very little in a given experiment (if $I_{o,c}$ is defined always at the same reference potential). Therefore a plot of the corrosion potential vs. the logarithm of the corrosion rate, which is necessarily equal to the cathodic current at the corrosion potential, should be either a straight line of slope $RT/\alpha_c z_c F$ (for the case of constant $I_{o,c}$ and $\alpha_c z_c$) or a gently curving line (for the case of slightly varying $\alpha_c z_c$ and $I_{o,c}$). Such a plot is shown in Fig. 2 for an experiment at 88°C, the open circles on the plot representing points determined from Eq. [4]. Because the potential-time behavior is known from the continuous potential recording, the rate-time curve can be found by combining the rate-potential and potential-time plots. In Fig. 3, the potential-time behavior of this experiment (No. 4) is given along with the potential-time behavior of a number of other experiments at about the same temperature. In Fig. 4 and 5 the rate-time curves are shown for two experiments each at 25°, 46°, 66°, and 88°. Rates are given as total current; current density may be obtained by dividing the numbers in the graph by 2.2 cm^2, the area of the electrodes. The notable features of the rate-time curves are the very sharp initial decline and the gradual leveling off. The shapes of the curves are approximately hyperbolic in time and rate. The open circles on the one 88° experiment in Fig. 5 show points de-

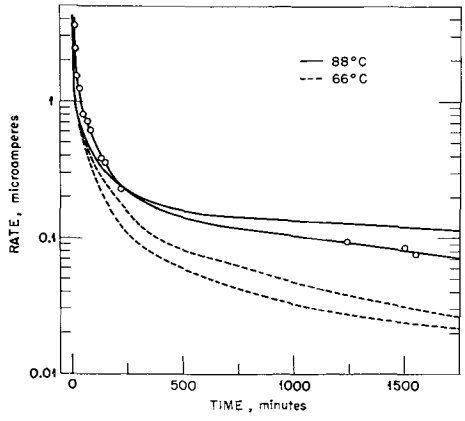

Fig. 5. Corrosion rate vs. time for zirconium in oxygenated Na_2SO_4 solution at 66° and 88°C.

termined directly by Eq. [4]; the rest of the curve was determined by the method described above.

It will be noted from Fig. 3 that the potential time curves do not exactly duplicate, although the general shape is the same. Because the rate changes by one power of ten for about every 300 mv change in potential, it is clear that a difference of 100 mv at a given time is not a serious irreproducibility. It is clearly impossible to duplicate precisely the surface of the electrode or the initial film thickness. The fact that the curves are as smooth as they are is of some significance, since such smooth curves could be obtained only if adequate solution purification and careful electrode preparation were carried out; otherwise jagged potential-time plots were observed.

As mentioned above, the constants $I_{o,c}$ and $\alpha_c z_c$ for the reduction of oxygen stayed fairly constant in a given experiment, i.e., the current-potential plots were almost superimposable. On the other hand, $\alpha_a z_a$ decreased with time, especially at 88°. In a typical experiment at 88°, the first determination of $\alpha_a z_a$ might yield a value as high as 0.3 or 0.35 while after several days $\alpha_a z_a$ might be as low as 0.1.

Discussion

Before attempting to describe the results in any mathematical form, some of the complexities of this system should be discussed. First, one has to be careful about applying the concept of a "single rate-determining step" since there are always two half-reactions present, anodic and cathodic, in any oxidation, and only if one were practically at equilibrium would it be justifiable to say that the other is a single rate-determining reaction. In the system considered here, neither the anodic nor the cathodic reaction is at equilibrium; hence, they both control the rate of the reaction. Furthermore, it is conceivable that in either the anodic or cathodic process there are two or more reaction barriers such that the concepts of consecutive reactions must be considered to analyze the system. Consecutive reactions are especially likely to occur in three-phase systems of the type considered here, when one must consider charged-particle transfer through the metal-film and film-solution interfaces and through the bulk of the film.

Another complexity that very likely occurs is the heterogeneous growth of the film. Variations in thickness and shape of the films can be produced easily by variations in activation energies and other kinetic factors which are caused by the presence of defects, grain boundaries, various exposed crystal faces, etc. Thus the actual growth of a film even in a carefully controlled experiment is very complex. The theoretical treatment of heterogeneous growth is extremely complex and, in common with most treatments of film growth, uniform growth will be assumed here.

The pertinent experimental facts that must be explained are the rapid decrease in rates, the decrease in α_a, and the rise in potential. The basic hypothesis that leads to an explanation of these observations is that a portion of the total potential drop occurs in the film and the field in the film decreases as the film thickens[3] and the potential changes. The field strength will be given by

$$F = \frac{V}{X} = \frac{V}{X_o + R\int Idt} \qquad [5]$$

where F is the field strength, V is the potential drop across the film, X is the film thickness, X_o is the initial film thickness, $\int Idt$ is the total charge passed, and R is the factor relating charge to thickness. If the structure of the film and the area of the electrode are known, R can be calculated easily. It will be assumed that the anodic current is controlled by a field-dependent rate-determining process within the film such that the activation energy will be lowered by the amount $(z_a elV)/(X_o + R\int Idt)$ where $(z_a e)$ is the charge of the moving particle and l is the distance through which the force acts. This rate-determining process could be the movement of an ion from one equilibrium position to another, and the location of the barrier to this movement could be either at one of the interfaces or in the bulk of the film. Neglecting any reverse current in the film, the anodic current will be given by

$$I_a = I_{k,a} \exp \frac{z_a elV}{(X_o + R\int Idt)kT} \qquad [6]$$

This equation, in the simpler form $I_a = A \exp BF$, where A and B are constants, has been verified ex-

[3] Such an explanation was proposed by Cabrera and Mott (11) in their treatment of thin films, but their subsequent treatment is different from that proposed here.

perimentally for the anodizing of zirconium by Charlesby (10); and a similar equation has been derived by Cabrera and Mott (11). The constant $I_{k,a}$ will contain a concentration term, a frequency factor, and an exponential term in activation energy. The assumption that reverse movement of the ions is negligible is good for high field strength or for a very high activation energy for movement in the reverse direction. The latter condition is most probable if the principal barrier to particle movement is at one of the interfaces. If there is a symmetrical energy barrier such as might occur in the bulk of a film, then the reverse current will not be negligible at low field strength.

The reduction of oxygen will entail a flow of electrons through the film against the field. It will be assumed that the height of this potential barrier in the film will determine the flow of electrons in the manner represented by

$$I_c = I_{k,c} \exp(-\alpha_c' eV/kT) \quad [7]$$

The constant α_c' should be distinguished from α_c of Eq. [2] because the former affects only the film potential and the latter affects the total potential including the double-layer potential at the film-solution interface.[4] This assumption is not strictly valid and agrees only approximately with experiment. The experimental α_c value decreases during the course of the experiment although not nearly as much as α_a decreases. This decrease in α_c could easily be due to changes in α_c'. Electronic film resistances are assumed negligible since the films are on the order of 100Å or less thick.

Equations [6] and [7] may be combined with the elimination of eV/kT to give

$$X_o + R\int I dt = -\frac{z_a l \ln(I/I_{k,c})}{\alpha_c' \ln(I/I_{k,a})} \quad [8]$$

recalling that $I_a = I_c = I$ at open circuit.

Differentiating with respect to time, Eq. [8] results in

$$\frac{dI}{dt} = -\frac{\alpha_c' R I^2 [\ln(I/I_{k,a})]^2}{z_a l \ln(I_{k,c}/I_{k,a})} \quad [9]$$

or

$$\frac{dI}{dt} = -AI^2 [\ln(I/I_{k,a})]^2 \quad [9a]$$

where $A = \dfrac{\alpha_c' R}{z_a l \ln(I_{k,c}/I_{k,a})}$.

Equation [9] can be integrated but the result is a series which is not easy to use. It is more convenient to integrate it graphically for various values of $(I/I_{k,a})$. Since the variation in the term $[\ln(I/I_{k,a})]^2$ is small compared to changes in I^2, a useful approximate integration can be made by assuming that $\ln(I/I_{k,a})$ is constant. This assumption may be further improved by the possibility that $I_{k,a}$ may decrease slightly with time along with I. Because particles in low activation energy positions are likely to react first in preference to particles in higher activation energy positions, the over-all average activation energy is likely to be increased and therefore $I_{k,a}$ decreased. If then $\ln(I/I_{k,a})$ is assumed constant, Eq. [9a] integrates to

$$1/I = A[\ln(I/I_{k,a})]^2 t + K \quad [10]$$

where K is an integration constant. Equation [10] is, of course, a hyperbola.[5]

The behavior of these functions is shown in Fig. 6 where Eq. [10] is plotted along with the results of the graphical integration of Eq. [9]. In order to emphasize the differences of the shapes of the curves, the constants are chosen so that all functions will have the same values at currents (rates) of one and 100. There is obviously little difference in the shape of the curves unless $I/I_{k,a}$ is less than about 10^4, which will occur for small fields. Thus these equations would predict that the rate-time behavior is almost hyperbolic at high field strength (or the thickness-time behavior is almost logarithmic). In Fig. 7 it is shown that by the proper selection of the constants, the theoretical expressions can account for experimental plots. For the sake of clarity, only three rate-time curves are shown, but the others can easily be fitted also. Of course, with three arbitrary constants, A, K, and $I_{k,a}$, this is relatively easy, so that all that Fig. 7 shows is the possibility that the theoretical expressions can account for the experimental rate curves.

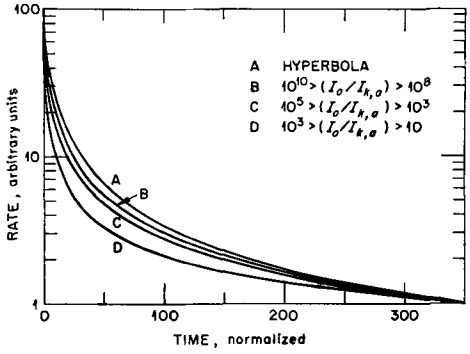

Fig. 6. Theoretical rate-time curves

[4] Experimental evidence obtained by the author suggests that the reduction of O_2 is best represented by a dual-barrier model, one barrier occurring at the film-solution double layer, and the other in the film as described above. For a more complete description of the dual-barrier model see Posey (12).

[5] This derivation is similar mathematically to a derivation presented by Vetter (13) for film growth at constant potential. It is interesting that film growth at constant potential and at open circuit follow essentially the same kinetics.

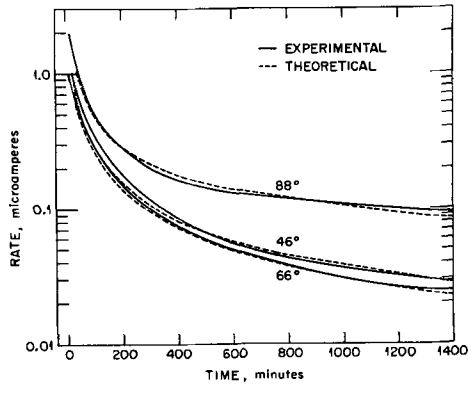

Fig. 7. Comparison of theoretical and experimental corrosion rates of crystal bar zirconium in oxygenated Na_2SO_4 solution.

It is appropriate to estimate the value of the constant A in order to see if it has the correct order of magnitude. This involves mainly an estimate of the quantity R, which relates charge to thickness of film. Assuming the film to be ZrO_2 of density 5.5 g/cc, R is equal to 5.79 x 10^{-5} cc/coulomb ÷ area. For these specimens of 2.2 cm^2, R is equal to 2.63 x 10^{-5} cm/coulomb. The constant α_c' will be assumed to be about one, l will be assumed to be 3 x 10^{-8} cm, z_a will be assumed to be 2 corresponding to oxide ion migration, and the term ln $(I_{k,c}/I_{k,a})$ will be assumed to be of the order of magnitude of ten.[6] Using these values A turns out to be about 40 $coulombs^{-1}$. In Fig. 7, the 46° and 88° runs are fit by the graphically integrated form of Eq. [9] with A equal to 3.4 and 190, respectively, and $I_{k,a}$ assumed to be 1.1 x 10^{-9} A at 88°C and $10^{-12}A$ at 46°. The 66° run was fit by the hyperbola $1/I = 540\ (t + 960)$, t being the time in seconds (the graph gives time in minutes). Since a hyperbola was used, $I/I_{k,a}$ must be greater than about 10^5 and hence $[\ln(I/I_{k,a})]^2$ must be greater than about 130 and A, which is equal to $540/[\ln (I/I_{k,a})]^2$ according to Eq. [10], must be less than about 4. Of course these values depend on how one decides to fit the curve, but they do not change their order of magnitude for various attempts at fitting the curves. The determined values of A therefore seem to be correct as to order of magnitude.

The rise in potential which is observed in these experiments is simply the result of the decrease in anodic current at a given potential due to film thickening. In order that anodic and cathodic currents always remain equal, the potential must rise, since the anodic current must increase and the cathodic current decrease as the potential rises.

The effect of temperature is complicated as can be seen by comparing the rate expressions at various temperatures. In order to obtain meaningful data from the temperature effects, values of $I_{k,a}$ and $I_{k,c}$ would have to be known with considerable precision. However, comparison of the rate-time curves shows that, with the exception of one of the 25° experiments, the rates were considerably higher at 88° than at the other temperatures. There is therefore much more film growth in these experiments, and this accounts for the fact that the decrease in α_a was far more noticeable in the 88° experiments than in the other experiments. The experiments at 25°C should not be given much significance since there was considerably more scatter in the data leading to the (smoothed) rate-time curves shown in Fig. 4.

The expressions given here can account for the shape of the rate-time curves, but it is clear that more information is needed on the mechanisms of the cathodic and anodic processes. Probably such information is obtained best by isolating the individual processes and studying them alone. Such studies now are being carried out, and the reduction of various reducible species on film-covered zirconium will be the subject of a future communication.

[6] This estimate results from the probability that the activation energy for the anodic process is higher than that for the cathodic process. Admittedly this estimate of ten for the value of ln $(I_{k,c}/I_{k,a})$ is only a guess.

Acknowledgment

The kind encouragement and helpful discussions of Dr. G. H. Cartledge, Dr. F. A. Posey, and Dr. A. L. Bacarella, all of this Laboratory, are gratefully acknowledged.

The Oxidation of Iron-Nickel Alloys

III. Kinetics of Oxidation of Three Commercial Alloys

R. T. Foley and C. J. Guare

General Engineering Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Three commercial iron-nickel alloys, containing 30, 41, and 78% nickel, were oxidized over the range 600°-1000°C in two atmospheres, laboratory air, and a 21.7% O_2-78.3% N_2 mixture. The oxidation of these alloys follows a parabolic weight gain-time relationship during the 60-min reaction time. Replicate experiments generally showed that the precision in determining the parabolic rate constants was better in the O_2-N_2 mixture than in laboratory air. This effect is probably the result of day-to-day variations in composition of laboratory air. Temperature dependences of the reaction rates were determined with the Arrhenius-type equation. Both the reaction rates and the apparent energies of activation of the 30-41% alloys are consistent with a rate-determining process of cation diffusion through a spinel structure $Ni_x Fe_{3-x} O_4$. It is hypothesized that the apparent energy of activation for the 78% alloy is due to the influence of the 3.8% Mo on the physical character of the film. Anomalously high rates were observed in both atmospheres at the higher temperatures, and this is discussed with reference to "over-temperatures," resulting from heat generated at the surface by oxidation.

An earlier study (1) had as its objective outlining the mechanism of high-temperature (600°-900°C) oxidation of an iron-nickel alloy containing 42% nickel. It had been pointed out that the iron-nickel system was of theoretical interest because these two elements form a continuous series of substitutional solid solution alloys with both components oxidizable. Furthermore, iron-nickel alloys of various compositions are used industrially for such purposes as glass-to-metal sealing, as magnetic materials, and as materials with special thermal properties. The earlier study demonstrated that the mechanism of oxidation involved diffusion through a nickel ferrite reaction product film, and the variation of activation energies and oxidation rates with surface preparation was explained on the basis of diffusion through ferrite structures of varying percentages of nickel. This study extends this work to two other commercial alloys and special atmospheres. Oxidation was studied over the temperature range 600°-1000°C. The objective of this paper is to report and interpret kinetic data so that ultimately a complete understanding of the mechanism of oxidation of iron-nickel alloys may be realized. It is expected that work reported and underway in two other laboratories (2-4) as well as in our own, will achieve this contribution to general oxidation theory.

Experimental

Oxidation Studies

The oxidations were carried out employing a Chevenard thermobalance. In this instrument the sample to be oxidized is supported on a fused silica rod and the furnace, at the desired temperature, is lowered around it. The change in weight of the sample is recorded automatically as a function of time.

Experiments were run at 600°, 700°, 800°, 900°, and 1000°C. The temperature of the furnace was controlled to ±1.4°C according to a General Electric protable precision potentiometer. This instrument was calibrated to be accurate to 0.05%. Usually the oxidation was allowed to proceed for 60 min. Two atmospheres were employed. The first was static laboratory air. This certainly changed from day to day because of humidity variation and other influences, all of which have not fully been assessed in high-temperature oxidation work. (Some of the experiments described here were made several years apart.) The second atmosphere consisted of a controlled mixture, 21.7% oxygen and 78.3% nitrogen by volume flowing at a rate of 263 ml/min. The dew point of this mixture was −20°F. In all cases at least duplicate, and usually triplicate, samples were oxidized. Weight changes were taken from the thermobalance curve at 6-min intervals and replotted to establish the rate constant. The spread of the parabolic rate constants is apparent from the tables listing the results. Usually this spread was less than ±6% of an average value. Where poorer precision was obtained, the experiment had usually been run in laboratory air. In several instances the first duplicate runs were within 3% of an average value. The experiment repeated several months later gave values with about the same precision. However, the first average might vary from the second by 60%. This must be due to variation in the composition of the atmosphere; experiments are now being run to clarify this point.

Composition of alloys.—The three iron-nickel alloys investigated represent compositions of interest to the electrical and electronics industry. Alloy A was nominally 30% Ni, 70% Fe; Alloy B—41% Ni, 59% Fe; Alloy C—78% Ni, 18% Fe, and 4% Mo.

Complete analyses of these alloy strips before oxidation were given in a previous report (5). Reanalysis for carbon gave a corrected value of 0.001% rather than the 0.01% reported. This agrees with what would be expected from the heat treatments. The alloys were obtained[1] in the form of strip 0.050-0.076 cm thick. The sheared coupons were annealed for 2 hr at 1125°C in hydrogen and then cooled in hydrogen to room temperature. Before oxidation the panels of about 20 cm^2 area were cleaned chemically.

Surface preparation.—The alloy strips were chemically cleaned at 90°C for 2 min in an acid mixture and with a procedure described before (5). The intent was to oxidize a surface free of disturbed metal. Electron diffraction examination of a surface prepared by this method gave only the pattern corresponding to the iron-nickel alloy (1). An objection to acid cleaning a binary alloy might arise from the possibility of selective dissolution. Presumably in an iron-nickel alloy the iron would be selectively dissolved, yielding a nickel-rich surface which would exhibit a lower oxidation rate. The magnitude of this effect was assessed by preparing samples of the 41% nickel alloy for oxidation at 900°C in the controlled O_2/N_2 atmosphere, the only variation in treatment being the time of pickling. The parabolic rate constant varied as follows:

Time in acid bath at 90°C, min	k_p (x 10^{10} g^2cm^{-4} sec^{-1})	
2	4.00, 3.94	avg 3.96
4	3.77, 3.54	avg 3.66
6	3.77, 3.54	avg 3.66

The extended pickling decreased the measured oxidation rate by 7.5%.

Electron Diffraction Analyses of Films

Electron diffraction analyses by the reflection technique were made with a General Electric electron diffraction instrument. This instrument was equipped with an attached high-temperature furnace enabling one to study the oxidation products at the temperature of reaction. These experiments, as well as the equipment, are described in more detail in another report (5).

Treatment of Data

The oxidation rate for these iron-nickel alloys may be represented by the parabolic rate equation:

$$(\Delta m)^2 = b + k_p t \qquad [1]$$

where Δm is gain in weight in g/cm^2 of a sample oxidized for t seconds; k_p is the parabolic rate constant expressed in $g^2cm^{-4}sec^{-1}$; b is a constant (g^2cm^{-4}).

The temperature dependence for the reaction is best described by an Arrhenius type equation as:

$$k_p = Ae^{\frac{-\Delta E^*}{RT}} \qquad [2]$$

in which ΔE^* is termed the apparent energy of activation and A the frequency factor. As discussed below, the significance of ΔE^* derived from the Arrhenius plot must be interpreted with caution at elevated temperatures.

Results

Results for Alloy A (30% Ni)

The parabolic rate constants, k_p in Eq. [1], are listed in Table I. Generally, the precision of the rate constants obtained in the controlled atmosphere is better than of those obtained in laboratory air. For all of the runs with alloy A, the average deviation from the mean for 2 or 3 runs was ±3.0% in the controlled atmosphere and ±5.4% in laboratory air. If duplicate runs were made in laboratory air on the same day, however, the precision would be ±2-3%. At 600°, 700°, and 800°C there is apparently no definite influence of the atmosphere by way of increased or decreased rate. At 900°C the rate in the laboratory air is greater than that in the controlled atmosphere by a factor of 2 and at 1000°C by a factor of 3.

The parabolic relationship gives an excellent representation for the data for all the controlled atmosphere data and most of the data in laboratory air. However, in the latter case at 900°C, there is a slight tendency for the plots to be concave upward. At 1000°C the k_p definitely increases after an oxidation time of about 20 min, and it is necessary to

Table II. Temperature dependence of oxidation reactions

Alloy	Atmosphere	"A" frequency factor, g^2 cm^{-4} sec^{-1}	ΔE^*, apparent energy of activation, cal/mole
A (30% Ni)	Laboratory air	0.044	41,800
	O_2-N_2 mixture	0.024	41,100

	O_2-N_2 mixture	0.020	40,900
	Ref. (1)	0.012	40,800
C (78% Ni)	Laboratory air	1.28×10^{-3}	38,230
	O_2-N_2 mixture	3.10×10^{-4}	35,450

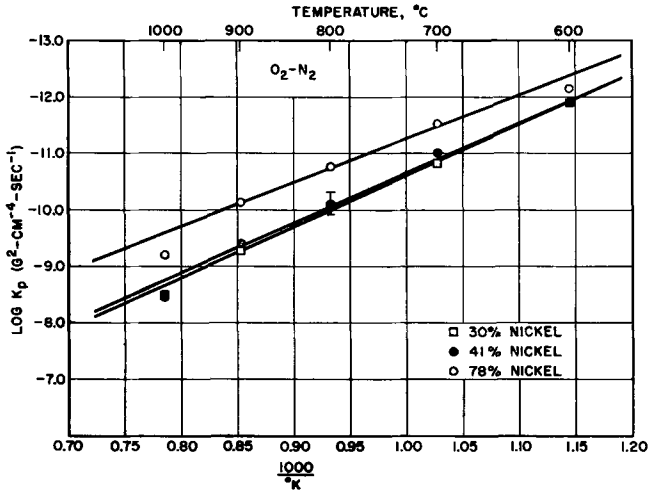

Fig. 1. Temperature dependence of oxidation rate of iron-nickel alloys oxidized in a controlled O_2-N_2 atmosphere.

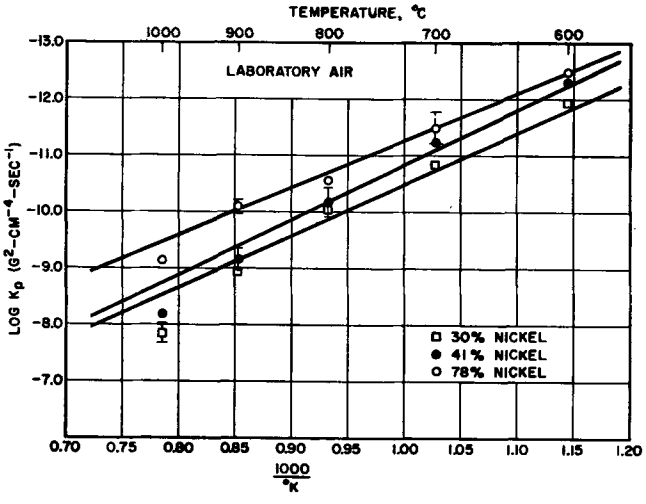

Fig. 2. Temperature dependence of oxidation rate of iron-nickel alloys oxidized in laboratory air.

represent the data by two stages. These two stages are represented by "a" and "b" in Table I. This is a reproducible effect. After the initial oxidation stage the rate almost doubles.

The temperature dependence of the reaction is described by "A" and "ΔE^*" in Eq. [2]. These quantities are given in Table II, and the curves are plotted in Fig. 1 and 2. The 5 points in the O_2-N_2 atmosphere fall close to the linear plot, but the 900° and 1000° points obtained in laboratory air fall in a direction indicating greater reaction. This point is discussed below.

Alloy B (41% Ni)

Rate constants describing the oxidation behavior of the 41% alloy are given in Table III. For comparison, results obtained about 4 years ago (1) on an alloy of almost the same composition are given. (The present alloy contained 40.9% Ni, the former contained 41.8%.) These results agree well with the present and the differences in the results are most likely due to variation in laboratory air.

In all cases excellent representation by Eq. [1] was achieved. The precision of the results obtained in the controlled atmosphere was again better than that of the laboratory air, 4.1% and 7.2%, respectively. In the last case the four 800°C values were considered as two groups. This is a good example of the variation in results, mentioned above, which is sometimes obtained when experiments are run in laboratory air many weeks apart.

The atmosphere effect in this case is not straightforward. Oxidation in laboratory air at 600° and 700°C proceeds at a rate distinctly less than in the controlled atmosphere. At 800° the rates are about the same, whereas at the higher temperature the laboratory air rate is double that in the controlled atmosphere.

The temperature dependence of the oxidation reaction is described in Table II and in Fig. 1 and 2. The actual plot of values obtained in the O_2-N_2 mixture is approximately linear within experimental error. The 900° and 1000°C values obtained in laboratory air fall off in the direction of the higher rate similar to the behavior of the 30% alloy.

Alloy C (78% Ni)

Rate constants for this alloy are listed in Table IV. The precision of runs made in the controlled O_2-N_2 atmosphere was ±6.6%, while that in laboratory air was ±15.2%. The considerable spread in results in laboratory air is explained by the variation in the composition of this atmosphere over the months the experiments were run. These data were represented quite well by a single parabolic equation of the Eq. [1] type with the exception of the 1000°C run in air. In this situation after an oxidation time of about 30 min, the parabolic plot followed a second straight line of lower slope. These two phases of reaction are given by "a" and "b" in Table III.

There was no consistent pattern established on comparison of rates in laboratory air and in the O_2-N_2 mixture. The spread of results in the laboratory air made this comparison difficult.

The temperature dependence of the reaction is given by "A" and "ΔE^*" values in Table II. In both atmospheres the 1000° point falls below the curve, indicating a higher rate of reaction than would be expected from extrapolation from the four lower

temperatures. The apparent energy of activation lower than that of alloy A or alloy B is significant.

Discussion

The "A" and "ΔE^*" values of Eq. [2] describe the temperature dependence for the oxidation of the three alloys and offer some clue as to the mechanism of oxidation. Based on this work and other work carried out in this laboratory, it is estimated that a value of about 41,000 cal/mole represents the heat of activation of diffusion and the heat of formation of vacancies through a structure of the composition $Ni_x Fe_{3-x} O_4$. This value is approximated by the 30% and 41% alloy. It is recognized that the oxide film on the 30% alloy and the 41% alloy is at least a duplex structure with the spinel growing at the metal-oxide interface and Fe_2O_3 further removed from the metal (1, 5). The composition of the spinel varies, being richer in Ni close to the alloy itself. Because of the duplex nature of the film and because of the variation of Ni/Fe ratio in the spinel, a theoretical derivation of the reaction rate would be difficult.

The rates summarized by the values in Table II indicate that all three of these alloys are more resistant to oxidation than iron, but not as resistant as the so-called "heat resistant alloys," typified by iron alloys containing 18% chromium, 8% nickel. This again is related to the rate-determining process, diffusion through the spinel structure. As has been pointed out by Yearian and co-workers (6), the more resistant alloys form a Cr_2O_3 type film while the more reactive alloys (in the heat resistant class) form spinel type structures upon oxidation. On the other hand, in comparison with pure iron these alloys are oxidation resistant. With alloys containing as much as 30% Ni, the formation of FeO at the alloy-oxide interface is suppressed. Diffusion of cations through the FeO structure is about 20 times as rapid as through Fe_3O_4 (3). Comparison of our results for the 30% alloy with those of Stanley (7) for iron yields rate ratios of 200-1000 rather than 20 expected on this basis. The lower rate is directly related to the Ni substitution in the spinel structure. Therefore, these alloys occupy a position on the oxidation resistant scale intermediate between iron (readily oxidized) and austenitic stainless steels (heat resistant).

The low apparent activation energy of Alloy C must be related to the presence of Mo in the alloy. Apparent activation energies of 40,000-45,000 cal/mole would be expected if the rate-determining step were diffusion through either the spinel structure or NiO, both of which are present in this alloy during oxidation at elevated temperatures. Electron diffraction examination of the alloys at elevated temperature indicates that MoO_3 is probably present in the first formed film (5). This point was not as well established as desired and more work is being done now to clarify this point. However, these prior observations fit those of Iitaka and co-workers (8) who found MoO_3 at the metal-oxide interface after oxidation of alloys of somewhat similar composition. The expectation that MoO_3 will simply evaporate and lead to catastrophic oxidation is an oversimplification. The Mo content, the Fe content, and the temperature all bear on the behavior (9). The effect of Mo, however, may be one of influencing the physical character of the film. This has been demonstrated to be a significant factor in oxidation processes, particularly where thermal cycling is involved (10).

In Fig. 1 and 2 it is very apparent that deviations occur at 900° and 1000°C, from the simple Arrhenius plot. These deviations from the Arrhenius plot may arise from changes in mechanism over the temperature range (11) or the production of local "over temperatures" on the reacting surface (12). Aside from these "experimental" causes, even on a theoretical basis one would not expect ΔE^* to be completely independent of temperature. This has been pointed out by Moelwyn-Hughes (13) and others. It is assumed here, as a first approximation, that, for a given alloy, the mechanism does not change to any considerable extent over this temperature range and an attempt is made to estimate the significance of the "over temperature."

When the reaction

$$\text{metal} + \text{gas} = \text{reaction product}$$

occurs rapidly and is accompanied by a high heat of reaction, it would be expected that the temperature of the sample would rise sensibly during the first few minutes of the reaction. This has been observed, for example, in the oxidation of iron near its melting point (14) and recently measured by Meussner and Birchenall (15). In the latter experimental work a temperature rise of 88°C was observed for the reaction between iron and sulfur at 900°C. In fact, this effect discouraged measurement of the reaction rate over 900°. Schmahl, Baumann, and Schenck (12) measured "over temperatures" during the oxidation of iron in the temperature range of 910°-950°C, to account for deviations from the parabolic law. Direct measurements of the rise in sample temperature were compared with calculated values. The calcu-

Table V. Comparison of calculated and measured over-temperatures

Alloy	Atmosphere		From Arrhenius plot (Fig. 1 and 2)	Calculated
A (30%)	Air	900°	32°	27°
		1000°	126°	106°
	O_2/N_2	900°	0°	31°
		1000°	34°	71°
B (41%)	Air	900°	43°	25°
		1000°	106°	70°
	O_2/N_2	900°	0°	18[b]
		1000°	52°	85°
C (78%)	Air	900°	0°	14°
		1000°	70°	39°
	O_2/N_2	900°	0°	8°
		1000°	92°	34°

lation was based on all of the heat evolved going into heating the iron panel. Following the method of Schmahl, *et al.*, we have calculated temperature rises for the three alloys. The heat evolved equivalent to the amount of oxidation occurring in the first 1½ min—the linear portion of the weight gain-time curve—was calculated. Values for the heats of formation for Fe_3O_4 of 261,700 at 900°C, and 261,800 cal at 1000°C, and for NiO, 56,770 at 900° and 56,650 cal at 1000°C were used (16). Heat capacity data (17) allowed an estimation of the temperature rise in the approximately 4-g sample employed in the experiments. This calculated value was then compared with the value on the basis that the entire deviation from the Arrhenius plot was "over temperature." Table V compares these values and there is a rough correspondence. This treatment introduces large errors, mainly in considering how the heat is dissipated. The assumption that no heat is lost by convection or radiation is obviously an oversimplification and would make the "calculated" values too high. Also, the k_p values given for 900° and 1000°C are based on a 60-min oxidation period rather than the 1½ min initial reaction time. This thermal effect is being studied more exactly because in the 1000°C range it must have an important influence on oxidation rates and their interpretation to develop an understanding of mechanism.

In a qualitative way this would in part account for the greater deviation from the Arrhenius plot observed for the 30% and 41% alloy in the (stagnant) air atmosphere in contrast to that observed in the (flowing) controlled O_2/N_2 mixture. Heat would be carried away in the gas stream in the latter case.

The oxidation of Ni-Fe alloys containing 5, 10, 20, 30% Ni over periods of up to several hundred hours has been reported by Benard and Moreau (18). The kinetics for the 20% alloy is reported up to about 15 hr. The oxidation follows a $y^n = kt$ relationship, y being the amount of oxygen picked up in time, t. At 675°C $n = 2$, indicating agreement with the parabolic relationship. At 800° $n = 2.4$ up to 5 hr and then changes to $n = 1.6$. At 900° the break in the plot is at 2 hr. Up till then $n = 2.6$ and above that 1.22. The authors postulate that during the first stage of the process the controlling factor is the diffusion of iron in the zone of the alloy depleted by a selective oxidation mechanism. During the second phase the controlling rate is the diffusion of oxygen in the superficial oxide layer. Benard and Moreau consider the significant mechanism for the Fe-Ni system to be one of selective oxidation. Some of Sachs's (19) work with low Ni alloys seems to agree in a general way. Their mechanism is based on the reduction of NiO with FeO. In our electron diffraction examination of films we have not seen FeO as a principle constituent and indeed it is rare when the patterns suggest this compound at all. Birchenall, *et al.*, have pointed out that the NiO makes for its instability (3). Our results do not support this selective oxidation mechanism. Perhaps the reason lies in the fact that these investigators have worked with alloys lower in nickel content for long times. Our work deals with relatively thin films. In our work subscale formation was not significant as it was during the lengthy experiments of Benard and Moreau.

We regard the oxidation mechanism for the 30% and 41% alloy as primarily one involving diffusion of cations through a spinel type film and for the 78% alloy diffusion through a film composed of spinel and NiO. In the latter case the MoO_3 enters into the film in a manner as yet unexplained but now under investigation in our laboratory.

Manuscript received Nov. 1, 1956. This paper was prepared for delivery before the Cleveland Meeting, Sept. 30-Oct. 4, 1956.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Oxidation Studies on the Nickel-Chromium and Nickel-Chromium-Aluminum Heater Alloys

Earl A. Gulbransen and Kenneth F. Andrew

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A systematic study was made of the oxidation resistance of five 80Ni-20Cr heater alloys and one 4Al-19Cr-77Ni alloy. Kinetic and crystal structure studies were made over the temperature range of 500° to 1100°C. The adhesion of the oxide film to the alloy was tested by the strain oxidation technique, and the over-all performance was evaluated by the ASTM useful life tests. The rate of oxidation of the several alloys could not be correlated with the ASTM useful life results, while the strain oxidation tests could be correlated with the ASTM useful life tests. Cr_2O_3 was the major oxide formed on the 80Ni-20Cr alloys at 1100°C. Although Al_2O_3 and Cr_2O_3 were observed below 1000°C on the 4Al-19Cr-77Ni alloy, no Al_2O_3 was observed in the oxide scale at 1100°C. A thermodynamic and kinetic interpretation was made of the results.

Due to their good oxidation resistant properties, the 80 nickel-20 chromium series of heater alloys are used for severe service conditions. The addition of silicon and small amounts of calcium, zirconium, cerium, etc., has resulted in a 600% improvement in the performance of these alloys over the past 40 years as measured by the ASTM useful life test (1) for heater alloys (2-4).

Several studies have been made on these alloys to determine the chemical and physical basis for the improved performance. Using a historical series of alloys, Gulbransen and Andrew (2) showed that the rate of oxidation at constant temperature could not be correlated with ASTM useful life test results. Crystal structure studies (3, 4) of eight alloys also showed no correlation with useful life test results.

This paper presents new studies on the oxidation of the 80Ni-20Cr series of alloys and of a 75Ni-19Cr-4Al alloy. Manganese and silicon compositions were varied in the 80Ni-20Cr series of alloys. These studies include: (*a*) kinetic studies from 500° to 1100°C to determine the rate of oxidation as a function of temperature, (*b*) strain oxidation studies to evaluate the adherence of the oxide to the alloy, and (*c*) crystal structure studies on the oxide scale to determine its structure and composition. These studies are interpreted by thermochemical analyses of the chemical reactions occurring in the system and by oxidation rate theory.

An extensive review of the scientific literature was given in earlier papers (2-4). The technical aspects of heater alloys have been reviewed by Hessenbruch (5). The recent work of Pfeiffer (6) should be noted.

Experimental

Method.—A vacuum microbalance was used for all of the rate studies. Its construction and use have been described (7). In addition to our standard quartz microbalance having a sensitivity of 0.91 μg/0.001 cm deflection, a low sensitivity microbalance of 3.30 μg/0.001 cm sensitivity was used. Two sizes of specimens 0.0127 cm thick were used. The first weighed 0.6826 g and had a surface area of about 14 cm^2. The second weighed 0.5300 g and had a surface area of about 10.5 cm^2.

Samples.—The alloys were prepared, analyzed, and life tested by the Hoskins Company and by the Driver-Harris Company. Table I gives a list of the alloys, their analyses, and the results of the ASTM useful life tests (1). Alloys containing Si were represented by two alloys with a constant Mn content, while alloys containing Mn were represented by three alloys having a given Si composition. Minor changes in composition result in a threefold change in the ASTM useful life value at 1177°C.

Specimens were abraded using 1/0 to 4/0 polishing papers under purified kerosene and then cleaned with petroleum ether, soap and water, distilled water and alcohol.

* 6-hr test.

The furnace tube, reaction system, and gas preparation system have been described (7, 8). Furnace temperature was maintained constant to ±1.5°C.

Strain oxidation.—The ASTM useful life test (1) involves an alternate heating and cooling cycle at 2-min intervals. At 1177°C several hundred thousands of cycles may be required to determine the useful life of a given alloy. The ASTM test involves both a test of the over-all resistance to oxidation and a test of the effect of stress developed by heating and cooling on the oxide-metal interface.

Gulbransen and Andrew developed a microgravimetric test (9) for study of the effect of a single large strain of 2% on the oxidation process. This strain oxidation test involves the following operations: (*a*) oxidizing the alloy to a given weight gain, (*b*) removal of sample from reaction system and straining 1, 2, or 4%, (*c*) reoxidation of the sample to evaluate the effect of strain on the oxidation behavior.

The effect of a strain can be studied quantitatively by comparison of the rate of oxidation before and after application of a strain. Strain can damage the oxide-metal interface and the oxide without visual evidence of cracking.

X-ray diffraction method.—Electrochemical (10) and chemical methods were used for stripping the oxide from the metal. For high Si alloys the oxide films were removed by the iodine-methanol chemical method. Oxide films were washed carefully in distilled water before being rolled on a glass capillary tube for mounting in the x-ray camera.

495	High Si, low Mn + trace elements	44.5	2	2.82×10^{-13}	1.6×10^{-13}	178
491	Intermediate Si, low Mn + trace elements	47.1	2	1.97×10^{-13}	1.77×10^{-13}	105
492	Intermediate Si, high Mn + trace elements	43.7	2	5.89×10^{-13}	4.63×10^{-13}	106
493	Low Si, low Mn + trace elements	45.4	2	5.62×10^{-14}	9.81×10^{-14}	63

All of the diffraction patterns were made using filtered CrK_α radiation from a fine focus x-ray diffraction tube. Diffraction patterns were made at room temperature using a 9 cm Unicam camera.

Results

Oxidation studies were made in the vacuum microbalance over the temperature range of 500° to 1100°C. Before oxygen was added, the apparatus was evacuated to a pressure of 10^{-6} mm Hg or less. The furnace was then raised about the sample and furnace tube, and thermal equilibrium was allowed to occur. Above 900°C decarburization of the alloy by the room temperature oxide occurred for some of the alloys (11). Weight gain was calculated in units of micrograms per square centimeter.

X-ray diffraction analyses showed that the oxide scales were Cr_2O_3 and $NiO \cdot Cr_2O_3$. To estimate the thickness in angstroms from the weight gain in micrograms per square centimeter a factor of 61 was used. This factor assumes Cr_2O_3 to be the oxide and a surface roughness ratio of unity.

Kinetic Studies

Alloy 493 (low Si, low Mn).—Figures 1 and 2 show weight gain vs. time curves for the oxidation of alloy 493 for the two temperature ranges 500°-900°C and 900°-1100°C. All of the curves show a rapid initial reaction, with the rate of reaction decreasing as the film thickens. Two series of temper colors were observed on the alloys at 900°C before the gray colored oxide formed. Table II shows a summary of the colors of the oxide films and the thickness after 2 hr of reaction. This alloy showed the lowest rate of oxidation of the series of alloys studied.

Alloy 495 (high Si, low Mn).—Figure 3 shows weight gain curves for alloy 495 for the temperature range 950°-1100°C. The results at 500°-900°C were similar to those for alloy 493. Alloy 495 having a higher Si content oxidizes at a more rapid rate than alloy 493. Figure 4 shows a comparison of three alloys at 900°C. Silicon increases the initial rate of oxidation of the 80 Ni-20 Cr alloys for all temperatures studied. ASTM useful life tests show the high Si alloy to have the longest life.

Effect of Mn.—An earlier study showed that Mn may have a deleterious effect on the oxidation process due to its very high vapor pressure. Small quantities of Mn are probably in the alloy as sulfide and oxide. However, larger amounts of the order of 1 and 2% must be present in solid solution in the alloy.

Since the trace elements Ca, Al, and Zr were not controlled in the earlier study two special alloys were prepared in which only the Mn content was varied. These are alloys 492 and 491 of Table I. Figure 5 shows a comparison at 900°C. The high Mn alloy containing 2.30% Mn and 1.01% Si gave a higher rate of oxidation than alloy 491 containing

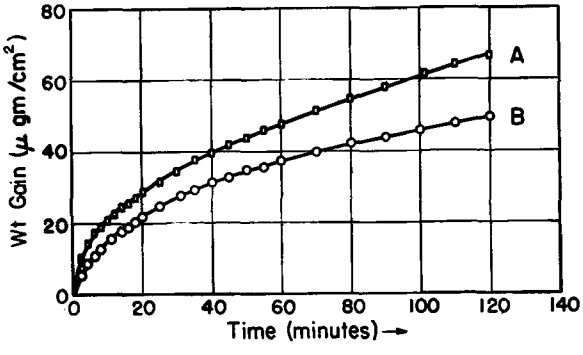

Fig. 5. Effect of Mn on oxidation of Ni-Cr alloys, 900°C, 7.6 cm of Hg of O_2, abraded through 4/0. Curve A, 492, 2.30% Mn; B, 491, 0.05% Mn.

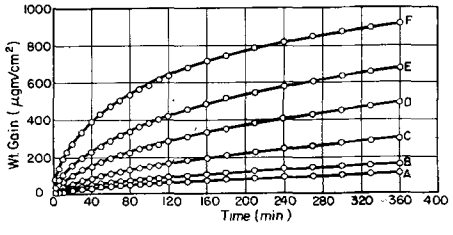

Fig.6. Effect of temperature on oxidation of alloy 245, 7.6 cm of Hg of O_2, abraded through 4/0. Curve A, 875°C; B, 900°C, C, 950°C; D, 1000°C; E, 1050°C; F, 1100°C.

0.05% Mn and 1.03% Si. ASTM useful life data were nearly identical.

Alloy 245 (high Si, high Mn).—Since Al has been shown to greatly improve the Fe-Cr series of heater alloys (12) a special Ni-Cr alloy containing 4.05% Al was studied. Figure 6 shows a 6-hr weight gain curve for this alloy from 875° to 1100°C. A comparison of Fig. 6 with Fig. 2 and 3 shows alloy 245 to oxidize at a more rapid rate than alloys 493 and 495. Table II shows the color of the oxides after 6 hr of reaction and the oxide thickness. Figure 6 shows that the total amount of oxidation after 6 hr is increasing with temperature from 875° to 1100°C. For the 5Al-22Cr-Fe alloys the total amount of oxidation remains nearly constant for the temperature range 950°-1050°C. Addition of Al to the Ni-Cr alloys does not have the marked effect on the oxidation reaction that was found for the Al-Cr-Fe alloys.

Parabolic rate law correlation.—A number of empirical rate laws have been proposed to interpret the rate of oxidation of metals and alloys. The parabolic rate law was used here since it has been derived from fundamental physical concepts involving the formation and diffusion of ions and electrons (13, 14). The equation states that $W^2 = A\,t + C$. Here W was the weight gain, t was the time, and A and C were constants.

Since the composition of the oxide was a function of time and temperature no one rate law could explain the complete time and temperature behavior. We used parabolic rate law plots to indicate changes in the oxide composition and to show whether the protective properties were improving or deteriorating.

To test the application of the parabolic rate law, graphs were made of the square of the weight gain vs. time. Figures 7, 8, and 9 show three plots for alloy 493. The 500°C plot shown in Fig. 7 indicates that the slope decreases continuously. Previous crystal structure studies (4) showed the initial oxide was NiO. After 30 hr of oxidation the oxide was identified as Cr_2O_3. The change in the parabolic rate law constants in Fig. 7 may be related to the change in oxide composition. Figures 8 and 9 at 900° and 1100°C show better agreement with the parabolic rate law after the initial deviation.

Temperature dependence.—To determine the temperature dependence of the parabolic rate law constants A, we use the relation $A = B\,e^{-\Delta H/RT}$. Here ΔH is the heat of activation of diffusion and heat of formation of the defects, B is a constant, and R the gas law constant. More elaborate rate expressions may be used for A so that the entropy terms may be evaluated (15). However, the complex nature of the alloy and oxide makes a complete interpretation very difficult. ΔH was evaluated from log A vs. $1/T$ plots of the rate law data.

Figures 10, 11, and 12 show plots of log A vs. $1/T$ for alloys 493, 495, and 245. All of the alloys gave two or more straight lines. The change in slopes may be related to crystal structure or composition changes in the oxide. Table III shows a summary of the parabolic rate law constants and heats of activation for three temperatures for all of the alloys and a comparison of these data with ASTM useful life tests.

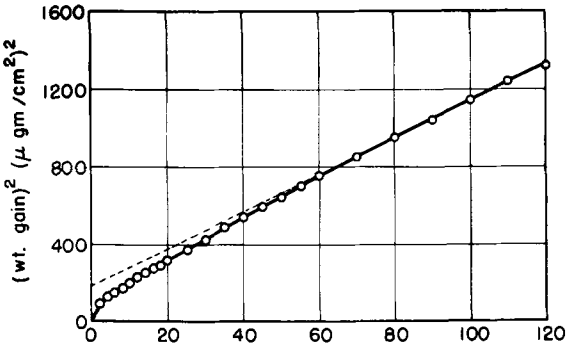

Fig. 8. Parabolic plot oxidation of Ni-Cr alloy 493, 900°C, 7.6 cm of Hg of O_2, abraded through 4/0.

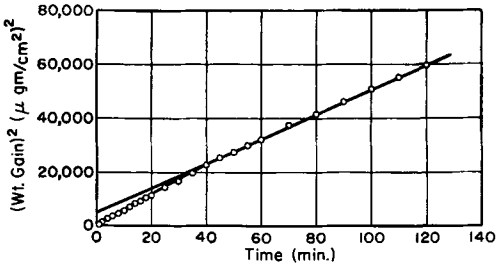

Fig. 9. Oxidation of Ni-Cr alloy 493, 1100°C, 7.6 cm of O_2, abraded through 4/0, parabolic plot. A = 7.08 x 10^{-12} $(g/cm^2)^2$/sec.

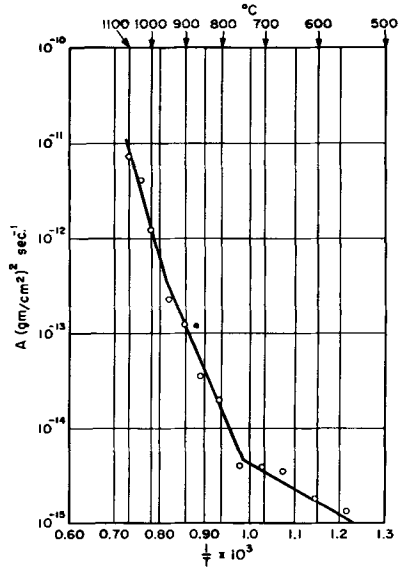

Fig. 10. Oxidation of Ni-Cr alloy 493 (low Si, low Mn), Log A vs. 1/T, ΔH = 76,250 cal/mole (950°-1100°C); ΔH = 49,730 cal/mole (750°-950°C).

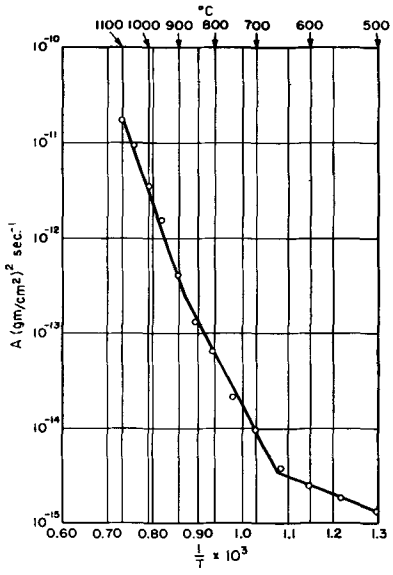

Fig. 11. Oxidation of Ni-Cr alloy 495 (high Si, low Mn). Log A vs. 1/T, ΔH = 61,200 cal/mole (880°-1100°C); ΔH = 40,850 cal/mole (650°-880°C).

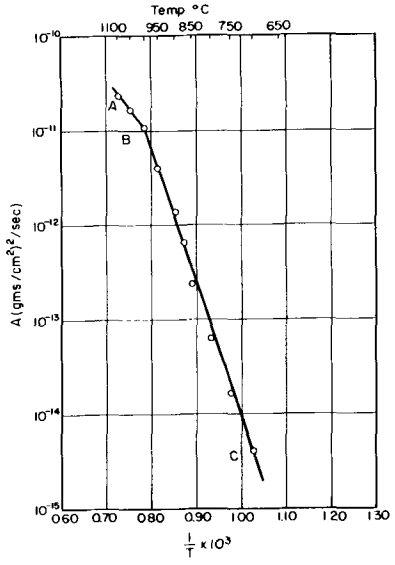

Fig. 12. Oxidation of alloy 245. Log A vs. 1/T, ΔH_{BC} = 65,300 cal/mole.

Strain Oxidation Studies

Samples of alloys 491, 492, 493, and 495 were oxidized individually at 900°C in 7.6 cm Hg of O_2 until a film of 45 $\mu g/cm^2$ was formed. The samples were removed and stretched 2% in a tensile testing machine. The marred surface held in the grips was removed and 4.5-cm length samples used for the reoxidation study.

Parabolic rate law plots of the data show that a 2% strain increased the parabolic rate law constants for the low silicon alloy 493 from 5.73 x 10^{-14} to 9.81 x 10^{-14} $(g/cm^2)^2$ sec^{-1}. A similar plot for the high Si alloy showed the parabolic rate law constants to decrease from 2.82 x 10^{-13} to 1.6 x 10^{-13} $(g/cm^2)^2$ sec^{-1} as a result of the 2 percent strain. Visually 2% strain has not effected the oxide-metal interface.

In addition to the long-term effect on the rate of oxidation a short-term effect was noticed especially on the low Si alloy 493. A rapid pickup of oxygen occurred on reoxidation. This reaction heals some of the damage in the oxide film. A very small short-term effect was noticed for the high Si alloy.

A summary of the effects of strain on the oxidation of the 80 Ni-20 Cr alloys is shown in Table IV.

These experiments indicate that minor elements such as Si and Ca in the alloy can greatly effect the resistance of the oxide and oxide-metal interface to stresses and strains. It is of interest to note that the results of the strain-oxidation test correlate with the ASTM useful life tests.

Crystal Structure Studies

Alloys.—X-ray diffraction studies were made on the alloys to test for the presence of second phases and the effect of minor elements on the lattice parameters of the alloy.

Table V shows the results of x-ray diffraction studies on alloys 493, 495, and 245. The alloys all have the face-centered cubic structure. A trace reflection was found at 2.122Å which suggests the presence of trace amounts of a second phase in the alloy. Three reflections were used in the calculation of the unit cell size a_o. Alloy 495 of the Ni-Cr series had the smallest value for a_o and the best ASTM useful life test. The effect of Al in replacing Ni is to increase the unit cell size.

Table V. Lattice parameters of alloys and pure nickel

Alloy	Composition	Lattice parameter a_o Å
493	Low Si, low Mn + trace elements	3.542 ±0.002
495	High Si, low Mn + trace elements	3.540 ±0.002
245	High Si, high Al	3.547 ±0.002
Ni(16)	Pure	3.52387

Oxide scales.—Crystal structure studies were made on the oxide scales over the temperature range 800°-1100°C. Results are shown in Table VI. A comparison of the crystal structures formed on alloys 493 and 495 shows similar oxide compositions at high temperatures. At 850°C alloy 493 showed Cr_2O_3 plus a trace of NiO while alloy 495 showed Cr_2O_3 alone. Several unidentified reflections were found in both alloys scales. We conclude that small composition differences exist in the oxide films. However, it is unlikely that the observed differences in oxide composition can be correlated with the major differences in performance as measured by the ASTM life test.

Alloy 245 showed $Cr_2O_3 + \alpha - Al_2O_3$ at 850°C. However, at 1100°C the oxide was Cr_2O_3 plus a spinel having a lattice parameter of 8.32Å. The spinel parameter can be compared to a value of 8.32Å for $NiO \cdot Cr_2O_3$ (16) or a value of 8.06Å found for $NiO \cdot Al_2O_3$ (16). The fact that $\alpha - Al_2O_3$ appears in the film at 800°-1000°C and not at 1100°C may be significant. In the 5Al-23Cr-72Fe alloy series Al_2O_3 forms in preference to Cr_2O_3 even at 1100°C.

X-ray diffraction analyses of the oxide scales is subjected to several limitations. (*A*) SiO_2 and other amorphous oxides may not be observed. (*B*) Oxides in amounts of 1-5% or less may not be recorded. (*C*) Oxides may be present in solid solution and not be recorded. (*D*) The chemical or electrochemical

stripping techniques also removed carbides, nitrides as well as oxides which can give extraneous reflections in the x-ray diffraction pattern.

Electron diffraction analyses was also attempted for the thinner oxide films. Many unidentified lines were present in addition to the oxide reflections. These we attribute to carbides, nitrides, etc.

Before a complete picture can be obtained of the oxide composition and crystal structure both x-ray diffraction and electron diffraction methods must be improved. Chemical analyses of these films must also be developed.

Discussion

Effects of Alloying Elements in Oxidation

Alloying elements can affect the nature of the oxidation reaction in several ways. First, the alloying element can affect the thermodynamic activity of the various metals in the alloys (17), the phase diagram of the alloy system, and the substructure of the alloy. Second, the alloying element can affect the composition, crystal structure, and physical and chemical properties of the oxide film (4). The alloying element may participate in the oxide film as follows: (*a*) form its own oxide in the outer layer of the oxide film at the oxide-gas interface, (*b*) form a mixed oxide in the outer layer or in the bulk of the oxide film, (c) form a mixed valency oxide changing the electrical and ionic transport properties of the oxide, (*d*) form its own oxide or compound with other oxides at the metal oxide interface, (*e*) remain in the metal at the metal-oxide interface, and (*f*) form a volatile reaction product.

The individual effect of the alloying element depends on its ionic size, charge, mobility, and thermodynamic activity. Since the chemical activity of the several oxides and the mobilities of the several ion species are temperature dependent, the specific effect of an alloying element may change with temperature.

Most of the elements which improve the performance of the 80Ni-20Cr alloy series are those which form very stable oxides and which do not participate in forming spinels or other oxides in the bulk of the oxide scale. These are: Si, Ca, Zr, Th, Ce, etc. To remain at the oxide-metal interface these elements form oxides which do not react with the major metallic components in the alloy.

Thermochemical Calculations

Table VII shows the principle types of chemical reactions which may occur during the oxidation of Ni-Cr and Ni-Cr-Al alloys. The composition of the oxide film and the distribution of the several oxides within the oxide is determined by the thermodynamic equilibria, the rates of the several chemical reactions, and by diffusion processes in the alloy (17). Calculations are made here only for the equilibrium state involving pure oxides and pure metals since information is not available on rates of diffusion of the metals in the alloys and in the oxides or on the chemical activities of the metals in the alloys.

A standard state of unit activity is assumed for the component metals in the alloy. Compared to the

	Log $_{10}K_P$ (atm.)					
Temp, °C	Ni	Cr	Al	Si	Mn	Fe
900	—11.0	—10.17	—7.6	—11.8	—5.3	
1000	—9.6	—8.8	—6.5	—10.3	—4.4	—9.67
1100	—8.2	—7.63	—5.5	—8.9	—3.5	—8.58
1200	—7.2		—4.7	—7.9	—2.8	—7.62

free energy change of the reaction the activity correction is small. Table VIII shows the dissociation pressures of the oxides from 25°C to 1200°C, as calculated from equations given by Kubaschewski and Evans (18). All of the oxides are stable in the oxidation atmospheres used.

Table IX shows calculations on the equilibrium constants for the several solid phase reactions which determine in part the composition of the oxide scale. Nickel oxide is reduced by Cr, Al, Si, and Mn. Chromium oxide is reduced by Al. For the 80Ni-20Cr alloys the equilibrium oxide should be largely Cr_2O_3. Cr_2O_3 was found experimentally by x-ray crystal structure studies shown in Table VI to be the main oxide in the scale. Although thermodynamic calculations cannot be made for the spinels, $NiO \cdot Cr_2O_3$ appears to be a stable compound since it is found also in the oxide scales.

For alloy 245 containing 4.05% Al, thermochemical calculations suggest the oxide should be Al_2O_3. This compound was observed except at 1100° where Cr_2O_3 and $NiO \cdot Cr_2O_3$ were observed.

Table X shows the vapor pressures of the several metals involved in these alloys. The vapor pressures of Ni, Al, Si, and Mn were calculated from the compilation of Stull and Sinke (19). Data for Fe and Cr were taken from a recent work by Gulbransen and Andrew (7).

According to calculations, Al should volatilize at high temperatures from the metal in vacuum or react at the surface to form Al_2O_3 in oxygen. Since Al_2O_3 forms at 800° and 1000°C but not at 1100°C, Al may be lost from the oxide film possibly as a lower oxide of Al.

Orientation Relationships

Tightly adherent oxide scales are one of the important characteristics of high heat resistant alloys. One of the factors in good adhesion is the matching of lattice parameters in the oxide and metal structures. Matching of lattice parameters is also important in determining the epitaxial relationships.

Bénard has suggested two rules for the directing influence of crystal structures in oxidation (20): (*a*) the oxide tends to orient itself to the metal structure to produce as near a coincidence as possible of the repeat distances between the metal atom in the two structures, and (*b*) planes of high atomic density in the oxide tend to orient to high density atomic planes in the metal consistent with the geometry of the two structures.

The orientation relationships of NiO on face-centered cubic Ni has been studied by Lawless, Young, and Gwathmey (21) and by Newkirk and Martin (22). The (111) plane of NiO was found to grow on both the (001) and (111) planes of the metal. A parallelism was found between the [110] directions of oxide and metal. Newkirk and Martin (22) calculate a 15.6% disregistry between the oxide and metal structures. If these relationships are correct, we must conclude that Bénard's simple rules (20) do not hold for NiO on Ni.

We have made an analyses of the simple repeat distances of $NiO \cdot Cr_2O_3$ formed on Ni-Cr-Al and Ni-Cr face-centered cubic alloys following Bénard's rules. A minimum disregistry is found for the growth of the (100) plane of $NiO \cdot Cr_2O_3$ spinel on the (111) plane of the alloy and a parallelism of the [100] direction of the oxide with the [111] direction of the alloy. However, a large disregistry is found for the [110] direction. Due to the influence of atoms outside of the lattice planes involved, the simple picture of coincidence of repeat distances does not apply for face-centered cubic structures. A more detailed picture of the orientation relationships must be developed to explain the good adherence of $NiO \cdot Cr_2O_3$ in Ni-Cr alloys.

We have not made an analyses of the simple repeat distances of Cr_2O_3 formed on the Ni-Cr and Ni-Cr-Al alloys due to the complexities of the Cr_2O_3 structure. Single crystal studies should be made to determine the orientation relationships for the oxides formed on these good oxidation resistant alloys.

Summary

1. Vacuum microbalance measurements were made on the oxidation of a series of 80Ni-20Cr and a 75Ni-19Cr-4Al heater alloys over the temperature range of 500°-1100°C.

2. Silicon and manganese compositions were varied in the 80Ni-20Cr series of alloy.

3. Kinetic studies showed the low Si and low Mn alloy oxidized at a lower rate than the alloy containing 2% Si. No correlation was formed between ASTM heater life tests and the rate of oxidation of a series of heater alloys.

4. Kinetic data were fitted to the parabolic rate law. However, a number of deviations were observed. For all experiments the initial parabolic rate law constant was larger than the final values found for thicker films. This change was attributed to chemical transitions occurring in the oxide films.

5. Parabolic rate law data plotted on a logarithmic plot as a function of $1/T$ showed two or three straight lines. Heats of activation for the several temperature ranges for each alloy were determined.

6. Strain oxidation studies on the alloys showed good correlation with ASTM life tests. This study suggests that the resistance of the oxide-metal interface to stresses or strain is the most important factor in determining the practical performance of heater alloys. Silicon and the other minor elements appear to help the metal resist the effects of stresses or strains at the oxide-metal interface.

7. X-ray diffraction crystal structure studies were made on three alloys over the temperature range. Cr_2O_3 and $NiO \cdot Cr_2O_3$ spinel were the principal oxides formed for the 80Ni-20Cr alloys. α-Al_2O_3 was found, in addition, on the 75Ni-19Cr-4Al alloy at 800° and 1000°C but not at 1100°C. The latter observation was unexpected.

8. Rate data and crystal structure observation were interpreted from thermochemical calculations in the several chemical reactions occurring in the system. Orientation relationships were also discussed.

Manuscript received Dec. 19, 1958. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Action of Nickel and Cobalt in Electroluminescent Zinc Sulfide Phosphors

Paul Goldberg

Sylvania Research Laboratories, Bayside, New York

ABSTRACT

Nickel and cobalt produce many of the effects in electroluminescent phosphors that are known for photo- and cathodoluminescent zinc sulfide. In addition, these elements bring to electroluminescent phosphors other changes in properties which are of practical and theoretical interest. Among these are (a) enhancement of emittance in blue-emitting phosphors, (b) marked changes in emittance-voltage and emittance-frequency characteristics, and (c) simplification of the brightness wave forms. The frequency and brightness wave effects can be understood in terms of "fast" and "slow" recombination processes which are influenced differently by the iron-group elements. The enhancement of electroluminescence is of uncertain origin but may arise from changes in the photocapacitive properties of the powder crystals due to the iron-group elements. The similarities and differences of nickel and cobalt in both blue and green-emitting phosphors are discussed.

The sensitivity of zinc sulfide phosphors to iron-group elements has a long history (1). Nickel, cobalt, and iron influence the intensity of luminous emission and the rate of luminescence decay in phosphors excited by ultraviolet or cathode rays (2-4). At concentrations much less than the activator content their action is to suppress the emission strongly. Consequently they are termed "killers" or "quenchers." The interpretation of these effects involves trapping and/or recombination of free holes and electrons (3, 5-7) at the killer site. The iron-group elements can influence excitation processes by

introducing absorption bands (8) and also weak emission bands (9).

The purpose of this paper is to discuss the way iron-group elements act in electroluminescent (EL) phosphors. Lehmann already has demonstrated that these elements depress the emittance and induce superlinear emittance-frequency characteristics (10).

In the experiments described below the EL emittance and brightness wave forms were followed as a function of voltage, frequency, and concentration of the iron-group elements. In addition to the effects seen by Lehmann it was found that: (*a*) The emittance of blue-emitting phosphors was increased with additions of 10^{-5} g at./mole or less of the iron-group elements. (*b*) In the range 10^{-5} to 10^{-4} g at./mole of Ni or Co dependencies of emittance on voltage and frequency may undergo marked changes. (*c*) With additions of 10^{-5} to 10^{-4} g at./mole of Ni the brightness waves take on a simplified form.

The ordinary names such as "killers" or "quenchers" given to these elements in the zinc sulfide system are clearly inadequate here. Therefore, in the remainder of this report reference will be made to the elements as "modifiers."

Nickel and cobalt have been shown to influence the dielectric properties of photoluminescent zinc sulfide (11). Also, it is known that the dielectric properties of EL phosphors are of consequence in their response in an electric field (12). Therefore studies were made to trace the importance of these observations on the materials of this report.

Experimental Technique

Phosphors.—The phosphors studied are of the ZnS: Cu,Cl type and contain roughly 3 x 10^{-4} g at. Cu/mole in the case of blue-emitting materials and 1.5 x 10^{-3} g at. Cu/mole for the green-emitting group. The modifiers were introduced during the preparation as aliquots of solutions of the following Johnson-Mathey salts: $Co(NO_3)_2 \cdot 6H_2O$ and $NiSO_4 \cdot 7H_2O$. Not all of the modifier enters the lattice in these preparations as shown in Table I.

For 1 x 10^{-4} g at. Ni/mole and above, the known (8) absorption band of Ni in ZnS appears as a distinct yellow body color.

In subsequent discussions the concentration of modifiers is specified in terms of the amount added in the preparation.

Optical and electrical measurements.—Emittance data were obtained from cells 25 x 25 x 0.125 mm in size with a castor oil dielectric. Brass and transparent conductive glass (500 ohms/square) served as electrode materials. An RCA 1P22 photomultiplier detector was used in conjunction with a Photovolt Model 520 photometer. A rough measure of the emission color was obtained as the blue/green (B/G) ratio with a Corning 4010 filter measuring the green and 5543 and 3389 filters together measuring the blue. The detector for obtaining the brightness waves was a Du Mont 6292 photomultiplier. Dielectric properties of the phosphors were obtained with cells similar to those described above at a field strength too low to give electroluminescent emission. The electrical loss and capacitance data were measured with a *Q* meter (Boonton Radio Co. Model 260-A) in both a dark environment and under room (fluorescent) illumination.

Table I.

Modifier added in the preparation, g at./mole	Ni found in phosphors (green emission) g at./mole	Co found in phosphors (blue emission) g at./mole
Zero (control)	1.3×10^{-6a}	$<8 \times 10^{-7a}$
1×10^{-6b}	1.3×10^{-6}	—
3×10^{-6}	3.6×10^{-6b}	—
1×10^{-5}	0.48×10^{-5}	1.2×10^{-5b}
3×10^{-5}	1.1×10^{-5}	2.3×10^{-5}
1×10^{-4}	0.46×10^{-4}	0.69×10^{-4}
3×10^{-4}	2.3×10^{-4}	1.65×10^{-4}
1×10^{-3}	0.43×10^{-3}	0.49×10^{-3}

[a] Measured by spectrographic analysis, the other data by wet chemical analysis.
[b] The apparent excess found over that added may arise from analytical inaccuracy at low levels of added modifier. The analytical error amounts to ±0.15 x 10^{-5} at the level of 1 x 10^{-5}, and 10% or less at all higher concentrations.

Experimental Results

Frequency Dependence of the Luminous Emittance

Green-emission.—Figure 1 shows the log-log plot of the integrated light output or emittance (*L*) as a function of frequency (*f*) for a family of green-emitting EL phosphors with varying amounts of Ni

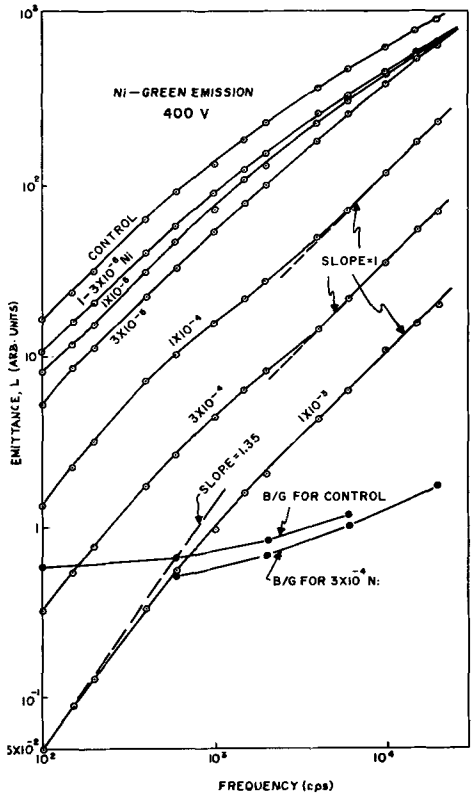

Fig. 1. Emittance-frequency characteristics of green-emitting electroluminescent phosphors with various nickel concentrations, at 400 v. Data for 1 x 10^{-6} and 3 x 10^{-6} g at. Ni/mole are coincident within experimental error.

at 400 v (rms). This family shows many of the characteristics of modifier activity: (*a*) For Ni concentrations up 3 x 10^{-5} g at./mole the *L-f* curves show linearity from 100 cps to nearly 1 kc. At higher frequencies the dependence is sublinear. This is similar to the known behavior of ordinary EL phosphors (15-17). (*b*) The *L-f* characteristics show linear portions at Ni concentrations of 1 x 10^{-4} g at./mole and higher, from frequencies of a few kilocycles up to the limit of measurement at 20 kc.[1] This stands in pronounced contrast to the usual sublinear behavior which sets in at lower frequencies. The effect is approximately independent of voltage. There is a continuing decrease in the average emittance for greater additions of nickel. (c) Superlinearity in the *L-f* characteristics appears at 1 x 10^{-4} g at. Ni/mole and higher. The effect disappears for a given Ni concentration at frequencies above 1 kc and is replaced by the linear behavior described above. The superlinearity is more severe in Co-containing phosphors. As will be shown later, *L* may increase as rapidly as the third power of the frequency. (*d*) There is a convergence at high frequencies of the curves of Ni in range 1 x 10^{-6} to 3 x 10^{-5} g at./mole. (Alternatively, this may be expressed as a decrease in the ability of Ni to suppress electroluminescence as the frequency is increased. The difference in emittance of about 40% between the control sample and that with 1 x 10^{-6} g at. Ni/mole was not found in subsequent preparations.) (*e*) The blue band is quenched more than the green band at higher Ni concentrations. Figure 1 shows the decrease in the B/G ratio upon incorporation of 3 x 10^{-4} g at. Ni/mole. The shift toward the green holds too for phosphors emitting mainly blue light.

The superlinearity and convergence phenomena described above are also brought on by Co. This element however does not provide linear *L-f* characteristics in the kilocycle region for any green-emitting phosphors studied here. Other differences between Co and Ni will be mentioned subsequently.

As a modifier, iron acts somewhat differently. It depresses the brightness with almost no change in the shape of the *L-f* curves. A weak red emission attributable to Fe was observed under field excitation. A similar band was reported previously by Gergely (9) for photoluminescent excitation.

It has been mentioned by others that emittance-frequency investigations should be coupled with temperature studies in order that ambiguous results be avoided (18, 19). However, the shape of the emittance-temperature characteristics of these materials with and without Ni shows a general insensitivity to frequency, except for a scale factor.

Blue-emission.—An analogous pattern to that discussed above is found in EL phosphors emitting mainly blue light. There is however one main difference. The lowest concentrations of modifier effect an enhancement in emittance. Figure 2 shows the *L-f*

[1] The linearity of *L-f* characteristics should be tested with a detector which counts photons. Such results would be unambiguous in spite of color shifts in the emission with frequency. The linearity, e.g., for 1 x 10^{-4} g at. Ni/mole shown in Fig. 1, measured with an RCA 1P22 photomultiplier, is therefore open to some question due to the color shift. In other results, however, e.g. Fig. 3, the linearity is quantitative since color shifts are minimal.

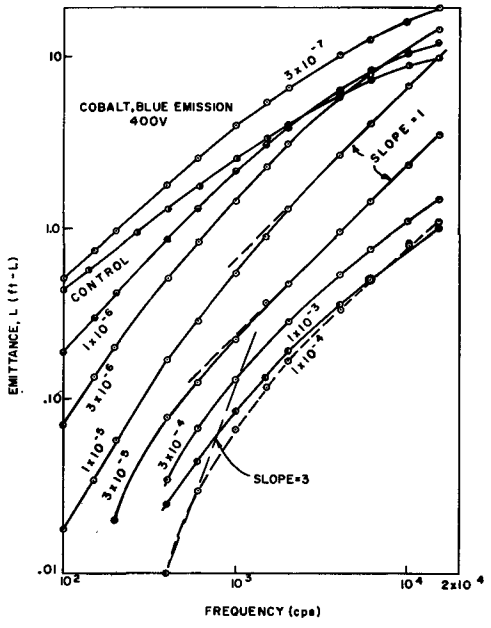

Fig. 2. Emittance-frequency characteristics of blue-emitting El phosphors with various Co concentrations.

characteristics of blue-emitting ZnS:Cu,Cl at various Co concentrations in the range 3 x 10^{-7} to 1 x 10^{-3} g at. Co/mole. The phosphors with 3 x 10^{-7} to 3 x 10^{-6} g at. Co/mole are all brighter than the control at higher frequencies. This increase partially obscures the convergence effect described previously. However, both the superlinearity and linearity relationships are evident. The existence of the enhancement effect has been suggested by Burns (20).

The integrated light output of phosphors containing Ni behave in much the same way as described above for Co although not as strongly. Figure 3 shows a family of curves at various levels of Ni. Cobalt induces superlinearity at 1 x 10^{-6} g at./mole which becomes pronounced at 10^{-4} g at./mole ($L \sim f^3$). Nickel first induces superlinearity at 1 x 10^{-4} g at./mole, and as in Fig. 1, the effect is weak. The emittance enhancement also has been observed for Fe and Cr additions.

The photoluminescence of these materials, in contrast to the electroluminescence, decreases monotonically with increasing modifier content. This is largely in agreement with the work of Arpiarian for the ZnS:Cu, Cl system (2).

A significant difference between Ni and Co in these phosphors is the reappearance of sublinearity in the range 1 x 10^{-4} to 1 x 10^{-3} g at. Co/mole. There is no equivalent to this in the Ni-containing family (cf. Fig. 2 and 3).[2]

Voltage Dependence

The voltage dependence of emittance of EL phosphors can be represented by a variety of empirical formulas. One of these, which receives some support from theory is

$$L = A \cdot f(V) \cdot \exp(-bV^{-1/2})$$

where *L* is the luminous emittance, *V* the rms volt-

[2] The reason the curve for 1 x 10^{-4} Co in Fig. 2 falls below that of 3 x 10^{-4} is not evident. Chemical analyses for Co in the finished phosphors cannot account for it (see Table I) although small temperature gradients during the synthesis may.

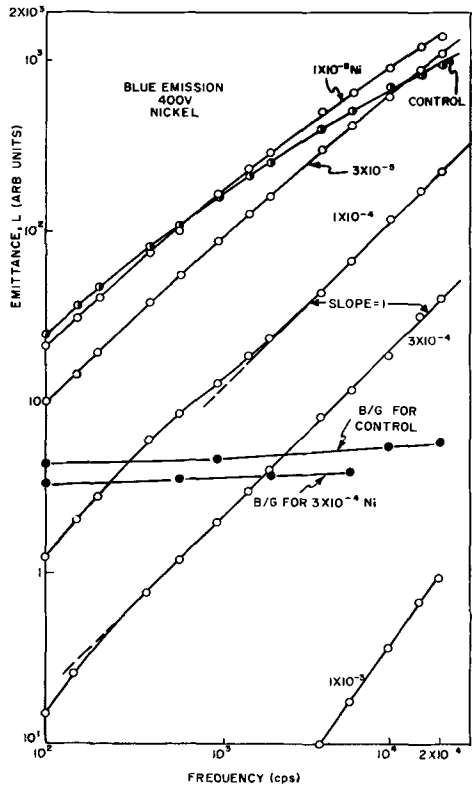

Fig. 3. Emittance-frequency characteristics of blue-emitting EL phosphors with various Ni concentrations.

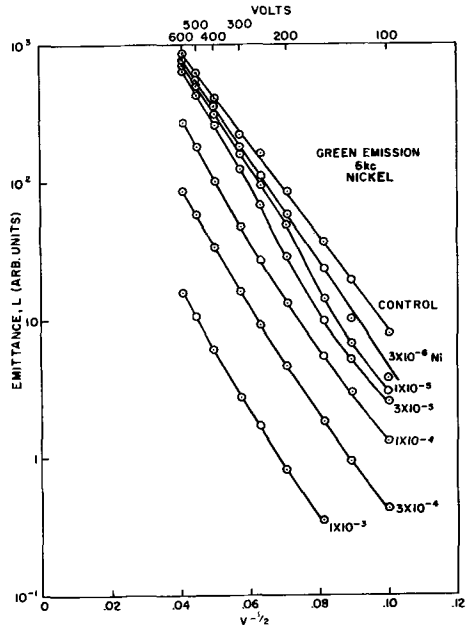

Fig. 4. Emittance-voltage characteristics of green-emitting EL phosphors with various Ni concentrations; $L \sim \exp(-b\ V^{-1/2})$.

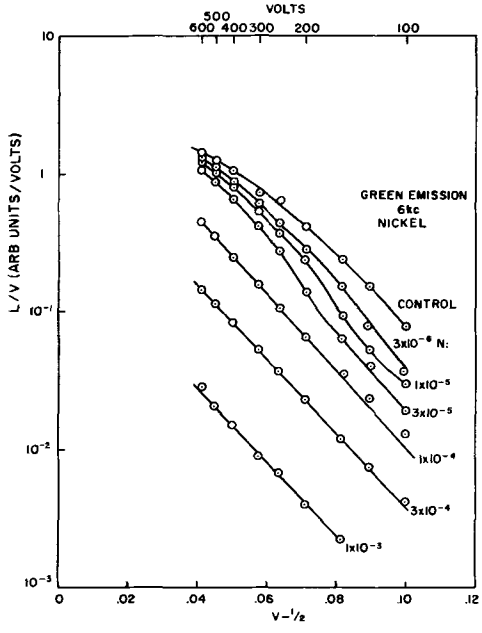

Fig. 5. Data of Fig. 4 plotted according to $L/V \sim \exp(-b\ V^{-1/2})$.

age; A and b are arbitrary constants (15, 18). Experimental work by various investigators shows two functionalities; $f(V)$ = constant (15, 18) or $f(V) = V$ (21). The $f(V)$ term is related to the particular trap distribution in the phosphor (18).

Blue-emission.—Here the behavior on increasing the nickel concentration is almost completely described by changes in the value of the constant A in Eq. [1] with $f(V)$ = const. A similar result was reported by Lehmann for his phosphors (10).

Green-emission.—Phosphors containing either Ni or Co show both functionalities depending on the concentration of modifier. Figure 4 shows the L-V characteristics of the same group of phosphors appearing in Fig. 1, at a constant frequency of 6 kc. It is evident that at Ni contents greater than 1 x 10^{-4} g at./mole, a new voltage dependence has fully developed. This voltage dependence corresponds to $f(V)$ equal to V. Figure 5 presents the data of Fig. 4 replotted such that $f(V)$ equals V (ordinate is L/V). The effect also is found for Co at a concentration one order of magnitude less than for Ni. The change in shape of the voltage characteristic is frequency-dependent. Experiments at 2, 6, and 20 kc all show the effect described above. At 100 and 600 cps, however, no change in shape was detected.

Table II summarizes some of the principal findings on the modifier action on emittance functionalities.

Brightness Wave Forms

Brightness waves have been used widely as a means of following electronic processes relating to electroluminescence in both powders (15, 19, 22-25) and single crystals (26). If the exciting voltage is sinusoidal, the waves show a major (primary) peak and at least one minor (secondary) peak per half cycle of voltage. Also there is usually a continuous component in that the light does not fall to zero at any time during a cycle. Destriau used the intensity of this continuous component as a measure of the mean lifetime of luminescent centers in the excited state (27).

The brightness wave characteristics are changed for phosphors containing modifiers. Figures 6a and 6b show the brightness waves of green-emitting phosphors containing no Ni and 1 x 10^{-4} g at. Ni/mole, respectively, for frequencies of 100 cps, 1 kc and 10 kc at 400 v. The central line in the figures indicates the level of zero light. The principal feature

Table II.

Dominant emission	Frequency dependence	Voltage dependence
Blue—No modifier	Sublinear above 100-200 cps	$L \sim \exp V^{-1/2}$
Low Ni conc., $<10^{-4}$	Sublinear above $\sim$ 600 cps	$L \sim \exp V^{-1/2}$
High Ni conc., $\geq 10^{-4}$	Linear to 20 kc*, superlinear below $\sim$ 400 cps	$L \sim \exp V^{-1/2}$
Low Co conc., $<10^{-5}$	Superlinear below 1 kc	$L \sim \exp V^{-1/2}$
Intermediate Co conc., $\sim 10^{-5}$	Linear to 20 kc, strongly superlinear below $\sim$ 1 kc	$L \sim \exp V^{-1/2}$
High Co conc., $>3 \times 10^{-5}$	Superlinear below $\sim$ 1 kc, sublinear above 1 kc	$L \sim \exp V^{-1/2}$
Green—No modifier	Sublinear above $\sim$ 400 cps	$L \sim \exp V^{-1/2}$
Low Ni conc., $<10^{-4}$	Sublinear above $\sim$ 500-1000 cps	Transition (See Figs. 4, 5)
High Ni conc., $\geq 10^{-4}$	Linear to 20 kc, superlinear below 1 kc	$L \sim V \exp V^{-1/2}$
Low Co conc., $<10^{-5}$ High Co conc., $>3 \times 10^{-5}$	Superlinear below 1 kc, sublinear at higher frequencies	Transition $L \sim V \exp V^{-1/2}$

* 20 kc is the limit of the frequency range examined.

Table III. Dielectric properties of blue-emitting electroluminescent phosphors

	Resistive photocurrent,* μa	ΔK, %	Electro-luminescence enhancement, %, at 15 kc, 400 v	
3×10^{-7} Co [3]	26	6.8	100	(Fig. 2)
No Co [3]	18	29		
1×10^{-6} Ni	10	6.6	45	(Fig. 3)
No Ni	14	30		

* The photocurrent is calculated from the voltage applied by the Q meter oscillator and the equivalent parallel resistance of the test cell.

[3] *Note added in proof*: Activation analyses of these samples show Co concentrations of 1.5 x 10^{-7} g at./mole for "No Co" and 2.0 x 10^{-6} g at./mole for "3 x 10^{-7} Co."

of these curves is the nearly complete absence of secondary peaks and continuous components in the phosphor containing Ni. At lower Ni content an intermediate behavior obtains: reduced height of the secondary peak and also a change in its phase to the descending portion of the primary peak.

The same phenomena result for blue-emitting phosphors. Figures 7a and 7b illustrate equivalent curves for two phosphors previously represented in Fig. 3. The brightness waves of the two Ni-doped phosphors are nearly identical. The phosphors in Figs. 6b and 7b are the same ones which show linear L-f characteristics in Figs. 1 and 3, respectively.

Cobalt-bearing phosphors show a different brightness wave pattern. All phosphors shown in Fig. 2 have brightness waves with a nearly constant continuous component, amounting to about 20% of the amplitude of the primary peaks. At 3 x 10^{-6} g at. Co/mole in that group however, the secondary peak has vanished fully. It reappears again at the same phase angle for all higher Co concentrations.

Dielectric Properties and the Electroluminescent Enhancement Effect

By increasing the matrix dielectric constant one obtains a greater field strength in the phosphor (12). Conversely it may be expected that an increase in the phosphor dielectric constant will reduce the field strength in the phosphor and result in reduced emittance.

In ZnS-type phosphors the dielectric constant increases under photo-excitation (13, 14). It is reasonable that a phosphor, excited to electroluminescence, will absorb part of its own radiation, especially in the blue region. It may then experience the ordinary photocapacitive effect by virtue of that absorption.

Roux has shown that the photocapacitive effect is suppressed by Ni and Co (11). The phosphors in this report which show enhanced emittance in the presence of modifiers may do so because of the suppressed photocapacitive effect and, therefore, because of a resulting higher field strength in the phosphor.

It is difficult to investigate dielectric effects of this sort under conditions of EL excitation because the electrical properties of the cells are dominated by voltage- and frequency-dependent losses (28). However, some information can be obtained by following the dielectric changes in the phosphor induced by external illumination. As mentioned above, this bears a relation to some of the processes in an EL cell, since the emitted radiation itself serves as a source of "external" illumination.

Data given in Table III obtain for phosphors showing electroluminescent enhancement. The results are expressed as the photocurrent and per cent increase in the dielectric constant of the phosphor-matrix mixture on exposure to room light.

The data are consistent with the idea that quenching of the photocapacitive effect is responsible for the electroluminescence enhancement. This is supported by observations that the enhancement occurs almost exclusively in blue-emitting phosphors

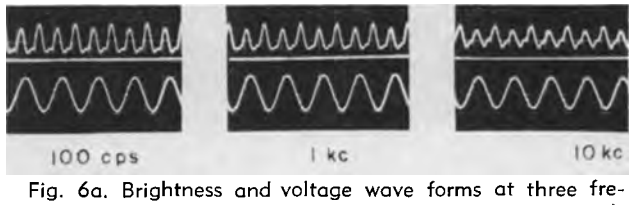

Fig. 6a. Brightness and voltage wave forms at three frequencies for the control phosphor of Fig. 1 (green-emission).

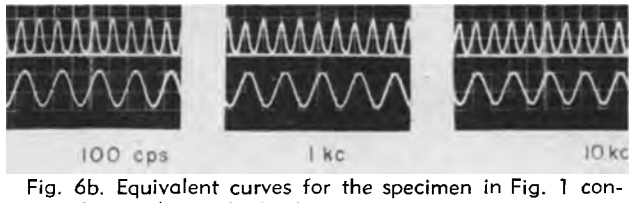

Fig. 6b. Equivalent curves for the specimen in Fig. 1 containing 1 x 10^{-4} g at. Ni/mole.

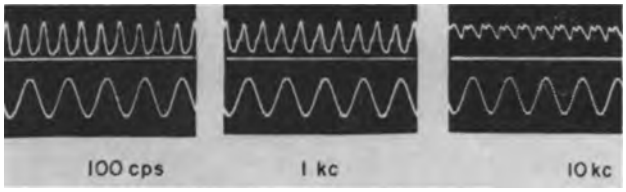

Fig. 7a. Brightness and voltage wave forms at three frequencies for the control phosphor of Fig. 3 (blue-emmission).

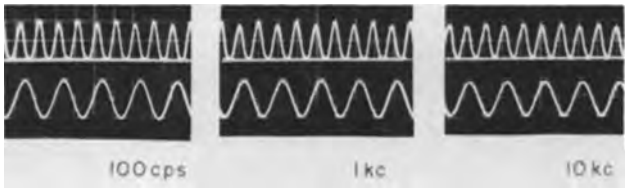

Fig. 7b. Equivalent curves for the specimen in Fig. 3 containing 1 x 10^{-4} g at. Ni/mole.

where self-absorption will tend to be greater than for emission predominantly in the green. Nevertheless, other factors will have to be considered before a definitive explanation of the enhancement is available. Among these are: (*a*) the degree of self-absorption of EL emission in phosphors, (*b*) the effect of such absorption on the phosphor dielectric constant and conductivity, and (c) the detailed field distribution changes within the grains resulting from the self-absorption.

The photocurrent data show that the enhancement is not related to that arising from the photoconductive effects recently reported by Ivey (29) and by Thornton (30). These workers state that external illumination is responsible for shifting the voltage distribution in phosphor crystals in favor of the barrier due to a more conductive bulk. Data in Table I show that the conductivity without Ni is greater than with Ni.

Discussion

Electroluminescence excitation is assumed to arise from impact ionization of luminescent centers by high energy electrons accelerated in a region of high field strength (31, 32). The electrons are swept away from the ionized centers by the field to remote parts of the crystal and contribute to a polarization field or become trapped. The voltage reversal brings many of the electrons back to the excitation region where radiative recombinations occur. The trapped electrons either cannot return at all (deep traps) or return at a later time (shallow traps) following field or thermal release (15, 18, 19, 25). Trapping of these electrons may enhance the continuous component (24). It has been proposed by Zalm, Haake, and others, that electron trapping is responsible for the secondary peak (15, 19).

This physical picture of excitation and recombination will serve as a basis for interpreting the experiments illustrating modifier action. Because Ni and Co behave differently in several respects, e.g., brightness waves and frequency response, they will be discussed separately. We shall refer to an unimpeded electronic recombination as a "fast" process. The delayed emission due to trapping or other causes will be viewed as a "slow" process.

The following model is proposed to account for the experimental result for Ni-bearing phosphors. Nickel offers to both trapped and conduction electrons a radiationless recombination site with a large capture cross section. At intermediate nickel concentrations (1 x 10^{-4} g at./mole) effectively all of the trapped electrons and some conduction electrons are brought back to the activator ground states through these recombination sites. This eliminates the contributions of the slow processes to the brightness waves, namely, the secondary peak and continuous component. Nonradiative escape of electrons from traps in zinc sulfide phosphors containing Ni has been suggested by Leverenz (1) and Kallman and Sucov (33). Only the fast process remains which can follow the field at all audio frequencies. The resulting linear *L-f* relationship of these phosphors up to 20 kc means that the area under each primary peak remains constant with frequency and is dependent only on the voltage. As the frequency is changed, the number of primary peaks per unit of time changes proportionately giving a linear *L-f* response.

At lower Ni concentrations (less than 1 x 10^{-4} g at./mole), the situation is somewhat more complicated. There are not enough recombination sites for all the trapped electrons to be affected. Furthermore, a finite relaxation time is required for the recombination sites to dissipate electronic energy radiationlessly and thereby return electrons to their ground states. The result of this is shown in Fig. 1. At low frequencies (e.g., 100 cps) Ni effects a reduction in brightness at the lowest concentrations. At high frequencies, where the number of conduction and trapped electrons is much larger, the radiationless recombination sites are swamped. The sites are neither numerous enough nor fast enough to be effective. Thus at 10 to 20 kc hardly any quenching action is observed for concentrations up to 3 x 10^{-5} g at. Ni/mole. Further increases in modifier concentration provide sufficient recombination centers, and the emittance is diminished at all frequencies. The concept of rapid capture and relatively slow release by radiationless recombination centers was suggested by Nail, *et al.* (4) as one explanation of superlinear photoluminescence in (Zn,Cd)S:Ag, Cl-Ni.

When large numbers of free electrons are produced by a voltage increase rather than by a frequency increase, the same result is observed. Figure 4 shows that for low modifier levels, the quenching action is more effective at low voltage (small supply of free electrons) than at high voltage (large supply of free electrons).

Zalm suggests that superlinearity in brightness-frequency characteristics is to be expected if the escape of holes to the valence band from ionized centers occurs (15). It is in these terms that the superlinearity seen in Fig. 1, 2, and 3 can be described. The presence of the modifier atom is assumed *ad hoc* to promote the escape of holes. Following this escape the electrons and holes recombine radiationlessly. The escape of holes to the valence band may have an appreciable relaxation time.

When the period of a cycle becomes smaller than this relaxation time superlinearity disappears. This is the case for frequencies above 1 kc in most of the samples studied.

The differences between Co and Ni as a modifier of electroluminescence has a direct counterpart in differences found in photoluminescence (3) and glow curve data (5). It can be argued, although with some reservations, that Ni serves as a recombination center but introduces no new trapping levels of importance to electroluminescence, while Co does both. One can then associate the continuous component and secondary peak in the brightness waves of Co-doped phosphors with this trapping level as well as the return to sublinearity in the L-f curves of Fig. 2. This argument is admittedly incomplete in that sublinearity returns in Fig. 2 at 1×10^{-4} g at. Co/mole while the secondary peak returns at 1×10^{-5} g at. Co/mole.

In one sense Co and Ni act alike. They both are able to change the shape of the voltage characteristic of green-emitting phosphors at frequencies above 1 kc (see Table II). This behavior is then a function of the activator (and/or coactivator) concentration as it is not found in blue-emitting phosphors. Thus it may be related to the particular trap distribution within the phosphor.

Duboc (34) and Klasens (35) discuss the processes in a two-level model which can introduce various functionalities in photoluminescence of photoconduction vs. exciting intensity. In spite of this, it does not seem profitable at the present time to fit the electroluminescence data into the band scheme in detail greater than that already done above. One must make assumptions to fit the models of Duboc and Klasens: (*a*) that the frequency in the electroluminescence case and the exciting light intensity in the photoluminescence case are comparable variables, and (*b*) that ZnS:Cu,Cl-Co/Ni is adequately represented by a two-state band scheme. These assumptions seem too restrictive for the present.

Acknowledgments

It is a pleasure to thank Drs. D. H. Baird, B. E. Bartels, A. L. Solomon, and R. N. Summergrad for many helpful discussions. The able assistance of J. W. Culp, S. Faria, and J. T. Ragusin in the synthesis of phosphors and in carrying out some of the measurements is acknowledged gratefully. Thanks are due J. Cosgrove and R. Weberling for analytical data.

Manuscript received April 17, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Optical Properties of Tin- and Lead-Activated Calcium Metasilicate Phosphors

Richard W. Mooney

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

The preparation and optical properties of two new tin-activated calcium metasilicate phosphors are described. The more efficient of these is a β-$CaSiO_3$: Sn phosphor emitting in the visible at about 520 mμ. The optical properties of the tin-activated species are compared to their lead-activated analogues; and from considerations of crystal structure as affected by firing temperature and activator concentration, it is concluded that changes in spectra result from changes in crystal structure and not from the degree of aggregation of the activator ions. It is suggested that the emission spectra correspond to the $^3P_1^0 \rightarrow {}^1S_0$ and the $^1P_1^0 \rightarrow {}^1S_0$ transitions of the lead- and tin-activator centers.

Calcium metasilicate activated by lead and manganese is a well-known phosphor with a visible emission band at 610 mμ and an ultraviolet emission band at about 350 mμ (1-3). A study of the effect on crystal structure (4) showed that the inversion temperature of β-$CaSiO_3$ (wollastonite) to α-$CaSiO_3$ (pseudowollastonite) is raised with increasing manganese concentration in agreement with results reported by Voos (5), who showed that $MnSiO_3$ (rhodonite), being an isomorph of β-$CaSiO_3$, forms mixed crystals with wollastonite. A more recent study (6) of the influence of crystal structure on β-$CaSiO_3$: Pb + Mn showed that at temperatures where both wollastonite and pseudowollastonite are formed, the manganese crystallizes in the wollastonite lattice to the extent that a red shift is produced by the concentration of manganese in the β-$CaSiO_3$, structure. It was shown also that the addition of magnesium oxide to calcium metasilicate increased the inversion temperature of β-$CaSiO_3$ to α-$CaSiO_3$, whereas the addition of strontium oxide lowered the inversion temperature thus favoring the formation of pseudowollastonite.

The calcium silicates activated by lead alone were studied in detail by Studer and Fonda (7). They found several emission bands in the ultraviolet which they attributed to differences in crystal structure as follows: two bands at 300 mμ and 385 mμ to α-$CaSiO_3$: Pb, a 345 mμ band to β-$CaSiO_3$: Pb, and a 334 mμ band to β-Ca_2SiO_4: Pb. The corresponding excitation spectra varied widely with several maxima between 200 and 300 mμ. In a later study of the mechanism of sensitized luminescence of solids, Schulman and co-workers (8) claimed that the differences in emission were due to differences in the nature of the lead activator center rather than to changes in crystal structure. Specifically, they claimed that the emission bands at 290 and 390 mμ in $CaSiO_3$: Pb were caused by Pb^{2+} singlet centers, i.e., Pb^{2+} activator ions which had no other Pb^{2+} nearest neighbors; whereas the single-band emission at 340 mμ observed at higher lead concentrations was attributed to the occurrence of Pb^{2+}-Pb^{2+} doublets or higher aggregates of Pb^{2+} ions, i. e., centers which had 2 or more Pb^{2+} ions in neighboring cation positions.

Due to the similarities in electronic configuration between lead and tin and the resulting similarities in chemical behavior, it was thought that tin also might function as an activator in the calcium silicate system. In addition, previous work on tin-activated phosphates (9) had shown that many of the tin-activated phosphors were moderately efficient. A study of the calcium silicate system activated by tin has shown that there are at least four phosphors present, two having metasilicate structures and two having orthosilicate structures. This paper gives the preparation and properties of tin-activated β-$CaSiO_3$ (wollastonite) and tin-activated α-$CaSiO_3$ (pseudowollastonite) and compares their spectra with their closely related lead-activated analogues. The preparation and properties of the tin-activated calcium orthosilicates will be reported in a later paper.

Experimental Procedure

Calcium carbonate and silicic acid were mixed in a mole ratio of 1.00 to 1.20 together with 0.01-10.0 mole % of stannic or stannous oxide for the tin-activated phosphors, or lead oxide for the lead-activated phosphors. The mixture was pebble-milled in a deionized water slurry, dried at 110°-120°C, and fired in silica trays at temperatures varying from 980°-1320°C depending on the particular crystal form desired. For maximum efficiency it was necessary to fire in a steam atmosphere, and since the tin-activated phosphors luminesce only when the tin is in a lower valence state, a reducing atmosphere, usually a mixture of hydrogen and steam, was maintained. The steam and hydrogen contents of the firing atmosphere were controlled carefully in order to obtain reproducible results.

The crystal structures of the phosphors were determined by conventional x-ray diffraction techniques using CuKα radiation from a Philips Norelco unit. In the majority of cases, identification was made by means of Debye-Scherrer powder patterns taken with large diameter (114.6 mm) cameras. In

Table I. Effect of tin-activator concentration on the inversion temperature for β- to α-$CaSiO_3$*

a few cases, diffractometer tracings were taken on a Norelco wide-range goniometer at a scanning speed of 1/4°/min. As would be expected, the two methods were in excellent agreement.

The quantitative analyses for per cent tin and per cent lead were made as follows. For tin the sample was dissolved in HCl, treated with lead to reduce any stannic tin to the stannous state, and then titrated at 10°C with a standard iodine solution. The determination of per cent lead was slightly more complicated. The sample was first decomposed with HF plus H_2SO_4 followed by a Na_2CO_3 fusion. The resulting $PbCO_3$ was dissolved in HNO_3 and precipitated as $PbMoO_4$ by a solution of $(NH_4)_2MoO_4$. The precipitate was filtered, washed, and fired. The activator contents are expressed in this paper as gram-atom tin or lead per gram-mole of $CaSiO_3$, i.e., as mole fraction.

The excitation-emission radiometer[1] used for the measurements of excitation and emission spectra will be described in detail elsewhere (10). Basically, it is a double monochromator system with a high-pressure xenon arc source and a 1P28 photomultiplier detector. A combination of optical and electrical components provides for constant-energy-level illumination of the sample during excitation measurements and gives an emission spectrum which is proportional to the true energy output of the sample regardless of source fluctuations or detector sensitivity as a function of wave length.

Results with $CaSiO_3$: Sn

A preliminary study of firing temperature disclosed that the more efficient β-$CaSiO_3$: Sn phosphor was obtained with good brightness between 1090° and 1150°C, whereas the less efficient α-$CaSiO_3$: Sn phosphor always was obtained at temperatures above 1150°C. Later it was found that the inversion temperature for β- to α-$CaSiO_3$ was dependent on the activator concentration as shown in Table I. In general, the results were in reasonable agreement with the phase diagram of Levin, McMurdie, and Hall (11) who list the inversion temperature of β- to α-$CaSiO_3$ as 1125°C.

It also was shown that the addition of other divalent cations changed the inversion temperature. For instance, the addition of oxides or fluorides of magnesium, zinc, or cadmium increased the optimum firing temperature for β-$CaSiO_3$: Sn to 1200°C and over, thus indicating an increase in the inversion temperature or a stabilization of the wollastonite structure. Conversely, the addition of the carbonates or fluorides of strontium and barium lowered the optimum firing temperature indicating a stabilization of the pseudowollastonite structure. For barium fluoride, for instance, optimum brightness was obtained at 980°C. These results agree in principle with those of Lange and Kressin (6) in that the addition of ions smaller than calcium, such as magnesium, stabilize the β-$CaSiO_3$ structure, whereas the addition of ions larger than calcium, such as strontium, stabilize the α-$CaSiO_3$ structure.

The phosphor β-$CaSiO_3$: Sn emits in the green with a peak of about 518 mμ when excited by 254 mμ radiation. The corresponding excitation spectrum has a maximum at 246 mμ. Plots of emission and excitation spectra of β-$CaSiO_3$: Sn are shown in the top half of Fig. 1. The emission spectrum is non-Gaussian indicating the possibility of a second unresolved emission band on the high-energy side of the peak. All samples identified as β in Table I gave an emission spectrum as shown in Fig. 1 with the exception of the sample containing the least tin (4.5 x10^{-4} gram-atom Sn/$CaSiO_3$) fired at both 1120° and 1150°C, for which an emission peak at 400 mμ as well as the usual peak at 518 mμ was obtained. This peak was not observed in unactivated samples. The excitation spectrum is characteristic of that obtained for tin-activated phosphors, i.e., broad, indicating the presence of several unresolved absorption bands. The fluorescence of β-$CaSiO_3$: Sn persists at low brightness after the exciting radiation is removed. No quantitative measurements of decay time were made.

The phosphor α-$CaSiO_3$: Sn is weakly fluorescent having two emission bands peaking at 562 and 450 mμ as shown in the top half of Fig. 2. All samples identified as α by x-ray diffraction gave the two peaks shown in Fig. 2 again with the exception of the sample having the least tin (4.5 x 10^{-4} gram-atom Sn/$CaSiO_3$). This sample fired at 1205°, 1260°, and 1320°C showed evidence of the 400 mμ band, although its definition was not as good as that obtained with the β-structure due to the 450 mμ band in the α-$CaSiO_3$: Sn phosphor. Those samples identified as a mixture of α- and β-$CaSiO_3$: Sn in Table I gave a broad band emission extending from 562 to

450 mμ, since the superposition of the α- and β-$CaSiO_3$:Sn emission gave bands at 562, 518 and 450 mμ which overlapped each other. There was no evidence of the 518 mμ band ascribed to β-$CaSiO_3$:Sn in samples fired at 1205°, 1260°, and 1320°C for the lowest or the highest tin concentration (mole fractions of 4.5×10^{-4} and 4.2×10^{-2}, respectively). The excitation spectra again consisted of several absorption bands as shown in the top half of Fig. 3. It is noteworthy that emission in the lower energy band (562 mμ) is favored by absorption at higher energies, i.e., the excitation spectrum is shifted toward higher energies for fluorescence in the red.

The addition of manganese gave rise to a new emission band at 610 mμ in addition to the band at 518 mμ. Manganese is especially effective in stabilizing the low temperature or β-form of $CaSiO_3$ and, therefore, firing temperatures as high as 1260°C with manganese present still gave the β-$CaSiO_3$ structure. The phosphor β-$CaSiO_3$:Sn + Mn is very similar to the well-known phosphor β-$CaSiO_3$:Pb + Mn (1-3) with the obvious difference in emission between tin- and lead-activation being demonstrated by the presence of the 518 mμ band due to tin rather than the 350 mμ band due to lead. Due to the close proximity of the tin band at 518 mμ and the manganese band at 619 mμ, an increase in manganese concentration produced an apparent shift in the peak emission due to a decrease in intensity of the tin band and an increase in intensity of the manganese band. The tendency of manganese to crystallize in the rhodonite-wollastonite structure stabilized the β-$CaSiO_3$ form over wide Ca/Si ratios (even up to 2.00/1.00 where Ca_2SiO_4 should form) as well as wide temperature ranges.

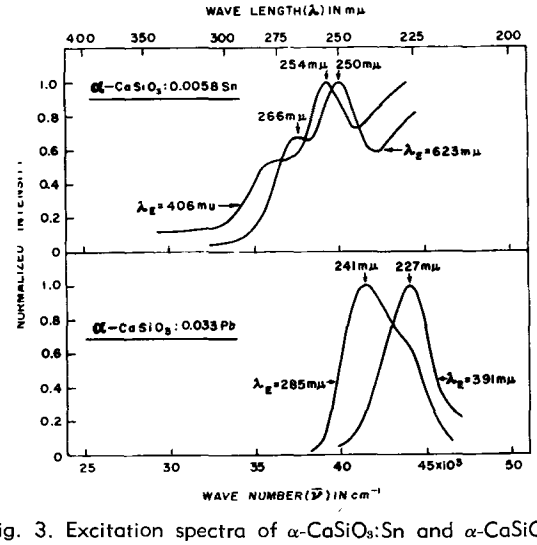

Fig. 3. Excitation spectra of α-$CaSiO_3$:Sn and α-$CaSiO_3$:Pb with activator concentrations given in atoms retained in the fired phosphor per mole $CaSiO_3$.

Results with $CaSiO_3$:Pb

A corresponding study of the lead-activated calcium metasilicates gave very similar results to those obtained on the tin-activated system. Thus, β-$CaSiO_3$:Pb was obtained below 1150°C, whereas the less efficient α-$CaSiO_3$:Pb phosphor always was obtained above 1150°C. Again the particular modification obtained at temperatures close to the transition temperature was dependent on the activator concentration (see Table II).

The β-$CaSiO_3$:Pb phosphor emits in the ultraviolet at about 340 mμ when excited by 254-mμ radiation. The corresponding excitation spectrum has its maximum at 255 mμ. Both the emission and the excitation spectra have Gaussian distributions as shown in the bottom half of Fig. 1. All samples identified as β in Table II had excitation and emission spectra as above. There was no evidence of a second emission band at very low concentrations, but the peak of the emission band did shift slightly from 337 to 350 mμ in going from the lowest to the highest lead concentration.

All lead-activated calcium metasilicates fired above 1150°C had the α-$CaSiO_3$ structure and displayed emission and excitation spectra characteristic of those shown in the bottom halves of Fig. 2 and 3. Thus α-$CaSiO_3$:Pb has two emission bands at 295 and 376 mμ and two corresponding excitation bands at 241 and 227 mμ. It is interesting, however, that irradiation in the lower-energy band at 241 mμ produced the higher energy band at 295 mμ, whereas irradiation in the higher energy band at 227 mμ caused the lower energy band at 376 mμ to appear. That is, the direct energy relationship between excitation and emission that one normally would expect is reversed. Those samples in Table II which were identified as a mixture of α- and β-$CaSiO_3$ gave all three emission bands depending upon the wave length of excitation. However, the greater absorption of β-$CaSiO_3$:Pb compared to α-$CaSiO_3$:Pb at the

Table II. Effect of lead-activator concentration on the inversion temperature for β- to α-$CaSiO_3$*

1120	β	$\beta(\alpha)$	$\beta(\alpha)$	$\beta(\alpha)$	$\alpha(\beta)$

* Minor constituent given in parentheses.

higher wave lengths made the β-$CaSiO_3$: Pb emission spectra predominant even for the sample containing 0.085 Pb/$CaSiO_3$ fired at 1120°C and identified as primarily α-$CaSiO_3$ (see Table II). Therefore, the emission spectra of lead-activated $CaSiO_3$ fired in the neighborhood of the inversion temperature exhibited the following characteristics with increasing lead content. At very low lead concentrations, the β-$CaSiO_3$: Pb band appeared at 337 mμ. As the structure changed to a mixture of β- plus α-$CaSiO_3$, all three bands appeared, and finally the β-$CaSiO_3$: Pb band now at 350 mμ was again the only band found at high lead concentrations. On the contrary, samples fired at 1260°C having the lowest (0.001) and the highest (0.085) lead concentrations exhibited only the typical α-$CaSiO_3$: Pb bands.

Discussion

The obvious conclusion to be drawn from these results is that the excitation and emission spectra of tin- and lead-activated calcium metasilicates are determined primarily by the particular activator used and the crystal structure of the matrix in which the activator is found. This conclusion is in agreement with the original work on lead-activated calcium metasilicates by Studer and Fonda (7), but is in sharp disagreement with the later work by Schulman, Ginther, and Klick (8), who ascribed the differences in spectra observed on lead-activated calcium metasilicates to the occurrence of singlet Pb^{2+} activator centers at low lead concentrations and doublet Pb^{2+}-Pb^{2+} activator centers at higher lead concentrations.

According to this later work, the singlet Pb^{2+} centers are excited only by absorption in the 235 mμ band, which is shown by Fig. 3 to be in reality two bands peaked at 227 and 241 mμ, and which gives a double-band emission peaked at 290 and 390 mμ (295 and 376 mμ according to Fig. 2). In this work, these paired excitation and emission bands are ascribed to the phosphor, α-$CaSiO_3$: Pb.

The 255 mμ absorption band with single-band emission peaking at 340 mμ was assigned to the presence of Pb^{2+}-Pb^{2+} doublets by Schulman, *et al.* However, while the experimental agreement between the measured spectra is excellent (see Fig. 1), the present work claims that these bands are associated with the β-$CaSiO_3$: Pb phosphor.

The evidence for these assumptions is given by a comparison of the spectra of the lead-activated calcium metasilicates as a function of activator concentration and firing temperature coupled with x-ray identification of the crystal structures of the phosphors. Thus, as related under results, phosphors fired at temperatures close to the inversion temperature (1125°C), i.e., at 1120° and 1150°C, have varying spectra depending upon the activator concentration and its effect on crystal structure. At very low lead concentrations, the spectra are characteristic of β-$CaSiO_3$: Pb as would be expected from the x-ray identification. At intermediate lead concentrations, the spectra are mixtures of that expected from β- and α-$CaSiO_3$: Pb. However, at the highest lead concentrations, the spectra are once more characteristic of β-$CaSiO_3$: Pb, whereas one would expect to find the α-$CaSiO_3$: Pb spectrum in view of the x-ray identification. To explain this result, it must be remembered that with increasing lead concentrations, the phosphors are becoming less efficient due to concentration quenching; and, since the α-$CaSiO_3$: Pb phosphor is inefficient even at low activator concentrations, its emission at high lead concentrations is below the limits of detection of the instrument. These results are in rough agreement with the observation of Schulman, *et al.*, as would be expected, since they used a firing temperature of 1150°C where both β- and α-$CaSiO_3$ may be formed under the right conditions.

The above observations are not convincing proof since the spectra of the phosphors are confused by crystal structure changes. However, it has been noted that firings above 1150°C gave only the α-$CaSiO_3$ structure. If the differences in spectra are due to the occurrence of lead singlet or doublet centers, these differences should depend only upon the activator concentration and not on the firing temperature with its effect upon crystal structure. Therefore, the experimental observation that lead-activated calcium metasilicates fired at 1260°C exhibited only the spectral characteristics of α-$CaSiO_3$: Pb as shown in Fig. 2 and 3 and never the spectrum of β-$CaSiO_3$: Pb as shown in Fig. 1, completely independent of activator concentration leads to the conclusion that the spectra are determined by the crystal structure and not by the degree of aggregation of the activator ions. The same conclusion also may be reached from the results on the tin-activated calcium metasilicate system.

The previous observation (8) that irradiation in the 235 mμ absorption band does not excite the visible Mn^{2+} emission in $CaSiO_3$: Pb + Mn is explained easily by the fact that Mn crystallizes preferentially in the β-$CaSiO_3$ lattice (5, 6) and therefore it is necessary to excite the Pb atoms in β-$CaSiO_3$: Pb, which absorbs at 255 mμ, but not at 235 mμ.

As usual in studies of this type, it is easier to demonstrate the incorrectness of a previous model than it is to propose with any degree of assurance a model which does explain the experimental observations. Due to the complexity of the silicate crystal structures and the resulting complex symmetry of their crystalline fields, it is not possible to explain the results in a quantitative manner as has been done for KCl: Tl (12). However, some rather interesting speculations concerning the nature and origin of the emission bands may be made. For instance, since the electronic configurations of the ground states of Tl II (Tl^+) and Pb III (Pb^{2+}) are identical and that of Sn III (Sn^{2+}) is very similar, having a $5s^2\ {}^1S_0$ ground state instead of the $6s^2\ {}^1S_0$ ground state of Tl II and Pb III, one might expect lead- and tin-activated phosphors to behave generally much like thallium-activated systems.

Therefore, proceeding by analogy with KCl: Tl, the higher energy emission bands in both tin- and lead-activated α-$CaSiO_3$ might be assumed to arise from the ${}^1P_1^0 \rightarrow {}^1S_0$ transition and the lower energy bands to arise from the ${}^3P_1^0 \rightarrow {}^1S_0$ transition of the activator

centers. Similarly, in view of its relative position with reference to the emission bands in the α-structure, the single band in tin- and lead-activated β-$CaSiO_3$ could be assigned arbitrarily to the $^3P_1^0 \rightarrow {}^1S_0$ transition. Such assignments of energy levels are not inconsistent with the trends that one should expect by comparison to the same energy level transitions for the free ions (13). However, the assignment of the $^3P_1^0 \rightarrow {}^1S_0$ transition to the green emission band in β-$CaSiO_3$:Sn is not consistent with the phosphorescence observed, which suggests a forbidden transition, whereas the $^3P_1^0 \rightarrow {}^1S_0$ transition is allowed if the selection rule $\Delta S = 0$ does not hold due to imperfect LS coupling.

In summary, it has been shown that the spectra of tin- and lead-activated calcium metasilicates are associated with the particular structure produced, i.e., α- or β-$CaSiO_3$ and not with the degree of aggregation of the activator ions. Instead it is suggested that the emission bands in both tin- and lead-activated α-$CaSiO_3$ are related to the $^3P_1^0 \rightarrow {}^1S_0$ and the $^1P_1^0 \rightarrow {}^1S_0$ transitions of the activator ions and that the single emission band in β-$CaSiO_3$:Sn or Pb is related to the $^3P_1^0 \rightarrow {}^1S_0$ transition, although the reason for the occurrence of a $^1P_1^0 \rightarrow {}^1S_0$ transition in the α-$CaSiO_3$ structure and not in the β-$CaSiO_3$ structure is not understood.

Acknowledgment

The author is indebted to several of his colleagues for their help with the preparations and measurements. Specifically, the author wishes to thank Mr. F. N. Shaffer for his aid and advice in the preparation of the first Sn-activated metasilicates, Dr. C. W. W. Hoffman for the x-ray identifications, and Mr. G. J. Meisenhelter for the analytical determinations. The author also wishes to acknowledge the advice and encouragement of Dr. J. S. Smith during the progress of this work.

Manuscript received May 18, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Phase Equilibria and Manganese-Activated Fluorescence in the System $Zn_3(PO_4)_2$-$Mg_3(PO_4)_2$

J. F. Sarver, Fred L. Katnack,[1] and F. A. Hummel

Department of Ceramic Technology, College of Mineral Industries,

The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Determination of the phase relationships on the $Zn_3(PO_4)_2$-$Mg_3(PO_4)_2$ join by the quench method has enabled the previously designated "gamma zinc phosphate" to be identified as a solid solution of zinc orthophosphate in magnesium orthophosphate. $Mg_3(PO_4)_2$ takes 95 mole % $Zn_3(PO_4)_2$ into solid solution at 1000°C. β-$Zn_3(PO_4)_2$ takes a small amount of $Mg_3(PO_4)_2$ into solid solution (about 3 mole % at 1000°) and, in order to satisfy the requirements of the Phase Rule, α-$Zn_3(PO_4)_2$ must take a small amount of $Mg_3(PO_4)_2$ into solution. The previously determined $Zn_3(PO_4)_2$-$Mn_3(PO_4)_2$ relationships are discussed in terms of the new data for the zinc-magnesium orthorphosphate system. Solid solution relationships in the system MgO-ZnO-P_2O_5 are diagrammed and discussed.

Data on peak emission and brightness of the β-$Zn_3(PO_4)_2$ solid solution and the $Mg_3(PO_4)_2$ solid solution were obtained using molar substitutions of manganese as an activator. The brightness of the β-$(Zn,Mg)_3(PO_4)_2$:Mn solid solutions compares favorably with commercial β-$Zn_3(PO_4)_2$:Mn phosphors and the N.B.S. standard. The manganese-activated phosphors near the high zinc end of the $Mg_3(PO_4)_2$ solid solution series are very bright relative to the β-$Zn_3(PO_4)_2$:Mn standard, but they peak near 6280Å, which may in part account for the higher brightness.

This paper is the last of a series which was intended to establish the identity and the manganese-activated emission characteristics of the α, β, and "gamma" zinc orthophosphate family of cathode-ray excitable phosphors. A second purpose in accumulating these data was to establish a general picture of the phase relationships in the system MgO-ZnO-P_2O_5.

The work of Smith (1) led to the development of these red fluorescing T.V. phosphors and the adoption of the alpha, beta, and "gamma" nomenclature.

Katnack and Hummel (2) established the nature of the alpha to beta zinc orthophosphate inversion and later Hummel and Katnack (3) furnished data on the manganese-activated cathode-ray emission characteristics of all the zinc phosphate compounds.

Recent work by Sarver and Hummel (4) established the nature of manganese-activated cathode-ray emission in the system $Mg(PO_3)_2$-$Zn(PO_3)_2$.

Experimental Procedure

Phase relationships.—The equilibrium relationships in the system were established using the seventeen compositions shown in Table I. The raw materials used were C.P. grades of ZnO, basic magnesium carbonate, and dibasic ammonium phosphate, $(NH_4)_2HPO_4$. The starting material for quench determinations in compositions 1-7 was a fused and recrystallized melt which had been held at 750°C for 24 hr. The starting material for the remaining portion of the work (compositions 8-17) was a calcine which had been heated to 200°C for 24 hr.

Phase identifications were made by petrographic and x-ray diffraction examination, using nickel-filtered CuKα radiation for the latter method.

Fluorescence.—Two sets of data on manganese-activated, cathode ray emission were obtained. The first series included data on the β-$(Zn,Mg)_3(PO_4)_2$:Mn solid solutions and a wide range of $(Mg,Zn)_3(PO_4)_2$:Mn ternary solid solutions. The second series included a brief investigation of the manganese activator concentration on the peak emission and brightness of one of the brightest compositions in the high zinc end of the $(Mg,Zn)_3(PO_4)_2$ solid solutions.

Spectral distribution curves were obtained with a demountable cathode-ray tube operating at 16 kv anode potential, 1.0 μa/cm^2 beam current density on a standard scan T.V. raster of 65 cm^2 area.

Brightness under the above conditions was measured using an eye-corrected Weston foot-lambert meter.

Results and Discussion

Phase Relationships on the Orthophosphate Join

The quench and heat treatment data shown in Table I were used to construct the equilibrium diagram shown in Fig. 1. The system is characterized by a small region of β-$Zn_3(PO_4)_2$ solid solutions, a still smaller region of α-$Zn_3(PO_4)_2$ solid solutions, and a very large region of $Mg_3(PO_4)_2$ solid solutions. The x-ray diffraction data for the β-$Zn_3(PO_4)_2$ and

β-Z_3P = β-$Zn_3(PO_4)_2$
M_3P = $Mg_3(PO_4)_2$

α-$Zn_3(PO_4)_2$ phases have been presented in a previous paper (2). The presence of magnesium in solid solution in the α and β phases produced no appreciable shift in the position of the lines in the x-ray diffraction pattern.

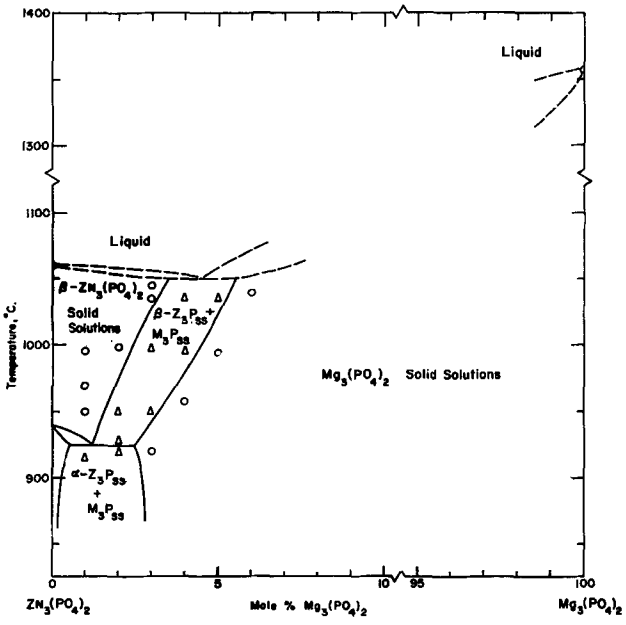

Fig. 1. Phase relationships on the $Zn_3(PO_4)_2$-$Mg_3(PO_4)_2$ join

The x-ray diffraction data for $Mg_3(PO_4)_2$, solid solutions containing 20, 40, 60, 80, and 95 mole % $Zn_3(PO_4)_2$, and the previously reported (3) manganese "gamma zinc orthophosphate" are listed in Table II. The patterns of the magnesium orthophosphate solid solutions are shown in Fig. 2 for convenience in following the changes which occur. A detailed study of the x-ray diffraction patterns of all the members of the $Mg_3(PO_4)_2$ solid solution compositions (7-17) listed in Table I showed that the series was actually continuous from pure $Mg_3(PO_4)_2$ to 95 mole % $Zn_3(PO_4)_2$. Petrographic examination confirmed the one phase nature of the compositions in this region.

Since the system was not glass-forming, the liquidus relationships were not determined and the phase boundaries in the high-temperature region are shown as dashed lines due to this uncertainty. Berek (5) reported the melting point of $Mg_3(PO_4)_2$

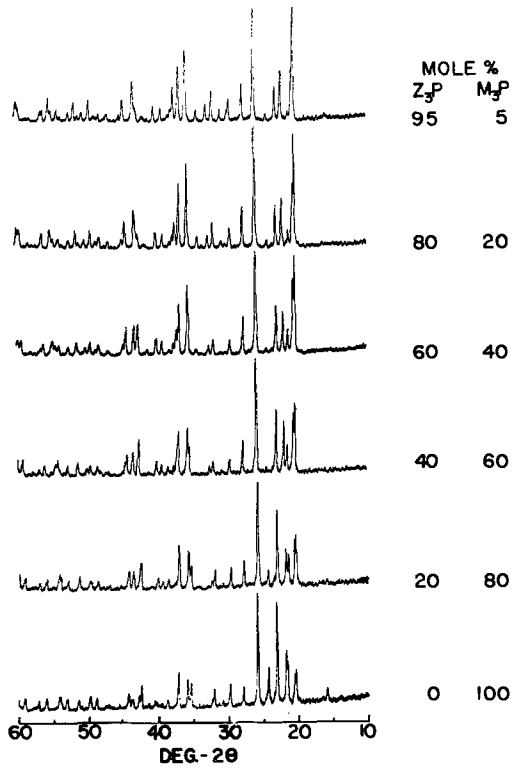

Fig. 2. X-ray diffraction patterns for magnesium orthophosphate solid solutions.

as 1357°C, and this value has been used in constructing Fig. 1.

A word about the previously determined relationships on the $Zn_3(PO_4)_2$-$Mn_3(PO_4)_2$ join (3) is now in order. The close structural relationship between the long series of (Mg, Zn)$_3(PO_4)_2$ solid solutions and the (Zn, Mn)$_3(PO_4)_2$ solid solutions ("gamma zinc orthophosphate") is now apparent from the data in Table II. It had been mentioned (3) and it is well known that oxidation of manganese hinders the complete determination of phase relationships in such a system when working in air. If a pure $Mn_3(PO_4)_2$ phase could be made by synthesis in nitrogen or other protective atmosphere, it is possible that a large range of (Zn,Mn)$_3(PO_4)_2$ solid solutions would exist, analogous to the zinc-magnesium series. Even without the benefit of a protective atmosphere to assure the retention of divalent manganese, it has been shown (3) that quite a broad region of ternary solid solutions do exist.

The Ternary System MgO-ZnO-P_2O_5

The subsolidus solid solution relationships in the ternary system are shown in Fig. 3.

The MgO-ZnO relationships were determined by firing mixtures of the oxides at 1300°C for 8 hr. Using nickel-filtered CuKα radiation ($\lambda = 1.5405$Å) and 10% by weight of silicon metal as an internal standard, diffraction patterns were run at ½° (2θ)/min. The results for MgO and the solid solution limit (ZnO in MgO) are shown in Table III.

The lattice expansion due to the inclusion of 32 mole % zinc oxide was 0.7%. Similar data for compositions near ZnO indicated about 3% of solid solution at 1300°C.

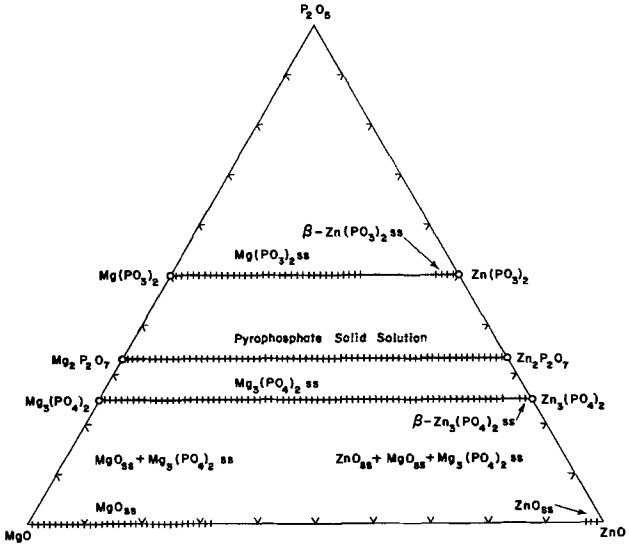

Fig. 3. Subsolidus solid solution relationships in the system MgO-ZnO-P_2O_5 (mole per cent).

Data on the orthophosphate join have been presented above and the data on the solid solutions on the metaphosphate join were presented previously (4).

According to some unpublished data obtained several years ago (6), it is probable that a complete (or nearly complete) series of pyrophosphate solid solutions exist. The generally high solid solubility of the zinc compounds in their magnesium analogues is thus apparent.

Fluorescence

Compositions shown in Table IV were fired at 1000°C for 48 hr, using 1 mole % MnO as an activator.

These results show that a little $Mg_3(PO_4)_2$ added to β-$Zn_3(PO_4)_2$ improves the brightness of the β solid solution, and that excessive amounts will damage brightness. A substantial shift in the position of peak intensity occurs with small additions of $Mg_3(PO_4)_2$.

The $Mg_3(PO_4)_2$ solid solutions containing high amounts of zinc are perhaps brighter than the β-type phosphors, but unfortunately the peak intensities are shifted to the neighborhood of 6300Å. Even the low intensity $Mg_3(PO_4)_2$ peaks at 6320Å.

It appears that there may be a minimum in the position of peak intensity in the solid series in the neighborhood of 70-80 mole % $Zn_3(PO_4)_2$.

G.E. 1092-1, Lot 11 β-$Zn_3(PO_4)_2$: Mn			6380	124

On the basis of the results shown in Table IV, a series of compositions was made to check the effect of activator concentration in the brightest $(Zn_{0.95}, Mg_{0.05})_3(PO_4)_2$ ("gamma") solid solution, as shown in Table V. These samples were fired at temperatures (see Table V) which were designed to prevent the formation of any unwanted β phase. It must be remembered that the $(Zn_{0.95}, Mn_{0.05})_3(PO_4)_2$ solid solution would transform to the β structure at temperatures around 940°C (3). If fired too high, the intermediate solid solutions would also begin to transform. Unfortunately, this technique does not permit a direct comparison of the brightness of phosphors fired at the same temperature. X-ray diffraction patterns of the fired samples showed them to be pure $Mg_3(PO_4)_2$ solid solutions.

This series of compositions shows that the solid solution is relatively insensitive to large changes in activator concentration. It should be noted that composition 6 when first measured gave a relative brightness of 133 compared to 120 when used as a comparative standard in the series in Table V. These differences are probably mainly due to variations in sample preparation and measuring technique.

The peak intensities hover around 6280-6300Å, indicating not quite as good "redness" as the beta phosphors.

Conclusions

1. "Gamma zinc phosphate" or "gamma zinc orthophosphate" has been shown to be an extended series of solid solutions of zinc orthophosphate in $Mg_3(PO_4)_2$.

2. Analogous series of $(Zn,Mg)_3(PO_4)_2$ and $(Zn,Mn)_3(PO_4)_2$ solid solutions exist in their respective ternary systems and probably form solid solutions in the quarternary system ZnO-MgO-MnO-P_2O_5.

3. The high zinc members of the $Mg_3(PO_4)_2$ solid solutions have good brightness and form the basis of a well-defined series of red cathode-ray phosphors. The brightness and peak emission of these phosphors are relatively insensitive to the amount of Mn^{++} which is substituted for Mg^{++} in the structure.

Cadmium Sulfide Photoconductive Sintered Layers

Martha J. B. Thomas and Edward J. Zdanuk[1]

Engineering Laboratories, Sylvania Electric Products Inc., Salem, Massachusetts

ABSTRACT

The preparation and performance of sintered photoconductive cadmium sulfide layers have been described. Although the photoconductive characteristics are directly dependent on composition, layer preparative techniques, and geometry of the unit, these parameters may be predicted and controlled to give a resultant reproducible layer of desired electrical and optical characteristics.

The use of photoconductive cadmium sulfide in electronic devices, such as light amplifiers and image converters, has increased greatly during the past few years (1-4). These devices usually have necessitated fabrication of photoconductive layers of large surface area. Such layers can be achieved most readily by means of powdered layer (5), sintered layer (1, 3), dielectric imbedment, or evaporated film (7) techniques. Sintered layers have become particularly popular in device fabrication because of their superior sensitivity (5, 8) uniformity, high mechanical strength, and ease of formation (5, 8).

Although a considerable amount of work has been done in determining the electrical and optical characteristics of pure cadmium sulfide and cadmium sulfide matrices in which traces of impurities such as copper and the halogens have been incorporated, these studies were conducted in the main on single crystals (9-11).

This paper describes some of the optical and electrical characteristics of sintered layers of cadmium sulfide and demonstrates the dependence of these characteristics on the initial chemical formulation and on the method of forming the final sintered layer.[2]

Experimental

Figure 1 presents schematically the process involved in the preparation of the sintered layer.

Phosphor quality cadmium sulfide (Sylvania or RCA) and analytical reagent quality cadmium chloride and copper chloride were used. A formulation found to be particularly suitable for general sintered layer application had the following composition:— 1 mole cadmium sulfide; 0.3 mole of cadmium chloride; 8 x 10^{-4} gram atoms of copper added as copper chloride or basic copper carbonate. All components were ground prior to blending. The blended composite, usually 100 g, was given an initial bulk firing for 35 min in covered porcelain crucibles. This resulted in a small amount of sintering and preliminary distribution of activator components into the cadmium sulfide. The partially sintered cadmium sulfide was milled in xylene to insure sufficiently fine particle size to yield a smooth-appearing sintered layer; to the suspension sufficient organic binder (ethyl-cellulose type) was added in order to insure a coherent layer during film formation prior to sintering. Usually this photoconductor suspension was sprayed although layers prepared with flow-on and doctor blade techniques gave identical results.

The sprayed layer was dried at room temperature for at least ½ hr during which most of the organic solvent volatilized. The layer was sintered in an electric muffle furnace in an air atmosphere, normally for 10 min at 550°C. Dependence of layer characteristics on presintering and sintering temperatures is discussed later.

Preparation of Test Cells

Standard cells.—Standard test cells of the geometry indicated in Fig. 2 were used for the determination of the desired characteristics. The cells were made on 1 x 2½ x ⅛ in. Pyrex slides which had been coated with a conductive film of transparent semiconducting tin oxide. The desired electrode structure with ⅛ x ¼ in. gaps was prepared by sand blasting the conductive film through a pattern mask. The slides were then thoroughly washed and dried in an oven at 150°C. The photoconductor suspension was sprayed in square patches between the electrodes using a suitable mask. Each slide had six in-

[1] Present address: Research Division, Raytheon Manufacturing Co., Waltham, Mass.

[2] After this paper had been submitted for publication a technical report was issued by Lincoln Laboratories (15). This report, which has limited circulation, describes similar studies of CdS sintered layers and supplements the present paper.

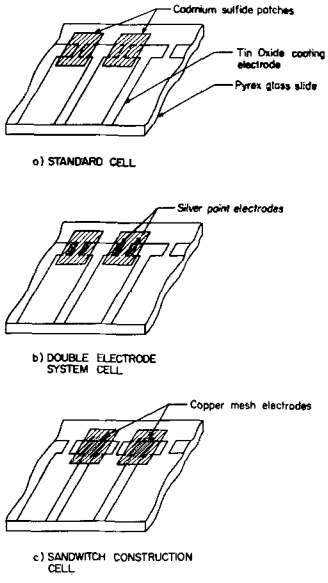

Fig. 2. Types of photoconductive cells used in measurement of photoconductor characteristics.

dividual test cells and measurements of electrical and optical properties of each individual cell were made. Values of the central four cells were found to be reproducible and consistent. The end cells yielded very erratic results, which will be discussed later in the paper.

Double electrode cells.—Double electrode cells (Fig. 2B) were made from the standard test cells by painting silver electrodes (Du Pont air dry conductive silver) on the top surface duplicating the gap structure of the tin oxide electrodes on the undersurface of the photoconductive layer.

Sandwich.—Sandwich cells (Fig. 2C) were also fashioned from the basic standard test cells by applying a ¼ x ¼ in. patch of very fine electroformed copper mesh. This copper mesh, 500 lines to the inch, was applied to the surface by a silicone adhesive. To have the measurement on these sandwich cells reflect only the volume conduction of the photoconductive layer, a mask of an opaque material, e.g., black plastic tape, was applied to prevent activation by light around the edges.

Electrode materials.—All surface conductivity measurements were made with cells having electrodes of semiconducting tin oxide. However, measurements made with cells using fired-on platinum electrodes did not differ significantly. The effect of any reaction of the sintered layer with electrode material as exemplified by the two types of electrodes is apparently confined to the interface between layer and electrode. Such reactions change primarily the resistance of the contact between electrode and layer. This contact resistance is a small fraction of the resistance of the layer and is only slightly photosensitive. Also, it tends to be eliminated in a surface conductivity measurement which is the difference between a light and dark photoresponse. In systems where an asymmetrical electrode system exists and rectifying phenomena are likely, difference in electrode material becomes important.

Techniques and methods of measurement.—The photosensitivity of the prepared layers was measured with a d-c applied voltage of 600 v and with an exciting light of 10 ft-L from a green electroluminescent lamp. For standard measurements this exciting light illuminated the electrode gap from the glass side. Rise and decay characteristics were determined by observing the photoconductor response on an oscilloscope screen. The "dark current" I_{30} was taken as the current measured 30 sec after the removal of the exciting light. Decay time γ_{10} represents the time necessary to reach 10% of photocurrent upon removal of activating light. Spectral response curves were determined using a Beckman D. U. spectrophotometer as a monochromator. By variation of the slit width, an equal quantity of energy at various wave lengths was allowed to excite the photoconductor cell with 600 v d-c applied potential. Slit width variations during measurements gave

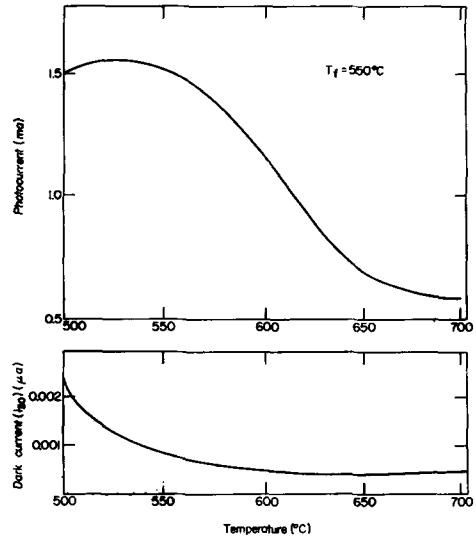

Fig. 3. Effect of presintering temperature on photoconductor characteristics. Final sintering of layer at 550°C for 10 min (600 v d-c potential, 10 ft-L, green El lamp excitation).

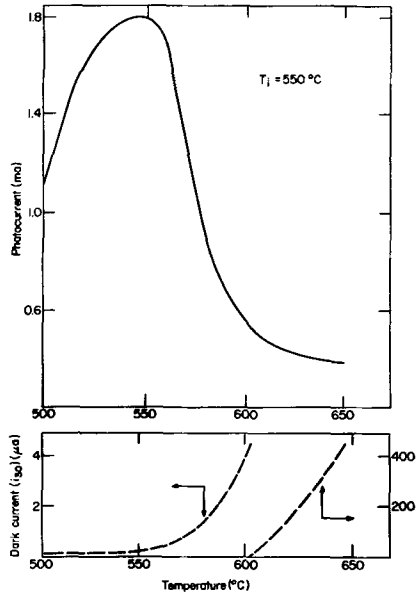

Fig. 4. Effect of sintering temperature on photoconductor characteristic. Presinter of layer at 550°C for 35 min (600 v d-c potential, 10 ft-L green El lamp excitation).

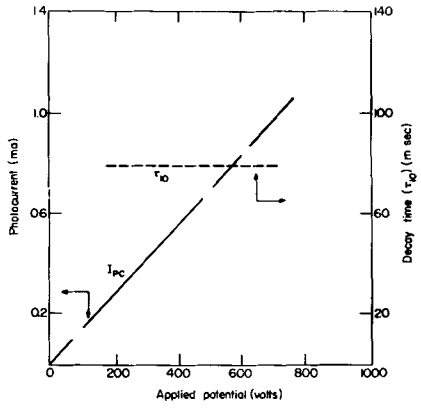

Fig. 5. Effect of applied potential on photoconductor characteristics (10 ft-L green El lamp excitation).

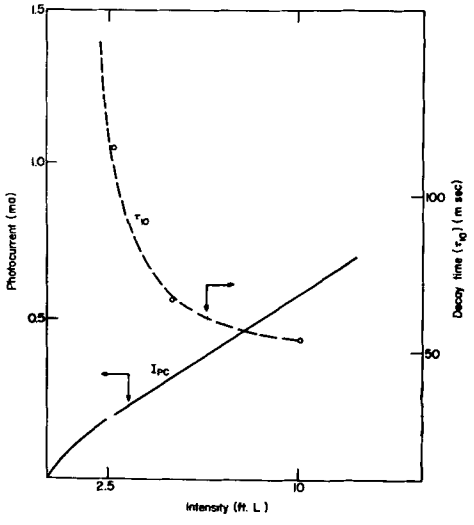

Fig. 6. Effect of intensity of illumination on photoconductor characteristics (green El lamp excitation, 600 v d-c potential applied).

a half intensity band width varying from 14 mμ at 550 to 18 mμ at 700 μ. This small variation of band widths in the peak response region resulted in a negligible shift in peak positions. The response was determined with an RCA electronic microammeter.

Reflectance measurements were made on a modified reflectance attachment to the Beckman D. U. spectrophotometer using basic magnesium carbonate as reference.

Effect of presintering temperature (T_i).—In an effort to establish conditions necessary to obtain maximum photosensitivity, a step-wise variation of the conditions at each part of the process was conducted. Figure 3 represents the effect of the variation of presintering temperature on the photocurrent and dark current. In each case, a 100 g mass of the photoconductor was fired in a covered crucible for a period of 20 min. The final sintering of the test slides was at a temperature of 550°C for 10 min. It will be noted that the greatest ratio of photocurrent to dark current occurs at T_i 550°C. Higher temperatures cause a decrease in the photocurrent while lower temperatures result in a layer which has relatively high dark current. This is probably the result of incomplete sintering combined with a relatively large amount of residual unincorporated $CdCl_2$.

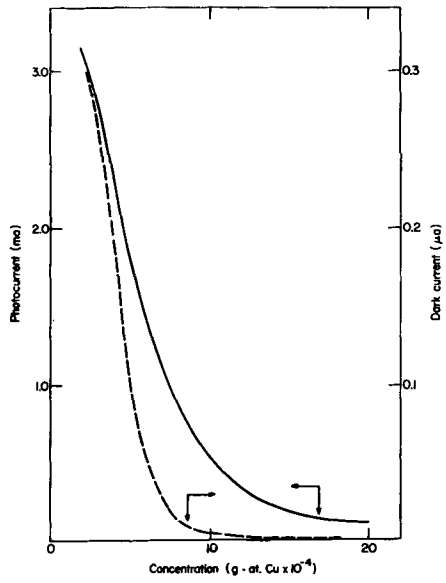

Fig. 7. Effect of copper concentration of photoconductor characteristics. (600 v d-c potential, 10 ft-L green El lamp excitation).

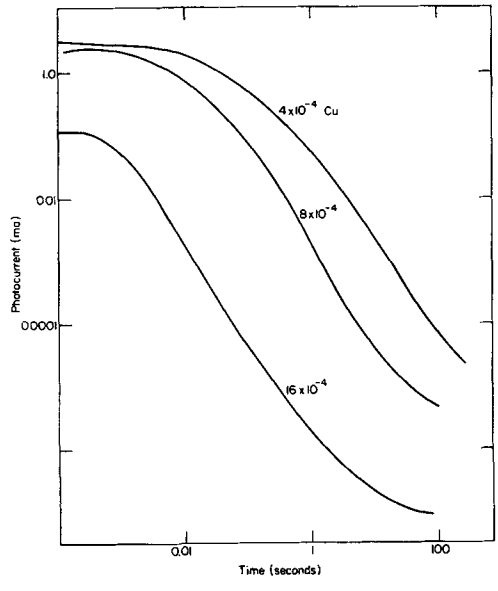

Fig. 8. Effect of copper concentration on decay characteristics of sintered layer cadmium sulfide (600 v d-c potential, 10 ft-L green El lamp excitation).

Effect of sintering temperature (T_f).—The temperature of sintering has a particularly great effect on both the photocurrent and the dark current. In all cases the slides were fired for a period of 10 min at temperatures from 500° to 700°C. With increasing temperatures the dark current increases until the material shows a high dark conductivity with little or no photoconductivity (Fig. 4). As a result of these observations a standard prefiring temperature and sintering temperature of 550°C was chosen for all samples. Cells with layer thickness of about 5 mils prepared under these conditions were used to determine the dependence of the photocurrent and the decay time on the applied voltage and the light intensity. The photocurrent varied linearly with increased voltage over the range of 100-800 v while voltage variation had little or no effect on the decay time γ_{10} (Fig. 5). A linear relationship was also ob-

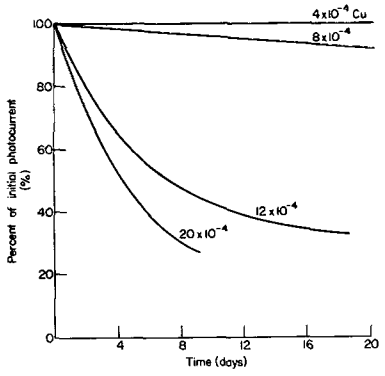

Fig. 9. Effect of copper concentration on shelf life (600 v d-c potential, 10 ft-L green El lamp excitation).

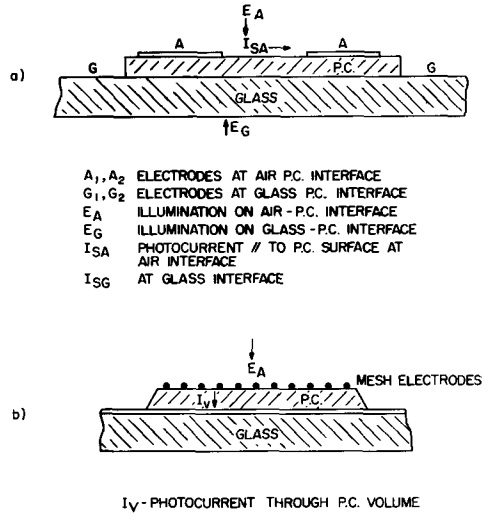

Fig. 10. Notations used describing photoconducting characteristics of layer.

served over most of the intensity range, although at the low intensities some divergence was noted. The decay rate appeared to be quite dependent on the intensity of excitation, being relatively slow at the lower intensities (Fig. 6).

All cell data are reported for excitation with 10 ft-L of green EL light and for 600 v applied potential. Whenever necessary the above linear relationships are applied for conversion to these conditions.

Effect of copper concentration.—Confirming what had been found in single crystal studies, (5, 9, 10, 12, 13), increasing copper concentration results in a decrease of both photocurrent and dark current (Fig. 7) with concurrent change of the body color of the sintered layer from yellow to a black-brown.

Increased copper concentration,[3] although decreasing the photocurrent of the layer, did increase the rate of decay to a considerable (Fig. 8) extent. However, this increased copper effected a decrease of the relative shelf life of the prepared layer (Fig. 9). Test slides measured to obtain these data were subjected to normal laboratory conditions including usual winter humidity variations indoors and fluorescent lighting. Measurements were made in every case at about the same time of day. In all cases the photoconductivity appeared to reach a steady state after the observed decay.

[3] All concentrations expressed in this paper are in units of gram atoms per mole of CdS.

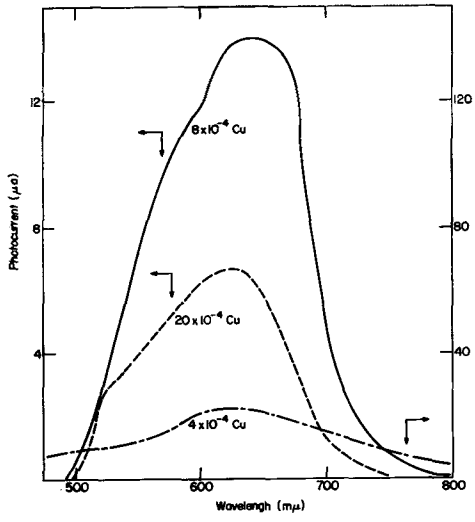

Fig. 11. Spectral response $I_{SG}{}^{G}$ for cadmium sulfide sintered layers (600 v d-c potential).

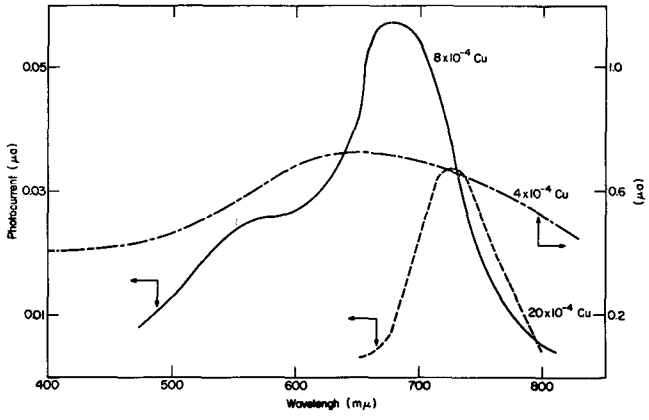

Fig. 12. Spectral response $I_{SG}{}^{A}$ cadmium sulfide sintered layers (600 v d-c potential).

Spectral response.—Although photoconductors have been further classified by the determination of their spectral response, there have been inconsistencies with respect to the published data. Variations in spectral response characteristics of cadmium sulfide photoconductor have been attributed not only to chemical composition but also to its physical state (5) and mode of operation (1). No definitive study of these parameters has been reported.

A consideration of a sintered layer photoconductor reveals the role of the cell structure or geometry on characteristics. Figure 10a represents a magnified view of a test cell showing the arrangement of the various parts involved in the measurement of surface-like conductivity. In the conductivity measurements used to evaluate the effects of different firing temperatures and different copper concentrations, illumination had been in all cases from the glass-CdS interface side (E_G) and voltage had been applied across the tin oxide electrodes in the plane of the same interface. Under these conditions the photocurrent will be designated by $I_{SG}{}^{G}$; the superscript G giving the direction from which the sample is illuminated, in this case the glass side, and the subscript SG indicating a surface-like conduction with voltage across the electrodes in the glass-CdS interface, G.

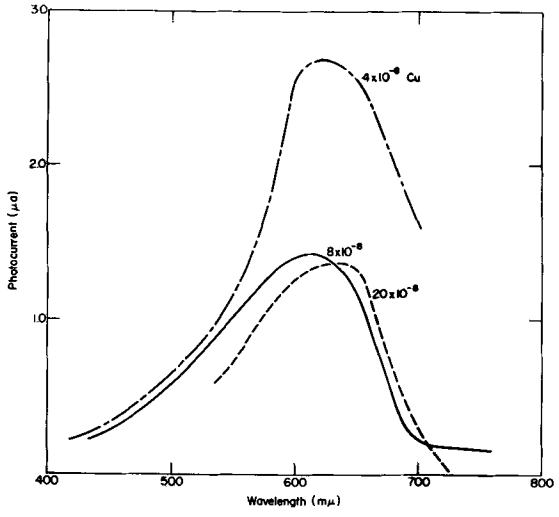

Fig. 13. Spectral response $I_{SA}{}^{A}$ for cadmium sulfide sintered layers (600 v d-c potential).

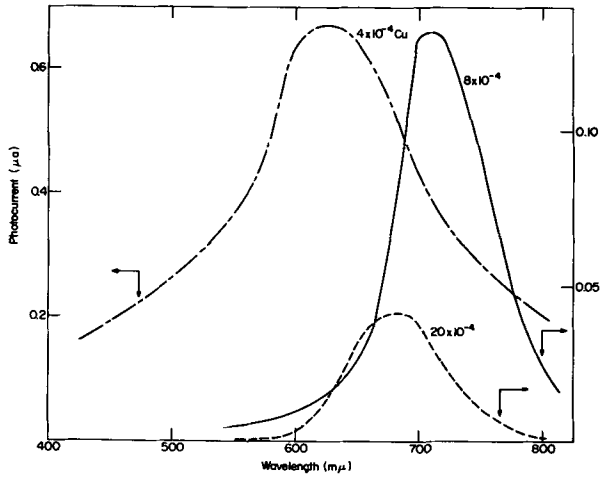

Fig. 14. Spectral response $I_{SA}{}^{G}$ for cadmium sulfide sintered layers (600 v d-c potential).

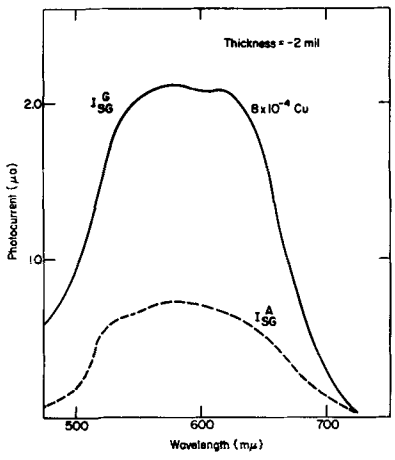

Fig. 15. Spectral response of 2-mil cadmium sulfide layer (600 v d-c potential).

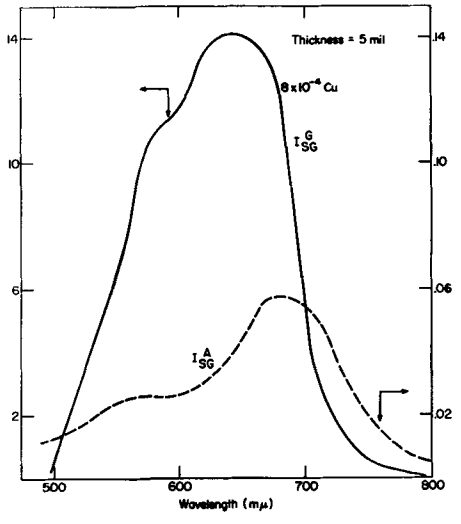

Fig. 16. Spectral response of 5-mil cadmium sulfide layer (600 v d-c potential).

The second surface, i.e., the air photoconductor interface can also be used to evaluate the sintered layer. Voltage was applied across silver electrodes painted on this surface, and the photocurrent $I_{SA}{}^{G}$ produced by exciting from the photoconductor glass side was determined.

Two additional surface type photocurrents may be determined if the direction of excitation is reversed. These currents may be symbolized as $I_{SG}{}^{A}$ and $I_{SA}{}^{A}$ using the same conventions as above.

Thus, the four possible surface photocurrents can be designated by $I_{SA}{}^{G}$, $I_{SG}{}^{G}$, $I_{SG}{}^{A}$, and $I_{SA}{}^{A}$.

In addition to the above surface-like conductivities, the contribution of any current produced within the body of the layer for the particular geometry of the cell should be determined. Using the standard-type cell and adding mesh electrodes to the air surface, the photocurrent through the photoconductor volume may be measured (Fig. 10b). Again, a current may be developed by exciting either through the glass or air interface yielding two possible types of volume currents ($I_V{}^{A}$ and $I_V{}^{G}$).

$I_{SG}{}^{G}$.—The spectral response of photoconductors excited through the glass with voltage applied across electrodes in the glass-photoconductor interface ($I_{SG}{}^{G}$) is shown in Fig. 11. Although the relative magnitude of the photocurrent varies with copper concentration, the optimum wave length or maximum-response occurs in all cases at a wave length of 625 mμ.

$I_{SG}{}^{A}$.—If the excitation occurs at the air-photoconductor interface, spectral response curves for variable copper concentrations show a dependence of the position of their maximum on copper concentration (Fig. 12).

$I_{SA}{}^{A}$,-$I_{SA}{}^{G}$.—The spectral response of the sintered layer as characterized by these two currents is shown in Fig. 13 and 14. There appears to be essentially no shift in the peak response toward longer wave length with increasing copper in these cases.

Effect of layer thickness on photoconductor characteristics.—Since the spectral response of the surface photocurrent appeared to vary with the surface excited, a variation of the chemical composition of the two surfaces might be suspected. If the thickness of the layer were decreased progressively, at some point it might be expected that this surface composition variation should disappear. Figures 15 and 16 represent spectral response curves ($I_{SG}{}^{A}$, $I_{SG}{}^{G}$) using cell layer thicknesses of 2 and 5 mils, respectively. In contrast to the 5-mil layer there is no difference in the shape and maxima of the spectral response

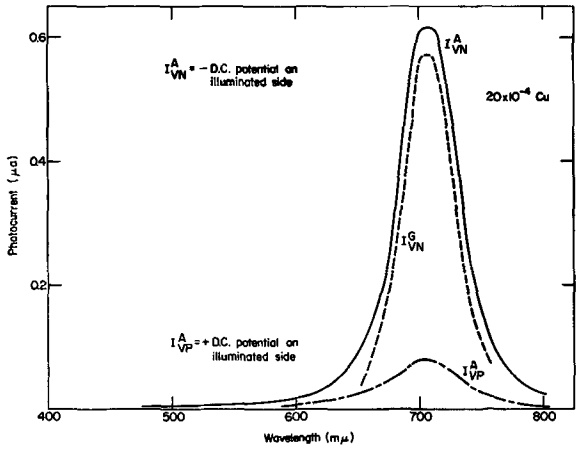

Fig. 17. Spectral response I_V for cadmium sulfide sintered layers (600 v d-c potential 10 ft-L green El lamp excitation).

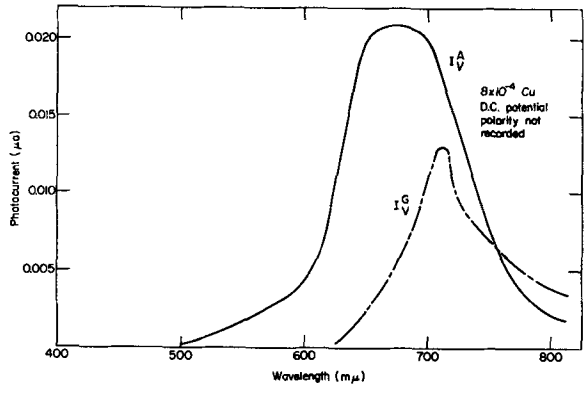

Fig. 18. Spectral response I_V for cadmium sulfide sintered layers (600 v d-c potential 10 ft-L green El lamp excitation).

curves in the case of the 2-mil layer. Also, the body color of thin layers was considerably lighter than that of the 5-mil layer even though the copper concentrations were identical. This difference can be attributed to the loss of a greater amount of chloride from the thin layer. This chloride is necessary for effective incorporation of copper into the lattice.

Volume conductivity I_V.—The spectral response of the volume type current I_V was determined with sintered layers of various copper concentrations. Curves for 8 x 10^{-4} and 20 x 10^{-4} copper are shown in Fig. 17 and 18. The characteristics of these curves are somewhat similar to $I_{SG}{}^A$ and $I_{SA}{}^G$. The layer with the lower copper concentration shows a difference in peak position depending on which side was illuminated. The layer with the higher copper showed no lack of symmetry. It should be noted that Fig. 18 indicates a rectification phenomenon the magnitude of which is dependent on the direction of illumination.

Reflectance curves.—Figure 19 represents the surface (air-photoconductor 5 mil) reflectance of the photoconductive layer. As may be seen from the curves, the body color becomes progressively darker with increased copper concentration.

Effect of firing atmospheres.—The importance of firing conditions with respect to both atmosphere and surroundings was exemplified by the different photoconductive properties associated with the end patches of the standard cells. To determine more ac-

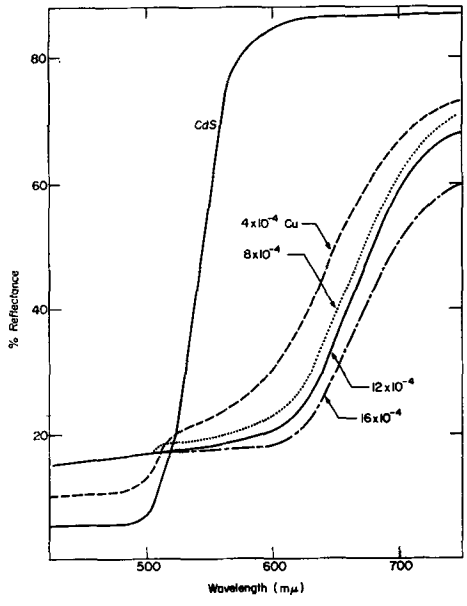

Fig. 19. Reflectance curves of photoconductor layers with variable copper concentrations.

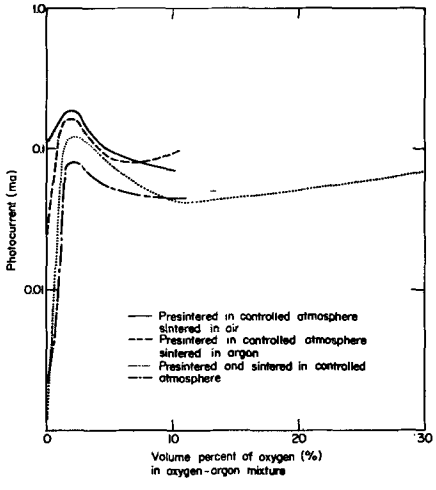

Fig. 20. Effect of oxygen in firing atmosphere on photocurrent $I_{SG}{}^G$ (600 v d-c potential 10 ft-L green El lamp excitation).

curately the importance of the composition of the firing atmosphere, the effect of variations on concentration of (*a*) oxygen and (*b*) cadmium chloride in the firing atmosphere on the photoconductivity of the layers was studied. In the former case, the layers were fired in atmospheres of various oxygen-argon mixtures. There is no doubt that some oxygen is required to achieve an optimum in sensitivity of the cadmium sulfide layer (Fig. 20), but it also appears that the beneficial effect of oxygen may be introduced in the presinter firing or the final sintering. The effect of oxygen on dark current is of importance only when long firing times are used. Some advantage may be gained if the oxygen content of the firing is kept small (about 2%). This is in agreement with improvement of photoconductive characteristics observed with restrictive firings in small volumes. However, conditions close to optimum are achieved simply by firing in air in a small electric muffle furnace for a time and at the temperature indicated earlier.

An atmosphere rich in cadmium chloride or some other chloride-containing compound is also necessary in the fabrication of a sensitive photoconducting layer. When the major portion of the halide is removed by repeated washing of an activated cadmium sulfide material (presintered only) until the wash liquid showed no test for chloride, the resultant sintered layer was pale yellow in color, powdery in character, and low in photoconductive characteristics. However, this same layer may be made sensitive by resintering in a closed volume with cadmium chloride crystals added to provide a suitable atmosphere. A similar effect may be achieved if the layer were exposed to a hydrogen chloride atmosphere prior to resintering. The resintered layer was not only photoconductive, but also the body color was nearly identical to that of the control.

Discussion of Results

Sintered layers of cadmium sulfide photoconductor (copper chloride-coactivated) can be prepared with a sensitivity ratio (ratio of photocurrent and dark current after 30 sec) of 10^7. In general, such layers have characteristics quite similar to those reported with respect to the single crystals. The sintered layer characteristics are, however, directly dependent on the method of preparation and the geometry of the system in which the layer is used.

In the system chosen for investigation, a system which is of practical application to device manufacture, the two surfaces have been shown to be chemically and physically quite different, and hence the optical and electrical responses are dependent on the geometry of excitation. These variations may be explained by differences in the relative activator-coactivator concentrations. During sintering, the halide coactivator is volatilized quite readily. Because of the large excess of cadmium chloride used in formulation, there is sufficient halide available so that some will remain within the photoconducting material itself as well as in the atmosphere surrounding the material. During sintering, the halide volatilizes evenly throughout the layer. Once this halide has diffused to the surface, however, it escapes into the atmosphere. Thus the surface of the layer may be considered as a diffusion boundary between an atmosphere of low chloride concentration and the relatively chloride-rich cadmium sulfide bulk. Upon cooling, some halide is reabsorbed by the surface of the layer. Such processes could explain a concentration variation of halide across the layer. During the sintering the copper concentration would simply equilibrate throughout the layer since copper is not volatile at the sintering temperatures.

Experimentally, the ease of migration of the chloride ion out of the cadmium sulfide lattice has been shown by the successful reactivation of a nonphotoconductive (chloride-free) CdS by means of a simple exposure to cadmium chloride or hydrogen chloride vapors. The unevenness of reabsorptions of the coactivator during cooling is indicated both by the difference in color between the two layer surfaces (especially at higher copper concentrations) and by the dependence of this body color variation on the thickness of the layer.

Assuming that sintering under the conditions used does result in a difference in coactivator concentration within the layer, the spectral response curves may be explained utilizing data obtained in single-crystal work.

Wood (14) ascribed the spectral response peak at 520 mμ to a stimulation of photoconduction resulting from lattice defects in the crystal associated with presence of chloride. The 700 mμ peak on the other hand, was directly associated with copper-type active centers. Considering the $I_{SG}{}^{G}$ spectral energy curves, the peak is in all cases about 625 mμ. This type of curve could result from the combined effects of Cu and Cl centers. Increasing the copper concentration should have little or no effect on the position of the peak response provided that there is sufficient chloride to keep the relative ratio of copper to chloride centers constant. The constancy of ratio would be dependent then on the initial composition of the photoconductor blend, the thickness of the layer, and duplicating of firing times and temperatures of layer.

With respect to the air-photoconductor interface ($I_{SG}{}^{A}$), the spectral response is found to shift toward the longer wave lengths with increasing copper concentration. Again applying the work of Wood, it may be assumed that this shift is the result of a higher ratio of Cu to Cl type centers. This increase in Cu over Cl-type centers would be the result of the lower chloride concentration existing at the surface. Accompanying this increase in the relative number of copper-type centers with respect to the chloride-type centers will be a deepening in the body color of the surface. This body color shift results in a more efficient absorption of longer wave lengths which, combined with the greater effectiveness of activation due to higher copper center concentration, further shifts the spectral response peak toward the red. The copper center concentration is not entirely dependent on initial copper concentration but is interrelated to chloride concentration.

The darkening of the body color associated with increasing copper observed primarily at the air photoconductor interface introduces the possibility of affecting the position of the spectral response peak by a simple filtering action, i.e., modifying the composition of the activating radiation reaching the portion of the layer involved in the conductance measurements by other portions of the layer which are not involved at all or to a much lesser degree.

The greatest effect of this filtering action is observed in the spectral response curves of $I_{SA}{}^{G}$ and $I_{SG}{}^{A}$ type photoconduction. In these cases the most effective wave length will be that which can penetrate through almost the entire layer and activate that part of the layer in the region of the electrodes on the surface opposite the illuminated surface. Since the longer wave lengths are more penetrating, the peak spectral response as measured by these conductances will be further toward the red than the peak responses of the other conductances. In $I_{SA}{}^{G}$ and $I_{SG}{}^{A}$ measurements the easily absorbed shorter wave

lengths will be filtered out by that portion of the layer which is least effective in contributing to the conductance. It will be noted that the peaks of the spectral responses I_{SG}^{A} and I_{SA}^{G} do in fact occur at longer wave lengths. The volume conductance is also dependent on the body color of the layer but to a slightly lesser extent than in the above situation. In this case light absorbed by any part of the layer can contribute effectively to the volume-like photoconduction. The peak response of these spectral response curves lies roughly between the two types of surface conduction responses.

Acknowledgments

Sincere thanks are due to C. Lagos, T. Barry, B. Rybinski, and R. Levitt for the preparation and measurement of many of the photoconducting layers. For frequent and helpful discussions and constructive criticisms the authors are indebted to Dr. K. H. Butler and F. Koury of the Engineering Laboratories as well as M. Zimmerman and R. Billups of the Lincoln Laboratories, M.I.T.

Part of the work reported here was carried out as a cooperative project with the Lincoln Laboratory, a technical center operated by the Massachussetts Institute of Technology with joint support of the Army, Navy, and Air Force under contract.

Manuscript received May 2, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Nature of Alumina in Quenched Cryolite-Alumina Melts

Perry A. Foster, Jr.

Alcoa Research Laboratories, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

The equilibrium primary phases that precipitate from cryolite-alumina melts are cryolite, to the left of the eutectic, and corundum, to the right of the eutectic. No solid solubility of alumina in the cryolite phase was found. Evidence is presented in the form of photomicrographs and x-ray powder patterns that a new alumina phase is obtained by extremely rapid quenching of the liquid. The x-ray pattern of this phase is similar to the aluminum silicate, mullite. It is thought to result from the disproportionation of an oxyfluoride complex in the melt and is perhaps a skeletal arrangement with some of the characteristics of the oxyfluoride precursor. This new alumina phase is metastable and transforms through eta-alumina to corundum on heating.

Although quenching methods are well established and have been used extensively to elucidate the phase relationships in many nonmetallic systems, little use has been made of the technique in studies of the alumina-cryolite system.

Zintl and Morawietz (1) reported that x-ray powder patterns showed only cryolite in quenched cryolite fusion products containing 5 and 10% alumina. Similar experiments with 15% alumina quenches showed corundum as well as cryolite, indicating that the solubility limit had been exceeded at the temperature employed. It is believed this temperature was approximately 1000°C. Zintl and Morawietz (1) also reported that the densities of those quenched products in which no corundum was found were the same as cryolite. Calculated densities, based on a mechanical mixture and the two types of solid solution, ruled out all but the primary or substitutional solid solution model. Zintl reasoned that it was probably impossible to quench fast enough from above the liquidus to preserve the molecular arrangement of that phase field, and that what one obtained was something characteristic of a lower temperature: in this case, a primary solid solution with an alumina dimer (Al_3AlO_6) substituted for Na_3AlF_6 in the cryolite lattice.

Ginsberg and Bohm (2) repeated Zintl's experiments and found that for alumina contents less than 12%, x-ray showed only cryolite in both slowly cooled and quenched samples. However, an aluminum sulfate extraction gave quantitative recovery of alumina for the slowly cooled specimens and a

40% recovery for the quenched specimens. They concluded that alumina is in solid solution at a concentration of 7-8% in the quenched melt.

Grjotheim (3) obtained cooling curves for melts of several compositions from 9 down to 5% alumina at a rather slow cooling rate of 0.7°/min. Eutectic halts were noted for all these compositions. At 2.5%, the halt was not established definitely. Grjotheim felt this might be due either to solid solubility or to the small amount of eutectic which forms at this composition producing an undectable heat effect.

The purpose of the present work is to determine the nature of alumina in alumina-cryolite melts quenched from above the liquidus; to determine the extent of solid solution on the low alumina side of the eutectic; and to obtain information concerning possible new compound formation on the high-alumina side of the eutectic. This is part of a larger program underway in these Laboratories to elucidate the phase relationships in the cryolite-aluminum system.

Experimental

Hand-picked natural Greenland cryolite was employed. The most prevalent impurities are: silicon (SiO_2) 0.14%, potassium (KF) 0.055%, calcium (CaF) 0.01%, and lithium (LiF) 0.035%. The alumina used was Alcoa, A-10 Grade. The most common impurities in this material are: soda, 0.092%, and silica, 0.19%.

The starting materials were prepared by prefusing, under argon, 5-g mixtures of cryolite and alumina in a covered platinum crucible at 1015° ±10°C. The fusion temperature was maintained for 5 min before slowly cooling to room temperature. Weight losses due to moisture and decomposition were of the order of 0.2%. The fused material was crushed to pass 200 mesh and then mixed thoroughly. Two 1-g samples were analyzed for alumina by extraction with a hot aluminum chloride solution. If these two determinations agreed within the usual experimental error, the gross sample qualified as the source material for the 20 mg quenching charge. Prefusing of high alumina samples (14-18%) presented some difficulty. Temperatures higher than 1015°C would be necessary to effect complete solution. However, cryolite begins to decompose above this temperature, evolving $NaAlF_4$, and consequently enriching the melt in NaF. It was found from duplicate alumina determinations of a number of different high alumina compositions that the fine grinding and mechanical homogenizing procedure, after partial fusion at 1015°C, was effective in obtaining a uniform distribution of unreacted and precipitated alumina.

Quenching Procedure

Small platinum tubes, 3-mm ID with 0.01-mm wall, were cut to lengths of approximately 1.5 cm. One end was crimped shut and fused with a Burrell "Kup-L-Weld" Thermocouple Welder, and 20 mg of a prefused, homogenized alumina-cryolite composition was loaded into the tube. The tube was flattened to remove some of the air; then the open end was arced shut. The tube was inserted into a platinum foil envelope, which was threaded with a platinum fuse wire, and suspended from two hooked conductors within 1 mm of a calibrated platinum, platinum-10% rhodium thermocouple (4). This assembly was inserted into a platinum-wound resistance furnace.

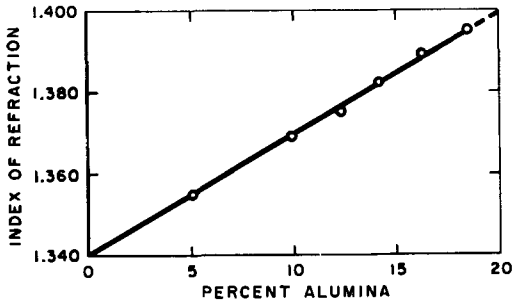

Fig. 1. Variation of the quenched liquid index of refraction with alumina content.

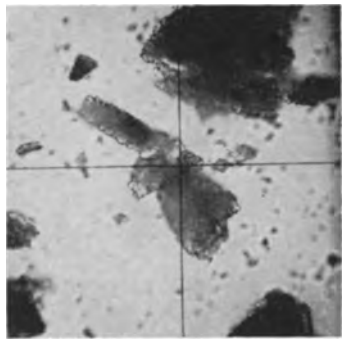

Fig. 2. Quenched liquid, 5% Al_2O_3. X250

The complete liquification of all compositions was insured by initially treating the samples at 1100°C for 30 min. Following this heat treatment, the temperature was lowered slowly to, and controlled at, the level required for that particular investigation. That temperature was maintained for a period of time sufficient to establish chemical and physical equilibrium. The sample was released from the hot-zone of the furnace into a quenching medium by running current through the hooked leads, thereby melting the fuse wire. The optimum time at temperature was determined by experience after microscopic examination of a number of samples.

The index of refraction of the various phases was observed, using the Becke line method. Positive identification was made from x-ray powder diffraction patterns.

Results and Discussion

X-ray powder diffraction patterns of cryolite-alumina melts having alumina contents ranging from 5-18.5%, quenched from above the liquidus, showed only cryolite lines. These observations were in agreement with those of Zintl and Morawietz (1) and Ginsberg and Bohm (2). However, the refractive index increased with increased alumina content (Fig. 1), thus appearing to contradict x-ray findings, which showed a constant parameter regardless of alumina content. The quenched liquid particles were quite opaque and had a fine mosaic crystalline structure (Fig. 2). This feature prohibited obtaining a very precise index. Nevertheless, the increase in re-

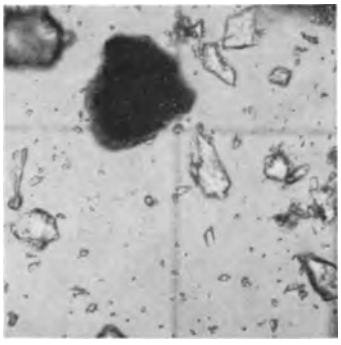

Fig. 3. Primary phase cryolite-quenched liquid, 5% Al_2O_3. X210.

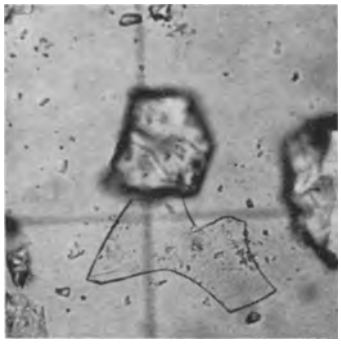

Fig. 4 Sub-solidus cryolite and alumina, 5% Al_2O_3. X210

fractive index above that of cryolite (1.339) was pronounced and nearly linear with alumina content.

If, as Zintl and Ginsberg suggested and the early phase diagram of Roush and Miyake (5) would predict, the primary phase on the low alumina side of the eutectic is a solid solution containing between 7 and 11% alumina, the index of refraction of that phase should be significantly greater than that of cryolite. The indices of refraction of the two phases present in quenches originating slightly below the liquidus along the 5% alumina isopleth indicated that the primary phase is cryolite (the well-formed clear crystals in Fig. 3). The dark, mosaic, quenched liquid particles constitute the other equilibrium phase. Quenches originating from lower and lower temperatures showed an increasing amount of cryolite crystals, as would be expected from the lever arm principle. Quenches from below the eutectic boundary (approximately 960°C) showed microscopically two equilibrium solid phases (Fig. 4). One phase (immediately above the crosshair)[1] is cryolite that precipitates below the liquidus and continues to do so until the composition of the liquid and the temperature of the melt are such (eutectic point) that a second solid phase (flat plate immediately at the crosshair) commences to form. The second phase had the refractive index of corundum. A density separation was performed on a sample quenched from just below the eutectic boundary. Methylene iodide, with a density of 3.33, was used as the separating medium. X-ray analyses showed that the light fraction was principally cryolite and the heavy fraction principally corundum.

Quenches along an isopleth on the high alumina side of the eutectic showed microscopically, and by x-ray, that the primary phase particle is corundum. This was consistent with the preceding observation that corundum appears below the solidus on the low alumina side of the eutectic. It is significant that x-ray diffraction techniques were not sensitive enough to show corundum in a specimen similar to that shown in Fig. 4. This could explain why Ginsberg, employing only x-ray techniques, was unable to observe corundum in either slowly cooled or quenched samples of low alumina content.

Thus it appears possible to quench from above the liquidus and preserve a phase that is not characteristic of anything that occurs at lower temperatures in the diagram. Attention, therefore, is focused on the nature of alumina as it exists in the sample quenched from above the liquidus.

The general consensus in the literature favors some sort of reaction between alumina and cryolite in the molten state to produce oxyfluoride complexes or aluminates, or both. For example, Treadwell (6) proposed $(F_2AlO_2AlF_2)^{=}$; Grunert (7), $AlOF_5^{\equiv}$ and $AlOF_3^{=}$; Boner (8), $AlOF_2^{-}$; Rolin (9), AlO_2^{-} and AlO^{+}; and Forland, *et al.*, (10), $AlO_2F_2^{\equiv}$.

Edwards, *et al.* (11) made density measurements on melts over a range of compositions above the liquidus. These measurements showed that, as the alumina content increased, the density of the melt decreased steadily below that of cryolite towards a minimum, indicating a chemical interaction. Frank and Foster (12), employing radioactive aluminum, demonstrated the complete exchange between the aluminum atoms of cryolite and alumina on fusion. This would not occur if alumina simply dissolved without ionization or dissociation in cryolite. The same workers (13) made density calculations using various possible reaction schemes to get a fit with Edwards' density curve. The best fit was obtained

with an equilbrium between Na_3AlF_6, $NaAlF_4$, NaF, $Na_3AlO_2F_2$, and $NaAlO_2$.

The identification of the primary phase on the high alumina side of the eutectic as corundum rules out the possibility of a stable solid oxyfluoride compound. X-ray powder patterns of the quenched liquid showed only cryolite, implying that the oxyfluorides are too unstable to retain their configuration on quenching, or are not present in sufficient amounts for detection. Of particular interest, then, is the structural form of the alumina in the quenched liquid particles.

The quantitative separation of alumina in alumina-cryolite fusion products customarily is performed by leaching with hot, 30%, aluminum chloride solution, followed by repeated washing and, finally, ignition of the residue at 1100°C. This procedure yields alumina contents with a precision of ±0.1% with a 1-g sample. With minor modifications, satisfactory precision was also obtained with the small samples, whether quenched or slowly cooled. X-ray diffraction patterns of the ignited residues invariably showed large proportions of corundum, with small amounts of beta- and zeta-alumina, and, occasionally, other forms. To retain the alumina structure as it existed in the quenched liquid, the ignition step was eliminated.

The x-ray patterns of the extraction residues showed a large amount of material that was similar to the aluminum silicate, mullite, $3Al_2O_3 \cdot 2SiO_2$, and a small amount of material resembling the lithium-containing zeta-alumina, although, in this case, the material was lithium free. This was true, regardless of the alumina content, within the concentration range of the experiments. Figure 6 compares Debye patterns of the mullite-like alumina (hereafter referred to as m-alumina for convenience) and true mullite. Table I lists the *d* values and relative line intensities.

Table II. X-ray analyses of heated m-alumina

X-ray analysis of the starting materials	Heating conditions	X-ray analysis after heating
m-Alumina	250°C 1 hr	m-Alumina
m-Alumina	300°C 1 hr	m-Alumina; eta-alumina
m-Alumina	600°C 1 hr	m-Alumina; eta-alumina
m-Alumina	650°C 1 hr	Eta-alumina
m-Alumina	700°C 1 hr	Eta-alumina
m-Alumina	750°C 1 hr	Eta-alumina; corundum
m-Alumina	775°C 1 hr	Corundum

The aluminum chloride extraction residues for compositions on the high alumina side of the eutectic, but originating at a temperature below the liquidus, contained a mixture of m-alumina and corundum. Corundum is the primary phase in this region of the phase diagram. Extraction residues of samples quenched from below the liquidus on the low alumina side of the eutectic contained only the m-alumina. The primary phase in this region, cryolite, is soluble in hot aluminum chloride solution. Residues from quenches originating below the solidus, regardless of their composition relative to the eutectic, contained only corundum, indicating that the amount of m-alumina present is a function of the amount of quenched liquid.

True mullite ($3Al_2O_3 \cdot 2SiO_2$) contains 13.2% silicon. Qualitative spectroscopic analysis of the m-alumina showed a silicon concentration near 1%. This can be accounted for by the accumulation of the silicon present in the original cryolite and alumina. It is not enough, of course, to account for the similarity to true mullite.

The m-alumina was heated at various temperatures to determine its stability. Table II lists the results of x-ray analyses of these materials. The conversion of m-alumina to corundum on heating demonstrates that it is a metastable phase.

Generally, x-ray analysis was too insensitive to detect m-alumina in the quenched liquid. Its occasional detection demonstrated, however, that the m-alumina is a component of the quenched liquid and was not produced during the aluminum chloride extraction. A refractive index of 1.604 ± 0.016 was determined for the extracted m-alumina. A more precise determination was not possible because of the extremely fine particle size of the precipitate (Fig. 5).

Conclusions

The following is offered to explain the observations of this work. Alumina dissolves in cryolite by a reaction mechanism to produce one or more species (perhaps oxyfluorides) that are stable only in the melt. These compounds disproportionate on equilibrium freezing to cryolite and corundum, which then are stable to room temperature. On the cryolite side of the eutectic, cryolite freezes as the primary

phase. If the liquid is rapidly quenched, however, there is insufficient time for the alumina from the disproportionation to recrystallize as corundum. Rather, it assumes the mullite-like configuration, which tentatively might be considered a skeletal arrangement having some characteristics of its oxyfluoride precursor. The quenched liquid is thus an intimate mechanical mixture of cryolite and m-alumina with an observable refractive index that is actually an average index of the two phases, taken in appropriate proportions.

A Study of the Iodide Niobium Process

Robert F. Rolsten[1]

Eastern Laboratory, E. I. du Pont de Nemours & Company, Gibbstown, New Jersey

ABSTRACT

It was established that the rate of deposition of niobium by the thermal decomposition of niobium iodides can be expressed in units of moles of niobium deposited per unit length of a deposition element per unit of time. The rate of deposition of niobium was studied (*a*) with deposition temperatures from 750° to 1100°C, (*b*) with feed material temperatures from 240° to 470°C, and (*c*) with crude niobium with different surface areas.

Van Arkel (1) prepared single crystal tungsten rods by the thermal decomposition of tungsten hexachloride on a resistively heated wire in an evacuated flask in 1923. Van Arkel, deBoer, and Fast (2-7) subsequently extended the technique to the preparation of other metals from their volatile halides. The metal iodides have been used extensively since they exhibit a low thermal stability. In addition, iodine is particularly well adapted as the basis for such a process because it reacts readily with most elements to form compounds which are moderately stable in the vapor state and which dissociate at a high temperature. Furthermore, iodine does not react directly with most oxides.

Fast (8) studied the rate of formation of titanium by the thermal decomposition of gaseous titanium iodides. The temperature of the deposition element was maintained constant while the temperature of the feed material was varied. The deposition rate increased from a minimum at room temperature to a maximum at about 175°C, decreased to a second minimum at about 300°-470°C, and then increased again to 520°C, the highest feed temperature employed in the series of measurements. However, Fast (8) noted, from experiments where the deposition bulb was fabricated from Supermax glass, that the deposition rate at a feed temperature of 620°C was considerably higher than at 520°C. Fast (7), Döring and Molière (9), and Emelyanov, Bystrov, and Evstyukhin (10) observed a deposition rate of zirconium vs. bath temperature curve that was similar in shape to the curve observed by Fast (8) for titanium.

It was reported (11) recently that high-purity niobium[2] could be prepared by an iodide decomposition process. The purpose of the investigation reported here was to determine the effect that such factors as (*a*) deposition and feed temperatures, (*b*) reactivity of the crude (feed) niobium to be refined, and (*c*) the predominant gas and condensed solid phase species would have on the rate of deposition of niobium.

Experimental

The deposition unit employed throughout this investigation is shown in Fig. 1. A 64-mm diameter Vycor cylinder was equipped with a 15-mm OD quartz reentrant tube or finger. The crease or constriction in the deposition bulb was 50 mm in diameter and 45 mm from the bottom of the cylinder. This crease served to position the 50 mm diameter perforated molybdenum retaining cylinder. Molybdenum does not form a volatile iodide under the experimental conditions for deposition and, consequently, is not transferred. The impure niobium was contained in the annular space between the Vycor bulb and the molybdenum cylinder.

[1] Present address: U.S. Borax Research Corporation, 412 Crescent Way, Anaheim, California.

[2] Niobium metal prepared by the thermal decomposition of the niobium iodides can be designated as iodide niobium.

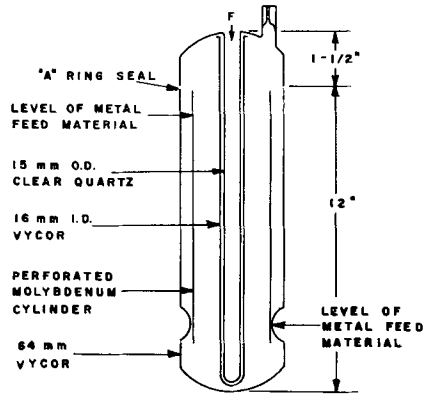

Fig. 1. Reentrant-type apparatus for the preparation of metals.

In a typical experiment, the deposition unit was thoroughly cleaned, charged with impure niobium, and the head assembly attached to the deposition bulb by fusing the Vycor at "A". Thermocouples were fastened to the wall of the deposition bulb, covered with a single layer of ⅛ in. thick asbestos cloth, and wound with 14 gauge Nichrome wire. This unit was positioned centrally in the 6 x 18 in. cavity of the empty salt bath and then connected (glass-to-glass) to a vacuum system composed of a 3-turn glass coil to eliminate fracture due to vibration or expansion, a McLeod gauge, a cold trap, a mercury diffusion, and a mechanical pump. Fifteen grams of resublimed iodine were added to an auxiliary bulb (reservoir) held in dry ice. The space between the steel wall of the salt furnace and the Nichrome heating element was packed with high-temperature insulating wool. The deposition bulb, with the crude metal was vacuum outgassed at 800°-850°C, and heat was supplied from the Nichrome element coiled around the deposition bulb. After the pressure in the system was maintained at 10^{-5} mm Hg or less for 48 hr, the Nichrome element was disconnected, the system cooled to room temperature under vacuum, and the wool insulation removed from the furnace. A salt mixture ($NaNO_3$-KNO_3-$NaNO_2$) was added to the tank of the furnace and was melted with power supplied from the furnace. The liquid salt was agitated with an auger-type screw that lifted salt from the bottom of the tank and distributed it at various levels and directions to the top of the tank. The temperature of the deposition bulb, located 2 in. from the bottom of the tank and 2 in. beneath the surface of the salt, was maintained at ±3°C. Deposition temperatures were attained independently and measured with a platinum-platinum 10% rhodium thermocouple located in the center of the Nichrome wire helical heating element, indicated by "F" in Fig. 1. At the termination of the deposition experiment, liquid salt was siphoned from the salt tank and the residual niobium iodide within the deposition bulb was condensed on the walls of the cold Vycor bulb. The temperature of the deposition element was maintained at 900°-1000°C to prevent any iodide from condensing upon the niobium deposit.

In some experiments, the deposition bulb was positioned centrally within a 100-mm ID furnace. Thermocouples were fastened to the wall of the deposition bulb. Additional thermocouples were located at ½ in. intervals from the top to the bottom of the 24 in. long furnace, and they extended ¼ in. from the inside wall of the furnace into the air gap between the furnace and deposition bulb.

The weight of metal deposited was determined directly by weighing. The Vycor tube with the niobium deposit was compressed between polished stainless steel (No. 316) plates. The ductile deposit deformed while the Vycor tube shattered and thus provided an easy method of separation.

The crude (feed) niobium used in this work was in the form of 4-10 mil sheet and 12 mm diameter by 4 mm thick sintered powder pellets. Both forms are available commercially. Typical analytical results, in weight per cent, of the starting and iodide niobium, are summarized below:

	Oxygen	Nitrogen	Hydrogen	Carbon	Iron	Silicon	Tantalum
Pellets	0.435	0.018	0.0021	0.050	0.05	0.1	~0.5
Iodide (from pellets)	0.064	0.001	0.0008	<0.001	<0.005	0.006	—
Sheet	0.195	0.012	0.0009	0.006	0.01	0.01	~0.4
Iodide (from sheet)	0.043-0.062	<0.001	0.0001	<0.001	<0.005	0.001	0.04-0.18

Oxygen and hydrogen were determined by vacuum fusion analyses utilizing a platinum bath at 1900°C, nitrogen by micro-Kjeldahl, carbon with a Leco No. 515 Carbon Determinator, and iron, tantalum, and silicon by spectrographic analysis.

Results and Discussion

Runnalls and Pidgeon (12) and Döring and Molière (9) reported that the deposition rate of titanium and zirconium, from their respective iodides, was dependent on the surface area of small diameter (0.13 to 0.75 mm) deposition elements. Shapiro (13) reported that the deposition rate of zirconium was independent of the surface area for cylindrical deposition elements with diameters between 2 and 25 mm. This was observed from zirconium (filament) deposition temperatures in the range from 1100° to 1450°C. In addition, Shapiro (13) observed that the rate of deposition of zirconium remained constant at a given bath or feed material temperature and concluded that the vapor pressure, the value of which is determined by the coldest spot in the vessel and which value would thus remain constant for a given feed (bath) temperature, fixed the rate of deposition at a given deposition temperature.

Five deposition experiments were made utilizing a liquid salt bath with the feed temperature and deposition temperature of 244° and 1000°C, respectively. The initial diameter of the Vycor deposition element was 19 mm. Each experiment was made with 450 g of niobium pellets. The results from these five

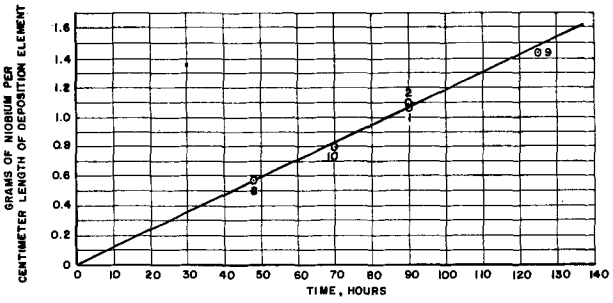

Fig. 2. Deposition element growth vs. time

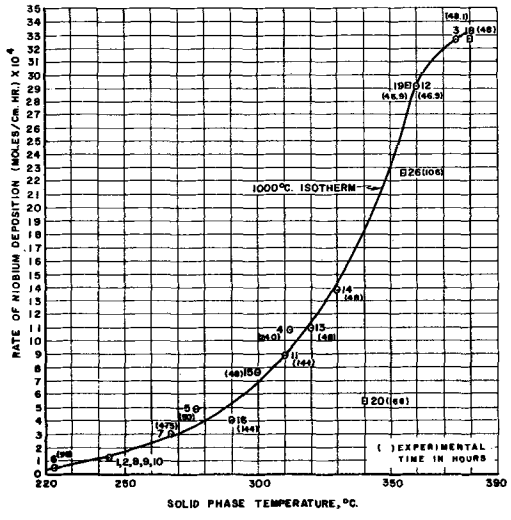

Fig. 3. Dependence of deposition rate on the condensed iodide temperature. Niobium pellet: ⊙ = salt bath; □ = air bath.

experiments, 1, 2, 8, 9, and 10, are shown graphically in Fig. 2, a plot of the grams of niobium deposited per centimeter of length of deposition element vs. the deposition time in hours. These data can be expressed by a straight line over the time interval from zero to 125 hr. Experiments 1 and 2 were made under identical conditions with the deposition time of 90 hr, to indicate the reproducibility of the measurements. The grams of metal deposited per centimeter of length of deposition element were 1.064 and 1.080 for experiments 1 and 2, respectively.

The constancy of deposition rate with time, with the steadily increasing surface area, clearly shows that the decomposition of the iodide on the deposition element cannot be rate controlling. If it were, the increased area of the deposition element would certainly affect the deposition rate. This leaves either (*a*) diffusion of iodide to or iodine from the deposition element or (*b*) the rate of reaction of the liberated iodine with the crude niobium as the possible rate controlling steps.

A total of sixteen experiments (charge of 450 g of niobium pellets) were made in the salt bath with a deposition temperature of 1000°C and feed temperatures from 224° to 375°C. The results from these experiments are summarized in Fig. 3, a plot of the deposition rate in moles of niobium per centimeter of length of the deposition element per hour vs. the condensed iodide[3] temperature. The experimental times, in hours, are reported in parentheses in Fig. 3. The low deposition rate of 0.00005 moles cm^{-1} hr^{-1} was observed at 224°C, and this rate steadily increased to the maximum of 0.00326 moles cm^{-1} hr^{-1} at 375°C, the highest temperature used in this series of experiments. It can be seen that the smooth curve which represents the data changes slope at about 350°C, which indicates that the maximum deposition rate may occur in the temperature range of 380° to 400°C for the 1000°C deposition isotherm.

Sixteen experiments (charge of 450 g of niobium pellets) were made in an air bath with a deposition temperature of 1000°C and at feed temperatures from 335° to 458°C. The results from the experiments for the 1000°C isotherm are summarized in Fig. 4, a plot of the deposition rate vs. feed temperature. The latter temperatures, measured at the surface of the deposition bulb, were about 90°C higher than the temperatures of the air bath. It can be seen that the low rate of 0.00050 moles cm^{-1} hr^{-1} was observed at the lowest condensed iodide temperature (335°C) employed. This rate increased steadily to a maximum of 0.0033 moles cm^{-1} hr^{-1} at about 370°-375°C and then decreased to a second minimum at about 410° to 440°C. From this minimum, the deposition rate again increased to 0.0015 moles cm^{-1} hr^{-1} which was observed at 458°C, the highest condensed iodide temperature employed.

There is a close similarity in the general shape of the deposition rate-temperature curves shown in Fig. 3 and 4. The best agreement occurs in the temperature range from 350° to 380°C, where both sets of data show a maximum in the deposition rate. However, considerable deviation occurs at about 340°C. For example, in experiment 20 (air bath) the observed deposition rate was 0.00054 moles cm^{-1} hr^{-1} while the deposition rate for the corresponding experiment (salt bath) was 0.00178 moles cm^{-1} hr^{-1}. The fact that the individual sets of data given in Fig. 3 and 4 can be expressed by a smooth curve, that is, each set of data are internally consistent but mutually consistent only over a limited range, strongly indicates that some unknown factor entered into the reaction process. In order to make experiment 20 (340°C) agree with the curve shown

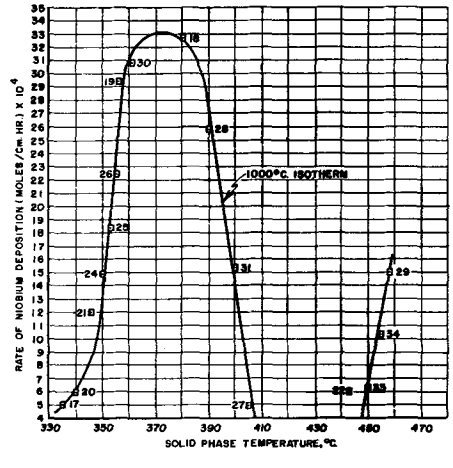

Fig. 4. Dependence of deposition rate on the condensed iodide temperature. Air bath-niobium pellet.

[3] The expressions, "condensed iodide temperature" and "deposition bulb temperature" are considered to be synonymous in this paper.

in Fig. 3, an error in temperature measurement of 50°C would have to be accounted for. It should be remembered, however, that the deposition bulb operated in the liquid salt would be susceptible to more accurate temperature measurement and operation at a more uniform temperature than the deposition bulb operated in the air bath. In addition the wall temperature of the bulb would be much closer to the temperature of the liquid salt.

Twenty-two experiments were made in which each charge consisted of 15 g of resublimed iodine and 500-600 g of 4-10 mil niobium sheet. All experiments were conducted in an air bath, and the temperature of the wall of the deposition bulb was about 70°C higher than the temperature of the air bath. Fifteen of these experiments were made with a deposition temperature of 1000°C and feed temperatures from 310° to 470°C, and five experiments were made with a deposition temperature of 1100°C and feed temperatures from 305° to 405°C. In addition, two experiments, 53 and 55, were made with the deposition temperature of 750° and 900°C, respectively. These deposition rate data are summarized in Fig. 5. It can be seen that the rate data for the 1000° and 1100°C isotherms are quite similar in shape to the curves given in Fig. 3 and 4. All curves start out at a low deposition rate, increase to a maximum rate at about 380°C, and then the rate decreases to a maximum at about 430°C. The deposition rate increases at condensed iodide temperatures greater than 430°C.

The most pronounced difference in the deposition rate data obtained by using sheet (Fig. 5) or pellet niobium (Fig. 4) as the starting material can be seen in the maximum rate of deposition that was attained for the 1000°C isotherms. For example, the maximum rate of 0.00082 moles cm^{-1} hr^{-1} was obtained with sheet niobium feed while the maximum rate of 0.00332 moles cm^{-1} hr^{-1} was obtained with

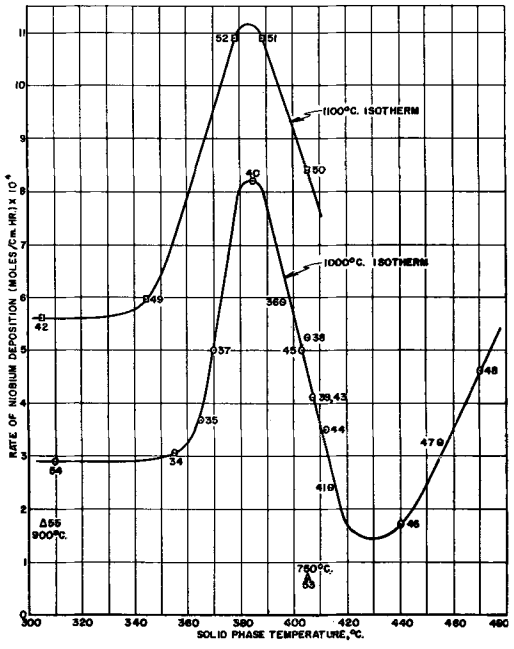

Fig. 5. Plot of deposition rate of niobium vs. condensed iodide temperature, air bath-niobium sheet.

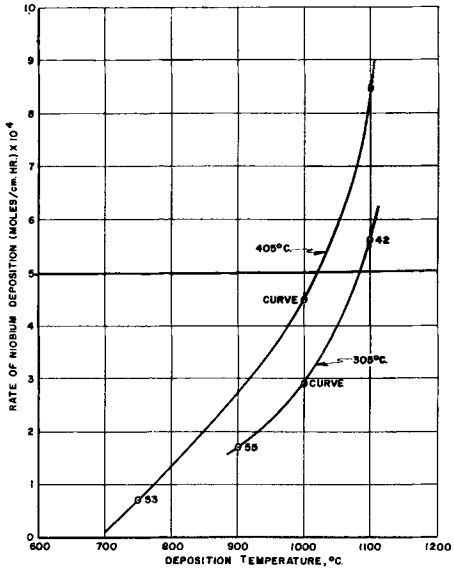

Fig. 6. Plot of deposition rate of niobium vs. deposition temperature.

niobium pellets as feed. Since the conditions under which the above experiments were conducted were identical except for the difference in the feed niobium, it is clear that the reaction of the feed material with the liberated iodine can determine the rate of deposition. Thus, the high surface area niobium pellets can react quickly with the liberated iodine to form iodide. Consequently the iodine pressure does not play as prominent a role in the deposition process when niobium pellets are used as the feed material.

The effect of the deposition temperature on the deposition rate of niobium at constant condensed iodide temperature can be seen in Fig. 6. The condensed iodide isotherm, 405°C, indicated that the deposition rate increased from 0.00007 moles cm^{-1} hr^{-1} at 750°C to 0.00084 moles cm^{-1} hr^{-1} at 1100°C. A similar curve was obtained for the 305°C isotherm. Extrapolation of the 405°C curve to zero deposition rate indicated that the minimum deposition temperature for niobium, that is, the temperature above which the niobium iodides are thermally unstable, would be somewhere in the range of 700°C. The minimum deposition temperature for the 305°C isotherm would, however, be expected to occur at a temperature below 700°C since the total pressure would be less than for the 405°C isotherm. Therefore, the two curves would cross.

In expressing the data given above in Fig. 3, 4, and 5, it was assumed that:

1. The method of expressing the deposition rate, moles cm^{-1} hr^{-1}, was valid for all feed temperatures and not just for the one temperature (244°C) investigated. The feed temperatures, which determine the total pressure in the system, were such as to permit deposition to be controlled by diffusion and the operating conditions did not permit deposition to occur in either the free molecule (lower pressure) or in the diffusion plus convection regions (higher pressure).

2. The deposition mechanism remained the same for all condensed iodide temperatures, that is, for

both the maximum and the minimum total pressures within the deposition bulb.

3. Only iodine and niobium iodides (not oxyiodide or hydrogen, etc.) contributed to the total pressure of the system.

The deposition rate of niobium must certainly be dependent on the availability of niobium iodide(s) at the deposition element. The quantity of gaseous niobium iodide depends on the reactivity of the crude niobium, the stability of the iodides in contact with excess niobium, and the vapor and disproportionation pressures of the various iodides. Therefore, a cursory study of the niobium iodides was made in order to determine the effect of the various iodides on the deposition process.

Niobium pentaiodide was prepared (14) by the reaction of iodide niobium and resublimed iodine in an evacuated tube at 280°-290°C. A high partial pressure of iodine was maintained during the reaction to stabilize the temperature sensitive pentaiodide. The excess iodine was sublimed at 114°C from the large bronze colored, plate-like crystals of the pentaiodide. Niobium was determined as Nb_2O_5 by dissolving and precipitating the sample in freshly filtered NH_4OH, filtering, and igniting in air in a platinum crucible. Iodine was determined by the modified (15) Volhard technique. Anal. calcd. for NbI_5: Nb, 12.77; I, 87.23; found: Nb, 12.81, 12.70, 13.1, 12.70; I, 87.33, 87.55, 87.52, 87.24, 87.17. Crystals of the pentaiodide were placed in a calibrated 10-ml pycnometer (inside a dry box) and the density was determined at 25°C by evacuating the pycnometer bulb containing the pure pentaiodide and then distilling, under vacuum, absolute carbon tetrachloride onto the solid sample. Density values for five different samples were 4.98, 5.04, 5.19, 5.14, and 5.08 g cc^{-1}. This pycnometric density can be compared to the x-ray density of 5.24 g cc^{-1} for the orthorhombic pentaiodide that contains 16 formula weights per unit cell.

A sample of this pentaiodide was placed in a Pyrex tube, equipped with a break seal that was broken under vacuum, and heated at 243°C for 145 hr. Iodine was liberated and the nonvolatile residue was observed to have an I/Nb ratio of 2.97. A second sample of pure pentaiodide was treated in the manner described above, but heated to 250°C. The observed I/Nb ratio was 3.07. X-ray diffraction data obtained from the two niobium iodide samples, $NbI_{2.97}$ and $NbI_{3.07}$, are in essential agreement.

Niobium pentaiodide was heated (16) to 270°C for 48 hr in 0.8 mm pressure of iodine to yield dark gray, metallic-appearing crystals of NbI_4 which were in the form of elongated hexagonal plates and fine needles. Heating a higher iodide to 425°-430°C for 48 hr in a partial pressure of iodine resulted (16) in the formation of pure NbI_3.

Samples of NbI_3 were placed in a Pyrex tube, equipped with a break seal that was broken under vacuum, and heated to 450°C for 123 hr. Material started to sublime at 250° to 260°C, and a brown to bronze colored solid was evolved at a temperature between 430°-450°C. Samples of this residue were observed to have an I/Nb ratio of 1.74. The condensed solid iodide phase removed from the deposition bulb at the termination of an experiment with the condensed iodide and deposition temperatures of 310° and 1000°C, respectively, was observed to have an I/Nb ratio of 2.74. In another experiment, some of the gaseous iodide was removed from the deposition bulb while deposition was in progress and was observed to have an I/Nb ratio of 3.12. The crude niobium was maintained at 430°C with the deposition element at 1000°C. It should be recognized that the solid iodide remaining after a deposition experiment necessarily does not have to be the same as the solid iodide existing during the experiment.

A possible explanation for the shape of the deposition rate vs. feed material temperature curves is now offered. It should be recognized that the following explanation for the deposition of niobium from its volatile iodides parallels the explanation offered by Fast (7, 8) for the zirconium-zirconium iodide and the titanium-titanium iodide systems. Pure niobium pentaiodide is not stable (forms lower iodides) at temperatures of about 200°C in vacuum or when heated in the presence of excess niobium. This thermal instability should be more pronounced inside the deposition bulb where a temperature gradient exists in the crude niobium. Metal at the surface of the molybdenum retaining screen, due to the location of the deposition element (~1000°C), will be considerably hotter than the metal at the wall of the deposition element. Therefore, the niobium at the retaining screen, due to its higher temperature, will be more chemically active toward the liberated iodine. This will prevent the development of a high partial pressure of iodine and this effect will tend to reduce further the thermal stability of the pentaiodide ($NbI_5 \rightarrow NbI_4 + \frac{1}{2} I_2$). The net result is that NbI_5 should not be an important condensed iodide species within the deposition bulb. This seems to have been realized since the solid iodide phase, with the condensed iodide and deposition temperatures of 310° and 1000°C, respectively, was observed to be I:Nb = 2.74.

Solid niobium tetraiodide was not observed in the deposition bulb after any of the experiments and, consequently, it may not be an important condensed iodide species. It should be noted, however, that in the case of tantalum, a compound corresponding to I:Ta = 3.91 was removed from the deposition bulb at the conclusion of a deposition experiment. Corbett and Seabaugh (16) reported that the heating of a higher iodide to 425° to 430°C in a partial pressure of iodine yielded NbI_3. The temperature of the crude niobium at the molybdenum retaining screen within the deposition bulb may be at this temperature level. The fact should not be overlooked, however, that the tetraiodide could enter into the deposition process according to the reactions at 300°C: $NbI_{4(c)} \rightarrow NbI_{4(g)}$ and $2NbI_{4(c)} \rightarrow NbI_{5(g)} + NbI_{3(c)}$. In any event, the quantity of iodide in the gas phase (a low partial pressure) is quite small in the condensed iodide temperature range of 300°-340°C which results in a low deposition rate. In the condensed iodide temperature range where the deposi-

tion rate is at a minimum (~300°C) to the maximum (~380°C), the quantity of iodide in the gas phase was increased as a result of the reactions specified above or for the following: $NbI_{3(c)} \rightarrow NbI_{3(g)}$ and $2NbI_{3(c)} \rightarrow NbI_{4(g)} + NbI_{2(c)}$.

The increase in deposition rate with the condensed iodide temperature in the lower temperature range can be explained on the basis of an increase in vapor pressure of the iodide; however, the behavior from the maximum (~380°C) to the minimum (~400°C) apparently has no simple explanation. Although there is an increase in the quantity of the nonvolatile, thermally stable, lower iodide in the condensed iodide temperature range of 380°-400°C, this alone should not cause the deposition rate to diminish. There can be a pressure over a mixture of solid lower iodides and this pressure, providing there is no solid solubility between the iodide species, will be independent of the quantity of the solid species present. The nonvolatile lower iodide could, however, coat the crude niobium and presumably prevent the iodine liberated at the deposition element from reacting with the crude niobium which would permit the partial pressure of iodine to increase. Thus, any increase in condensed iodide temperature would permit the formation of more lower iodide to coat the crude niobium and prevent the reaction between the niobium and iodine. This would result in a still higher partial pressure of iodine with a necessary shift in the equilibrium and could conceivably permit the iodine to attack and remove niobium from the deposition element. Thus, the net or apparent deposition rate would be quite small.

Upon further increasing the condensed iodide temperature, that is, from about 440° to at least 470°C, the diiodide can enter into the deposition process as a result of the possible reactions:

$$NbI_{2(c)} \rightarrow NbI_{2(g)},\ 2NbI_{2(c)} \rightarrow NbI_{4(g)} + Nb$$
$$\text{and } 2NbI_{2(c)} \rightarrow NbI_{(c)} + NbI_{3(g)}$$

and the deposition rate again increases. In one deposition experiment (sheet niobium was used as the crude) a sample of the gaseous species (iodide and iodine) was removed from the deposition bulb and observed to be I:Nb = 3.12. This would of course indicate that NbI_3 is the principal gaseous iodide within the deposition bulb at condensed iodide temperatures from 430° to 470°C.

The difference in thermal stability of the various niobium iodides manifests itself in that the same deposition rate of niobium can be obtained from at least three different condensed iodide temperatures. For example, the deposition rate of 0.0015 moles cm^{-1} hr^{-1} can be obtained with condensed iodide temperatures of 350°, 399°, and 459°C as shown in Fig. 4.

Reactions in the Niobium-Hydrogen System

W. M. Albrecht, W. D. Goode, and M. W. Mallett

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Equilibria and elevated-temperature x-ray studies show that a solid solution of hydrogen in niobium is produced throughout most of the system. A miscibility gap was found at low temperatures and pressures with a critical point at about 140°C, 0.01 mm of mercury hydrogen pressure, and 0.3 H/Nb. Sorption rates at 300°-550°C were initially linear. At higher temperatures, sorption rates were controlled by diffusion in the metal matrix. Diffusion coefficients at 600°-700°C can be expressed by:

$$D = 0.0215 \exp\left[(-9370 \pm 600)/RT\right]$$

Desorption rates were slower than those predicted by diffusion.

In a previous study (1), the authors investigated the equilibria in the niobium-hydrogen system in the ranges 100°-900°C, 10-1000 mm of mercury hydrogen pressure, and at atomic ratios of hydrogen to niobium, H/Nb, of 0.01-0.85. A single-phase solid solution was produced throughout most of the system. However, the presence of a two-phase region in the system was indicated at low temperatures and hydrogen pressures. The present study was made to establish more definitely the extent of this region. Equilibria were established at pressures lower than those of the preceding work. Equilibrium products were identified by x-ray diffraction. Also, studies were made of the kinetics of the reaction of hydrogen with niobium and of the diffusion of hydrogen in the metal.

Paxton and Sheehan (2) measured the solubility of hydrogen in niobium at 1 atm pressure to establish partially the phase diagram of the system. They also made permeability experiments to measure the rate of diffusion of hydrogen in the metal. Gulbransen and Andrew (3) have reported the kinetics of the reaction of hydrogen with niobium for 200° to 900°C at hydrogen pressures up to 57 mm Hg. Both of these studies have a bearing on the present investigation.

Material

The original niobium bars were cut and fabricated to approximately 0.3 to 0.9 cm rods and to 0.03 cm sheet. Samples for the reaction rate and diffusion studies were vacuum annealed at 1150°C for ½ hr. Analysis of the fabricated niobium after annealing has been reported (1). The major impurities were 0.15 w/o Ta and 0.043 w/o oxygen. All other impurities were below 0.02 w/o.

Pure hydrogen was obtained from the thermal decomposition of uranium hydride prepared from dry tank hydrogen and degassed uranium chips.

Experimental Methods

The method to obtain equilibria data has been described (1). However, for this work, the micro-Sieverts apparatus was equipped with a differential oil manometer to measure pressures in the range 0.1-50 mm Hg. Briefly, data were obtained as follows. A measured amount of hydrogen was added to the calibrated reaction tube containing 3-4 g of sheet (0.03 cm thick) niobium. At the desired temperature, the system was allowed to come to constant (equilibrium) pressure as measured on the differential oil manometer. The equilibrium composition was calculated from the equilibrium pressure, specimen weight, volume of gas addition, and volume capacity of the reaction system at the experimental temperature.

Sorption rates were measured with another modified Sieverts apparatus (4). Essentially, the apparatus consists of a reaction tube, pressure regulator, gas buret, and a high vacuum-pumping system. Cylindrical specimens approximately 0.3, 0.6, and 0.9 cm in diameter and 1-3 cm long were dry abraded through 240-, 400-, and 600-grit silicon carbide paper. Each specimen was weighed, measured, and spot welded to a Pt-Pt + 10% Rh thermocouple. After a light final polish with dry 600-grit silicon carbide paper, the sample was hung in the reaction tube and sealed to the Sieverts apparatus. The system was evacuated to less than 0.01 μ of mercury, then heated to the temperature of the run.

The reaction was initiated by admitting hydrogen through the pressure regulator to the reaction tube. The buret was kept balanced at atmospheric pressure at all times. Readings of the buret were taken at convenient time intervals depending on the speed of the reaction. The amount of gas reacted with the sample was the difference between the volume added from the buret and the volume remaining in the gas phase in the calibrated dead space of the reaction tube.

Diffusion coefficients for hydrogen in niobium were determined from sorption rate data obtained at 600°-700°C. A few experiments were made to determine diffusion rates by a technique based on measuring rates of outgassing of specimens in a vacuum of 10^{-6} to 10^{-5} mm Hg at various temperatures. The apparatus and procedure have been described previously (5, 6). The rates of hydrogen outgassing were measured for 0.6 cm diameter niobium cylin-

Results and Discussions

Equilibria

Equilibrium data obtained in the present study have been combined with those previously reported for the niobium-hydrogen system to give comprehensive coverage of the ranges 100°-900°C, 0.1-1000 mm Hg pressure, and 0.01-0.85 H/Nb ratios. Figure 1 is a logarithmic plot of equilibrium pressure against composition for various temperatures. It is seen that none of the isotherms show invariant pressures. This indicates that there is no two-phase region within these ranges. Equilibrium data could not be obtained at lower temperatures and pressures because of the extremely long times required.

Equilibria in the niobium-hydrogen system were interpreted in terms of the conditions required to form various products (solid solutions) having definite H/Nb ratios as discussed in the previous paper

Table I. Thermodynamic data for formation of various niobium-hydrogen compositions

0.70	5005	10.670	22.90 ±0.71	35.65 ±0.97

(1). For a given composition, the equilibria can be expressed by the equation,

$$\log_{10} P_{mm} = -[A/T(K)] + B \qquad [1]$$

From plots of the logarithm of the equilibrium pressure against reciprocal temperature, various isopleths are obtained from which the constants, A and B, can be calculated. Several representative isopleths are shown in Fig. 2. Values of the constants determined by the method of least squares are given in Table I. Using the familiar Gibbs-Helmholtz and van't Hoff equations, and defining the activity of hydrogen as equal to the inverse hydrogen pressure in atmospheres, the constants can be defined as,

$$A = -\overline{\Delta H}/2.303\ R \qquad [2]$$

and

$$B = -\overline{\Delta S}/2.303\ R + \log 760 \qquad [3]$$

Partial molar heats of solution, $\overline{\Delta H}$, and partial molar entropies, $\overline{\Delta S}$, calculated from Eq. [2] and [3] are also given in Table I. It is seen that there is a general increase in the magnitude of the partial molar heat of solution and entropy with hydrogen composition.

X-ray diffraction measurements were made at room temperature to 400°C on niobium and on specimens containing 0.097, 0.24, and 0.54 H/Nb ratios. Data were obtained from x-ray patterns of

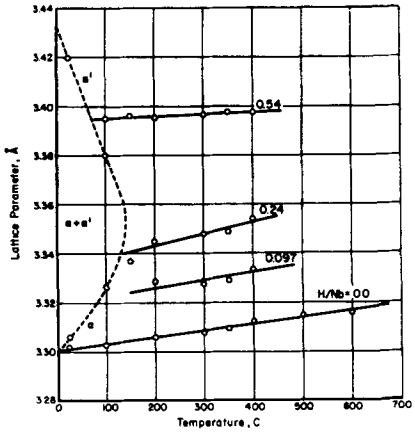

Fig. 3. Variation of lattice parameter with temperature and composition.

the specimens contained in sealed quartz capillaries. In all cases body-centered cubic structures were found. The variation of lattice parameters with temperature and composition are shown in Fig. 3. Specimens having compositions of 0.097 and 0.54 H/Nb contained two phases at room temperature and a single phase at 100°C and above. The specimen having a 0.24 H/Nb ratio showed two phases at room temperature and 100°C and one phase at 150°C and above. In the single phases, the lattice parameters increased with temperature and with hydrogen content. From the data for niobium, the thermal expansion coefficient for the metal was calculated to be 7.9 x 10^{-6}/°C. This is in good agreement with the handbook value of 7.1 x 10^{-6}/°C (7). It can be seen in Fig. 3 that the thermal expansion of the specimens containing hydrogen is approximately the same as that of the metal. The change in lattice parameter with hydrogen concentration was calculated to be 0.0023 ± 0.0002Å/1a/o hydrogen.

X-ray data in Fig. 3 can be used to outline a two-phase region in the niobium-hydrogen system. The limits of the two-phase region were calculated to be 0.024-0.75 H/Nb ratios at room temperature and 0.099-0.52 H/Nb ratio at 100°C. Also, by extrapolating the equilibrium data to lower pressures, isobars of 0.01 and 0.001 mm Hg were calculated which pass through the two-phase region. The phase diagram showing various isobars for the niobium-hydrogen system is presented in Fig. 4. It is seen that the critical point where the two phases become identical is at about 140°C, 0.01 mm of mercury hydrogen pressure, and 0.3 H/Nb ratio. It should be noted that the designation of the high-hydrogen phase which was reported (1) previously as beta has been changed to alpha prime. This is in keeping with the customary nomenclature for solid solutions showing a miscibility gap.

Values for hydrogen solubility in niobium at 1 atm pressure were reported recently by Paxton and Sheehan (2). Their results are compared with those of Sieverts and Moritz (8) and of this study in Table II. It is seen that solubilities of Paxton and Sheehan

Table II. Comparison of equilibria data at 1 atm pressure for the niobium-hydrogen system

Temp, °C	Equilibrium composition, H/Nb		
	Paxton and Sheehan	Sieverts and Moritz	Present study
800	0.047	0.051	0.051
600	0.16	0.15	0.16
500	0.22	0.39	0.42
400	0.55	0.64	0.68
300	0.66	0.73	0.77

below 600°C are considerably lower than those of the other studies. On the basis of the solubility study and high-temperature x-ray data, Paxton constructed a phase diagram for the niobium-hydrogen system showing the presence of the hydrides, Nb_2H having a hexagonal structure, and NbH having a body-centered cubic structure. The presence of the hydride Nb_2H is not indicated in the present study. Such a hexagonal structure has been attributed to impurities, probably nitrides, by Brauer and Hermann (9). The NbH structure of Paxton and Sheehan corresponds to the alpha prime structure of the present study.

Sorption Kinetics and Diffusion

Kinetic data for the sorption of hydrogen by niobium to produce compositions of 0.05, 0.10, 0.50, and 0.70 H/Nb were determined in the range 300°-700°C. Experimental conditions of temperature and pressure were determined from the isopleth (Fig. 2) of the desired product. Representative rate data are shown in Fig. 5 and 6. For every reaction up to 550°C, the initial sorption rate was linear (see Fig. 5). After a time depending on the conditions of the run, the rate decreased and stopped when equilibrium was established. Usually the reactions remained linear until about 40-50% of saturation was attained. At 300° to 450°C only the initial part of the sorption curves were obtained because of the very long times required to reach equilibrium. At 600°-700°C no initial linear rate was noted (see Fig. 6). A summary of all the linear rate constants ob-

tained at 300°-550°C is given in Table III. The variation of the initial linear rate constants with temperature for the various compositions is shown in an Arrhenius plot in Fig. 7. Data for the equation,

$$k = A \exp [-Q/RT] \qquad [4]$$

for each composition are given in Table IV. It was found that at a given temperature the initial linear rate increased with increasing hydrogen composition of the product. Also, the activation energies increased with H/Nb ratio.

Gulbransen and Andrew (3) found no consistent rate type for the niobium-hydrogen reaction from 250° to 900°C at pressures up to 5 cm. A linear reaction rate was reported only at 300°C and 21 mm of mercury hydrogen pressure. At these conditions, a composition of 0.6 H/Nb would be produced. The rate constant calculated from their data is 1.6 x 10^{-4} ml/cm²/sec. This rate constant is in line with the present work. However, at 700° and 900°C Gulbransen and Andrew found rather slow reaction

rates. They show reactions continuing up to 2 hr using 3.3 mil (0.008 cm) thick specimens. In the present study, a specimen 0.6 cm in diameter attained equilibrium solubility in about 5 min at 700°C (see Fig. 6).

At 600°-700°C the sorption curves could be described by a diffusion equation in which sorption is initially parabolic. Modifying the derivation of Demarez, *et al.* (10) the solution of Fick's second law for diffusion in a finite cylinder can be expressed as

$$C/C_o = 1 - \frac{32}{\pi^2} \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} \frac{1}{\beta^2_m (2n+1)^2} \exp\left\{ -Dt \left[\frac{(2n+1)^2\pi^2}{l^2} + \frac{\beta^2_m}{a^2} \right] \right\} \qquad [5]$$

where: C = average hydrogen concentration at time, t; C_o = final equilibrium hydrogen concentration; β_m = a root of the Bessel function, $J_o(\beta)$; D = diffusion coefficient; l = length of cylinder; and a = radius of cylinder.

The cylindrical specimens used in the sorption experiments had a length five times the radius ($l/a = 5$). Substituting $5a$ and l, Eq. [3] becomes,

$$C/C_o = 1 - \frac{32}{\pi^2} \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} \frac{1}{\beta^2_m (2n+1)^2} \exp\left\{ \frac{-Dt}{a^2} \left[\frac{(2n+1)^2\pi^2}{25} + \beta^2_m \right] \right\} \qquad [6]$$

The theoretical curve obtained from Eq. [6] is shown in Fig. 8, in which C/C_o is plotted against

$(Dt/a^2)^{1/2}$ so as to yield a straight line for the initial parabolic behavior. The parabolic rate is followed until about 40% of saturation ($C/C_o = 0.4$) is attained. If the sorption of hydrogen is diffusion controlled, a proper choice of D would result in the experimental curves coinciding with that of theory. The excellent agreement of several experimental curves at 600°, 650°, and 700°C with theory is also seen in Fig. 8. It should be pointed out that the sorption curves obtained at the lower temperatures (350°-550°C) did not follow the theoretical diffusion curve. Probably some surface reaction affected the sorption rates.

The diffusion coefficients that were calculated from sorption and desorption rate data are summarized in Table V. It is seen that the diffusion coefficients from the outgassing (desorption) experiments are somewhat lower than those obtained from sorption rates. There was a poor agreement of the desorption rates with diffusion theory so that diffusion coefficients calculated from desorption are of doubtful worth. The diffusion rates obtained from sorption data give the best values for the diffusion coefficients for hydrogen in niobium.

Diffusion coefficients reported by Paxton and Sheehan (2) and included in Table V are considerably lower than those of the present work. Paxton and Sheehan infer that a slow surface reaction in the

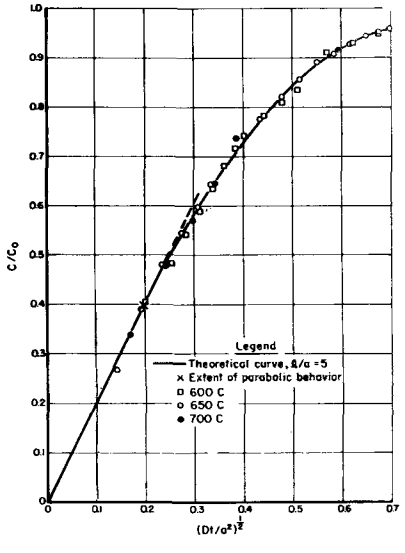

Fig. 8. Theoretical and experimental diffusion curves for sorption of hydrogen in niobium.

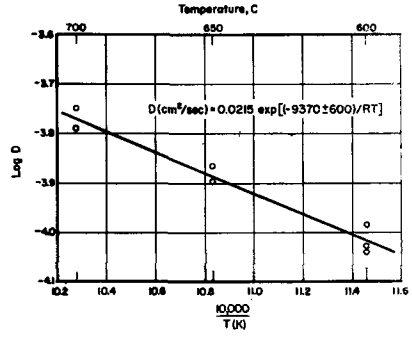

Fig. 9. Temperature variation of diffusion coefficients for hydrogen in niobium.

Table V. Diffusion coefficients for the niobium-hydrogen system

Temp, °C	Diffusion coefficient, $D \times 10^5$, cm² sec⁻¹		
	This work		
	From sorption	From desorption	Paxton and Sheehan (2)
500	—	0.58	0.00011
600	10	2.4	0.00063
600	9.4	—	0.001
600	9.2	—	—
650	14	4.3	—
650	13	—	—
700	16	—	0.0063
700	18	—	0.0036

permeation experiments may have affected their values of D. This is highly probable since they found that the niobium permeation membranes became discolored during their experiments.

The variation of the diffusion coefficient with temperature is described by the equation,

$$D = D_o \exp(-E/RT) \quad [7]$$

Data obtained from sorption rates are shown in Fig. 9. The equation for the best straight line through the points as determined by the method of least squares is

$$D = 0.0215 \exp[(-9370 \pm 600)/RT] \quad [8]$$

where 9370 ± 600 cal/g-atom is the activation energy. The entropy of diffusion can be calculated from D_o and E using the theory of Wert and Zener (11,12) for interstitial diffusion. For a body-centered-cubic lattice

$$D_o = 1/6\, a_o^2\, \nu \exp(\Delta S/R) \quad [9]$$

where a_o is the lattice constant and ν is the frequency of vibration of a solute atom in an interstitial position. The vibration frequency can be approximated from the relationship,

$$\nu = (E/2m\lambda^2)^{1/2} \quad [10]$$

where E is approximately equal to the activation energy, m is the mass of the solute atom, and λ is the distance between the interstitial positions ($\lambda = a_o/2$). From Eq. [7] and [8], ΔS for diffusion of hydrogen in niobium was calculated to be 3.8 cal/g-atom degree. According to theory this low positive value of ΔS is characteristic of interstitial diffusion and not diffusion through grain boundaries or other short circuiting paths.

Conclusions

Equilibria and x-ray studies show that in the ranges 100°-900°C, 0.1 to 1000 mm Hg pressure, and 0.01 to 0.85 H/Nb ratios the niobium-hydrogen system consists of a single-phase solid solution in which the basic body-centered-cubic structure of the metal expands as the hydrogen concentration increases. Equilibria in the system are best described by a series of isopleths since the heat of solution increases with hydrogen content. A two-phase region showing a miscibility gap was found at relatively low temperatures and pressures. Calculations based on the equilibrium and x-ray data place the critical point

where the two phases become identical at about 140°C, 0.01 mm of mercury hydrogen pressure, and 0.3 H/Nb ratio. The two phases, alpha and alpha prime, are both body-centered-cubic structures differing only in lattice parameter and are considered to be solid solutions of hydrogen in niobium.

Rates were obtained for the sorption of hydrogen by niobium to produce several solid solutions having hydrogen compositions of 0.05, 0.10, 0.50, and 0.70 H/Nb. The initial rates determined from 300° to 550°C were linear and increased with temperature and composition. At 600°-700°C sorption rates were diffusion controlled.

The diffusion coefficients obtained from desorption are lower than those obtained for sorption. Actually the desorption curves show a poor agreement with diffusion theory. Apparently some surface reaction influences the desorption rate.

Acknowledgment

The authors wish to express their thanks to Mr. D. A. Vaughan for making the many x-ray measurements. Work on this project was performed under AEC Contract W-7405-Eng-92.

Manuscript received April 27, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Some Investigations of the Ag/AgCl in LiCl-KCl Eutectic Reference Electrode

Ling Yang and Robert G. Hudson

Metals Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

ABSTRACT

In electrochemical studies of metal chlorides dissolved in LiCl-KCl eutectic melt it is often desired to convert the metal-metal ion oxidation potentials E_a relative to a Ag/AgCl in LiCl-KCl eutectic reference electrode to those E_b based on the chlorine reference electrode. Such conversion can be made by using the emf E_c of the Ag/AgCl in LiCl-KCl eutectic/Cl_2 cell, and involves a correction term ΔE. By using cases where both E_a and E_b can be determined independently, studies have been made of the variation of ΔE with the nature and concentration of the metal ions in the melt, the temperature of the melt, the concentration of AgCl in the reference electrode, and the nature of the membrane separating the reference and metal electrodes. This information gives an estimate of the reliability of data obtained when the two reference electrodes are interchanged.

In electrochemical studies of chloride melts, the thermodynamic properties of metal chlorides dissolved in molten chloride solvents are often calculated from observed potentials between the metal electrodes and a chlorine reference electrode in these melts. The standard potentials may be determined experimentally or calculated from thermodynamic data (1). The information gained has been very helpful to our understanding of the constitution of these systems. There are occasions, however, where the chlorine electrode cannot be used directly. For instance, if the metallic ion of the chloride melt has more than one stable valence state under prevailing experimental conditions and chlorine gas can oxidize it from the lower to the higher state, the potential of the metal and its lower valence ion can be studied only with other reference electrodes. However, for the calculation of thermodynamic properties of the dissolved metal chloride, the observed potential must be converted to the chlorine reference electrode scale.

This problem occurred in our study of thermodynamic properties of polyvalent metal chlorides (MCl_n) dissolved in LiCl-KCl eutectic melt. A suitable reference electrode (2-9) was that suggested by Bockris, et al. (9), namely Ag/AgCl in LiCl-KCl eutectic/Pyrex membrane, which is of interest because of its simple construction. The Pyrex membrane avoids mixing of the electrolytes.

To convert the observed oxidation potential of a metal to such a reference electrode, to that of the same metal to a chlorine reference, we must know

Table I. Observed emf's of cell [c]

how they are related. Let E_a, E_o, and E_c represent, respectively, the emf's of the cells

M/MCl_n in LiCl-KCl eutectic/Pyrex membrane/AgCl in LiCl KCl eutectic/Ag [a]

M/MCl_n in LiCl-KCl eutectic/Cl_2 [b]

Ag/AgCl in LiCl-KCl eutectic/Cl_2 [c]

The cell reactions are

$M + n\,Ag^+ = M^{+n} + n\,Ag$ [A]

$M + n/2Cl_2 = M^{+n} + n\,Cl^-$ (MCl_n in LiCl-KCl eutectic) [B]

$n\,Ag + n/2\,Cl_2 = n\,Ag^+ + n\,Cl^-$ (AgCl in LiCl-KCl eutectic) [C]

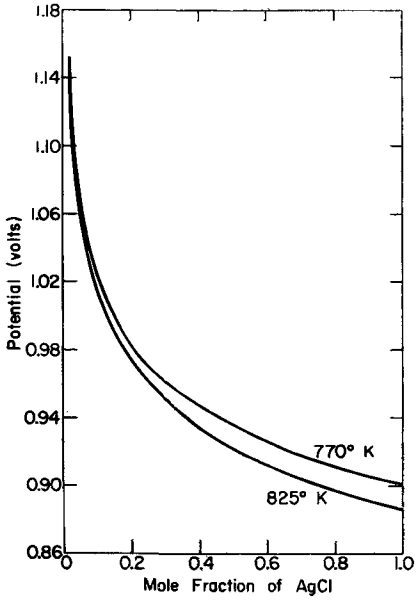

Fig. 1. Emf's E_c of cell [c] for various concentrations of AgCl.

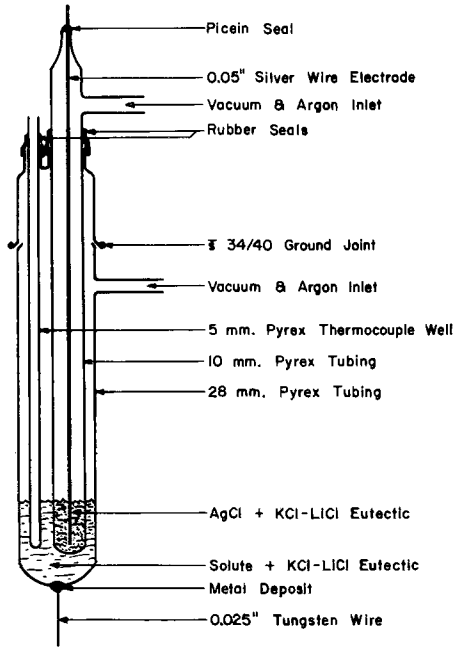

Fig. 2. Cell arrangement for measuring E_a

Define the quantity $\Delta E = E_a + E_c - E_b$. It can be shown from thermodynamics that

$$\Delta E = (1/F)\,[\mu(Cl^-\text{ of } MCl_n \text{ in eutectic}) - \mu\,(Cl^-\text{ of AgCl in eutectic})] + E_m \quad [1]$$

where the μ's are chemical potentials and E_m is the membrane potential in cell [a]. The conversion of E_a to E_b thus requires a knowledge of both E_c and ΔE. Sufficient data do not yet exist to calculate ΔE from Eq. [1]. Our paper attempts an experimental evaluation of ΔE from measured values of E_a, E_b, and E_c.

Determination of E_c

Potentials of metal-chlorine cells have already been studied over a range of temperatures and concentrations (10). The data E_c for the AgCl melts are quoted in Table I. It can be shown from these that mixtures of AgCl and LiCl-KCl eutectic behave as regular solutions, with AgCl deviating positively from Raoult's law.

The derivative dE_c/dT was obtained from the slope of a plot of E_c [after correction to $(Cl_2) = 1$] vs. T, it is essentially constant for a given composition, and its sign changes at a mole fraction N(AgCl) of about 0.03. The data of Table I, after correction to $(Cl_2) = 1$ and to 770° and 825°K, are plotted in Fig. 1. This figure can be used to estimate any value of E_c within or near the concentration and temperature ranges shown.

Experimental Estimation of ΔE

As shown in Eq. [1], ΔE consists of two parts, one due to the difference of chemical potential of chloride ion in the two melts, the other due to the membrane potential E_m. Bockris, *et al.* (9) compared the observed emf's of the concentration cells

Ag/AgCl (0.13M) in LiCl-KCl eutectic/Pyrex membrane/AgCl (0.05-1.3M) in LiCl-KCl eutectic/Ag [d]

with those calculated from the Nernst equation, by assuming the activity coefficient of Ag^+ constant in the range of compositions used. They concluded that the discrepancies were mainly due to the differences of activities of alkali metal ions across the membrane. In general, however, the situation may not be so simple, especially when the metal chloride solute on one side of the membrane is different from that on the other side. Exact evaluation of ΔE is impossible without knowing the conditions prevailing at the two melt-membrane interfaces and that inside the membrane, as well as the transport mechanism through the membrane. So far the study of membrane potential has been confined mostly to aqueous solutions (11); molten salt systems have not received much attention.

In spite of these difficulties, useful information may be obtained on the magnitude of ΔE by studying cases where independent measurements can be made on both E_a and E_b. In our previous investigations (10), measurements have been made of E_b. Therefore if we determine the corresponding values of E_a against AgCl reference electrodes whose E_c evaluated from Fig. 1, we should be able to calculate ΔE and find out how it is affected by the nature and concentration of the metal chloride in the melt, the concentration of AgCl in the reference electrode, the temperature, and the membrane material, e.g. Pyrex, Vycor, or quartz.

Measurement of E_a.—E_a was measured by using the arrangement shown in Fig. 2. The AgCl reference electrode consisted of a 0.05 in. diameter Ag wire (99.99% pure) dipped in a LiCl-KCl eutectic melt containing AgCl of the desired concentration and situated inside a Pyrex (Vycor or quartz) tube.

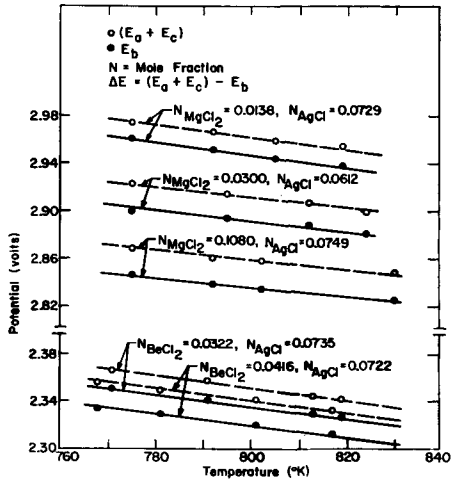

Fig. 6. Comparison of $E_a + E_c$ with E_b; $MgCl_2$ and $BeCl_2$ melts.

The bottom of the tube was sealed and blown thin to form the membrane. The exact thickness of the membrane was unknown but was found immaterial to the results obtained. The metal electrode consisted of the desired metal electrodeposited from the melt containing the metal chloride on a 0.025 in. tungsten wire sealed to the bottom of the cell. Deposition was carried out by using a graphite anode (not shown in Fig. 2) which was then withdrawn. The chlorine gas evolved was removed by pumping and the cell filled with purified argon. The potential between the Ag electrode and the metal electrode was followed to 0.1 mv on a Brown recorder connected in series with a L&N K-2 potentiometer and another potentiometer covering a range of 0-10 v until a steady value was reached. The temperature of the melt, as indicated by a calibrated chromel-alumel thermocouple, was changed to different values and the corresponding steady potentials recorded. Finally the melt was brought back to the original temperature and the steady potential reached was compared with that obtained before. The agreement was usually within ±2 mv. In addi-

tion, the reversibility of the electrode reactions was established by the close agreement (within ±1 mv) between the steady potential obtained in the above manner and that obtained after a few milliamperes had been drawn from the cell for about 2 min. For metals which attack glass, such as La and Y, the tungsten wire was inserted from the top of the cell so that the metal deposit was not in contact with glass. Although only one Ag/AgCl reference electrode is shown in Fig. 2, in actual measurements, four or five of them can be put in the same melt for the study of the effect of AgCl concentration in the reference electrode or the nature of the membrane material on ΔE. The observed steady potential, after correction for the emf of the Ag-W thermocouple (Fig. 3), is E_a. The correction was made by converting the thermal emf's of Fig. 3 to those for a cold junction at room temperature. Thermal emf data were determined experimentally by coupling the tungsten wire and the silver wire used in this work. Methods for purifying and heating the melts were the same as described previously (10).

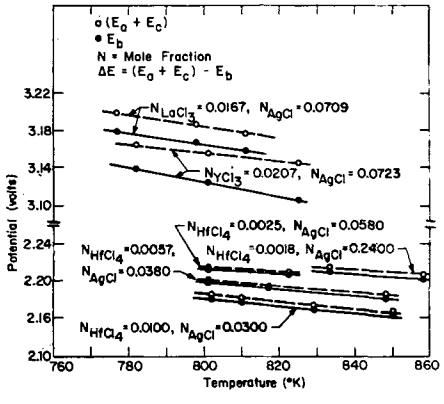

Fig. 7. Comparison of $E_a + E_c$ with E_b; $LaCl_3$, YCl_3, and $HfCl_4$ melts.

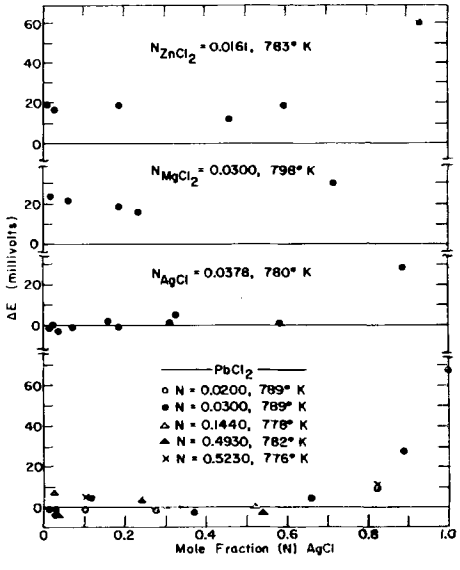

Fig. 8. Effect of AgCl concentration in the reference electrode on ΔE.

After the run, the AgCl reference electrode was raised out of the melt. Both the AgCl and the MCl_n melts were cooled quickly in an argon atmosphere and analyzed. On the basis of the analytical results, E_c was interpolated or extrapolated from Fig. 1, and E_b was taken from our previous data (10). ΔE was then computed from the data.

Variation of ΔE with various factors.—Results obtained are shown in Fig. 4-8, which can be summarized as follows:

1. *Nature of* MCl_n.—ΔE is negligible when MCl_n is AgCl (Fig. 8) and is less than a few millivolts for $PbCl_2$ (Fig. 4). This is true for a wide range of AgCl and $PbCl_2$ concentrations. For the others (Fig. 5-8), ΔE amounts to 5-40 mv. It is interesting to note that melts containing Ag^{++} and Pb^{++} which have less tendency to form complex ions with the chloride ions of the solvent have negligible ΔE, while those containing Be^{++}, Mg^{++}, Zn^{++}, Cd^{++}, which have been shown

Table III. Studies of charge carriers through Pyrex membrane

Negative side, AgCl (1.2131 g)	11.99	5.97			73.1	74.5

to have a higher tendency to form complex ions exhibit higher ΔE (10).

2. *Concentration of* MCl_n.—For those melts having appreciable ΔE values, ΔE decreases as the concentration of MCl_n decreases (Fig. 5 and 6).

3. *Temperature.*—In the temperature range used in this work, ΔE does not seem to vary appreciably with temperature (Fig. 4-7), except for YCl_3 (Fig. 7).

4. AgCl *concentration of the reference electrode.*—Change of the AgCl concentration of the reference electrode over a wide range does not seem to affect ΔE appreciably (Fig. 8). However, for $N_{AgCl} > 0.6$, ΔE becomes abnormally high (Fig. 8).

5. *Membrane material.*—As shown in Table II, ΔE values for Vycor and quartz membranes are about the same, and they are higher than for Pyrex. Vycor and quartz are therefore less suitable membrane materials than Pyrex.

Some Transport Studies

In addition to the above investigations on ΔE, a few experiments have been performed to determine whether metal ions other than the Li^+ and K^+ are responsible for carrying the current through the Pyrex membrane. These were carried out by using the following cell arrangements with M = Ag or Zn,

M/MCl_n in LiCl-KCl eutectic/Pyrex membrane/

AgCl in LiCl-KCl eutectic/Ag [e]

A known amount of current was passed through each cell so that the Ag or Zn at the left dissolved into the melt while the Ag^+ in the melt at the right deposited out as Ag. The increase in the amount of Ag^+ or Zn^{++} in the melt at the left and the decrease in the amount of Ag in the melt at the right of the glass membrane were then determined by chemical analysis and compared with what would be expected on the basis of the amount of current passed through the cell if the membrane is impermeable to Ag^+ and Zn^{++}. The Ag^+ and the Zn^{++} contents of the melts were determined by precipitation and weighing as AgCl and $Zn(C_9H_6ON)_2$, respectively. The current of electrolysis was controlled manually and its time integral was determined by using a silver coulometer. Results are shown in Table III.

It can be seen that the amount of current carried by the Ag^+ or Zn^{++} through the Pyrex membrane, if any, cannot be more than a few per cent. Spectroscopic analyses of the glass used for making the membrane showed that it contains 0.02% Li_2O, 0.05% K_2O, and less than 0.0005% Ag_2O. The glass membrane in the AgCl cell, recovered after the electrolysis, was found to contain 0.75% Li_2O, 0.12% K_2O, and 0.001% Ag_2O. The large increase in the Li content seems to indicate that Li^+ is the predominant current carrier through the Pyrex membrane.

Reproducibility and Stability

The reproducibility of the Ag/AgCl in LiCl-KCl eutectic/Pyrex membrane reference electrode was studied by comparing the potentials of various reference electrodes made from melts of the same AgCl concentration N(AgCl) = 0.030 or 0.1020. Agreement was found to be within ±2 mv. The stability of this reference electrode was also investigated by following the change of the potential of AgCl concentration cells with N(AgCl) in the range 0.060 to 0.200, in LiCl-KCl eutectic melts with time. It was found that if oxygen and moisture were excluded from the melt, the change in potential was less than a few millivolts after the cells had been maintained at about 800°K for 40 hr.

The investigations described above cover some of the characteristics of the silver chloride-Pyrex reference electrode. Although the information available still does not allow us to calculate ΔE theoretically, these studies may serve to evaluate the reliability of potential data obtained in changing reference electrodes from AgCl to chlorine.

Acknowledgments

The authors wish to thank Drs. G. Derge and G. M. Pound of Carnegie Institute of Technology and Mr. Frank Kerze, Jr., of the U. S. Atomic Energy Commission for their interest in this work and their valuable help. They also are indebted to Drs. C. L. McCabe and P. Fugassi of Carnegie Institute of Technology, Dr. J. O'M. Bockris of the University of Pennsylvania and Dr. S. Senderoff of the National Carbon Company for stimulating discussions. This work is a part of a research program sponsored by the U. S. Atomic Energy Commission under Contract No. AT(30-1)-1432 and was presented at the June 1958 Symposium on Analytical Techniques for Molten Systems, sponsored by the American Chemical Society.

Manuscript received March 5, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Oxygen-Evolution Reaction at Gold Anodes

II. Overpotential Measurements and Reaction Mechanism in Sulfuric Acid Solutions

Sidney Barnartt

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The oxygen-evolution reaction at gold anodes was studied in sulfuric acid solutions, with and without added potassium sulfate, over the pH range 0 to 2.7 at 25°C. Overpotential measurements were made with an accuracy of ±1 mv in a cell having uniform current distribution over a spherical anode. Within current density limits imposed by the cell and the solution, Tafel's equation was obeyed to ±1 mv. The Tafel slope was $b = 2.303(3RT/4\mathbf{F})$ in each solution. At constant current density the overpotential was independent of pH or neutral salt additions. Several proposed mechanisms of the oxygen evolution reaction predict this independence, but in each case the theoretical Tafel slope is smaller than the observed value.

Overpotential data in the literature relating to the oxygen-evolution reaction have not been sufficiently accurate to settle the reaction mechanism unequivocally. In a previous paper (1) the factors involved in obtaining accurate overpotential measurements were evaluated with reference to a new cell design. Within current density (c.d.) limits dictated by this cell, it was found that steady-state measurements of oxygen overpotential at gold anodes in 0.1M H_2SO_4 were reproducible to ± 1 mv. Within the same deviation the overpotential (η) varied with c.d. (i) in accordance with Tafel's Eq. (2):

$$\eta = a + b \log i = a' + b \log i' \qquad [1]$$

where $i' = qi$ is the apparent c.d., q is the surface roughness, a and b are constants and $a' = a - b \log q$ is the extrapolated overpotential at 1 amp cm^{-2} apparent c.d. These measurements are extended in the present paper to include the effects of pH and neutral salt additions, effects which are diagnostic of the reaction mechanism (3-5).

Experimental Procedure

The experimental procedure was that of the previous paper, cell II and the solid gold electrode described therein (1) being used for almost all of the overpotential measurements. The electrode was polished to an almost mirror-bright surface with diamond polishing compound, ending with 3μ particle size. It was precleaned with solvents, cathodic treatment in hot 3M NaOH and immersion in 10M HNO_3. It was then made anode in 1M H_2SO_4 at 5 x 10^{-2} amp cm^{-2} for 5 min, the thin oxide layer thus formed being dissolved in 5M HCl, after which the electrode was rinsed thoroughly and inserted in the cell.

Sulfuric acid was distilled, and water redistilled from alkaline permanganate, in all-Pyrex stills. Reagent-grade K_2SO_4 was used without further purification; the experiments described below indicated that no deleterious impurities were present. Sulfuric acid solutions of concentration 0.01 to 1M, some with 0.5M K_2SO_4 added, were studied at 25.0°C. Overpotentials were determined by use of a saturated calomel reference electrode, as previously described (1).

The lower limit to the c.d. range for accurate measurements in 0.1M H_2SO_4 has been shown to be 3 x 10^{-5} amp cm^{-2}, and was attributed to cathodically produced H_2O_2 (1). Depolarization by H_2O_2 should depend on the cathode and cell geometry used, and not on solution concentration. Thus the lower c.d. limit of 3 x 10^{-5} was expected for all of the solutions studied, and this was found to be the case.

Although a brown film of hydrated Au_2O_3 formed slowly and continuously over the gold anode in each solution, the current efficiency for film formation was assumed to be sufficiently small to be negligible, as was shown for 0.1M H_2SO_4 (1).

The upper c.d. limit for accurate measurements varies with concentration and is determined either by the IR drop between the capillary tip and the electrode surface (V_{IR}) or by concentration polarization. The IR drop may be computed (1) from the equation:

$$V_{IR} = (ir_o^2/\kappa)\,[1/r_o - 1/(r_o + 3d - d/3)] \qquad [2]$$

where κ is the solution conductivity in mhos per centimeter, $r_o = 0.50$ cm is the radius of the spherical electrode, and $d = 0.02$ cm is the diameter of the capillary tip, the latter being positioned at a distance $3d$ from the electrode surface. The maximum c.d. i_1 for making accurate IR drop corrections is obtained from Eq. [2] by setting $V_{IR} = 0.01$ v (1).

In order to avoid concentration polarization effects an upper limit of 3% was selected as the maximum allowable change in H_2SO_4 concentration at the anode. The c.d. i_2 corresponding to this concentration change was calculated from the equation:

$$\Delta C = 10^3(1 - t_+)\, i\, l/2\mathbf{F}D \qquad [3]$$

by setting $\Delta C = 0.03\ C_o$, where ΔC is the increase in acid concentration at the anode surface, C_o the bulk concentration (mole/l), l the thickness of the diffu-

sion layer, **F** the faraday, D the diffusion coefficient, and t_+ is the hydrogen ion tranference number.[1] For the sulfuric acid solutions studied, the mean values $l = 0.005$ cm for gas-bubbling conditions (7), $t_+ = 0.82$ (8) and $D = 1.9 \times 10^{-5}$ cm^2 sec^{-1} (9) were substituted into Eq. [3] to obtain:

$$i_2 = 0.12\, C_o \qquad [4]$$

Table I lists the calculated values of i_1 and i_2. The smaller of these was taken to be the maximum allowable c.d. for each solution and was not exceeded in this investigation, as shown in the last column.

Results

For each solution studied, oxygen overpotential varied with c.d. in accordance with Tafel's equation. Average values of the measured Tafel constants are given in Table II. The overpotential at an apparent c.d. $i' = 10^{-4}$ amp cm^{-2} ($\eta_4 = a' - 4b$) is included as a reference value within the actual c.d. range studied. Also tabulated is the apparent exchange current density qi_o; this quantity may be calculated from

$$qi_o = 10^{-a'/b} \qquad [5]$$

and is of the order of magnitude of 10^{-22} amp cm^{-2}.

The maximum deviation of the experimental overpotential values from the Tafel lines described in Table II was ± 1 mv, with the exception that at 10^{-2} amp cm^{-2} apparent c.d. the η-values in 1M and 0.5M H_2SO_4 were 3-4 mv high. The latter discrepancy, although small, was reproducible. In each solution, the steady-state overpotential readings obtained with decreasing and increasing currents agreed within ±1 mv and duplicate runs with fresh batches of solution showed the same good agreement previously reported for 0.1M H_2SO_4 (1).

The variation of overpotential with pH at constant c.d. is shown for typical runs in Fig. 1. There is no consistent change in overpotential with acid concentration or with salt addition. The small variations from the mean values (lines of Fig. 1) found for 1M and 0.05M H_2SO_4 reflect changes in the Tafel a and not in the slope b. The mean values yield a linear Tafel plot with deviations ≦ 1 mv, as shown in Fig. 2; the constants from this plot are appended to Table II. The mean slope of 0.045_8 may be closely represented by $b = 2.303\ (3RT/4\mathbf{F})$, which is 0.0443 at 25°C.

The only pertinent[2] data in the literature for gold in sulfuric acid solutions is that of Hickling and Hill (11), for electroplated gold in 0.5M H_2SO_4 at 20°C. These are also plotted in Fig. 2 for comparison, the vertical length of each point representing their stated reproducibility of ± 10 mv. The latter data indicated a slope of 0.07, a value appreciably greater than that found in the present work taking into consideration the 5° temperature difference. The actual experimental points, however, are in good agreement with the curve of Fig. 2 at 10^{-4} and 10^{-3} amp cm^{-2} apparent c.d., taking $\partial\eta/\partial T = -3$ mv/degree (19). The deviation at 10^{-5} amp cm^{-2} indicates depolarization by competing anodic reactions.

[1] Equation [3] is an approximation applicable to ideal solutions. Corrections for deviations from ideality (6) were ignored because only small concentration changes are considered here.

[2] Other work on this system (12-15) did not include studies of steady-state overpotential.

Discussion

Theoretical values of the Tafel slope and of other parameters useful for interpretation of the experimental data have been compiled by Bockris (4) for various mechanisms of anodic oxygen evolution. Three of the mechanisms include rate-determining steps for which overpotential is predicted to be independent of pH or neutral salt additions in acid solutions, in agreement with the experimental results of the present study. These mechanisms are listed in Table III. In each case the predicted slope is smaller than the experimental value.

The theoretical slopes of Table III involve no assumptions as to the value of the symmetry factor β (3, 4), but do involve assumptions concerning the degree of coverage of the electrode surface with adsorbed radicals. The combination mechanism Ib, for example, wherein the slow step is the combina-

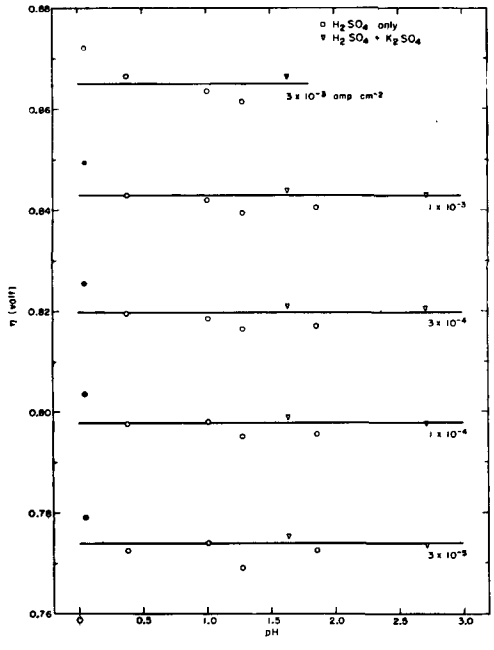

Fig. 1. Variation of oxygen overpotential with pH at constant apparent c.d., gold anodes in sulfuric acid solutions at 25.0°C.

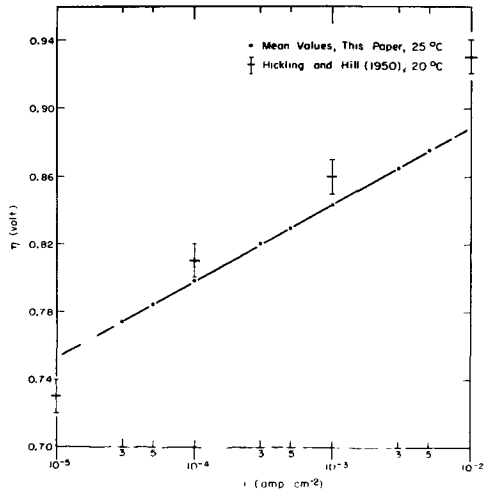

Fig. 2. Oxygen overpotential at gold anodes in sulfuric acid solutions, plotted vs. apparent c.d.

tion of two adsorbed hydroxyl radicals, corresponds to the Tafel slope listed ($RT/2\mathbf{F}$) only when coverage of the electrode surface with OH is very small. If the surface coverage is relatively high, the slope may be greater; this has been shown for an analogous case, the combination mechanism of hydrogen evolution (30). Thus the observed slope of 3/4 $RT/\mathbf{F}$ may correspond to one of the rate-determining steps listed in Table III when adsorption effects are taken into consideration. It may be concluded that the present data for gold are not in strict accord with any one of the mechanisms listed by Bockris (4). Further experimental data are needed to settle the mechanism unequivocally.

Oxygen overpotential at platinum in sulfuric acid solutions has been investigated by Bockris and Huq (16) under conditions of extreme purification (without, however, insuring uniform current distribution over the anode). The mean Tafel slope, measured in H_2SO_4 solutions with and without excess Na_2SO_4, was $b/2.303 = 3RT/2\mathbf{F}$ (± approximately 10%). This is double the value reported here for gold. Not one of the proposed mechanisms predict this slope (4), and the authors assumed that it was sufficiently close to $2RT/\mathbf{F}$ to indicate a discharge mechanism. With the additional assumption of $\beta = 0.5$, measurements of stoichiometric number plus pH and neutral salt effects led to the conclusion that discharge of water molecules is the rate-determining step on platinum.

The value $3RT/2\mathbf{F}$ observed by Bockris and Huq is the same as that previously found for platinum in 1933 by Hoar (17). A slope of less than half this value has been found recently for dilute solutions by Kheifets and Rivlin (29). Several earlier papers (see Table IV), however, reported the value $2RT/\mathbf{F}$, in agreement with the discharge mechanism.

The discharge mechanism is generally assumed also for lead anodes (covered with β-PbO_2) in sulfuric acid solutions on the basis of a slope of $2RT/\mathbf{F}$, although the other confirming parameters have not been measured for this metal. It is interesting that an α-PbO_2 electrode (over platinum) behaved quite differently, giving the slope (3/4) $RT/\mathbf{F}$ which was found here for gold.[3]

Reliable data for oxygen evolution on iron are exiguous. At pH 4, values of both b and i_o found by Wade and Hackerman (18) are remarkably close to those found here for gold. At a slightly lower pH (2.5), however, an appreciable decrease in b and in i_o (the latter by a factor of 10^6) was reported; this strong pH dependence merits confirmation.

In alkaline solutions, oxygen overpotential measurements to date have been discrepant (5). It may be concluded that little basis exists for selecting any one of the currently proposed mechanisms of anodic oxygen evolution as having general applicability for sulfuric acid solutions. There is a pronounced paucity of reliable experimental para-

[3] Revised data of Rüetschi, *et al.* (31) show a significantly higher slope for α-PbO_2 in 4.4M H_2SO_4 at 30°C, namely, 1.2 $RT/\mathbf{F}$.

Technical Note

The Formation of Carbides at the Interface of Liquid Germanium and Graphite

A. Epstein[1] and I. G. Geib

Department of Physics, Purdue University, Lafayette, Indiana

In the course of an investigation into the properties of liquid germanium, it was found that Ge solidified in contact with graphite becomes joined to it if a metal soluble in liquid Ge is added. When pure graphite and pure Ge are used, a good mechanical joint is not obtained.

Spectroscopically pure Ge (10-15 g) was placed in a porcelain crucible and heated to about 1000°C at a pressure of about 10^{-6} mm Hg. A hollow spectroscopically pure graphite cylinder of 22 mm internal diameter and about 25 mm height and an inner, concentric cylindrical graphite probe of diameter 3.2 mm were lowered into the molten Ge and were maintained at the stated temperature for periods from 8 to 12 hr. When the entire apparatus was brought to room temperature, the graphite cylinder could be lifted out of the Ge ingot without difficulty. The procedure was repeated with currents of 5-10 amp maintained while the Ge was molten, but the presence of the radial electric field had no effect on the ease of separation of the Ge and graphite.

Either a tungsten rod or a tantalum rod of diameter 0.76 mm (0.030 in.) was placed in the cylindrical arrangement on one of the radii extending from the central graphite probe with its length parallel to the cylinder axis. The arrangement was lowered into the liquid Ge and maintained at about 1000°C for about 8 hr with and without an electric field. On cooling to room temperature, the graphite cylinder and rod could not be separated from the Ge. To examine the area of contact, it was necessary to fracture the ingot and cylinder. The material adhering tightly to the inner wall of the cylinder over the area of contact was examined by x-ray diffraction by obtaining powder patterns of specimens scraped from the inner wall. Ge was removed from the contact by etching with HF, HNO_3, and $Cu(NO_3)_2$ to disclose a layer on the area of contact. Powder patterns were obtained of material from these layers. The Ge-layer-C contact was checked for rectification with area contacts.

With the tungsten rod, the etching revealed a bluish-black layer on the area of contact. A powder pattern of material from this layer showed, in addition to graphite lines, lines which belong to a hexagonal structure, $a = 2.905$Å, $c = 2.839$Å. Westgren and Phragmen (1) found that WC is hexagonal with $a = 2.907$Å, $c = 2.836$Å (calculated from values in kX). Subtraction of these lines and the Ge and graphite lines from the boundary region pattern obtained before etching left 8 lines, 6 of which belong to a hexagonal structure, $a = 3.00$Å, $c = 4.73$Å. Westgren and Phragmen found that W_2C is hexagonal with $a = 2.992$Å, $c = 4.722$Å. This evidence indicates that a layer containing WC and W_2C is formed at the germanium-graphite interface. That the W_2C and not the WC is dissolved by the etchant agrees with a table of solubilities given by Brewer, *et al.* (2).

With the Ta rod, the layer exposed by etching away the Ge has a reddish-brown color. The powder pattern of the reddish-brown material contains a strong pattern, which agrees with that calculated for a NaCl type structure, $a_o = 4.456$Å, in addition to graphite and weak Ge and unknown lines. TaC is cubic (3), $a_o = 4.454$Å.

The Ge-tungsten carbide-C contact gave rectification ratios of better than 200 to 1. The Ge-TaC-C contact gave no measurable rectification. The formation of the carbides must result from the metal dissolving in the Ge, diffusing through the liquid, and reacting with the carbon on coming into contact with it. Qualitative observation of the thickness of the carbide layer indicated that the diffusion or reaction occurred much faster in the presence of an electric field, suggesting that this procedure might be useful for the purification of Ge.

A Study of the Zinc-Noble Metal Couple in Alkaline Solutions

Thedford P. Dirkse and Edwin G. Vrieland

Department of Chemistry, Calvin College, Grand Rapids, Michigan

ABSTRACT

A metal-like coating is formed frequently on copper or silver leads which are attached to the zinc electrodes in commercial zinc-alkaline cells. This coating is zinc or a zinc-rich alloy. The conditions under which this coating is formed have been studied, and several possible mechanisms for its formation are presented and discussed.

It is generally known to those in the battery industry that when silver or copper is coupled with zinc in an alkaline solution, a zinc-like deposit is formed on the noble metal (1). However, so far as is known, no satisfactory explanation has been given for this phenomenon. For that reason, a study of this reaction was undertaken.

Experimental

Thin metal strips about 1 x 5 cm were used, and coupling was accomplished by twisting the ends of the strips together or by wrapping a zinc strip or screen around the noble metal. In some of the runs the entire couple was completely immersed in the KOH solution while at other times a part of the couple was exposed to the air. Nickel, silver, copper, platinum, and lead served as the noble metals, but most of the work was done with Ag and Cu. All runs were carried out at room temperature in 35% KOH. C.P. reagents were used without further purification.

At first there was some difficulty in obtaining a coating on the Ag or Cu. Various anions usually found in commercial KOH, such as Cl^-, $CO_3^=$,$SO_4^=$, HO_2^-, were added to the electrolyte, but had no effect on the formation of the coating. Amalgamating the zinc electrode also failed to influence the formation of this deposit. However, addition of ZnO to the KOH solutions hastened the formation of this coating considerably. Coatings were formed on Ag, Cu, Pb, and Pt, but not on Ni.

The nature of the coating was checked by several methods. The deposit was very thin and, except for Ag, produced no detectable alteration in the x-ray pattern of the noble metal. With Ag, the coating gave two faint lines that could be attributed to a solid solution of Ag in Zn, and one line that is also found in the Zn pattern. The coating produced in 24 hr weighed only about half a milligram. It was removed from the noble metal by treatment with HCl or dilute HNO_3. Ordinary chemical analysis of this solution gave no certain indication of Zn due to the small amount of deposit. Analysis with a Todd Spectranal, however, did give definite evidence for the presence of Zn.

The potential of the coated Cu and Ag in these solutions was within 25 mv of that of pure Zn. This substantiates the suggestion that this coating is Zn or a Zn-rich alloy or solid solution.

When Ni was used as the noble metal it appeared as if a coating was formed on the Ni, but repeated attempts at analysis failed to produce any substantial evidence for Zn. In one experiment three cells were set up under identical conditions using, respectively, Ag, Cu, and Ni as the noble metals in KOH-ZnO solutions which had been deoxygenated. A coating seemed to form on all three electrodes but later, when they were rinsed, the Ni appeared shiny whereas the other two coatings were not affected. These latter coatings did contain Zn, but no certain evidence for Zn could be obtained from the Ni specimen.

There was also evidence that dissolved oxygen tends to hinder the coating process. The coating appeared to form more quickly in solutions which had been deoxygenated.

Discussion

The above results show that Zn is deposited on Cu, Ag, Pb, and Pt when these metals are coupled with Zn in strong KOH solutions containing dissolved ZnO. No such deposit is formed when Ni is coupled with Zn. Any mechanism for this process, then, must allow for a difference between Ni and these other metals. A few possibilities are considered below.

1. The possibility that this phenomenon is due to mere adsorption was ruled out by the fact that strips of Ag and Cu received no coating when they were immersed for 24 hr in a KOH solution containing dissolved ZnO.

2. A more likely explanation involves an electrochemical mechanism, i.e., the potential of reaction [1]

$$Zn + 4\,OH^- \rightarrow Zn(OH)_4^= + 2e \qquad [1]$$

which is the reaction at the Zn electrode, is sufficient to bring about reaction [2]

$$Zn(OH)_4^= + Ag + 2e \rightarrow Zn(Ag) + 4\,OH^- \qquad [2]$$

One requirement of this mechanism is that the energy or potential necessary to reduce Zn onto Ag or Cu is less than that needed to reduce it onto Zn. This is not a case of the simultaneous deposition of Zn and the noble metal (2). The noble metal was always coupled to the Zn and it is difficult to see how any noble metal ions could go into solution. Further, Straumanis and Fang (2) noted the formation of Cu-Zn, Ag-Zn, and Ni-Zn alloys. In our

work Ni definitely did not form an alloy with Zn. Yet Ni and Zn form much the same type of alloy system as do Ag-Zn and Cu-Zn. It is possible that a thin oxide film on the Ni prevents the formation of the Ni-Zn alloy here. However, H_2 is always evolved from the noble metal in such a couple and this could reduce the oxide film. Furthermore, a slight Zn deposit was formed on stainless steel (which also possibly has a thin oxide film) when it was used as the noble metal and coupled with Zn.

It has been shown that there is, in some instances, an undervoltage associated with the deposition of small amounts of metal (3). It was suggested that this undervoltage is dependent on the closeness of approach of the lattice parameters of the noble metal and the deposited metal. Using the data in reference (3) the nearest neighbor in Ag is 2.88Å; in Zn, 2.66Å; in Cu, 2.55Å; in Ni, 2.49Å; in Pb, 3.49Å; and in Pt, 2.77Å. The mismatch then is +31.9% for Pb; +8.3% for Ag; +4.1% for Pt; −4.1% for Cu; and −6.4% for Ni, where + indicates that the parameters are larger for the noble metal than for Zn. These values suggest that Cu and Ni should behave similarly. In both of these metals the atoms are closer together than in Zn. The small difference between Cu and Ni would hardly seem sufficient to account for the fact that Zn deposits readily on Cu but not on Ni. If an undervoltage phenomenon is responsible for this Zn coating, then the extent of the mismatch is not the controlling factor. If it were, then no coating should have been formed on Pb.

The phenomenon of undervoltage is associated with the deposition of thin metallic films such as are deposited on the noble metal of the zinc-noble-metal couple. That only thin films are produced argues for the fact that certain sites on the noble-metal surface are responsible for this undervoltage, and hence the x-ray diffraction pattern of the noble metal is but slightly altered, if at all, by the deposition of the zinc. If, for example, the active sites were submicroscopic pits on the surface, the Zn atoms could fit easily into such pits on Ag, Pb, and Pt, but would do so with difficulty on Ni. In considering the possibility of an undervoltage phenomenon here, it should also be noted that the work in reference (3) was carried out in acid solutions and the shift of potential did depend in part on the pH. The solutions used in this work were approximately 8M KOH. In such solutions the Zn^{++} concentration is only about 10^{-15}M. Any undervoltage associated with this process must be rather small because the Zn-noble metal couple had a potential only about 15 to 25 mv more anodic than that of Zn.

3. Another possible mechanism involves a chemical in addition to an electrochemical reaction at the noble metal surface. When Zn and the noble metal are coupled in KOH solutions, hydrogen gas is evolved at the noble metal, reaction [3].

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \qquad [3]$$

The deposition of Zn at the noble metal then can be due to the reduction of the zinc-containing ions or $Zn(OH)_2$ by H_2, Eq. [4].

$$H_2 + Zn(OH)_2 \rightarrow Zn + 2H_2O \qquad [4]$$

However, the reaction does not proceed with molecular hydrogen. Hydrogen gas was bubbled for several hours over a Ag electrode in KOH-ZnO electrolyte, but no Zn was deposited or produced. This suggests that the reduction is accomplished with atomic hydrogen.

At such an electrode surface there is a competition between reactions [5] and [6].

$$2H + Zn(OH)_2 \rightarrow Zn + 2H_2O \qquad [5]$$

$$2H \rightarrow H_2 \qquad [6]$$

Whether or not Zn is deposited at a noble metal electrode in a Zn-noble metal couple will depend on the relative rates of reactions [5] and [6]. According to Bonhoeffer (4) the efficiency of different metals in causing the combination of hydrogen atoms is almost exactly in the reverse order to their overvoltage values, i.e., the higher the hydrogen overvoltage the slower the rate of reaction [6]. It is difficult to find comparable hydrogen overvoltage data for strongly alkaline solutions. However, it has been suggested (5) that the relative overvoltage values are the same in alkaline as in acid solutions. If this is true, then the hydrogen overvoltages vary in the following order: Pb>Cu=Ag>Ni>Pt (5, p. 420). This order is not to be accepted without question. When Zn was coupled with these metals, gas was evolved most copiously at Pb which would indicate a lower overvoltage value. This would favor reaction [6] rather than [5]. But, since Zn was deposited on Pb and Pt, it would seem then that it should also have been deposited on Ni.

It is possible that a third competing reaction enters in. This reaction involves the dissolving of Zn from the coating deposited on the noble metal. It has been noted that a coating that appeared to form on Ni disappeared during rinsing. Furthermore, when a coated Cu strip was placed in water, the Zn redissolved within a day or two. To check this further, Ag-Zn and Cu-Zn couples were allowed to stand in KOH-ZnO solutions for a week. Then the Zn strip was removed from each couple. After standing for a few days the coating began to disappear from the Cu but not from the Ag. After a week the Cu was clean but the Ag was still coated.

When Zn is deposited on a noble metal, a Zn-noble metal couple is formed and reactions [1] and [3] can take place on the coated metal. This, of course, opposes the deposition of Zn on the noble metal. This opposing process appears to occur most readily on Ni, to some extent on Cu, and hardly at all on Ag.

A likely explanation for this concerns the lattice parameters of these metals. As has been noted earlier, Ni has the smallest "nearest neighbor" distance, less than that of Zn. Consequently, Zn is deposited merely on the surface of the Ni and is not held there tenaciously. The "nearest neighbor" distance for Cu is larger than that for Ni but still it is smaller than that for Zn. Zinc, therefore, deposits with less difficulty on Cu than on Ni, is held more firmly, and shows less tendency to reenter the elec-

trolyte. With Ag, Pb, and Pt, the Zn fits easily into pits on the surface and, consequently, is held rather firmly there, perhaps forming solid solutions in which the activity of the Zn atoms is less than one. This reduces the tendency of Zn to reenter the solution.

An attempt was made to verify the suggestion that the Zn is produced by the reduction of $Zn(OH)_2$ or $Zn(OH)_4^=$ with atomic hydrogen. A strip of Ag was placed in KOH-ZnO electrolyte and the potential on this strip was gradually increased until bubbles of gas just became visible on the surface of the metal. The potential of the Ag was then about 20 mv more anodic than that of Zn. The Ag electrode was held at this potential for about 6 hr. Small amounts of H_2 were formed during this interval and, at the same time, a deposit of Zn formed on the surface of the Ag. When the Ag was more anodic than this, no visible deposit was formed.

In summary, it is suggested that the Zn coating formed on the noble metal in a Zn-noble metal couple placed in KOH-ZnO electrolyte results from the reduction of the dissolved Zn species by atomic hydrogen. Whether the Zn coating persists depends on how well the deposited Zn atoms fit into the lattice of the noble metal. The more easily the Zn atoms are accommodated the more likely a solid solution will be formed thereby reducing the activity of the deposited Zn atoms. This reduced activity lessens the tendency of the deposited Zn to redissolve.

The mechanism suggested above is intended to deal only with the first layer or film of Zn deposited on the noble metal. However, very little additional deposit of Zn takes place. The deposition in such a Zn-noble metal couple seems to stop after several hours and the evolution of H_2 practically ceases then also.

The Anodic Dissolution and Electrolytic Polishing of Metals

J. K. Higgins

Metallurgy Division, Atomic Energy Research Establishment, Harwell, Didcot, Berks, England

ABSTRACT

An experimental study has been made, using the potentiostat technique, of the anodic dissolution and electrolytic polishing of nickel in hydrochloric acid. The effect of experimental conditions on the potential/current density curves and the value of the limiting current density has been investigated. Results have been interpreted on the basis of a simple diffusion mechanism, and complications arising from the thick salt films found in the more concentrated solutions have been considered. Some results showing the connection between polishing and passivity have been collected for copper anodes in potassium cyanide solutions containing potassium hydroxide.

Theories of the anodic dissolution of metals under conditions such that electrolytic polishing occurs have been referred largely to the case of copper in phosphoric acid (1). Some authors have emphasized the role played by salt and oxide films during polishing (2, 3). In order to extend the theory to include another metal besides copper the anodic behavior of nickel in hydrochloric acid was studied. Results confirm the general theory and provide clear evidence of the occurrence and importance of salt films during electrolysis. The system was studied by constructing potential/current density (C.D.) curves under various experimental conditions. The potentiostat technique (4) was used in which the anode potential is set at any arbitrary value, the current being controlled by the potentiostat to maintain this value. In order to investigate the relationship between electrolytic polishing and passivity some data on the anodic dissolution of copper in potassium cyanide were obtained under conditions favorable to oxide film formation, in strongly alkaline solution.

Experimental Technique

The electrolytic cell consisted of a 400-ml squat beaker containing 250 cc of electrolyte in all cases. The anodes of projected area 0.15 cm^2 were made by drawing wire (S.W.G. 16) to the appropriate length through a rubber bung in one end of a glass tube and filing the end of the wire flat. The glass tube fitted with the rubber bung and wire anode was mounted vertically, exposing about 2.5 mm of the wire to the electrolyte. The cathode was a Pt spiral of area 1 cm^2 in a tube whose end was closed with a filter paper plug. A Zn/0.1M — $ZnSO_4$ reference electrode was connected to the working electrode by means of a Luggin capillary, and was chosen be-

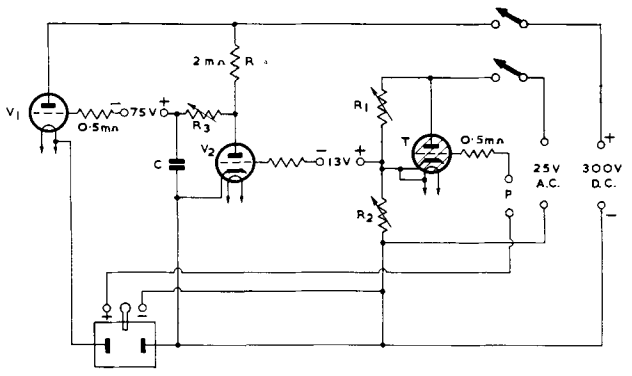

Fig. 1. Potentiostat A. V_1, Osram triode PX25; V_2, Brimar pentode 8 Al strapped as triode; T, Osram thyratron GTIC; C, 8 μF electrolytic condenser; R, 20,000 ohms; R_1, 100,000 ohms; R_2, 1000 ohms.

cause its potential always would be more negative than any it might be required to maintain. The potential of the electrode remained constant at −0.80 v on the hydrogen scale for about 4 weeks. All the anode potentials quoted are expressed on the standard hydrogen scale, the values being obtained by subtracting 0.8 v from the cell voltage of the combination anode (or working electrode)/reference electrode. The electrolyte was usually maintained at 20° ± 0.5°C.

The circuit diagram of the first electronic potentiostat is shown in Fig. 1 and is due to Hickling (4). Upon the application of 300 v d.c. the condenser C charges up through the resistance R, opposes the 75-v negative bias applied to the grid of the triode valve V_1 and thus allows a progressively increasing current to flow through V_1 and the cell. However, C can discharge through V_2 when its negative grid bias of 13 v is opposed by a voltage across V_2; this voltage is developed when the thyratron T fires. T is set 50 times a second by the 25-v a-c supply; it is adjusted to its critical tripping voltage by the automatic biasing potentiometer R_1-R_2. Into the grid circuit of the thyratron are placed the potentiometer P (connected to make the grid more negative) and the working/reference electrode combination in opposition. When the voltage of the electrode combination is greater than that set upon P, then the thyratron will fire, the current through V_1 will drop momentarily and will be controlled to maintain the potential of the working electrode at this point indefinitely. The 300, 75, and 13 v d.c. supplied were obtained from suitable rectifying circuits. The potentiostat could deliver 0.1 amp; its control circuit was sensitive to ± 0.01 v; the current taken from the reference electrode was less than 1 μamp.

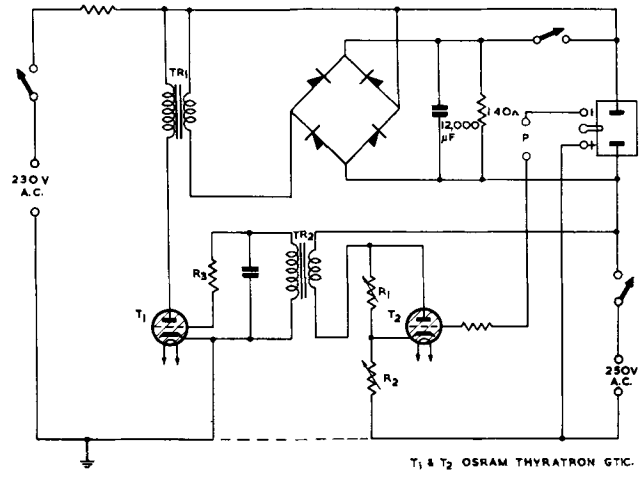

Fig. 2. Potentiostat B

The circuit of the second potentiostat, also due to Hickling, is shown in Fig. 2. The thyratron T_2 is included in a circuit similar to that used in the first potentiostat. When the voltage between the working/reference electrode combination is greater than that set on the potentiometer P, then T_2 fires and induces a voltage across the secondary of TR_2, 180° out of phase due to the condenser; this voltage being applied to the grid of T_1, this valve does not fire.

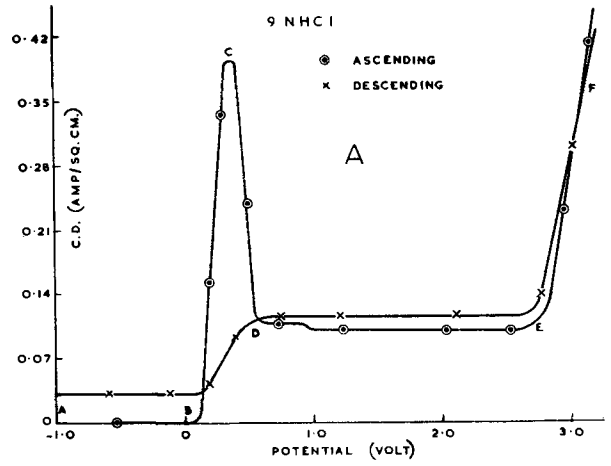
When the voltage of the working/reference electrode combination is less than that across P then T_2 does not fire, the biasing voltage on T_1 is absent, T_1 fires and induces a voltage across the secondary of TR_1 which is rectified, smoothed, and fed to the electrolytic cell. The current through the cell is thus controlled to maintain the potential of the working electrode indefinitely. In practice it was found that the negative bias on T_1 was not sufficient to withhold any one pulse of electricity, and consequently a 140-ohm resistance was connected across the output to by-pass some of the current. The output current is not limited by having to pass through a triode valve, and an output of several amperes could be obtained with the instrument at low output voltages; but as the output voltage increased the current fell off considerably. The two potentiostats are called A and B, respectively.

Experimental Results

Nickel in Hydrochloric Acid

Potential/C.D. graphs were obtained for nickel anodes in hydrochloric acid of concentration from 0.1*N* to 10.0*N*. The anode potential was increased in steps of 0.2 v, the current becoming constant after a few seconds, when it was read off. The current stabilized to a constant value almost immediately as the anode potential was reduced in steps of 0.2 v to give the descending curve. In Fig. 3A and B are given the curves obtained in 9*N* HCl.

The C.D. was undetectable in Fig. 3A until an anode potential of + 0.15 v was reached, when it rose rapidly for a small increase in potential, attaining a high value of about 0.40 amp/cm^2. As the potential was increased by a further small amount then the C.D. fell, and remained substantially constant with further increase in potential, the limiting C.D. region, until chlorine gas was evolved at about 2.5 v and the C.D. rose. The descending curve followed the ascending curve closely except that the high peak at C on the ascending curve did not recur. Before the limiting C.D. region was reached the anode was etched to a gray matt surface, while in the limiting C.D. region a thick green film formed, the anode being seen to be brightened underneath on removal from the electrolyte.



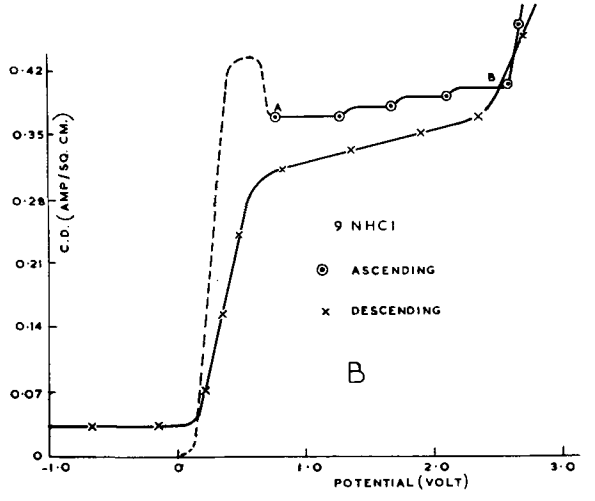


Fig. 3. A and B. Nickel in 9N HCl : Anode C.D. vs. Anode Potential.

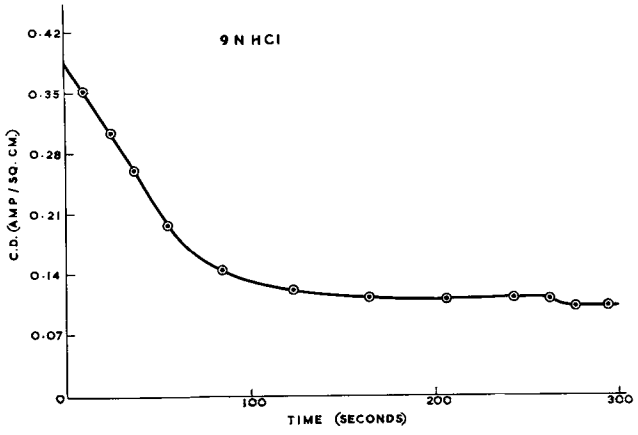

Fig. 4. Nickel in HCl : Limiting C. D. vs. Time

In order to remove the thick green film formed in the limiting C.D. region the following technique was adopted: the anode potential was increased in steps of 0.2 v, up to 1.0 v as in Fig. 3A; the circuit was broken for 1 min, then again completed, the anode potential being 1.0 v, i.e., greater than the potential at which the etching region and high peak value of the C.D. occurred at C in Fig. 3A. The C.D. rose rapidly to about 0.37 amp/cm^2 as recorded in Fig. 3B; the green film fell away to be replaced by a thick green layer of rapidly dissolving salt which streamed away from the anode; the anode was brilliantly polished. The rest of the graph was plotted as Fig. 3A.[1]

It is clear that in this electrolyte there are two limiting C.D.'s of approximately 0.10 and 0.40 amp/cm^2.[2] The operation of raising the potential to 1.0 v, breaking, and remaking the circuit will be called prepolarization.

If a prepolarized anode in 9*N* HCl is electrolyzed in the limiting C.D. region for about 5 min then I_{LIM} sinks gradually to the value for the nonprepolarized anode; the layer of rapidly dissolving salt is replaced by a thick green film. This is shown in Fig. 4, the anode potential being 1.0 v.

The nature of the anodic process occurring in each section of the curve was determined by carrying out constant-potential electrolyses at a series of increasing potentials and comparing the loss in weight of a nickel micro-electrode with the gain in weight of a cathode in a copper coulometer in series with the cell. Results obtained in electrolytes varying from 0.5*N* to 9.0*N* HCl showed that up to a potential of 2.5 v the current efficiency for dissolution of nickel in the nickelous state was practically 100%; above 2.5 v gas evolution set in and the current efficiency dropped.

Influence of experimental factors on I_{LIM}.—The limiting C.D.'s for the ascending curves were found to be reproducible with an accuracy of about ± 5% and ± 7% using potentiostats A and B, respectively.

In Table I are summarized the limiting C.D.'s for solutions of HCl of concentration from 10*N* to 0.1*N*.

The prepolarized values are the greater until the concentration drops below 7*N* HCl when the two sets of figures approximate the same values. Below a concentration of 7*N* HCl the thick green film at the nonprepolarized anodes does not appear, and all the electrodes are surrounded by a thick layer of rapidly dissolving salt streaming away. The limiting C.D.'s for both nonprepolarized and prepolarized anodes increase as the concentration of HCl decreases until 0.5*N* HCl when they decrease rapidly.

Potential/C.D. graphs were constructed for solutions of 7*N* HCl alone and with additions of 5, 10, 20, 25, and 30% glycerol to increase the viscosity, using both nonprepolarized and prepolarized anodes. Results are shown in Fig. 5, I_{LIM} being plotted against the reciprocal viscosity. For the prepolarized

Table I. Influence of concentration of HCl on I_{LIM} at 20°C

Concentration, g mole/l	10	9	8	7	6	4	2	1	0.5	0.1
Limiting C.D., amp/cm^2	0.07*	0.10*	0.24*	0.68*	1.18	1.83	2.37	2.54	1.59	0.19
Limiting C.D., amp/cm^2, prepolarized	0.34*	0.45*	0.54*	0.95*	1.22	1.83	2.24	2.43	1.62	0.19

* Values marked with an asterisk were obtained using potentiostat A, the rest potentiostat B.

[1] The limiting C.D. regions for the ascending and descending curves could not be brought any closer together by leaving the anode potential for 15 sec at each 0.2 v step for both Fig. 3A and B.

[2] When the C.D. passing in the limiting C.D. region is not constant a mean value is taken; the limiting C.D. is denoted in all cases by I_{LIM}.

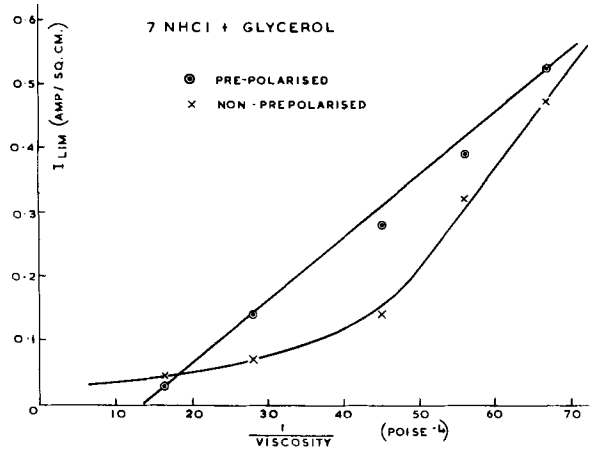

Fig. 5. Nickel in 7N HCl with glycerol additions : Influence of viscosity on limiting C.D.

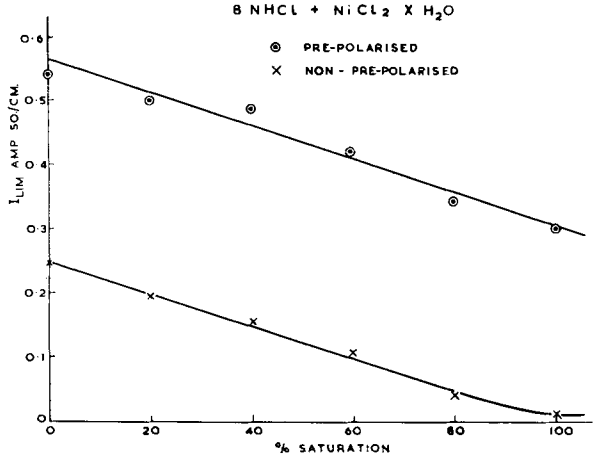

Fig. 6. Nickel in 8N HCl with nickelous ion addition; influence of dissolved nickel on limiting C.D.

anodes I_{LIM} varies linearly as the reciprocal viscosity, but this is not so for the nonprepolarized anodes.

Stirring solutions of 7*N* HCl + 20, 25, and 30% glycerol, at 450 rpm with a glass paddle stirrer, results in an increase in I_{LIM} of 3.9, 5.6, and 4.5 times for nonprepolarized anodes; increases for prepolarized anodes were 3.1, 5.6, and 3.7 times. In the case of 7*N* HCl + 20% glycerol, I_{LIM} increased from 0.09 to 0.35 amp/cm^2 for nonprepolarized anodes and from 0.14 to 0.43 amp/cm^2 for prepolarized anodes.

Rise in temperature from 20° to 70°C caused a rise in the limiting C.D. of 1.5 and 1.9 times for anodes in 0.5 and 6*N* HCl.

Solutions of 8*N*, 4*N*, and 0.5*N* HCl were saturated with A.R. $NiCl_2$. 6 H_2O by mechanical shaking for a few hours; by diluting these with the pure acid, solutions 80, 60, 40, and 20% saturated with nickel salt were obtained. Potential/C.D. curves were of the usual type. Typical curves of I_{LIM} against per cent saturation are given in Fig. 6 and 7 for 8*N* and 0.5*N* HCl.

For the nonprepolarized anodes in 8*N* and 0.5*N* HCl the values of I_{LIM} decrease linearly with per cent saturation of nickel salt; the value of I_{LIM} at 100% saturation is very nearly zero. Although there is a linear decrease in I_{LIM} for prepolarized anodes,

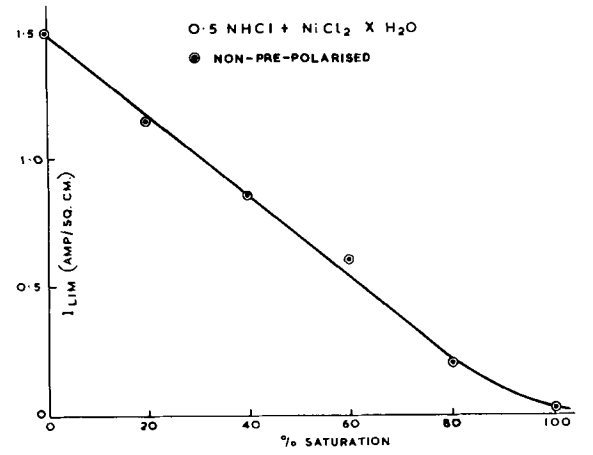

Fig. 7. Nickel in 0.5N HCl with nickelous ion addition; influence of dissolved nickel on limiting C.D.

the graph does not cut the x axis at 100% saturation.

Copper in Potassium Cyanide

The anodic dissolution and electrolytic polishing of copper in potassium cyanide has been discussed in a previous paper (2). An attempt was made to induce passivity gradually by slowly increasing the alkalinity of the electrolyte.

In Fig. 8 is given a typical potential/C.D. graph for a copper anode in 2M KCN. The anode was etched in the rapidly ascending region; it was polished in the limiting C.D. region, although the polish was not comparable in brilliance with those obtained at nickel anodes in hydrochloric acid or copper anodes in phosphoric acid. When the anode potential exceeded 1.0 v a thick brown film formed on it.

In Fig. 9, which is a graph for 2M KCN + 0.5M KOH solution, a pronounced dip occurs in both ascending and descending curves. If the concentration of KOH is increased to 0.75M, then the behavior shown in Fig. 10 is observed. The C.D. attains a high peak value of about 0.09 amp/cm^2 before it drops almost to zero on increasing the potential beyond 0 v; at 1.0 v the next process, formation of the brown film, sets in and the C.D. can again rise. The descending curve does not show a limiting C.D. region but the C.D. remains almost zero until about

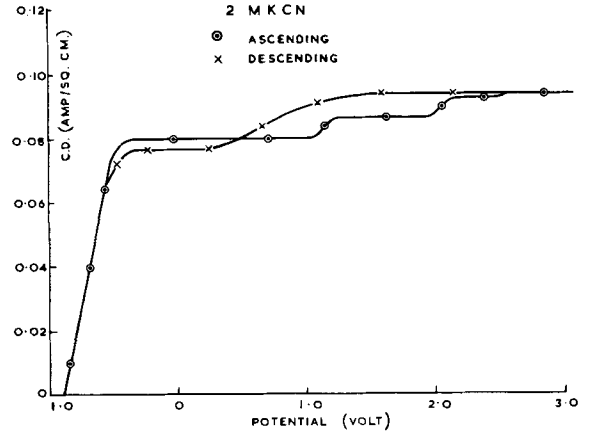

Fig. 8. Copper in 2M KCN; anode C.D. vs. anode potential

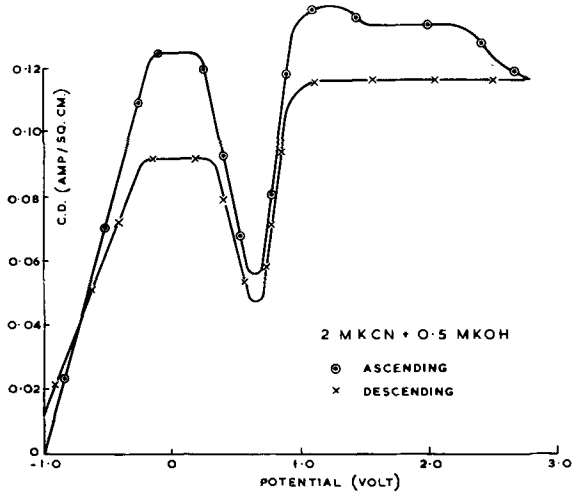

Fig. 9. Copper in 2M KCN + 0.5M KOH; anode C.D. vs. anode potential.

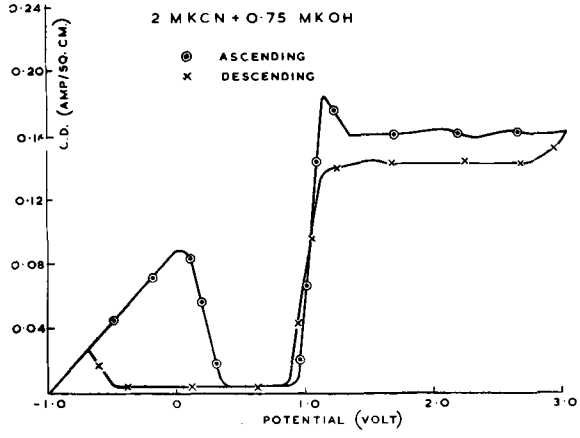

Fig. 10. Copper in 2M KCN + 0.75M KOH; anode C.D. vs. anode potential.

−0.5 v when it rises to the value for the ascending curve.[3]

The behavior in 2M KCN + 0.75M KOH solution up to a potential of 1.0 v is typical of an anode undergoing passivity (5) and the anode was not polished in this electrolyte. Passivity can be induced gradually by increasing the alkalinity of the medium in small steps.

Discussion

The increase in the limiting C.D.'s on stirring and the decrease when the viscosity is increased, together with the effect of temperature, constitute a clear indication that the anodic dissolution of nickel in hydrochloric acid is diffusion controlled at high current densities. The effect on the limiting C.D. of the addition of nickel salts to the solution suggests that it is the diffusion of the nickelous ion away from the anode which is rate determining.

Assuming Fick's law and the existence of a linear concentration gradient over the diffusion layer, the limiting C.D. is given by (2, 6).

$$I_{LIM}\ (\text{amp/cm}^2) = \frac{DFZ\ (C_s - C_o)}{\delta} \qquad [1]$$

[3] The ascending and descending curves in Fig. 9 and 10 could not be brought closer together by leaving the anode potenial for 15 sec at each 0.2-v step.

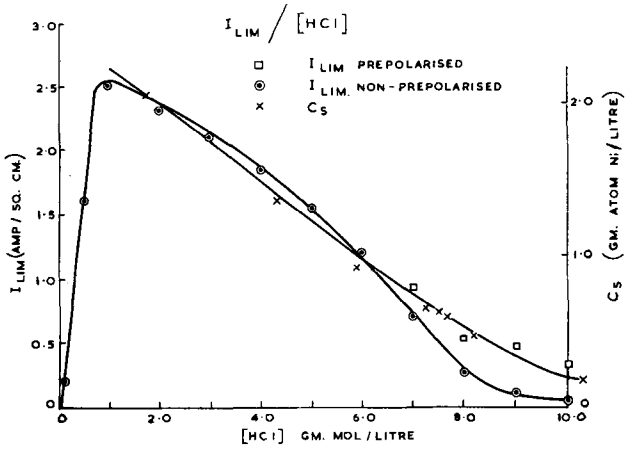

Fig. 11. Comparison of influence of HCl concentration on limiting C.D. and nickel chloride solubility.

where D is the diffusion coefficient of the nickelous ion, $\mathbf{F}$ the Faraday, Z the valency of the dissolving ion, and δ the thickness of the diffusion layer; C_s and C_o (g ion/liter) are the solubility and bulk concentration, respectively, of the nickelous ion. For a solution initially free from nickel $C_o = 0$, and we have

$$I_{LIM} = \frac{DFZ\,C_s}{\delta} \qquad [2]$$

According to Eq. [1] for constant values of C_s any factor such as stirring, tending to decrease δ, should increase I_{LIM}. Increasing the viscosity of the solution should decrease D and therefore I_{LIM}, while increase of temperature should increase D and therefore I_{LIM}. All these predictions are borne out by experiment.

For constant values of D and δ in Eq. [1], I_{LIM} should be proportional to $(C_s - C_o)$ and zero when $C_s = C_o$, i.e., at 100% saturation with nickel salt. This is confirmed experimentally as shown in Fig. 6 and 7 except for prepolarized anodes in 8N HCl.

If Eq. [2] is correct, I_{LIM} should be proportional to C_s in the simple acid solutions. In Fig. 11 the graphs of I_{LIM} and C_s are plotted against concentration of HCl; the shape of the two curves is similar, confirming the above prediction.

By substituting values of D, C_s, and I_{LIM} in [2] it is possible to calculate δ. The values of D were calculated from the equation (6)

$$D = \lambda RT/\mathbf{F}^2 \qquad [3]$$

where λ, reciprocal ohms, is the equivalent conductivity of nickel chloride at 18°C (7). The results obtained using λ values from the International Critical Tables for the solutions shown are: $D = 1.85 \times 10^{-5}$ cm^2/sec^{-1}, 18°C, 10N, 8N HCl; $D = 1.74 \times 10^{-5}$ cm^2/sec^{-1}, 18°C, 7N HCl; $D = 1.63 \times 10^{-5}$ cm^2/sec^{-1}, 18°C, 6N, 1N HCl. Substituting these values in [2] the values

Table II. Thickness of diffusion layer in HCl solutions

Concentration HCl, g mole/l	10	9	8	7	6	4	2	1
δ cm	0.0110	0.0112	0.0070	0.0033	0.0024	0.0024	0.0026	0.0028
δ cm, prepolarized	0.0021	0.0021	0.0030	0.0023	0.0024	0.0024	0.0029	0.0028

of δ for the nonprepolarized and prepolarized anodes are given in Table II for the simple HCl solutions. Apart from the first four values for the nonprepolarized anodes δ is between 0.002 and 0.003 cm; this is much less than the 0.03 cm normally found for cathodic diffusion processes in unstirred solutions. However, at the present vertical anodes and the high C.D.'s encountered there will be a large amount of convective stirring which will decrease δ as discussed by Tobias, Eisenberg, and Wilke (8). Values of δ for nonprepolarized anodes in the concentrated HCl ($> 7N$) solutions are higher than the rest. When the thick salt film is removed, i.e., the anodes are prepolarized, then δ is lowered and is of the same order as the values found in the dilute solutions. It is clear that the simple diffusion mechanism does not hold for the nonprepolarized anodes in the concentrated acid solutions.

The above conclusion is borne out by the graphs of Fig. 11; the I_{LIM} and C, curves agree most closely for the prepolarized anodes. Finally, Fig. 5, where I_{LIM} is plotted against the reciprocal viscosity for solutions of HCl containing glycerol, shows that the linear relationship holds for prepolarized anodes only. This relationship has been found for the anodic dissolution of copper in phosphoric acid and potassium cyanide; both are examples of diffusion-controlled processes (2). It would seem that the process in the dilute ($< 7N$ HCl) solutions is diffusion controlled as it is at the prepolarized anodes in the more concentrated ($> 7N$ HCl) solutions. At the nonprepolarized anodes in the concentrated solutions complications set in due to the formation of thick salt films.

The hydrate of nickel chloride stable in HCl solutions from 1.75 to 7.26N is the hexahydrate, at 7.5N the pentahydrate, and from 7.65 to 10.35N the tetrahydrate (9). It is probable that the thick salt films observed in HCl solutions more concentrated than 7N are films of the tetrahydrate; Fig. 11 shows that this salt, stable in concentrated acid solutions, is less soluble than the more hydrated forms.

If the prepolarized anode in 9N HCl is electrolyzed in the limiting C.D. region for about 5 min, then I_{LIM} sinks gradually to the value for the nonprepolarized anode (see Fig. 4); the diffusion layer is replaced by a thick light green film. It would seem at the prepolarized anode that the nickel first dissolves as an unstable species which then gradually reverts to the sparingly soluble tetrahydrate which forms a film on the anode.

Results for the dissolution of prepolarized anodes in 8N HCl, partly and completely saturated with nickel chloride, are puzzling (Fig. 6). All the evidence suggests that it is the reaction at the prepolarized anodes which is diffusion controlled, and yet it is the nonprepolarized anodes which show nearly zero I_{LIM} in solutions 100% saturated, as would be expected from Eq. [1] for a diffusion-controlled process. It may be because the prepolarized anodes are dissolving as an unstable species that I_{LIM} remains so high in solutions containing nickel chloride; when the nickel goes into solution directly as the stable tetrahydrate (nonprepolarized anodes) then the predictions of Eq. [1] are verified.

On the basis of the diffusion treatment given it is to be expected that in the limiting C.D. region, when the layer of electrolyte adjacent to the anode becomes saturated with salt, a film of salt will be deposited. This film usually dissolves as quickly as it is formed, its thickness depending on the solubility of the salt and its degree of hydration. Williams and Barrett (10) have identified the film formed on copper anodes in phosphoric acid as copper phosphate by electron diffraction measurements. It is invisible during electrolysis as are the films formed in the dilute HCl solutions at nickel anodes. In concentrated HCl solutions at nonprepolarized anodes the salt films are clearly visible, the electrode still being polished underneath.

The smoothing action during electrolytic polishing in the limiting C.D. region can be explained satisfactorily by assuming the absence of a concentration gradient of metallic cations between peaks and cavities in a roughened surface and consequently faster dissolution of the peaks. An additional factor aiding smoothing is the earlier deposition of a salt film in the cavities than on the peaks. However, while this theory is satisfactory for the dilute solutions of HCl, it is not sufficient to explain why nonprepolarized nickel anodes are polished underneath the thick salt film in the concentrated ($> 7N$) HCl solutions; the films are much thicker than the cavity depth of a few microns. Hoar and Mowat (3) have explained the absence of crystallographic etching in the limiting C.D. region by assuming that the metallic cations pass from the metallic surface into vacant sites in an oxide lattice, the oxide dissolving as fast as it is formed. The random distribution of vacant sites would then account for the absence of etch figures. If it is assumed that the oxide film is present underneath the salt film, then the brightening of the nickel in solutions where a very thick film of salt is formed can be understood. Probably both the smoothing and brightening mechanism are present at polishing anodes in dilute solutions.

It is well known from the work of Evans and others (5) that the occurrence of passivity is associated with the formation of a thin, coherent, insoluble oxide film on the anode. The fact that the transition from polishing to passivity behavior can be brought about gradually (Cu in KCN + KOH) by increasing the alkalinity of the electrolyte is evidence for the presence of a dissolving oxide film during polishing and leads to the view that polishing and passivity are two limiting cases of the same general phenomenon.

Conclusions

1. The anodic dissolution of nickel in dilute ($< 7N$) HCl solutions is diffusion controlled.

2. At prepolarized anodes in concentrated ($> 7N$) HCl solutions the dissolution is diffusion controlled.

3. At nonprepolarized anodes in conc. ($> 7N$) HCl solutions the simple diffusion mechanism breaks down.

4. The onset of thick salt film formation in the

more concentrated (> 7*N* HCl) solutions is associated with a decrease in the degree of hydration of the dissolving salt.

5. The state of the prepolarized anode is unstable; it reverts to the nonprepolarized condition in a short time.

6. Polishing in the dilute solutions can be explained satisfactorily by the differential solution of peaks and cavities due to different concentration gradients at peaks and cavities and the deposition of freely soluble salt films.

7. The brightening effect observed under very thick salt films in concentrated acid solutions is best explained by the dissolving oxide theory of polishing.

8. Passivity can be induced gradually in a polishing bath by increasing the alkalinity of the electrolyte in steps and this supports the theory mentioned in 7.

Manuscript received March 3, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

An Investigation of Chemical Variables Affecting the Formation of Films on Copper in Aqueous Solutions

W. H. Davenport, V. F. Nole, and W. D. Robertson[1]

Chase Brass and Copper Company, Waterbury, Connecticut

ABSTRACT

The growth of copper oxide films in aqueous solutions has been studied by an electrometric method. Quantitative data have been obtained on the growth of films as a function of the solution variables; anion type and concentration, *p*H, and oxygen concentration. In air-stirred chloride solutions, film thickness increases with increasing chloride concentration, passes through a maximum in solutions approximately 0.01M, and then decreases. A maximum also is obtained for *p*H dependence in the range *p*H 5.9-9.0. Cuprous oxide is formed below about *p*H 10.5 and cupric oxide predominates at higher values. For equimolar solutions (0.1M), film growth rate in sodium chloride solutions is about double that in sodium sulfate. In both cases the rate is linear and limited by oxygen availability under the conditions described. In high-purity water, in the presence of excess oxygen, the rate of growth is approximately parabolic, but the extremely thin films formed preclude detailed analysis with the present technique.

Many investigators (1-8) have studied the rate of film formation on copper as a result of oxidation in air at various temperatures. The composition of these films, which is affected by environmental factors such as temperature and oxygen partial pressure, has been verified by electron diffraction studies (9-12). A generally accepted mechanism for the reaction relates oxidation rate to the movement of copper cations through vacancies in the oxide lattice and, it has been shown (4, 7, 8) that over a limited range of film thickness or temperature the parabolic equation may be used to express the growth of films with time. In the case of copper, all of the oxidized metal remains on the surface as a film, and a measure of film growth rate is also a direct measure of oxidation rate.

When copper corrodes in an open aqueous solution the rate of reaction is affected likewise by the nature of the corrosion product film formed on the surface. However, in an aqueous solution, all of the products of corrosion do not necessarily remain on the surface; depending on solution composition and *p*H, corrosion products may dissolve in the solution or form at a site removed from the reacting area. Accordingly a study of oxidation of copper in aqueous solution, based on film growth, can become quite complex. This perhaps explains why very little quantitative information is available on this subject.

The growth of films on copper in aqueous potas-

[1] Yale University, New Haven, Connecticut, Consultant.

sium chloride solutions was measured by Hill (13) in a study of the initial corrosion reaction. His tests, however, were limited to the pH range 7.0-8.3 in which the films were essentially insoluble. Kruger (14) studied the effect of illumination on films formed in air-saturated distilled water.

The present paper describes an investigation of the effect of certain solution variables on the growth and composition of films formed on copper in solutions where information appears to be lacking. It is designed to supplement previous work (15) dealing with the effect of the same variables on the corrosion rate of copper under similar conditions.

Experimental Procedure

Specimens.—Rod specimens, 0.125 in. diameter x 12 in. long, were prepared from oxygen-free high-conductivity copper drawn 85%. Chemical composition was: Cu-99.98%, Fe-<0.003%, Ni-<0.005%, Pb-<0.0005%, and Zn-<0.01%. The surface was scrubbed with water and pumice, rinsed in distilled water, and dried in alcohol. Specimens then were inserted in 3/16 in. ID glass tubes through a short section of ⅛ x ¼ in. rubber tubing which served as a gasket. By sliding the rod in or out, the specimen area could be varied. For very thin films the area was adjusted to 4 cm^2. Thicker films were developed on a 2 cm^2 area. Prior to exposure, the projecting portion was etched for 3 min in 10% ammonium persulfate and rinsed in high-purity demineralized water. The specimen assembly then was transferred quickly to the test solution without drying.

This chemical etching technique for preparing the specimen surface was adopted as a reproducible method which minimizes the blank reading that is obtained by other chemical or mechanical methods, not involving preparation in an inert atmosphere. In view of the fact that film growth was to be studied over some considerable period of time, and that the increased thickness is an average quantity, more elaborate methods did not seem warranted for this preliminary investigation of the comparative effects of solution variables.

Film development.—Films were developed at room temperature in the corrosion cell previously described (15), using a continuous flow technique to maintain essentially constant solution composition. The test solution was fed to the bottom of the cell at 220 ml/hr and the appropriate gas stirring mixture was introduced by means of a gas lift side arm at 500 ml/hr (28 bubbles/min). Alternatively, in tests where increased oxygen availability was desired, the stirring gas was supplied to the bottom of the cell through a medium porosity, 10-15 micron pore size, fritted disk (10 mm diameter) at a rate of 250 ml/min.

When gas mixtures other than air were used, the system was kept under a slight positive pressure to maintain the desired atmosphere over the solution.

Three specimen assemblies were inserted in each cell and held in a uniform geometrical arrangement by means of a plastic spacer ring placed approximately at the mid point of the cell.

Air-formed films also were prepared by exposing specimens in an electric furnace equipped with a circulating fan.

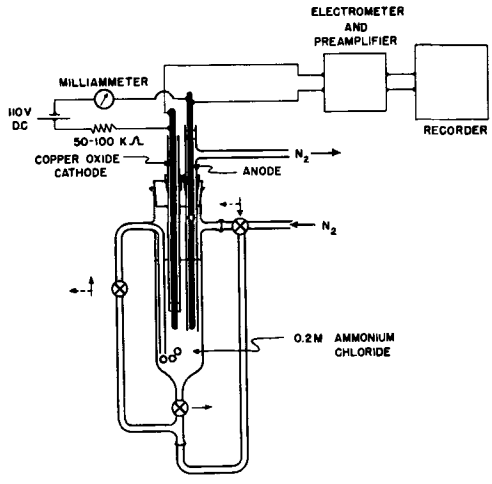

Fig. 1. Electrolytic reduction apparatus

Film analysis.—Following exposure, films were analyzed by an electrometric method, Fig. 1, similar to that used by Miley (4) in his investigation of air-formed films on copper. In principle, the copper compound composing the film is reduced cathodically and the thickness is calculated from the number of coulombs required and the bulk density. This calculation assumes that the surface is a plane and that the film is uniformly distributed. The errors resulting from these assumptions will depend on the magnitude of surface roughness, relative to film thickness, and on the degree of conformity of the contour of oxide and original metal surface. Certainly in the early stages the absolute value of the thickness may be largely in error due to nonuniformity of film and roughness of surface; the error should decrease significantly as the film thickness increases. In the present case the thickness has been used as a measure of changing conditions in the solution usually after 48 hr when a considerable thickness of film has been formed.

Reduction was carried out in a closed glass cell designed so that nitrogen could be either bubbled through the solution or passed over the surface to maintain a protective atmosphere. The film bearing specimen was made the cathode, a copper rod the anode, and 0.2M ammonium chloride was used as the electrolyte. Although the data reported herein were obtained using rod specimens, the apparatus can also be adapted to sheet or tube by using a hooked platinum wire as the cathode and hanging the specimen from this hook.

Current was obtained from a 110 v d-c source consisting of a 90-v "B" battery and a 22½-v "C" battery connected in series. Voltage was applied through a high resistance of 50,000-100,000 ohms. The use of such a large external resistance resulted in a small constant current of 1-2 ma which was unaffected by the relatively minor changes which took place in the cell. The potential developed by the voltage drop across the cell was fed to a Brown electrometer and preamplifier (an instrument which draws no significant current while measuring voltage) and then to a high speed recording potentiometer.

Table I. Oxidation of OFHC copper rod (0.125 in. diameter) in air at 245°C

Prior to analysis the electrolyte was deaerated by bubbling nitrogen for 30 min. The stopcock was turned to pass the gas over the surface and the exposed specimen assembly was inserted.

During the course of reduction the cell potential was followed and recorded to obtain the potential-time curves characteristic of the method. Film thickness then was calculated from the time and current required for reduction using the appropriate factors.

On the basis of Miley's observations and also x-ray diffraction studies, cuprous oxide, Cu_2O, was assumed to be the product which was reduced at a potential of approximately 300 mv and cupric oxide, CuO, the product reduced at 550 mv. Measured against a saturated calomel reference electrode, the corresponding reduction potentials would be 350 mv and 600 mv, respectively.

Experimental Results and Discussion

In order to check the apparatus and the procedure, a portion of Miley's work, dealing with film growth rate in air at 245°C, was repeated. The results are shown in Table I and in Fig. 2.

Good agreement was obtained. Miley's data did not indicate the ratios of cuprous and cupric oxide encountered but, in later work in conjunction with Cruzan (5), they reported that the proportions of the two oxides varied with film thickness. Below 400Å, films contained only cuprous oxide, above 800Å, all films contained a mixture of both, and in the intermediate range some films contained a mixture and others cuprous oxide alone. The films produced in the present work were all too thick to verify the latter conclusions; however, the increase in the proportion of cupric oxide with increasing film thickness does appear to agree with the trend established in the work of Cruzan and Miley.

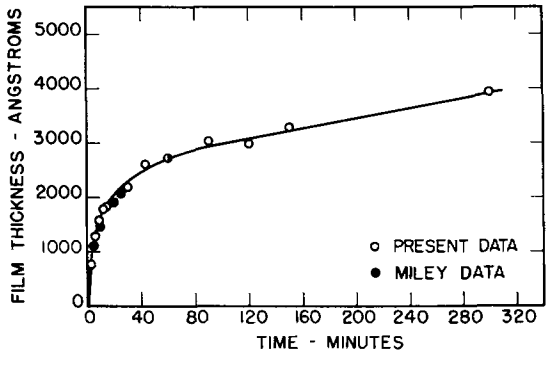

Fig. 2. Oxidation of OFHC copper in air at 245°C

Since the apparatus and analytical procedure proved reliable, the method was applied to the study of film formation in various aqueous salt solutions. The solution variables investigated were anion type and concentration, pH, and oxygen. Reproducibility of results varied with exposure conditions, with the greatest spread, ±5%, appearing in nearly neutral solutions where pH was quite sensitive to small changes in composition. A "blank" corresponding to a film thickness of 20Å is associated with the method and the necessary corrections have been made. The "blank" was traced to air oxidation during specimen preparation and probably could be reduced by preparing specimens in an inert atmosphere.

Effect of Anion Type and Concentration

The growth of films with time in 0.1M sodium chloride and 0.1M sodium sulfate solutions is shown in Fig. 3.

The rate of film growth is considerably higher in sodium chloride solutions and in each case it appears to be approximately linear over the range investigated. In both solutions only cuprous oxide was detected.

Results were about the same in either 0.1 or 0.01M sodium sulfate. However, a change in chloride concentration produced an appreciable change in film thickness as shown in Fig. 4.

For constant time and varying chloride concentration, maxima in thickness are obtained in 0.01M chloride solutions. The effect of chloride ion on film thickness does not correlate with previous observations (15) on the effect of chloride on corrosion rate, where it was shown that corrosion rate increased linearly with increasing chloride ion under the same conditions. The lack of correlation would appear to indicate that corrosion rate is not solely dependent

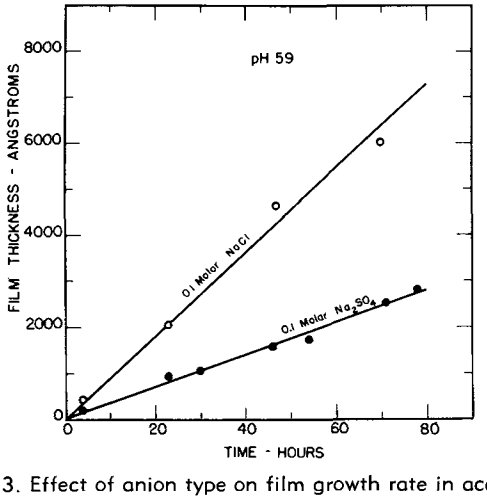

Fig. 3. Effect of anion type on film growth rate in acqueous salt solutions.

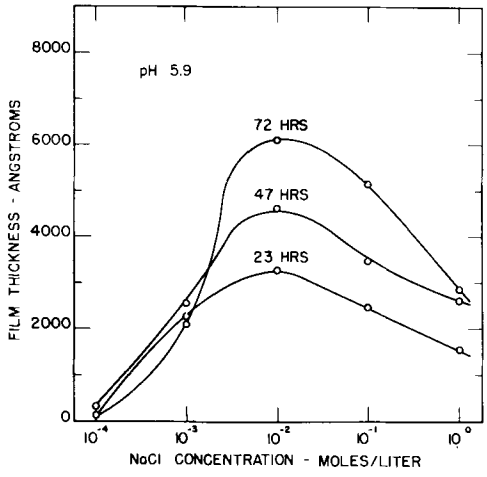

Fig. 4. Effect of concentration on film growth in sodium chloride solutions.

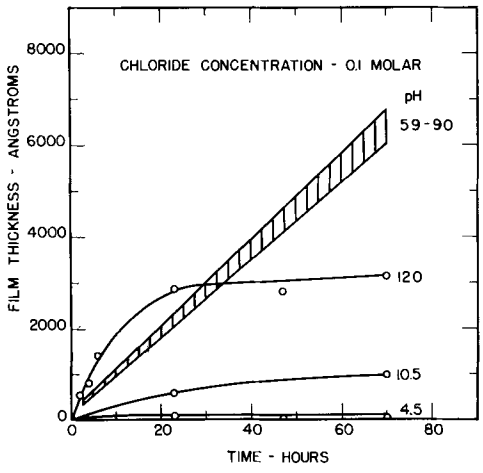

Fig. 6. Effect of pH on film growth rate in chloride solutions

on film thickness for the conditions described. Further studies are being conducted.

Asselin and Rohrman (16) studied the corrosion rate of copper as a function of sodium chloride concentration and reported a maximum at much higher concentrations, 2-3*N*, but none in the range under consideration at present. They attributed the maximum to the net result of the opposing factors oxygen solubility and solution conductivity.

Effect of pH

The effect of *p*H was studied in solutions, 0.1M in chloride ion. Hydrochloric acid or sodium hydroxide was added to sodium chloride solutions as necessary in order to achieve the desired *p*H. It was also necessary to remove carbon dioxide from the incoming air in order to minimize drift in *p*H. Results are shown in Fig. 5.

A fairly flat maximum is obtained in the *p*H range 5.9-9.0. In this range films are essentially cuprous oxide, Cu_2O. Film thickness decreases rapidly below *p*H 5.9, or as the *p*H is raised from 9 to 10.5. At higher *p*H values, however, film growth again starts to increase. Films formed in the high *p*H range, around *p*H 12, are predominantly cupric oxide.

The effect of *p*H is complicated by the fact that the shapes of film growth rate curves vary at different *p*H values as shown in Fig. 6.

Films formed in the *p*H range 5.9-9.0 all fall in the band shown in Fig. 6 and they are still growing after 70 hr. Films formed below or above this range appear to reach a maximum thickness at shorter times and then remain fairly constant. Presumably, in the latter cases, a steady state has been reached where the film formation rate is equal to the dissolution rate.

The absence of measurable films below approximately *p*H 3 is consistent with previous observations (15) and, if the films can be assumed to be partially protective, then the effect of *p*H on films is also consistent with general experience regarding the increase in corrosion rate with decreasing *p*H.

Effect of Oxygen

The effect of oxygen was studied in 0.1M sodium chloride solutions by varying the composition of an oxygen-nitrogen mixture used as the stirring gas. Three mixtures were investigated; 21% (air), 50%, and 100% oxygen. Film thickness increased with increasing oxygen, as shown in Fig. 7, indicating that the process is under oxygen control in every case. The shape of the curve suggests that, at 100% oxygen, conditions were being approached where

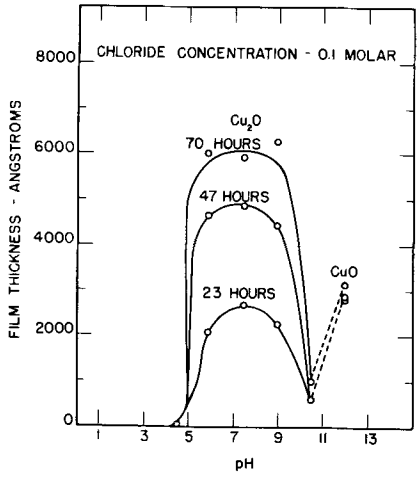

Fig. 5. Effect of pH on film growth in chloride solutions

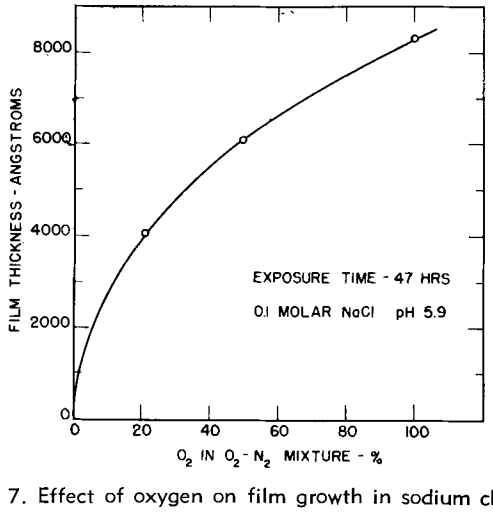

Fig. 7. Effect of oxygen on film growth in sodium chloride solutions.

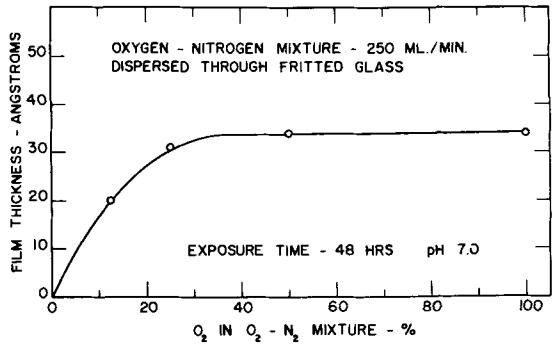

Fig. 8. Effect of oxygen on film growth in high-purity water

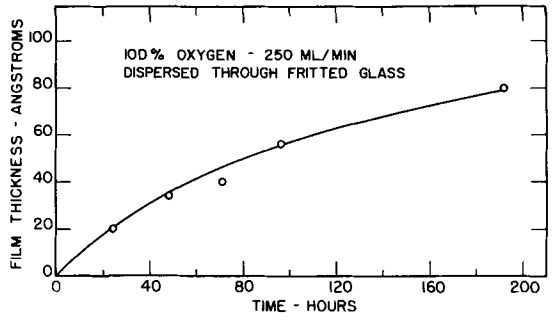

Fig. 9. Film growth rate in high-purity water in the presence of excess oxygen.

rate is independent of further increases in oxygen. This point has not been reached, however, and an increase in stirring rates at this point resulted in films of greater thickness for the same exposure times.

The interdependence of the variables anion concentration, pH, and oxygen makes it difficult to develop a general expression for the growth rate of films on copper in aqueous salt solutions. Thus, a statement regarding the rate in 0.1M chloride solutions must also define the conditions of pH and oxygen availability. In order to obtain a more general expression it was necessary to conduct tests under conditions where variables were either eliminated or reactants were supplied in excess. This was accomplished by using high-purity demineralized water as a corrosive medium. The effect of anions other than the hydroxyl ion present in water was thus eliminated and pH, which was determined before and after test, remained constant at 7.0. An oxygen-nitrogen mixture was supplied to the solution through the medium porosity fritted glass disk which served to increase the availability of oxygen. Under these conditions a mixture containing about 40% oxygen is sufficient to provide an excess of oxygen as shown in Fig. 8.

The film growth rate of copper in high-purity water in the presence of excess oxygen then was determined for times up to 200 hr, Fig. 9. However, under these conditions, the films formed are so thin that the limit of sensitivity of the method is approached. Reproducibility in film formation may also be a factor. Kruger (17) has shown that the nature of oxide films formed in pure water may vary considerably with method of surface preparation and environmental control. The curve is approximately parabolic in form, but the precision of the data, the blank correction, and possible failure of the assumptions involved in the calculations of thickness of thin films preclude detailed analysis of the rate law.

Conclusions

The growth of copper oxide films in aqueous solutions has been studied by an electrometric method. Quantitative data have been obtained on the growth of films as a function of the solution variables, anion type and concentration, pH, and oxygen concentration.

In air-stirred chloride solutions, film growth rate is affected by chloride concentration and pH with a maximum appearing in 0.01M solutions and in the pH range 5.9-9.0. Films are cuprous oxide exclusively except at very high pH values, >10.5, where the rate again increases and cupric oxide predominates.

In equimolar solutions (0.1M) the rate in sodium chloride is about double that in sodium sulfate. In both cases the rate is linear and limited by oxygen availability, even when oxygenation is effected by stirring with a 100% O_2 mixture.

Films formed in high-purity water in the presence of excess oxygen are relatively thin which precludes detailed analysis of the growth rate law from data obtained with the present technique.

The Formation of Porous Oxides on Metals

D. W. Aylmore, S. J. Gregg, and W. B. Jepson

Department of Chemistry, University of Exeter, Exeter, England

ABSTRACT

The porosity of the oxide scales formed on a number of metals during oxidation in dry oxygen has been investigated by measurements of specific surface and of density. The oxides formed during the linear oxidation of the eight metals: calcium, cerium, lead, magnesium, niobium, thorium, tungsten, and uranium are porous whereas those formed during the parabolic oxidation of copper and cobalt are impervious to oxygen gas.

The oxidative behavior of a metal in oxygen depends to a marked extent on the physicochemical properties of the oxide layer formed on its surface. If the layer of reaction product remains continuous during oxidation, reaction can proceed only by the diffusion of either one or both of the reactants in the ionized form through the oxide lattice. In some cases, as with aluminum (1, 2) at 600°C, the rate of oxidation falls off to a negligibly small value as time proceeds, while in others, as for example copper (3) at 1000°C, the oxidation follows a parabolic rate law and the rate of attack is such that a sheet of material is oxidized completely in a few hours.

On the other hand, some metals, usually above a certain characteristic temperature, oxidize at a constant rate which is maintained until the whole of the metal is consumed, a behavior exemplified by magnesium (4) at 500°C. This "linear oxidation" usually is interpreted in terms of the formation of an oxide scale which is porous in the sense that oxygen gas is able to pass freely through its thickness; the rate of oxidation is believed to be controlled by the rate of diffusion either of metal ions or oxygen anions through a thin barrier film of oxide adhering to the metal.

The present study was undertaken in order to provide experimental evidence for the postulated porosity of the oxide layer formed during linear, or almost linear, oxidation and to show that the oxide layer formed during parabolic oxidation is, in fact, impervious to oxygen gas. The metals whose oxides were investigated were calcium, cerium, lead, magnesium, niobium, thorium, tungsten, and uranium, which oxidize at a linear rate, and cobalt and copper which oxidize at a parabolic rate. Two distinct experimental techniques were used to investigate each of the oxide products: the specific surface was measured by the method of krypton sorption (5) at −195°C and the density (6) by immersion in mercury and in carbon tetrachloride, respectively.

Experimental

Each oxide was prepared by oxidizing the metal in dry oxygen at atmospheric pressure in a glass or silica reaction chamber on a thermal balance. The experimental arrangement was the same as that previously described (4) except that the oxygen was further dried by passing it through a column packed with Linde molecular sieves (7).

The percentage purity of the metals was: Ca, >99.4; Ce, >99.99; Co, 99.999; Cu, 99.999; Pb, 99.998; Mg, 99.95; Nb, >99.8; Th, >99.6; W, >99.95; and U, >99.9. Except for calcium, cerium, and lead, the metals were in the form of sheet, 1/32 in. thick for niobium and tungsten and 1/16 in. thick for the others; a sample in the form of a rectangle (4 x 1.5 cm) was cut from the sheet and abraded down to Grade 00 emery under petroleum ether and finally degreased in benzene vapor. The tungsten had to be hot-sheared (8) and the copper after abrasion was etched (9) in a 2.5% aqueous solution of ammonium persulfate for 15 min, washed with water followed by acetone, and finally dried. The calcium was oxidized in the form of a slice, 5 mm thick which was cut from the 1 in. diameter extruded rod; the surface treatment was filing on a "middle cut" file. Lead was oxidized in the molten state in an alumina crucible and cerium in the form of a single lump without surface preparation.

The temperatures of oxidation (Table I) were chosen so as to produce sufficient oxide within a reasonable period of time. The samples of cerium, cobalt, copper, niobium, and tungsten were oxidized to completion, while those of calcium, magnesium, and thorium were only partially oxidized since their oxides spalled from the respective metals on cooling. The oxides of uranium and lead were chipped and scraped from the cooled, oxidized samples.

The apparatus for measurement of krypton sorption (5) at −195°C was designed for the determination of an absolute area of about 1 m^2 of solid with a precision of about ±1%. The use of this quantity of material presented no difficulty with most of the oxides but, as will be seen, there were three whose specific surface was so small that a weight of solid equivalent to 1 m^2 could not be accommodated in the apparatus.

Special experimental techniques (6) were developed for the measurement of the density of the oxide by immersion in mercury and in carbon tetrachloride, respectively, in order to deal with the small amounts of oxide which were available. Briefly, the oxide, contained in a special density bottle, was first outgassed at 110°C to a pressure of 10^{-4} mm Hg and the

bottle then filled with liquid while still in the vacuum system. A quantity of solid equivalent to about 0.3 cm^3 was used for most of the measurements, and both the reproducibility and the absolute accuracy of the method were tested with Iceland spar. With 0.3 cm^3 of solid the density was reproducible to ±0.1% in mercury and to ±0.3% in carbon tetrachloride, and the absolute values agreed with the literature value (10) within these limits.

Results

Kinetic measurements.—The kinetic measurements were of course only ancillary to the main study and the results are described only briefly.

The oxidation curves (of weight gain against time) of magnesium (4) and calcium (11) were the same as those found in earlier work; the former was oxidized for a period such that only the white oxide scale was formed. The cerium was in the form of a single lump of irregular shape so that its oxidation curve could not be classified with certainty; the rate of oxidation at first decreased with time, then reached a constant value [cf. (12) and (13)], but subsequently increased possibly because of self-heating of the metal.

Thorium (Fig. 1) gave a complicated curve consisting of four branches, OA, AB, BC, and CD, over which, respectively, the rate of oxidation decreased, increased, was constant, and decreased; beyond D the rate of oxidation became constant again. Examination of a separate sample which had been oxidized for a shorter period indicated that, as with magnesium, the oxide scale gradually extended laterally over the sample surface. Levesque and Cubicciotti (14), in an experiment covering a much shorter period, found an increase in rate corresponding to branch AB, but the actual weight gains and times were different from those in the present work. The sharp rise in oxidation rate at A probably corresponds to a breakdown of the continuous oxide layer in local regions thus marking the beginning of lateral growth.

Niobium almost from the start of the experiment oxidized at a constant rate of 4.2 mg cm^{-2} hr^{-1} [Baur, Bridges, and Fassell (15) found 6 mg cm^{-2} hr^{-1}] and a breakaway reaction occurred after about 14 hr oxidation. The oxide consisted of a fairly brittle scale together with some powdered oxide, only the former being used for the physical measurements.

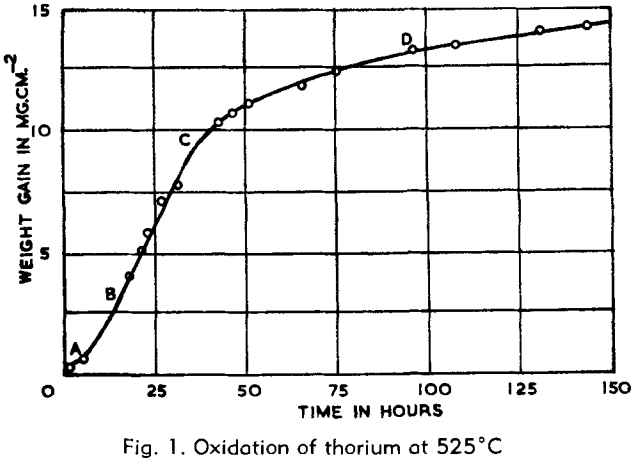

Fig. 1. Oxidation of thorium at 525°C

With tungsten, the rate of oxidation decreased in the very early stages but became constant after about 1 hr, the linear rate of 10.6 mg cm^{-2} hr^{-1} agreeing with the value of 11.5 mg cm^{-2} hr^{-1} found by Webb, Norton, and Wagner (16). The rate of oxidation fell below the linear rate after about 5 hr; the weight gain after this time corresponded to 30% conversion of the metal, and since there was no preferred oxidation at the edges of the sample (8) it is unlikely that the decrease in geometric area is the sole cause.

The rate of oxidation of uranium decreased with time, becoming constant after about 90 hr at 0.8 mg cm^{-2} hr^{-1} [Loriers (17) found 1.0 mg cm^{-2} hr^{-1}]. The oxidation of uranium is complicated by the fact that several oxides probably are involved, perhaps uranium dioxide being first formed and then itself oxidizing (18); at the end of the run the weight gain was in excess of that required for complete conversion to uranium dioxide and yet some metal remained unoxidized. With lead, the rate of oxidation became constant after about 80 hr.

Copper was found to oxidize according to a parabolic rate law ($w^2 = k_p t$), the value of k_p, viz., 238 mg^2 cm^{-4} hr^{-1}, being in good agreement with that calculated from literature data (9) for lower oxygen pressures. The temperature and oxygen pressure were such that both CuO and Cu_2O are stable (19) and the presence of some CuO in the oxide product was confirmed by the fact that the final weight gain

[a] The oxides are classified into Groups A and B according to whether they were formed at a linear or a parabolic rate.
[b] T = temperature of formation, S = specific surface, ρ_m and ρ_o are the densities in mercury and in carbon tetrachloride, respectively, and ρ_o is the theoretical density calculated from the data of Wyckoff (21) unless otherwise stated.
[c] n.d. = not determined because of insufficient material.
[d] This value is significantly greater than the theoretical density. A second determination gave the same result.
[e] Quoted by Gulbransen and Andrew (22).
[f] Calculated from the data of Anderson (23).

was in excess of that required for complete conversion of the metal to Cu_2O; similarly with cobalt, two oxides, CoO and Co_3O_4, are stable (20) under the conditions of the reaction; this may account for the time dependence of k_p which increased from 45 mg^2 cm^{-4} hr^{-1} after 3.5 hr to 49 mg^2 cm^{-4} hr^{-1} after 90 hr oxidation.

Specific surface and density.—The values of the specific surface and of the density in mercury and in carbon tetrachloride are summarized in Table I. The density of each oxide has been calculated on the assumption that the density of the bulk liquid is unchanged at the solid-liquid interface: any error from this source is probably negligible.

With magnesium oxide and niobium pentoxide, it was noticed that the mercury only penetrated the oxide face which had been nearest to the metal. The other oxides did not appear to be penetrated at all by mercury.

Discussion

Group A Oxides

As seen in Table I, the measured specific surface S of the oxides exceeds the geometric surface by several orders of magnitude: the oxides possess an "internal surface" which is made up of the walls of numerous cracks and pores which permeate the solid. A crude but nevertheless useful measure of the degree of dispersion of the oxide is obtained by considering it to be made up of equal-sized cubelets of edge-length l. By simple geometry:

$$l = 6/S\rho_o$$

where ρ_o is the theoretical density of the oxide calculated from the x-ray lattice spacing. The measured surface area then comprises the faces of these cubelets which are accessible to krypton molecules, in other words there are gaps at least two molecules wide between the faces of neighboring cubes: the oxide scale is thus porous to krypton molecules and therefore to oxygen molecules [collision diameters (25): Kr, 4.16Å; O_2, 3.61Å]. The numerical values of l (Table II) cover a wide range, from 3 x 10^2Å for magnesium oxide to 9 x 10^3Å for tungstic oxide.

Somewhat more direct evidence as to the porosity is provided by the data for the density of the oxide in carbon tetrachloride (ρ_c) and in mercury (ρ_m). The difference between $1/\rho_o$ and $1/\rho_c$ or $1/\rho_m$ represents the volume, per gram of oxide, of those pores which are inaccessible to carbon tetrachloride or to mercury, respectively; the volumes of void ϵ_c and ϵ_m, expressed as a fraction of the total volume of the oxide, are thus given by:

$$\epsilon_c = 1 - \frac{\rho_c}{\rho_o}, \qquad \epsilon_m = 1 - \frac{\rho_m}{\rho_o} \qquad [1]$$

Since mercury at 1 atm pressure cannot enter pores of diameter less than about 10^5Å (26) while carbon tetrachloride can penetrate all pores with diameters in excess of about 5Å, ϵ_m and ϵ_c are made up of all the pores finer than 10^5Å and 5Å, respectively. Both values, of course, include those pores which are totally sealed off.

Table II. Calculated void fractions and cube and pore sizes of the Group A oxides

Oxide	α[a]	ϵ_c	ϵ_m	l, Å	δ, Å[b]
CaO	0.28	0.042	0.34	3000	880
CeO_2	0.20	—	0.28	320	73
PbO_2	—	—	—	3020	—
MgO	0.27	0.079	0.73	300	330

ThO_2	<0.26	—	0.36	960	310
WO_3	0.62	0.02	0.21	8900	150
UO_2 ?	0.21	(0.149)	(0.263)	(840)	180

[a] Values calculated from the melting points listed in (24).
[b] Calculated from Eq. [2] using ρ_o for ρ.

The values of ϵ_m (Table II) are all relatively large, varying from 0.15 for niobium pentoxide to 0.73 for magnesium oxide, a figure which implies that almost three-quarters of the oxide scale is composed of void. Values of ϵ_c are, as might be expected, considerably smaller and they vary over a narrower range.

The ϵ_m-value of 0.34 for calcium oxide agrees surprisingly well with the 34% porosity which was estimated by Pilling and Bedworth (27) from geometric measurements of the completely oxidized sample. The ϵ_m-value of 0.21 for tungstic oxide is significantly less than the figure of 30% for the porosity quoted by Webb, Norton, and Wagner (16); it is not clear, however, whether their solid had been outgassed.

The data all refer to the oxide scale after it has been cooled down from reaction temperature, but it is reasonable to assume that the state of subdivision of the scale at the temperature of the reaction is not markedly different. It must also be borne in mind that the scale tends to sinter after it has been formed. Such sintering, which would manifest itself in a reduction in specific surface and an increase in density, must come about as a result of either plastic (or viscous) flow or of transport of material through the crystallite by diffusion. Both processes are known to be greatly accelerated at temperatures above a critical value T_c, characteristic of the solid but lying within the range 0.37 T_f to 0.53 T_f where T_f is the mp of the oxide (28). (T_c often is termed the Tammann temperature and sometimes is defined as $T_c = 0.5\ T_f$.) The quantity $\alpha = T/T_f$, where T is the oxidation temperature, is given in Table II for each oxide: that tungstic oxide has the lowest specific surface and with it, the largest crystallite size of all the oxides in Group A, correlates in an interesting way with the fact that its α-value is the highest of the series and well above the Tammann range. It is also satisfactory that the values $\epsilon_c = 0$ and $\epsilon_c = 0.02$ for niobium and tungstic oxides, respectively, are in agreement with their relatively high α-values of 0.43 and 0.62, although it is perhaps surprising that all the fine pores in niobium pentoxide have apparently been eliminated. It is well known that in sintered oxides the measured density does not in general reach the true density unless the oxide is heated for very long periods near its melting point; indeed, sealed-off pores have been

seen with the electron microscope (29). Reference to Table I shows that for niobium pentoxide ρ_c was significantly greater than ρ_o, and it is possible that this oxide was not the exclusive reaction product (22, 30).

Yet another way of expressing the porosity of the oxide scale is to calculate the mean linear separation δ of the cubic blocks of our crude model; we have

$$\delta = 2l\left\{\left(\frac{\rho}{\rho_m}\right)^{1/3} - 1\right\} \qquad [2]$$

here ρ is within the range ρ_o and ρ_c, its exact value being dependent on the relative volumes of sealed and open pores making up the void fraction ϵ_c. Since the oxide scale contains a variety of pores of widely differing shapes and sizes, the numerical values of δ (Table II) can represent no more than the order of magnitude of the gaps within the oxide layer; but they clearly demonstrate the presence of pores sufficiently wide to permit the free passage of gaseous oxygen. A simple calculation, assuming Poiseuille flow, shows indeed that the pores could permit a flow of gas at a rate greater by many orders of magnitude than that actually required by the consumption of oxygen in the reaction.

Group B Oxides

The specific surface of the copper and the cobalt oxides was extremely small, being within the limits of the apparatus and probably representing little more than the geometric surface of the sample.

Conclusions

The findings of the present paper correlate in a satisfactory manner with inferences extant in the literature of metal oxidation as to the porosity of the oxide scale.

Thus the oxides formed during the linear oxidation of calcium, cerium, lead, magnesium, niobium, thorium, tungsten, and uranium are shown to be porous to molecular oxygen which therefore can diffuse freely through the oxide scale; the rate of oxidation probably is controlled by the diffusion, either of metal ions or of oxygen anions, through a thin barrier film of oxide (nonporous to gaseous oxygen) which remains adherent to the metal and whose thickness remains effectively constant.

For parabolic oxidation it generally is accepted that the rate determining step is the diffusion either of interstitial ions or of cation vacancies across the oxide layer which by implication is non-porous to oxygen gas. The present results provide evidence as to this lack of porosity with the oxide layer on copper and on cobalt.

Galvanic Relationships between Aluminum Alloys and Magnesium Alloys

I. Galvanic Couples

M. R. Bothwell

Metallurgical Laboratory, The Dow Metal Products Company, Midland, Michigan

ABSTRACT

High-purity aluminum has nearly perfect galvanic compatibility with magnesium AZ31B alloy during saline exposure. This compatibility is little changed by additions to the aluminum of magnesium, silicon, or manganese, but it is rapidly and proportionately decreased by the addition of iron, copper, and nickel, and more gradually decreased by the addition of zinc. The addition of magnesium to the alloy or magnesium ion to the environment can greatly suppress the effect of the above deleterious constituents.

Their active potentials and lack of appreciable anodic polarization make magnesium alloys susceptible to galvanic effects during exposure to salt-laden environments. The suppression of these effects by the removal or metallurgical complexing of low hydrogen overvoltage constituents in magnesium alloys is one of the classic examples of the application of local-cell theory to a corrosion problem (1). Due to these operations the commercial magnesium alloys are generally serviceable in salt-laden atmospheres when they are painted with moderate care. However, when these alloys are incorporated in structures with other metals it is frequently not the inherent corrosion resistance of the magnesium alloy which determines the protective system needed, but rather the galvanic characteristics of the macro cells set up between the magnesium alloy and the other metals or alloys in the structure.

Galvanic relationships between magnesium alloys and aluminum alloys are extremely important since the two metals are combined so frequently in light metal structures. Even when the structure is dominantly magnesium, it will often be fastened together by aluminum rivets, for magnesium alloys generally lack the room-temperature plasticity necessary in the cold-driving rivet. Over the years it has been discovered that there is a tremendous range in the galvanic effect of the commercial aluminum alloys on magnesium alloys. Thus, the magnesium-rich aluminum alloys such as 5056 are generally quite compatible with magnesium alloys, whereas the copper-rich aluminum alloys such as 2024 alloy are generally poorly compatible. It is the purpose of this paper to demonstrate some of the principles which determine the compatibility of aluminum alloys toward magnesium alloys and to illustrate how these principles can be used in corrosion control.

Experimental

The cathodic polarization curves for the aluminum materials in Fig. 1 were obtained with an automatically regulated, linear current sweep rate of 30 min from nil to full current and 30 min full to no current. Each aluminum cathode consisted of a 3/8 in. diameter cylinder mounted as a section in a Bakelite holder of the same diameter and located at the axis of a magnesium AZ31B alloy hollow cylinder which was used as the anode. Potentials were recorded in respect to a Beckman Model 1170 saturated calomel electrode which was located in a Luggin capillary salt bridge filled with the corrodent solution. Potentials were recorded by a modified Brown recording potentiometer operating with its chart drive in synchronization with the current sweep. The one aluminum cathode consisted of commercial 2S aluminum rod which contained 0.47% Fe, 0.23% Si, and 0.087% Cu as determined by chemical analysis. The 99.99% purity electrode in these studies was machined from ingot containing 40 ppm respectively of Fe and Cu, 10 ppm Si, and 4 ppm Ni as determined by chemical analysis.

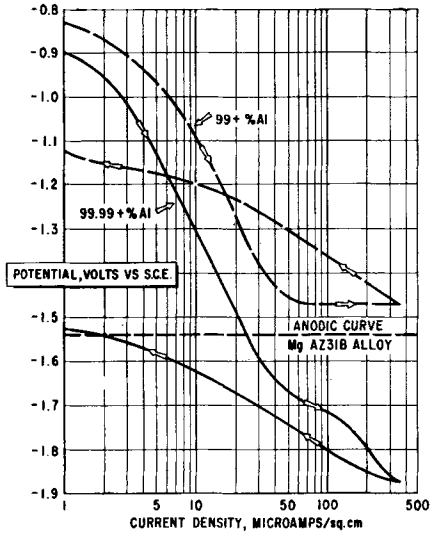

Fig. 1. Cathodic polarization of two grades of aluminum in 3% NaCl solution saturated with air and with $Mg(OH)_2$.

Except where a different base material is indicated, experimental aluminum alloys were prepared

starting with 99.99% purity Al from the same lot mentioned above or from another lot certified by the manufacturer to contain 10 ppm Cu, 20 ppm Fe, 10 ppm Mg, and <10 ppm of any other anticipated impurity. The 99.9% Al contained 300 ppm Fe, 270 ppm Si, 30 ppm Cu, and <100 ppm of any other anticipated constituent. Magnesium was alloyed directly from doubly sublimed material containing 5 ppm Fe. The zinc was also alloyed directly starting with 99.99% purity ingot. The copper, manganese, iron, and silicon bearing alloys were all prepared from master alloys based on 99.99% purity Al and respectively high conductivity, electrolytic copper, electrolytic manganese, high-purity alcoholized iron powder, and silicon of undefined quality. The basic alloying procedure was as follows: pure aluminum was melted in a spectroscopic-grade graphite crucible and heated to 1400°F, after which the alloying constituents were added and stirred in vigorously. This melt was heated to 1500°F for 30 min and then cooled to 1400°F before pouring into spectroscopic-grade graphite molds. Immediately after solidification each casting was water quenched.

Each melt produced two castings, a 1 x 4 x 4 in. miniature rolling slab and a disk specimen for spectroscopic analysis. After its surfaces were removed by grinding on Aloxite cloth, the rolling slab was reduced to sheet of 0.020 in. thickness on carefully cleaned and well-lubricated rolls at 300°F following the schedule, 25% reduction per pass with 15 min reheats at 700°F between passes.

The disk castings of all alloys were subjected to spectroscopic analysis. This was supplemented by chemical analysis in selected cases. Except where the level of an element is specified in the results, analysis has shown it to be negligibly different from the level in the aluminum base stock.

The galvanic corrosion specimens consisted of 2 pieces of the aluminum alloy sheet in the form of squares, ½ in. on the side, which were centrally mounted on the opposite sides of 1½ x 1½ in. squares of commercial, magnesium AZ31B alloy.[1] These specimens were held together by ⅛ in. diameter rivets of a high-purity aluminum-2% magnesium alloy. Prior to assembly the aluminum pieces were ground with fine Aloxite cloth to remove possible cathodic contamination introduced during the rolling, drilling, and shearing operations. The magnesium AZ31B alloy coupons were pickled to a depth of 1 mil per side in a solution of 25½ fluid oz of glacial acetic acid and 6 2/3 oz sodium nitrate per gal of aqueous solution. Following pickling and water rinsing, these magnesium alloy coupons were dried and weighed.

Following the exposure, the test pieces were disassembled and the magnesium alloy coupons were rinsed with gentle scrubbing under tap water. The corrosion product was then removed by immersion for 2 min in a solution of 20% chromic acid plus 1% silver nitrate at 180°F. Following this the specimens were rinsed in tap water, dried, and reweighed to obtain the weight loss due to corrosion. Since tests showed that this method caused <0.5 mg weight change on specimens not previously corroded, no correction for cleaning error was made. All test exposures were made by suspending each specimen in approximately 200 ml of the corrodent concerned. The test temperature was 95° ±2°F. The time of exposure was generally 1 week. However, this period had to be curtailed for those couples with which the galvanic effect was excessively large. The mean deviation for triplicate tests was generally <10% of the average rate and at no time did it exceed 20% of the average rate.

[1] The nominal composition of AZ31B alloy is Mg-3% Al-1% Zn-0.4% Mn.

Results and Discussion

The peculiarity of the pure aluminum cathode in respect to its extremely low limiting current for depolarization by dissolved oxygen has been pointed out by Pryor and Keir (2). It will be seen shortly that their hypothesis of impurity-rich sites as the effective cathodes in the aluminum macro cathode agrees with the data presented here. In fact, it was observation of this same phenomenon in the cathodic polarization of commercial aluminum alloys and a similar analysis of its implications which led to the work to be described here. Hansen and Wetmore (3) arrived at a similar conclusion when they noted that super purity aluminum has a much higher hydrogen overvoltage in acids than does commercial-purity aluminum.

In Fig. 1 can be seen the cathodic polarization curves of 99.99+% purity aluminum and commercially pure aluminum while exposed to 3% NaCl solution saturated with magnesium hydroxide and air. The dotted line represents the potential of magnesium AZ31B alloy which is without significant anodic polarization in this environment. It can be seen that the high-purity aluminum cathode polarizes so readily that it should cause very little galvanic attack to the magnesium alloy, whereas rather severe attack can be expected when the latter is coupled to commercially pure aluminum.

Because of the pronounced hysteresis in the cathodic polarization curves for aluminum and its alloys, the analysis of polarization data was abandoned in favor of measurements on the couples themselves. The configuration of the test couple chosen was felt to meet the following desiderata: (*a*) was easily prepared, (*b*) generally prevented electrolyte entry at faying surfaces, (*c*) invariably maintained contact, (*d*) was sensitive to cathode effects, and (*e*) introduced no significant third electrode effect.

Complete immersion of the test specimen was used rather than the more conventional alternate immersion or salt spray testing in order to utilize more effectively the available cathode and thus make the test more sensitive. While complete immersion testing was believed satisfactory here, since oxygen reduction is relatively unimportant in couples between magnesium alloys and aluminum alloys, such is generally not the case when magnesium alloys are coupled with other metals.

Iron is rarely a deliberate constituent in the commercial aluminum alloys but it is usually present in them to the extent of a few thousand ppm as a major

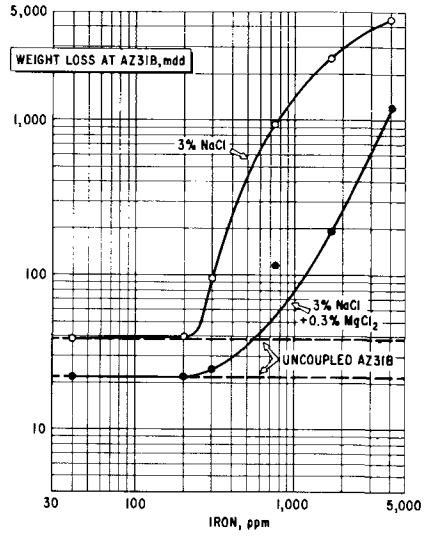

Fig. 2. Effect of iron in aluminum on the corrosion of AZ31B alloy coupled thereto.

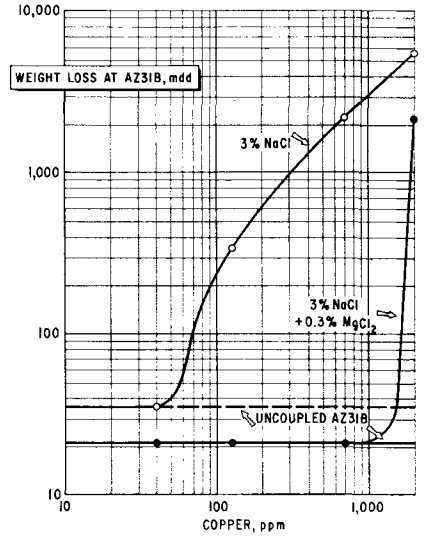

Fig. 3. Effect of copper in aluminum on the corrosion of AZ31B alloy coupled thereto.

impurity. In Fig. 2 it is seen that iron in the aluminum alloy can have a very adverse effect on its compatibility with magnesium AZ31B alloy. Up until the time that the iron content does not exceed 200 ppm, in this particular couple configuration, the iron is without appreciable galvanic effect, but as this level is exceeded, galvanic attack of the magnesium alloy increases rapidly. The addition of 0.3% magnesium chloride to the 3% sodium chloride solution was made to reproduce effects observed in natural seawater. The justification for this will be shown in Part II of this paper (4). Although this addition does not greatly change the iron level at which galvanic attack of the magnesium alloy becomes appreciable, it does greatly reduce such attack once the critical iron level is exceeded.

The results in Fig. 3 are in accord with past observations on the poor compatibility of copper-rich aluminum alloys with magnesium alloys. In the 3% NaCl environment, copper can have a deleterious effect at even lower levels than was seen in the case of iron in the previous figure. However, if 0.3% $MgCl_2$ is added to the environment, copper does not have a significant deleterious effect until it exceeds 1000 ppm.

Table I. Effect of various constituents on the galvanic compatibility of Al toward AZ31B alloy

	Weight loss at AZ31B, mdd	
	3% NaCl	3% NaCl + 0.3% $MgCl_2$
99.9+% Al (unalloyed)	94	24
+ 0.16% Zn	400	59
+ 0.27% Si (0.041% Fe)	78	33
99.99+% Al (unalloyed)	36	22
+ 0.015% Ni	127	
+ 0.30% Mn	34	23
Uncoupled control	38	23

In Table I it can be seen that nickel at low levels has a deleterious effect that is of the same order as that of iron and copper. The effect of nickel has been less extensively studied here because it is not of great importance in aluminum alloys either as a major impurity or a common alloying constituent. Zinc also has a deleterious effect, but it is much milder than that of iron, copper, and nickel. Furthermore, the effect of zinc is very effectively suppressed by the addition of magnesium chloride to the environment. Silicon and manganese have little effect even at moderate levels. Next to iron, silicon is the most prevalent impurity in commercial-purity aluminum and its alloys. Silicon is also an extremely important deliberate constituent in many aluminum alloys as are zinc and manganese as well. Since silicon is innocuous, the marked difference in the cathodic polarization behavior of the two purity grades of aluminum shown in Fig. 1 can be attributed primarily to the iron content of the less pure grade. This is substantiated by couple tests where it is found that the weight loss occasioned by the latter metal is nearly equal to that produced by a high-purity aluminum-iron binary alloy of the same iron content.

Figures 4, 5, and 6 illustrate the basis for the good performance in service of the magnesium-rich alu-

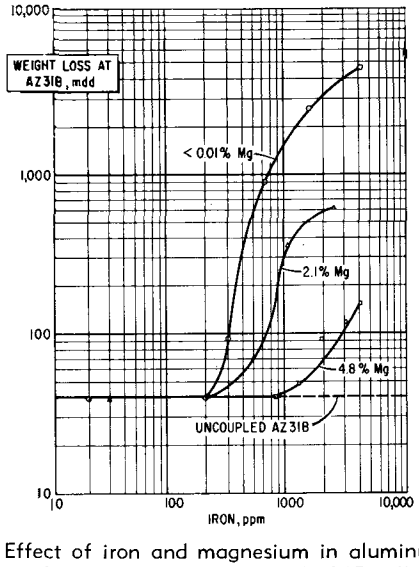

Fig. 4. Effect of iron and magnesium in aluminum on the corrosion in 3% NaCl solution of AZ31B alloy coupled thereto.

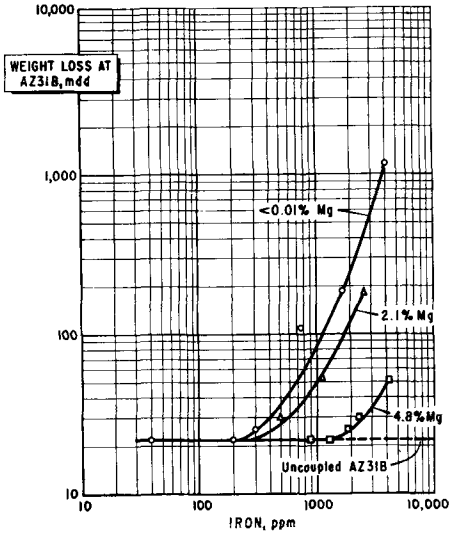

Fig. 5. Effect of iron and magnesium in aluminum on the corrosion in 3% NaCl plus 0.3% $MgCl_2$ solution of AZ31B alloy coupled thereto.

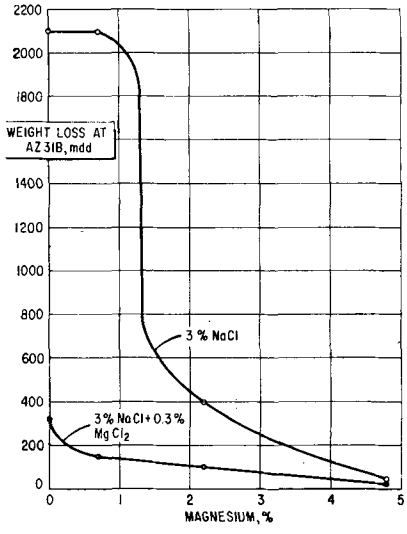

Fig. 6. Effect of magnesium in aluminum plus 0.13% iron on the corrosion of AZ31B alloy coupled thereto.

minum alloys in structures with magnesium alloys. It can be seen that the addition of magnesium to the aluminum alloy greatly improves its tolerance for iron. For example, aluminum 5056 alloy, which has long been used as the standard rivet material for magnesium alloy structures, has a nominal composition of aluminum-5.2% Mg-0.1% Mn-0.1% Cr. Its maximum permissible iron content is 0.4%, but in practice, it will generally be about one-half of this value. The results here indicate that 5.2% Mg should largely suppress the effect of 0.2% Fe and thus 5056 alloy should be a highly compatible material. This conclusion is substantiated by several years of trouble-free service with 5056 alloy rivets in AZ31B alloy structures.

In Table II it can be seen that magnesium can suppress the deleterious effects of copper and of iron and copper in combination. It is also extremely effective in suppressing the mildly deleterious effect of zinc that is observed in couple tests in 3% NaCl solution.

Table II. Suppression by alloyed Mg of the deleterious effects of Cu, Ni, and Zn on the galvanic compatibility of Al toward AZ31B alloy. (Al alloys containing Zn here were coupled with a different lot of AZ31B alloy from that used in remainder of study. Furthermore, duration of exposure to 3% NaCl was only one day.)

	Weight loss at AZ31B, mdd	
	3% NaCl	3% NaCl + 0.3% $MgCl_2$
Suppression of Cu effect		
Al + 0.013% Cu	332	24
Al + 0.014% Cu + 0.36% Mg	40	22
Al + 0.089% Fe + 0.018% Cu + 4.8% Mg	40	24
Al ± 0.078% Fe + 0.74% Cu	>4000	>2000
Al ± 0.078% Fe + 0.74% Cu + 4.5% Mg	81	35
Suppression of Ni effect		
Al + 0.015% Ni	127	
Al + 0.056 ± Ni + 4.8% Mg	46	
Suppression of Zn effect		
Al + 3.6% Zn + 0.05% Fe	3630	43
Al + 4.8% Zn + 0.05% Fe + 3.4% Mg	266	45
Uncoupled control	150	48

On the basis of these results, it can be seen that there is much freedom within which to design aluminum alloys which will have both satisfactory mechanical properties and excellent galvanic compatibility with magnesium alloys. The work hardening aluminum-magnesium alloys and the age hardening aluminum-magnesium-silicon and aluminum-magnesium-zinc alloys are the best prospects to meet these requirements. Contingent upon the magnesium content of the alloy, it may be necessary to reduce its iron content from the levels prevalent in the commercial purity materials.

An example of the effect of iron content on the compatibility of a commercial aluminum alloy is shown in Fig. 7. 6061 alloy is a moderately strong, age-hardening alloy with the nominal composition of aluminum-1.0% Mg-0.6% Si-0.25% Cu-0.25% Cr. The maximum permissible iron content for this alloy is 0.70% and, in practice, about one-half this amount is the general expectation. It can be seen here that this alloy cannot be made completely compatible with AZ31B alloy during exposure to 3% NaCl solu-

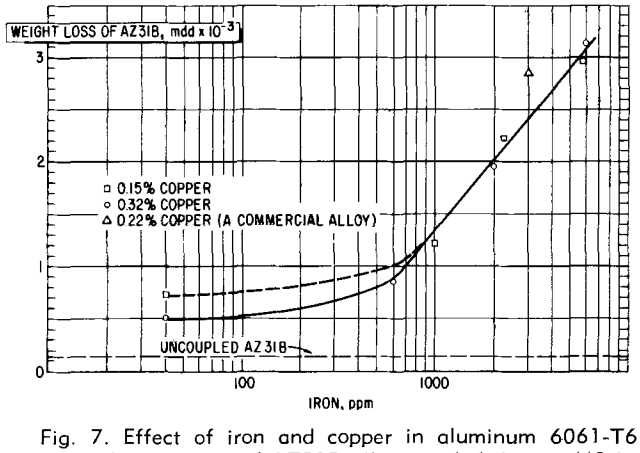

Fig. 7. Effect of iron and copper in aluminum 6061-T6 alloy on the corrosion of AZ31B alloy coupled thereto (48 hr immersion in 3% NaCl).

Table III. Compatibility of 6061-T6 alloy with AZ31B alloy during exposure to substitute ocean water per ASTM designation D-1141-52

	Weight loss at AZ31B, mdd
Commercial 6061-T6 (0.30% Fe, 0.22% Cu)	43
Experimental 6061-T6 (0.005% Fe, 0.15% Cu)	31
Experimental 6061-T6 (0.005% Fe, 0.32% Cu)	33
Uncoupled control	32

tion because the ratio of copper to magnesium is too high. Nevertheless, a decrease in the iron content from the usual levels of the commercial alloys can do much to improve the compatibility. In contrast to the results in 3% NaCl solution, even commercial purity 6061 alloy is highly compatible with AZ31B alloy during exposure to substitute ocean water (see Table III).

It is interesting to note that the constituents which have the greatest deleterious effect on the compatibility of the aluminum alloys with AZ31B alloy are iron, copper, and nickel. Since these are metals with rather low hydrogen overvoltages, it is reasonable to assume that the effective cathodes in an aluminum macro-cathode are regions rich in elements displaying substantially their bulk hydrogen overvoltage characteristics rather than areas in which elements have become incorporated in the film to make it semiconductive as Pryor and Keir have suggested for the case of extremely pure aluminum.

Magnesium constituent in the alloy may suppress the deleterious effect of the above constituents by increasing the resistance of the aluminum alloy to attack by cathodically generated alkali and thereby decreasing their rate of exposure. Since the pH should decrease as the distance from the low overvoltage phase is increased, it is reasonable to expect that enhancement in the alkali resistance of the matrix phase will favor a sharper gradient of cathodic attack and thus favor a higher ratio of impurity undercutting to impurity exposure. This view gains some support from the observation that, at the same deleterious impurity level, the addition of magnesium to the aluminum decreases its cathodic attack as well as the anodic attack of the AZ31B alloy coupled to it. However, this result is not readily resolved in terms of cause and effect. Efforts to confirm this mechanism through a cursory study of the metallography of cathodic attack have been unsuccessful.

Summary

High-purity aluminum causes substantially no galvanic corrosion to magnesium AZ31B alloy during exposure to 3% NaCl solution. The addition of increasing amounts of iron, copper, and nickel to the aluminum results in a rapid loss in compatibility whereas the addition of zinc causes more moderate loss at comparable levels. The addition of magnesium, silicon, and manganese is without noticeable deleterious effect. When magnesium is present in the alloy the deleterious effects of iron, copper, nickel, and zinc are greatly suppressed. The effects of these same deleterious constituents are also suppressed when a small amount of magnesium chloride is added to the corrosion environment. These results are consistent with the view that at the potential of magnesium AZ31B alloy, the bulk of the surface of an aluminum macro-cathode is galvanically inert while the effective cathodes are areas rich in low overvoltage constituents. The beneficial effect of magnesium in the alloy is probably related to its ability to suppress the accumulation of low overvoltage impurities at the alloy's surface.

Galvanic Relationships between Aluminum Alloys and Magnesium Alloys

II. Aluminum Claddings on Magnesium

M. R. Bothwell

Metallurgical Laboratory, The Dow Metal Products Company, Midland, Michigan

ABSTRACT

The cladding of magnesium AZ31A alloy with 99.99% aluminum greatly improves its resistance to saline environments. The protective ability of the cladding is little changed by incorporation therein of magnesium, silicon, or manganese, but it is impaired greatly by iron and copper and more mildly by zinc. The presence in seawater of soluble magnesium salts greatly diminishes the effects of iron, copper, and zinc from that seen in sodium chloride solution. This decrease is probably due to decreased cathodic attack of the aluminum at the lower equilibrium pH of the seawater environment.

While magnesium alloys generally withstand mild weathering very well without recourse to any protection beyond that of their naturally formed film, such weathering is accompanied by the gradual formation of a gray patina which is objectionable in some applications. Furthermore, it would be desirable for some applications to have magnesium sheet which could withstand moderately severe salt exposure when unpainted. Early experimental claddings of aluminum alloys on magnesium alloys showed a substantial improvement in the maintenance of a reflective surface during weathering, but unfortunately, rather than affording any protection to the magnesium alloy during salt exposure, they greatly accelerated corrosion due to strong galvanic effects. The experimental claddings described here were prompted by the recognition that extremely pure aluminum combines its well-known excellent resistance to corrosion in saline environments with remarkable galvanic inertness toward magnesium alloys.

Experimental

The aluminum alloys used here were prepared in the same manner as those in Part I of this paper (1). The aluminum base stocks used were 99.99% purity Al containing 40 ppm Fe, 40 ppm Cu, 4 ppm Ni, 10 ppm Si, and <10 ppm of any other anticipated constituent, and 99.9% purity Al containing 300 ppm Fe, 270 ppm Si, 30 ppm Cu, and <100 ppm of any other anticipated constituent.

Aluminum alloy sheet of 0.020 in. thickness was wire-brushed and then wrapped around 0.250 in. thick, magnesium AZ31A alloy[1] plate. This composite was rolled to 0.040 in. total thickness on clean, well-lubricated rolls according to the schedule described in Part I (1). The resulting thickness of the cladding was slightly over 0.003 in. per side.

These clad composites were cut into 1½ by 2½ in. coupons which were given a 1 min pickle in cold, 10% sodium hydroxide solution. After drying and weighing, they were subjected to alternate immersion testing at 95° ± 2°F in approximately 200 ml of the environments concerned by the method described by Hanawalt, *et al.* (2). Following the exposure, the samples were cleaned for 4 min in the chromic acid cleaning solution mentioned in Part I of this paper (1). Since it was found that individual coupons not previously corroded lost less than 1 mg during this cleaning, no correction for cleaning loss was made. Fortunately this cleaning process is sufficient to remove the corrosion product from all but the most severely corroded specimens, and thus the chromic acid-phosphoric acid baths that are used customarily to remove corrosion product from aluminum corrosion specimens, but which would attack the magnesium alloy wherever exposed, were not necessary.

The mean deviation for quintuplicate tests was generally <10% of the average rate and only rarely exceeded 20% of the average rate.

Results and Discussion

The clad coupons of this study can be considered as galvanic couples with an unusually high ratio of cathode area to anode area, e.g., approximately thirty to one when first exposed. In addition to the anodic attack of the core at the exposed edges, the cathodic attack of the cladding and the exposure of additional core metal thereby must be considered. Experience with galvanic couples shows that the cathodic attack of the aluminum alloy is almost as severe as the anodic attack of the magnesium alloy. Thus, it may be surmised that the aluminum cladding must polarize to the potential of the core with extraordinary ease if the composite is to have useful resistance to saline exposure.

In Fig. 1, it can be seen that a cladding of 99.99% purity Al meets this requirement very well, whereas a cladding of commercial purity aluminum is much worse than no cladding at all. At the edges of the

[1] The nominal composition of AZ31A alloy is Mg-3% Al-1% Zn-0.4% Mn-0.15% Ca.

Fig. 1. Bare, 99% Al clad, and 99.99% Al clad AZ31A alloy after exposures to 3% sodium chloride. Period of exposure 7, 2, and 25 days, respectively.

coupons with 99.99% Al cladding, the AZ31A core exposed during shearing suffers little more than its open circuit corrosion. On the other hand, even beyond the edge damage apparent in Fig. 1, the cores of the coupons with commercial purity cladding were corroded to an average depth exceeding ⅛ in.

Not surprisingly, clad composites are more sensitive to low overvoltage constituents in aluminum than were the galvanic couples of Part I (1). Indeed from the shapes of the curves in Fig. 2 and 3, it may be surmised that even the 40 ppm Fe and 40 ppm Cu levels of the 99.99% Al are producing a significant harmful effect during exposure to 3% NaCl solution and that this level of iron, but not copper, is producing a significant harmful effect during exposure to seawater. However, if the limiting assumption is made that the exposed core alone suffers attack, the steady state rates of Fig. 4 correspond to core corrosion rates of about 180 mdd for sodium chloride exposure and about 120 mdd for seawater exposure. If these rates are compared to the steady-state rates of unclad core metal in each environment, it is deduced that the elimination of all cladding corrosion and all galvanic effects will only produce about a fivefold reduction in corrosion of the composite in either environment. This suggests that further purification of aluminum will yield comparatively small returns.

In Fig. 2 and 3 it can be seen that iron and copper are less deleterious during seawater exposure than

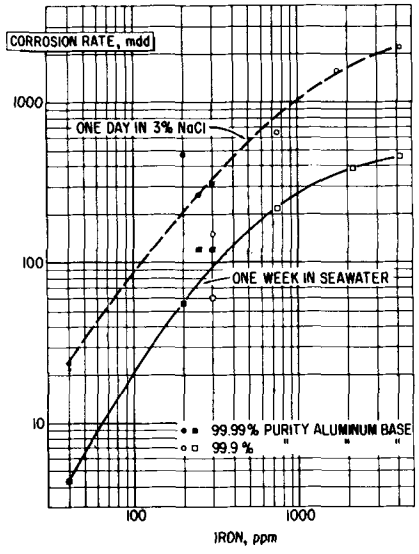

Fig. 2. Effect of iron in cladding on corrosion of Al clad AZ31A alloy sheet.

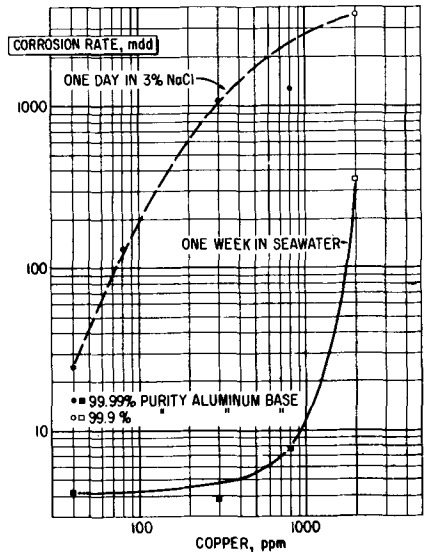

Fig. 3. Effect of copper in cladding on corrosion of Al clad AZ31A alloy sheet.

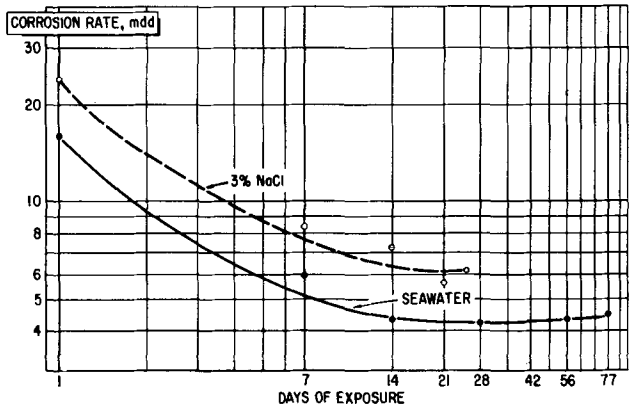

Fig. 4. Decrease in corrosion rate of 99.99+% Al clad AZ31A alloy sheet with time.

they are during exposure to 3% NaCl solution. Although the lesser test time in 3% NaCl solution prevents direct comparison of the environments from these results, there can be little doubt that iron constituent is much less aggressive and copper constituent enormously less aggressive during seawater exposure. Indeed the shorter test time in 3% NaCl was dictated by rapid disintegration of the coupons at the higher iron and copper levels. It is also interesting to note the appearance of a well-defined tolerance for copper in the cladding when exposure is made to seawater.

The effects of some additional cladding constituents are shown in Table I. Zinc is more mildly detrimental than iron and copper during exposure to 3% NaCl solution and, even at very high levels, it has no detrimental effect during seawater exposure. Magnesium, silicon, and manganese are substantially innocuous in either environment.

Difficulties in achieving bonding between magnesium AZ31A alloy cores and aluminum claddings containing large amounts of magnesium prevented a good test of the ability of magnesium constituent to suppress the effects of iron, copper, and zinc here as it did in the galvanic couples of Part I (1). Such an effect is likely in view of the similarity of all other results for the two types of specimens.

Table I. Effect of various constituents on corrosion of Al clad Mg AZ31A alloy sheet

	Corrosion rate, mdd	
	One day—3% NaCl	One week—seawater
99.9% Al	150	60
+0.16% Zn	300	28
+2.05% Zn	800	46
+0.53% Mg	190	86
+1.14% Mg	110	51
+0.10% Si (0.034% Fe)	250	86
+0.10% Si (0.038% Fe)	140	23
+0.27% Si (0.041% Fe)	250	130
+0.58% Si (0.039% Fe)	190	25
+0.05% Mn (0.036% Fe)	340	210
+0.29% Mn (0.042% Fe)	100	110
+0.51% Mn (0.059% Fe)	380	230
99.99% Al	29	4.3
+0.70% Mg	31	4.0
+0.05% Si	30	3.9
+0.30% Mn	69	4.9

The enormous difference in corrosivity between 3% NaCl solution and seawater toward some of the composites is of obvious interest. In Table II are shown the results on the corrosion of a particularly sensitive composite of the addition to 3% NaCl solution of two important seawater constituents, viz., Mg^{++} and $SO_4^{=}$. It can be seen that the addition of 0.3% Na_2SO_4 to the 3% NaCl solution decreases the corrosion of the composite by a small but probably significant amount. When 0.3% $MgCl_2$ is added to the sodium chloride solution, however, the corrosion of the composite is greatly reduced and indeed is nearly the same as the corrosion in seawater. The addition of 0.3% Na_2SO_4 to the above solution of sodium chloride plus $MgCl_2$ appears to have a rather trivial effect.

The difference in corrosivity between sodium chloride solutions and seawater probably depends on the difference in their buffering characteristics as shown in Fig. 5. Because of dissociation of the slightly soluble magnesium hydroxide corrosion product, the sodium chloride solution characteristically buffers at about pH 10.5. However, soluble magnesium salts in the seawater depress the solubility of the magnesium hydroxide and thus cause the system to buffer at a substantially lower pH. The lower bulk pH of the system in turn decreases the attack of the aluminum cladding by cathodically generated alkali. The consequences of this decreased attack of the cladding in order of increasing importance is probably: (a) reduction in the corrosion of the cladding per se, (b) slower exposure of the less resistant core at pits in the cladding, and (c) a smaller accumulation of low overvoltage constituents at the aluminum surface and thus less galvanic attack of the exposed core.

Table II. Effect of constituents in seawater on corrosion of AZ31A clad with 99.99% Al plus 0.08% Cu

Environment	Corrosion rate, mdd Two-day alternate immersion
3% NaCl	1980 ± 100
3% NaCl + 0.3% Na_2SO_4	1320 ± 80
3% NaCl + 0.3% $MgCl_2$	19 ± 1
3% NaCl + 0.3% $MgCl_2$ + 0.3% Na_2SO_4	17 ± 3
Seawater	15 ± 2

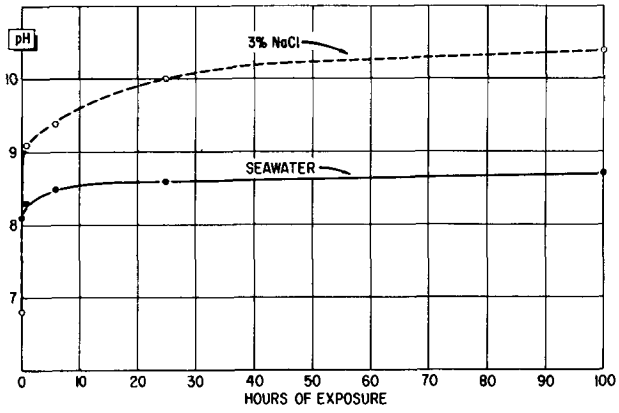

Fig. 5. pH as a function of time during corrosion in 3% NaCl and seawater of AZ31A clad with Al plus 0.08% Cu.

Just as in the case of the addition of magnesium to aluminum in the couples of Part I (1), the reduced galvanic effect from the addition of magnesium ion to the environment probably depends more on the distribution of cathodic attack rather than the total cathodic attack. Thus, a lower bulk pH should produce a sharper decrease in pH as a function of distance from each impurity-rich local cathode, and this should favor a higher ratio of impurity undercutting to impurity exposure.

Summary

High-purity aluminum cladding is extremely effective in protecting magnesium AZ31A alloy during saline exposure. The addition of iron or copper to the aluminum cladding materially impairs this protection by increasing the corrosion of the cladding and by making the cladding more aggressive galvanically toward the magnesium core. Zinc constituent has a milder effect than iron and copper while magnesium, silicon, and manganese are innocuous.

The above deleterious constituents have a much smaller effect during seawater exposure than they have during exposure to 3% NaCl solution because of the presence in seawater of a substantial concentration of magnesium ions which buffer the environment at a lower pH and thereby reduce the corrosion of the cladding by cathodically generated alkali. In addition to prolonging the life of the cladding, this also helps prevent the accumulation of low overvoltage constituents on the cladding surface and thus moderates its galvanic aggressiveness toward the magnesium core.

Electrical Conduction in Liquid Dielectrics under Pulse Conditions

K. A. Macfadyen and G. C. Helliwell

Department of Physics, University of Birmingham, Birmingham, England

ABSTRACT

The need for a method of measuring conduction in pure nonpolar dielectric liquids under pulse conditions is considered, and details of a measurement technique are given. Experiments with hexane show that currents greater than 10^{-6} amp flow with certain electrode conditions, at a field strength of about 200 kv/cm, although the d-c conduction is much lower. A tentative explanation is offered.

Knowledge of the electrical conduction of dielectrics immediately after the application of an electric field is desirable not only as a means of understanding the mechanism of conduction in general but also to throw light on the breakdown process. This paper reports some experiments with a technique for revealing the time variation of conduction current during the first few microseconds after the application of a pulse of voltage between electrodes immersed in highly insulating liquids. Although applicable equally to polar liquids, the conduction mechanism of which is still not free from doubt (1), the method has so far been applied only to a typical nonpolar liquid (hexane) since views on the processes at work both in conduction and in electrical breakdown show considerable divergence.

Resumé of Present Theories

At low field strengths (about 1 kv/cm) the ultimate conduction in highly purified nonpolar liquids seems to be due to ionization by cosmic rays (2, 3) and other radiation. With stronger fields (over 100 kv/cm) there appears an added component of conduction attributed by different investigators to various forms of electron emission from the cathode with or without the additional influence of collision-ionization of the liquid molecules. Thus, Baker and Boltz (4) pictured thermionic emission from the cathode (without ionization) as the basic mechanism, a view modified in details by LePage and DuBridge (5) and by Dornte (6). Young (7) added the feature of collision ionization, a mechanism put forward earlier by Nikuradse (8). More recently Morant (9) and House (10) have produced evidence favoring a return to the thermionic emission theory. Green (11) considered cathode emission to be due to the combined effects of the applied field and the intense local fields set up by undischarged ions separated from the cathode by a superficial insulating layer.

Experiments leading to the foregoing views were carried out with d-c fields; some (10, 11) involved a lengthy process of "conditioning," whereby stable d-c conduction at field strengths near to breakdown could be obtained. It would clearly help in resolving these divergent views if the value of the conduction current during the first few microseconds after the application of the field, i.e., during the time of transit of an ion between the electrodes, could be established as a function of time. This is one object of the present research.

Apart from its intrinsic interest, the mechanism of conduction has an important bearing on our understanding of electrical breakdown in liquids. It was formerly held that there was no connection between these phenomena. In the case of pure, nonpolar liquids, however, present-day theories of breakdown are based mainly on the assumption that conduction and breakdown are in fact linked.

Thus, Goodwin and Macfadyen (12, 13) have explained their experimental results on the breakdown of various liquids under pulse conditions by a mechanism based on (*a*) a field-dependent cathode emission, and (*b*) intensification of the field at the cathode by positive space charge resulting from collision-ionization.

It is shown that these two relationships constitute a feedback mechanism leading to a catastrophic situation at a certain field strength even though emission and ionization may increase smoothly with field strength. Goodwin (14) later showed by electro-optical means that the predicted intensification of cathode field did in fact occur in certain cases. The breakdown condition is expressed in terms of ionic mobilities, ionization coefficients (Townsend's α), and cathode emission characteristics, all of which are hard to determine at field strengths approaching breakdown. The only estimates are either indirect or based on extrapolation from d-c measurements. Unless the "conditioning" process used by House (10) and by Green (11) is used, the available evidence points to conduction currents of the order of microamperes near breakdown. The object of the present investigation was to develop means for measuring currents of this order during a 5 μsec pulse. The fact that much of the experimental evidence on breakdown is derived from pulse tests is an added reason for the investigation.

The theory of Lewis (15), which has been strikingly successful in correlating breakdown strength with molecular vibration energy levels, does not enable specific predictions regarding conduction current to be made. The criterion here is that breakdown is contingent upon the setting-up of conditions

favorable for ionization by collision. Sharbaugh, Bragg, and Crowe (16), however, on the evidence of the effect of gap width on breakdown strength, suggest more explicitly that breakdown occurs when, on the average, each electron emitted by the cathode undergoes a certain fixed number n of ionizing collisions before reaching the anode. Their experiments suggest that for hexane $n = 9$ approximately. This would result in a current magnification by the factor 8100 (e^9) at breakdown. Cathode emissions of only 10^{-9} amp would thus be expected to yield currents of some microamperes, as in the theory of Goodwin and Macfadyen already considered.

Choice of Method

In order to facilitate interpretation, pulse breakdown measurements are usually carried out with a flat-topped pulse of voltage. The chief difficulty in measuring conduction under such conditions is the presence of very large charging and discharging currents at the beginning and end of the pulse. For example, in applying a 10 kv pulse to a pair of suitably spaced plane parallel electrodes (0.5 cm²) the rate of rise of voltage (10^{11} v/sec) gives rise to a charging current of about 1 amp, which is many orders of magnitude higher than the conduction current expected. In a similar way, irregularities in the pulse-top would produce spurious indication of conduction. Some form of bridge circuit in which the capacitive current is balanced out is necessary.

Gledhill and Patterson (17) in their work on electrolytic conduction at high field strengths used a 3-winding differential pulse transformer to compare the conduction in two cells. This method was tried but found unsuitable for the present work for two reasons: first, a display of conduction current vs. time was required, comparison by null method against a standard resistance or conduction cell being unacceptable for this work; and, second, the above requirement coupled with the smallness of the currents to be measured compared with the large charging current pulses resulted in a transformer design problem impossible of solution with existing materials.

The Schering bridge circuit (Fig. 1) was therefore used, and although a pulse output transformer was ultimately necessary with this circuit the design problem was much less severe, the main requirement being extremely good electrostatic shielding.

In Fig. 1, C_3 represents the capacitance in the conduction cell and i_c the conduction current. C_4 is a compensating condenser and C_2 an adjustable condenser for balancing the stray capacitance C_1. R_0, R_1, and R_2 are equal noninductive high-stability resistors. A flat-topped pulse, negative to ground, was applied to X.

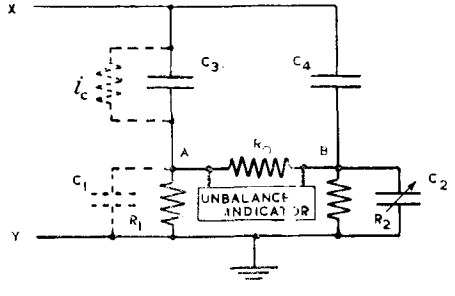

Fig. 1. Schering bridge circuit

An upper limit to the value of R_1 and R_2 was set by consideration of time constants (see below) and a lower limit by tube noise in the ensuing amplifiers. The first form of unbalance indicator to be used was a 2-stage differential amplifier. The requirements were onerous, since pulse potential differences of about a millivolt had to be amplified in the presence of unwanted pulses of some hundreds of volts. The method was abandoned because, whether triodes or pentodes were employed, it was found impossible to avoid spurious indications resulting from interelectrode capacitances. Nonlinearity was also troublesome.

The method of detecting the out-of-balance voltage finally adopted was to use a specially designed screened and balanced pulse transformer followed by conventional wide-band amplifiers and a cathode ray oscilloscope. Details are given below.

The Conduction Cell

The removable parallel plane electrode system (Fig. 2) was enclosed in a borosilicate glass vessel V provided with plane windows for microscopic examination. The vessel was included in a closed-circuit distillation system with a sintered glass filter to exclude particles larger than 1.5 μ in diameter.

The electrode system was designed to be suitable for d.c. as well as pulse measurements. The cylindrical electrodes A, B were supported in accurately milled V-grooves in the blocks C, D. C was highly insulated by its composite quartz-metal mounting E, F, G. Contact with A was made by a spring attached to the rod J. The metal plate F acted as a guard ring to intercept surface conduction over the fused quartz blocks E, G. The quartz-metal joints were made by soft-soldering the chemically silvered quartz blocks to a nickel-iron alloy ("Nilo 36") of low thermal expansion. The bond was strong enough to permit the V-grooves in the block to be milled in one operation. Thus, if A and B were accurately

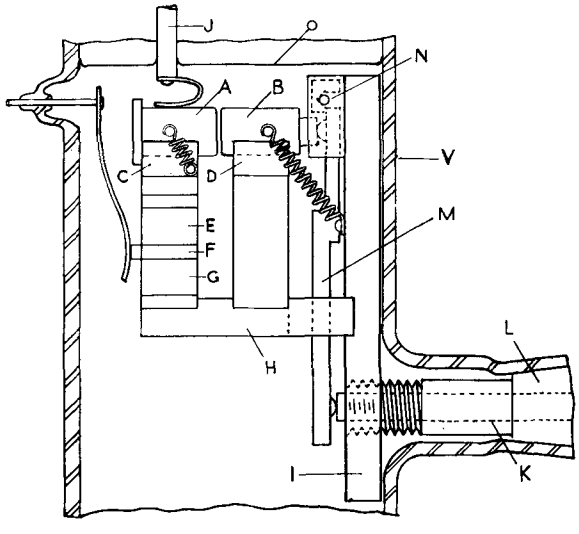

Fig. 2. Electrode assembly in conduction cell. Glass parts are shown in section.

turned, the adjacent surfaces automatically became exactly parallel. In lapping and polishing the end surfaces a special holder was used to preserve accurate geometry.

The pillars supporting A and B were attached to a base plate H. This was supported from the side-plate I which was curved to fit the inside of the glass vessel against which it was held by the screwed sleeve shown. Through this sleeve, to which was attached the cone L, there passed a spring-returned push-rod K sealed by a Neoprene O-ring and operated by a micrometer head (not shown) beyond L. Axial movement of the rod actuated the 10:1 lever M pivoted at N and thus enabled the gap between A and B to be adjusted to an accuracy of 1μ.

A phenomenon inseparable from measuring pulse currents at high field strengths is electrode movement resulting from electrostatic attraction. At a field strength of 1 megavolt/cm this force amounts to about 1 kg-wt/cm^2. With any practicable means of supporting the electrodes their natural frequency of vibration would be no higher than the "near ultrasonic" range; for 5 μsec pulses we may therefore regard the motion as limited by inertia rather than constraint, and attempts at extreme rigidity will be futile.

Solid cylindrical electrodes lightly constrained at the end remote from the gap were employed to make the movement predictable. If a mutual attraction of T dynes cm^{-2} is suddenly set up between the ends of the cylinders at a certain instant, the propagation of the tension pulse in one cylinder results in a steady rate of advance v of its end surface. If Y denotes Young's modulus of the material and ρ is density

$$v = T/\sqrt{(Y\rho)}$$

and since both electrodes move with this velocity the rate of change of capacitance C (in e.s.u.) is

$$\frac{dC}{dt} = 2\,CT/l\sqrt{(Y\rho)}$$

where l is the gap width. The value of T is given by

$$T = \epsilon E^2/8\pi$$

If the voltage, V, is maintained constant while this movement occurs the charging current will be

$$i_c = V\frac{dC}{dt} = E^3\,C\,\epsilon/4\pi\sqrt{(Y\rho)}\ \text{e.s.u.} \qquad [1]$$

where E is the field strength in the gap and ϵ the permittivity of the liquid.

With a 10 kv pulse applied between cylinders 7 mm in diameter with ends 100 μ apart the charging current is 11 μa, the velocity of each electrode surface 0.3 cm sec^{-1} and the velocity of the tension wave 3.4 x 10^5 cm sec^{-1}. With cylinders 0.85 cm long the time of a double passage of the wave from the electrode face to the far end and back is 5 μsec. By this time the required information has been displayed by the oscilloscope. A correction must be applied, according to Eq. [1], for the current due to the electrode movement; this probably sets a lower limit of about 1 μa to the current that can be measured under these conditions. With narrower gaps the charging current is higher, (Eq. [1]).

In principle it is possible to balance out this current by means of a similarly constructed vacuum condenser on the other side of the Schering bridge. It can be deduced from Eq. [1] that if the vacuum condenser has electrode area S'

$$\frac{S'}{S} = \epsilon^{2/3}$$

for equalization of the charging currents.

This procedure has not been necessary in the experiments reported here as measurable currents were found with field strengths at which electrode movement was not serious. Polystyrene parallel plate condensers were used as compensators in the bridge circuit, the design being such as to make plate movement negligible. Bridge balancing was done by fine adjustment of the electrode separation in the conduction cell and by the variable condenser C_2 (Fig. 1).

The Bridge Circuit

Assuming a symmetrical bridge circuit (Fig. 1) with $R_1 = R_2 = R_0$ (=R, say) and other corresponding quantities approximately equal, an analysis of the effect of applying a step-function voltage V_s to the input terminals XY leads to the expression

$$v_{AB} = V_1\,e^{-t/\tau_1} + V_2\,e^{-t/\tau_2} \qquad [2]$$

for the potential of A relative to B at a time t after the application of the step. The time constants are given by

$$\tau_1 = \frac{1}{3}R(C_1 + C_3)$$

$$\tau_2 = R(C_1 + C_3)$$

In the present case τ_1 and τ_2 are about 20 and 60 mμsec, respectively. It is this time which limits the value permissible for R, for in the event of any capacity unbalance the oscilloscope deflection will not be a measure of the conduction current i_c until long after the lapse of time τ_2. Moreover, the indication of changes in i_c will be delayed by a time of the order of τ_2. This sets an upper limit to the value of R which can be used. A lower limit is set by tube noise in the amplifier which amplifies v_{AB}. The conduction current is related to v_{AB} thus

$$i_c = \frac{3\,v_{AB}}{R}$$

The factors V_1 and V_2 in Eq. [2] depend on the degree of capacity unbalance. If C_3 (capacity of the conduction cell) and C_2 are the adjustable capacitances we find

$$\left.\begin{aligned} V_1 &= \frac{3\delta(C_2C_3) - (C_2 + C_3)\delta C_3}{2(C_2 + C_3)^2}\,V_s \\ V_2 &= \frac{-\delta(C_2C_3) + (C_2 + C_3)\delta C_3}{2(C_2 + C_3)^2}\,V_s \end{aligned}\right\} \qquad [3]$$

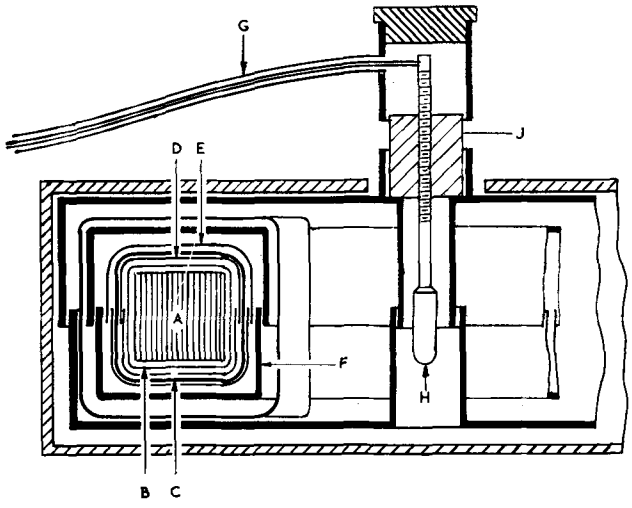

Fig. 3. Section of screened and balanced pulse transformer

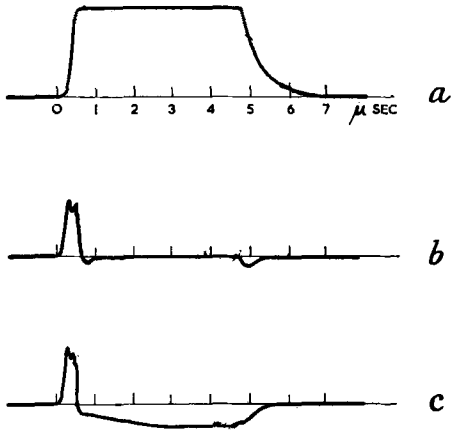

Fig. 4. Oscilloscope traces. (a) Voltage pulse applied to bridge circuit; (b) Output voltage pulse. The residual pulses are probably due to distributed inductance; (c) Output voltage pulse showing conduction current in cell. The shape of the conduction portion depended on the electrode surface conditions.

where δ represents the departure of the quantity in question from the value for perfect balance.

In practice the finite rise-time of the pulse renders Eq. [3] useful only in a general way. The final adjustments of C_2 and C_3 are made experimentally.

As mentioned earlier the essential feature of the unbalance indicator was a screened and balanced pulse transformer. This was wound on a spiral core (A, Fig. 3) of "Supermumetal" ($\mu \sim 50{,}000$) contained in a plastic case B. The primary winding C, occupying only a portion of the circumference, was surrounded by a complete earthed screen F, but in order to avoid spurious secondary emf's due to unbalanced capacity currents from primary to earth, two split foil screens D, E, each part being connected to the appropriate end of the winding, were interposed between the winding and its surroundings. In order to improve the balance still further the primary (52 turns of 38 S.W.G. enamelled wire) was wound back on itself. The final adjustment of balance was achieved by means of a "compensating turn" consisting of a short length of screened cable G leading from one primary terminal to the earthed case by way of a screw-plunger H having very low adjustable capacitance to the case. By joining both primary terminals to (say) point A (Fig. 1) the nut J could be adjusted to give the best discrimination against response to equal potential pulses at A and B simultaneously.

The whole transformer was enclosed in a "Mumetal" case and the entire circuit comprehensively screened. The first two stages of amplification, placed close to the transformer, gave a gain of about 100. When followed by the wide-band amplifier (5 Mc/s) in the oscilloscope (Solartron CD 513) this gave a screen sensitivity of 1 cm/75 μa of cell current.

Procedure

Early tests with the apparatus described were made with brass electrodes, lapped with wet rouge on a pitch block and lightly polished with "Silvo" polish on a "Selvyt" cloth stretched on a plate glass base. Then, after thorough degreasing, a layer of gold 1000Å thick was evaporated *in vacuo* onto the electrode faces. The electrodes were mounted as in Fig. 2 and the whole assembly continuously degreased in cold running refluxed hexane for at least an hour. The unit was mounted in its glass tube and washed out with several changes of hexane which had been dried with phosphorus pentoxide distilled and filtered in the same apparatus. The apparatus was normally filled with dried nitrogen from a cylinder. Microscopic examination of the gap was maintained during tests.

With a 1 kv pulse (Fig. 4a) applied to the bridge, balancing of capacitances was done by adjusting the electrode gap and the condenser C_2 (Fig. 1), giving an optimum oscilloscope trace as in Fig. 4b. The residual pulses were considered to be due to stray inductance in the connections, particularly those in the conduction vessel. Conduction was shown by the displacement of the trace in the center part of the pulse (Fig. 4c) and, although there seems to be some risk that "hangover" from the spurious initial pulse might invalidate this indication, it was possible to eliminate the uncertainty in the course of taking readings with different applied pulse voltages. The residual pulses were proportional to applied voltage while the conduction followed a different law.

Results

With the gold-plated electrodes described above the raising of the pulse input voltage from the balancing value of 1 kv to about 3 kv gave conduction as shown in Fig. 4c. The relatively slow rise of current with time was not an invariable feature.

Figure 5 shows the relationship between peak current and field strength. The two different symbols for the graph points indicate two experimental runs with different capacitance-balance conditions. In both cases breakdown occurred at a pulsed field strength of 0.52 mv/cm.

Similar results, with somewhat smaller currents, were obtained with other pairs of electrodes prepared in a similar way, but currents of this order could not always be obtained. A 5-times enhancement of the emission was obtained on occasion by prolonged exposure of the electrodes to air.

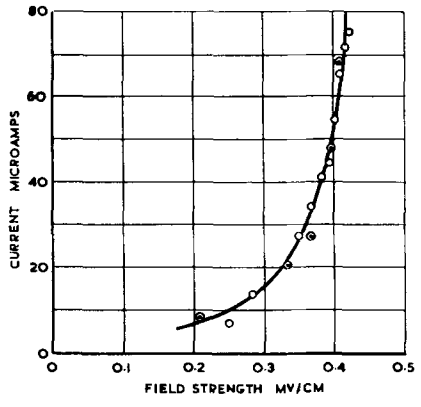

Fig. 5. Conduction characteristic of gold-coated electrodes in hexane. Electrode area: 0.35 cm^2. Electrode separation: 120μ.

With uncoated electrodes the conduction current was much lower. For example, stainless steel, mechanically polished with chromic oxide, gave a barely observable conduction, (about 5 μa). However, after several breakdowns had occurred currents up to about 150 μa were observed.

Experiments carried out to investigate the nature of the conduction included flushing the vessel and refilling with freshly distilled hexane. This produced no substantial change of conduction current. Conversely, when electrodes giving no measurable conduction were used with hexane which had been neither dried nor distilled, no conduction was observable.

Tests with double pulses, the second occurring at times down to 4 μsec after the first, showed no observable difference in behavior on the second occasion.

A further significant result was found in the course of comparing pulse and d-c conduction currents. A pair of electrodes giving a pulse current of 38 μa at 2.2 kv gave a steady conduction of only 0.07 μa with the same voltage and polarity. Furthermore, when the pulse test was again applied after a d-c test of this kind the pulse conduction was found to be reduced by about an order of magnitude.

In a similar way, the enhanced conduction from stainless steel after several breakdowns had occurred was largely suppressed by prolonged d-c testing, e.g., 45 hr with a current of 6 x 10^{-9} amp at 100 kv/cm. Microscopic examination of the electrodes after this treatment showed globular particles about 5μ in diameter mainly clustered around the 70μ craters left by previous breakdowns. These particles were apparently made of the wax-like substance reported by previous observers (5) and assumed to be a polymer resulting from electronic bombardment of the liquid molecules.

Discussion

In view of the preliminary nature of these experiments it would be unwise to attempt to deduce too much from them. The high values of pulse conduction current observed are far greater, having regard to the field strength, than the predictions of any previous measurements or theory. Ionic conduction seems to be ruled out by the dependence of conduction on electrode surface preparation and the lack of correlation between conduction and liquid sample.

Simple calculations show that the total charge during the 5 μ pulse is many orders of magnitude greater than could be explained by orientation of impurity dipoles. Time considerations also make this idea untenable. We are thus led to the conclusion that the conduction current originates at the electrode surfaces, the most likely mechanism being electron emission from the cathode, with or without magnification by collision-ionization in the liquid. The latter point must remain uncertain as conditions prevented a series of measurements with differing gap widths.

The magnitude of the current suggests that it may be limited by negative space charge. An analysis of the case of parallel plane electrodes of separation l and p.d. V volts drawing a space charge-limited current of negative ions having a mobility u cm/sec per volt/cm gives the expression

$$I = \frac{A\,u\,\epsilon}{32\,\pi\,10^{11}\,l^3}\,V^2 \text{ (amp)} \qquad [4]$$

where A is the plate area and ϵ the permittivity. With $l = 0.01$ cm, $\epsilon = 2$, $A = 0.5$ cm^2, $u = 4.4$ x 10^{-4} cm/sec per volt/cm (18) and $V = 4$ kv we find $I = 7$ x 10^{-4} amp, which is only one order of magnitude higher than the observed current. A logarithmic plot of Fig. 5, however, shows a law of variation of about the 5th power, which is different from Eq. [4], but the orders of magnitude of the quantities show that space charge cannot be ruled out as a factor in conduction of this kind, especially when it is remembered that emission from the cathode almost certainly occurs from small areas ($\sim 10^{-4}$ cm^2) as the papers by Dornte (6) and by Goodwin (14) show. Although it can be proved in general that a law of the form $I \propto V^2$ is to be expected for a copiously emitting cathode and an anode, irrespective of their shapes, the argument does not apply when the emission is confined to limited areas on the cathode surface. In this case the influence of negative space charge will be enhanced.

The fact that prolonged exposure to air promoted emission from evaporated gold layers suggests an emission mechanism of the type envisaged by Green (11), namely, extraction of electrons by positive ions on a thin layer, in this case perhaps of CO (19). Some support for this view can be obtained for the high emissions after breakdown and from the effects observed after prolonged d-c conduction. A possible explanation of these phenomena is that a layer of wax (or other material) of suitable thickness results in copious emission according to the mechanism envisaged by Green, but that prolonged conduction results in a wax layer of excessive thickness, reducing emission and ultimately becoming visible under the microscope. Although the present experiments have not been carried far enough for a definite conclusion it seems possible that deposition of solid matter may be an important factor in "electrode conditioning." The experiments are continuing with improved apparatus including a Wagner earth to improve the accuracy of the capacity balance.

Luminescence of Copper-Activated Calcium and Strontium Orthophosphates

W. L. Wanmaker and C. Bakker

Light Division, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Copper produces a strong luminescence in $Ca_3(PO_4)_2$. Luminescence in $Sr_3(PO_4)_2$ occurs only in the presence of small amounts of foreign ions such as Ca, Zn, Cd, Mg, or Al. These additions give rise to a new crystal phase which is probably isomorphous with β-$Ca_3(PO_4)_2$. The emission peaks under excitation with 2537Å of β-$Ca_3(PO_4)_2$, α-$Ca_3(PO_4)_2$, and of $Sr_3(PO_4)_2$ modified with Al are found at 4800, 5700, and 4950Å, respectively. Sensitization occurs with Mn, giving rise to a red emission peak. The temperature dependence of the fluorescence is good, especially that of β-$Ca_3(PO_4)_2$-Cu and $Sr_3(PO_4)_2$ partly substituted with Mg and Ca. Phosphor application in lamps presents difficulties due to the materials' sensitivity to air at binder bake-out temperatures.

In sulfides, copper is a well-known activator. In this type of phosphor copper does not in general act as a characteristic activator like manganese, but as an indirect one, facilitating the excitation of electrons of the neighboring sulfur ions (1).

In oxygen-dominated phosphors, however, activation by copper is not so generally known. It appears from the survey given by Kröger (2) that carbonates, oxides, halides, phosphates, and silicates may be activated by copper. In some cases copper acts only as an intensifier of the luminescence of the pure substance, as with $ThSiO_4$ described by Leverenz (3). Copper-activated alumino-silicate phosphors were investigated by Claffy and Schulman (4) and found to have a brightness of about one-third of that of calcium tungstate. Recently Wilke (5) also reported the preparation of copper-activated silicates.

Among copper-activated phosphates the following luminescent materials are known: AlBaMg-phosphate glass (6) with a pinkish white fluorescence; calcium apatites giving a blue emission (7); calcium metaphosphate, also with a blue emission (8); and finally the red-emitting magnesium orthophosphate (9).

Quite recently Uehara and Kofuya (10) described the properties of β-calcium orthophosphate activated with Cu and with Cu and Mn. The preparation of β-$Ca_3(PO_4)_2$ modified with the foreign ions Cd, Sr, Mg, and Zn is also given in the patent literature. With manganese, sensitization occurs, giving rise to a red emission band in addition to the blue band due to copper (11).

In this paper the preparation and properties of the efficient β-$Ca_3(PO_4)_2$-Cu and of $Sr_3(PO_4)_2$-Cu phosphors, substituted with small amounts of Al, Mg, Zn, and Cd, are described in some detail. Similar phosphors are prepared by substituting a small part of the Sr by Ca with a resulting green emission. While β-$Ca_3(PO_4)_2$-Cu has a narrow emission peak at 4800Å, the corresponding Sr compound with a small amount of Al has its peak wave length at 4950Å. Incorporation of zinc and magnesium into $Sr_3(PO_4)_2$-

Cu gives rise to an emission peak at about 4900Å, and incorporation of Cd and Ca gives a peak at 5100Å.

Method of Phosphor Preparation

The ingredients used in the firing mixtures were reagent grade $CaHPO_4$, $SrHPO_4$, $CaCO_3$, Cu_2O, $CuSO_4$, Al_2O_3, and $MnNH_4F_3$ or $MnCO_3$. The required amounts of the dry materials were thoroughly mixed and subsequently fired. The firing was done in a special tube furnace, in which alumina boats filled with the firing mixture were gradually passed through the heating zone in a neutral or slightly reducing atmosphere (N_2 with O to 0.5% of pure hydrogen). The furnace exit was provided with a gas lock to prevent the entry of air when the fired samples were removed from the furnace. The best results were obtained by a double firing at temperatures of 1160°-1240°C, in N_2 with 0.03% H_2, for periods of 1 hr each.

Incorporation of the Activator in the Host Crystal Lattice

Air-fired copper-activated phosphors give no luminescence at all or at best a very weak one, whereas firing in a slightly reducing atmosphere produces strongly luminescent materials. With too high a concentration of hydrogen in the firing atmosphere, metallic copper is produced, while too low a concentration of hydrogen gives products with a slightly blue body color, due to divalent copper. This shows that the copper ion should be present in the monovalent state.

Chemical analysis confirmed that, in the strongly luminescent products, all the copper is present in the monovalent state, e.g., in a β-$Ca_3(PO_4)_2$-Cu phosphor ($Cu/P_2O_5 = 0.01$ and $Al/P_2O_5 = 0.10$) the amounts of total and of monovalent copper were both found to be 0.19 wt%. The percentage of monovalent copper was determined by dissolving the phosphor sample in hydrochloric acid in the presence of an excess of potassium dichromate and measuring the amount of unused dichromate by titration with an 0.01*N* Fe^{II}-sulfate solution.

With large amounts of copper, brown colored products are mostly formed, indicating that part of the copper added is not incorporated in the crystal lattice. With the simultaneous addition of Al, the ratio of Cu/P_2O_5 at which the brownish discoloration occurs, increases. Obviously Al facilitates the incorporation of the monovalent Cu^+ ion in the crystal lattice. This phenomenon can be explained easily by the theory of charge compensation, with one Cu^+ and one Al^{3+} ion substituting for $2Ca^{2+}$ or $2Sr^{2+}$ ions, respectively (12).

Although this hypothesis may be applicable to β-$Ca_3(PO_4)_2$-Cu phosphors, other effects must also be taken into account with $Sr_3(PO_4)_2$-Cu.

The β-$Ca_3(PO_4)_2$-Cu phosphor is efficient without the addition of Al, whereas unsubstituted $Sr_3(PO_4)_2$-Cu shows only a very weak, deep blue emission (peak wave length at 4450Å). X-ray analysis showed that the latter substance has the normal $Sr_3(PO_4)_2$ lattice structure (13). However, with $Sr_3(PO_4)_2$-Cu a strong luminescence develops when ions such as Al, Ca, Mg, Zn, and Cd are added. At the same time, the partial substitution of Sr by Al, Ca, Zn, Mg, and Cd gives a pronounced change in the crystal lattice. A new structure appears which is identical with that of $Sr_3(PO_4)_2$-Sn phosphors, where part of the Sr has been replaced by smaller divalent ions like Mg. This structure is similar to the structure of the β-$Ca_3(PO_4)_2$ lattice, as described by Koelmans (14).

Apparently the presence of foreign ions transforms the $Sr_3(PO_4)_2$ structure in such a way that a different structure is obtained which is probably isomorphous with β-$Ca_3(PO_4)_2$ and which gives rise to a strong luminescence with Cu as the activator.

The brightest phosphors are made with a slight excess of P_2O_5, resulting in a total metal to P_2O_5 ratio of about 2.90-2.95. Usually better results are obtained with $CuSO_4$ than with Cu_2O. This may be due to the decomposition of the $CuSO_4$ during the firing process, which forms a more reactive copper compound in the process.

Calcium Orthophosphate Phosphors

$Ca_3(PO_4)_2$ exists in two crystal structures, viz., α-$Ca_3(PO_4)_2$, stable at a temperature above 1180°C, and β-$Ca_3(PO_4)_2$, stable below this temperature. Kroeger found (15) that the transition temperature is raised by the incorporation of small amounts of Ce, Al, or Mn in $Ca_3(PO_4)_2$·Ce,Mn. Similar results were obtained by Butler (16) who also found a high transition temperature with a composition different from the stoichiometric one and in the presence of the activator Sn. From the foregoing it is clear why we obtained the β-$Ca_3(PO_4)_2$ modification in nearly all cases. This compound, when activated with copper, gives a blue emission with a peak at 4800Å (Fig. 1).

It was interesting to investigate the luminescent properties of the α-modification. The α-$Ca_3(PO_4)_2$ structure (as identified with x-ray analysis) was obtained by firing unactivated $Ca_3(PO_4)_2$ at 1270°C

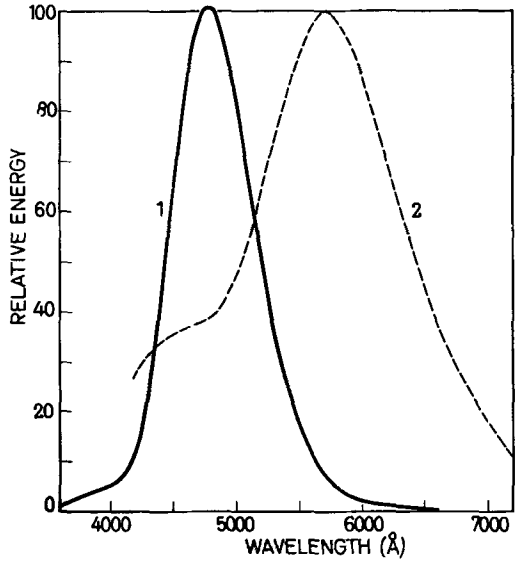

Fig. 1. Spectral energy distribution curves of the emission of β-$Ca_3(PO_4)_2$-Cu [curve 1] and of α-$Ca_3(PO_4)_2$-Cu [curve 2]. Mole ratios: $Cu/P_2O_5 = 0.005$ [2] and 0.01 [1]. $Me/P_2O_5 = 2.99$ [2] and 2.90 [1]. Firing temperature: 1160°C [1] and 1280°C [2]. Firing atmosphere: N_2 with 0.03% H_2.

in air. A low percentage of copper ($Cu/P_2O_5 = 0.005$) in the form of $CuSO_4$ was added to the fired product and the mixture was refired at 1280°C. X-ray analysis showed that the crystal structure did not change during this refiring process and that the crystal structure was entirely the same as that of α-$Ca_3(PO_4)_2$ described by Mackay (17). In this way a nearly white luminescent product (with 2537Å excitation) was prepared, the emission peak lying at 5700Å (Fig. 1). With 3650Å excitation a yellow emission occurs. The small emission peak at 4800Å is attributed to a small amount of β-$Ca_3(PO_4)_2$ in the refired product. When the refiring temperature is lowered to 1100°C only the blue-emitting phosphor is obtained.

With an increase of the amount of copper added, a shift of the emission peak of β-$Ca_3(PO_4)_2$-Cu to longer wave lengths is observed, the crystal structure remaining the same. The shift starts from a Cu/P_2O_5 ratio of 0.05 and reaches an emission peak of 4900Å at a ratio of $Cu/P_2O_5 = 0.20$. In order to obtain the high u.v. absorption desirable for application in fluorescent lamps, a Cu/P_2O_5 ratio of about 0.05 is needed. With the simultaneous addition of Cu^+ and Al^{3+}, the incorporation of the copper ion is obviously facilitated, as deduced from the increase in brightness found. The Al shifts the emission peak to shorter wave lengths and gives a narrower emission band.

With the introduction of manganese, a second emission peak arises at 6550Å. With increasing amounts of manganese, the intensity of the red manganese band is raised and that of the blue copper band is lowered, as is generally known to be the case with sensitized phosphors. This is illustrated in Fig. 2. The brightness of the phosphors activated with copper and manganese is lower than that of the single activated phosphors and falls off rapidly with increasing amounts of manganese. With $Mn/P_2O_5 = 0.08$ a brightness of about 25% of that of Mg-arsenate is reached.

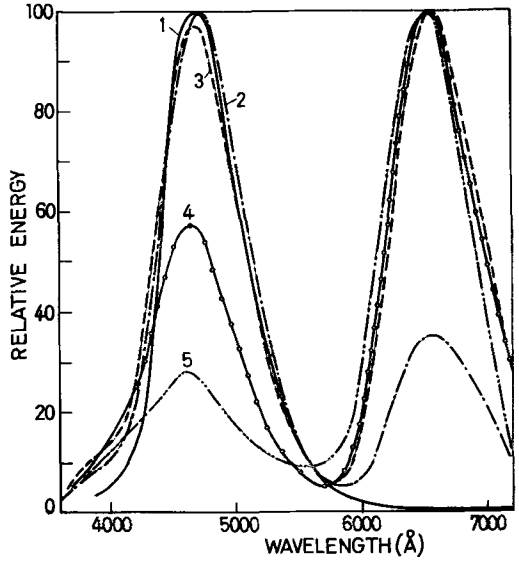

Fig. 2. Spectral energy distribution curves of the emission of β-$Ca_3(PO_4)_2$-Cu·Mn modified with Al, with increasing amounts of Mn. Mole ratios: $Cu/P_2O_5 = 0.02$ and $Al/P_2O_5 = 0.05$

In contrast to the modified Sr-orthophosphate phosphors the partial replacement of Ca in β-$Ca_3(PO_4)_2$ by foreign ions such as Mg, Zn, and Cd decreases the efficiency of the phosphor. Confirming the results of Uehara and Kofuya (11) the addition of a small amount of Mg and Zn, respectively, was found to shift the emission peak to shorter wave lengths. The partial substitution of Ca by Cd does not change the emission. With addition of La and Ce, a change in the spectral distribution is observed. For example, with a mole ratio of $Al/P_2O_5 = 0.06$, $Cu/P_2O_5 = 0.02$, and $Me/P_2O_5 = 0.25$ (Me = La or Ce), Ce, in addition to its own characteristic band at 3500Å, gives rise to the development of a sensitized Cu-band at 4700Å and La to one at 4900Å.

X-ray diffraction analysis shows that all of the latter substituted $Ca_3(PO_4)_2$ phosphors have the β-$Ca_3(PO_4)_2$ structure. Thus the variations observed in the emission spectra are not caused by a change in the crystal structure but by the perturbing action of the foreign ions on the ground and excited states of the activator ion.

Strontium Orthophosphate Phosphors

$Sr_3(PO_4)_2$ phosphors with Cu give only a very weak deep-blue luminescence with an emission peak at 4450Å. In the presence of even a small amount of Al a strong blue-green emission occurs. With a sufficiently high amount of Al the deep blue emission disappears completely. This effect may be clearly seen from Fig. 3. The brightness of $Sr_3(PO_4)_2$-Cu modified with Al may reach a value of 125% of the brightness of Sb-activated calcium halophosphate.

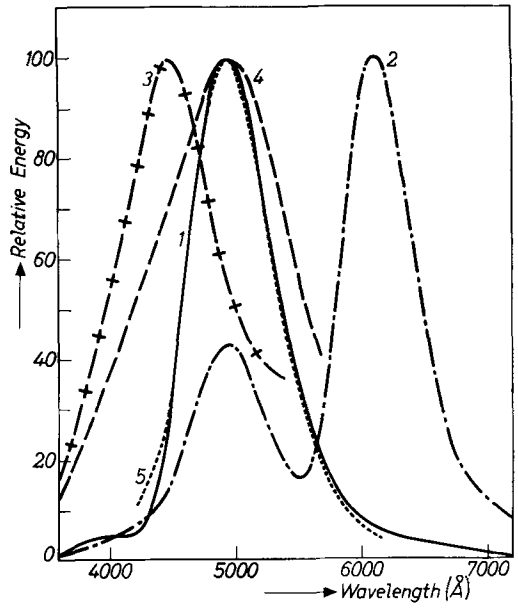

Fig. 3. Emission of Cu- and Cu,Mn-activated Sr orthophosphates. Mole ratio Cu/P_2O_5: curves 1 and 2 = 0.07, curves 3, 4, and 5 = 0.04; Al/P_2O_5: curves 1 and 2 = 0.21, curve 3 = 0, curve 4 = 0.005, curve 5 = 0.02; Mn/P_2O_5: curves 1, 3, 4, and 5 = 0, curve 2 = 0.06.

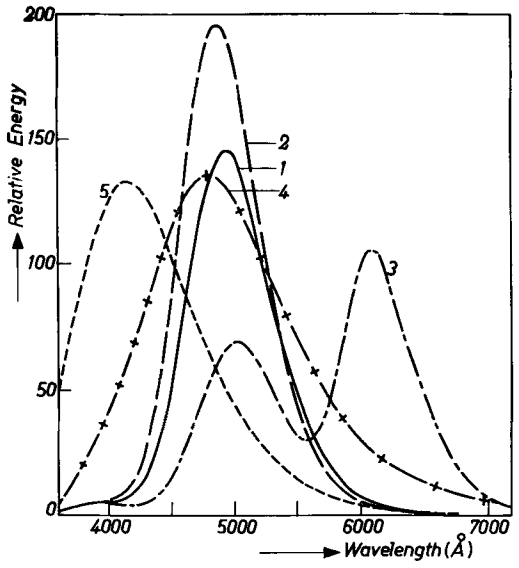

Fig. 4. Emission of Cu-activated Sr orthophosphates, modified with Zn [curve 1], Mg [curve 2], and Cd [curve 3]. The intensities are compared with those of Sb^{3+}-activated calcium halophosphate [curve 4] and of $CaWO_4$ [curve 5]. Composition of phosphors in Table I.

Besides Al, other foreign ions, such as Ca, Zn, Mg, and Cd also give strongly luminescent products, with a brightness higher than that of the known calcium tungstate and Sb-activated calcium halophosphate, as illustrated in Fig. 4. In this figure the intensities of the new phosphors are compared with those of the blue-emitting (Sb-activated) calcium halophosphate and of calcium tungstate. The influence of these foreign ions on the luminescence is due to the effect they have on the crystal structure. Koelmans (14) stated already that the normal Sn-activated $Sr_3(PO_4)_2$ gives only a weak u.v. emission, whereas ions such as Al and Mg cause a transformation into a structure analogous to that of β-$Ca_3(PO_4)_2$. Only the latter structure produces any luminescence. In fact the structures of the Sn-activated phosphors described by Koelmans and of the present Cu-activated ones are identical. As with calcium orthophosphate, the corresponding strontium compound can be activated by Cu and Mn and gives an additional red manganese band at 6100Å (Fig. 3). The intensities of the green Cu and the red Mn bands vary with increasing Mn content in the same manner as already described for the Ca-orthophosphate phosphor.

Modified Orthophosphate Phosphors

Koelmans (14) found that, starting from β-$Ca_3(PO_4)_2$, a gradual replacement of Ca by Sr results in a widening of the β-$Ca_3(PO_4)_2$ lattice until a Ca/Sr ratio of about 0.2 is reached. With more Sr, there is a rather sharp transition to the normal Sr orthophosphate structure and the emission of the Sn-activated phosphor changes from 6200 to 3700Å. With part of the Sr replaced by Ca ($CaO/P_2O_5 = 0.2$) the emission peak of the Cu-activated phosphor lies at 5150Å. The gradual replacement of Sr by Ca shifts this emission peak to shorter wave lengths, until the emission of pure β-$Ca_3(PO_4)_2$-Cu is reached. With the further addition of Al to the SrCa-orthophosphate activated with copper, the emission peak shifts to the blue region of the spectrum.

Table I. Quantum efficiency of Cu-activated orthophosphate phosphors with Al; excitation 2537Å; activator concentration $Cu/P_2O_5 = 0.02$; Al concentration $Al/P_2O_5 = 0.06$; x = Ca, Cd, Zn, and Mg

Phosphor	Activator	x/Sr	Q.R., %
β-$Ca_3(PO_4)_2$	Sn	—	81
$(Sr, Mg)_2(PO_4)_2$	Sn	0.12	87
β-$Ca_3(PO_4)_2$	Cu	—	76
$(Sr, Zn)_3(PO_4)_2$	Cu	0.07	68
$(Sr, Mg)_3(PO_4)_2$	Cu	0.09	82
$(Sr, Ca)_3(PO_4)_2$	Cu	0.11	73
$(Sr, Cd)_3(PO_4)_2$	Cu + Mn	0.11	69

With the partial substitution of Sr by Zn and Mg, respectively, the emission peak is found at 4900Å and at still shorter wave lengths in the presence of additional Al. In accordance with Koelmans' results (14) we found that the amount of foreign ion required to obtain the desired structure of $Sr_3(PO_4)_2$ is smallest with a small substituting ion, e.g., Mg. With the low ratio of $Mg/P_2O_5 = 0.08$ a fluorescence intensity of 70% of that of blue calcium halophosphate is already reached.

The substitution of Sr by Cd gives an emission peak at 5150Å. Besides the foreign ions already mentioned, it was also found that the addition of the rare earth ions La and Ce to $Sr_3(PO_4)_2$ produces luminescent products with an emission maximum at 4500Å. In accordance with Koelmans' results the maximum brightness of the substituted Sr-orthophosphates is achieved with a molar ratio Me/P_2O_5 of about 0.2-0.3 (Me being Mg, Zn, or Cd).

Quantum Efficiency

The efficiencies at room temperature of a number of phosphors, as measured by Bril (18), are given in Table I, together with the values for β-$Ca_3(PO_4)_2$-Sn and $Sr,Mg(PO_4)_2$-Sn, as reported by Koelmans (14). It is seen that the quantum efficiencies of the Cu-activated β-$Ca_3(PO_4)_2$ and of the modified Sr orthophosphates are nearly as high as those of the corresponding Sn-activated phosphors. We cannot state definitely that, for each of the phosphors mentioned in the table, the preparation has been studied sufficiently thoroughly so as to be certain that the figures given for the quantum efficiency are the highest attainable.

Reflection and Excitation Spectra

Figure 5 shows the reflection spectra of some Cu-activated phosphors, together with those of the unactivated product. The small amount of Al which is present does not affect the absorption materially. It may be seen that the introduction of the copper ions produces an absorption in the 2500-3500Å region. The excitation spectra of some phosphors are also shown. From this figure it may be seen that the phosphors investigated are strongly excited by the 2537Å mercury line. Thus this new type of phosphor might be very suitable for low-pressure mercury discharge lamp use, were it not for the difficulty presented by the application of these phosphors. This will be pointed out below. Excitation with cathode rays gives only a weak luminescence, the emission color being the same as with u.v.-excitation.

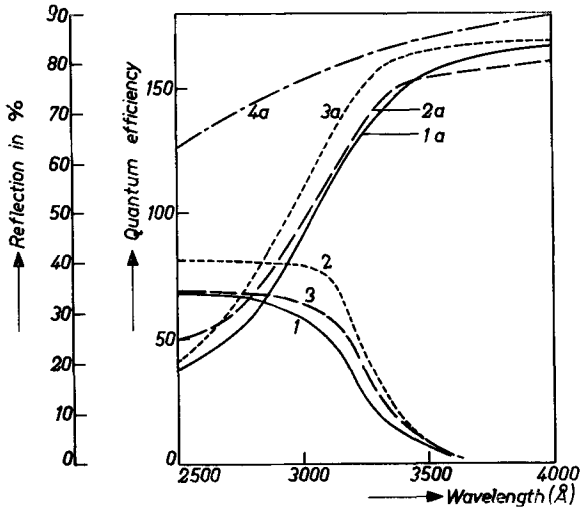

Fig. 5. Reflection (1a-4a) and excitation (1-4) spectra of some Cu- and Cu, Mn-activated Sr orthophosphates. Composition of phosphors in Table I. [1] $(Sr, Zn)_3 (PO_4)_2$ · Cu; [2] $(Sr, Mg)_3 (PO_4)_2$ · Cu; [3] $(Sr, Cd)_3 (PO_4)_2$ · Cu · Mn; [4] $Sr_3 (PO_4)_2$.

Temperature Dependence of Fluorescence

The temperature dependence of the fluorescence of phosphors can hardly be predicted, the behavior of an activator in different matrices varying considerably. Generally speaking, the fluorescence intensity decreases rapidly with increasing temperature when there is a large interaction between the activator ions and the surrounding ions, and vice versa. This is the reason why phosphors with activator ions such as Ce^{3+} and Mn^{4+} with an excited electron in an inner shell generally show a good temperature dependence of the fluorescence. A narrow emission band is, in many cases, evidence for a small disturbing action of the surrounding ions on the activator ion.

As the Cu-activated phosphors described have a band-width of 700-800Å, which is smaller than that of most phosphors, a good temperature dependence of fluorescence of these phosphors could be expected. Figure 6 shows that this is true for β-$Ca_3(PO_4)_2$-Cu and modified $Sr_3(PO_4)_2$-Cu phosphors. With the substitution of some of the Sr in $Sr_3(PO_4)_2$ by other ions, a marked effect on the quenching temperature (i.e., the temperature at which the fluorescence intensity drops sharply) is observed. Figure 6 shows that the quenching temperature decreases in the sequence: Ca, Mg, Zn, and Cd. Similar curves, but with a lower quenching temperature of about 20°C, were obtained with the corresponding phosphors activated with Cu and Mn. It is interesting to note that the ions of group IIa elements of the periodic table (Ca and Mg) have only a small influence on the quenching temperature, whereas the ions of the second sub-series (Zn and Cd) exert a strong one.

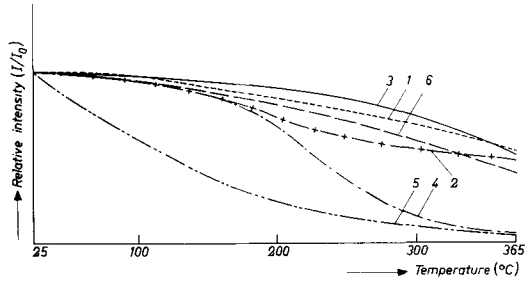

Fig. 6. Variation of fluorescent intensity with temperature for copper-activated calcium orthophosphate [curve 1], and modified strontium orthophosphates [curves 2, 3, 4, 5, and 6]. Composition: moles Me, etc., per 1 mole P_2O_5: Me = 2.90 or 2.95 [curve 2]. Me = Ca(Sr) + Cu + 3/2 Al. Cu = 0.02; Al = 0.06; X = 0.30 (X = Ca, Zn, Cd, or Mg). X = 0.30 (X = Ca, curve 3; Zn, curve 4; Cd, curve 5; or Mg, curve 6).

Obviously the Zn^{2+} and Cd^{2+} ions with a different electronic configuration have a greater disturbing effect on the copper ions than have the Mg and Ca ions. It should be noted that the emission peak of the phosphors investigated shifts to shorter wave lengths at increasing temperatures. An increased activator concentration gives a lower quenching temperature, as was also found with willemite (19) and Mg arsenate (20).

With a constant amount of Cu present, an increase in the Al content improves the temperature dependence of the fluorescence. From the shape of the curves it follows that this type of phosphor may be used in lamps in which good temperature stability is required, namely, high-pressure mercury discharge lamps with an outer bulb coated with a color-correcting phosphor. The difficulties encountered in the application, however, are the same as those met in fluorescent lamps (see below). Moreover the excitation with 3650Å radiation is rather poor (Fig. 5).

Decay of the Cu-Activated Phosphors

The decay of some Cu-activated orthophosphates was measured with the apparatus developed by Bril and Klasens (21). Decay curves are shown in Fig. 7 for Sr orthophosphate modified with Ca and activated with Cu and Mn. Similar curves were obtained with the other Cu-activated orthophosphates. The decay proved to be exponential for Cu, as may be expected for a characteristic activator. The decay constant for Cu in the various phosphors is approximately constant, viz., 40 x 10^{-4} sec. This means that the life time of the excited state is rather long. The decay constant of the Mn emission of some double-activated phosphors was also measured, using an RG 1 filter (transmitting only the radiation with a wave length greater than 6000Å), in order to remove the blue emission produced by the copper ions. For the Mn emission a decay of 1.9 x 10^{-2} was found, in accordance with the figures from the literature for the Mn^{2+} emission in other phosphors.

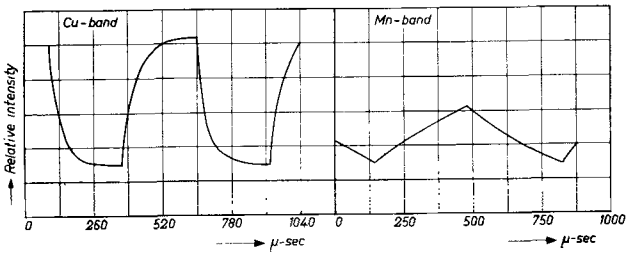

Fig. 7. Build-up and decay of $(Sr, Ca)_3 (PO_4)_2$-Cu, Mn. Composition: Me = 2.90; Cu = 0.02; Al = 0.06; Mn = 0.04; P_2O_5 = 1.

Application

From Fig. 4 and from the quantum efficiencies given in Table I, it is to be expected that this new type of phosphor may be of great importance for fluorescent lamps. In practice, however, serious difficulties arise when the current techniques of lamp making are followed. In order to remove the binder used for applying the phosphor coating, the bulbs are heated to 450°-550°C in air. However, the Cu-activated phosphors are very sensitive to oxidation at temperatures higher than 400°C. Thus after the binder bake-out at 550°C, the phosphor may lose as much as 80% of its efficiency. Phosphors of small grain size are especially sensitive in this respect.

From the foregoing it follows that the phosphors described cannot be applied in the usual way, but special techniques will be required in order to maintain the brightness of the phosphor. The problem of the application of the Cu-activated phosphors is analogous to that of some phosphors which are activated with trivalent cerium, as described by Henderson and Ranby for the calcium halophosphate phosphors (22).

Acknowledgments

The authors wish to express their thanks to Dr. A. Bril for the measurements of the quantum efficiency, the reflection and the excitation spectra of the phosphors; to Dr. H. Koelmans for many helpful discussions regarding the structure of the phosphors; to Mr. E. G. Berns for the determination of the monovalent copper; to Mr. J. Riemens for the measurement of the spectral emission curves; and to Mr. J. G. Verlijsdonk for part of the experimental work.

Manuscript received June 10, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Copper and Tin-Activated Halophosphate Phosphors

B. E. Hunt and A. H. McKeag

Research Laboratories, The General Electric Company Limited, Wembley, England

ABSTRACT

New copper- and tin-activated halophosphate phosphors, fired in mildly reducing atmospheres and of potential practical importance, are described. They include copper- and tin-activated barium chlorophosphates with good thermal characteristics. Copper-activated barium chlorophosphate shows a moderate red fluorescence at ambient temperatures, under long u.v. excitation, which becomes brighter at higher temperatures due to a marked color shift toward the yellow. The same matrix, activated with tin, shows a strong pale green fluorescence at ambient temperatures when excited by 2537Å radiation which is shifted toward the blue at elevated temperatures.

Since the introduction in 1942 of the alkaline earth halophosphate phosphors activated with antimony and manganese (1) a number of additional activators have been described. These include arsenic, bismuth, tin, lead (1), silver (2), uranium (3), and cerium (4). Copper has been mentioned as an activator of hydroxyphosphates (1) but has not been found previously to be very effective as an activator of halophosphates.

This paper describes a number of new copper-activated halophosphates prepared by heat treatment in mildly reducing conditions. Under similar conditions improved tin and tin-manganese activated halophosphates also have been prepared. Some of

these phosphors are of potential importance for use in discharge lamps of both high- and low-pressure mercury vapor types.

Preparation of Copper- and Tin-Activated Halophosphate Phosphors

Phosphors of this type were prepared by conventional halophosphate techniques, but firing treatments were carried out in mildly reducing atmospheres of nitrogen containing a low concentration of hydrogen. Tin-activated phosphors require about 0.5% vol/vol of hydrogen to nitrogen, while copper-activated phosphors, which are more sensitive to reducing conditions than those containing tin, require lower concentrations of hydrogen. With copper, the best results were obtained with about 0.25% vol/vol or less of hydrogen to nitrogen. Excessive reduction of copper and tin compounds is evidenced by discoloration of the samples, and this effect frequently can be corrected by subsequent refiring in "pure" nitrogen. Although nitrogen of the highest commercial purity was used throughout these experiments, it is possible that traces of oxygen present in the gas may contribute to the balance between reducing and oxidizing conditions necessary to maintain copper in the required valency state. It would seem probable that copper in the cuprous state and tin in the stannous state may be the conditions necessary for activation of these phosphors.

The useful ranges for copper and tin are from 0.1 to 1.0% (by weight) for copper and 0.5 to 5.0% for tin. Part of the copper is lost by volatilization during the firing treatment, and this may amount to as much as 50% of the initial quantity added. Preliminary analytical determinations suggest that part of the copper which remains may be present in the cuprous state. Firing temperatures depend on the nature of the halophosphate matrix but were usually in the range of 900° to 1200°C. Samples usually were prefired at a low temperature (900°C) to stabilize the matrix composition of the phosphors.

Fluorescence of Copper- and Tin-Activated Halophosphates

Copper- and tin-activated halophosphates of the alkaline earth metals (Ca, Sr, and Ba) were prepared with varying fluorine and chlorine ratios. X-ray examination of the more interesting phosphors confirmed that the apatite structure had been formed, and no noteworthy matrix impurities other than apatite phases were detected. The results of the various combinations tested are summarized below.

Calcium halophosphates.—Of this group, phosphors with a high chlorine content gives the best results. Copper activation produces a moderate blue fluorescence with short u.v. (2537Å) excitation, and the strongest emission occurs at a fluorine to chlorine molar ratio of 0.3:0.7.Manganese, in addition to copper, modifies the color to orange. Tin, by itself, gives a weak blue fluorescence which is modified to an orange-pink color by the addition of manganese.

Strontium halophosphates.—The best results are obtained in this group with strontium fluorophosphate activated with tin and manganese. Excitation by short u.v. radiation produces a strong yellow-green to orange-yellow fluorescence as the manganese content is increased. Replacement of fluorine by chlorine diminishes the brightness of these phosphors markedly. Copper, alone, (in strontium halophosphates) gives a weak red fluorescence with long u.v. excitation (3650Å).

Barium halophosphates.—These phosphors are more responsive to the effect of copper activation and give a moderately strong orange-red to red emission with long u.v. excitation. Tin, by itself, produces a moderate blue fluorescence in barium fluorophosphate and a strong greenish blue fluorescence with barium chlorophosphate. Manganese, in addition to copper or tin, is ineffective as an activator in these materials.

Among other phosphate combinations which were investigated with copper activation, calcium orthophosphate gives a strong blue fluorescence with short u.v. excitation which is modified to a pink fluorescence by the addition of manganese. This phosphor has also been described by Uehara and Kofuya (5).

Excitation and Emission Characteristics

Copper activation.—Two distinct types of emission are observed in the copper activated halophosphates, a blue or blue green emission in calcium halophosphates excited by short u.v. and a red emission in barium halophosphates excited by long u.v. radiation (Fig. 1, peak values normalized). With barium halophosphates the peak of the excitation curve for the red emission occurs at about 3000Å and declines rapidly at shorter wave lengths. In the presence of sulfate ions (added as copper or barium sulfate) these phosphors also show a weak blue fluorescence when excited by short u.v. radiation (2537Å). A

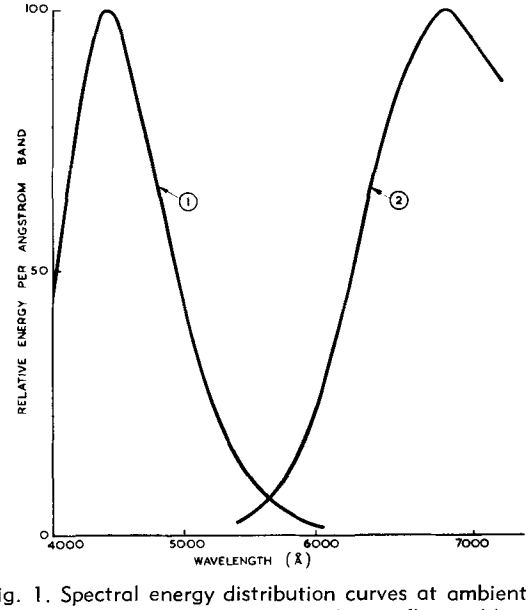

Fig. 1. Spectral energy distribution curves at ambient temperature of: 1. copper-activated calcium fluoro-chlorophosphate excited by 2537Å radiation $3Ca_3(PO_4)_2 \cdot 0.3\ CaF_2 \cdot 0.7\ CaCl_2$ (0.5% Cu by weight of matrix, as introduced), fired at 1200°C (0.1% vol/vol of H_2 to N_2; 2. copper-activated barium chlorophosphate, excited by 3650Å radiation (0.4% Cu, as introduced, fired at 1100°C, 0.25% vol/vol of H_2 to N_2).

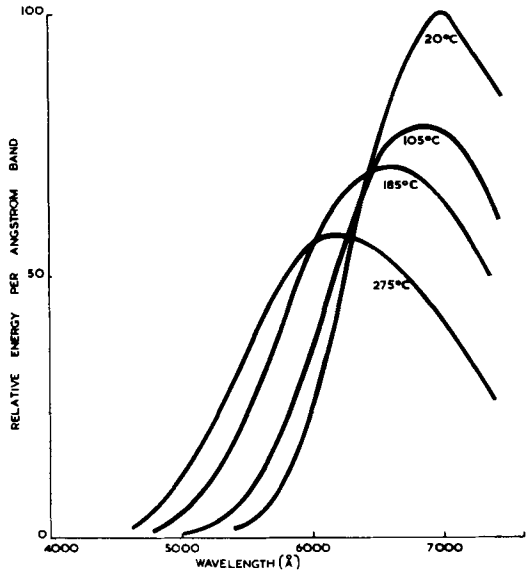

Fig. 2. Change of spectral energy distribution of copper-activated borium chlorophosphote with temperature, excited by 3650Å radiation (0.4% Cu, as introduced, fired at 1100°C, 0.2% vol/vol H_2 to N_2).

weak green emission is also obtained under short u.v. excitation if an attempt is made to compensate for charge difference between the monovalent cuprous ions and the divalent barium ions by the addition of trivalent cations such as cerium or lanthanum.

An unusual feature of the emission spectra of these phosphors is the marked shift in the position of the long u.v. excited band as the temperature of the phosphor is raised. This is most pronounced with barium chlorophosphate (Fig. 2) and is accompanied by an increase in visual brightness due to this shift in color from red toward the yellow.

Brightness-temperature measurements for copper-activated barium halophosphates, shown in Fig. 3, were made visually with a modified Macbeth photometer using suitable matched color filters of known transmission values. Curve 1 was normalized to give a peak value of 100, and curve 2 is relative to curve 1 on the same scale. With copper-activated barium chlorophosphate, the maximum brightness amounts to some three times the brightness at ambient temperatures and the maximum is reached at about 300°C. The corresponding fluorophosphate phosphor

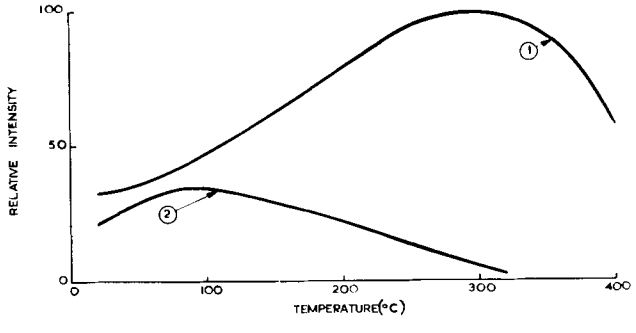

Fig. 3. Variation of visual brightness with temperature of: 1. copper-activated barium chlorophosphate, excited by 3650Å radiation (0.4% Cu, as introduced, fired at 1100°C, 0.2% vol/vol H_2 to N_2; 2. copper-activated barium fluorophosphate, excited by 3650Å radiation (0.4% Cu, as introduced, fired at 1100°C, 0.2% vol/vol of H_2 to N_2).

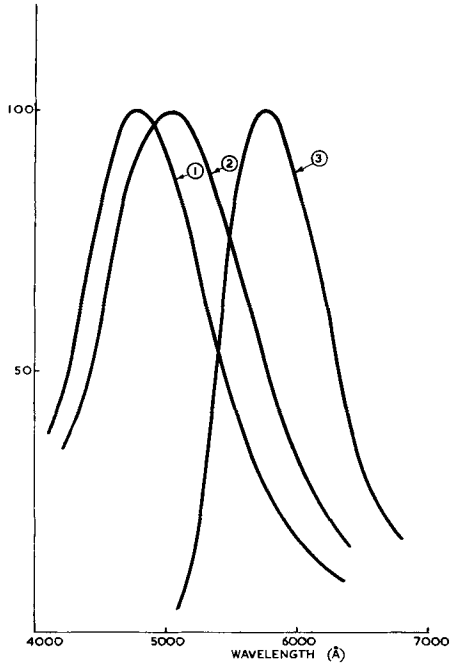

Fig. 4. Spectral energy distribution curves at ambient temperatures of: 1. tin-activated barium fluorophosphate, excited by 2537Å radiation (1% Sn, as introduced, fired at 1200°C, 0.5% vol/vol H_2 to N_2); 2. tin-activated barium chlorophosphate, excited by 2537Å radiation (1% Sn, as introduced, fired at 1150°C, 0.5% vol/vol H_2 to N_2). 3. Tin- and manganese-activated strontium fluorophosphate, excited by 2537 Å radiation (1% Sn, 2% Mn, as introduced, fired at 1050°C, 0.2% vol/vol of H_2 to N_2).

shows a much smaller change in color and has poorer temperature characteristics. These temperature effects are not critically dependent on activator concentration, although somewhat poorer results are obtained with high concentrations of copper. Phosphor samples which were heated in air during these measurements showed no marked permanent deterioration in brightness in the temperature range used for these observations.

Blue fluorescing calcium orthophosphate also shows good temperature characteristics and resembles in this respect certain copper activated aluminosilicates described by Claffy and Schulman (6). Instability of the calcium orthophosphate phosphor itself is evidenced by discoloration which occurs after baking the phosphor in air at temperatures of about 400°C.

Tin activation.—Barium halophosphates activated with tin are strongly excited by short u.v. radiation to give broad emission bands in the blue or blue-green regions of the spectrum (Fig. 4, peak values normalized). Barium chlorophosphate, activated with tin, like the corresponding copper activated phosphor, shows a marked shift in the position of the spectral band toward shorter wave lengths as the temperature is raised (Fig. 5). In this case, however, the shift in color is away from the green, and a reduction in visual intensity occurs (Fig. 6). Nevertheless, the phosphor is superior in temperature characteristics to most other blue emitting phosphors which are relatively poor in this respect, notable exceptions being copper-activated calcium orthophosphate and the aluminosilicates referred to above.

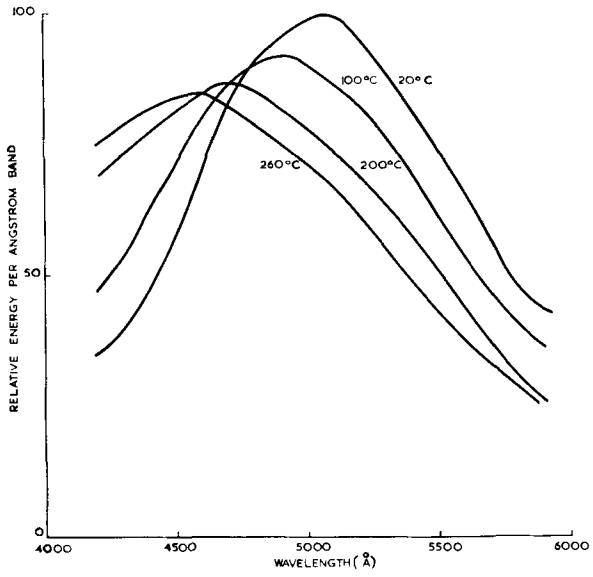

Fig. 5. Change of spectral energy distribution of tin-activated barium chlorophosphate with temperature, excited by 2537Å radiation (1% Sn, as introduced, fired at 1150°C, 0.5% vol/vol of H_2 to N_2).

Strontium fluorophosphate activated with tin and manganese is of potential importance because of the strong yellow emission excited by short u.v. radiation. The spectral energy distribution of a phosphor containing 1% by weight of tin and 2% by weight of manganese, fired at 1075°C, is shown in Fig. 4.

Applications in Lamps

Certain of the phosphors described above are of potential practical interest for use in discharge lamps. Barium chlorophosphate activated with copper, for example, applied to high-pressure mercury lamps is capable of utilizing the longer wave-length u.v. radiation (beyond 3000Å) from these lamps to give improved color rendering properties. In this instance it is an advantage to operate the phosphor at a relatively high temperature (ca. 250°C) in order to obtain the maximum light output.

Of the short u.v. excited phosphors, tin- and manganese-activated strontium fluorophosphates may be useful in mixtures with conventional red emitting phosphors to provide colors suitable for use in lamps of good color rendering qualities of the "De Luxe" types. The chromaticity values of 40-w fluorescent lamps coated with phosphors of varying manganese contents lie on an arc above the black body locus of the C.I.E. chromaticity diagram. The values range from $x = 0.400$, $y = 0.433$ for a phosphor containing 1.0% by weight of Mn to $x = 0.433$, $y = 0.445$ for a similar phosphor containing 2.0% Mn. Phosphors of this type show an appreciable and fairly rapid reduction in brightness when exposed externally to short u.v. radiation from a low-pressure mercury vapor quartz discharge tube. The effect occurs in air or in an evacuated quartz tube and is accompanied by a slight brown discoloration of the phosphor. After the initial reduction in brightness, further exposure produces little subsequent change. The effect is consistent with a chemical change in the surface state of the phosphor produced by the short u.v. radiation and may be similar to the formation of "color centers" produced in other materials by x-rays or cathode rays.

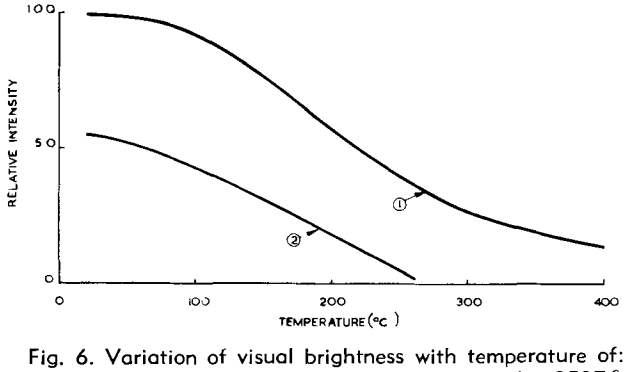

Fig. 6. Variation of visual brightness with temperature of: 1. tin-activated barium chlorophosphate, excited by 2537Å radiation (1% Sn, as introduced, fired at 1050°C, 0.2% vol/vol of H_2 to N_2); 2. tin-activated barium fluorophosphate, excited by 2537Å radiation (1% Sn, as introduced, fired at 1100°C, 0.2% vol/vol of H_2 to N_2).

Lumen maintenance characteristics of lamps coated with these phosphors show a rapid drop in efficiency during the first 100 hr of operation but this is succeeded by a relatively slow depreciation. In 40-w lamps "initial" (100 hr) efficiencies of 40-45 lpw have been obtained with these phosphors. After 4000 hr operation, lamp efficiencies were about 80% of the "initial" values. Of the other phosphors described, tin-activated barium chlorophosphate gives an "initial" efficiency in 40-w lamps of 45 lpw with a chromaticity value of $x = 0.250$, $y = 0.345$. The good temperature characteristics of this phosphor also make it potentially useful in high-pressure mercury vapor lamps.

Discussion

It has been shown that the temperature characteristics of barium chlorophosphates activated with copper and tin are markedly superior to the corresponding fluorophosphates. Both copper- and tin-activated barium chlorophosphates show a pronounced color shift as the temperature is raised. Uranium-activated barium halophosphates (3) also were tested for temperature dependence of fluorescence, but both fluoro- and chlorophosphates were markedly inferior to the copper- and tin-activated chlorophosphates and fluorophosphates. These observations support the view that temperature quenching effects are not a property of the lattice as such but of the emission centers and their surroundings (7). These differences in surroundings produce the marked difference in temperature characteristics between fluoro- and chlorophosphates activated with either copper or tin. As these phosphors are chemically and structurally similar, the differences observed may therefore be associated with the changes in spatial atomic arrangements in the matrix due to the replacement of fluorine by chlorine atoms in the apatite structure.

Besides the question of temperature properties the difference in emission characteristics between the various copper-activated phosphates is also of interest. Blue emission observed in halophosphates and calcium orthophosphate is typical of a number of

other copper-activated phosphors previously reported (1, 6). The long u.v. excited red emission observed in barium and to some degree in strontium halophosphates is more unusual. As both types of emission are obtained under certain conditions of preparation in the same barium halophosphate phosphor, it would seem that two different types of copper centers may be responsible for the blue and red emission bands. As the atmosphere conditions observed in the preparation are the same throughout, it may be assumed that copper is present in the same valency state in these phosphors. If this is so, the possibility of copper atoms occupying alternative sites in the halophosphate lattice might explain the observed differences in excitation and emission characteristics.

Electrical Properties of High-Purity Silicon Made from Silicon Tetraiodide

L. V. McCarty[1]

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Resistivities, type of conduction, and lifetimes of minority carriers of single crystals of iodide silicon are recorded as a function of the purification procedure for silicon tetraiodide. Samples of silicon have been prepared by decomposition of silicon tetraiodide on hot tantalum and hot quartz surfaces in vacuum. Distillation in a 12 plate quartz column of silicon tetraiodide prepared from 99.7% silicon results in single crystals of silicon that are uniformly n-type with maximum resistivities at the seed end in the range 0.3-1 ohm-cm. Two recrystallizations from solvents before the distillation step result in both p- and n-type crystals with, respectively, 150-650 ohm-cm and 75-170 ohm-cm resistivity ranges at the seed ends. Distillation of silicon tetraiodide is particularly effective in removing boron, while recrystallization and zone melting are effective for removing group V impurity iodides.

Silicon tetraiodide has been recognized as a potential source of semiconductor silicon for several years. Litton and Andersen (1) first made iodide silicon from silicon powder using iodine vapor in a Van Arkel-de Boer type of apparatus and observed some purification, but, unfortunately, both donor (group V) and acceptor (group III) impurity elements were transferred in the operation. In order to improve the quality of their product they decided to isolate silicon tetraiodide, which probably carried the silicon through the vapor phase of their iodide cells, and to purify it by fractional distillation in an all-quartz column. The electrical properties of their product indicate that they met with considerable success.

Later Szekely (2) reported on the hydrogen reduction of silicon tetraiodide, but electrical data with which one might calculate the purity of the product are not included.

A different approach to the purification problem was adopted by Rubin and his associates (3). They took advantage of the solubility of silicon tetraiodide in toluene from which it can be recrystallized as the first step in their procedure. Their final steps are sublimation and zone melting of the solid, but the electrical properties of silicon made from their purified material are not discussed.

In this work still another sequence of purification steps has been used to prepare silicon tetraiodide for decomposition into silicon and iodine. These techniques include recrystallization from n-heptane and distillation in an all quartz column, and a very brief investigation of zone melting. Electrical properties of single crystals grown from the silicon are interpreted as a measure of crystal purity rather than depending on chemical analyses for individual elements, because the estimated quantity of electrically active impurities is in the range of parts per ten billion for elements that affect the resistivity of this silicon, and even less for those that affect the recombination of holes and electrons. It is true that the electrical properties do not give much detail concerning specific impurity elements, but the tests are more readily made and indicate the presence of broad classes of electrically active impurities. Any one of these would be much more difficult to detect

[1] Present address: Lamp Development Department, General Electric Company, Nela Park, Cleveland, Ohio.

chemically, and, if undetected, might render the silicon quite useless as a semiconductor. The objective of this work was the preparation of the purest silicon possible.

Experimental

Preparation of silicon tetraiodide.—The method of making silicon tetraiodide is quite similar to the one described by Szekely (2). A nitrogen purge was used instead of argon, and a reaction temperature of 600°C was sufficient when the Electrometallurgical Company's 99.7-99.9%, 30-80 mesh silicon powder was used. When DuPont hyper-pure silicon crystals were placed in the reactor, a temperature of 800°C was required to achieve about the same reaction rate. The higher temperature may have been necessary because there is less impurity present to act as catalyst in the latter silicon, but it was also much coarser and did not pack as well.

Recrystallization of silicon tetraiodide.—Silicon tetraiodide was dissolved in sufficient solvent in a Pyrex flask to make a 50 mole % solution at the boiling point. After cooling to room temperature the solvent is drained off, and residual solvent and tetraiodide are transferred to the distillation apparatus after two or more recrystallizations.

Solvents used include Phillips Petroleum 99+% n-heptane, Phillips Petroleum commercial heptane, and reagent grade toluene and benzene.

Distillation of silicon tetraiodide.—The distillation apparatus for most of this work is made entirely of quartz. The smaller column consists of a one liter pot sealed to a 4-ft length of 1 in. OD tubing which is packed with ¼ in. sections of ¼ in. tubing (Raschig rings). The condensing head is a conventional design with a magnetically operated quartz valve to control the take-off, and an electrically heated delivery tube to conduct the tetraiodide into its receiver flask. The larger column is made from a 5 liter pot sealed to a 2 in. OD tube 66 in. long. Both columns have a rectification efficiency equivalent to 12 theoretical plates as tested with a mixture of methycyclohexane and normal heptane. Either is purged with nitrogen before tetraiodide is melted or distilled into the pot, and a flow of 20-30 cc/min is maintained throughout the distillation. The apparatus remains on total reflux overnight before starting the first cut. The minimum reflux ratio is 24:1 while product is taken off at 50-150 g/hr into quartz storage flasks. A first cut of 25% of the charge is discarded, and the second cut, which is later decomposed to silicon and iodine, contains 50% of the tetraiodide.

Decomposition of SiI_4 on tantalum.—The deposition on tantalum is similar in many respects to the technique described by Litton and Andersen (1). A tantalum rod, ⅛ in. in diameter by 3 ft, in the form of a hairpin is suspended in an evacuable chamber by means of a 65/40 ball and socket joint to which are sealed ¼ in. molybdenum electrodes. The 2 in. OD deposition chamber and the reservoir for silicon tetraiodide are an integral unit made of quartz.

After drying the equipment thoroughly, silicon tetraiodide is transferred into its reservoir in a dry nitrogen atmosphere. The tantalum hairpin is placed in position next using silicone grease or, preferably, a silicone rubber gasket on the ball joint. A dry ice bath is placed around a trap to condense iodine and unreacted silicon tetraiodide, and the system is pumped down to about 1 μ. The tantalum rod is heated electrically to 950°C as observed without correction by an optical pyrometer, and, last, the tetraiodide is warmed to about 100°C. The estimated vapor pressure of tetraiodide in the system is of the order of 1 mm.

After all of the iodide in the pot has sublimed, the electrical power is turned off, permitting the silicon and tantalum to cool to room temperature. Cracking noises are heard as the two partially separate due to thermal fracture. When cool, the system is filled with dry nitrogen, and the tantalum rod and silicon are removed and wrapped in a sheet of polyethylene. Gentle flexing separates the silicon from the rod, and the larger spears are broken up. The yield of silicon is about 80-90% in a 20-30 hr run.

Decomposition of SiI_4 on quartz.—For reasons discussed later, tantalum did not seem to be the ideal deposition surface. Quartz is used at much higher temperatures in the crystal growing operation than are needed for the decomposition of silicon tetraiodide, so it seemed reasonable to use it for the latter operation because the requirements are not nearly so severe. Figure 1 shows the kind of equipment designed after preliminary experiments. The silicon tetraiodide storage pot and reactor tube are an integral unit made of quartz. A socket joint is ring sealed into the bottom of the reactor to support a thin walled quartz tube on which deposition actually occurs. The purpose of the tube within a tube construction is to keep the outer portion of the reactor from breaking when the furnace is allowed to cool after silicon has deposited. Silicon adheres to quartz very strongly and, since the coefficients of expansion are different, the deposit and tube fracture on cooling. A tungsten spiral in 1½ in. OD tubes kept fragments from falling into the flask.

The spiral winding on the connection between the decomposition apparatus and the trap is a nichrome ribbon to keep the tube warm and thus prevent condensation of unreacted silicon tetraiodide. The refrigerant usually used around the trap is trichloroethylene-dry ice, and during operation the pressure is of the order of 1 μ or less at the vacuum gauge, but it is much higher in the reactor.

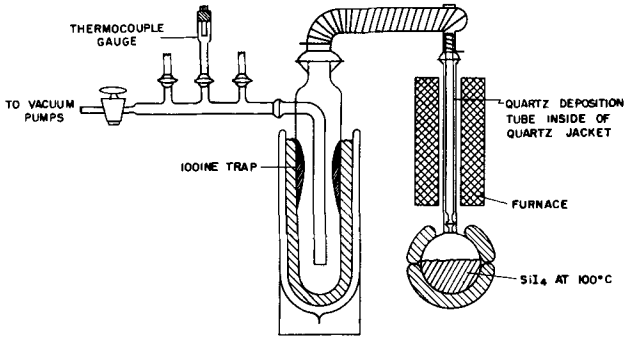

Fig. 1. Apparatus for deposition of silicon on quartz

At the end of a run the silicon with quartz adhering to it is placed in concentrated hydrofluoric acid for a day or two to dissolve the latter. Next it is thoroughly washed with water, then methyl alcohol, and air dried. The yield from 1000 g of SiI_4 is about 70% in a three day run at 1000°C. The reaction probably takes longer on quartz than on tantalum because the corrected temperature for the silicon deposit on the latter may be well above 1000°C.

Cleaning of equipment.—All equipment was thoroughly cleaned after each use with either 1% or 5% hydrofluoric acid followed by rinsing with water and drying by baking wherever possible. The hope was to standardize the surface of the vessels for each experiment rather than making it a function of the history of the equipment.

Crystal growing.—All crystals for this work were prepared in quartz crucibles by the Czochralski technique (4). A stainless steel pull rod held the single crystal seed, and the furnace atmosphere was argon. Heat was supplied to the crucible by a graphite resistance element supplied with a-c power from a Variac stabilized with a Sorensen regulator.

Electrical measurements.—Resistivities were generally measured with a calibrated four-point probe on a lapped surface. Occasionally there was reason to suspect the values obtained, and in these cases resistivities were checked by passing a small current through the sample and measuring the potential drop along the surface.

The relationship between the number of uncompensated impurity atoms per cubic centimeter and the resistivity (above 10 ohm-cm) can be approximated by (5, 6)

$$n = \frac{1}{\rho e \mu_n} \approx \frac{3.6 \times 10^{15}}{\rho} \qquad [1]$$

$$p = \frac{1}{\rho e \mu_p} \approx \frac{1.3 \times 10^{16}}{\rho} \qquad [2]$$

where ρ is the resistivity, e is the charge of one electron in coulombs, and μ_n and μ_p are the mobilities of electrons (~1750 cm^2/v sec) and holes (480 cm^2/v sec) at room temperature, respectively.

Another measurement which typifies the quality of silicon single crystals is the lifetime of the minority carriers. The method used for this measurement has been described by Watters and Ludwig (7) who give detailed data as a function of temperature for sample 3 of Table V, which is referred to as C-Si-170.

Drift and conductivity mobility data for C-Si-170 have also been determined by Ludwig and Watters (8).

Results and Discussion

Spectrographic Data

Impurity elements detected spectrographically in a typical sample of Electromet silicon as received, and after processing by conversion to silicon tetraiodide with subsequent decomposition to silicon, are shown in Table I. The four elements in the right-hand column were detected in a sample of iodide silicon made from unpurified silicon tetraiodide. When recrystallization from solvents or distillation of the tetraiodide were incorporated in the process, the aluminum concentration occasionally dropped so low as to become undetectable. The data show that the iodination and decomposition processes are powerful purification steps in their own right merely from the number of elements rejected. But for semiconductor purposes these spectrographic analyses of iodide silicon have only a very limited value because they are insufficiently sensitive.

Iodide Silicon Made from Unpurified Silicon Tetraiodide

The most difficult element to remove from silicon by zone melting or crystal growing techniques is boron, and it is almost imperative that it be removed from the compounds used to make silicon before the actual preparation. It is not difficult to recognize a crystal whose resistance is dominated or controlled by boron, however, because its segregation coefficient is about 0.9 (9), and such crystals have a characteristically "flat" resistivity profile.

Because of the importance of removing boron from silicon, it was desirable to determine how the various purification steps affect its removal. In order to establish a base line for comparison purposes, enough silicon was prepared by decomposition of unpurified silicon tetraiodide on quartz so that elements other than boron could be removed by 5 zone passes in a zone melting apparatus. A single crystal grown from the zone melt bar was p-type and had resistivities in the range 0.25-0.14 ohm-cm, about 0.20 ohm-cm on the average. (In this paper the first resistivity quoted will be for the "seed" end of the crystal, while the second number refers to a measurement near the "sprout", or tail end. In general, impurities segregate toward the sprout.) The conductivity mobility, μ_p, for this resistivity range (5) is about 350 $cm^2\ v^{-1}\ sec^{-1}$, and the number of boron atoms per cubic centimeter, p, can be calculated as

$$p = \frac{1}{\rho e \mu_p} = \frac{1}{0.20 \times 1.60 \times 10^{-19} \times 350} = 9 \times 10^{16}$$

or about 1.7 boron atoms per million silicon atoms. Rubin, Moates, and Weiner (3) found considerably more boron than this in their silicon tetraiodide

which was made from a different grade and different kind of silicon.

Iodide Silicon Made from Distilled Silicon Tetraiodide

In the first attempts in the present experiments at purification of silicon tetraiodide distillation in an all-quartz, 12 plate column was used. Results are shown in Table II. Two things about this data are impressive: all samples are n-type, and the resistivities near the seed end of the crystal (the first number quoted) are reasonably uniform. This means that some group V element, a donor impurity, is the chief contaminant rather than boron. The relatively slow decrease in resistivity along the crystals of samples 1, 5, and 7 indicates a material with a segregation coefficient similar to phosphorus or arsenic (9).

James and Richards have shown that phosphorus can be found in amounts of 0.1 to 10 ppm in iodine (10), and the very careful analysis of 97% silicon performed by the Bureau of Standards (11), as well as the work of Rubin, Moates, and Weiner (3), indicates that this quality of silicon can have as much as 80 ppm of phosphorus. The latter authors (3) also have shown the presence of 150 ppm of arsenic which is mostly eliminated by the iodination reaction.

Either n-type impurity as an iodide might be contaminating the crude silicon tetraiodide. Phosphorus triiodide is more volatile than silicon tetraiodide (1), and it should tend to concentrate in the condensing head of the apparatus. If it were not completely removed from the condenser through faulty technique, the electrical conductivities of Table II ought to show considerable scatter. Since they do not show a broad range of values, it seems more reasonable to believe that the source of n-type contamination is in the crude tetraiodide in the still pot, which should come to equilibrium with the still head during the prolonged initial operation at total reflux. Arsenic triiodide is less volatile than silicon tetraiodide (1). It would concentrate in the still pot, and it may be the n-type impurity responsible for these results.

Potassium iodide was added to the distillation pot of the last sample in an attempt to form complexes with group V iodides which would reduce their vapor pressure.

In order to determine the amount of boron in these samples it is necessary to prepare enough silicon for zone melting to remove n-type impurities. It would have been extremely tedious to do this with the original small quartz equipment, so a large 12 plate Pyrex column was used for the distillation. The use of Pyrex introduces certain complications which will be discussed later, but it is believed that the boron concentration obtained after zone melting represents the maximum amount coming through the distillation step. Sample No. 4 of Table VI was prepared in this way. Its maximum resistivity of 125 ohm-cm, which dropped only gradually over the first part of the crystal, corresponds to about 2 boron atoms per billion silicon atoms. This represents a reduction in the boron concentration by a factor of approximately 850 by a 12 plate distillation. Because of the experimental errors involved, however, it might be better to say that the factor is in the range 500 to 1000.

Litton and Andersen (1) have given a value of 6.8 for the relative volatility of boron triiodide compared to silicon tetraiodide. By assuming that the same relative volatility applies to a dilute solution of boron triiodide at 300°C, one can write

$$\frac{\dfrac{\text{mole fraction of } BI_3 \text{ in vapor}}{\text{mole fraction of } SiI_4 \text{ in vapor}}}{\dfrac{\text{mole fraction of } BI_3 \text{ in liquid}}{\text{mole fraction of } SiI_4 \text{ in liquid}}} =$$

$$\frac{\text{mole fraction of } BI_3 \text{ in vapor}}{\text{mole fraction of } BI_3 \text{ in liquid}} = 6.8$$

since the mole fraction of silicon tetraiodide is within parts per million of being unity in either phase. The number of effective plates realized from the observed separation in the "12 plate" column is:

$$6.8^x \sim 850$$

$$x \sim 3.5 \text{ effective plates}$$

If the total purification achieved in the best samples reported in this study were ascribed to the action of the distillation column, less than 4.5 plates would be required for the removal of boron triiodide to the indicated levels.

Green and Kafalas (12) have shown that the separation factor, α, for dilute solutions of arsenic trichloride in germanium trichloride is remarkably lower than in solutions containing an excess of arsenic trichloride. The α for the system boron triiodide-silicon tetraiodide may behave similarly, in which case many more theoretical plates would be realized than indicated.[1]

There are two other reasons that might be advanced for the discrepancy between the calibrated effectiveness of the column and that actually realized. The mixture of hydrocarbons is so different in physical properties from silicon tetraiodide that our calibration may indicate many more plates than can ever be realized in systems consisting mostly of silicon tetraiodide.[1] The other reason concerns the reduction and solution of boron impurities in quartz boats and crucibles containing molten silicon (13).

[1] The author is indebted to C. S. Herrick and J. G. Krieble for this suggestion.

Table III. Effect of tantalum doping on the electrical properties of silicon

	Type	Resistivity, ohm-cm	Lifetime of minority carriers, μsec
Starting material	p	150	125
Portion of crystal before Ta doping	p	150	150
After doping with 0.1% Ta	p	140	10

This effect may add a small amount of boron which places a limit on what can be achieved experimentally when molten silicon contacts quartz equipment as one of the processing steps.

Tantalum as an Impurity in Silicon

Litton and Andersen (1) have indicated that there is a discontinuous alloy zone formed at the tantalum-silicon interface during deposition. Neutron activation analyses of silicon removed from our tantalum rods showed that tantalum was present, and apparently in variable amounts[2] which supports their observation. In order to determine the effect of occluded alloy or metal, a silicon melt was doped with a small piece of tantalum metal when the crystal was partially grown (14). Table III gives data for the electrical properties of this crystal before and after tantalum doping. There is only a minor change in the resistivity of the silicon, but the lifetime of the minority carriers has dropped rather dramatically.

An n-type impurity in the tantalum metal could conceivably be diffusing through the metal-silicon interface to cause the low resistivities of Table II. Two samples of iodide silicon prepared on tantalum from distilled tetraiodide made from DuPont hyperpure silicon showed that this was not so, however. The resistivity range for an n-type single crystal was 114-8 ohm-cm, while a p-type crystal of another sample was in the range 200-100 ohm-cm.

Because of the tantalum contamination we decided to use another kind of deposition surface to try to avoid any adverse influence tantalum might have on the lifetime properties. Quartz is used at much higher temperatures in the crystal growing operation than is needed for the decomposition of silicon tetraiodide, so it seemed reasonable to use it for the latter operation because the requirements are not nearly so severe. Decomposition on quartz was used for all succeeding samples discussed in this paper.

Iodide Silicon Made from Recrystallized Silicon Tetraiodide

Residual solvent was removed from two samples of recrystallized silicon tetraiodide by heating to the boiling point and distilling a small portion to purge the apparatus. The first sample of Table IV indicates that two recrystallizations from a solvent are more effective than distillation in a 12 plate column, since this material contains less than one-fifth as many excess n-type impurities as the best example of Table II. [The mobility of the current carriers decreases as the resistivity drops in this range (9).] A detailed study of the effectiveness of two recrystallizations from other solvents was not carried out, but we believe that all would be approximately equally effective.

[2] W. W. Schultze performed the neutron activation analysis.

Table IV. Electrical properties of single crystals of iodide silicon prepared from recrystallized silicon tetraiodide[a]

Sample No.	Notes on purification of SiI_4	Type	Resistivity, ohm-cm	Lifetime of minority carriers, μsec
1	Recrystallized twice from toluene as a coarse powder; washed each time with 3 portions of n-heptane	n	5 max.	
2[b]	Recrystallized twice from commercial heptane, and then 6 times from n-heptane	n	94-130-94-22	200-75

[a] SiI_4 made from 99.8% Electromet Si and deposited on quartz.

[b] SiI_4 decomposed at 1200°C.

Eight recrystallizations from two kinds of heptane resulted in the second sample of Table IV which shows that the purity of the tetraiodide is a function of the number of recrystallizations. This sample had the same treatment as No. 4 of Table V except for the distillation step in the latter which seems to have removed the n-type impurity. Superficially the n-type sample appears purer because it has about 4×10^{13} excess carriers per cubic centimeter, while the distilled p-type sample has approximately 7×10^{13} excess carriers. Actually, the n-type sample might have as much as 11×10^{13} n-type carriers of which 7×10^{13} are compensated by p-type carriers.

Table V. Electrical properties of single crystals of iodide silicon prepared from recrystallized and distilled silicon tetraiodide[a]

Sample No.	Type	Resistivity, ohm-cm	Lifetime of minority carriers, μsec
	35 g lots of Si; n-heptane and commercial heptane as solvents:

10	p	245-85	110-25

[a] SiI_4 made from 99.8% Electromet Si, recrystallized twice except where noted, distilled in 12 plate quartz column, and decomposed on quartz.

[b] Normal heptane used as solvent.

[c] Commercial heptane used as solvent.

[d] Distilled n-heptane used as solvent.

[e] Recrystallized 2X from commercial heptane, 6X from n-heptane.

[f] Quartz flask used for recrystallization.

If this latter picture is correct, the p-type distilled sample really is the purer, of course.

Iodide Silicon Made from Recrystallized and Distilled Silicon Tetraiodide

Table V contains data for experiments in which two recrystallizations were combined with distillation in a 12 plate quartz column as the purification steps. Comparing these results with those of Table II it is clear that two recrystallizations are exerting a very profound effect on the quality of silicon produced. Apparently the main function of recrystallization is the removal of n-type impurities.

In all but one of the experiments Pyrex flasks were used for the recrystallizations. As the next section shows there is some reason to be concerned about the extraction of impurities from Pyrex, so one set of the recrystallizations was performed in quartz. Sample 1 shows that no marked improvement over other samples was realized by this treatment.

The solvents used might also place a limit on the purification of the tetraiodide. For this reason the n-heptane for sample 2 was carefully distilled before use, but no decrease in impurity content was detected.

Since increasing the number of recrystallizations had improved the quality when this was the sole purification used (cf. Table IV), eight recrystallizations were combined with a distillation for sample 4 for Table V. Apparently two recrystallizations are as effective as more when combined with distillation because sample 4 showed no improvement.

One rather serious criticism of the first three samples of Table V is that they are obviously compensated because the resistivities tend to increase in some portion of the crystal proceeding from seed end to sprout (the portion which freezes last). This difficulty was rather common for the smaller size lots prepared, but it seemed to resolve itself in the larger batches. It may simply reflect a somewhat improved operating efficiency in the larger distillation column.

It was shown that, with very careful preparation of high resistivity crystals, boron contamination from the crucible amounted to only 2 to 3 x 10^{13} atoms/cc of silicon (14, 13). This corresponds so closely to the better resistivities for p-type crystals that contamination from the crucible may limit the results achieved for many crystals of this work. [Data for crystals with higher resistivities, however, are contained in a paper by Herrick and Krieble (15).]

In any event the chief impurity left in our best p-type samples is probably boron. If this assumption is correct, the best sample of Table V has at least 4 boron atoms per ten billion silicon atoms, which is a decrease in the boron content by a factor slightly greater than 4000 compared to the original silicon and represents only a modest improvement over distillation alone for purification.

Iodide Silicon Made from Silicon Tetraiodide Distilled in Pyrex

The distillation column for this work was a Pyrex duplicate of the larger of our quartz columns.

Table VI. Electrical properties of single crystals of iodide silicon prepared from silicon tetraiodide distilled in Pyrex[a]

Sample No.	Type	Resistivity, ohm-cm	Lifetime of minority carriers, μsec
	Recrystallized samples:		
1[b]	p outside n core	3000-120 not measured	
2[c]	p outside n core	1200-1800-25 not measured	
3[d]	p outside n core	2200-3500-250 11-140-35	
	Zone melted samples:		
4[e]	p	125-46	150 (seed end)
5[e, f]	p	200-50	100-10

[a] 12 plate Pyrex still used for all samples

[b] Recrystallized 2X from toluene.

[c] Recrystallized 2X from commercial heptane; decomposition apparatus broke at 800°C exposing sample to air; etched 12% from sample used to grow crystal.

[d] Recrystallized 2X from n-heptane; sample exposed to air at 400°C when decomposition apparatus broke.

[e] No recrystallization step used; Si zone melted with 5 zones.

[f] SiI_4 recovered from first and third cuts of previous distillations.

The complex pattern of electrical resistivities observed in the first three samples of Table VI is probably caused by the presence of traces of both donor and acceptor impurities which segregate at differing rates from liquid silicon as it circulates by the growing crystal to produce compensated p-type crystals near the surface with n-type cores of much lower resistivity. Toluene has not been thoroughly investigated as a solvent for silicon tetraiodide in this work, and, as the notes indicate, difficulties were experienced in handling the other two samples. A single crystal could not be grown from sample 2 before it was etched. In spite of these difficulties we believe that these data are characteristic of iodide silicon made from Pyrex-distilled tetraiodide.

Samples 4 and 5 were zone melted[3] after their preparation from silicon tetraiodide that was purified by distillation in the Pyrex column. This treatment effectively removes n-type impurities and reveals the amount of boron present as a p-type impurity. While the resistivities of these samples are not the best that have been obtained in this work, it is clear that the extraction of boron from Pyrex glass is not a serious problem even though boric oxide is a major constituent of this kind of glass.

Since the first three samples exhibited a kind of compensation which was not observed in comparable samples prepared from tetraiodide distilled in quartz equipment, it seems that the extraction of an n-type impurity from Pyrex is the real problem. Green and Kafalas (12) have shown that germanium tetrachloride can extract arsenic from Pyrex glass, and they have also explained the earlier results of Cluley and Chirnside (16) who found that Pyrex equipment was not suitable for the removal of traces of arsenic even though reasonably effective for relatively large amounts. Assuming that the arsenic is present as the pentoxide in Pyrex, thermodynamic estimates

[3] W. C. Dash performed these operations and evaluated the material.

of the free energy of extraction of arsenic as the triiodide are more favorable for silicon tetraiodide than for germanium tetrachloride. (Of course, it can also be estimated that the free energy for the extraction of boron as the triiodide is favorable.) While the present work does not unequivocally demonstrate the extraction of an n-type impurity from Pyrex, we feel that this is the real problem rather than the extraction of boron even though this may indeed seem like a paradox.

In view of these comments on the use of Pyrex glass for distillation, the use of Pyrex recrystallizing equipment may seem questionable. The best results were obtained when recrystallization was followed by distillation of the silicon tetraiodide, and all that was demanded of recrystallization is an upgrading of the quality of silicon tetraiodide rather than providing the ultimate in purity. If recrystallization alone were to be used for purification it might be desirable to use quartz equipment and specially purified solvents.

Iodide Silicon Made from Silicon Tetraiodide Purified by Zone Melting

The zone melting equipment differs from the kind described by Rubin and Moates (3). The main quartz tube, 2⅜ in. OD by 36 in. long, was held in a horizontal position and was not quite half filled by 2.5 kg of silicon tetraiodide. Alternate freezing and thawing caused no trouble with tube breakage. The rate of zone travel varied between 0.68 and 1.14 iph, but most of the time it was kept very nearly at 0.80 iph. The gas space above the iodide was continuously flushed with 40-50 cc/min of hydrogen.

After ten zones had passed down the tube (two passes of a 5 element heating unit), most of the first 40% of the silicon tetraiodide was a light clear yellow with a small wedge of salmon pink material towards the middle of the tube. The "impure" end of the tube was salmon pink to red in color, and this portion was removed first by rotating the tube 180° about its long axis, tipping slightly, and melting the impure tetraiodide with an air gas flame. The tube was then tipped in the opposite direction and the "pure" tetraiodide was transferred to the apparatus used for decomposition on quartz.

A single crystal prepared from the product was p-type over its entire length and had the following resistivity profile: (seed end) 20-20-20-20-20-100 (sprout end). The relatively uniform resistivity values indicate that boron is the impurity controlling this property except near the sprout end, where compensation results from the segregation of an n-type impurity.

A rather bad feature of the present equipment is the amount of back diffusion occurring in the gas phase as evidenced by needle-like crystals growing above the surface of the refrozen tetraiodide. Impurities that are more volatile than silicon tetraiodide, such as boron triiodide, would contaminate these needles resulting in a smaller degree of purification than actually realized by the zone melting.

In spite of the limitations of the equipment used in this work, the purification achieved is impressive. The n-type impurities have been effectively eliminated, and the boron content has been reduced by a factor of approximately 130 since 20 ohm-cm corresponds to about 1.3 boron atoms per hundred million silicon atoms. If the same ratio continued for ten additional zone passes, the rejection of boron would be impressive indeed.

According to Pfann (17), the boron content will have reached some equilibrium distribution after a sufficient number of zones have passed through a bar of tetraiodide, depending on its distribution coefficient and the ratio of zone length to bar length. In our equipment the zones were approximately one tenth as long as the quartz tube. Rubin, Moates, and Weiner (3) have given two figures for the distribution coefficient of boron in a silicon tetraiodide matrix: 0.16 ±0.07 for the boron contained in a sample of crude tetraiodide, and 0.42 ±0.22 for a boron triiodide doped sample. At equilibrium, zone melting would reduce the average boron content of the first 40% of the bar by a factor 2.3 x 10^7 for the first coefficient, and 4.1 x 10^8 for the second. There is room for a modest amount of improvement or a really significant improvement depending, apparently, on the chemical species containing the boron.

It is interesting, although perhaps superficial, that both recrystallization from solvents and zone melting seem to be particularly effective in removing n-type impurity iodides from silicon tetraiodide.

Acknowledgments

The author is particularly indebted to Dr. C. B. Collins and Dr. F. H. Horn for the preparation of single crystals of silicon, for the measurement and interpretation of the electrical properties, and much valued discussion. Mr. L. C. Landauer and Miss J. M. Binkowski prepared many of the samples of silicon.

Manuscript received April 3, 1959. This paper was prepared for delivery before the New York Meeting, April 28-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Rare Earth Compound Semiconductors

J. F. Miller, F. J. Reid, and R. C. Himes

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Selenides of La, Er, and Y, and tellurides of La, Er, Gd, and Y were prepared by direct reaction of the elements. Measured electrical characteristics indicate semiconducting behavior, with the possibility that a wide range of properties can be obtained within these series of rare earth compounds. Observed room-temperature resistivities, for example, ranged from about 10^{-4} ohm-cm for La_2Te_3 and ErSe to the insulator range for Y_2Se_3. All the compounds prepared possess high melting points (1400°-2000°C) and exhibit good thermal stability. The dissociation pressure of Gd_2Te_3 at its melting point appears to be as low as 0.01 atm.

Semiconductors with interesting and potentially useful properties have been found within a number of classes of intermetallic compounds. Several of these groups of compounds, notably the III-V's and II-VI's, are currently receiving considerable attention. This is the initial report on a study which is concerned with the electrical properties of a group of compounds which has, to date, received little attention—namely, binary intermetallic compounds containing a rare-earth element. Specifically, this paper deals with the preparation and observed electrical properties of the selenides of La, Er, and Y, and the tellurides of La, Er, Gd, and Y.

Preparation

The compounds were first prepared in granular form by reacting selenium or tellurium vapor with filings of the rare earth metal at moderate temperatures. The advantage of increased reaction rate was thought, for these initial experiments, to overcome any disadvantage of contamination through filing. Reactions were carried out in sealed, evacuated Vycor tubes, which were designed so as to maintain physical separation of the liquid selenium or tellurium and the solid rare earth metal. This measure was taken to preclude the possibility of the rapid, violent reaction which takes place on direct contact of the condensed phases. To carry out the desired reaction, vapor of the metalloid was distilled over the rare earth metal filings; temperature was increased slowly to 950°C over a period of about 24 hr and was held at this level for an additional 72 hr.

The granular reaction product was then melted down and cast into ingots to obtain bulk specimens which were suitable for electrical evaluation. The melting was done in tantalum or graphite containers under argon at 1 atm pressure; induction heating was used. Although relatively high temperatures were involved, residence times at temperature were short. Under these conditions, there was little evidence of reaction between the compounds and properly outgassed tantalum (i.e., tantalum which had been outgassed above 1600°C in a hard vacuum). Graphite also appeared to be satisfactory as a container material.

Procedures discussed to this point were used for initial preparations of the compounds. Additional studies concerned with more refined preparation and characterization of the compounds are in progress. Initial work of this type was done with gadolinium telluride. Table II, discussed in greater detail later, includes data for a series of specimens of this compound taken from ingots which were prepared under various conditions noted in the table. The first of these specimens was taken from an ingot which was prepared by distilling tellurium vapor over molten gadolinium metal. Since temperature of the protective quartz envelope was not controlled, the pressure of tellurium vapor prevailing during this initial experiment is not known. The remaining specimens were cut from ingots which were cast by carefully controlled directional freezing under various known pressures of tellurium vapor. Freezing rates varying from ½ in. to 1-½ in./hr were used. In this range, crystallization rate did not appear to have a significant effect on properties of the compound.

Whereas tantalum apparently had been satisfactory as a container material in which simple melting of the compounds could be carried out, the tantalum boats were attacked severely during the prolonged periods of exposure to tellurium vapor encountered in freezing the ingots directionally. Graphite containers appeared to be more satisfactory for this purpose since they were not attacked noticeably.

Physical Properties

Melting points have been determined for three of the compounds. In making the determinations, specimens were placed in a horizontal cylindrical cavity at a depth equal to 12 times the diameter of the cavity so as to obtain near black-body conditions (1). The specimens were of triangular cross section and were supported by contact of the edges with the wall of the cavity. Incipient melting at the edges produced readily detectable movement of the speci-

Table I. Observed electrical properties (measured at room temperature) rare earth selenides and tellurides

Compound	R_H, cm^3 $coul^{-1}$	ρ, ohm-cm	μ, cm^2 v^{-1} sec^{-1}	α, μ v deg^{-1}	η, cm^{-3}

Y_2Te_3	−1400	10.0	140	—	4×10^{15}

mens. Temperatures were measured by means of an optical pyrometer and are estimated to have an accuracy of ± 25°C. Values obtained were: 1520°C for the melting point of Er_2Se_3, 1420°C for Gd_2Te_3, and 1525°C for Y_2Te_3. Indirect observations made in the course of the preparative work indicate that melting points for some of the other compounds may be higher, ranging up to about 2000°C.

Thermal conductivity of Gd_2Te_3 has been determined at room temperature by use of the "Z-meter" (2, 3). Values for n- and p-type specimens were found to be 0.026 and 0.023 watts cm^{-1} deg^{-1}, respectively. Since the lattice component of thermal conductivity usually predominates at room temperature for materials of this type, the nearly identical values are to be expected.

Electrical Properties

Table I presents a tabulation of electrical properties observed for some of the selenides and tellurides in their initial preparations as polycrystalline, cast ingots. It will be noted that resistivities for the sesquiselenides are somewhat higher than those for the corresponding tellurides. In general, resistivities, in both classes of compounds, increase with progression through the rare earth series, the yttrium compounds falling at the end.

The resistivity of Y_2Se_3 appears to be in the insulator range. In attempts to eliminate possible high contact resistance, a number of different methods of contacting specimens of this compound were used. Various techniques explored utilized pressure contacts with probes of Pt, W, Mo, Cu, Fe, Al; contacts of conducting silver paint; leads of Cu, W, Fe applied by spot welding; solder contacts of Pb-Sn, In, Al, Ga applied with various fluxes by both normal and ultrasonic soldering techniques. However, under applied potentials up to 60 v, there was in no instance a detectable current through the sample.

At the other extreme, resistivity for the monoselenide of erbium was found to be quite low. Low resistivities would be expected for the 1:1 compounds if only two of the valence electrons of the rare-earth atom are involved in the chemical bonds, leaving the third free to act as a charge carrier with rather low activation energy. Iandelli (4) also concluded that this was the case through analysis of structures and interatomic spacings for the cerium-group compounds.

Seebeck coefficients were measured over a range of temperatures for specimens of Gd_2Te_3 and La_2Te_3 and were found to remain constant up to 450° and 525°C, respectively, the highest temperatures to which measurements were extended. High-temperature thermoelectric properties of these rare earth compounds may be of practical interest and are being investigated currently.

It will be noted that carrier concentrations for most of the specimens are high. In synthesizing the compounds, high-purity selenium and tellurium were used (i.e., better than 99.99%). However, purity of available rare earth metals is relatively low (i.e., 99⁺%). It is therefore probable that carriers, other than those resulting from excess of one of the component elements, were introduced principally as impurities present in the rare earth metals or as contaminants incorporated during synthesis of the compounds.

Electrical data for specimens of Gd_2Te_3 from ingots cast under various pressures of tellurium vapor (Table II) indicate that, if evolution of tellurium is permitted (specimens 67, 88), *n*-type material is

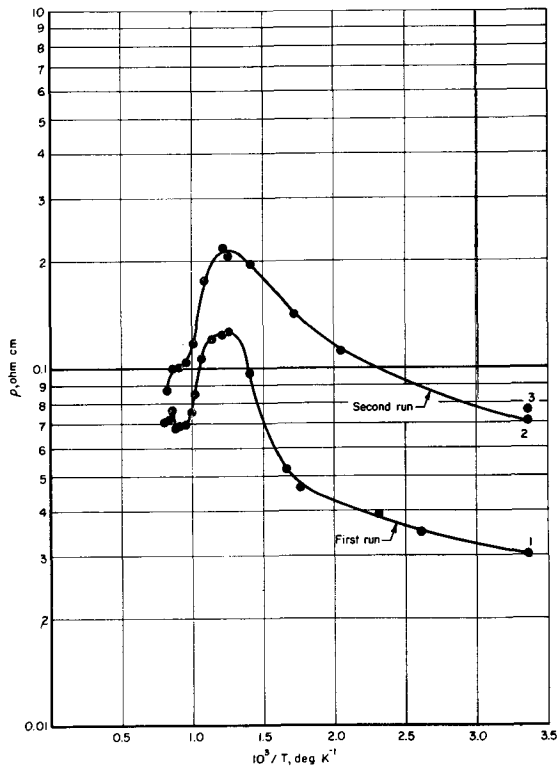

Fig. 2. Resistivity as function of temperature for n-type Gd_2Te_3.

obtained, but in the presence of moderate concentrations of tellerium vapor, (specimens 71-77), p-type material can be cast. However, dissociation pressure of the compound at its melting point appears to be relatively low since it was possible to cast a reasonably good p-type ingot (specimen 77) under only 0.01 atm of tellurium vapor pressure. Similarity of data for specimens from ingots which were cast under similar conditions in tantalum and graphite, (consider specimens 67 and 88, 74 and 75) indicates that any tantalum which may have been taken into solution, as a result of the aforementioned attack, had little effect on electrical properties of the compound at these carrier concentrations.

Figure 1 shows variation of Hall coefficient and resistivity with temperature for a p-type specimen of gadolinium telluride. Up to about 875°C, the curves are typical of those for an impure semiconductor. Above this temperature, however, behavior of resistivity is anomalous. As far as could be determined, the Hall coefficient continued to decrease (up to 950°C) and did not change sign. As temperature was decreased, resistivity followed the dotted curve, and room-temperature values for both Hall coefficient and resistivity were found to be lower following the run. (Points indicated by crosses, for both Hall coefficient and resistivity, were taken as temperature was decreased.) The variation of Hall mobility with temperature for this p-type specimen suggests that impurity scattering is important up to relatively high temperatures (i.e., at temperatures as high as several hundred degrees centigrade).

Figure 2 shows resistivity as a function of temperature for an n-type specimen of gadolinium telluride. Again, what appears to be typical behavior for an impure semiconductor was observed up to about 750°C, and anomalous variation of resistivity with temperature was noted through the range of higher temperatures. An irreversible heat-treating effect was also noted. Room-temperature resistivity was found to be considerably higher (point 2, Fig. 2) after the first temperature run. With the second

temperature run, the specimen appeared to be approaching a stable condition, as is indicated by the much less pronounced irregularity in variation of resistivity with temperature above 700°C, and the fact that room-temperature resistivity (point 3) returned to approximately its initial value (point 2).

The effects of heat treatment on electrical properties of a number of specimens of gadolinium telluride were studied in an attempt to explain the observed behavior. Data for the heat-treated specimens, which are presented in Table III, indicate that after a sufficiently long period of heat treatment, the samples approach a stable condition.

Because of conflicts in the data (e.g., changes in carrier concentrations vs. changes in mobilities), it is not possible to reach a firm conclusion concerning the nature of heat treating effects. However, it may be seen that for the n-type specimens resistivity is increased and carrier concentration is decreased by heat treatment in vacuum, and for the p-type specimens resistivity is decreased and carrier concentration is increased by the same treatment. Such changes are consistent with loss of n-type impurities. This is a possibility since spectrographic analyses show that relatively high concentrations of Ca, Mg, Fe, Ni, Ta, Si, and Al are present in the specimens.[1] Since tellurium has already been shown to give p-type doping, loss of tellurium is not suspect as a cause for the changes observed.

Manuscript received June 15, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959. This investigation was supported by the Rare-Earth Research Group (Davison Chemical Co., Union Carbide Metals Co., Heavy Minerals Co., Lindsay Chemical Div. of American Potash and Chemical Corp., Mallinckrodt Chemical Works, Rare Earths and Thorium Div. of Michigan Chemical Corp., and Molybdenum Corp. of America).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Diffusion of Cerium and Zirconium in Molten Uranium

Tennyson Smith

Atomics International, A Division of North American Aviation Incorporated, Canoga Park, California

ABSTRACT

Coefficients for the diffusion of cerium in molten uranium have been measured over the temperature range 1170°-1480°C. An equation relating the diffusion coefficient with temperature is: $D = 4.5 \times 10^{-3}\, e - 11{,}000/RT$. At 1200°C the diffusion coefficient for cerium in uranium is $(1.00 \pm 0.17) \times 10^{-4}$ cm²/sec. An estimate of the coefficient of diffusion for zirconium in uranium at 1270°C is $(1.9 \pm 0.9) \times 10^{-4}$ cm²/sec. A discussion of experimental errors involved in measuring diffusion coefficients at high temperatures is given.

A study has been made of the reactions and mechanism involved in the oxide-drossing of fission products from uranium. The oxide-drossing process is a pyrometallurgical method of reprocessing spent uranium with an oxide such as urania, zirconia, or alumina. Those fission products that are more stable than the oxide used are removed selectively from the melt. Elements such as the rare earths react with the oxide, while elements such as cesium, iodine, and the rare gases volatize off.

The diffusion of cerium and zirconium in molten uranium was studied in a preliminary investigation. Cerium and zirconium were selected as representatives of the lanthanide series and high melting elements, respectively. Diffusion characteristics of fission products in uranium are of interest since the mass transfer of these elements to the oxide surface is the first step in the extraction mechanism. A knowledge of the diffusion coefficient for these elements in molten uranium will help determine the slow step in the mechanism.

Most of the studies on the diffusion of metals in molten metals have been done with low melting metals or alloys (300°-700°C) (1). Diffusion coefficients generally range from about 2×10^{-5} to 7×10^{-5} cm² sec^{-1}, which is close to that found for diffusion in other liquids.

At higher temperatures (between 1000° and 1700°C) only a few experiments have been reported, and the diffusion coefficients cover a wider range. Paschke and Hautmann (2) obtained 2.4×10^{-5} cm² sec^{-1} and 10.8×10^{-5} cm² sec^{-1} for the diffusion of silicon in molten iron at 1480° and 1560°C, respectively, and a value of 1.2×10^{-4} cm² sec^{-1} for manganese in iron in the same temperature range. Holbrook, Furnas, and Joseph (3) studied the diffusion of sulfur, manganese, phosphorus, silicon, and carbon in molten iron over the temperature range 1200°-1700°C. The average diffusion coefficients for silicon, phosphorus, sulfur, and manganese was about 1×10^{-4} cm² sec^{-1} in this temperature range. The variation of the diffusion coefficient with tem-

perature was less than the experimental error. They found the diffusion coefficient for carbon in liquid iron to be much larger, about 6 x 10^{-4} cm^2 sec^{-1}. Penetration curves did not correspond well with ideal diffusion curves, probably because of experimental errors such as convection. It is difficult to avoid this problem completely.

A recent paper by Morgan and Kitchener (4) describes an experiment to determine the diffusion coefficients of cobalt and carbon in iron. They obtained D values of 5.5 x 10^{-5} cm^2 sec^{-1} for cobalt at 1638°C and 4.3 to 6.7 x 10^{-6} cm^2 sec^{-1} for the diffusion of carbon in iron, depending on the carbon concentration and temperature. They took particular interest in eliminating the problem of convection.

Experiments to measure diffusion coefficients in molten metals generally have been carried out using one of the three techniques described by Niwa, *et al.* (5). Their third method, used by Kitchener and Morgan (4), was to place a pure metal or an alloy containing the diffusate next to a long, narrow column of solvent. Samples are taken along the length of the metal column after it had been to temperature for a specific time. Morgan and Kitchener point out that this method allows detection of deviations from Fick's law due to convection, etc. This same technique was used in the study reported here, except that metal columns of the order of 7 mm rather than 2 mm diameter were used in order to obtain larger samples for analysis. The larger diameter allowed convection at the higher temperatures which increased the uncertainty of the results at these temperatures (1400°-1480°C).

This paper reports experiments to measure the diffusion coefficient of cerium in molten uranium over the temperature range 1170°-1480°C. An estimate of the diffusion coefficient for zirconium in molten uranium is also given.

Experimental

A slug of natural uranium was machined to fit the crucible, then etched clean with dilute HNO_3. The desired amount of cleaned cerium or Zr-U alloy was placed on top of the uranium, and the unit was placed in the vacuum furnace tube (Fig. 1). The McDanel ceramic tube could be evacuated to 0.1 μ, filled with an inert gas, then placed in a Globar furnace. Three thermocouples were placed in the system so that the temperature could be

measured at various points with respect to the sample. The temperature was controlled with a temperature controller and recorded on a millivolt recorder.

In each experiment, the system was first evacuated to about 0.1 μ, then flushed and filled with argon to 1 atm of pressure. The argon was purified by passing it through a uranium trap held at about 600°C. The furnace was brought to the desired temperature, held at temperature for the experiment, then allowed to cool as fast as possible without breaking the ceramic tube. The time to heat the sample from the melting point of uranium to temperature was 3 or 4 min, and the time required to cool the sample below the freezing point of uranium was not more than 4 or 5 min.

Three different crucibles were used in the experiments. A tantalum crucible, 1.5 cm OD by 9 cm high, with a hole 0.75 cm ID and 7.5 cm deep, was used for the experiments reported in Fig. 2, 3, 4, and 5. In two of these experiments (Figs. 3 and 4) a 3 cm slug of uranium-cerium alloy (0.67 w/o, Fig. 3; 0.6 w/o, Fig. 4) was placed on top of a 3 cm slug of pure uranium. In the other two experiments, (Fig. 2 and 5) a thin layer of pure cerium about 2 mm thick was placed on top of a 6 cm slug of pure uranium. The slug of uranium was counter-sunk at the top, with a shallow hole, leaving thin uranium sides and just deep enough to contain the molten cerium when it melted. This was done so that the molten cerium would not run down the sides of the uranium before it melted (mp: Ce, 793°C; U,1133°C) (6).

For the experiment which corresponds to Fig. 6, the uranium was placed in a zirconia crucible approximately 1.5 cm OD x 5.5 cm high, with a hole 1 cm ID and 5 cm deep. In this experiment, pure cerium metal was placed on top of the uranium in the manner mentioned above, and the system was held at 1200°C for 26 min.

Figure 7 gives the results of an experiment carried out in a tungsten crucible at 1350°C for 155 min. Again, the pure cerium metal was placed on the counter-sunk uranium slug. The approximate

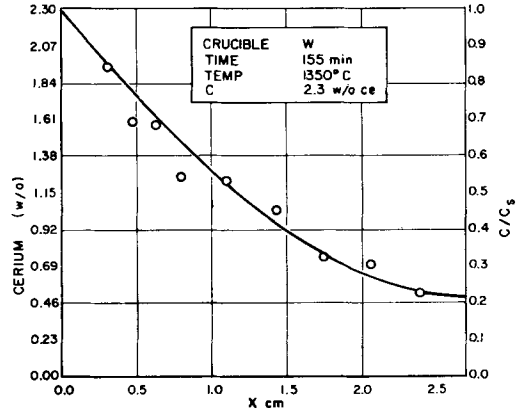

Fig. 7. Penetration curve: cerium diffusing into molten uranium at 1350°C from pure cerium. The solid line is based on an average value of $D = 1.46 \times 10^{-4}$ cm^2 sec^{-1}. The reflection principle was used.

dimensions of the tungsten crucible were: 2.5 cm OD by 4 cm high, with a hole 1.4 cm ID and 3.5 cm deep.

One experiment was conducted with a 3% zirconium-uranium alloy placed on top of pure uranium in the tantalum crucible. The system was held at 1270°C for 40 min.

After each experiment, samples were taken from the uranium at known distances from the top of the slug by drilling lengthwise through the center of the ingot. The samples were washed and dried, then weighed and analyzed. The higher concentrations of cerium were analyzed volumetrically (7) and the low concentrations calorimetrically (8). In two experiments, the cerium had been irradiated, and analysis was accomplished with a gamma-ray spectrometer after extracting the uranium with tributyl phosphate. Analyses for zirconium in uranium was made gravimetrically (9).

Errors and Uncertainties

When taking samples for analysis, there is an uncertainty as to the exact position of the interface due to its shape. The shape of the interface is a function of the interfacial tensions between cerium, uranium, and the crucible wall. Since the interface is not flat, there will be some samples at the interface that will cut both phases simultaneously and will give invalid results.

The uncertainty of the position of the interface generates an error in the value of X, which is increasingly significant as X approaches zero. This is shown by the equation: per cent error (in D) = $100\,(X_1^2 - X^2)/X^2$ where X is the true distance and X_1 is the apparent distance. In the present work, the uncertainty in X is approximately 0.2 cm; consequently, at $X = 0.2$ cm and $X_1 = 0.4$ cm, the per cent error is 300, while at $X = 4$ cm and $X_1 = 3.8$ cm, the per cent error is 10. This same effect is seen for uncertainties in λ (note Eq. [1] below) where λ is small, since $D \propto 1/\lambda^2$. Errors in λ result from uncertainties in the measured variables C or C_s since λ is obtained from a plot of C/C_s vs. λ. C is the concentration of the diffusate in the solvent at any specified time, and C_s is the constant concentration in the solvent at the interface between the solvent and the

* From data shown in Fig. 2.

diffusate. Small discrepancies in C or C_s cause increasingly larger uncertainties in λ as λ increases; therefore, large inherent errors are to be expected at small and at large values of X. This is clearly shown in Table I where the per cent error is given as a function of X for a difference of 0.2% in C_s. The most accurate values of D are those calculated for X between 1 and 2 cm.

The residuals for the values of D falling within the above mentioned band are considered random; only the values of D having random residuals are used in the determination of the average value of D.

The per cent error recorded in Table I is based on the assumption that the correct value for C_s is 1%.

It is well known that D, the diffusion coefficient, is rarely a constant with change in concentration; however, it does approach a constant value at low concentrations. Since the concentrations in these experiments were low, the assumption of D constant is good.

Although the uranium and the cerium were cleaned of oxide before each experiment, and the experiments were made in a purified argon atmosphere, it is quite possible that a thin film of oxide existed between the uranium and the cerium in the U-Ce couple. If the film was very thin or if no film existed, the value of C_s should be just the solubility of cerium in uranium at the temperature of the experiment. However, if the oxide film was thick enough to provide a resistance to the diffusion of cerium to the uranium surface, then the value of C_s might be something less than the solubility of cerium in uranium. With or without the oxide, correct values of the diffusion coefficients will be obtained as long as C_s is constant and can be measured.

The curve C/C_s vs. 2λ becomes linear as 2λ approaches zero. The best values of C_s, then, are those obtained by extrapolating the experimental curves of per cent cerium vs. X back to the interface, since $X \propto \lambda$, (note Fig. 2, 5, 6, and 7) this is the manner in which values of C_s were obtained for the calculations.

For the experiments in which an alloy was used instead of pure cerium (Fig. 3 and 4) only values of C_o, the initial concentration of the alloy, was needed rather than C_s. Values of C_o were found before the diffusion experiments were made by analyzing a number of samples from the alloy.

All but two experiments were made in a tantalum crucible. Tantalum is slightly soluble in uranium, and it is to be expected that some interference will result from its presence. Since the two experiments, in which a zirconia crucible and a tungsten crucible were used, gave results consistent with those of the experiments in which tantalum crucibles were used, the effect of the presence of tantalum can be considered to be within the experimental error. It is noted that the use of zirconia crucible will also cause interference, because some of the cerium reacts with the ZrO_2 at the surface. Every known container material would interfere to some extent. The best crucible would be one made of CeO_2, but this was not available for these experiments.

Discussion and Results

Results for diffusion experiments are shown in Fig. 2 through 7 as penetration curves for cerium in molten uranium. The weight per cent cerium plotted as open circles at various distances, X, from the cerium-uranium interface are average values for the concentration of cerium at that position. The length X is the distance from the cerium uranium interface to the center of the sample that was taken for analysis. The solid lines in the graphs are theoretical penetration curves based on average values of the diffusion coefficients.

Diffusion equations.—Diffusion coefficients were measured under three different experimental conditions requiring three separate solutions of Fick's equation.

Case 1.—The simplest experimental situation, that of nonsteady-state diffusion in a semi-infinite media, consisted of two elements in contact, having a sharp boundary between them initially, contained in a cylinder having impermeable sides. Consider only half of such a couple; the dimensions in the direction of diffusion must be large compared to the distance over which measurable composition change occurs during the experiment. The initial concentration of the diffusing element in the semi-infinite media must be uniform, and the surface must be brought instantaneously to some concentration C_s which remains constant during the experiment.

These boundary conditions may be written:

$$C = C_o \text{ at } t = 0 \text{ and } 0 < X < \infty$$

$$C = C_s \text{ at } X = 0 \text{ and } 0 < t < \infty,$$

where C is the concentration of the diffusing species at time, t, C_o is the initial homogeneous concentration of the diffusing species, and X is the distance from the interface in the direction of diffusion.

The solution (10) of Fick's second law corresponding to these boundary conditions and for a constant diffusion coefficient, D, is

$$\frac{C_s - C}{C_s - C_o} = \frac{2}{\sqrt{\pi}} \int_0^{X/(2\sqrt{Dt})} e^{-\lambda^2} d\lambda \qquad [1]$$

where λ is an integration variable. The term on the right is the normalized probability integral or the error function, (erf); its compliment, 1-erf, is known as erfc and is equal to $(C-C_o)/(C_s-C_o)$. Values of

$(C-C_o)/(C_s-C_o)$ vs. 2λ are tabulated (10) and were used to determine the diffusion coefficients recorded in Tables I and II.

Case 1 is useful for experiments with low melting metals such as cerium and lanthanum where the pure metal is in contact with uranium.

Figures 2, 5, and 6 show penetration curves for cerium in uranium at 1170°, 1200°, and 1480°C, respectively. The experiments for 1170° and 1200°C were made at close to the same temperature but with different types of crucibles, tantalum and zirconia. Both experiments gave an average diffusion coefficient of 1.0×10^{-4} cm^2 sec^{-1}.

In these experiments, pure cerium was contacted with pure uranium and the data were interpreted as in Case 1.

Case 2.—In order to measure the diffusion coefficients of elements such as Zr, Mo, Y, Nb, and Ru that have high melting points, it is necessary to make alloys of these elements with uranium and measure the diffusion from the alloy into pure uranium. The boundary conditions are: $C = C_o$, $X < 0$; $C = 0$, $X > 0$, and $t = 0$. The solution (10) of Fick's second law for these boundary conditions is

$$C(X,t) = \tfrac{1}{2}\, C_o \operatorname{erfc} \frac{X}{2\sqrt{Dt}} \qquad [2]$$

or, $C/(\tfrac{1}{2}C_o) = \operatorname{erfc} \lambda$, which is identical with the expresssion for C/C_s in Case 1. It is seen, then, that the two processes are the same except that, in the second case, $C_s = \tfrac{1}{2}C_o$. It is interesting to note that at $X = 0$ the concentration remains constant, at $\tfrac{1}{2}C_o$, with time.

In order to evaluate D, the experimental value for C/C_s at X is determined and a corresponding value for 2λ is found from the error function tables, then $D = (1/t)\ (X/2\lambda)^2$.

The data reported in Fig. 3 and 4 for cerium and one experiment with zirconium were interpreted as in Case 2 above; pure uranium was contacted with a U-Ce or U-Zr alloy.

Case 3.—One other case must be considered to interpret the data from the experiment shown in Fig. 7. In this experiment the time period was long enough that at $X = l$ (where l is the distance from the interface to the bottom of the crucible), C was not equal to zero as in Case 1. The boundary conditions are:

$$C = C_s, X = 0; C = 0, t = 0; \text{and} \frac{\partial C}{\partial X} = 0, x = l$$

It becomes necessary to use the principle of reflection. The appropriate solution to Fick's second law can be found in Crank's (10) book on diffusion, if his equation 2.54 (section 2.43) has X replaced by $(1-x)$ and C_o replaced by C_s. The equation becomes:

$$C/C_s = \operatorname{erfc} \frac{X}{2\sqrt{Dt}} + \sum_{n=1}^{\infty} (-1)^n \operatorname{erfc} \frac{2nl+x}{2\sqrt{Dt}} - \operatorname{erfc} \frac{2nl-x}{2\sqrt{Dt}} \qquad [3]$$

This equation reduces to Eq. [1] if only the first term is needed, i.e., where x is small or t is short. Only two terms of this equation are needed to interpret the results in Fig. 7:

$$C/C_s = \operatorname{erfc} \left(\frac{X}{2\sqrt{Dt}}\right) + \operatorname{erfc} \frac{2l-x}{2\sqrt{Dt}} \qquad [4]$$

since the other terms are too small to be significant. Diffusion coefficients for the experiment reported in Fig. 7 were obtained by using the family of curves on page 46 of Crank's book (10).

Temperature Effect

Although an attempt was made to reduce thermal convection by controlling the temperature along the diffusion couple, it appears that convection currents did occur, particularly at the higher temperatures. If one assumes that deviation of the experimental points from the theoretical penetration curves is an indication of convective interference (4), it is seen from Fig. 2 through 7 that convection becomes more of a problem as the temperature increases.

Table II reports the average diffusion coefficients which correspond to Fig. 2 through 7 as a function of temperature. This table also gives the values for the average error and LnD.

It is felt that the diffusion coefficients reported in Table II up to 1350°C are accurate to within the error recorded for two reasons: first, the experimental points fall fairly close to the theoretical penetration curves in Fig. 2, 3, 6, and 7; second, even though the experiments reported in Fig. 2 and 3 were conducted in a crucible with different dimensions (0.75 cm ID) than that reported in Fig. 6, (1 cm ID), the diffusion coefficients proved to be the same. However, the experimental points at 1400° and 1480°C deviate considerably from the penetration curves (Fig. 4 and 5). It is thought that this deviation is due to convection and that the resultant average values for the diffusion coefficients are too high.

Data in Table II are plotted in Fig. 8; the open circles are based on the average diffusion coefficients and the solid lines indicate the maximum deviation from the mean. An estimate of the activation energy for diffusion, neglecting the data at 1400° and 1480°C, is 11 kcal $moles^{-1}$, and an equation relating the diffusion coefficient and temperature is: $D = 4.5 \times 10^{-3}\ e^{-11,000/RT}$.

For low melting metals (up to 700°C) activation energies have been reported from 4 to 10 kcal $moles^{-1}$ (1, 4, 11, 12). At higher temperatures (1100°-1500°C) the approximate activation energy reported here for cerium in uranium (11 kcal

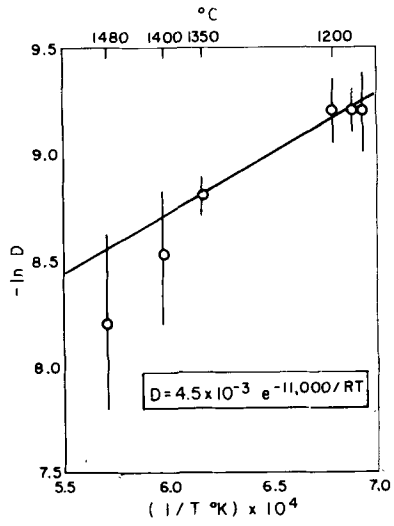

Fig. 8. An Arrhenius plot of the diffusion coefficient of cerium in molten uranium.

mole^{-1}) is close to that reported by Morgan and Kitchener (4) of about 10 to 11 kcal mole^{-1} for cobalt and carbon in molten iron (1350°-1650°C).

An estimate of the diffusion coefficient of zirconium in molten uranium at 1270°C was found from one experiment to be (1.9 ±0.9) x 10^{-4} cm^2 sec^{-1}. The large experimental error for this experiment is attributed to the error in chemical analysis although some turbulence may have had effect.

The diffusion of cerium and zirconium in molten uranium is somewhat faster than diffusion in other molten metal systems. The diffusion coefficients for many elements in molten metals (1) varies between (1 and 10) x 10^{-5} cm^2 sec^{-1}. Most of the work has been carried out below 1000°C, and it may be that the higher melting metals behave differently. Further experimentation with particular attention given to the convection problem is needed for measuring diffusion coefficients in metals at high temperatures.

Diffusion-Exchange of Exchange Ions and Nonexchange Electrolyte in Ion-Exchange Membrane Systems

Marvin A. Peterson and Harry P. Gregor

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The following parameters of cation- and anion-permeable membrane systems were measured: water content; ohmic resistance; exchange capacity; diffusible electrolyte content; concentration potential; rate of exchange-diffusion of electrolytes; rate of diffusion of nonelectrolytes; effect of rate of stirring on diffusive flux. From these were calculated: the thickness of the unstirred film, which varied from 1 to 30 microns; the diffusion coefficient of the potassium ion in a sulfonic acid cation-permeable membrane, which was found to vary from 1.09 x 10^{-7} cm^2 sec^{-1} to twice that value as the ambient solution concentration was changed from 0.001 to 0.1M; the diffusion coefficient of the chloride ion which remained at about 3 x 10^{-7}; the diffusion coefficients of nonelectrolytes. A theoretical treatment showed that diffusion coefficients and other parameters could be estimated from a consideration of pore diameters, a tortuosity factor, and water contents.

Of primary importance in any detailed analysis of free and forced transport of ions across ion-selective membranes is the determination of boundary conditions which define film, membrane or coupled film-membrane diffusion mechanisms as being rate controlling. The appropriate application of Fick's law to diffusion across a membrane and its bounding unstirred films results in an expression which dictates the rate-controlling mechanism under given experimental conditions. The general theory of diffusive processes in ion-exchange resin systems has been described previously by several authors (1-3)

and analyzed by Tetenbaum and Gregor (4). Two different mechanisms, namely, film or particle diffusion, were found to be distinguishable when the resin system was operating in certain limited extremes, and a coupled mechanism was found to be operative in the region between these extremes.

With ion-exchange resin systems it was found that the diffusion coefficient of the exchange ion or the counter ion decreased as the degree of crosslinking or the density of the resin increased and that the diffusion coefficient of nonexchange or co-ions (anions in the case of cation-exchange resins) was proportional to that of the exchange ions and generally somewhat larger (1-6).

Diffusion studies are more complex for ion-selective membrane systems than for ion-exchange resin systems in that two diffusion films are encountered in membrane studies. Matters generally become simplified for the membrane case, however, once concentration gradients are established as compared to the resin system where a point source, nonstationary state prevails. Until steady state has been attained in the membrane system, the application of Fick's law presented by Lowan (7) holds for each of the successive layers, namely, film-membrane-film. Once concentration gradients have been established in each of the layers and a steady state is allowed to prevail, a new set of relations may be developed using Fick's law so as to determine the conditions which will dictate whether film, membrane, or a coupled diffusion mechanism is controlling.

The membrane-system model is characterized by the chain:

Solution' | Film' | Membrane | Film" | Solution"

Subscripts on concentration terms denote ionic species. Primed terms refer to solution' and solution", respectively; o and l refer to interfacial concentrations at $x = 0$ and $x = l$, respectively; a superscript bar refers to concentrations within the membrane phase (see Fig. 1). Assumptions applied to the membrane system include the following: (*a*) steady state prevails; (*b*) the membrane is ideally ion-selective; (*c*) discontinuities at the interfaces present no resistance to interfacial diffusion; (*d*) negligible transfer of solvent occurs; (*e*) the ratio of the diffusion constants of the two diffusing counter ions remains constant throughout the system. The use and validity of these assumptions have been described in detail by many authors including Helfferich (8) and Soldano and Boyd (9).

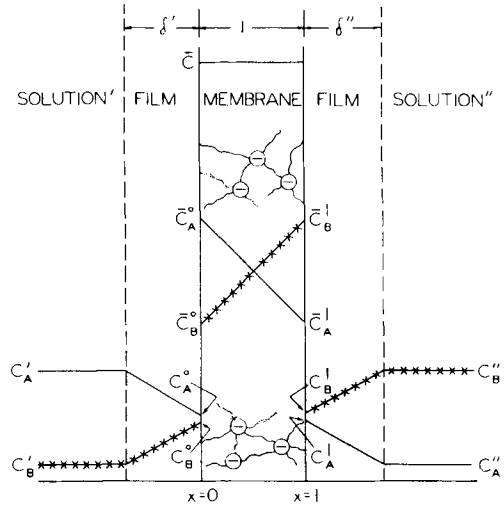

Fig. 1. Concentration profiles for the steady state where a coupled mechanism is rate controlling and where $Z_A = Z_B$ and $\bar{D}_A = \bar{D}_B$. Total membrane capacity is $\bar{C}_A + \bar{C}_B = \bar{C}$ and $C' = C''$.

The flux of ions across a membrane can be defined as the product of mobility, concentration, and driving force. Components of the driving force include gradients of activity, electric potential, and hydraulic pressure. These are summed up algebraically in the Nernst-Planck flux equation and the resulting flux, J, for a cation across a cation-permeable membrane is generally expressed as

$$J_+ = -\bar{U}_+\bar{C}_+\left(\frac{RT}{\bar{C}_+}\frac{d\bar{C}_+}{dx} + Z_+\mathbf{F}\frac{d\phi}{dx}\right) \qquad [1]$$

where $\bar{U}_+$ and $\bar{C}_+$ represent the mobility and concentration of a single ionic species within the membrane and where the potential ϕ is generally taken as $\phi = 0$ at $x = 0$, and where $\mathbf{F}$ is the Faraday. With the aid of the Nernst-Einstein equation it is possible to relate the mobility of an ion in the membrane phase to its self-diffusion coefficient in the membrane phase (10). Direct or modified application of the above expression allows one to calculate interfacial concentrations, but this is a cumbersome approach.

A more direct approach may be made by defining an integral diffusion coefficient, D_{AB},

$$\bar{D}_{AB} = J_A\frac{l}{\bar{C}^\circ_A - \bar{C}^l_A} = J_B\frac{l}{\bar{C}^l_B - \bar{C}^\circ_B} \qquad [2]$$

where the total concentration $C = C_AZ_A + C_BZ_B$ and where similar defining expressions apply for the integral diffusion coefficients in the unstirred films.

Because of discontinuities at the membrane-film interface, a partition coefficient k must be defined for each interface, such that $k_i = \bar{C}_iC/C_i\bar{C}$. For steady-state conditions the flux J for each ionic species remains constant through each layer so that $J_i' = \bar{J}_i = J_i''$.

Application of Fick's law to this model results in the following expressions for the interfacial concentration of ion A at the coordinates $x = 0$ and $x = l$, in the case where $C = C' = C''$,

$$C^\circ_A = C - \frac{k^\circ_AC + \dfrac{D'_{AB}Cl}{\bar{D}_{AB}\bar{C}\delta}C'_B + k^l_A\dfrac{D'_{AB}}{D''_{AB}}C'_B - k^l_AC''_A}{\dfrac{D'_{AB}Cl}{\bar{D}_{AB}\bar{C}\delta} + k^l_A\dfrac{D'_{AB}}{D''_{AB}} + k^\circ_A} \qquad [3]$$

$$C^l_A = \frac{k^\circ_AC + \dfrac{D''_{AB}Cl}{\bar{D}_{AB}\bar{C}\delta}C''_A + k^\circ_A\dfrac{D''_{AB}}{D'_{AB}}C''_A - k^\circ_AC'_B}{\dfrac{D''_{AB}Cl}{\bar{D}_{AB}\bar{C}\delta} + k^\circ_A\dfrac{D''_{AB}}{D'_{AB}} + k^l_A} \qquad [4]$$

Partition coefficients must be determined experimentally. Integral diffusion coefficients can be eval-

uated from flux data by assuming activity coefficients independent of ionic composition and $\bar{D}_i$ constant throughout the membrane phase.

With the aid of these expressions the flux across any layer may be written. For the unstirred film[1] on the side adjacent to solution" and for the case where A and B have equivalent diffusive characteristics ($D_A = D_B = D$) and where $\delta' = \delta''$, the flux for ion A becomes,

$$J''_A = \frac{D}{\delta}(C^l_A - C''_A) = \frac{D}{\delta}\left[\frac{C}{\frac{DCl}{\bar{D}\bar{C}\delta} + 2} - C''_A\right] \quad [5]$$

For the same conditions the flux across the unstirred film on the side adjacent to solution' becomes,

$$J'_A = \frac{D}{\delta}(C'_A - C^\circ_A) = \frac{D}{\delta}\left[C'_A - C\left[1 - \frac{1}{\frac{DCl}{\bar{D}\bar{C}\delta} + 2}\right]\right] \quad [6]$$

These expressions are exact when applied to the unstirred films and dictate whether film, membrane, or a coupled film-membrane diffusion mechanism is controlling. Expressions for the flux of ion B may be written similarly; these must satisfy the electroneutrality assumption inherent in the above derivation. The key parameter in these expressions is $DCl/(\bar{D}\bar{C}\delta)$ which is the ratio of the maximum attainable flux in the unstirred film to that in the membrane and has been used by Helfferich (8).

From these expressions it is noted that if $DCl/(\bar{D}\bar{C}\delta) << 1$, corresponding to a case where, under the same concentration gradient, the flux in the membrane phase is much larger than that in the unstirred film, then where $C'_A >> C'_B$ and $C''_B >> C''_A$ the expression for C°_A simplifies to $C^\circ_A = C/2$. Here the gradient in the unstirred film has reached its maximum value, or pure film control exists. The gradients are almost entirely in the unstirred films, and $C^\circ_A = C^\circ_B = C^l_A = C^l_B = C/2$. Similarly, if $DCl/(\bar{D}\bar{C}\delta) >> 1$, corresponding to cases where the resistance of the film to diffusion is much less than that of the membrane, then $C^\circ_A = C^l_B = C$ and $C^l_A = C^\circ_B = 0$, or the gradients are located almost entirely in the membrane phase. Where the ratio $DCl/(\bar{D}\bar{C}\delta)$ has intermediate values, neither process is purely rate-determining and a coupled mechanism prevails, as shown in Fig. 1. Analogous systems wherein water transport occurs have been described by Schlögl and Schödel (11).

Experimental

Homogeneous interpolymer membranes have been described by Gregor, *et al.* (12-16). These may be prepared by casting a homogeneous film from a solution of a polyelectrolyte and a hydrophobic film-forming polymer in a suitable solvent, allowing the film to dry, and using directly. A series of interpolymer films were examined in a preliminary way to ascertain their characteristics as regards transport phenomena. Transport across ion-exchange membranes proceeds by essentially the same process for all membrane types; however, there are certain basic differences between homogeneous and heterogeneous films as regards the exact mechanisms of transport, particularly of water transport (16). Since there are commercially available membranes of the homogeneous type, ones which show similar properties to the interpolymer membranes, it was decided to carry out the detailed examination of transport processes in commercial membranes. The films selected were quite strong mechanically and capable of withstanding high rates of stirring. The cation-permeable membrane used was the sulfonic acid-type film Nalfilm 1;[2] the anion-permeable membrane was Nalfilm 2, a quaternary ammonium-type obtained from the same source.

The effective exchange capacity of a membrane is the number of acidic or basic exchange sites within the membrane structure which are titrable while leaving the membrane intact. With strong acid (sulfonic) or strong base (quaternary ammonium) membranes simple mass-action exchange of neutral ions (potassium or nitrate) for counter ions (hydrogen or chloride) was utilized to make all exchangeable groups readily titrable (12).

All of the experiments were performed at room temperature, 24°-26°C, unless otherwise stated. In most cases the systems were thermostated at 25.0°C. All data were corrected to 25°C, unless the temperature deviation or the effect of temperature was negligible.

The cation-permeable membranes were equilibrated with 1M hydrochloric acid, washed with water to remove diffusible salt, and then blotted. Elution of the hydrogen ions was accomplished by placing the membrane samples, each having an area of about 100 cm², in 250 ml of 1M potassium chloride; these conditions provided at least a 250-fold excess of potassium ion. After a 24-hr period of shaking (much longer than the time required for equilibrium), an aliquot of the solution was titrated. The molality of this membrane was 2.86 ± 0.02, defined as milliequivalents of hydrogen ions per gram of sorbed water.

The anion-permeable membranes were equilibrated in potassium chloride solutions, the diffusible salts removed by washing with water and blotting, and elution of the chloride accomplished by shaking in 250 ml of 1M potassium nitrate for 24 hr. The membrane was removed, rinsed into the eluate, and the latter titrated potentiometrically with silver nitrate. The anion-permeable membrane was found to have a molality of 4.58 ± 0.04.

The thickness of each membrane was determined, following equilibration in 0.1M potassium chloride, with a micrometer which provided results accurate to ±1%. The water content of each membrane in the same state was determined by first eluting the diffusible salt, blotting with filter paper to remove surface moisture, and weighing immediately. This procedure was shown by Gregor and Sollner (17) to yield accurate and reproducible wet weights. The membranes were then dried at 10 mm Hg and 60°C

[1] The "diffusion layer" of "effective thickness" δ.

[2] Obtained from the National Aluminate Corporation.

for 24 hr and reweighed. Drying for an additional 24 hr under these conditions removed less than 0.2% additional water.

Characterization ohmic resistance measurements were made with a Klett conductivity bridge at 1000 cps on membranes in a plastic flow cell with fixed platinized platinum electrodes and provisions to interpose the membrane (18). The cell resistance was determined for various potassium chloride solutions with and without the membrane. Membrane resistance was calculated from the difference in resistance and consideration of the cell constant and the thickness of the membrane. In the more concentrated solutions the calculated resistance is quite accurate, while in dilute (0.001M) solutions the reliability decreases to ±4%.

Concentration potentials were determined for the chain:

$$\text{S.C.E.} \mid C_2 \mid \text{Memb.} \mid C_1 \mid \text{S.C.E.}$$

where S.C.E. refers to the saturated calomel electrode and where $C_2:C_1 = 2:1$. These measurements were carried out in a plastic cell with provisions for stirring at the membrane-solution interface by means of an air stream. The measuring circuit employed a L&N Type K-2 potentiometer and a Type E galvanometer. Corrections were applied as described by Wetstone (19) to the concentration potential measurements for the salt bridge liquid junction, the S.C.E. asymmetry and temperature. These measurements are summarized in Table I.

Nonexchange of diffusible electrolyte is that which enters the membrane phase in excess of those ions which compensate electrically for the fixed ions. In a cation-permeable membrane system in potassium chloride solution, for example, the mobile potassium ions are designated as counter-ions and the chloride ions as co-ions. Then the molality of co-ions is numerically equal to that of the diffusible electrolyte and is equal to the number of equivalents per gram of sorbed water. Membrane samples approximately 40 cm² in area were equilibrated in 0.100, 0.500, and 1.00M potassium chloride solutions, blotted quickly to remove surface solution, and placed in 25 ml of distilled water with gentle shaking for 24 hr. The amount of eluted diffusible electrolyte was evaluated from resistance measurements of the eluate. Water contents were determined on similar samples in equilibrium with the same solutions. Calculated molalities are presented in Table II.

Ion-exchange membranes, like the ion-exchange resins, show some variation in the properties of different samples. This is particularly the case with materials still in the developmental stage. For a given batch of membranes, a high level of uniformity was encountered; all of the work described in this contribution was carried out on the same batch.

Rate of exchange studies were conducted in an apparatus which consisted essentially of two identical plastic (methylmethacrylate) chambers with a common window such that an interposed membrane was exposed on one side to solution' and on the other side to solution". Each chamber had provisions for an inlet and outlet stream, identical rates of stirring, and cooling coils for precise temperature control. Identical high rates of stirring very near the membrane-solution interface were obtained by means of a 3-bladed flat paddle stirrer which swept the entire exposed membrane area with controlled peripheral linear velocities of 55 to 330 cm sec^{-1} at a distance of

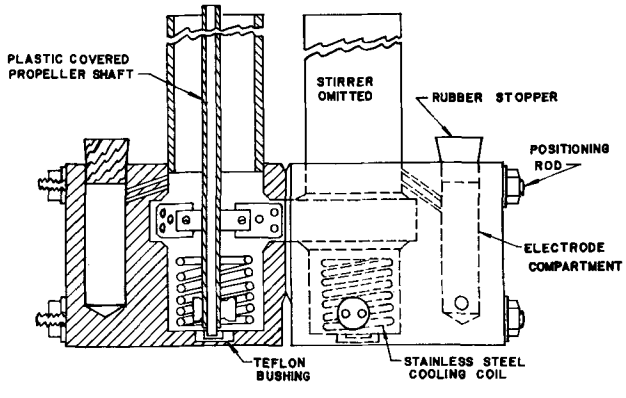

Fig. 2. Cell used for variable, high rates of stirring. The three detachable plastic flat-paddle blades are 0.1 to 0.2 cm from the interposed membrone. The assembly is symmetrical, and each compartment has provision for an entrance and exit stream. Volume of each compartment—115 ml.

1 to 2 mm from the interposed membrane. This cell is illustrated schematically in Fig. 2.

Water can be transported across ion-exchange membrane systems as a result of differences in the activity of water in solution' and solution", or by electro-osmosis. This was recognized by Donnan in his earliest papers, where he suggested the addition of a nonpermeable nonelectrolyte such as sugar to the side of higher solvent activity. Water transport can manifest itself in the measurement of any irreversible phenomenon, including that of a concentration potential, transport number, and diffusion coefficient. Water transport is negligble under almost all experimental conditions (excepting electro-osmosis) with membranes of low water content, such as the homogeneous membranes of Gregor and Sollner (17), the interpolymer membranes (12-16), and the films used in this study. Water contents of about 25% or less usually mean that water transport may be neglected; at water contents of 50% and greater, large effects are observed and have been evaluated by Schlögl and Schödel (11).

Another cell similar to that shown in Fig. 2 was constructed, where the exposed membrane area was about 15 cm^2. One side was maintained at constant volume with a mercury-sealed stirrer, and a capillary permitted direct observation of any volume changes. The imposition of an osmotic concentration difference as large as 1M gave such low rates of water transport as to be neglected.

Three series of runs at solution concentrations of 0.001, 0.1, and 0.5M were made using the cation-permeable membrane with potassium chloride as solution' and ammonium nitrate as solution". These ions resemble one another closely enough to serve as "tracers" for each other. Similar runs including a 0.0001M series were made using the anion-permeable membrane. Each series consisted of a number of runs ranging in time from 10 to 30 min and at stirring rates from 200 to 1200 rpm (corresponding to linear rates of 55 to 330 cm sec^{-1}).

The membranes were equilibrated in the respective potassium chloride solution for 24 hr prior to the rate experiments. Zero time for each run was not critical because essentially no potassium could be detected in the ammonium nitrate solution after a period of 1 hr with no stirring. That the membrane was highly ion-selective was verified when essentially no chloride could be detected in the nitrate solution after 15 min at 800 rpm in the 0.1M series, at which time an appreciable amount of cation-exchange had occurred. Duplicate runs gave essentially identical results.

The cation-permeable membrane contained 0.00846 meq of potassium per square centimeter of surface area. A constant area of 3.422 cm^2 was common to both solutions, so that before steady-state concentration gradients could be established approximately 0.015 meq of potassium (50% of capacity) would, of necessity, be displaced from the membrane sites to the ammonium nitrate cell side in return for the ammonium ion since the membrane was initially equilibrated in 0.001M potassium chloride for the 0.001M series of runs, etc.

Rate data were collected as follows: after a 10-min run both cells were drained and replenished with the original solutions. This was repeated once and followed by a third run for 20 min and a fourth for about 30 min. Once the 0.015 meq of potassium had been displaced it was assumed that the membrane retained a steady-state concentration gradient with respect to potassium and ammonium.

Solutions were analyzed for potassium with a Perkin-Elmer 52A flame photometer. These determinations were accurate to better than ±2% at a solution concentration above 5 x 10^{-4}M. A colorimetric method of analysis was used for chloride, capable of detecting chloride ion quantitatively at concentrations as low as 2 x 10^{-5}M with an accuracy better than 2% (20). The procedure involves the indirect evaluation of the chloride ion by displacement of the chromate ion from silver chromate solution. Analysis of the chromate ion was made using a Beckman DU spectrophotometer at 370 mμ against a

suitable standard. The nonelectrolytes employed were analyzed for by standard procedures.

Table III gives the results of a series of exchange-diffusion experiments performed with the solution chain:

0.001M KCl | Cation-Permeable Memb. | 0.001M NH_4NO_3

measured at 25°C and with different rates of stirring. The amount of potassium exchanged was not proportional to the elapsed time at a given rate of stirring because the concentration gradients had changed. The flux for each time interval was evaluated, and by extrapolation to zero time it was possible to calculate the flux under the initial conditions J^*; then $C'_B = C''_A = 0$ and the calculation of δ and $\bar{D}$ followed.

Initial flux values were used to evaluate δ from the following general expression for the case where a coupled-mechanism prevails

$$J = \frac{D(C'_{K+} - C^\circ_{K+})}{\delta} \qquad [7]$$

At the zero time under steady-state conditions

$$C^\circ_{K+} = C\left[1 - \frac{1}{\frac{DCl}{\bar{D}\bar{C}\delta} + 2}\right] \qquad [8]$$

$C'_{K+} = C$ and $k = 1$. The general expression becomes,

$$J^* = \frac{D}{\delta}\left[\frac{C}{\frac{DCl}{\bar{D}\bar{C}\delta} + 2}\right] \qquad [9]$$

or

$$\delta = \frac{DC}{2}\left(\frac{1}{J^*} - \frac{l}{\bar{D}\bar{C}}\right) \qquad [10]$$

In order to evaluate δ as a function of the stirring rate it was necessary to determine $\bar{D}_{K+}$. This was obtainable for the 0.001M system from conductance data using the appropriate application of the Nernst-Einstein equation (10)

$$\bar{\kappa} = \frac{l}{\Omega} = \frac{\mathbf{F}^2}{1000\,RT}(Z_+\bar{D}_+\bar{C}_+ + Z_-\bar{D}_-\bar{C}_-) \qquad [11]$$

and $\bar{D}_+ = 2.66 \times 10^{-7}\,\bar{\lambda}_+/Z_+$ where $\bar{\lambda}_+ = 1000\,\bar{\kappa}_+/\bar{C}_+$ where λ is the equivalent ionic conductance (mho cm^2 eq^{-1}) in the absence of electro-osmosis, κ is the specific conductance (ohm^{-1} cm^{-1}), Ω is the membrane resistance in ohm cm^2, and $\bar{C}$ the concentration (meq cm^{-3}) of the membrane phase. From Table II the concentration of nonexchange electrolyte would be negligible at 0.001M compared to that of the exchange ions and $\bar{D}_+ = 1.03 \times 10^{-7}$ cm^2 sec^{-1} in 0.001M solutions.

Values of δ and $DCl/(\bar{D}\bar{C}\delta)$ as a function of rate of stirring were calculated then, based on the $\bar{D}_+$ value from conductance data, for all experiments performed at 0.001M concentrations. Film thicknesses were found to range from 1 to 30 μ at stirring rates ranging from 1200 to 200 rpm. Values of $DCl/(\bar{D}\bar{C}\delta)$ for this 0.001M series ranged from 18.8 at 1200 rpm to 0.99 at 300 rpm and 0.65 at 200 rpm. Thus, on the basis of these calculations, a coupled mechanism prevailed at all rates of stirring.

$\delta_{avg} = 30.9 \pm 0.6$.

Experimental results for a series of runs at 0.0001M and 200 rpm are presented in Table IV. Since the parameter $DCl/(\bar{D}\bar{C}\delta)$ equals 0.65 at 200 rpm in 0.001M solution, it was postulated that film control would predominate in 0.0001M solutions at 200 rpm where $DCl/(\bar{D}\bar{C}\delta)$ would equal 0.065 if all values other than C were unchanged. Under these conditions $C^\circ_i = C^l_i$ and the concentrations at the membrane surfaces would be equal to the mean value of C' and C'', or $C/2$. For this determination, an anion-permeable membrane was used because chloride analysis could be performed with greater accuracy at these extreme dilutions. Postulating pure film control, $J = DA/\delta(0.00005 - C''_{avg})$ since C° and C^l are constant and equal to 5×10^{-5}M. Table IV presents calculated values of δ where C''_{avg} is the average concentration of chloride in solution" during the appropriate time interval and A the membrane area.

Table IV shows that δ is 30.9 ± 0.6 μ at 200 rpm, agreeing well with δ as determined in 0.001M solutions wherein the coupled mechanism prevailed, as will be shown later. The constant values of δ over each time interval verifies the assumption that diffusion through the unstirred film was rate determining for 0.0001M concentrations.

The establishment of δ at 200 rpm in the 0.0001M series allowed an independent evaluation of $\bar{D}_+$ for 0.001M solutions from flux data for the 0.001M series, and good agreement was noted between $\bar{D}_+$ (conductance) and $\bar{D}_+$ (flux), as will be shown later.

From consideration of the dimensionless parameter $DCl/(\bar{D}\bar{C}\delta)$ it is seen that membrane control will predominate at values greater than 50, with the film being rate controlling at values less than 0.1. In the system under investigation, $l \cong 0.01$ cm, $\bar{C} \cong 1.0$M, $D/\bar{D} \cong 100$ and $0.0001 < \delta < 0.0030$ cm. Accordingly, film control can be expected at $C <$ 0.00001M at 1200 rpm and $C < 0.0003$M at 200 rpm; deviations from membrane control can be expected at $C < 0.005$M at 1200 rpm and $C < 0.15$M at 200

rpm. Intermediate ranges should exhibit a coupled mechanism.

The rate of diffusion-exchange processes in 0.1 and 0.5M solutions was measured with anion- and cation-permeable membranes. Solution concentrations remained essentially constant throughout the experiments, changing by less than one part in 500, and a constant flux was observed over the various time intervals. Table V presents the flux values. Values of δ were assumed to be concentration independent and taken from the 0.001M data. Corresponding data for the diffusion-exchange of chloride ions in the cation-permeable membrane are given in Table VI.

From the general flux expression it is noted that J^* approaches $\overline{D}\,\overline{C}/l$ in the limiting case of $DCl/(\overline{D}\,\overline{C}\delta) >> 1$ where membrane control prevails. The general expression for $\overline{D}$ in the coupled diffusive process is

$$\overline{D}_+ = \left[\frac{\overline{C}}{Jl} - \frac{2\overline{C}\delta}{DCl}\right]^{-1} \qquad [12]$$

From the expression relating specific conductance and diffusion coefficient, the diffusion coefficient for the anion is given by

$$\overline{D}_- = \left[\frac{\overline{\kappa}RT}{\mathbf{F}^2} - \frac{Z_+\overline{D}_+\overline{C}_+}{1000}\right]\frac{1000}{Z_-\overline{C}_-} \qquad [13]$$

Exact values of $\overline{D}_i$ can be calculated from flux data for that ion and values of δ; these can be calculated also from values of the specific conductance of the membrane phase together with values of $\overline{C}_i$ for each ionic species present and values of $\overline{D}_i$ for all other ionic species, subject to the applicability of the Nernst-Einstein equation. Where both kinds of data are available, an independent check is possible. Diffusion coefficients and other parameters for the cation-permeable membrane system are presented in Table VII.

From Table VII it is seen that within experimental accuracy the diffusion coefficients in the membrane phase for a given solution concentration are independent of the rate of stirring. This is not true of the flux unless complete membrane control prevails. As fluxes in the 0.1M solution series decrease, with lower rates of stirring, $\overline{C}/Jl$ increases; however, there is a corresponding increase in the values of $2\overline{C}\delta/(D_{Cl})$ due to an increase in δ, resulting in a constant value of $\overline{D}$. At higher concentrations (C = 0.5M) the film effect is diminished and in the limit

where membrane control is absolute, it is essentially zero and $\overline{D} = Jl/\overline{C}$.

In order to illustrate increasing membrane control with increasing solution concentration, $DCl/(\overline{D}\,\overline{C}\delta)$ values for 0.001, 0.1, 0.5, and 1M solutions are presented in Table VIII. Parameter values ranged from 0.65 at 200 rpm with 0.001M solutions to 8650 at 1200 rpm with 1M solutions.

From values of diffusion coefficients of exchange and nonexchange electrolyte, mobilities and transport numbers can be evaluated. A sequence of concentration potential measurements was made and is presented in Table IX. Good agreement is noted between transport numbers determined from exchange-diffusion studies and those calculated from potential measurements.

From flux data obtained with anion-permeable membranes, values of the anionic diffusion coefficients were calculated to be $(\overline{D}_{Cl})_{0.1M} = 0.78 \times 10^{-7}$ and $(\overline{D}_{Cl})_{0.5M} = 0.85 \times 10^{-7}$ cm^2 sec^{-1}. Subscripts outside the parentheses refer to the ambient solution concentrations.

A calculation of $(\overline{D}_{K+})_{0.1M}$ in this membrane requires either nonexchange electrolyte content and flux data or the former and conductance data. A good approximation of the nonexchange electrolyte concentration can be made by analogy with the ion-exchange resins. Gregor, Gutoff, and Bregman (21), Gregor and Gottlieb (22), and Gottlieb and Gregor (23) measured diffusible electrolyte contents and mean activity coefficients for sulfonic acid cation- and quaternary ammonium anion-exchange resins of different resin phase molalities. Postulating that these systems are comparable, as seems to be the case from nearly all points of view, one can evaluate these parameters for the membranes.

t_+*—Transport numbers from exchange-diffusion experiments in 0.001, 0.1, 0.5, and 1M solutions.

Cation-exchange resin mean activity coefficients were calculated from the Gibbs-Donnan equations applied to systems of this type by Gregor, *et al.* (21-25). It was shown that mean activity coefficients for uni-univalent electrolytes defined by the expression $\overline{m}_+\overline{m}_-\overline{\gamma}_\pm^2 = m_+m_-\gamma_\pm^2$ were, for cation-exchange resins, as follows: where $(\overline{m}_+)_{0.1M} = 1.6$, $(\overline{\gamma}_\pm)_{0.1M} = 0.37$; for $(\overline{m}_+)_{0.1M} = 4.0$, $(\overline{\gamma}_\pm)_{0.1M} = 0.31$. For anion-exchange resins, where $(\overline{m}_-)_{0.1M} = 2.9$, $(\overline{\gamma}_\pm)_{0.1M} = 0.32$ and where $(\overline{m}_-)_{0.1M} = 4.6$, $(\overline{\gamma}_\pm)_{0.1M} = 0.28$. Accordingly, $\overline{\gamma}_\pm$ values for both resin types are quite similar when systems of the same resin phase molality are compared.

Since diffusible and nondiffusible electrolyte contents were determined for the cation-permeable membranes, values of $(\overline{\gamma}_\pm)$ could be calculated. These were: $(\overline{\gamma}_\pm)_{0.1M} = 0.273$ at $(\overline{m}_+)_{0.1M} = 2.89$; $(\overline{\gamma}_\pm)_{0.5M} = 0.465$ at $(\overline{m}_+)_{0.5M} = 3.02$; $(\overline{\gamma}_\pm)_{1M} = 0.483$ at $(\overline{m}_+)_{1M} = 3.33$. With the sulfonic acid resins, $(\overline{\gamma}_\pm)_{0.5M} = 0.40$ at $(\overline{m}_+)_{0.5M} = 2.3$, while $(\overline{\gamma}_\pm)_{1M} = 0.44$ at $(\overline{m}_+)_{1M} = 3.1$. Good agreement between the resin and membrane systems is observed.

Accordingly, it is possible to estimate diffusible nonexchange electrolyte contents for the anion-permeable membrane and calculate a $\overline{D}_+$ value from flux data for the anion and conductance data. Having determined $(\overline{m}_-)_{0.1M} = 4.58$, and assuming a value of $(\overline{\gamma}_\pm)_{0.1M} = 0.28$ (since $\overline{m}_-$ is quite constant in dilute solutions), then one can calculate $(\overline{m}_+)_{0.1M} = 0.017$. The calculated value of $(\overline{D}_K)_{0.1M}$ in the anion-permeable membrane was 2.41×10^{-7} cm^2 sec^{-1}, or three times that of the counter-ion.

Measurements were also made of flux values of urea and acetic acid in the cation-permeable membrane in 0.1M potassium chloride solution. In both cases the solution concentration of the nonelectrolyte (also treating the acid as such) was 0.1M. A high rate of stirring was not required since these solutes were not strongly accumulated by the membrane; concentration gradients of these solutes in the membrane phase were about 5% of those found for exchange species. The parameter $DCl/(\overline{D}\,\overline{C}\delta)$, accordingly, increased by a factor of 20, meaning that in all cases where even moderate stirring prevailed, diffusion was almost entirely membrane controlled. Flux values were constant in every case over an interval of several hours. For urea it was found that the flux was 2.37×10^{-10} moles sec^{-1} cm^{-2} from a 0.1M solution stirred at 400 rpm into water across the membrane (0.0096 cm) where the molality of urea in the membrane was 0.180 or its molar concentration was 0.0555 moles liter^{-1} of membrane phase. Then, $\overline{D}_{urea} = 4.11 \times 10^{-8}$ cm^2 sec^{-1}. In free solution, $D_{urea} = 1.36 \times 10^{-5}$ cm^2 sec^{-1}, so that $\overline{D}/D = 0.0030$.

These figures should be compared with those for the diffusion of urea in a sulfonic acid cation-exchange resin system, as measured by Gregor, Col-

lins, and Pope (26). Here $\overline{D}_{urea} = 12.2 \times 10^{-7}$ cm^2 sec^{-1} in a 10% cross-linked resin where the distribution coefficient or $\overline{m}/m = 1.31$, where the water content of the resin was 40%, and where $(\overline{D}_{K^+})_{0.1M\ KCl} = 4.7 \times 10^{-6}$ cm^2 sec^{-1} (4).

For acetic acid, the flux was 3.91×10^{-10} moles sec^{-1} cm^{-2} from a 0.1M solution of the acid in 0.1M potassium chloride. Here a determination of the solution phase molality was not made, but from other sources (26, 27) it appears likely that the distribution coefficient is nearly unity. The diffusion coefficient for acetic acid was calculated to be 3.76×10^{-8}, compared to the free solution value of 1.20×10^{-5} cm^2 sec^{-1}; then $\overline{D}/D = 0.0031$. Manecke and Heller (28) also measured the diffusion of acetic acid across a phenolsulfonic acid-formaldehyde cation-permeable membrane, but diffusion coefficients were not calculated.

Discussion

This discussion is concerned with the cation-permeable membrane systems, unless otherwise stated. Turning first to a comparison between the cation-selective membrane and a cation-exchange resin of the sulfonate type, it is seen that the two systems are quite comparable from almost all points of view. For systems of equal cationic molality, it is seen that the concentrations of diffusible electrolytes vary in the same way with the ambient solution concentration, with respect to both absolute and relative values. These Donnan systems absorb an amount of diffusible electrolyte at low concentrations which is much larger than that calculated for ideal systems. This is presumably because the counter-ion is bound electrostatically to the polymeric chains by their high potential. The system cannot exert its ideal Donnan potential, and excess diffusible electrolyte enters so that low values of mean activity coefficients are calculated.

As additional diffusible electrolyte enters the resin or membrane system with increasing solution phase concentration, the concentration of co-ions increases quite sharply and has a profound influence on the mean activity coefficient. Presumably, at high external solution concentrations the activity coefficient of diffusible electrolyte in the membrane phase would approach that in the solution phase, as was observed with the resin systems.

Turning to the change in the diffusion coefficient of the mobile ions in the cation-permeable membrane phase, it is observed that the diffusion coefficient of the cation rises significantly with increasing concentration of the ambient solution phase, while that of the anion decreases slightly, although the latter effect is within experimental error. This rise in the diffusion coefficient of the counter-ion with increasing ambient solution concentration amounted to a 1.7-fold increase in $\overline{D}_+$; this has been observed by Schlögl (29), Schlögl and Helferich (30), Ishibashi, Seiyama, and Sakai (31), Despic and Hills (32), and Richman and Thomas (33). Some of these authors observed a larger increase in the diffusion coefficient of the counter-ion with ambient solution concentrations than was observed here; this was probably due to their use of systems having a lower fixed-ion concentration and consequently a larger and more variable diffusible electrolyte content. In some cases the resistance due to the unstirred film has been neglected; such calculations are suspect.

In the cation-permeable membrane systems, the diffusion coefficient of the chloride ion was found to be significantly larger than that of the cation, varying by a factor of 3:1 to one of 2:1 as the solutions became more concentrated. At a 0.1M ambient solution concentration, the factor was approximately 2:1. With the anion-permeable membranes, a factor of 3:1 for the co-/counter-ion diffusion coefficients was observed. These differences are expected because the chloride ion is bound significantly to the fixed groups in anion-exchange resin systems and presumably also in anion-exchange membrane systems. The former effect was observed by Gregor, Belle, and Marcus (34). These differences have been observed previously by Schlögl (29) in his study on the diffusion of sodium bromide in an anion-selective membrane system.

As was shown in Table IX, transport numbers calculated from emf data are in good agreement with those calculated from the product of diffusion coefficients and membrane phase concentrations. This agreement is as expected in view of the fact that the solvent transport correction term is negligible in these membranes of low (15-25%) water content.

The absolute magnitude of the diffusion coefficients of the counter- and co-ions is of considerable interest. In dilute solutions (0.001M) the ratio $\overline{D}_+/D_+ = 0.0050$, taking $D_+ = 22 \times 10^{-6}$ cm^2 sec^{-1}, the value for potassium chloride of approximately the same molal concentration ($4M$) as in the membrane. As the ambient solution concentration increased to 0.1M, $\overline{D}_+/D_+$ increased to 0.0078. The value of $\overline{D}_-/D_-$ was 0.014.

It is of considerable interest to compare the diffusion coefficient of an ion in a condensed phase (such as a membrane phase) with the value it has in free solution, and examine each of the factors contributing to the markedly lower diffusion coefficient. Here, three factors must be considered. A large fraction of the membrane area is composed of the matrix polymer and the bulk of the polyelectrolyte. Consequently, ions are free to diffuse only in the interstitial solution, or the true area for diffusion is proportional to the water content; a factor of 0.235 must be applied.

Second, in a membrane system composed of interconnecting pores, a "tortuosity factor" must be applied because presumably only one-third of the pore lengths permit diffusion in a direction perpendicular to the face of the membrane; a factor of 0.333 is assumed. Carman (35) discusses this factor in porous media; Schlögl and Stein (36) have also considered the tortuosity factor.

The third is the so-called "drag factor." The viscous drag on a sphere moving in a homogeneous medium contained in a cylindrical pore will increase as the sphere diameter approaches that of the pore itself. While Stokes' law technically should not be

applied to the motion of an ion in water where both are of comparable size, nevertheless a considerable body of data has shown that Stokes' treatment does apply, although the constant term may be different. The applicability of Walden's rule is a case in point.

The determination of average pore diameters in the same cation-permeable membrane system was made by Gregor and Jacobson (37) who measured the conductivity of the unhydrated quaternary ammonium ions of different size, and applied the equation of Faxen (38),

$$F = \bar{D}/D = 1 - 2.104(s/S) + 2.09(s/S)^3 - 0.95(s/S)^5 \quad [14]$$

where s is the diameter of the sphere, S the diameter of the uniform pore, and F the drag factor. Gregor and Jacobson calculated an effective pore diameter of 6.0Å for a Nalfilm 1 membrane.

From this value of the pore diameter, Gregor and Jacobson (37) were able to calculate the diameter of the hydrated potassium ion *in the same membrane* from its conductivity. While several authors have observed that the conductances of the alkali metal cations in a resin or membrane phase were approximately proportional to their conductances in free solution, the importance of the drag factor was not considered. This proportionality is the result of a diminution in the size of the hydrated ion, proportional to its hydration. Since the velocity of an ion is $v_i \sim F_i/r_i$, where r_i is the hydrated radius, and since F_i increases with r_i, for the alkali metal cations the effect of viscous drag is compensated by an equivalent reduction in the hydrated diameter. An effective hydrodynamic diameter for the potassium ion of 2.5Å was calculated, while for the chloride ion the diameter was 4.0Å. The drag factor for the potassium ion in the cation-permeable membrane was calculated to be 0.54, and for the chloride ion, 0.21.

Accordingly, in the cation-permeable membrane the diffusion coefficient of the potassium ion is calculated to be $22 \times 10^{-6} \times 0.235 \times 0.333 \times 0.54 = 9.3 \times 10^{-7}$. The calculated value for the diffusion coefficient of the chloride ion is 3.6×10^{-7}. Then, the calculated value of $\bar{D}_+/D_+ = 0.042$ and $\bar{D}_-/D_- = 0.016$; in 0.1M solutions, the corresponding experimental ratios are 0.0078 and 0.014. For the co-ion, the agreement is excellent indeed for these ions are not bound electrostatically to fixed charges. For the counter-ions, the experimental value is but one-eighth the calculated value at $M = 0.001$, and one-fifth the value at $M = 0.1$. Obviously, electrostatic binding makes for a significantly higher activation energy for its diffusion.

Since the co-ion can act as a "carrier" for the counter-ions, it is easy to see why it can exert such a strong effect on the diffusion rate of the latter even when present at very low relative concentrations; in 0.1M solution, $\bar{m}_-/\bar{m}_+$ is only 0.01.

Various attempts have been made to calculate from purely theoretical considerations the diffusion coefficient of a counter-ion in a system of fixed charges. These calculations are made difficult by lack of accurate information on the sizes of the fixed and mobile ions and the distance of nearest approach, and on the effective dielectric constant of the system between unlike charges. Robinson and Stokes (39) discuss in some detail the uncertainties in each of these parameters.

Turning to the cation-permeable membrane systems, the average distance between fixed charges cannot be calculated from the molality alone since the fixed charges and the membrane matrix make up a large part of the volume of the system. However, since the actual pore structure is comparable to an ion-exchange resin of the same type and molality, the properties of the latter can be used as a first approximation. The volume of a potassium polystyrenesulfonate resin cross-linked with 6% divinylbenzene and having approximately the same volume of $\bar{m}_+$ as the cation-permeable membrane was found to be 2.02 ml for 5.09 millimoles of exchange groups (21). Assuming that each fixed site is at the corner of a simple cubic lattice, an average distance of separation of 8.7Å can be calculated.

An estimation of the distance of closest approach certainly cannot be made using the conditions that prevail in dilute solution, for in the membrane phase a considerably smaller hydration of the ions occurs. The variation of selectivity coefficients with temperature constitutes direct experimental evidence (40). In dilute solutions the distance of closest approach $\mathring{a}$ for potassium methanesulfonate was calculated from activity coefficient data using the extended Debye-Hückel equation,

$$\log_{10} \gamma_\pm = \frac{0.509\sqrt{M}}{1 + 0.329 \times 10^{-8} \mathring{a} \sqrt{M}} \quad [15]$$

by Fine, Rothenberg, and Gregor (41), and found to be 3.96Å. This compares with 4.0Å calculated from similar measurements with potassium chloride.

It is evident that $\mathring{a} = 4$Å is not a realistic value for this system; the value of 2.5Å (37) is more realistic.

In view of the fact that most of the water present in these membrane systems must be part of hydration spheres, one must take a value of $\bar{\epsilon}$, the dielectric constant in the membrane phase, as being considerably less than its value in dilute solution. The discussion in Robinson and Stokes (39) suggests a value of $20 < \bar{\epsilon} < 60$, which means that the exponential term can vary by e^3 or a factor of about 20. Obviously, agreement between theory and experiment is fortuitous indeed. Actually, in making these calculations an error in $\mathring{a}$ of 0.1Å can alter the result by a factor of two.

That the activation energy for the diffusion of counter-ions is larger than in free solution has been noted by several authors, particularly Boyd and Soldano (5). Frenkel (42) and Carman and Raal (43) have shown that surface diffusion coefficients likewise have higher activation energies.

Turning to any correlation that might exist between the diffusion coefficients of ions and of neutral molecules in the same cation-permeable membrane system, it was found that $\overline{D}_-/D_- = 0.014$, $\overline{D}/D = 0.0030$ for urea and 0.0031 for acetic acid. The relatively greater retardation of urea and acetic acid may be due to their adsorption and immobilization by the matrix, or because they must diffuse *around* the counter-ions. The generally good agreement between the relative diffusion coefficients of all mobile species corroborates our general picture of the relative simplicity of these membrane systems.

Any correlation between diffusion coefficients of counter-ions in systems of different degrees of cross-linking or matrices will depend in large part upon pore diameter data. For example, $\overline{D}_+$ here was 2×10^{-7}, compared to 5×10^{-6} in an approximately 10% cross-linked resin (26). However, the latter system is highly permeable to sucrose molecules, while the pores of our membrane system exclude this solute to a pronounced degree (37).

Acknowledgment

The authors wish to express their thanks to the Office of Saline Water, Department of the Interior and to the National Science Foundation for their support of this study. This paper was abstracted from the thesis of one of the authors (M.A.P.) submitted in partial fulfillment of the requirements for a Ph.D. degree in chemistry at the Polytechnic Institute of Brooklyn.

Manuscript received April 6, 1959. This paper was prepared, in part, for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

LIST OF SYMBOLS

Subscripts on concentration terms denote ionic species; superscripts on concentration terms denote interfacial solution concentration. The superscript bar refers to parameters within the membrane phase. Primed terms refer to ambient solutions.

A, B — Cationic species.
l — thickness of membrane, cm.
δ — thickness of unstirred film, cm.
C — concentration, molarity, meq cm^{-3} of membrane.
x — spatial coordinate in membrane in cm.
D — diffusion coefficient, $cm^2\ sec^{-1}$.
U — mobility, $cm^2\ sec^{-1}\ volt^{-1}$.
J — flux in equivalents (or coulombs) $cm^{-2}\ sec^{-1}$.
ϕ — potential, volts.
R — gas constant.
T — absolute temperature, °K.
Z — valence.
$\mathbf{F}$ — the Faraday.
k — partition coefficient.
κ — specific conductance, ohm^{-1}, cm^{-1}.
Ω — membrane resistance, ohm cm^2.
λ — equivalent conductance, mho $cm^{-2}\ eq^{-1}$.
m — concentration, molality, meq g^{-1} water.
M — ambient solution concentration, molarity.
$\gamma_\pm$ — mean activity coefficient.
F — drag factor.
s — diameter of sphere in cm.
S — diameter of uniform pore in cm.
ϵ — dielectric constant.
$\mathring{a}$ — distance of closest approach in A.

A Method for Evaluating Battery Grade Manganese Dioxide

F. Kornfeil

U. S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

It is well known that, apart from its composition, several factors determine the quality of MnO_2 for use in Leclanché cells. Methods of chemical analysis have, therefore, in the past been supplemented by investigations of the structure of MnO_2, chiefly by studying the diffraction of x-rays and electrons and by measurements of certain magnetic and thermal properties.

In view of the large number of properties which determine the electrochemical behavior of the MnO_2 electrode, it is not surprising that no single test method has as yet been devised which would provide by itself the complete information necessary to predict the performance of the cathode in a dry cell. It is indeed doubtful that such a method will ever be found. Nevertheless, various attempts have been made in recent years to develop relatively simple laboratory techniques for the evaluation of MnO_2 (1, 2). These techniques permit a rather broad classification of the oxides but fail to show a clear quantitative relationship between a measured quantity and the capacities obtained from complete dry cells containing the same oxides.

Experimental

Another method and device for evaluating MnO_2 is suggested in this paper. The principle of operation of this method is quite similar to that of the discharge tests of dry cells. However, the tedious and expensive procedure of manufacturing dry cells for testing purposes is eliminated. Moreover, the length of the discharge period is reduced to approximately one-eighth of the time required in the 16-2/3 ohm continuous drain discharge test on A-size dry cells. The reduction of a 0.500-g compressed pellet of a mixture of MnO_2 and Shawinigan black (weight ratio 10:1) is accomplished in a test cell (Fig. 1) consisting of the two Lucite halves A and B and a plastic piston ("Hysol No. 3110")[1] through the center of which a graphite rod insures good electrical contact with the depolarizer mixture. The pellet is discharged against a circular amalgamated Zn anode to an end-voltage of 1.00 v at 63.5 ma, corresponding to a current density of 50.0 ma cm^{-2} of the cathode-electrolyte interface. The electrolyte is an aqueous solution of 280 g NH_4Cl and 145 g $ZnCl_2$ per liter.

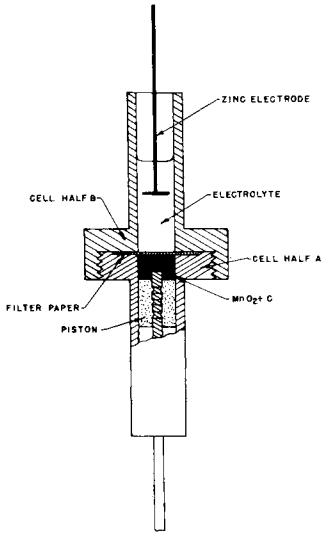

Fig. 1. Completely assembled test apparatus

The test circuit is based on the interrupter principle and is described in detail elsewhere (3, 4). Its essential feature is that the drop of potential due to the internal resistance of the cell is eliminated from the reading of the cell voltage. Therefore, it is not necessary to control some of the factors contributing to the internal resistance, such as the distance between the electrodes, conductance of the graphite rod, and, within a rather wide range, the pressure used in the preparation of the depolarizer pellet.

The results obtained with this method, expressed as length of time required to decrease the cell voltage to 1.00 v (*IR*-drop eliminated), are reproducible within $\pm 2.5\%$. This agreement is remarkably good compared to the results of dry cell tests which normally show a scatter of $\pm 10\%$.

About fifty different samples of MnO_2 were selected for each of which high drain dry cell test results were available of a uniformity considerably greater than $\pm 10\%$. These samples then were discharged in the apparatus at 25°C. Three typical discharge curves are shown in Fig. 2. The results of these tests are plotted against the corresponding dry cell test results (A-size cells) in Fig. 3. The resulting curve was used subsequently to predict the capacities in dry cells of about two hundred additional samples of MnO_2.

The agreement between the present method and the dry cell test results is generally very satisfactory. However, it should be pointed out that, although this method in its present form gives a quantitative measure of the inherent capacity of the

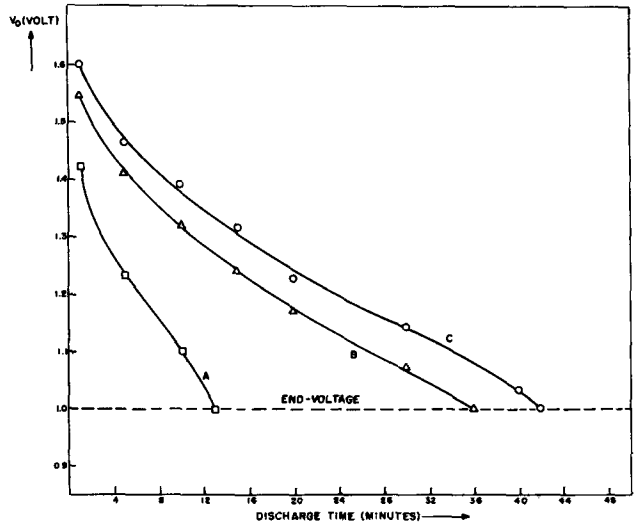

Fig. 2. Discharge curves. Curve A: African ore; Curves B, C: electrolytic manganese dioxides. V_o: Terminal voltage minus IR-drop.

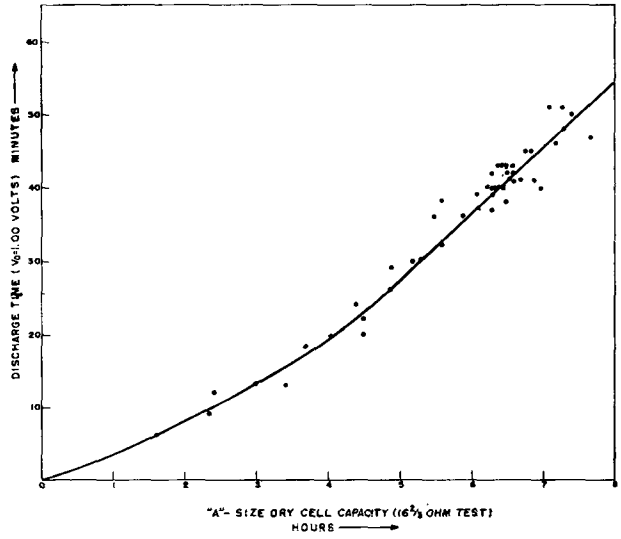

Fig. 3. Correlation between discharge time in test apparatus (end-voltage 1.00 v) and 16-2/3 ohm continuous drain dry cell test.

MnO_2 tested, this capacity need not necessarily be obtainable in an actual dry cell. For example, it has been observed that an oxide of an extremely low apparent density has a lower capacity in a dry cell than would be expected using the curve in Fig. 3, because the dry cell simply contains a comparatively smaller quantity of this particular oxide. This difficulty probably can be overcome by modifying the test procedure so that a constant volume is used instead of a constant mass of the depolarizer.

Acknowledgments

The author wishes to express his appreciation to Mr. H. L. Suchan who carried out a large number of the discharge tests, and to Mr. W. F. Nye, this Laboratory, and Mr. F. Keller, Bright Star Industries, for their continued interest and many helpful suggestions.

A Study of Stripping Anodized Coatings from an Aluminum Alloy

Walter Beck, John Danovich, and Sara J. Ketcham

Aeronautical Materials Laboratory, Naval Air Material Center, Philadelphia, Pennsylvania

A study has been made of the effect of a HF-HNO_3 mixture in stripping anodized coatings from an aluminum alloy. Comparison of efficacy and amount of metal attack was made with that of the CrO_3-H_3PO_4 solution usually used for this purpose. Information about some of the variables which control the process of film stripping was obtained from weight loss determinations, microscopic and electron microscopic studies.

Experimental Procedure

Pretreatment, anodizing, and stripping.—Unless otherwise reported, panels 5 x 10 x 0.13 cm of 5052 aluminum alloy, which contains 2.5% Mg and 0.25% Cr, were vapor degreased, immersed for 15 min in a nonetching alkaline cleaning solution, and water rinsed. Immediately following this pretreatment cycle, the panels were anodized in a 7% CrO_3 bath, operated at 35°C with air agitation. The average current density was 155 ma/dm^2 and the applied voltage 40 (1). Specimens to be used for weight loss measurements were anodized to a coating weight[1] of 48 mg/dm^2 (450 mg/ft^2). Samples for microscopic studies were buffed to a mirror finish, then anodized to a weight of 113 mg/dm^2 (1050 mg/ft^2), the heavier coating being required to permit metallographic examination at a reasonably low magnification.

The CrO_3-H_3PO_4 solution which contained 0.6N CrO_3 and 1.6N H_3PO_4, was used at 88°C, the HF-HNO_3 solution which contained 0.1N HF and 3.5N HNO_3 at room temperature.

Preparation of specimens for photo and electron micrographs.—Before sectioning and mounting, the

[1] The weight of an anodic coating is determined by weighing the anodized panel, stripping the coating in the CrO-H_3PO_4 acid mixture described here for 10 min, and reweighing the panel. The weight loss represents coating only, as this solution does not attack the base metal in any measurable amount.

specimens were covered with an epoxy resin to protect the anodized film against damage during the preparation for microscopic examination. Specimens were sectioned at an angle of 45° to obtain a greater thickness for study.

For electron microscopic inspection, the panels were cut into 1.59 by 1.59 cm (0.625 by 0.625 in.) squares, cleaned with benzene, and molded between layers of polystyrene at 121°C-149°C (250°-300°F) under 3000 to 4000 psi. The plastic was cut along the edge of the specimen and removed after cooling on dry ice. In order to depict the pore structure of the coatings, silicon monoxide replicas were employed. In this technique, a thick film of silicon monoxide was vapor deposited approximately normal to the surface of the impression. The pores in the impression are represented as peaks, and because of their geometry, they appear as holes in the silicon monoxide replica.

To obtain greater surface detail, a thin carbon replica, shadowed with chromium at an angle of 30°, was employed.

The replicas were floated off the polystyrene impression in benzene, washed twice in this liquid, placed on screen supports, and examined in the electron microscope.

Experimental Results and Discussion

Microscopic and electron microscopic observations. —The photomicrographs in Fig. 1 illustrate the effect of the CrO_3-H_3PO_4 stripping solution, showing the coating as anodized (Fig. 1*a*), after immersion for 10 sec during which the thickness was reduced very slightly but uniformly (Fig. 1*b*), and after immersion for 30 sec during which the coating was completely removed (Fig. 1c).

Results of electron microscope studies are given in Fig. 2. The surface of the aluminum alloy after buffing but before anodizing shows the typical furrow structure of sub-grain boundaries and some contaminants (Fig. 2*a*). The as-anodized surface

reveals an average pore diameter of 300Å, the pores being the white areas (Fig. 2*b*). Immersion in the CrO_3-H_3PO_4 for 10 sec enlarged the average pore diameter to 600Å (Fig. 2c), attack of the pore walls is following an elliptical pattern and produces ridges in the coating (Fig. 2*d*). After 30 sec immersion, weight loss measurements (to be discussed in the last section) indicate complete removal of the coating and (Fig. 2*e*) shows that the surface of the base metal has been roughened to a considerable degree, an effect which has been related to the anodizing process (2).

The mechanism which controls the action of the CrO_3-H_3PO_4 system may be discussed in the light of the well-known oxide cell structure of anodized coatings (3). By the attack of the pore walls demonstrated in Fig. 2*d*, the enlargement of the pores, shown in Fig. 2c is achieved (4).

It may be surmised that the enlargement of pores due to the dissolution of oxides which build up the pore walls, in the CrO_3-H_3PO_4 solution, facilitates its access to the barrier at the base of the pores.

The HF-HNO_3 *System*

The electron micrograph depicted in Fig. 3*a* reveals a random attack of the coating which, after an

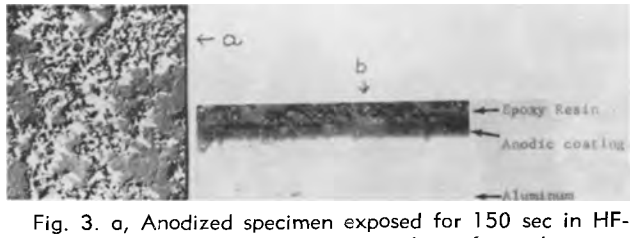

Fig. 3. a, Anodized specimen exposed for 150 sec in HF-HNO_3; chromium shadowed carbon replica of a polystyrene impression, magnification 10,000X before reduction for publication; b, anodized specimen exposed for 450 sec in HF-HNO_3; magnification 500X before reduction for publication.

immersion period of 150 sec, is in a progressive stage of decay; pits can be distinguished in the layer. As depicted in Fig. 3*b*, after an immersion period of 450 sec, the metal underneath the coating is attacked at numerous spots (5) and the layer partially loosened but not yet completely removed.

Figure 3*a* indicates that oxide dissolution is again one of the variables involved in the mechanism which determines the removal of the coating. In addition, as demonstrated in the photomicrograph in Fig. 3*b*, undermining of the coating because of metal attack is another parameter (5). Apparently, in the HF-HNO_3 solution, the rate of oxide dissolution is slower than in the CrO_3-H_3PO_4 solution, and coating removal is partially dependent on film undermining.

Coating Weight Loss

Since the CrO_3-H_3PO_4 stripper does not attack the base metal to any measurable extent, differences in weight found before and after exposure to this solution can be assumed to represent coating weight loss only. However, in HF-HNO_3 solution, the possibility of metal attack had to be considered because immersion of an uncoated specimen in this solution had resulted in considerable weight loss.

After the total weight loss in this solution was obtained for each exposure time, the amount that represented only coating weight loss was determined in the following manner: These specimens were subsequently immersed in the CrO_3-H_3PO_4 acid stripper to see whether any residual coating remained. The weight of this residual coating (if any was present) was then subtracted from the average coating weight of 48 mg/dm^2 (3.1 mg/in.^{2}) to obtain the coating weight loss only. The difference between this figure and the total weight loss was considered to be the amount of metal attack. If no residual coating was present, the amount of weight loss in excess of 48 mg/dm^2 (3.1 mg/in.^{2}) was considered to be the amount of metal attack.

Weight losses plotted in Fig. 4 are the averages of 3 measurements with a maximum deviation not exceeding 6%. With the CrO_3-H_3PO_4 system, a coating weight loss of 25%, determined after a 10-sec exposure, correlates qualitatively with a 10% loss in coating thickness (measured microscopically) and the appreciable increase in pore diameter, as shown in Fig. 2*c*. Also, a coating weight loss of about 75% can be considered to be in a fair agreement with the fact that, after the 30-sec exposure, both the microscopic and the electron microscopic investigation disclosed complete removal of the anodized layer. In the HF-HNO_3 solution, the weight loss determinations and the optical findings indicated a much slower rate of coating removal than in the CrO_3-H_3PO_4 system. Figure 4 also illustrates that almost from the very beginning of the stripping process the removal of the coating is accompanied by the dissolution of metal from beneath the oxide layer when specimens were exposed to the HF-HNO_3 solution. Within an initial period of about 100-sec duration, the rate of dissolution of the aluminum from underneath the anodized layer is considerably slower than that of an uncoated specimen. After exceeding this time interval, the metal is dissolved at a rate similar to that resulting on the unanodized specimen. Also, the electron micrograph 3*a* taken after an immersion of 150 sec showed that the coating was strongly attacked and pitted, while the photomicrograph taken after 450 sec revealed strong metal attack underneath a partially loosened coating. From the last experiments, it has to be concluded that uncritical use of the HF-HNO_3 system may lead to a much greater metal attack than is necessary for coating removal.

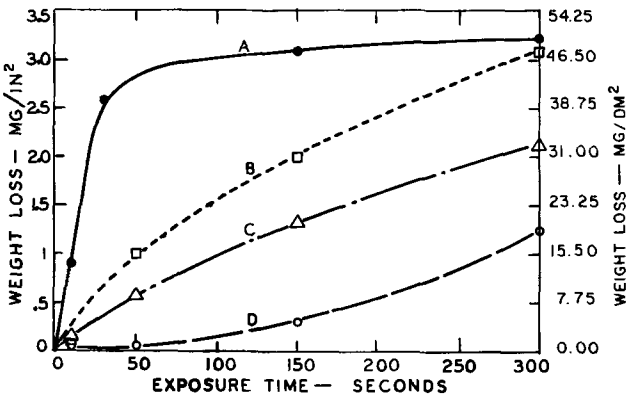

Fig. 4. Plot of weight loss vs. exposure time. Weight loss due to: A, solvation of anodized coating in CrO_3-H_3PO_4; B, removal of anodized coating in HF-HNO_3; C, dissolution of metal from uncoated specimen in HF-HNO_3; D, dissolution of metal from underneath anodized coating in HF-HNO_3.

HF-HNO_3 solutions have come into widespread use for removal of oxide coatings not only from aluminum alloys but also from numerous other metals such as Ti, Mo, Zr, and Ta (6). Metal losses due to over etching are avoidable, and the HF-HNO_3 containing systems should only be used when the concentrations and time of exposure are controlled carefully.

Acknowledgment

The authors are much indebted to Mr. F. S. Williams and Dr. G. K. Holmes, Superintendents of the Metallurgical and Chemical Engineering Divisions, respectively, Aeronautical Materials Laboratory, and Mr. Jack Smith, Head of the Chemical Branch for the great interest taken in this study.

The Gudden-Pohl Effect of ZnS:Cu

Yoshihide Kotera and Kiyotake Naraoka

Government Chemical Industrial Research Institute, Tokyo, Japan

The Gudden-Pohl effect (1) on the phosphorescence of various ZnS:Cu phosphors was studied by means of an applied alternating electric field. The phosphors were prepared by a method similar to that described by Bube (2). They comprised two series of hexagonal and cubic ZnS:Cu (2% NaCl) phosphors and contained 10^{-6}, 3 x 10^{-6}, 10^{-5}, 3 x 10^{-5}, 10^{-4}, 3 x 10^{-4}, and 10^{-3} moles Cu per mole ZnS. The hexagonal and cubic phosphors were fired at 1200° and 900°C, respectively.

All phosphors were embedded in Acrylite (polymethylmethacrylate) and measured in an electroluminescent cell of common construction. The electric field was obtained from a 50 cps source, and the field intensity was estimated to be about 10,000 v/-cm. The integral of the light flash (i.e., the area under the curve shown in Fig. 1, in which the abscissa is time and the ordinate is the photocurrent from a photomultiplier) during the application of the field was taken as a measure of the magnitude of the Gudden-Pohl effect (Fig. 1). Prior to the measurement the phosphors had been excited with near ultraviolet radiation. The exciting radiation was then removed and the electric field was applied 1 min after removal of the radiation.

The integrals of the light flashes of both hexagonal and cubic ZnS:Cu increased with increasing copper content and reached a maximum at a content of 10^{-5} mole. With further increasing copper contents they decreased again. In general, the effect was stronger with cubic phosphors than with hexagonal ones of the same copper content. The phosphorescent intensity after one minute's decay and the infrared stimulation during illumination with infrared after one minute of normal phosphorescent decay were measured. Results were nearly identical with those reported by Bube (3).

It has been known that the Gudden-Pohl effect may be caused by electrons released from filled traps by the action of a field. Accordingly, from the knowledge of trap characteristics, the existence of a Gudden-Pohl effect might be predicted. Figure 2 shows the temperature dependence of the Gudden-Pohl effect and the thermoluminescence above room temperature. For cubic ZnS:Cu, the effect becomes smaller at rising temperatures between 20° and 120°C. There is no glow peak in this temperature range. In contrast, the effect increases at higher temperatures with hexagonal ZnS:Cu and it reaches a maximum at 70°C, while the glow curve has its peak at 550°C (Fig. 2).

Two glow curves were obtained for hexagonal ZnS:Cu (10^{-5}), one with and the other without previous application of an electric field. It was found that the two glow curves have about the same height.

From the above observations it is concluded that the deeper traps which correspond to a glow peak at 55°C do not produce the Gudden-Pohl effect at room temperature. Rather, the increase of the effect at higher temperatures may be ascribed to the emptying of the deeper traps which are able to release their electrons thermally at higher temperatures.

Diffusion of Oxygen in Hafnium

J. Paul Pemsler

Nuclear Metals, Inc., Concord, Massachusetts

Hafnium shares with titanium and zirconium the unusual ability to dissolve large amounts of oxygen in interstitial solid solution. No data have been found regarding the hafnium-oxygen phase diagram other than the existence of a stable oxide HfO_2, and no studies on the diffusion of oxygen in hafnium are reported. The techniques used in this study are similar to those used by the author in a study of the diffusion of oxygen in zirconium (1).

Experimental

The diffusion of oxygen in hafnium was measured by following the rate of dissolution of anodically deposited thin oxide films when annealed *in vacuo*. The thickness of the oxide film was determined periodically during the experiment by observing its color (arising from optical interference) and comparing it with a series of standards.

Reactor grade hafnium samples containing 1.45 w/o Zr and measuring 1.8 x 4.5 x 0.4 cm were obtained from Knolls Atomic Power Laboratory. They were annealed in a vacuum for 1 hr at 800°C, furnace cooled, paper polished on 4/0 emery paper, and then etched for 2 min in a bath of 50% HNO_3, 5% HF, 45% H_2O.

Oxide films were deposited anodically from a 1% KOH solution in distilled water, with the sample as anode and a platinum wire as cathode. Several thicknesses of oxide were deposited on different areas of the same sample. The weight gain on anodization, as measured on a microbalance, was found in separate experiments to be a linear function of the applied voltage over the range studied (0-120 v), and independent of time. Assuming a value of 10.22 g/cm^3 for the density of HfO_2, the oxide thickness deposited during anodization corresponds to 18.9Å/v.

Anodized hafnium samples, sealed off in a Vycor tube, were placed in a horizontal furnace having a view hole for continuous observation of the sample while at temperature. The color of each zone changed with time, indicating a decreasing film thickness. At any given time, the decrease in film thickness was found to be independent of the original film thickness in a particular anodized area; thus identical results were obtained from any one of the color areas.

Results

Microscopic examination of samples which had been anodized and subsequently vacuum annealed revealed that, as in zirconium (1), the dissolution process was not homogeneous, and that, macroscopically, an average process was being observed. A wide range of colors, sharply defined by grain boundaries, was observed under a microscope. The diffusion coefficients calculated are therefore based on a macroscopic, average estimate of color. Variation in the diffusion coefficient by a factor of about two among the differently oriented grains was observed.

The parabolic rate of disappearance of the oxide film on hafnium suggests that the rate-determining step in the dissolution process is the diffusion of oxygen in hafnium metal. The consumption of oxide, generating additional metal, is accompanied by an outward motion of the oxide-metal boundary until the oxide is entirely consumed. Mathematically this case falls within a limited class of moving-boundary diffusion problems, for which solutions are readily found. The diffusion equation is discussed in detail elsewhere (2). From the solution found on the assumption of constant diffusivity, D can be expressed as

$$D = \frac{1}{4b^2}\left(\frac{x'}{\sqrt{t}}\right)^2$$

where b satisfies the equation

$$b\,(1 + \operatorname{erf} b) = \frac{1}{\sqrt{\pi}}\frac{C_o}{m_o}e^{-b^2}$$

Here in time, t, there is a displacement of the oxide-metal boundary, x', which is related to the observed decrease ΔL in thickness of oxide film by the following expression involving the respective molecular volumes

$$x' = \frac{\rho HfO_2}{\rho Hf \text{ saturated}}\,\frac{\text{Formula weight } (HfO_{sat})}{\text{Formula weight } (HfO_2)}\,\Delta L$$

The quantity ρ is the density, and C_o is the difference between the saturated concentration, C_s, and initial concentration of oxygen in the metal. The quantity m_o represents the weight of oxygen removed from the HfO_2 consumed in the generation of unit volume of saturated hafnium (HfO_{sat}), and may be expressed as

$$m_o = \frac{\text{Formula weight } (HfO_2) - \text{Formula weight } (HfO_{sat})}{\text{Formula weight } (HfO_{sat})}\,\rho HfO_{sat}$$

The precise value of the diffusion coefficient cannot be calculated at this time because the saturation concentration of oxygen in hafnium (O_{sat}) is not known. Nevertheless, by considering the titanium-oxygen and zirconium-oxygen systems (saturation oxygen concentration values 34 a/o and 29 a/o, respectively), reasonable estimates of this value may be made. In this work the diffusion coefficient was calculated for each of three saturation values: 20 a/o, 30 a/o, and 40 a/o oxygen in hafnium. Thus,

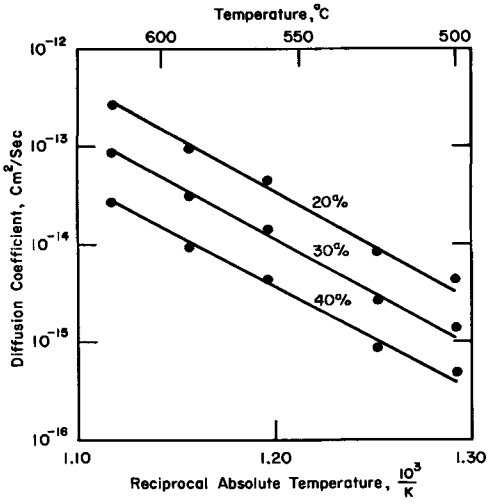

Fig. 1. Temperature dependence of the diffusion coefficient of oxygen in hafnium. The three curves represent results calculated assuming the three indicated oxygen solubilities in hafnium.

$C_o = C_s = 0.30$ g/cm^3, 0.50 g/cm^3, or 0.76 g/cm^3 (the initial concentration was taken as zero); $m_o = 2.07$ g/cm^3, 1.83 g/cm^3, or 1.52 g/cm^3; $x' = 0.657\ \Delta L$ cm, $0.667\ \Delta L$ cm, or $0.678\ \Delta L$ cm; $b = 0.067$, 0.120, 0.218. The density of HfO_2 was taken as the calculated x-ray value equal to 10.22 g/cm^3, and the density of hafnium saturated with oxygen was estimated to be about 13.5 g/cm^3.

A plot of the logarithms of the diffusion coefficients vs. the reciprocal of the absolute temperature for each of the three assumed oxygen solubilities is shown in Fig. 1. The equation for the diffusion coefficient of oxygen in hafnium in the temperature range of 500°-620°C is given by D, cm^2/sec $= 1.4 \exp [(-51{,}850 \pm 200/RT)]$ for 20 a/o; $0.47 \exp [(-51{,}850 \pm 200/RT)]$ for 30 a/o; and $0.14 \exp [(-51{,}850 \pm 200/RT)]$ for 40 a/o oxygen saturation solubility in hafnium.

The diffusion coefficient of oxygen in hafnium is smaller by a factor of about ten than that of oxygen in zirconium, but the energies of activation are identical.

This work was performed under AEC Contract No. AT(30-1)-1565.

Technical Feature

The Fuel Cell and the Carnot Cycle

Herman A. Liebhafsky

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

To provide a basis for considering the combination of nuclear reactor (or other heat source) and fuel cell, the well-known fact that the fuel cell escapes the Carnot-cycle limitation is reviewed briefly. Then it is shown that the combination cannot escape this limitation and, in some cases, can only approach the Carnot-cycle efficiency.

The Fuel Cell Alone

The fuel cell is an electrochemical device in which the chemical energy of a conventional fuel is converted directly and usefully into electrical work. As has long been appreciated (1), the fuel cell is potentially attractive because the energy conversion it accomplishes is not subject to the Carnot-cycle limitation. This electrochemical conversion can be isothermal: for the Carnot-cycle limitation to operate, heat must flow from a higher to a lower temperature and be partially converted into work.

More precisely, the chemical energy mentioned above is the free energy

$$\Delta G = \Delta H - T\Delta S \qquad [1]$$

of the reaction

$$\text{Fuel} + \text{Oxygen} = \text{Reaction Products} \qquad [2]$$

(In Eq. [1], ΔH is the change in heat content, and ΔS the change in entropy for reaction [2].) Note, however, that the heat $T\Delta S$ absorbed or liberated in reaction [2] is characteristic of the reaction carried

out reversibly. It can be absorbed or liberated isothermally, and it must on no account be confused with heat that is converted into work in a Carnot-cycle process.

A more detailed analysis of this thermodynamic argument is desirable. In Eq. [1], ΔG is the maximum useful work realizable if reaction [2] is carried out isothermally and reversibly. If, instead, we choose to carry out this reaction nonisothermally with no work done, all the chemical energy will appear as heat. Because heat is random in nature, and work is a directed process, a price must be paid to convert heat into work; this price is the Carnot-cycle limitation. To escape this price, it is necessary to avoid randomizing the chemical energy as heat.

The electrochemical cell permits one to avoid this randomization. In such a cell, reaction [2] will occur in two parts (or half-cell reactions) schematically as follows:

Anode Reaction: Fuel = Ions + Electrons [2a]

Cathode Reaction: Oxygen + Electrons = Ions [2b]

When reaction [2] is carried out in this way, randomization never occurs because the electrons liberated at the anode flow unidirectionally to the cathode through the external circuit. They flow in this direction because they are driven by an electromotive force proportional in the limit to the free energy change. Because of this driving force, it is possible to make the electrons do work before they reach the cathode. Randomization of the chemical energy is thus avoided, and the Carnot-cycle limitation does not apply.

If the chemical energy of reaction [2] is randomized as heat that is later converted to work in a heat engine, the maximum useful work recoverable will be the familiar $\Delta H(T_1 - T_2)/T_1$, where the temperatures apply to the heat engine; that is, T_1 might be the inlet temperature of the first stage in a turbine; of course it is less than the temperature under the boiler.

In assessing the possible advantage a fuel cell might have over a conventional power plant, it is thus necessary to compare $\Delta H(T_1 - T_2)/T_1$ with ΔG (Eq. [1]). But the relationship of ΔH to ΔG depends on $T\Delta S$. Now, the sign and magnitude of this last term depend on the heat capacities of the substances in reaction [2] because

$$d(\Delta S) = \Delta Cp\, d\ln T \text{ (at constant pressure)} \quad [3]$$

(Assume ΔCp constant. In general, the integration of this equation also requires the statement about entropy changes at the absolute zero that is known as the Third Law of Thermodynamics. This need not concern us here.)

The three possible relationships of ΔH and ΔG are summarized in Table I.

The present outlook is that all successful fuel cells will use gaseous fuels, hydrogen and carbon monoxide being the most likely. These gases may prove necessary intermediates even when hydrocarbons are used, for the direct anodic oxidation of hydrocarbons to water and carbon dioxide is difficult to accomplish. Because the oxidation of hydrogen and of carbon monoxide to gaseous products reduces the number of gaseous molecules, only Case 3, Table I, is of immediate practical concern. (The sign and magnitude of ΔCp for reaction [2] are determined primarily by the change in the number of gaseous molecules during reaction. Note that this change is zero for the oxidation of methane.)

Table I. Maximum useful work and change in heat content for reaction [2]

Case	ΔCp	Heat exchange*	Arithmetic relationship
1	Positive	Absorbed by cell	$\Delta G > \Delta H$
2	Zero	None	$\Delta G = \Delta H$
3	Negative	Rejected by cell	$\Delta G < \Delta H$

* Heat exchange with environment when reaction [2] proceeds isothermally and reversibly.

To illustrate the relationship between ΔG and ΔH, let us examine the gaseous reaction

$$H_2 + \tfrac{1}{2} O_2 = H_2O \quad [4]$$

for which data (2) are given in Table II.

The ratio in the last column may be compared with $(T_1 - T_2)/T_1$ equals 64%, which is the Carnot efficiency for a good modern steam plant that might attain an actual over-all efficiency of 40%. Table II shows clearly that the potential advantage of this fuel cell over the steam plant will disappear with increasing temperature unless the rejected heat is properly used. This is a much more serious consideration in our day than in Ostwald's (1), when a fuel cell would have been called on to compete with steam plants having an over-all efficiency of only 10%.

Nuclear Reactor and Fuel Cell

As nuclear power bcomes increasingly available, one hears more frequently the suggestion that a fuel cell (or other battery) be combined with a nuclear reactor so as to convert heat into electric energy. Any other source of heat could in principle serve as well. In the fuel cell, for example, elements A and B would be consumed at temperature T_2 to produce electric energy and to form the compound AB, which would flow to the reactor at temperature T_1, where it would be dissociated to regenerate A and B.

The compound AB and its elements may be regarded as a working fluid in a thermal cycle in which heat is changed into work. On general grounds, one is justified in concluding that this conversion of heat into work must be Carnot-cycle limited in accord with the Second Law. The conclusion applies even though the working fluid is un-

Table II. $\Delta G°$ and ΔH for a hydrogen fuel cell

T, °K	ΔH, cal/mole	$\Delta G°$, cal/mole*	$\Delta G°/\Delta H$
400	−58,040	−53,520	0.92
500	−58,270	−52,360	0.90
1000	−59,210	−46,030	0.78
2000	−60,260	−32,310	0.54

* This free energy change, $\Delta G°$, is for all three gases in their standard states (about 1 atm). The superscript must be used also for entropy changes at the standard state ($\Delta S°$), but may be omitted in the present cases from ΔH because this function is virtually independent of volume.

usual in that it undergoes dissociation and recombination. Although the fuel cell alone escapes the Carnot-cycle limitation, the combination of fuel cell and nuclear reactor does not. Detailed analysis is necessary, however, to show whether the Carnot-cycle efficiency can actually be attained.

To make the analysis, let us represent the cycle as follows:

Dissociation in Reactor: AB = A + B at T_1 (I)
Recombination in Fuel Cell: A + B = AB at T_2 (II)

Heat Exchange (connecting link) A and B initially at T_1 (III)
with AB initially at T_2

The maximum efficiency will be attained if the cycle is reversible throughout. We would then have a reversible isothermal process (I) at T_1, which is the reverse of a reversible isothermal process (II) at T_2. The heat exchange process (III) cannot, however, be reversible unless ΔCp is zero.

That a value of ΔCp other than zero lead to irreversible heat flow in process (III) is easily shown. If, for example, ΔCp in process (II) is negative, then the combined molal heat capacities of A and B exceed that of AB. If ΔCp is negative also at T_1, then AB in passing from fuel cell to reactor cannot en route absorb enough heat from A and B to keep infinitesimal the temperature difference between the two legs of the heat exchanger. Consequently, A and B will reach the fuel cell at a temperature above T_2, where the irreversible flow of heat will continue until temperature equilibrium is established.

Because further discussion of such irreversible heat flow is not necessary to the main argument, let us proceed with Table I, Case 3, for which ΔCp is negative.

We need not inquire into the nature of the isothermal reversible processes (I) and (II). We know that each (and the cycle) must obey the Laws of Thermodynamics. We obtain the ideal efficiency in three steps. We postulate A, B, and AB to be in their standard states at T_1 and at T_2.

1. For the two isothermal processes only, with the working fluid initially at T_1, the net maximum useful work under the postulated conditions is

$$\Delta G^\circ_2 - \Delta G^\circ_1 = (\Delta H_2 - \Delta H_1) - (T_2\Delta S^\circ_2 - T_1\Delta S^\circ_1)$$

or

$$\Delta G^\circ_2 - \Delta G^\circ_1 = (\Delta H_2 - \Delta H_1) + (T_1\Delta S^\circ_1 - T_2\Delta S^\circ_2) \quad [5]$$

(Here, as in Table II, the superscripts indicate that standard states are involved. In practice, of course, A, B, and AB are not likely to be in their standard states, but this does not affect the argument.)

2. The heat absorbed from the nuclear reactor is $T_1\Delta S^\circ_1$.

3. The ideal efficiency is

$$\frac{\Delta G^\circ_2 - \Delta G^\circ_1}{T_1\Delta S^\circ_1} = \frac{(\Delta H_2 - \Delta H_1) + (T_1\Delta S^\circ_1 - T_2\Delta S^\circ_2)}{T_1\Delta S^\circ_1} \quad [6]$$

Were our thermal cycle completely reversible, we should expect it to have the Carnot efficiency. The right side of Eq. [6] degenerates to the Carnot efficiency if

$$\Delta H_1 = \Delta H_2 \text{ and } \Delta S^\circ_1 = \Delta S^\circ_2 \quad [7]$$

Noting that

$$d(\Delta H) = \Delta Cp\, dT \quad [8]$$

(assume ΔCp constant)

and considering Eq. [3], we conclude that Eq. [7] is valid if ΔCp is zero. This is true for Table I, Case 2, in which the heat exchange process (III) can be made reversible. With complete reversibility, the combination of nuclear reactor and fuel cell will attain Carnot efficiency.

Let us now examine Table I, Case 3, beginning with a numerical illustration. Let us consider that a hydrogen fuel cell at 500°K(T_2) is combined with a nuclear reactor at 2000°K(T_1). By use of Eq. [6] and of data in Table II, we find

$$\frac{-20{,}050}{\dfrac{-52{,}360 + 32{,}310}{-27{,}950}} =$$

$$\frac{+1990 \qquad -22{,}040}{\dfrac{(-58{,}270 + 60{,}260) + (-27{,}950 + 5910)}{-27{,}950}} \text{ or } 73.3\% \quad [9]$$

This efficiency is less than 75%, the efficiency of a Carnot cycle operating between 2000° and 500°K. Why? Because of the irreversibility in the heat flow process (III), which is traceable to the negative ΔCp.

The difference between 73.3 and 75% subdivides into (*a*) the effect of changing temperature on ΔH and (*b*) the effect of changing temperature on ΔS. (*a*) As Eq. [9] shows, the heat of reaction [4] increases numerically (from −58,270 to −60,260 cal) as the temperature increases from 500° to 2000°K. Consequently, the numerator in Eq. [9] decreases by 1990 cal and this acts to *reduce* the efficiency below the Carnot value. (*b*) Suppose the reduction just described were absent. Then Eq. [6] would yield the Carnot efficiency if ΔS°_2 were replaced by ΔS°_1. What is the effect of this replacement? $T_2\Delta S^\circ_2$ is −5910 cal, and $T_2\Delta S^\circ_1$ is −6990 cal; consequently, the use of the (correct) $T_2\Delta S^\circ_2$ term in Eq. [9] gives a larger (negative) number (by 1080 cal) in the numerator than would the insertion of $T_2\Delta S^\circ_1$, which insertion would yield the Carnot efficiency under the conditions stipulated. On this basis, we may say that the effect of changing temperature on ΔS° tends to *counteract* the analogous effect on ΔH.

It will now be shown that the effect on ΔH is always numerically the larger.

For this to be true, we must have (Eq. [3] and [8])

$$\int_{T_2}^{T_1} \Delta Cp\, dT > T_2 \int_{T_2}^{T_1} \Delta Cp\, d\ln T \quad [10]$$

If we write $T_1 = T_2 + \Delta T$, relation [10] is tantamount to

$$\Delta T > T_2 \ln \frac{T_2 + \Delta T}{T_2} \quad [11]$$

or

$$e^{\Delta T/T_2} > 1 + \frac{\Delta T}{T_2} \quad [12]$$

The correctness of relation [12] is easily established by comparing it with the series

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \text{- - -} \qquad [13]$$

It follows therefore that the combination of nuclear reactor and fuel cell will, even under ideal conditions, have an efficiency somewhat below the Carnot if ΔCp for reaction [2] is negative. As the foregoing analysis has shown, the difference generally will be small owing to the interaction of the changes in heat content and in entropy.

If ΔCp were positive, A and B could not heat AB to temperature T_1 in the heat exchange process (III). The deficit would have to be made up from the nuclear reactor, and it would therefore appear as an added term in the denominator of Eq. [6]. No doubt detailed calculations for the case of positive ΔCp would also show the Carnot-cycle efficiency to be an upper limit.

Although thermodynamics does not require it, let us examine the combination of nuclear reactor and fuel cell in more detail. Water, especially water vapor, is a poor electrolyte. We shall therefore have to add an electrolyte so that the cell can function. This electrolyte may very well interact with water, and the energy of such interaction will have to be considered. In particular, the work required to separate the water from the salt will have to be subtracted from the work output of the nuclear reactor-fuel cell system. This will reduce the attractiveness of the scheme.

To bring the entire picture nearer reality, we point out, as did Yeager (3), that electrolysis is the simplest process for dissociating AB reversibly and isothermally at temperature T_1. From the electrical energy ΔG_2, ΔG_1 will have to be diverted to accomplish this dissociation. If A and B are gases, electrolysis has the great advantage of separating them at the minimum energy cost, which is ΔG_1. This seems the simplest solution to the separation problem, a problem that can be formidable enough to make the nuclear reactor-fuel cell scheme unattractive.

The energy cost of transferring the gases from reactor to cell and back to reactor has been neglected. No matter how small the cost, the need for this transfer will further reduce the attractiveness of the scheme.

Instead of behaving like water, AB might be stable in state 2 but unstable in state 1. One might then assume that AB does not dissociate until it is passed over a catalyst at temperature T_1, when it dissociates *spontaneously* to regenerate A and B. A substance such as this is unlikely to have a large value of ΔG°_2, and the useful work recoverable from the cycle is likely to be small. Appreciable irreversibility anywhere in the cycle, for example, in the separation of A and B at temperature T_1, will then be a serious matter.

In summary, the combination of nuclear reactor and fuel cell cannot operate at an efficiency exceeding that of a Carnot cycle. It cannot attain this efficiency if the heat capacity relationships among the reacting substances lead to irreversibility in heat transfer. The combination has other limitations that will not usually be offset by factors such as elimination of the need for turbines and generators.

This paper has been restricted to simple fuel cells. In more complex systems (the "redox systems") for the generation of electricity, oxidation-reduction couples are used as intermediates to promote reaction [2]. The conclusions about the Carnot cycle apply to these systems also.

Acknowledgment

The author wishes to thank his colleagues, E. J. Cairns, D. L. Douglas, G. E. Moore, and B. H. Zimm, for helpful discussions of the material in this report.

Manuscript received April 8, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of The Electrochemical Society, Vol. 105, No. 1, 8, and 9 (January, August, and September 1958), and Vol. 106, No. 1-6 (January-June 1959). Discussion not available for this issue will appear in the Discussion Section of the June 1960 JOURNAL.

The Anodic Oxidation of Zinc and Zinc-Tin Alloys at Very Low Current Density

S. E. S. El Wakkad,[1] A. M. Shams El Din, and H. Kotb
(pp. 47-51, Vol. 105)

M. Prazák[2]: The fact described by Dr. S. E. S. El Wakkad and co-workers, namely that Sn-Zn alloy is more easily passivated than pure zinc or pure tin, is very interesting indeed. According to the binary diagram, two phases exist in this alloy: practically pure tin and zinc. According to x-ray investigation, this is true also for electrolytically deposited alloy. Nevertheless, the electrochemical behavior of the alloy does not correspond to the sum for both components present, as we found in the case of the alloys Fe-Cr-Ni.[3]

We have studied the electrochemical behavior of the Sn-Zn alloy and that of pure zinc and tin in 1*N*-NaOH by means of impedance measurements and also by the potentiostatic method (*see* the polarization curves in Fig. 1 and 2 of this discussion). We found that:

(*A*) The corrosion current in the passive state for the alloy is lower (about 0.5 ma/cm^2) than would correspond to 25% Zn and 75% Sn (2.1 ma/cm^2), as shown in Fig. 1 and 2 at +0.2 to 0.8 v.

(*B*) On pure zinc, two types of passive layers may be found according to the potential imposed. In the range −0.92 to −0.56 v (vs. the normal hydrogen electrode), there exists a colorless thin layer possessing good electron conductance; in the range above +0.2 v, a thicker dark layer grows up, showing a higher corrosion current in the passive state. On this type of layer, oxygen is evolved with an overpotential of about 0.8 v (*see*, also, the paper of

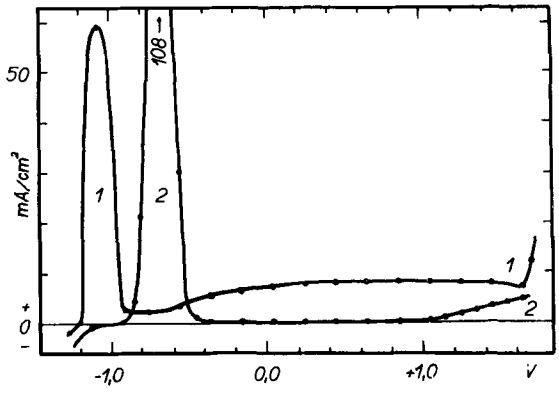

Fig. 1. Potential-polarization curves of Zn (1) and Sn (2) in 1N-NaOH.

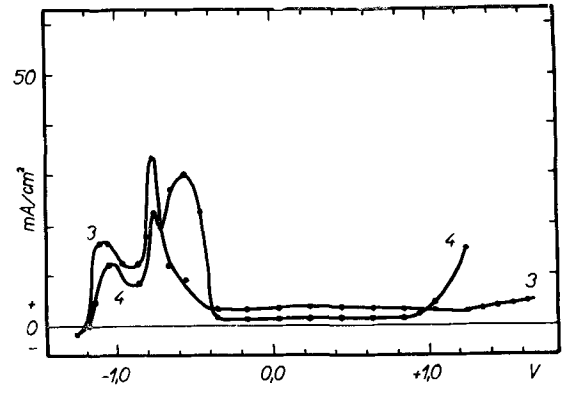

Fig. 2. Potential polarization curves of Sn75-Zn alloy (3—prepared by melting, 4—electrodeposited) in 1N-NaOH.

Landsberg[4]). In the case of the Sn-Zn alloy, this change in the behavior of the zinc component was not found.

To explain these facts, it must be accepted that a homogenous passive layer grows up on the non-homogenous Sn-Zn alloy.

We believe that this and the other works of Dr. El Wakkad and co-workers will do much to clear up the problems concerning passivity of alloys of different types.

Higher Oxides of Silver

W. S. Graff and H. H. Stadelmaier (pp. 446-449, Vol. 105)

J. A. McMillan[5]: Graff and Stadelmaier, in an interesting paper dealing with the higher oxides of silver, have affirmed that Ag_7NO_{11} cannot exist since the same product is obtained from AgF as from $AgNO_3$ solutions. They assume that the x-ray diffraction pattern is due to the presence of silver in an oxidation state higher than two (Ag_2O_3?). The discussor wishes to add that the same pattern is obtained from $AgClO_4$[6] and Ag_2SO_4 solutions. These facts, however, do not necessarily mean that all of the four products are the same oxide with different impurities, as believed by Graff and Stadelmaier, since the patterns could be due to isomorphous substances. The discussor believes that a series of compounds $(Ag_3O_4)_2Ag^IAn$, where An stands for NO_3, ClO_4, F, or SO_4H, exists, on the basis of the following facts.

I. Skanavi Grigoieva and Shimanovich[7] have obtained, during the electrolysis of $AgClO_4$ solutions, a black deposit whose composition was $(Ag_3O_4)_2Ag^IClO_4$.

[4] R. Landsberg, *Zeitschr. f. Physik. Chemie*, 206, 291 (1957).
[5] Instituto de Física de San Carlos de Bariloche, Bariloche, Río Negro, Argentina; present address: Chemistry Div., Argonne National Lab., Lemont, Ill., where the discussor is spending the duration of a Guggenheim Fellowship.
[6] W. S. Graff and H. H. Stadelmaier, *This Journal*, 105, 446 (1958).
[7] M. S. Skanavi Grigoieva and I. L. Shimanovich, *Zhur. Obshchei Khim.*, 24, 1490 (1955): *Chem. Abstracts*, 49, 5165a (1955).

II. de Boer and van Ormondt[8] have obtained, on electrolyzing Ag_2SO_4 solutions under similar conditions, black deposits whose composition was $(Ag_3O_4)_aAg^{II}SO_4$ with $a = 2 - 2.5$. These authors believed that all silver atoms were in higher oxidation states. Nevertheless, if one hydrogen is added (impossible to identify from the results of the analysis) and only the value $a = 2$ is taken into account (values of a greater than 2 correspond to partial decomposition), the formula becomes $(Ag_3O_4)_2Ag^{I}SO_4H$. It should be noted that the oxysalts give insoluble AgO when boiled with water, according to

$$(Ag_3O_4)_2Ag^{I}An \rightarrow 6\,AgO + Ag^{+} + An^{-} + O_2,$$

which permits a straightforward analysis.

III. Kappanna and Talaty[9] have observed a black deposit during the electrolysis of AgF solutions, whose magnetic susceptibility was $+0.37 \times 10^{-6}$ emu/g. Comparing this with the value observed by the discussor[10] in the case of oxynitrate and oxyperchlorate, $+0.41$ and $+0.49 \times 10^{-6}$ emu/g, respectively, it is plausible to infer that the compound was $(Ag_3O_4)_2Ag^{I}F$, earlier reported by Tanatar,[11] and found to exhibit the same x-ray diffraction pattern as the other oxysalts.[6]

IV. $Ag_7NO_{11} = (Ag_3O_4)_2Ag^{I}NO_3$ is a chemical compound that certainly could be questioned until the outstanding papers of Noyes and co-workers, cited by Graff and Stadelmaier, appeared, but not later.

In addition to the above, the discussor's own results[10] support the existence of such a series of compounds. Their space group is $\overline{F}43m - T^2_d$, with $a \cong 10$Å, the anions occupying the tetrahedron (¼, ¼, ¼), the tetrahedron (¾, ¾, ¾) being occupied by monovalent silver atoms. The anions orient as the trigonal axes. Interchanging of different anions gives the different oxysalts. Twenty-four silver atoms center the edges of each of the eight ½a-cubes. Oxygen atoms arrange in two sets of four tetrahedrons each, surrounding anions and monovalent silver atoms, respectively. This structure explains the magnetic behavior.

The interpretation of these patterns is straightforward, and the discussor's experience, in disagreement with Graff and Stadelmaier's, is that quite pure patterns can be obtained, free from AgO lines, at least in the cases of oxynitrate and oxyperchlorate.

With respect to AgO, Graff and Stadelmaier have arrived at the same conclusion as the discussor, although the discussor believes that their values for a, b, and c are more accurate than his own.

Independently, Scatturin, Bellon, and Zannetti[12] have arrived at the same conclusion. Nevertheless, if AgO were a divalent silver oxide, it would be strongly paramagnetic (Ag^{2+} is a $4d^9$ ion), which is not the case. AgO is diamagnetic, its susceptibility having been found to be[13]

$$\chi = -0.15 \times 10^{-6}\ \text{emu/g}.$$

The discussor[10] has modified the structure and adopted the space group $P2_1c - C^5_{2h}$, the oxide then being a silver(I)-silver(III)-oxide, with silver(III) ions coordinated in a planar arrangement with four oxygens (hybridization dsp^2), which explains its diamagnetism.

These results, together with the results on the oxysalts, will be published in detail.

H. E. Swanson[14]: Graff and Stadelmaier have pointed out that the sample we used in reporting the x-ray diffraction powder pattern of argentic oxynitrate $Ag_7O_8NO_3$[15] was not analyzed to show the existence of the NO^-_3 ion and that the nature of the compound was dependent only upon documentation in the literature.[16-20] Graff and Stadelmaier believe this compound to be a higher oxide of silver.

In the four years that have elapsed since our x-ray pattern was prepared, a recent x-ray analysis of the original material shows that it has decomposed, in the vial in which it was stored, into the components AgO and $AgNO_3$, indicating the presence of nitrogen in the original sample. When compared to physical mixtures of AgO and $AgNO_3$, the peak heights of the decomposed sample agree with a six to one molecular ratio mixture.

Graff and Stadelmaier also showed that the $Ag_7O_8NO_3$ is decomposed by boiling in water to AgO. What they did not note was that, when it is so treated, oxygen is released and $AgNO_3$ remains in this solution which may be readily analyzed quantitatively.

This decomposition procedure was used to break down a fresh sample prepared by D. Norman Craig at the National Bureau of Standards. We obtain stoichiometric percentages of 6AgO, O_2, and $AgNO_3$. Oxygen was determined volumetrically over water at 90°C. $AgNO_3$ was obtained by evaporation of the filtrate, and weighed as such.

	AgO	$AgNO_3$	O
Found	785 mg/g	181 mg/g	31.4 mg/g
Calc.	784	179	33.8 oxygen

The reported close similarity of the x-ray patterns of the salts formed by electrolysis of a silver fluoride bath and that of a silver nitrate bath may be easily explained if they are found to be of the same type structure. However, the two patterns published by Graff and Stadelmaier show significant differences in both spacing and intensity values which we feel are due to difference in composition.

We recently have been able to check the similarity in cell dimensions of these two crystals and find about the same values reported by Graff and Stadelmaier.

	Silver oxynitrate	Silver (oxyfluoride?)
Graff and Stadelmaier	5.890	5.834
NBS	5.893 at 26°C	5.823 at 25°C

Since Graff and Stadelmaier's paper did not come to our attention until recently, we have not verified the composition of the fluoride bath material as the oxyfluoride counterpart of the oxynitrate. However, we are planning to investigate this portion of the problem further.

W. S. Graff and H. H. Stadelmaier: The authors do not agree that the compound they reported to be a higher silver oxide can be, as McMillan suggests, a series of isomorphous compounds of the type $(Ag_3O_4)_2 \cdot Ag(I)AN$, where AN is NO_3^-, ClO_4^-, F^-, or SO_4H. Our points in answer to McMillan's and Swanson's arguments along this line are as follows.

I. All the preparations reported (Braekken, Swanson, Graff and Stadelmaier, Zvonkova and Zdanov), regardless of the anion present in the preparation (NO_3^-, ClO_4^-, F^-, or $SO_4^=$), yield a substance with a similar diffraction pattern and with lattice constants that differ from each other by no more than 0.5%. We attribute these small differences to varying amounts of absorbed impurities. An additional paper, not cited in our original bibliography,[21] also adds confirmation in that the preparation of a substance that yields the same diffraction pattern is reported from the oxidation of silver in a stream of $O_2 + 5\%$ O_3 with no N_2 present.

The regular presence of anions of such widely differing sizes (NO_3^-, ClO_4^-, F^-, or SO_4H^-) in the lattice as McMillan suggests would likely cause a larger variation in lattice constants than observed, even if we assume that such a series of isomorphous compounds does exist. Furthermore, it seems to us that the structure as postulated by McMillan with Ag(I) and the complex anion tetrahedrally surrounded by oxygen atoms is impossible from the standpoint of Pauling's radius ratio rules. The radius ratio of Ag(I) to $O^=$ is 0.9 and the radius ratio of NO_3^- to $O^=$ is 1.26. These ratios do not appear to be compatible with a coordination number of four.

II. We do not question the validity of Noyes' work in identifying Ag_7NO_{11}; we only feel that after the preparation is washed and dried the resulting decomposition product is the same as can be obtained from other means of preparation (fluoride, perchlorate, etc.) and very probably is a higher oxide of silver.

McMillan's comment on the structure of AgO is very interesting. If the compound is in fact diamagnetic, we agree that this would preclude the existence of a simple Ag^{++} state, because this state would involve an unpaired electron in the bonding with surrounding oxygen atoms and hence would be paramagnetic. Neiding and Kazarnovskii[22] also report that AgO is diamagnetic. This, we agree, indicates that AgO is a more complex structure, and not similar to CuO where Cu^{++} is known to exist.

Preparation and Properties of Aluminum Antimonide

A. Herczog, R. R. Hoberecht, and A. E. Middleton
(pp. 533-540, Vol. 105)

H. F. Matare[23]: Four years ago (1953), we[24] produced AlSb-diodes from laboratory-grown crystals. We found a possible use for high-frequency diodes, e.g., as mixer diodes. The characteristic feature was a small diffusion voltage. Blocking voltages were low and corresponding to the order of magnitude given by the authors. Stability over long time periods was not very good. Encapsulation under oil as proposed by the authors was used also.[25]

A. Herczog: In the production of mixer diodes, one has to apply a special surface treatment to bring out the lowest forward resistance. This treatment is known to make the surface rather sensitive and corrosive.

Other treatments capable of producing more stable surface conditions will yield inferior forward characteristic but much higher blocking voltage (85 v).

The Flade Potential of Iron Passivated by Various Inorganic Corrosion Inhibitors

H. H. Uhlig and P. F. King (pp. 1-7, Vol. 106)

G. H. Cartledge[26]: It is gratifying that the authors have independently confirmed the earlier work of Cartledge and Sympson,[27] which showed that the passivating films produced on iron or carbon steel in aerated solutions in inhibitors display the Flade potential upon activation. This indicates that the films have the same electrochemical character, although formed in a variety of ways. In later work, to be published elsewhere, it has been shown that the Flade potential may be demonstrated also on films produced by passivation in an aerated solution containing benzoate ions.

It is not believed that the apparent variation of the activation potential reported by Uhlig and King for different passivators is real. Their measurements were made after the specimens were transferred to unbuffered solutions, whereas those of Cartledge and Sympson were made in the inhibitor solution itself, in which the pH value was accurately determinable. With the exception of the pertechnetate ions, all the inhibitors used have some buffering action. It may be noted in Fig. 2 and 3 of Uhlig and King that the observed points fell on the noble side of the curve of Franck[28] when passivation was conducted in acid media, and on the other side for passivation in alkaline media. The data make one suspicious that the films had some "memory" of their origin, because of incomplete equilibration with the new, unbuffered environment. No such variation was apparent in the observations of Cartledge and Sympson.

[28] U. F. Franck, *Z. Naturforsch.*, **4a**, 378 (1949).

From the standpoint of theory, if the Flade potential actually corresponds to some electrochemical state that is reproducible, albeit metastable, one should expect to measure it best in as nearly a steady state as possible, rather than during rapid activation. This was the justification of the procedure used by Cartledge and Sympson.

The attempt of the authors to relate the Flade potential to a free energy calculable from data on heat of adsorption of gaseous oxygen on iron powder suffers from the weakness that two entirely different processes are being compared. Adsorption of oxygen in an aqueous medium involves both displacement of adsorbed water and competitive adsorption with all other species present. It would, therefore, be a strange coincidence if the adsorption in the two environments were the same in extent or energy.

The authors' discussion of the passivation process in the presence of a pertechnetate also must be questioned. They suggested that the writer's failure to find more than minute amounts of a technetium compound on the passivated specimen might be due to the formation of a soluble reduction product. This is quite contrary to the facts. Thorough study of the chemistry of technetium in this laboratory has shown that soluble compounds derived from the quadrivalent state (the important one) can be made only by forming complexes in strongly acidic solutions, such as hydrochloric acid of 1*N* concentration or greater.[29] Furthermore, in one experiment on the passivation of cast iron, which reduced an appreciable amount of the inhibitor, a material balance was obtained, within analytical accuracy, by adding the amount found from the beta activity of the specimen to the residual technetium in solution as determined spectrophotometrically as TcO_4^-.

Finally, if one uses the authors' estimate of the free energy of "$Fe{\cdot}O{\cdot}O_2$" in combination with the normal potential of the Tc(VII)-(IV) couple,[30] in accordance with their Eq. [9], it is calculable that 10^{-4} *f* TcO_4^- could passivate by this process only if the pH value were less than 4.9. The corresponding number is 4.0 if Franck's value for the Flade potential is used. As a matter of fact, passivation results best at higher pH values in aerated solutions. It is not believed, however, that such calculations are reliable, in view of the abnormal and unknown free energies of the surface components.[31]

H. H. Uhlig and P. F. King: In view of his extended studies along similar lines, Dr. Cartledge's comments are especially welcome. His comments indicate that he is reluctant to believe that the Flade potential varies with specific passivators, but the facts are quite clear that the observed variations are larger than the experimental error of our measurements, and we believe that the explanations that we have outlined suggest reasons why these variations are to be expected. The observed variation in stability of passivity depending on the passivator used is part of the evidence that differences in Flade potential can be predicted.

It is not likely that the deviations we find can be explained by a "memory" of the electrodes for the pH of the solution in which the electrodes were passivated, as Dr. Cartledge proposes. Other than the fact that each electrode was carefully washed in three separate beakers of distilled water before breakdown of passivity was followed by potential measurements, it is clear from Fig. 2 and 3 that acidity of the solution in which passivation occurred did not appreciably influence the observed Flade potential measurements. For example, iron passivated anodically in 5% H_2SO_4 or in concentrated HNO_3 (16*N*) gave the same Flade potential and the same slope of E_F plotted vs. pH of the solutions in which the passivity decayed despite a large difference in acidity. Furthermore, potassium ferrate solution, which by slow decomposition and hydrolysis was very alkaline, gave the same Flade potential as sodium molybdate or potassium chromate solutions which were near neutral.

We found that the use of buffer solutions is not ideal because of the tendency of some buffer anions in their usual high concentration to accelerate decay of passivity. This probably accounted for our observation that there was a variation in the Flade potential at the same pH when the buffer system was varied.

It is true that, when passivation occurs in an aqueous medium, competitive adsorption is expected to occur, and that this is not the case when oxygen is adsorbed directly on iron. In a subsequent paper,[32] we have shown that the calculated displacement effects amount to about 6000 cal/mole H_2O adsorbed on iron. This corresponds to only a minor part of the free energy accompanying adsorption of oxygen, and hence is not of great significance.

The relative absence of technetium on the surface of iron after passivation by TcO_4^- indicates that either TcO_4^- is not reduced at the surface of iron during passivation, which we discuss as being unlikely, or that the reduction products of TcO_4^- are soluble (or they are dispersed) in the solution. The latter situation is contrary to that for CrO_4^{--} for which chromium ions or compounds tend to remain on the iron surface after passivation and can be counted if the chromium is radioactive. It is difficult to foresee any other possibility explaining lack of Tc on an iron surface passivated by TcO_4^-.

The calculated value for critical pH in accord with our Eq. [9] depends on the particular value of the Flade potential which is assumed to apply to pertechnetates, and hence the calculated pH can be less than 4.9. We are somewhat more optimistic than Dr. Cartledge regarding thermodynamic calculations in which surface reactions are involved, provided that the composition of the surface product and the corresponding free energy are known. The practical use of the Ag-AgCl and Pb-$PbSO_4$ electrodes constitutes proof that thermodynamics also applies rigorously to thin films on metal surfaces. In many cases, of course, composition of surface films is not known, and cannot be readily established by the usual analyses, but potential

[32] H. H. Uhlig and P. F. King, In press, *J. Phys. Chem.*

measurements are still useful nevertheless as a first step in diagnosing the possible composition and structure of such films.

D. M. Brasher [33]: If we have interpreted this paper correctly, Uhlig and King suggest that the very slow film growth on steel in dichromate solutions takes place by means of a dual mechanism. During depolarization of cathodic areas by $Cr_2O_7^{-2}$ ions, deposition of chromic oxide (possibly hydrated) or adsorbed Cr^{3+} ions occurs on these areas; this depolarization causes an equivalent amount of (chemisorbed) $O.O_2$ to be deposited on anodic areas, followed by (it is implied) the gradual conversion of this to Fe_2O_3 with fresh deposition of $O.O_2$.

This is of interest to us as the over-all reaction quoted:

$$Cr_2O_7^{2-} + 8H^+ + Fe_{surface} \rightarrow 2Cr^{3+} + 4H_2O + O{:}O_2$$

with, presumably, in addition

$$2Fe + O.O_2 \rightarrow Fe_2O_3$$

is stoichiometrically equivalent to the reactions we have assumed[34] in the interpretation of film growth in deaerated chromate or dichromate solutions. These reactions have been assumed to be, in the absence of oxygen:

$$2Fe + 2CrO_4^{2-} + 2H_2O \rightarrow Fe_2O_3 + Cr_2O_3 + 4\ OH^- \ (pH\ 7.5)$$

or $$2Fe + 2HCrO_4^- \rightarrow Fe_2O_2 + Cr_2O_3 + 2\ OH^- \ (pH\ 4.2)$$

In each case, the growing film should contain equivalent amounts of Fe and Cr.

In our work,[35] we have shown that Cr uptake, and hence film growth, proceeds as a function of the logarithm of time, and that the rate constant for this growth is similar to that for oxide film growth in dry air. We (Kubaschewski and Brasher) have explained this growth on the basis of theories of Mott, Hauffe, and Ilschner in which electron transfer through the film is the rate-controlling step. It would be interesting to know if Uhlig and King's suggested mechanism, cathodic deplorization with concomitant anodic polarization, can account for logarithmic film growth.

H. H. Uhlig and P. F. King: Miss Brasher's observations are a welcome supplement to our own, and in our opinion comprise a reasonable explanation of what may be expected if iron is passivated by chromates. In fact, similar continuous oxidation should be observed with any of the passivators, such as nitrites, molybdates, etc., for which the Flade potential is approximately the same as for iron anodically passivated in H_2SO_4.

If the passive film formed by passivators is essentially chemisorbed oxygen or an adsorbed oxygen complex, as our data lead us to believe, the further slow oxidation of iron to form iron oxide would be expected to follow a rate curve similar in shape to that observed when iron is exposed to dry oxygen. It has been demonstrated by others that the rate of oxidation in dry O_2 is logarithmic, and the fact that Miss Brasher finds this relation, assuming that reduced chromate is incorporated into the iron oxide film, is confirming evidence that the assumptions and explanations she and her co-workers propose are reasonably correct.

It is not certain that the absolute rates of oxidation should be identical. The presence of chromate adsorbed on the outer boundary of the passive film, and absence of chromate in dry oxidation, may well cause the rates to differ, but the logarithmic equation is expected to hold in either instance.

It may be well to point out that the application of Mott's early derivation of the logarithmic equation relating thin film oxidation to the tunnel effect, and its more recent adoption by Hauffe and Ilschner, is subject to some doubt. The Mott derivation leads to an oxidation rate independent of temperature, and suggests that the logarithmic equation should hold for films not thicker than about 40Å, both being contrary to observation, as Lustman pointed out.[36] A subsequent derivation of Cabrera and Mott based on a quasi-exponential migration of ions in an electric field within the oxide leads to the inverse logarithmic equation instead of the logarithmic equation, and does not account, as we have pointed out earlier, for the observed effects of grain orientation, lattice transformation, and Curie temperature on thin film oxidation rates.[37, 38]

Potential Studies on Passivity to Corrosion Induced by Pretreatment Processes for Metals, I. Aluminum

K. S. Rajagopalan (pp. 113-117, Vol. 106)

S. L. Chisholm[39]: Similar studies of passivating and corrosion inhibitive treatments and compounds have been performed on a variety of aircraft, nonferrous, and ferrous metals, by employing a Beckman *p*H meter and measurement of potentials against silver-silver chloride electrodes made in quantity by fusing silver chloride on strips of pure silver. The purpose was to develop direct screening methods and prospective specification requirements for useful corrosion inhibitors and inhibitive compounds, such as corrosion inhibitive paint films, since development and testing of such materials normally involves inordinate amounts of time for field test exposure. In the case of inhibitive paint primers, such as zinc chromate primer, an interesting variation of the test method is to determine the differential potential of the primed vs. the unprimed metal in separate cells when immersed in ground or saline water. Initial values are of the order of 450 mv on aluminum alloys, which decrease with extended time to a steady state. Increasing salinity increases the initial differential, but also the rate of change. In all of this work, it has been found difficult to obtain exact reproducibility. Replicate samples normally furnish families of similar curves of potential vs. time, as reported and illustrated in the subject paper. By

this method, it is also possible to detect and determine the persistence of nonvisible passivation effects, such as that produced by nitric or chromic acid treatment of corrosion resistant steels.

K. S. Rajagopalan: I am glad to note that observations similar to those made by me have also been made by Dr. Chisholm. Dr. Chisholm is correct in stating that the order of reproducibility of the potential changes observed should be higher from the point of view of using the changes as a method for the assessment of the performance of the pretreatments considered. This aspect has received particular attention in the paper. I think it should be possible to get better reproducibility if the conditions of treatment are better understood. However, it should be noted that the results have an even greater significance from the point of view of the light it throws on the mechanism of passivation of the metal surface. The results show that there are a number of systems where the potential shift is in a negative direction following passivation. The explanation given by the author brings into relief a factor which has not been given adequate attention in the consideration of changes in potential with time and changes in potential with application of external current. This is the important part played by changes in anodic and cathodic areas. It has been shown that, under certain ideal conditions assumed, the potential changes can be attributed either to a change in the ratio of anodic and cathodic areas or a change in the ratio of the velocity factors for the anodic and cathodic reactions. It may be that these two factors cannot be separated ordinarily. But it is possible to visualize the conditions under which one can be studied independent of the other.

Reaction of Aluminum and Carbon Tetrachloride, I

J. D. Minford, M. H. Brown, and R. H. Brown (pp. 185-191, Vol. 106)

R. A. Hine[40]**:** The authors have presented a thorough and most useful study of this reaction, which has considerable practical importance in connection with the use of aluminum vessels and equipment for handling halogenated compounds.

Rather surprisingly, the tremendously increased rate of reaction brought about by mechanical activation has not been referred to; this was first described by Shaw.[41] In our laboratories, we have demonstrated that a very rapid and vigorous reaction takes place when aluminum is abraded, drilled, machined, or filed under the surface of warm carbon tetrachloride. In the case of aluminum powder ground in a mortar and pestle with a little warm carbon tetrachloride, the reaction starts suddenly and may be almost explosively violent with evolution of large amounts of hexachlorethane and aluminum chloride fume. If further portions of liquid and powder are added to the reacting mass, incandescence is reached and a secondary reaction involving direct formation of $AlCl_3$ and liberation of carbon takes place. In the primary reaction, the formation of the red intermediate complex is always strikingly produced.

[40] Aluminium Labs. Ltd., P. O. Box 84, Kingston, Ont., Canada.
[41] M. C. Shaw, *J. Appl. Mechanics*, 15, 37 (1948)

The reaction has been discussed by Grunberg[42] who explains it by taking account of the Kramer and Russell effects (emission of electrons from an abraded metal surface) and formulates the steps as:

$$Cl_3C^+Cl^- + e \text{ (from abraded metal)}$$
$$\rightarrow Cl_3Cl\cdot Cl^- \rightarrow Cl_3Cl\cdot + Cl^-$$
$$Al^{3+} + 3Cl^- \rightarrow AlCl_3$$
$$2Cl_3C \rightarrow C_2Cl_6$$

The above sequence does not explain the formation of the red complex and in my view the present authors' electrochemical theory can be held just as tenable as the free radical theory.

R. H. Brown, E. H. Cook, M. H. Brown, and J. D. Minford: The authors appreciate R. A. Hine's interest in their paper.

It is not surprising that mechanical abrasion of the surface in warm carbon tetrachloride produces a rapid reaction. Our experiments to cathodically protect an aluminum rod whose surface was freshly scratched under boiling carbon tetrachloride were unsuccessful. In order to achieve cathodic protection, it is necessary to supply at least the minimum current as would be calculated from the initial reaction rate at the scratched surface. Because of the high resistance of the solution, such currents could only be obtained with excessively high applied potentials.

Conductivity measurements by the authors indicate the existence of an ionic species before the visible detection of the red complex, and that the conductivity continues to increase after the red complex is detected.

Principles and Applications of the Iodide Process

A. C. Loonam (pp. 238-244, Vol. 106)

A. A. Woolf[43]**:** We wish to comment on Loonam's conjecture that boron and rhenium can be deposited from the vapors of their iodides.

Recent work has confirmed that rhenium iodides cannot be made directly from the elements alone, or in complexing and noncomplexing solvents for iodine, but only indirectly via the hexaiodorhenates (IV).[44,45] The rhenium iodides so prepared are decomposed to rhenium by heating in vacuo without appreciable volatilization of the iodide, indicating that their dissociation pressures are high compared with their vapor pressures. Thus, refining of rhenium is impossible by a continuous iodide process. It is the kinetics, rather than the thermodynamic equilibria, of the reaction of iodine with some elements which limits the method, because reaction only occurs at an appreciable rate at temperatures at which the iodide is no longer stable. Boron is similar in that no appreciable reaction occurs with iodine at temperatures up to 1200°C.[46]

[42] L. Grunberg, *Proc. Phys. Soc. (London)*, **66B**, 153 (1953).
[43] Research Lab., Associated Electrical Industries Ltd., Aldermaston Court, Aldermaston, Berkshire, England.
[44] A. A. Woolf, *J. Inorg. & Nuclear Chem.*, 7, 291 (1958).
[45] R. D. Peacock, A. J. E. Welch, and L. F. Wilson, *J. Chem. Soc.*, 2901 (1958)
[46] H. C. Oldland, Ph.D. Thesis, Imperial College, London (1956); "Gmelins Handbuch der Anorganischen Chemie," 13, 128 (1926).

A. C. Loonam: I am very grateful indeed for Dr. Woolf's comments. However, I believe that they were covered adequately in the paper by the "perhaps" before the "Re" in the statement to which he refers and by the succeeding one: "In some cases, e.g., carbon, it would be necessary to prepare the iodide by an external process," which, of course, includes indirect methods. These would almost certainly be necessary for the preparation of carbon-iodine compounds, since the common forms of this element, graphite and amorphous carbon, in my definite experience, do not react directly with iodine at temperatures up to at least 1100°C.

Formation of a volatile product by the direct action of iodine vapor on metallic rhenium has been reported [47,48] but, even if this should prove to be the oxyiodide found by Dr. Woolf, I would be unwilling to place the metal in the same category with carbon because of recent evidence that other metals ordinarily considered resistant can be made to react with iodine. Not long ago, it was stated that tantalum is resistant to iodine vapor up to 1000°C and that it can be used as a shield in the de Boer-van Arkel process; yet TaI_5 has been prepared by the action of iodine vapor on the metal at temperatures as low as 300°[49] and the metal has actually been refined by the iodide process[50] with bulb temperatures as low as 311°, using commercial sheet as the "crude" material. Moreover, molybdenum, which gives very satisfactory service in iodide process units, can react with iodine under suitable conditions;[51] while the recent announcement by the General Electric Co.,[52] of a compact high-intensity incandescent lamp containing a small amount of iodine to return the volatilized tungsten from the interior surface of the quartz bulb to the filament, shows that even this metal can be attacked and transferred. Even more pertinent to Dr. Woolf's remarks is the report that direct reaction of one form of crystalline boron with iodine at 900° gave as high as 70% yields of the triiodide; and that the vapor of this compound produced deposits of elementary boron at temperatures as low as 800°.[53] Indeed, a new allotropic modification of boron was produced.[54]

Furthermore, the rhenium iodides should be studied in the presence of a high partial pressure of iodine vapor before it is concluded that they cannot exist in the gaseous state. Dr. Woolf's finding of the volatile oxyiodide indicates that the Re-I bond is not excessively weak. Niobium, which forms a similar oxyiodide, has been refined by the iodide process[55] even though heating NbI_5 in an evacuated tube gave results similar to those obtained by Dr. Woolf with the rhenium iodides, the unvolatilized residue being converted slowly to metal at 540° and rapidly at 800°.[56] It is true that evidence for the existence of gaseous NbI_5 was found in these experiments, whereas Dr. Woolf obtained no similar evidence; but this may be due to a lower volatility of the rhenium compounds resulting from the lower valence state and the higher atomic weight of the metal.

I would not be at all astonished to learn that considerable volatilization occurs when the rhenium iodides are heated to 600°-1000° in a stream of iodine vapor at atmospheric pressure. If such proves to be the case, I believe that conditions will be found under which rhenium can be deposited from the vapors of its iodides, perhaps by a "straight-flow" process rather than the conventional de Boer-van Arkel method.

The System LiF-LiCl, LiF-NaCl, LiF-KCl

H. M. Haendler, P. S. Sennett, and C. M. Wheeler, Jr.
(pp. 264-268, Vol 106)

M. A. Bredig[57]: It appears that the most recent values for the heat of fusion of LiF, NaCl, and KCl were used in the calculations presented in the tables. However, this does not seem to be true for the so-called Clausius-Clapeyron Limit in Fig. 1-3, especially for NaCl in Fig. 2 and above all for both LiF and LiCl in Fig. 1. If for the LiF-LiCl system the latest, correct heats of fusion of 4.80 kcal for LiCl[58] and 6.46 for LiF are used to draw the Clausius-Clapeyron Limit, it becomes apparent that as expected there is no positive deviation from Raoult's Law in this system, but rather very slight *negative* deviations due to the different size of the F^- and Cl^- ions.

H. M. Haendler, P. S. Sennett, and C. M. Wheeler, Jr.: The calculations presented in the tables of this paper used values for the heat of fusion of LiF, NaCl, and KCl listed by Flood. The Clausius-Clapeyron Limit was inadvertently drawn using values for the heat of fusion of these salts as found in National Bureau of Standards Circular 500. These values for, particularly, LiCl and LiF are low and should not be used. Replotting the Clausius-Clapeyron Limit using either the values from Flood or those supplied by Dr. Bredig indicates, as he states, that there is a slight negative deviation in the LiF rich systems.

The Stability and Solubility of AgO in Alkaline Solutions

T. P. Dirkse and B. Wiers (pp. 284-287, Vol. 106)

J. A. McMillan[59]: As Salkind and Zeek[60] have pointed out, the structure of AgO has been of interest to members of the Society, and I should add to chemists in general, during the last years. Dirkse and Wiers, in an interesting paper on the behavior of AgO in alkaline solutions, found that samples of an assumed AgO prepared by different methods ex-

[56] J. D. Corbett and P. X. Seabaugh, *J. Inorg. & Nuclear Chem.*, 6, 207 (1958).

[58] A. S. Dworkin and M. A. Bredig, In press.
[59] Chemistry Div., Argonne National Lab., Lemont, Ill., on leave of absence from Instituto de Física de San Carlos de Bariloche, Bariloche, Río Negro, Argentina, spending the duration of a Guggenheim Fellowship.
[60] A. J. Salkind and W. C. Zeek, *This Journal*, **106**, 366 (1959).

hibit different x-ray diffraction patterns. They have a point, namely: difference in x-ray patterns indicates a difference in structure, or at least the existence of AgO samples with somewhat larger lattice parameters. This latter can be true, but I suspect that the results quoted above stand for the production of a black deposit obtained during the electrolytical oxidation of silver anodes in sulfuric acid medium[61] that should rather be identified with $(Ag_3O_4)_2AgSO_4H$, isomorphous with Ag_7NO_{11}, Ag_7ClO_{12}, and perhaps with Ag_7O_8F (interchanging NO_3, ClO_4, SO_4H, F),[62] also obtained by de Boer and van Ormond[63] during the oxidation of $AgNO_3$ solutions with $K_2S_2O_8$. It should be noted in this respect that the latter method leads to AgO if the medium is alkaline.[64]

The unit cell edge of Ag_7NO_{11} is 9.89Å. This value cannot vary strongly when substitution by other anions takes place. In fact it does not, as can be seen in the table, published here where values of spacings for silver oxinitrate[65,66] and oxifluoride[66] are given. The values found by Jones and Thirsk[61] are quoted in the same table, showing a good agreement with the exception of spacing 1.45Å, presumably due to reflections 311 or 022 of AgO.[67] It should be borne in mind that the oxisalts decompose to give rise to AgO, oxygen, and the corresponding monovalent silver salt. Jones and Thirsk's compound seems to be like the compound obtained by Schwab and Hartmann[68] using ozone for the oxidation, as can also be seen in the table.

I wish to make good use of the opportunity to call to the attention of workers on this problem that the compounds obtained from electrolytical oxidation of silver anodes are not at all clear up to the present time.

T. P. Dirkse and B. Wiers: One of the purposes in reporting on our work with AgO was to show that all that is called AgO is not necessarily AgO. The x-ray data of Schwab and Hartmann, Footnote 68, show that the AgO prepared by decomposition of Ag_7NO_{11} with boiling water is not the same as that prepared by oxidation of $AgNO_3$ with alkaline persulfate. There are also differences in chemical properties between these two substances, such as the effect of boiling water as noted in our article.

Water-Stabilized Arc Tests on Nonmetallic Materials

M. Dank, R. A. Nelson, W. R. Sheridan, and W. H. Sutton
(pp. 317-321, Vol. 106)

Charles Sheer[69]: Comment on peak temperatures reported by Burham, Maecker, and Peters in Germany (~50,000°K): "Peak temperatures of this order exist only on the axis of the plasma jet over a very small radial distance (<1 mm). The extreme high temperature region extends a short distance beyond the nozzle opening into the plasma jet, but not enough to be useful in testing samples of materials at these temperatures."

On the subject of temperature measurement in plasma jet environments, rotational temperatures, determined spectroscopically, appear to be abnormally high. However, Stark effect broadening of the hydrogen lines is reported to yield effective temperature measurements with about 10% accuracy.

The Anodic Oxides of Lead

J. Burbank (pp. 369-376, Vol. 106)

P. Rüetschi and B. D. Cahan[70]: *p*H potential diagrams, as developed by Pourbaix, are convenient means to describe the regions of thermodynamic stability of solid phases or ionic species in solution. In applying these diagrams, one must keep in mind that concentration terms other than the H-ion concentration (*p*H) are determining the thermodynamic reversible potentials. For example, in the case of the *p*H-potential diagram of Pb, the nature of the particular anions present is of profound influence. Considering a *p*H of 1, the lead ion concentration could vary over many orders of magnitude with a corresponding shift in potential of several tenths of a volt. This means that, for each anion present, the *p*H-potential diagram might look entirely different.

In Fig. 1 of J. Burbank's paper, the regions of stability of corrosion products *at the solution interface* are given without specifying nature and concentration of other ionic species (in particular anions) present. Looking at the diagram, it is hard to understand the presence of PbO, $Pb(OH)_2$, and αPbO_2 in an acid media of, e.g., *p*H 1, in direct contact with the acid solution. At this *p*H, the existence of PbO, $Pb(OH)_2$, and αPbO_2 are difficult to picture thermodynamically or kinetically. In Fig. 3 of J. Burbank's paper, which refers to a *p*H of 1, no such substances are shown in direct contact with the acid media. Only $PbSO_4$ and βPbO_2 are shown in direct contact with the solution. This is in contrast with the data of Fig. 1.

It should be made clear that the definition of a *p*H *in the interior* of a corrosion layer is ambiguous. The *p*H in the very fine cracks and pores of the cor-

[69] Vitro Labs., West Orange, N. J.
[70] Electrochemistry Div., Electric Storage Battery Co., Yardley, Pa.

rosion layer must be quite different from the pH in the bulk of the electrolyte, due to strong diffusion and depletion effects. It does not make much sense to assume that only H^+ ions and water are penetrating into the layer, since equal amounts of anions and cations must be present in the pores at any time to maintain electroneutrality. In the double layer, an excess charge on the solution side is neutralized by an equal excess charge on the electrode side; however, in any case, the conditions in the interior of the corrosion layer are then not ideal, and the energetic states of the same ionic species in the interior of the corrosion layer and in the bulk must be different.

We feel that the experimental evidence of the presence of PbO, $Pb(OH)_2$, and αPbO_2, which is well confirmed, is connected with a pH effect in the interior of the corrosion layer, due to diffusion effects. It seems that J. Burbank does not sufficiently stress the importance of nonequilibrium conditions with regard to pH in the corrosion film. In a basic media, the formation of PbO, $Pb(OH)_2$, and αPbO_2 would be readily understood. One could visualize a system where the corroding electrode is separated from the solution by a diaphragm, such that the electrode compartment of the corroding electrode has much higher pH than the solution. This diaphragm insulating the electrode from the solution would in practice consist of a $PbSO_4$ or βPbO_2 layer. This would now mean that the corroding electrode would be at a higher pH and thus, for a given impressed over-all electrode potential, the formation of PbO_2 would become possible far below the theoretical thermodynamic value as determined from the bulk pH of the solution. If the undefined virtual pH in the interior of the corrosion layer were effectively basic, then PbO_2 could be formed down to an apparent external potential of 0.6 v or so as can easily be seen from the pH-potential diagram.

In practice, the corrosion of lead might proceed underneath a partially protecting coverage of $PbSO_4$ or βPbO_2 by migration of oxygen species (e.g., OH^-) along the surfaces of the $PbSO_4$ and PbO_2 grains or crystals to produce PbO, $Pb(OH)_2$, or αPbO_2 from metallic lead. The formation of these substances is therefore related to a lack of acid in the interior of the corrosion film.

It has been described by Rüetschi and Cahan[71] that the ratio of α to βPbO_2 in the corrosion layers of lead-antimony alloys in H_2SO_4 depends on the Sb concentration of the corroding grid. It was indicated that with high Sb content generally more βPbO_2 is formed due to the higher porosity of the corrosion film. The Sb, corroding out of the metal, is oxidized to Sb oxide and Sb sulfate.These substances subsequently are leached out of the corrosion film, rendering it more porous and more pervious to H_2SO_4, which is inducive for the formation of βPbO_2 rather than αPbO_2 or PbO. With pure lead or Pb-Ca alloys, one observes often very dense, impervious corrosion films, containing in the interior much PbO. The latter substance can impair, under certain conditions, the contact between grid and active material in positive plates of storage batteries made with Ca-alloy.

J. Burbank prefers not to make any reference to an article of Rüetschi and Cahan[72] where the occurrence of the second modification of PbO_2 (orthorhombic αPbO_2) has for the first time been reported in *corrosion layers of lead.* This material had been described previously in foreign papers, particularly of Russian origin. Its preparation with chemical and with electrochemical plating techniques had been established, but it had not been known as a corrosion product of lead. Prior to the publication date of the article of Rüetschi and Cahan, J. Burbank never mentioned the existence of αPbO_2 in her papers. But since, she also has found αPbO_2 as a corrosion product.

During prolonged corrosion at elevated potentials, αPbO_2 is the major corrosion product. Electrode potentials of α and βPbO_2 in H_2SO_4 solutions have been measured experimentally with good precision by Rüetschi and Cahan in the article referred to, and by S. J. Bone, Symposium of Batteries, Signal Research and Development Establishment, Ministry of Supply, Christchurch, Hampshire, England, October 21, 1958. These measurements agreed very well. In 5M H_2SO_4, e.g., αPbO_2 has an electrode potential 7 mv higher than βPbO_2. The presence of the two different corrosion products has also been demonstrated by the two-step reduction of the corrosion layer.[73] The experimentally determined potential values for α and βPbO_2 do not coincide with the theoretical pH potential diagram of J. Burbank, which is due, as discussed previously, to the presence of other ionic species in the electrolyte.

Recently, Kabonov (*loc. cit.*) has shown that on αPbO_2 less SO_4^{--} ions are adsorbed than on βPbO_2. Inversely, βPbO_2 is formed preferentially in the presence of SO_4^{--} ions, which means at low pH values. Addition of cobalt sulfate to the electrolyte is inducive for the formation of αPbO_2 and to the desorption of SO_4^{--} ions from the surface. Rüetschi and Cahan (*loc. cit.*) have demonstrated that αPbO_2 has a lower oxygen overvoltage than βPbO_2. The lower oxygen overvoltage for αPbO_2 can be associated with a smaller amount of SO_4^{--} ions adsorbed. Oxygen overvoltage is indeed decreased by the addition of cobalt sulfate to the electrolyte.[74]

J. Burbank has not been very consistent with the designations for the various anodic oxides of lead. For instance, she uses intermittently the designations $PbO_t \cdot xPbO_2$ and $PbO \cdot xPbO_2$ for what is apparently the same material. More serious, however, is the use of such composite formulations. The formula $PbO_t \cdot xPbO_2$ is misleading because these substances are not mixtures of PbO_t and PbO_2, but have a definite and separate crystal structure. The designation PbOx is more satisfactory. However, Pb_3O_4 should not be included in the group of PbOx materials. The designation PbOx should be used for substances like Pb_7O_{11} ($PbO_{1.57}$), Pb_5O_8 ($PbO_{1.60}$), Pb_2O_3 ($PbO_{1.50}$), which have a very similar composi-

tion, varying only by a few per cent. Also, these substances have basically an orthorhombic symmetry, whereas Pb_3O_4 is tetragonal.

The thermodynamic stability of Pb with regard to PbO_2 (Eq. [1] in J. Burbank's paper) has no practical implication, since both Pb and PbO_2 are unstable at the indicated potential with regard to other possible divalent corrosion products of lead (PbO, $PbSO_4$). Thus, at a potential of, e.g., 0.67 v at *p*H 1, metallic lead *is not stable* thermodynamically even in the presence of PbO_2 since it will form divalent corrosion products first, and the thermodynamic stability of Pb cannot approach that of PbO_2. On the other hand, PbO_2 is reduced to divalent corrosion products not only above 0.67 v but of course also below this value, and metallic lead is unstable above and below this potential. The experimental evidence for the presence of PbO_2 below the thermodynamic theoretical value is more plausibly explained by nonequilibrium concentration (in particular *p*H) in the interior of the corrosion layers.

J. Burbank: This extension of the discussion of the anodic reactions of lead is very interesting. A detailed discussion of ionic equilibria in general is contained in the work of Pourbaix[75,76] and the differences brought about by the presence of sulfates and carbonates was presented in the original lead diagrams.[77] The variations in solubilities among the salts of lead with other anions and the differences in free energies of formation will give rise to as many diagrams.

In the first part of the paper under discussion, solubilities, anions, and ionic equilibria were intentionally and specifically stated to be excluded, and a comprehension of the works of Pourbaix was assumed. The data recorded in Fig. 1 were obtained by diffraction examination of surfaces of anodes as stated in the paper. The picturization of Fig. 3 presented under the heading "anions and passivation" is thought to represent the conditions under which such oxide mixtures are possible—by formation of a salt layer. Fig. 1 must not be read out of context. The text appears clear enough on these points.

It is gratifying to know that Rüetschi and Cahan now accept the appearance of lower oxides of lead on the anode in acid solutions, a fact they were unable to verify at an earlier date. The concept of film formation in the passivation of Pb in H_2SO_4 is rather widely accepted. A change in *p*H toward higher values at local cathodes is a normal expectation of static corrosion phenomena. In the instance under discussion external anodic polarization was applied, and anodic reactions were to be considered. Rüetschi and Cahan did not state by what anodic reaction the area near an anode may become alkaline. The reactions believed to effect an increase in *p*H were not written out in full in the comments so as to permit a more considered analysis of the situation described. No difficulty whatsoever is encountered in visualizing a consumption of hydrogen ion during cathodic reactions, but merely stating that an increase in *p*H occurs adjacent to the film-carrying lead anode does not make it a fact. It would be most convenient if the anodic phenomena could be written off as an increase in *p*H.

Migration of hydroxyl ion along with others through a primary layer of $PbSO_4$ may take place, but it is not clear that a marked increase in *p*H adjacent to an anode may be developed. It is clear that an increase in *p*H can not accompany electrochemical formation of the oxides, oxygen, or similar anodic products.

Experimental work remains to be done to realize a final determination of the mechanisms of the anodic processes on lead, but it is believed that the Hirsch[78-80] effect describes the phenomena encountered with $PbSO_4$ films. If one accepts Hirsch's work, a $PbSO_4$ film is permeable to hydrogen ion and water but not to plumbous or sulfate ion. Furthermore, it appears likely that the charge exchange mechanism of the $PbSO_4/PbO_2$ electrode itself may be elucidated by such a process.

The paper contained no discussion regarding the cited work of Rüetschi and Cahan, but it may be well at this time to indicate that some of the experimental results reported by them may be otherwise interpreted. For one example, the two-step discharge of PbO_2 has been attributed to another phenomenon.[81] It is hoped that Rüetschi and Cahan will continue their experimental work, and that ultimately all experimental facts may be properly interpreted.

The designation $PbO_t \cdot xPbO_2$ should have been uniform through the manuscript; this and several other typographical errors should cause no confusion. It is redundant to reiterate that the stoichiometry Pb_3O_4 is exhibited by at least two structurally different materials. It seems doubtful that a simple mechanical mixture of PbO and PbO_2 could possibly be understood by the definition given for the symbol in the paper.

Some would hesitate to state unreservedly that the equilibrium between Pb and PbO_2 is without "practical" implication. Other factors could prove this to be a most "practical" and significant equilibrium: consider the processing of positives for "dry charge" use.

Role of Thiourea in the Electrodeposition of Copper

B. Ke, J. J. Hoekstra, B. C. Sison, Jr., and D. Trivich
(pp. 382-388, Vol 106)

S. C. Barnes[82] and G. G. Storey[83]: We have studied the effect of thiourea additions to acid copper sulfate solutions on the type of deposit subsequently obtained on electrolysis. All our work has been carried out on flat single crystal cathodes: on which deposits formed at low current densities, from thiourea-free solutions, continue the base orientation

and develop well-defined crystallographic surface structures.[84, 85] The particular surface plane studied in the thiourea investigation was near to {100} on the <110> zone: this develops a sharp straight-edged platelet surface structure (when the deposit is approximately 14 μ thick) at 20 ma/cm^2 and 35°C, and a partially polycrystalline deposit at 40 ma/cm^2.[86] Additions of thiourea in concentrations ranging from 5 x 10^{-10} to 10^{-2}M were made to the bath, and effects on the deposit structures obtained at these two current densities noted. The results obtained from the solution containing an approximately equal amount of thiourea to the one used by Ke, *et al.*[87] (10^{-4}M) were in complete agreement with their observations and conclusions. Our evidence for adsorption was that the overpotential associated with the deposition was considerably increased by the addition of this amount of thiourea, indicating some interference with the normal growth process. However, the results obtained from solutions containing lower concentrations of the addition agent were more interesting. These are briefly summarized below.

At 20 ma/cm^2, 10^{-9} to 10^{-6}M thiourea decreased the overpotential and led to development of deposits characteristic of lower current densities in a thiourea-free solution.[86] 10^{-5}M had negligible effect on polarization but caused a habit change in the deposit: pyramids with sides near {211} developed instead of platelets. Above 10^{-4}M overpotential was increased in proportion to the thiourea content, the deposits becoming increasingly uneven and containing polycrystalline material. With 10^{-2}M thiourea, the deposit was very uneven, nodular, and cracked.

Deposits produced at 40 ma/cm^2 from solutions containing thiourea showed more variations: concentrations from 5x10^{-10} to 10^{-8}M caused an increase in overvoltage and more polycrystalline material to develop. 5 x 10^{-8} to 10^{-6}M reduced overpotential and platelet type deposits were obtained; 5 x 10^{-6} to 10^{-5}M produced deposits with pyramidal habit and only small changes in polarization. These deposits from solutions containing 5 x 10^{-8} to 10^{-5}M, at this current density, were complete continuations of the base, and contained no polycrystalline material. Bright even deposits were produced when 5 x 10^{-5} and 10^{-4}M thiourea was added, that at the higher concentration being almost featureless. At all concentrations above 5 x 10^{-5}M, polarization was increased. 10^{-3}M caused uneven nodular deposits to form, while that obtained from the solution containing the highest concentration studied (10^{-2}M) was covered with needle-like growths at a small angle to the surface. Deposits formed at this current density from solutions containing more than 5 x 10^{-5}M contained polycrystalline material.

This work at present is continuing and an explanation of these, and allied, phenomena is being sought in the relation between relative rates of crystal growth and adsorption of surface active material.

The Role of the Metal-Ion Concentration Cell in Crevice Corrosion

G. J. Schafer and P. K. Foster (p. 468, Vol. 106)

Saul B. Bien[88] and Herbert D. Ayers, Jr.[89]: It was suggested by Schafer and Foster that the metal-ion concentration cell cannot be a cause of crevice corrosion and that crevice mouth attack is a special case of differential aeration. In the case of solder joints, it was clearly demonstrated[90] with autoradiographs made by flux tagged with fluorine-18 that fluoride salts are deposited at the interface between the solder and chromium alloys. We postulated that the crevice mouth attack was initiated by solution through convection and/or diffusion of irregular areas of residue at the interface. Following this, the development of the crevice continues. We discussed[91] the role of the differential aeration cell as described by LaQue[92] and the active-passive cell of Logan[93] in the continued development of the crevice.

A further significant finding was that, after one year of exposure to the room atmosphere in the laboratory, discoloration appeared (at X375) on the polished surface of the cross sections of the solder joints on areas corresponding approximately to those which produced radiopacities on the autoradiographs. The surface was repolished removing all stains. After six months of re-exposure to the air in the laboratory, discoloration again reappeared in the same areas of the surface adjacent to the interface. There is therefore a correlation between the areas of the autoradiographs showing the deposition of fluoride salts at the interface and the discolored areas observed on surface of the cross section of the solder joints. The discoloration appears to result from corrosive action in the areas which were most radioactive. The dissociation of salts deposited at the interface between the solder and the chromium alloy and the movement of ions over the polished surface of the specimen may have been facilitated by moisture from the atmosphere.

G. J. Schafer and P. K. Foster: The investigations of Bien and Ayers[90, 91] are not related to crevice corrosion in the sense used by us in the discussed paper. Their work is concerned with the initiation and propagation of failure at bimetallic soldered joints containing entrapped flux residues. Perhaps it should have been explicitly stated that our concern was solely with the mechanism responsible for maintaining steady-state corrosion in crevices consisting of only *one* homogeneous alloy.

We agree that once a crevice is present between a solder and the base metal due to incomplete bonding in the soldering operation, differential aeration

[88] 76 Union Ave., Lynbrook, N. Y.

[92] F. L. LaQue, "Nature of Corrosion of Metals," New York Chapter American Society for Metals, October 10, 1955.
[93] H. L. Logan, *J. Research Nat. Bur. Standards*, 48, 99 (1952).

would have an important effect[91] particularly with stainless steels which are passivated by oxygen. It seems to us, however, that the potential difference between the two different alloys (solder and base metal) should have been considered. Evidence of potential differences is provided by preferential attack of the base metal in Fig. 7 (upper) and Fig. 10 (upper) in the work cited in Footnote 91.

The "crevice corrosion" failures observed by Bien and Ayers[91] may be due to purely physical effects, i.e., the solution of flux from the interface, since "crevice corrosion is characterized by a failure of the bond with little or no macro corrosion of the soldered joints or the solder. In the appliances where the bond failed either clinically or experimentally, there was no obvious corrosion or pitting of any metal."[91]

Alternatively, it may be that a thin layer of a base metal/solder alloy is formed at the interface, and that this layer is anodic to both the solder and the base metal under the conditions of test.[94] This would explain the formation of crevices sufficiently long and narrow to cause separation of the joint without gross corrosion of either the solder or the base metal.

We agree that the experiments cited in the second paragraph of Bien's and Ayer's comments confirm the entrapment of flux at the solder/base metal interface.

On the Internal Resistance of Dry Cells. A New Pulse Method

R. J. Brodd (pp. 471-475, Vol. 106)

J. J. Coleman[95]: I have two specific comments to make on Dr. Brodd's paper, the first specific to the paper, and the second more general in character.

The author's method of measurement involves a comparison of a potential developed across a dry cell, by pulses ranging from 1 to 10 μsec with a potential developed across a simple resistor. This assumes that the "equivalent circuit" in a dry cell is a simple resistor and not, for example, a resistor shunted by a condenser. The author directs his attention to the problem of what *is* a proper "equivalent circuit" in the first paragraph under "Results and Discussion." He found his internal resistance measurement unaffected by a change in the length of the pulse from 1 to 10 μsec and the change in the rate of the pulses from 100 to 5000 pulses per second. He concludes from this, mistakenly I believe, that the "equivalent circuit" can be taken as a simple resistor. Fig. 2 indicates that the pulse is approximately a square wave and the shape of the pulse as exhibited on the experimenter's oscilloscope is more important than its length. Dr. Brodd does not interpret the shape and hence does not come to grips with the problem of determining the "equivalent circuit" of a dry cell.

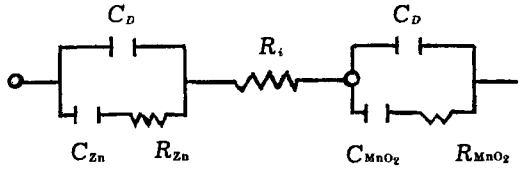
Now for the second comment, I believe that the method described by the author, and all similar methods, give the same results as conventional methods employing alternating currents. There is a feeling that a short, direct-current pulse is superior to an alternating current because the battery develops direct current and not alternating current. However, the phrases "direct current" and "alternating current" lose many of their usual meanings when applied to very short pulses. These phrases are usually applied to steady states. For example, one may say that a.c. will pass through a condenser and d.c. will not. Certainly this is not true if the d.c. is a very short pulse. A short d-c pulse has much more in common with steady state a.c. than with steady state d.c. This relationship appears mathematically in the Fourier analysis of a square wave. One represents a square wave pulse by the superposition of alternating currents of many frequencies.

Any steady state direct current in a dry cell must flow through the manganese dioxide particles or be coerced in some similar fashion. Alternating current or short pulses of direct current can pass directly from the black to the electrolyte. Hence, I do not regard measurements by short d-c pulses as pertinent to any study of the dry cell as a machine developing electrical energy.

R. J. Brodd: The comments of Dr. Coleman will serve to clear any misunderstanding in my original paper. The purpose of the paper was to report a method for measuring the true internal resistance of the battery. It appears that the method is successful in measuring the pure resistive element of a battery.

Dr. Coleman seems to have missed the significance of my statement concerning the shape of the voltage and current pulses. As was emphasized in the paper, the two traces were identical. The rise and decay of the pulses were instantaneous and the tops of both pulses were flat. This behavior is characteristic of a circuit containing a resistor with no capacitive effects. The ringing at the leading edges of the pulses, as suggested by Dr. Jacopetti,[96] is probably due to lead inductance of the instrument and cell. There is no evidence of a rounding of the leading edge of the pulses as would be expected from capacitive elements. The variation of repetition rate and pulse length without changing the measured resistance supports the conclusion reiterated above that the measuring technique reported in my paper determines the purely resistive element of a dry cell.

The equivalent circuit of a Leclanché cell which results from impedance measurements is



where R_i is the internal resistance, C_D the capacitance of the electrical double layer, C_{Zn}, R_{Zn} and C_{MnO_2}, R_{MnO_2} are the capacitance and resistance of the

[94] J. D. Dowd, *Welding J. (N. Y.)*, 33, 113s (1954).

[96] M. M. Jacopetti, Private communication.

zinc and manganese dioxide electrode reactions.[97, 98] As Dr. Coleman mentioned, the pulse method used was essentially a very high-frequency a-c measurement as the pulse may be constructed from a suitable Fourier analysis. The very high-frequency character of the pulse method is emphasized by the 3000 repetition rate of 3 μsec pulse used in the paper. Inspecting the equivalent circuit above, we see that at very high frequencies the impedance of the electrode reactions would be shunted by the capacitance, C_D. At very high frequencies, the impedance of C_D will become negligible. As a result, the pulse measurement of the impedance of the Leclanché cell determines only the resistive element of the circuit R_i, the internal resistance of the cell. Thus, the conclusion reached in the pulse measurement concerning the measured resistive element of a cell is strengthened by results of impedance measurements on the cell.

The comparison of the a-c bridge measurements to the pulse method has been discussed elsewhere.[98] However, a few words of comment are in order. The a-c results reported in the past are often misleading for measurements often were made at only one frequency. The errors involved in this procedure are clearly evident considering the equivalent circuit of a cell. Also, the results of Euler and myself[97, 98] illustrate the effect of frequency on the measured resistance and capacitance of a cell.

It is possible to use the a-c bridge measurements of the resistance and capacitance at various frequencies to calculate the values of all components of the equivalent circuit. My results show that the resistive element R_i determined by the analysis of a-c bridge measurements is identical with the true internal resistance determined by the pulse method

I do not think it is accurate to say, as Dr. Coleman did, that a determination of R_i is not pertinent to the study of dry cells. The resistance polarization of a cell plays an important role in any experimental measurement or use of a cell. The change in R_i as a cell is discharged is interesting as it offers a clue to possible cell reactions and possibly a prediction of cell life. The internal resistance is the most important factor in determining the short circuit current a cell will deliver. The true internal resistance, R_i, is indeed an important part of a cell.

June 1960 Discussion Section

A Discussion Section, covering papers published in the July—December 1959 JOURNALS, is scheduled for publication in the June 1960 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1959 Discussion Section will be included in the June 1960 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than March 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.
